Message from the General Chair

Welcome to the 17th Conference of the European Chapter of the Association for Computational Linguistics (EACL). This is the flagship European conference dedicated to European and international researchers, covering a broad spectrum of research areas of Computational Linguistics and Natural Language Processing.

Organizing a scientific conference of the prestige and size of EACL is always a great honor associated with several challenges. Our team had to tackle unusual complexities: this conference was one of the first scheduled to be in person after the long period of online conferences forced by COVID pandemic. The bidding process for a location, which typically takes place several years before the actual start of the conference, is mainly driven by the aim of expanding and involving the science community of all European countries: EACL selected Kyiv, Ukraine, as the physical location. As you all know, in February 2022, an unpredictable and dramatic event happened, the war between Russian and Ukraine, which made the organization in Kyiv impossible.

Considering the importance of physical interaction among researchers, especially after the restrictions imposed by the COVID pandemic, we worked hard with the EACL and ACL boards to find an alternative location, able to delight our attendees. Our team achieved this seemingly impossible goal of organizing a conference in a new location a few months before its start: we selected Dubrovnik, Croatia, while preserving the original aim of strengthening the connection with the Ukrainian community. In this respect, the Ukraine local committee will feature a dedicated panel session, “Low-resource languages in NLP products”, and a workshop to highlight work on Ukrainian language technologies. Following the latest conference, EACL 2023 will be “hybrid,” serving both virtual and in-person participants. As our official local chairs are not from the physical location, we needed a local team from Croatia for helping with the logistics. As a result, the main unexpected novelty of EACL 2023 is to have two local organizing committees from two different European countries.

In the remainder of this preface, I would like to thank EACL contributors chronologically with respect to my work timeline for EACL: Roberto Basili and Shuly Wintner, the new and former Presidents of ACL, along with the EACL board – thanks for having trusted me to manage the organization of the conference in rather complicated times. I started to be confident that we would have done a good job after Isabelle Augenstein and Andreas Vlachos accepted the role of PC Chairs. They have performed amazing work, creating an outstanding program, and also helping me in recruiting our fantastic organization team. A special thank is due to Preslav Nakov (EACL officer) for his support: thanks to his action, the proactiveness of David Yarowsky, and the fairless effort of Jennifer Rachford (our new secretary of the ACL business office), we successfully implemented the apparently unrealistic idea of switching from the already planned online conference to a hybrid setting with a physical location in Dubrovnik. Regarding the online side of our hybrid conference, we partnered with Underline (Sol Rosenberg, Damira Mrsic and Luka Simic), who also gave us support for managing the entire conference. While finalizing the location, we started to activate the different sections of the conference, for which my acknowledgements are again in chronological order:

- Ukraine Local Committee, Viktoria Kolomiets, Mariana Romanyshyn, Oleksii Molchanovskyi, Oles Dobosevych, was instrumental in preserving our initial goal of connecting the Ukraine research community, organizing a panel and a workshop.

- The website chairs, Pepa Atanasova and Julius Cheng, started immediately to design our website, even when almost no information was available.

- The workshop chairs, Zeerak Talat and Antonio Toral, selected our conferences and led the selection of workshops for the joint ACL call.

- The tutorial chairs, Sameer Pradhan and Fabio Massimo Zanzotto, together with the ACL chairs, took care of the tutorial selection for the ACL related conferences.

- The demonstration chairs, Danilo Croce and Luca Soldaini, created a parallel conference program to select exciting demos.

- The Publicity Chairs, Laura Biester, Leshem Choshen and Joel Tetrault, have been our interface with the science community through social media platforms.

- The Publication Chairs, Carolina Scarton and Ryan Cotterell, produced high-quality proceedings, thanks to their competence and experience.

- The diversity and inclusion chairs, Sara Tonelli, Elena Cabrio, Verena Rieser, Spandana Gella, took care of DI and performed an amazing job, also working on hundreds applications.

- The Local Organising Committee of Croatia, Marko Tadić, Krešimir Šojat, and Daša Farkaš, gave essential help for the logistics, Visa, and student volunteers.

- Student Research Workshop Chairs, Matthias Lindemann, Alban Petit, and Elisa Bassignana, along with their faculty advisors Valerio Basile and Natalie Schluter, helped in setting the bases for forming great NLP researchers of the future.

- Our entire program committee, Senior Area Chairs, Area Chairs, reviewers, and best paper committee, was essential for obtaining our high-quality scientific program.

- The ACL's sponsorship director Chris Callison-Burch took care of our sponsorships.

- The student volunteers, as usual, are essential for a successful conference execution.

- Priscilla Rasmussen, our former ACL business office secretary, continued to provide us with useful advice.

Finally, I would like to thank our sponsors for helping us to fund scholarships and DI initiatives.

Alessandro Moschitti

EACL 2023 General Chair

ACL Statement on the Ukraine situation

March 11, 2022

The Association for Computational Linguistics (ACL) condemns in the strongest possible terms the actions of the Russian Federation government in invading the sovereign state of Ukraine and engaging in war against the Ukrainian people. We stand together with Ukrainian NLP colleagues, the Ukrainian people, Russian NLP colleagues and Russian people who condemn the actions of the Russian Federation government, and all those around the world who have been impacted by the invasion.

As a small token of our solidarity with the Ukrainian people, the ACL has decided to temporarily sever its ties with Russia-based organizations, while at the same time allowing Russian scientists to remain part of the ACL community. In practice, this means that the ACL will refrain from accepting any sponsorship or allowing any exhibits from Russian-headquartered entities at ACL-run events. Russian scholars are still welcome to participate in ACL events and publish at ACL venues.

The ACL is committed to peace and condemns any form of violence and harassment. We are also committed to peaceful co-operation, mutual understanding, and tolerance across borders. NLP scholars from both Ukraine and Russia are welcome to get in touch with the ACL with any concerns.

Tim Baldwin, on behalf of the ACL Executive

Message from the Program Chairs

Welcome to the 17th Conference of the European Chapter of the Association for Computational Linguistics (EACL). After the last edition in 2021 having been held fully online due to the COVID pandemic, EACL 2023 is being held in "hybrid" mode this year, serving both virtual and in-person participants in Dubrovnik, Croatia. While the original plan was to hold the conference in Kyiv (which was the plan originally for EACL 2021), the ongoing war made the organisation in Ukraine impossible. In order to ensure that the original aim of strengthening the connections with the Ukrainian community is still served, our program features a dedicated session and a workshop to highlight work on Ukrainian language technologies.

Submission and Acceptance

EACL 2023 accepted direct submissions, as well as submissions via ARR. For direct submissions, abstracts were needed to be registered one week prior to the submission date.

In total, EACL 2023 received 1550 submissions, the largest number to date, with the 2021 edition having received 1400 submissions. Out of those, 1045 were long and 505 were short paper submissions. 81 were ARR papers that were committed to EACL. 249 submissions were withdrawn throughout the reviewing process, including before the full paper submission deadline. 55 papers were desk rejected for various reasons (missing the limitations section, anonymity policy, multiple submission policy, plagiarism or formatting violations).

By the time we as the programme chairs made acceptance decisions, 1166 submissions were still active in the system. We kept the acceptance rate in line with previous *ACL conferences, resulting in 281 papers accepted to the main conference (24.1%), and 201 papers accepted to the Findings of EACL (17.2%), with the remaining 58.7% being rejected. One paper accepted to the main conference and four papers accepted to Findings were subsequently withdrawn. Out of the final set of accepted main conference papers, we invited 178 to be presented orally, and all 281 papers accepted to the main conference to be presented during in-person sessions, as well as a plenary virtual poster session. The EACL 2023 program also features six papers from the Transactions of the Association for Computational Linguistics (TACL) journal, and one from the Computational Linguistics (CL) journal.

Limitations Section

Following EMNLP 2022, we required that each submitted paper must include an explicitly named Limitations section, discussing the limitations of the work. This was to counterbalance the practice of over-hyping the take-away messages of papers, and to encourage more rigorous and honest scientific practice. This discussion did not count towards the page limit, and we asked reviewers to not use the mentioned limitations as reasons to reject the paper, unless there was a really good reason to.

Areas

To ensure a smooth process, the submissions to EACL 2023 were divided into 21 areas. The areas mostly followed these of previous EACL, and more broadly *ACL conferences, reflecting the typical divisions in the field. We also had a special area for papers for which both SACs had a conflict of interest. Those papers were reviewed by the reviewers and ACs in their original areas, but the paper recommendations were made by a dedicated SAC, who was a senior member of the NLP community. The most popular areas with over 100 submissions were "Generation and Summarization", "Language Resources and Evaluation", and "Machine Learning in NLP".

Best Paper Awards

From the papers submitted to EACL 2023, we selected 25 papers accepted to the main conference as candidates for a Best Paper award, based on nominations by the reviewers. These papers were assessed by the Best Paper Award Committee, who also determined the types of paper awards, following the ACL Conference Awards Policy. The selected best papers and runner-ups will be announced in a dedicated plenary session for Best Paper Awards on 4 May 2023.

Programme Committee Structure and Reviewing

Similar to prior NLP conferences, we adopted the hierarchical program committee structure, where for each area we invited 1-2 Senior Area Chairs (SACs), who worked with a team of Area Chairs (ACs), and a larger team of reviewers. We relied on statistics from prior years to estimate how many SACs, ACs and reviewers would be needed and ended up with 43 SACs, 118 ACs and 1634 reviewers. For identifying ACs and reviewers, we used the reviewer lists from prior *ACL conferences, and also encouraged all EACL 2023 authors to serve as reviewers, using a mandatory form requesting further information on their ability to serve as ACs, reviewers or emergency reviewers, which authors had to fill in on Softconf when registering their abstracts. We passed this information on to SACs, who were responsible for recruiting ACs and reviewers.

Rather than making assignments using a matching algorithm, we asked ACs and reviewers to bid on registered abstracts within their areas, to achieve a better fit. We went with this solution as the number of papers per area was relatively small, and we wanted to avoid poor reviewing assignments as much as possible. We then made an initial paper assignment, in which we ensured that each paper would be reviewed by at least one reviewer who bidded "yes" for the submission, and by no reviewers who bidded "no" for the submission.

Afterwards, we asked the SACs to fine-tune the allocations, and ensure each paper had one AC and three reviewers assigned to it.

To ensure the review quality, we provided detailed guidelines about what reviewers should and shouldn't do in a review, based on the EMNLP 2022 guidelines. We also asked reviewers to flag papers for potential ethical concerns.

For pre-reviewed ARR papers, we asked SACs to not rely mainly on the reviewer scores, but to make their recommendations based on the text of the reviews, meta-reviews and the papers themselves. For making acceptance decisions, we mostly followed SAC recommendations, though also taking into account the overall quality of papers submitted to the conference. Where recommendations seemed overly harsh or lenient given the reviewers' scores, reviews, author responses, or discussions amongst reviewers, we engaged in a dialogue with the respective SACs to make the final decision about the papers in question.

Ethics Committee

We also formed an Ethics Committee (EC) dedicated to ethical issues. The ethics committee considered 21 papers that were flagged by the technical reviewing committee for ethical concerns. Out of these, 10 were conditionally accepted, meaning the ethics issues had to be addressed in the camera-ready version, to be verified by the EC prior to final acceptance, and the other 11 were accepted as is. The authors of all conditionally accepted papers submitted the camera-ready version and a short response that explained how they had made the changes requested by the EC. The EC double-checked these revised submissions and responses, and confirmed that the ethical concerns had been addressed. As a result, all conditionally accepted papers were accepted to the main conference or Findings.

ACL Rolling Review

ACL Rolling Review (ARR) is an initiative of the Association for Computational Linguistics, where the reviewing and acceptance of papers to publication venues are done in a two-step process: (1) centralized rolling review and (2) the ability to commit the reviewed papers to be considered for publication by a publication venue. For EACL 2023, we decided to follow EMNLP 2022's example and run a process which is separate from ARR, but also allows for ARR submissions. Specifically, authors could either submit papers to EACL 2023 directly, or commit ARR reviewed papers by a certain date. We coordinated with the ARR team to extract the submission, review and meta-review from the OpenReview system, according to a submission link that the author provided when committing their ARR submission to EACL. The ARR commitment deadline was set one month after the direct submission deadline since the ARR submissions already have their reviews and meta-recommendation. These ARR papers were then ranked by the SACs together with the direct submissions in the track, and based on the reviews and meta-reviews from ARR. Overall, EACL had 81 papers committed from ARR, of these 24 were accepted to the main conference and 20 were accepted to Findings of EACL.

Presentation Mode

We made the decision on which papers would be invited for oral poster presentations based on several factors: the relative rank of the paper according to SAC recommendation, whether the paper had been recommended for a best paper award by at least one reviewer, and for TACL and CL papers, the authors' preference of presentation mode.

Keynotes and Panel

Another highlight of our program are the plenary sessions, for which we scheduled three talks, as well a panel:

- a keynote talk by Joyce Chai (University of Michigan) on "Language Use in Embodied AI!
- a keynote talk by Edward Greffenstette (Cohere AI and University College London) on "Going beyond the benefits of scale by reasoning about data"
- a keynote talk by Kevin Munger (Penn State University) on Chatbots for Good and Evil"
- a panel on "low-resource languages in NLP products" led by Mariana Romanyshyn with Viktoria Kolomiets (Grammarly), Mariana Romanyshyn (Grammarly), Oleksii Molchanovskyi (Ukrainian Catholic University) and Oles Dobosevych (Ukrainian Catholic University)

Thank Yous

EACL 2023 is the result of a collaborative effort and a supportive community, and we want to acknowledge the efforts of so many people with whom we worked directly and made significant efforts in putting together the programme for EACL 2023!

- Our General Chair, Alessandro Moschitti, who led the whole organising team, and helped with many of the decision processes;
- Our 43 Senior Area Chairs, who were instrumental in every aspect of the review process, from recruiting Area Chairs, correcting reviewer assignments, to making paper acceptances;
- Our 118 Area Chairs, who had the role of interacting with the reviewers, leading paper review discussions, and writing meta-reviews;

- The 1634 reviewers, who provided valuable feedback to the authors; The emergency reviewers, who provided their support at the last minute to ensure a timely reviewing process;
- Our Best Paper Selection Committee, who selected the best papers and the outstanding papers: Jonathan Kummerfeld (chair), Joakim Nivre, Bonnie Webber, Thamar Solorio and Hanna Hajishirzi;
- Our Ethics Committee, chaired by Zeerak Talat, for their hard work to ensure that all the accepted papers addressed the ethical issues appropriately, under a very tight schedule;
- Our amazing Publication Chairs, Carolina Scarton and Ryan Cotterell for compiling the proceedings in good time for the conference;
- Our Publicity Chairs, Laura Biester, Leshem Choshen and Joel Tetrault, for their work on managing the communications on social media platforms;
- Our website chairs, Pepa Atanasova and Julius Cheng for putting together the website for the conference and keeping it up to date;
- Damira Mrsic from Underline, for her support in developing the virtual conference platform;
- Jennifer Rachford, who has worked tirelessly online and on-site to ensure that EACL 2023 is a success.

We’re looking forward to a great EACL 2023!

Keynote Talk: Going beyond the benefits of scale by reasoning about data

Edward Grefenstette
Cohere

Tuesday, May 2, 2023 – Time: **09:30 – 10:30** – Room: **Elafiti 1, 2, 3 & 4**

Abstract:

Transformer-based Large Language Models (LLMs) have taken NLP—and the world—by storm. This inflection point in our field marks a shift from focussing on domain-specific neural architecture design and the development of novel optimization techniques and objectives to a renewed focus on the scaling of model size and of the amount of data ingested during training. This paradigm shift yields surprising and delightful applications of LLMs, such as open-ended conversation, code understanding and synthesis, some degree of tool-use, and some zero-shot instruction-following capabilities. In this talk, I outline and lightly speculate on the mechanisms and properties which enable these diverse applications, and posit that the training regimen which enables these capabilities points to a further shift, namely one where we go from focussing on scale, to focussing on reasoning about what data to train on. I will briefly discuss recent advances in open-ended learning in Reinforcement Learning, and how some of the concepts at play in that work may inspire or directly apply to the development of novel ways of reasoning about data in supervised learning, in particular in areas pertaining to LLMs.

Bio:

Ed Grefenstette is the Head of Machine Learning at Cohere, a provider of cutting-edge NLP models that's solving all kinds of language problems; including text summarization, composition, classification and more. In addition, Ed is an Honorary Professor at UCL. Ed's previous industry experience comprises Facebook AI Research (FAIR), DeepMind, and Dark Blue Labs, where he was the CTO (acquired by Google in 2014). Prior to this, Ed worked at the University of Oxford's Department of Computer Science, and was a Fulford Junior Research Fellow at Somerville College, whilst also lecturing students at Hertford College taking Oxford's new computer science and philosophy course. Ed's research interests span several topics, including natural language and generation, machine reasoning, open ended learning, and meta-learning.

Keynote Talk: Chatbots for Good and Evil

Kevin Munger
Penn State University

Wednesday, May 3, 2023 – Time: **15:45 – 16:45** – Room: **Elafiti 1, 2, 3 & 4**

Abstract:
The capacities of LLM-powered chatbots have been progressing on the order of months and have recently passed into mainstream public awareness and adoption. These tools have been used for a variety of scientific and policy interventions, but these advances call for a significant re-thinking of their place in society. Psychological research suggests that intentionalityis a key factor in persuasion and social norm enforcement, and the proliferation of LLMs represents a significant shock to the intentionalitycontained in text and particularly in immediate, personalized chat. I argue that we are in a period of informational disequilibrium,where different actors have different levels of awareness of this technological shock. This period may thus represent a golden age for actors aiming to use these technologies at scale, for any number of normative ends; this includes social scientists and computational linguists. More broadly, I argue that the ethicalframeworks for evaluating research practices using LLM-powered chatbots are insufficient to the scale of the current challenge. This is a potentially revolutionary technology that requires thinking in moral and political terms: given the power imbalances involved, it is of paramount importance that chatbots for good do not inadvertently become chatbots for evil.

Bio:
Kevin Munger is the Jeffrey L. Hyde and Sharon D. Hyde and Political Science Board of Visitors Early Career Professor of Political Science and Assistant Professor of Political Science and Social Data Analytics at Penn State University.Kevin's research focuses on the implications of the internet and social media for the communication of political information. His speciality is the investigation of the economics of online media; current research models Clickbait Mediaand uses digital experiments to test the implications of these models on consumers of political information.

Keynote Talk: Language Use in Embodied AI

Joyce Chai
University of Michigan

Thursday, May 4, 2023 – Time: **14:15 – 15:15** – Room: **Elafiti 1, 2, 3 & 4**

Abstract:

With the emergence of a new generation of embodied AI agents, it becomes increasingly important to enable language communication between humans and agents. Language plays many important roles in embodied AI. In this talk, I will share some of the experiences in my lab that study the pragmatics of language, for example, in mediating perceptual differences, learning from language instructions, and planning for joint tasks. I will talk about how the embodied context shapes language use and influences computational models for language grounding to perception and action. I will show the importance of collaborative effort and theory of mind in language communication and how they affect common ground for situated tasks. I will discuss key challenges as well as new perspectives on these problems brought by recent advances in LLM and generative AI.

Bio:

Joyce Chai is a Professor in the Department of Electrical Engineering and Computer Science at the University of Michigan. Before joining UM in 2019, she was a Professor of Computer Science and Engineering at Michigan State University. She holds a Ph.D. in Computer Science from Duke University. Her research interests span from natural language processing and embodied AI to human-AI collaboration. She is fascinated by how experience with the world and how social pragmatics shape language learning and language use; and is excited about developing language technology that is sensorimotor grounded, pragmatically rich, and cognitively motivated. Her current work explores the intersection between language, perception, and action to enable situated communication with embodied agents. She served on the executive board of NAACL and as Program Co-Chair for multiple conferences – most recently ACL 2020. She is a recipient of the National Science Foundation Career Award and has received several paper awards with her students (e.g., the Best Long Paper Award at ACL 2010 and an Outstanding Paper Award at EMNLP 2021). She is a Fellow of ACL.

Panel: Low-resource languages in NLP products

Wednesday, May 3, 2023 – Time: **16:30 – 18:00** – Room: **Elafiti 1, 2, 3 & 4**

The panel discussion will bring together experts from industry and academia to share their experience building solutions for low-resource languages. We anticipate a lively discussion about the advantages and limitations of multilingual solutions and language-specific models, the challenges of evaluating models for low-resource languages, and the level of language awareness needed in the development process. In addition, the panelists will explore ways to increase the acceptance rate of papers that target low-resource languages at *ACL conferences. We hope that the panel discussion will increase the visibility of research for low-resource languages and emphasize its relevance.

Moderator: Mariana Romanyshyn, **Grammarly**

Mariana Romanyshyn is an Area Tech Lead for Computational Linguistics at Grammarly, Ukraine. She has professional experience in syntactic parsing, sentiment analysis, named entity recognition, fact extraction, and text anonymization. For the last eight years, Mariana has been working on error correction and text improvement algorithms at Grammarly. Mariana is an active speaker at AI conferences, co-organizer of the yearly Grammarly CompLing Summer School, co-organizer of the UNLP workshop, struggling reformer of Ukrainian university syllabuses, and active contributor of the Lang-uk group, focused on advancements in Ukrainian NLP.

Panelists:

Antonios Anastasopoulos, **George Mason University**

Antonios Anastasopoulos is an Assistant Professor in Computer Science at George Mason University. He received his PhD in Computer Science from the University of Notre Dame and then did a postdoc at Language Technologies Institute at Carnegie Mellon University. He also holds a BSc-MSc in Electrical and Computer Engineering from the National Technical University of Athens, Greece. His research is on natural language processing with a focus on multilinguality, low-resource settings, cross-lingual learning, and endangered languages, with the ultimate goal of building language technologies for under-served communities around the world. He is currently funded by the NSF, the NEH, the US DoD, Google, Amazon, and Meta.

Mona Diab, **Meta**

Mona Diab is the Lead Responsible AI Research Scientist with Meta. She is also a full Professor of Computer Science at the George Washington University (on leave) where she directs the CARE4Lang NLP Lab. Before joining Meta, she led the Lex Conversational AI project within Amazon AWS AI. Her current focus is on Responsible AI and how to operationalize it for NLP technologies. Her interests span building robust technologies for low-resource scenarios with a special interest in Arabic technologies, (mis) information propagation, computational socio-pragmatics, computational psycholinguistics, NLG evaluation metrics, language modeling, and resource creation.

Julia Makogon, Semantrum
Julia Makogon is a Lead ML/NLP Engineer at Semantrum, a Ukrainian AI company that specializes in media analytics and reputation management. She studied Applied Mathematics at DSTU, Kamyanske, Ukraine, before pursuing a career in NLP. Julia developed multiple NLP applications for media monitoring, sentiment analysis, and legal document analysis for Ukrainian and other European languages. Her expertise lies in building industry solutions with limited resources. Julia serves at the Program Committee of the Ukrainian NLP workshop and is passionate about advancing solutions for the Ukrainian language.

Ivan Vulić, University of Cambridge
Ivan Vulić is a Principal Research Associate and a Royal Society University Research Fellow in the Language Technology Lab, University of Cambridge. He is also a Senior Scientist at PolyAI. He is a member of the Steering Committee of the Centre for Human Inspired Artificial Intelligence (CHIA) at Cambridge. Ivan holds a PhD in Computer Science from KU Leuven awarded summa cum laude. In 2021 he was awarded the annual Karen Spärck Jones Award from the British Computing Society for his research contributions to NLP and Information Retrieval. His core expertise is in representation learning, cross-lingual learning, conversational AI, human language understanding, distributional, lexical, multi-modal, and knowledge-enhanced semantics in monolingual and multilingual contexts, transfer learning for enabling cross-lingual NLP applications such as conversational AI in low-resource languages, and machine learning for (cross-lingual and multilingual) NLP. He has published numerous papers at top-tier NLP and Information Retrieval conferences and journals, and his research work also resulted in several best paper awards. He serves as an area chair and regularly reviews for all major NLP and Machine Learning conferences and journals. Ivan has given numerous invited talks at academia and industry and co-organised a number of NLP conferences and workshops.

Abstract

While contextualized word embeddings have been a de-facto standard, learning contextualized *phrase* embeddings is less explored and being hindered by the lack of a human-annotated benchmark that tests machine understanding of phrase semantics given a context sentence or paragraph (instead of phrases alone). To fill this gap, we propose PiC—a dataset of ∼28K of noun phrases accompanied by their contextual Wikipedia pages and a suite of three tasks for training and evaluating phrase embeddings. Training on PiC improves ranking-models' accuracy and remarkably pushes span-selection (SS) models (i.e., predicting the start and end index of the target phrase) near human-accuracy, which is 95% Exact Match (EM) on semantic search given a query phrase and a passage. Interestingly, we find evidence that such impressive performance is because the SS models learn to better capture the common meaning of a phrase *regardless* of its actual context. SotA models perform poorly in distinguishing two senses of the same phrase in two contexts (∼60% EM) and in estimating the similarity between two different phrases in the same context (∼70% EM).

1 Introduction

Understanding phrases in context is a key to learning new vocabularies (Nagy et al., 1985; Fischer, 1994), disambiguation (Pilehvar and Camacho-Collados, 2019), and many downstream tasks, including semantic search (Finkelstein et al., 2001). Yet, the contextualized *phrase* embeddings (Yu and Ettinger, 2020) in existing systems mostly capture the common meaning of a phrase, i.e. without strong dependence on its context (Yu and Ettinger, 2020). While there are *word*-sense disambiguation datasets (Edmonds and Cotton, 2001; Pilehvar and Camacho-Collados, 2019), no such benchmarks exist for *phrases*. Existing phrase-similarity benchmarks (Pavlick et al., 2015; Turney, 2012; Asaadi et al., 2019; Zhang et al., 2019; Yang et al., 2019) compare phrases alone (without context) and some of them (Pavlick et al., 2015; Zhang et al., 2019) contain a large, undesired amount (∼15% to 99%) of phrase pairs that have lexical overlap (Table 1).

Others generated the context for a phrase by querying GPT-2 (Wang et al., 2021) or by retrieving from Wikipedia (Yu and Ettinger, 2020). Yet, there was no human verification of the realism of generated text (Wang et al., 2021) and no human annotation of how a phrase's meaning changes w.r.t. the context (Yu and Ettinger, 2020). All above drawbacks are limiting the evaluation of phrase understanding.

To advance the development of contextualized phrase embeddings, we propose Phrase-in-Context (PiC), a suite of three tasks: (1) Phrase Similarity (PS), i.e. compare the semantic similarity of two phrases in the same context sentence (Fig. 1b); (2) Phrase Retrieval (PR), which is divided into PR-pass and PR-page (Fig. 1c–d), i.e. from a passage or a Wikipedia page, retrieve a phrase semantically-similar to a given query phrase; and (3) Phrase-Sense Disambiguation (PSD), i.e. find the target phrase $\boldsymbol{p}$ semantically similar to the query phrase from a 2-paragraph document where $\boldsymbol{p}$ appears twice, each time in a different context paragraph that provides a *unique* meaning to $\boldsymbol{p}$ (Fig. 1e). Our ∼28K-example dataset is rigorously (a) *annotated* and *verified* by two groups of annotators: linguistics experts on `Upwork.com` and non-experts on Amazon Mechanical Turk (MTurk); and then (b) *tested* by models, linguists, and graduate students. Our contributions are:

1. We build PiC[1], the first, human-annotated benchmark for evaluating and training contextualized phrase embeddings (Sec. 4). Compared to existing phrase similarity datasets, PS is the first to require models to rely on context.

---

2. After training on PR-pass, i.e. finding a phrase from a passage, SS models perform at a near-human accuracy (92–94% vs. 95% EM). They also score high (84–89% EM) on PR-page, i.e. semantic phrase search in a Wikipedia page (Sec. 5.4), suggesting our training set and learned embeddings are useful for real-world semantic search.

3. Interestingly, on PR-pass, harnessing these SS models' phrase embeddings in a ranking approach (i.e. comparing the similarity between the query and *all* candidate phrases) yields poor accuracy of $\leq 59\%$ EM (Sec. H), setting a challenge for future research into learning contextualized phrase embeddings.

4. After training on PR-pass, state-of-the-art (SotA) models perform relatively well on PR-pass and even PR-page but not on PSD (Sec. 5.5). On PS, SotA models perform poorly (below 70% accuracy) in binary classification of phrase similarity given a context sentence (Sec. 5.1).

2 Related Work

Each of our tasks (PS—phrase similarity; PR—phrase retrieval; and PSD—disambiguation) is related to a separate research area discussed below.

Phrase similarity First, most existing phrase similarity datasets—e.g. PPDB-annotated (Wieting et al., 2015), PPDB-filtered (Wang et al., 2021), BiRD (Asaadi et al., 2019), and PAWS-short (Wang et al., 2021; Zhang et al., 2019)—contain a large percent of instances with lexical overlap between two paired phrases while our PS contains the least percent (5.34%; Table 1). Second, PS compares each pair of phrases in a context sentence while existing datasets only compare phrases alone (no context). Third, the phrases in PS are, on average, 2-token long, comparable to that of other datasets (Table 1). Fourth, unlike other datasets, PS contains exclusively *noun-phrases*, the most common phrase type according to Yahoo's search-query statistics (Yahoo, 2022a) (79.54%; Appendix D) and Adobe (internal Acrobat Pro data not shown).

Question answering (QA) Our phrase-retrieval tasks—PR and PSD—follow the format of QA datasets except that our queries are *phrases* instead of questions and hence shorter (Table 2). Like SQuAD 1.1 (Rajpurkar et al., 2016) and HotpotQA (Yang et al., 2018), our documents and queries are extracted from Wikipedia articles. While our PR dataset is ∼3.5× smaller than those two datasets, the paragraph document length in PR-pass and PSD is ∼2× longer than those of SQuAD 1.1 and HotpotQA (Table 2). For our task, intuitively, the longer the document, the harder the task since there would be more candidates a model must compare with the query.

Table 1: Our Phrase Similarity (PS) dataset has a lower percent of lexical-overlap instances and is the *only* human-annotated dataset that provides phrases, each in a context sentence.

	PS (ours)	WiC	PPDB-annotated	PPDB-filtered	BiRD	Turney	PAWS-short
# of All instances	10,004	7,466	3,000	15,532	3,345	2,180	1,214
# of Unique phrases	7,488	2,345	6,000	12,023	2,840	9,776	1,214
Lexical overlap (%)	5.34	100	70.10	97.93	14.98	0	99.42
Mean length (in tokens)							
• phrase_1	2.06	1	3.67	2	2	2	9.52
• phrase_2	2.46	1	3.73	2	1.49	1	9.42
• context sentence	22.53	8.40	0	0	0	0	0

Table 2: Our PR-pass, PR-page and PSD datasets are smaller in size compared to common QA datasets and contain shorter queries that are noun phrases instead of questions. However, our tasks require searching in much longer documents.

	PR-pass	**PR-page**	**PSD**	SQuAD 1.1	HotpotQA
All instances	28,147	28,098	4,858	98,169	105,257

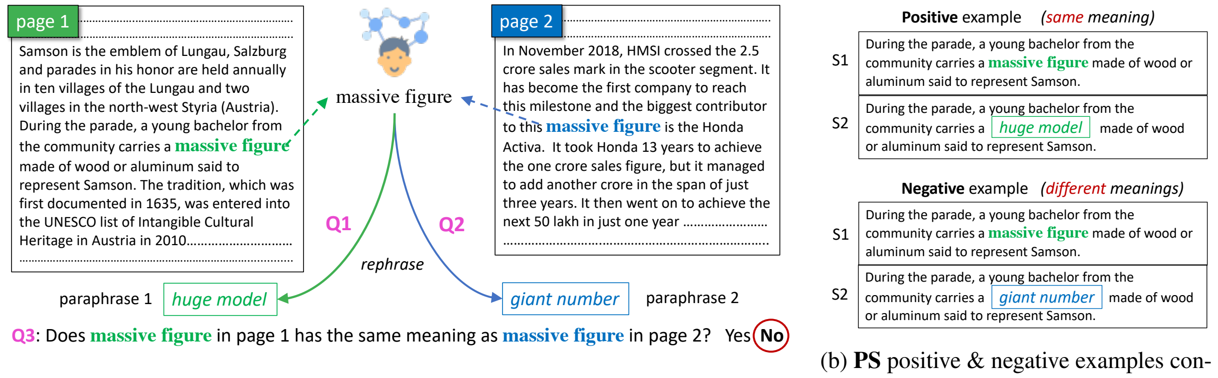
Unique answers	13,458	13,423	2,314	72,469	57,259
Mean length of					
query (tokens)	2.42	2.42	2.45	11.42	20.03
answer (tokens)	2.17	2.17	2.07	3.46	2.35
sentence (tokens)	23.22	24.08	23.00	27.62	26.77
document (sentences)	10.26	119.32	20.37	5.10	4.14
document (tokens)	238.34	2,872.73	468.48	140.92	110.72

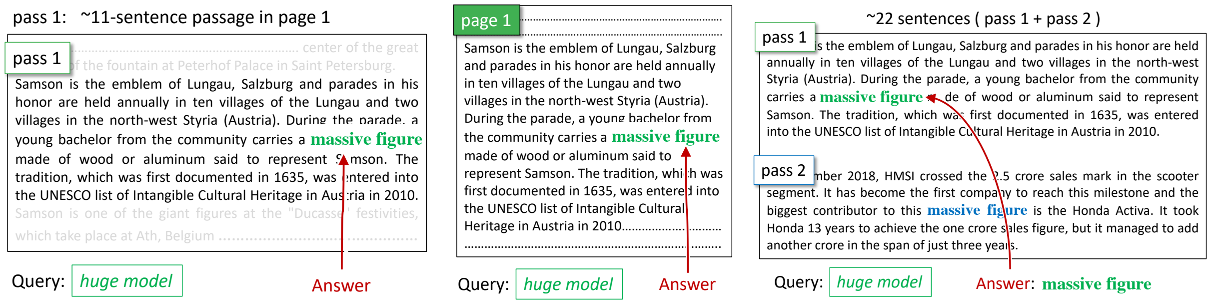
Sense disambiguation While word-sense disambiguation (WSD) is a long-standing problem in NLP, recently, SotA models have reached super-human accuracy (80% F_1) on the common English WSD (Bevilacqua et al., 2021). Interestingly, these high-scoring models still struggle with rare senses that may be outside of the predefined sense inventories or have few training examples (Blevins et al., 2021). Without the need for predefined senses, WiC (Pilehvar and Camacho-Collados, 2019) poses disambiguation as a binary classification task where the goal is to predict whether the same target word in two different sentences carries the same or different meanings.

Compared to WiC PS is also a binary classification task, but with two major differences: (1) in



(a) Q1 & Q2 ask annotators to rephrase "massive figure" in page 1 and page 2. Q3 asks whether this phrase's meaning is the same in both pages.

(b) **PS** positive & negative examples constructed using page 1 context (similarly, we repeat for page 2).



(c) A **PR-pass** example.

(d) A **PR-page** example.

(e) A **PSD** example.

Figure 1: Given a phrase, two associated Wikipedia pages, and expert annotations, i.e. answers to Q1, Q2, and Q3 (a), we are able to construct *two* pairs of positive and negative examples for PS (b), a PR-pass example (c), a PR-page example (d), and a PSD example *only if* the answer to Q3 is No (e).

WiC, the same target word appears in two different sentences while in PS, two different phrases appear in the same context sentence; (2) PS compares phrases composed of ≥ 2 words instead of a single word as in WiC and WSD. While word senses are defined in WordNet and BabelNet dictionaries (Bevilacqua et al., 2021), there are no English dictionaries of senses for multi-word noun phrases (mNPs). Thus, it is more challenging to acquire and learn the senses of mNPs, hence the importance of our PiC dataset. Like WiC, PSD tests disambiguating the meanings of the same n-gram in two different contexts. Yet, PSD is a phrase search task, which involves many more phrase comparisons per example than PS or WiC.

Before the deep learning era, phrase-sense disambiguation was already proposed (Carpuat and Wu, 2007a,b) but only as an auxiliary task for training machine-translation models. And their phrase senses were not annotated by humans but inferred by performing word-alignment on a bilingual corpus. Here, our PSD is the first phrase-sense disambiguation task annotated by experts and requires understanding of phrase-senses in a passage.

3 PiC Dataset Construction

We first collect a set of phrases with context and human annotations. Then, we derive the examples and labels for three main tasks: PS, PR, and PSD (Fig. 1). Our idea is to mine a set of triplets ($\boldsymbol{p}$, page$_1$, page$_2$) from Wikipedia where the phrase $\boldsymbol{p}$ is a polysemous mNP that carries two different senses in two Wikipedia pages (e.g., "massive figure" means *a large number* in page$_1$ but *a huge physical shape* in page$_2$; Fig. 1a). Then, we ask experts to rephrase $\boldsymbol{p}$ into two paraphrases $\boldsymbol{q}_1$ and $\boldsymbol{q}_2$, maintaining the two original senses of $\boldsymbol{p}$ in page$_1$ and page$_2$, respectively. The resultant set of 5-tuples ($\boldsymbol{p}$, $\boldsymbol{q}_1$, $\boldsymbol{q}_2$, page$_1$, page$_2$) enables the tests for (1) comparing the semantic similarity of two phrases given the same context sentence (PS; Fig. 1b); (2) finding a semantically similar phrase in a document (PR-pass & PR-page; Fig. 1c); (3) disambiguating the senses of the same target mNP given two context paragraphs (PSD; Fig. 1e).

3.1 Data Collection

As there are no English dictionaries that contain sense inventories for mNPs, the key **challenge** to our data collection is to mine mNPs that have (1) multiple senses; and (2) a Wikipedia context page for each sense. To do that, we take a Wikipedia dump and perform a **6-step** procedure that essentially extracts all the mNPs that occur in more than one Wikipedia page and that contain at least one polysemous word defined in the WiC dataset. From the triplets of ($\boldsymbol{p}$, page$_1$, page$_2$), we programmatically narrow down to ∼600K triplets where the context sentence of the mNP in page$_1$ is the most semantically *dis*similar to the context sentence in page$_2$ (according to SimCSE (Gao et al., 2021)). We continue filtering down to the top 19,500 triplets where page$_1$ and page$_2$ have *the most* semantically dissimilar lists of Wikipedia categories. That is, 19,500 triplets are estimated to yield ∼15K annotated triplets (the target size based on our budget) after the human annotation process where annotators are allowed to skip the cases they are not confident labeling. See Appendix C for a detailed description of the data collection and **dataset biases**.

3.2 Data Annotation

Via Upwork, we hire 13 linguistics experts who are native English speakers at a rate of \$30/hour to annotate 15,021 out of 19,500 examples. For each phrase, we provide Upworkers with a triplet ($\boldsymbol{p}$, passage$_1$, passage$_2$) where each passage$_i$ consists of 5 sentences centered at the phrase-containing sentence in the corresponding page$_i$. We ask them to answer the three below questions (Fig. 1a):

Q1 Rephrase the target phrase $\boldsymbol{p}$ to a paraphrase $\boldsymbol{q}_1$ such that its meaning is constant in passage$_1$.

Q2 Similarly, rephrase $\boldsymbol{p}$ w.r.t. passage$_2$ to obtain a paraphrase $\boldsymbol{q}_2$.

Q3 Answer Y/N if $\boldsymbol{p}$ has the same meaning in both contextual passage$_1$ and passage$_2$.

Upworkers are asked to provide paraphrases that (1) have at least two words and (2) minimize lexical overlap with each other and the target $\boldsymbol{p}$. See the annotation guidelines (PiC, 2021a) and a sample annotation assignment (PiC, 2021b) given to Upworkers. After receiving annotations, we use LanguageTool (2022) to automatically find syntactical errors when the paraphrases are replaced by the original target phrase in the original passage and ask Upworkers to fix them. We also have annotators fix the remaining errors that we find via manual inspection.

3.3 Annotation Verification

To verify the annotations obtained in Sec. 3.2 (i.e. 2 × 15,021 = 30,042 paraphrases; and 15,021 Y/N labels), first, we present the same Q1, Q2, and Q3 questions to 1,000 qualified MTurkers and ask whether they agree with the answers by expert annotators in Sec. 3.2. And then, for the cases that the MTurkers disagree with, we seek second opinions from 5 Upwork experts. After these two verification rounds, we discard all the examples where Upwork verifiers reject and arrive at the final 28,325 paraphrases and 13,413 Y/N labels (i.e. those annotations that *either* an MTurk or Upwork verifier endorses). See more details in Appendix J.

The total fee for both MTurk and Upwork combined is around USD 30,000.

4 Three Phrase Understanding Tasks

Using the human-annotated data, we construct three tasks of PS, PR, and PSD (as summarized in Fig. 1) for evaluating contextualized phrase-embeddings and semantic-search models.

4.1 Phrase Similarity (PS)

PS is a binary classification task that asks whether two mNPs are semantically similar or not given *the same context* sentence. The unique challenge of PS is that, *without* context, the two given phrases can be easily interpreted as synonymous. Yet, in our PS context sentence, the two phrases *may* or may *not* carry distinct meanings (Fig. 1b).

Construction From the annotated data, a positive example is a triplet of (an original phrase $\boldsymbol{p}$, a paraphrase $\boldsymbol{q}_1$, an original page$_1$'s sentence that contains $\boldsymbol{p}$). To create a negative example, from the same triplets, we select only those where the paraphrase $\boldsymbol{q}_2$ holds a *different* meaning than $\boldsymbol{q}_1$ given the page$_1$ context of $\boldsymbol{q}_1$ (i.e., when the answer to Q3 is No; see Fig. 1b). For quality assurance, we also hire three extra Upwork experts to double-check PS annotations (see Appendix E), keeping only examples that at least 2 out of 3 experts endorse. In total, we obtain 5,002 *negative* examples. Then, we randomly select 5,002 *positive* examples to form a class-balanced PS dataset.

4.2 Phrase Retrieval (PR)

PR is a task of finding in a given document $\boldsymbol{d}$ a phrase $\boldsymbol{p}$ that is semantically similar to the given query phrase, which is the paraphrase $\boldsymbol{q}_1$ (the answer by annotators to Q1) or $\boldsymbol{q}_2$ (the answer to

Q2). We release two versions of PR: **PR-pass** and **PR-page**, i.e. datasets of triplets (query $\boldsymbol{q}_1$, target phrase $\boldsymbol{p}$, document $\boldsymbol{d}$) where $\boldsymbol{d}$ is a random 11-sentence passage that contains $\boldsymbol{p}$ (Fig. 1c) or an entire Wikipedia page (Fig. 1d). While PR-pass contains 28,147 examples, PR-page contains slightly fewer examples (28,098) as we remove those examples whose Wikipedia pages coincidentally also contain exactly the query phrase (in addition to the target phrase). Both datasets are split into ~20K/3K/5K for train/dev/test, respectively.

4.3 Phrase Sense Disambiguation (PSD)

The task is to find the location of the target phrase $\boldsymbol{p}$ where it has a similar meaning to that of the given query $\boldsymbol{q}$ in a 2-paragraph document where, by construction, $\boldsymbol{p}$ appears exactly twice but only one location is the correct answer (Fig. 1e).

Construction From the verified annotations in Sec. 3.3, there are in total 4,938 phrases that both annotators and verifiers agree to hold *different* meanings across the two context Wikipedia pages (i.e., "No" answer to Q3 in Fig. 1a). To create a PSD example, given a phrase $\boldsymbol{p}$ from the above 4,938, we extract two corresponding ~11-sentence paragraphs (from its associated page$_1$ and page$_2$ as in PR-pass) and concatenate them (separated by an empty line) into a single document (Fig. 1e). Since a PSD example shares a pair of phrases (*query* and *answer*) with one PS *positive* example (*phrase*$_1$ and *phrase*$_2$), we filter out that PSD example if the corresponding PS example is removed from the additional verification round (Appendix E). As the result, we exclude 80 examples and obtain 4,858 examples in total for PSD.

5 Experiments and Results

We test SotA models on PS, PR-pass, PR-page, and PSD to (1) assess how the models are able to leverage context to improve accuracy; and (2) quantify the headroom for future research.

Phrase embeddings Besides training and testing SotA BERT-based classifiers, we also test a ranking approach that involves computing the cosine similarity between the query's and each candidate's embedding. To compute a *contextualized* phrase embedding, following Yu and Ettinger 2020, we feed the entire phrase-containing sentence (e.g. S$_1$ in Fig. 1b) into a model, e.g. BERT, and then take the mean pooling of the last-layer embeddings over the words of the given phrase only. For non-contextualized phrase embeddings, we repeat the same process but input to the model only the phrase (instead of the entire sentence).

Models We choose SotA models in (a) phrase similarity: PhraseBERT (Wang et al., 2021); (b) sentence similarity: USE-v5 (Cer et al., 2018), SentenceBERT (Reimers and Gurevych, 2019), and SimCSE (Gao et al., 2021)); (c) question-answering: Longformer (Beltagy et al., 2020), DensePhrase (Lee et al., 2021); and (d) contextualized embeddings: SpanBERT (Joshi et al., 2020) and BERT (Devlin et al., 2019).

For DensePhrase, we use their Phrase-Encoder (as opposed to the Query-Encoder) to compute phrase embeddings. USE-v5 is only available via public APIs (TensorFlow, 2022) that do not support extraction of contextualized phrase embeddings.

5.1 Phrase Similarity: Contextualized phrase embeddings improve accuracy

Q: *Does incorporating context improve the phrase-similarity accuracy on PS?*

Experiment We split the PS dataset 70/10/20 for train/dev/test and test two approaches: (1) using the cosine similarity score between two pre-trained phrase-embeddings (with and without context) to predict phrase similarity; (2) training BERT-based binary classifiers directly using PS training set. We use 6 backbone BERT models that are all "base" versions unless specified otherwise (Table 3).

Approach 1: *Cosine similarity* First, we test how *pre-trained* phrase embeddings alone (without finetuning or extra weights) can be leveraged to solve PS. For each PS example of two phrases, we compute their non-contextualized phrase embeddings and compute their cosine similarity score. To evaluate the pre-trained embeddings on PS, we follow Yang (2022) and tune the binary-classification threshold T to maximize the training-set accuracy, and then use the same optimal T to report the test-set accuracy. We repeat the experiment for *contextualized* phrase embeddings.

Approach 2: *BERT-based classifiers* To complement Approach 1, we test Approach 2, i.e. building a binary classifier by adding two extra MLP layers on top of the pre-trained embeddings used in Approach 1. For a phrase pair, we concatenate the two 768-D phrase embeddings from BERT$_{\text{base}}$ into a 1,536-D vector, and then place one ReLU layer (256 units) and a 1-output linear classification layer with sigmoid on top. Following Wang et al.

Table 3: Accuracy (%) of state-of-the-art BERT-based models on the PS test set. Contextualized phrase embeddings ("Phrase + Ctx") yield substantially higher performance on PS than non-contextualized embeddings ("Phrase"). The random baseline is 50%.

Model	*Approach 1: Cosine similarity*		*Approach 2: BERT-based classifiers*	
	(a) Phrase	(b) Phrase + Ctx	(c) Phrase	(d) Phrase + Ctx
PhraseBERT	51.75	63.40 (+11.65)	33.60	66.10 (+32.50)
BERT	51.05	64.10 (+13.05)	37.00	68.85 (+31.85)
SpanBERT	49.30	64.00 (+14.70)	40.15	66.85 (+26.70)
$\text{SpanBERT}_{\text{Large}}$	50.40	**66.30** (+15.90)	35.95	**69.25** (+33.30)
SentenceBERT	50.35	60.30 (+9.95)	31.50	62.55 (+31.05)
SimCSE	52.15	62.50 (+10.35)	34.20	66.65 (+32.45)
mean ± std	50.83 ± 1.04	**63.43** ± **1.98**	35.40 ± 3.01	**66.71** ± **2.40**

(2021), we finetune these models for a maximum of 100 epochs (with early stopping and patience of 10 epochs) on the train set. See Appendix A for more training details.

Results *Without* context, all models perform at ≤ 50% accuracy (i.e. the random chance; Table 3a & c). Interestingly, incorporating context information into phrase embeddings substantially improves mean model-accuracy on PS for both Approach 1 (from 50.83% to 63.43%; Table 3b vs. a) and Approach 2 (from 35.40% to 66.71%; Table 3d vs. c), showing evidence that **PS requires models to rely on context**. While starting from the same backbone models, Approach 2 yields higher mean accuracy than Approach 1 (Table 3; 66.71 vs. 63.43), which is expected as Approach 2 models have more capacity and the backbones are allowed to be finetuned on PS. See Figs. A3–A6 for qualitative PS predictions from a PhraseBERT-based classifier.

5.2 Human Baselines and Upperbound (95% Exact Match) on Phrase Retrieval

To interpret the progress of machine phrase-understanding on PR, here, we establish multiple human baselines for both non-experts and linguistics experts (with and without training them).

Experiment We recruit participants and have them perform one or two tests per person. A test consists of 20 PR-pass examples. That is, PR-pass documents are 11-sentence long and are feasible for a person to read in minutes (compared to reading an entire Wikipedia page). We test three groups: (1) 21 graduate students at our institution (1 test per person); (2) five Upwork experts (1 test per person); and (3) another five Upwork experts (2 tests per person, i.e., for a total of 2 × 5 = 10 tests).

Table 4: Best SS models reach near the Upperbound (95%) on PR-pass. Yet, ranking models based on phrase embeddings significantly *underperform* SS models.

Accuracy of human groups and models	EM (%)
Group 1: 20 Non-experts (w/o training)	73.60 ± 7.90
Group 2: 05 Experts (w/o training)	82.00 ± 12.00
Group 3: 05 Experts (w/ training)	**90.50** ± 3.70
Best human accuracy (4 people)—Upperbound	**95.00** ± 0.00
Best untrained, ranking model (BERT)	47.44
Best PR-trained, ranking model (PhraseBERT)	59.02
Best PR-trained, SS model ($\text{Longformer}_{\text{Large}}$)	**94.28**

The students in Group 1 volunteer to help our study unpaid while the Upworkers (Group 2 and 3) are hired using the same procedure as in Sec. 3.2.

Results First, we find an unsurprising, large gap between non-experts and experts (Table 4; 73.60% vs. 82.00%). Second, we train experts in Group 3 by having each do a preliminary test and giving them feedback before the real test. We find the training to substantially boost expert accuracy further (from 82.00% to 90.50%). Importantly, we find the Human Exact Match (EM) Upperbound to be 95%, i.e. the highest scores that 4 people (among all groups) make. Upon manual inspection of the submissions of these best performers, we find their incorrect answers sometimes partially overlap with the groundtruth or are sometimes reasonable. In other cases, the best performers find acceptable answers but that do not overlap at all with the groundtruth labels in PR. That is, we estimate a 5% of noise in the annotations of PR.

5.3 Phrase Retrieval: In ranking, context only helps BERT embeddings but not others

One way to evaluate the quality of SotA phrase embeddings is by testing:

Q: *How well do phrase embeddings perform in the **ranking** approach on PR?*

Ranking is a challenging and meaningful phrase-embedding test because the embedding of the query is compared against that of all phrase candidates (extracted by tokenizing the document), which can include syntactically-incorrect phrases, meaningless phrases or rare phrases. Such out-of-distribution challenge appears less often in PS or WiC, i.e. a binary classification setting.

Experiment As described in Sec. 4.2, the PR train/dev/test splits are 20,147/3K/5K examples and we only use the 5K-example test set to test the models in this ranking experiment (no training). We follow (Lee et al., 2017) for span enumeration to construct a list of candidate phrases, we split each PR document into multiple sentences (using NLTK sentence splitter) and tokenize each sentence into tokens (using NLTK tokenizer) and build an exhaustive list of n-grams (here, $n \in \{2, 3\}$ only for computational tractability). For every example, we add the groundtruth phrase (which can be longer than 3 words) to the list of candidates (since we are only interested in testing phrase embeddings, not the phrase extractor).

Results We report top-k accuracy (for k = 1, 3, 5) and top-5 Mean Reciprocal Rank (MRR@5) on the PR-pass test set in Table 5a. First, for most SotA embeddings, incorporating context sentence *hurts* the accuracy (*except for BERT* embeddings). That is, interestingly, for all BERT embeddings (base and large), the accuracy increases substantially (+17.64 and +19.04; Table 5) when the one-sentence context is the input. In contrast, most models that started from BERT but were later fine-tuned lost the capability to leverage the context information (e.g., PhraseBERT, DensePhrase, and SpanBERT in Table 5).

Second, the best top-1 accuracy scores on PR-pass for non-contextualized (USE-v5; 43.36%) and contextualized (BERT; 47.44%) embeddings are substantially lower than the non-expert baselines (73.60%; Table 4) and Human Upperbound (95%). Future work is required to learn more robust, phrase embeddings for ranking. See Figs. A10–A11 for qualitative examples.

5.4 Phrase Retrieval: Span-selection models reach near-human accuracy

Consistent with Yu and Ettinger (2020), our ranking results in Sec. 5.3 reveal that there exists a large headroom for improving both non-contextualized and contextualized phrase embeddings. Yet, because ranking is a naive approach and SS models (Huggingface, 2022b; Devlin et al., 2019) are the SotA approach on many QA tasks (Rajpurkar et al., 2016), here we train SS models on the train set of PR-pass and PR-page in order to test:

Q: *How well do SotA semantic-search models perform on PR-pass and PR-page?*

Experiment We take the SotA embeddings tested in Sec. 5.3 and add a linear classification layer on top and finetune each entire classifier on the train set of PR-pass or PR-page for 2 epochs using the default HuggingFace hyperparameters (see Appendix B for finetuning details). Following the standard setup of BERT architectures for QA tasks (Devlin et al., 2019), each SS model predicts the start and end index of the target phrase. Additionally, since PR-page documents are much longer than a typical QA paragraph (Table 2), we also test training Longformer (Beltagy et al., 2020), which has a max sequence-length of 4,096, sufficient for an entire Wikipedia page. We take the models of the smallest dev loss and report their test-set performance in Table 6.

Results On PR-pass, in contrast to the poor performance of ranking models (Sec. 5.3), our PR-pass-trained SS models perform impressively at a near-upperbound level (∼93–94% EM; Table 6a) surpassing the accuracy of trained experts (90.50% EM). Surprisingly, on PR-page where the documents are substantially longer (around 12×) than the documents of PR-pass, SS models' accuracy only drops slightly (from ∼94% to ∼85–89% EM; Table 6b). Note that in a full Wikipedia page of PR-page, there might be phrases that can be considered correct but are *not* labeled groundtruth according to our annotations. This remarkable result suggests that training on PR-pass can enable high-performing models on real-world semantic search.

5.5 Phrase Sense Disambiguation: Best models also perform poorly

We find that SotA PR-pass-trained SS models reach superhuman accuracy on PR-pass, i.e. finding a phrase of the same meaning (Sec. 5.4). Yet, PR-pass only tests models' understanding of a *single sense* of the target phrase at a time. It is interesting to study:

Q: *Do PR-pass-trained SS models understand contextualized phrases sufficiently to separate two different senses of the same target phrase?*

Experiment To do that, here we test the best PR-pass-trained SS models on PSD. Note that, PSD has the same task format as PR-pass (see Fig. 1c–e) except that the document is twice as long and contains **two occurrences of the same target phrase**. We do not test the ranking models as they perform much worse than the SS models in Sec. 5.3.

Results Although the PR-pass-trained SS models are never trained on PSD, they interestingly frequently find one occurrence of the target phrase (mean of 94.01% EM; Table 6c). However, they mostly locate the **target phrase in the wrong context passage** with high confidence scores. That is, if we consider also the correctness of the loca-

Table 5: **Ranking** accuracy (%) on **PR-pass** using the state-of-the-art pretrained phrase embeddings. See Appendix F for the results on PR-page. Δ (e.g. -3.62) denotes the differences between the Top-1 accuracy in the contextualized ("Phrase + Context") vs. the non-contextualized ("Phrase") setting.

Model	Phrase				Phrase + Context			
	Top-1	Top-3	Top-5	MRR@5	Top-1 (Δ)	Top-3	Top-5	MRR@5
PhraseBERT (Wang et al., 2021)	36.62	66.96	75.90	52.20	33.00 (-3.62)	49.60	56.70	41.90

Table 6: **Test**-set performance (%) of **SS models** on PR-pass (a), PR-page (b), and PSD (c). When trained on PR-pass (a) and PR-page (b), SotA SS models perform well. However, testing the PR-pass-trained models on PSD shows a significant drop in accuracy (c). That is, SotA SS models tend to understand a *single sense* of a phrase in context well (high PR-pass, PR-page, and PSD EM scores). Yet, they are not able to differentiate two senses of the same phrase (e.g., here, PhraseBERT accuracy drops -41.27 points between EM+loc vs. EM scores on PSD).

Model	(a) PR-pass		(b) PR-page		(c) PSD			
	EM	F$_1$	EM	F$_1$	EM	F$_1$	EM+loc	F$_1$+loc
PhraseBERT (Wang et al., 2021)	93.42	94.97	85.24	87.19	92.98	94.08	51.67 (-41.31)	51.83
BERT (Devlin et al., 2019)	93.26	94.65	85.64	87.77	93.50	94.57	54.84 (-38.66)	55.07
BERT$_{\text{Large}}$ (Devlin et al., 2019)	93.64	95.16	87.36	89.52	94.67	95.57	55.43 (-39.24)	55.61
SpanBERT (Joshi et al., 2020)	93.50	95.02	87.28	87.66	92.26	93.30	52.20 (-40.06)	52.34
SentenceBERT (Reimers and Gurevych, 2019)	93.24	94.54	84.66	86.89	93.21	94.15	52.74 (-40.47)	52.85
SimCSE (Gao et al., 2021)	92.90	94.51	85.68	87.66	92.96	94.05	53.83 (-39.13)	53.94
Longformer (Beltagy et al., 2020)	94.26	**95.58**	**89.54**	**91.15**	96.17	96.88	**62.72** (-33.45)	**62.83**
Longformer$_{\text{Large}}$ (Beltagy et al., 2020)	**94.28**	95.53	87.58	89.32	**96.32**	**96.91**	59.72 (-36.60)	59.82
mean	93.56	95.00	86.92	88.85	94.01	94.94	55.39 (-38.62)	55.54
± std	0.49	0.42	1.93	1.73	1.54	1.36	3.90	3.88

tion of the predicted phrase, their EM+loc[2] accuracy drops significantly to an average of 55.39%. Also, finetuning on a 2K-example train set of PSD only slightly improves the EM+loc to an average of 64.24% on a 3K-example PSD test set (Appendix G). Note that we estimate the Human Upperbound on PSD to be 95%, i.e. the same as that of PR-pass. See qualitative examples and predictions of Longformer (i.e. the best model tested) in Figs. A7–A9.

In sum, there is a large headroom for future research on PSD. SS models are *not* yet capable of leveraging surrounding words to differentiate between two senses of the same phrase. Interestingly, after training on PR-pass, their contextualized phrase embeddings perform much worse in the ranking experiments on PR-pass (Appendix H).

6 Discussion and Conclusion

While WiC and English WSD rely exclusively on dictionaries (Pilehvar and Camacho-Collados, 2019) to obtain word senses and example sentences, our data collection depends on Wikipedia, WiC, & NLP models and our annotation depends on experts. In sum, we present PiC, the first 3-task suite for

---

[2] For a PSD example, if the predicted span does not intersect at all with the groundtruth span, the EM+loc and F$_1$+loc scores would be 0. If they intersect, the two scores would be equal to EM and F$_1$, respectively.

evaluating phrases in context. SS models can obtain high accuracy on semantic search after training on our PR-pass and PR-page datasets. Yet, their capability is limited to finding a semantically-similar phrase given a single context that contains the target phrase (in PR-pass). The results on PS and PSD show that SotA phrase embeddings are still limited in encoding contextualized phrases. It is interesting future work to improve these models for disambiguating the senses of a phrase in context (PS and PSD).

7 Limitations

Our dataset is currently limited to multi-word, English noun-phrases. Furthermore, it is expected to contain around a 5% error on PR-pass (i.e. the best human performance is 95% EM). On PR-page, there may be more than one correct target phrase; however, we only label one phrase as the correct answer per document. We use only phrases that contain at least one WiC word.

Acknowledgement

We thank Qi Li, Peijie Chen, Hai Phan, Giang Nguyen, and Naman Bansal from Auburn University for helpful feedback on the early results. We also thank graduate students from AN's Deep Learning class for helping us with the human study. We are grateful for the valuable support and feedback from Phat Nguyen. AN is supported by NaphCare Foundations, Adobe gifts, and NSF grants (1850117, 2145767).

Appendix for:
PiC: A Phrase-in-Context Dataset for Phrase Understanding and Semantic Search

A Training models on Phrase Similarity

Hyperparameters We train each *BERT-based classifier* for a maximum of 100 epochs with early stopping monitored on validation accuracy (patience of 10 epochs). We use a batch size of 200 and Adam optimizer with learning rate α = 0.0001, β_1 = 0.9, β_2 = 0.999, and $\epsilon = 10^{-8}$.

Training time On average, with early stopping, training a single model using one V100 GPU takes $\sim$5 and $\sim$8 mins for non-context and context settings, respectively.

B Training SS models on Phrase Retrieval

We finetune each SS model that consists of a linear layer on top of a pretrained model selected in Sec. 5 to predict the start and end indices of answers (as the common setup in BERT SS models (Devlin et al., 2019; Arici et al., 2020)). The format of a tokenized input is "[CLS] query [SEP] document [SEP]" with maximum sequence length of 4,096 for $\text{Longformer}_{\text{Base}}$ and $\text{Longformer}_{\text{Large}}$ and 512 for the remaining models. If the document exceeds the maximum sequence length, it is split into smaller features for prediction and thus start and end indices with the highest confidence scores are selected.

Hyperparameters We follow HuggingFace scheme to finetune the SS models for 2 epochs using Adam optimizer with learning rate α = 0.00003, β_1 = 0.9, β_2 = 0.999, $\epsilon = 10^{-8}$. The batch size varies from 1 to 8 for each model: On one V100 GPU, the "base" models can handle 8 examples while the "large" BERT models can only fit 2–4 examples into 16GB of memory. For $\text{Longformer}_{\text{Large}}$, we use an A100 GPU to feed one PR-page example into the model. We take the smallest dev-loss models from the training and report their test-set results.

Training time On average, training a single SS model for 2 epochs using one A100 GPU takes $\sim$20 mins for base models and $\sim$9.5 hours for $\text{Longformer}_{\text{Large}}$.

C Data collection

From a Wikipedia dump, we perform a 6-step procedure (summarized in Table A1) for mining a list of mNPs sorted descendingly by their likelihood of containing multiple senses. The most polysemous 19,500 mNPs are then passed to experts for annotation (Sec. 3.2) and others for verification (Sec. 3.3).

Step 1: Download Wiki articles We download a Wikipedia dump file (Team, 2021b) that contains $\sim$15.78M Wikipedia articles and filter out all empty pages to arrive at $\sim$6.27M non-empty articles.

Step 2: Extract phrases We use NLTK sentence splitter (Bird et al., 2009) to split each Wikipedia article into multiple sentences. And then we use SpaCy (Honnibal et al., 2020) to extract noun phrases and proper nouns as we do not collect syntactically strict phrases. For each phrase, we remove all preceding and succeeding stopwords (those among the 179 stopwords in NLTK v3.6.5) and non-alphanumeric characters. We remove stopwords because they tend to create more pairs of phrases with lexical overlap, rendering the phrase similarity task easier. We then remove *unigram* phrases to arrive at ∼286.78M mNPs. For example, from "a massive figure", we changed to "massive figure", which would be our final phrase after this step. For each mNP, we construct a 3-tuple (phrase, sentence, metadata), i.e. the phrase, its container sentence, and metadata for identifying the Wikipedia webpage (hereafter, page).

Step 3: Remove phrases of a single context We further remove all phrases that (1) contain non-ASCII characters (e.g. "phaenná nâsos", which are non-English); and (2) appear only once, i.e. keeping those that occur in multiple sentences since we look for *polysemous* mNPs, which have multiple senses and contexts. After this step, ∼17.96M phrases remain.

While some phrases with non-ASCII characters are also commonly used in English (e.g., "déjà vu"), we find only 2.48% of phrases at this stage contain non-ASCII characters, and 29% of them are common in English. In short, we are removing only 0.72% of the English phrases that contain non-ASCII characters in Step 3.

Step 4: Find phrases of polysemous words To increase the chance of collecting polysemous mNPs, we only keep mNPs that have at least one word in the list of 2,345 unique multiple-sense words of WiC (Huggingface, 2022a), arriving at ∼6.5M mNPs, each appearing in ≥ 2 sentences and in ≥ 1 Wikipedia pages. We empirically find that Step 4 is important and substantially increases our chance of finding polysemous mNPs (compared to skipping Step 4).

Step 5: Find phrases in distinct contexts We observe that a mNP is likely to be polysemous when (a) its context sentences are semantically different; and (b) its context Wikipedia pages are of dissimilar categories (e.g. "massive figure" in finance vs. history; Fig. A8).

To implement this filter, we form all possible triplets (phrase, sentence$_1$, sentence$_2$) from the list of context sentences of each mNP[3]. We compute the cosine similarity of two sentences at the CLS embedding space of a SimCSE (Gao et al., 2021) provided on HuggingFace (Group, 2022). To find triplets where the two sentences are semantically dissimilar, we keep only the triplets where (sentence$_1$, sentence$_2$) has a low cosine similarity, i.e. $\in [-0.3, 0.2]$ and the length difference of the two sentences is < 4 words (as two sentences of substantially different lengths often have a low cosine similarity regardless of their semantic differences). As the result, there are ∼600K triplets remaining after this step.

We further re-rank these ∼600K descendingly by the dissimilarity of the lists of Wikipedia categories[4] of the context pages that contain sentence$_1$ and sentence$_2$. That is, we treat each Wikipedia page's comma-separated list of categories as an input text to SimCSE and sort the ∼600K descendingly by the cosine similarity of the resultant embeddings.

Step 6: Select data for annotation Before asking annotators to label our sorted phrases we perform final filtering by removing proper nouns and phrases whose Wikipedia documents contain missing words.

We perform final filtering to ensure the data given to annotators is in a proper format. That is, from ∼600K phrases, we filter down to ∼475K phrases by applying two filters: (1) Remove all phrases that are proper nouns (i.e. POS tagging returns PROPN) since proper nouns often refer to a single identity and thus unambiguous; (2) Remove all phrases that have a newline character and all phrases whose context Wikipedia page contains missing words (i.e. errors in the Wikipedia dump).

As the result, we obtain a list of ∼475K phrases sorted by their estimate chance of carrying two different senses. After manual inspection, we take the top 19,500 triplets of the format (phrase, page$_1$, page$_2$)—i.e. a phrase $\boldsymbol{p}$ and its two context Wikipedia pages where $\boldsymbol{p}$ is the most likely to have two different senses (e.g., see "massive figure" in Fig. 1a)—and hire linguistic experts to annotate them.

Our manual inspection involves taking 1,000 random triplets and manually reading them. We find that at least ∼30% of the 1,000-triplet subset contain a polysemous target phrase $\boldsymbol{p}$ and two Wikipedia pages that give $\boldsymbol{p}$ two unique meanings. We perform this manual inspection repeatedly throughout the

---

[3] For computational tractability, we only keep at most 32 context sentences per mNP where each sentence's length in words is $\in [5, 25]$.

[4] We use the provided Wikipedia API (Team, 2021a) to obtain the categories for each article as the dump file has no category-related information.

process of inventing and refining the data collection process in order to arrive at the final list of steps as presented in this paper.

C.1 Biases in the data collection

While there are many filtering steps in our data collection above, most of them are data cleaning filters that are typically needed in a regular NLP dataset construction.

We recognize that there are *three key filters* in our system that impose strong biases:

1. In Step 4, we use only phrases that contain one word in the WiC. That is, we find Step 4 to substantially increase our chance of finding triplets with a polysemous target phrase. We have added this note in the Data Collection description. It is possible to remove Step 4, but that would require a larger human annotation effort to reach the same 15K labeled triplets.
2. In Step 5, we rely on SimCSE to find target phrases that are placed in two sentences of dissimilar meanings.
3. In Step 5, we rely on SimCSE to find target phrases that are placed in two Wikipedia pages of distinct topics.

D Statistics for search queries in Yahoo Search Query dataset

We analyze 4,496 user queries released in the Yahoo Search Query Log To Entities dataset (Yahoo, 2022b) and use SpaCy tokenizer (Honnibal et al., 2020) to classify them into 4 main categories: Noun phrases, verb phrases, URLs and others. As a result, noun phrases are the most common query type from users with 3,576 queries ($\sim$79.54%) followed by URLs with 675 queries ($\sim$15.01%) while verb phrases and other types are less preferred by users. Moreover, the average length of the real user queries is $\sim$1.60 which is quite close to our PS task with $\sim$2.27.

Table A2: Statistics of Yahoo queries across different query types.

Query type	# queries	Percentage (%)
Noun phrases	3,576	79.54
Verb phrases	148	3.29
URLs	675	15.01
Others	97	2.16
Total	4,496	100.00

E Verification of Phrase Similarity

To enhance the quality of the proposed PiC benchmark, we hire three additional Upwork experts to verify the correctness of PS examples where two phrases are supposed to be *non-equivalent* for negative examples (e.g. massive figure and giant number in Fig. 1b) or *equivalent* for positive examples (e.g. massive figure and huge model in Fig. 1b), and keep an example if it is endorsed by at least two experts (the rest is discarded from PS).

Two Upwork verifiers A_1 and A_2 start checking 5,104 *negative* examples and the third verifier A_3 is responsible for breaking the ties if A_1 and A_2 disagree with each other (see Fig. A1). Both A_1 and A_2 are asked to provide corrections when they do not agree with the labels. As a result, 4,935 out of 5,104 examples are accepted by pairs of (A_1, A_2), (A_1, A_3) or (A_2, A_3), 68 examples incorrect at first but are modified by either A_1 or A_2 and endorsed by A_3. In total, we reject 101 negative examples because there are not at least two experts agreeing with the annotations.

We repeat the same procedure to verify 5,104 *positive* examples. In sum, we retain 5,002 examples including 4,904 examples accepted by pairs of two verifiers and 98 examples incorrect at first but are modified by either A_1 or A_2 and endorsed by A_3. There are 102 positive examples rejected because there are not at least two experts agreeing with the annotations (Fig. A2).

After this verification round, we collect 5,003 *negative* examples and 5,002 *positive* examples. and randomly exclude 1 negative example to make the dataset balance which results in 10,004 examples in total for PS.

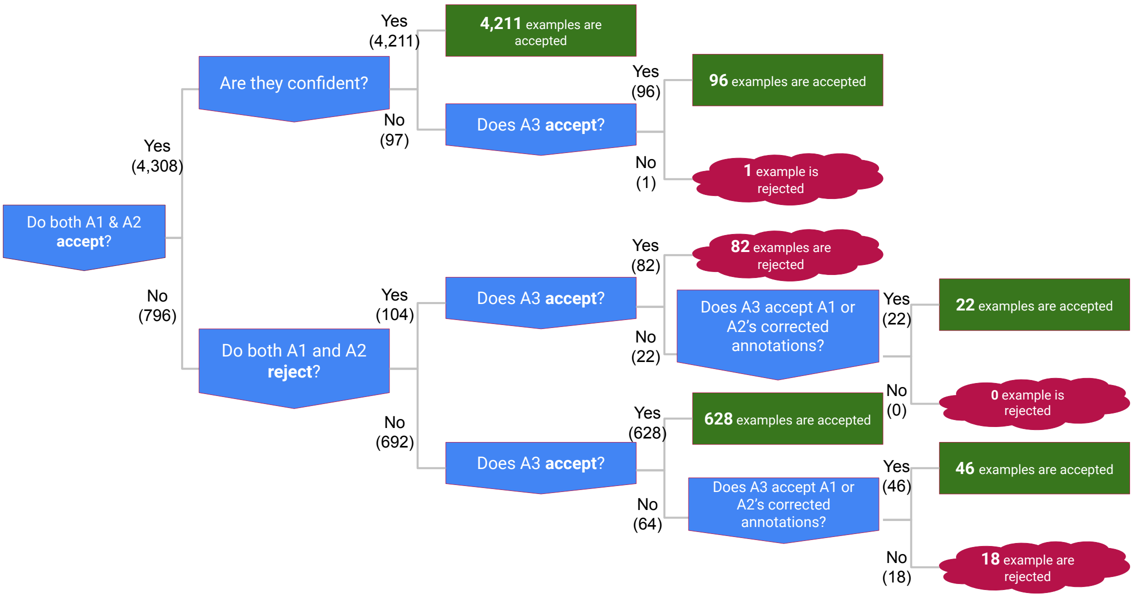

Figure A1: A decision tree describing our verification process for PS that involves three experts. Red, green and blue cells represent Reject, Accept decision and Questions. The numbers of examples for each branch are shown in parentheses.

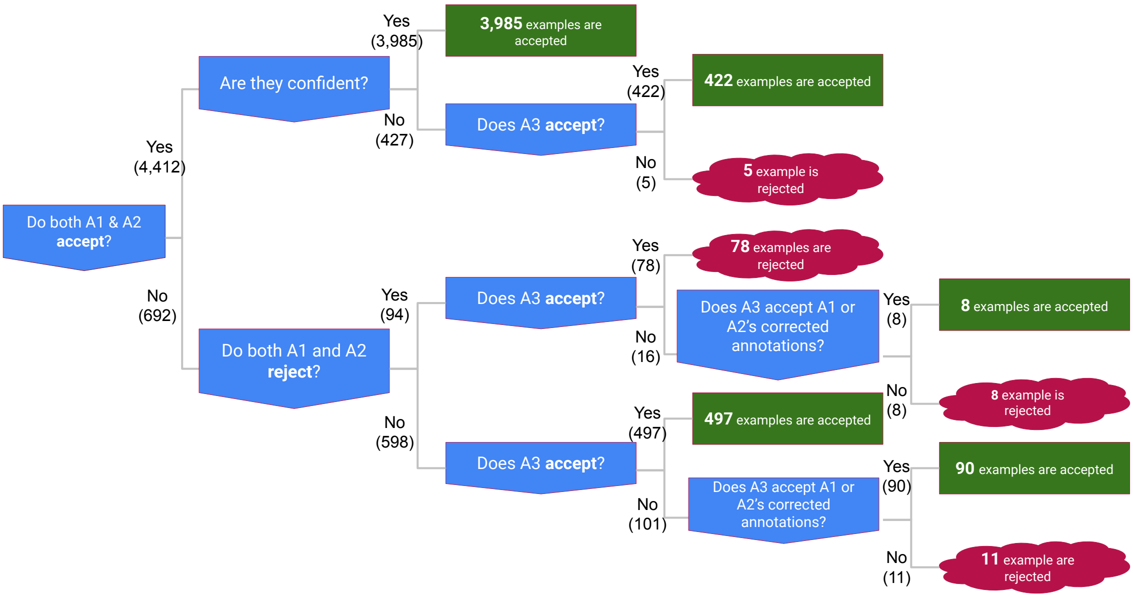

Figure A2: A decision tree describing our verification process for PS that involves three experts. Red, green and blue cells represent Reject, Accept decision and Questions. The numbers of examples for each branch are shown in parentheses.

Table A1: Summary of our 3-stage data construction. $\boldsymbol{p}$, s, m d, q, l denote target phrase, sentence, metadata, document, query, and label, respectively.

	Remaining #	Data type	Description
Sec. 3.1 Data Collection			
Step 1: Download Wiki articles	$\sim$6.27M	articles	Remove $\sim$9.51M empty articles.
Step 2: Extract phrases	$\sim$286.78M	($\boldsymbol{p}$, s, m)	Extract noun phrases and proper nouns along with their context sentences from Wikipedia articles.
Step 3: Remove phrases of a single context	$\sim$17.96M	($\boldsymbol{p}$, $[s_1, ..., s_n]$, m)	For each phrase, gather all sentences where that phrase is used.
Step 4: Find phrases of polysemous words	$\sim$6.5M	($\boldsymbol{p}$, $[s_1, ..., s_n]$, m)	Filter those phrases that do not contain WiC words.
Step 5: Find phrases in distinct contexts			Sort by X_i and apply filters to find pairs of sentences where their phrase potentially has different meanings.
- Sort and filter by semantic dissimilarity	$\sim$600K	($\boldsymbol{p}$, s_1, s_2, m)	X_1 : cosine similarity scores of sentences embeddings.
- Sort by domain dissimilarity	$\sim$600K	($\boldsymbol{p}$, s_1, s_2, m)	X_2 : cosine similarity scores of domain embeddings i.e., use categories of each article to get embeddings.
Step 6: Select data for expert annotation	19,500	($\boldsymbol{p}$, d_1, d_2)	Remove proper nouns and phrases with missing information and select top 19,500 examples for annotation.
Sec. 3.2 Data Annotations	30,042	($\boldsymbol{p}$, d, q)	Create a query i.e., paraphrase from the given phrase in each context document.
	15,021	($\boldsymbol{p}$, d_1, d_2, l)	Create a Yes/No label for each pair of documents.
Sec. 3.3 Verifying Annotations			
Round 1: MTurk verifier	22,496	($\boldsymbol{p}$, d, q)	Verify queries and Yes/No label by MTurkers.
	10,043	($\boldsymbol{p}$, d_1, d_2, l)	
Round 2: Upwork verifiers	28,325	($\boldsymbol{p}$, d, q)	Verify instances rejected in Round 1.
	13,413	($\boldsymbol{p}$, d_1, d_2, l)	

F Quantitative results on PR-page

Table A3: **Ranking** accuracy (%) on **PR-page** using the state-of-the-art pretrained phrase embeddings (a) and those finetuned on PR-pass via SS-style training (b).

Model	Phrase				Phrase + Context			
	Top-1	Top-3	Top-5	MRR@5	Top-1	Top-3	Top-5	MRR@5
(a) Pre-trained embeddings								
BERT (Devlin et al., 2019)	20.70	34.30	41.00	28.20	**35.40** (+14.70)	**52.10**	**59.10**	**44.50**

(b) PR-pass-trained SS models' phrase embeddings								
PhraseBERT (Wang et al., 2021)	**49.40**	**69.40**	**76.70**	**60.10**	14.70	21.60	26.10	18.70
SimCSE (Gao et al., 2021)	44.20	66.60	73.50	55.70	24.60	37.80	43.20	31.70

G Finetuning on PSD does not substantially improve accuracy

As PSD has only 4,858 examples, we use all examples for testing in Sec. 5.5 and find the best PR-trained SS models to perform poorly. To further understand the challenge of PSD, here, we ask:
Q: *How much does training on PR-pass and finetuning on PSD improve accuracy on PSD?*

Experiment We take the PR-pass-trained SS models and further finetune them on a subset of PSD to measure how training directly on PSD improves SS models. We split PSD into 1,438/500/3,000 examples for train/dev/test sets, respectively, and finetune the PR-pass-trained SS models on this PSD train set. For comparison with the results in Sec. 5.4, we use the same set of hyperparameters as when finetuning on PR-pass in Sec. 5.4. Below, we report the test-set results of the lowest dev-loss models.
Results On the PSD-3K test set, all models perform poorly at a mean EM score of 55.14% (Table A4a; mean). Interestingly, finetuning the original models using the 1,938 examples (hereafter, PSD-2K) instead of PR-pass decreases accuracy, on average by -6.51 points. An explanation is that 1,438 PSD training examples are too few for the finetuning to be effective. Indeed, finetuning the PR-pass-trained SS models further on PSD-2K increases the scores for all models by +9.10 on average (Table A4c; mean). The best model is Longformer$_{\text{Base}}$ (Beltagy et al., 2020) (Table A4; 71.10 EM), which is still substantially lower than the human upperbound of 95%.

Table A4: Performance of **SS models** on 3,000 PSD **test** examples. (a) and (b) models are **finetuned** only on PR-pass and 1,938 PSD examples (PSD-2K), respectively. (c) models are finetuned on PR-pass first and then finetuned on PSD-2K. All models are "base" unless otherwise specified. The definitions of EM+loc and F$_1$+loc are in Table 6's caption.

Models finetuned on	(a) PR-pass		(b) PSD-2K		(c) PR-pass + PSD-2K	
	EM+loc	F$_1$+loc	EM+loc	F$_1$+loc	EM+loc	F$_1$+loc
PhraseBERT (Wang et al., 2021)	51.00	51.15	35.43 (-15.57)	36.02	56.53 (+5.53)	56.81
BERT (Devlin et al., 2019)	54.53	54.75	44.33 (-10.20)	45.28	63.83 (+9.30)	64.14
BERT$_{\text{Large}}$ (Devlin et al., 2019)	54.77	54.99	54.07 (-0.70)	54.82	67.13 (+12.36)	67.36
SpanBERT (Joshi et al., 2020)	52.27	52.37	44.67 (-7.60)	45.35	69.93 (+17.66)	70.14
SentenceBERT (Reimers and Gurevych, 2019)	52.27	52.41	38.63 (-13.64)	39.31	58.93 (+6.66)	59.21
SimCSE (Gao et al., 2021)	53.47	53.59	43.67 (-9.80)	44.38	60.60 (+7.13)	60.80
Longformer (Beltagy et al., 2020)	**62.47**	**62.58**	61.97 (-0.50)	62.69	**71.10** (+8.63)	**71.30**
Longformer$_{\text{Large}}$ (Beltagy et al., 2020)	60.33	60.42	**66.27** (+5.94)	**67.10**	65.87 (+5.54)	66.10

H SS-style training improves *non*-contextualized but not contextualized phrase embeddings

As the SS models trained on PR-pass and PR-page perform impressively (Sec. 5.4), almost 1.5× better than the ranking models that are based on pre-trained embeddings, an interesting question is:
Q: *Does SS training also improve contextualized phrase embeddings?*

This is important to understand because the impressive SS-models' performance gain may come from the extra linear-classification layer (not necessarily from the finetuned embeddings).

Experiment We extract the phrase embeddings (both non-contextualized and contextualized) from the PR-pass-trained SS models from Sec. 5.4 (i.e. discarding the classification layer) and test them in the PR-pass ranking experiments (as in Sec. 5.3).

Results After finetuning on PR-pass, the *non*-contextualized phrase embeddings improve substantially for most models at an average gain of +16.61 in top-1 accuracy (e.g., PhraseBERT top-1 accuracy increases from 36.62% to 59.02%; Table A5b). This result shows that training on PR-pass improves non-contextualized phrase embeddings. In stark contrast, the ranking scores of *contextualized* phrase embeddings drop significantly, -11.95 points on average (Table A5c), compared to before finetuning on PR-pass.

In sum, we are observing a consistent trend that the contextualized phrase embeddings of the original pre-trained BERT (both "base" and "large") are remarkably beneficial for retrieval (i.e. PR). However, after finetuning, e.g. on PR-pass or using other techniques (e.g. in PhraseBERT or SentenceBERT), such benefits of leveraging context disappear. Aligned with Yu and Ettinger (2020), we find that incorporating context effectively into phrase embeddings is an open research challenge.

Table A5: **Ranking** accuracy (%) on **PR-pass** using the state-of-the-art pretrained phrase embeddings (a) and those finetuned on PR-pass via SS-style training (b). See Appendix F for the results on PR-page. Δ (e.g. -3.62) denotes the differences between the Top-1 accuracy in the contextualized ("Phrase + Context") vs. the non-contextualized ("Phrase") setting.

Model	Phrase				Phrase + Context			
	Top-1	Top-3	Top-5	MRR@5	Top-1 (Δ)	Top-3	Top-5	MRR@5
(a) Pre-trained embeddings								
PhraseBERT (Wang et al., 2021)	36.62	66.96	75.90	52.20	33.00 (-3.62)	49.60	56.70	41.90
BERT (Devlin et al., 2019)	29.80	47.90	55.40	39.50	**47.44** (+17.64)	**65.78**	**73.30**	**57.30**
$\text{BERT}_{\text{Large}}$ (Devlin et al., 2019)	23.76	38.52	45.40	31.70	**42.80** (+19.04)	**58.90**	**64.90**	**51.30**

mean differences	+16.61				-11.95			

I Qualitative examples for PS, PR-pass, PR-page and PSD

PS example. Groundtruth: "positive"	
P_1	moderate speed
P_2	steady pace
S_1	Deforestation due to logging and land conversion has likely caused the population to decline at a moderate speed.
S_2	Deforestation due to logging and land conversion has likely caused the population to decline at a steady pace.

Figure A3: PhraseBERT-based classifier **correctly** predicts "positive" given two phrases P_1 and P_2 with and without the presence of context S_1 and S_2. Here, to humans, the phrases are non-polysemous and have the same meaning.

PS example. Groundtruth: "negative"	
P_1	greatest emphasis
P_2	highest stress
S_1	However, the rock art had the greatest emphasis on domesticated cattle.
S_2	However, the rock art had the highest stress on domesticated cattle.

Figure A4: PhraseBERT-based classifier **correctly** predicts "negative" given two phrases P_1 and P_2 with and without the presence of context S_1 and S_2. Here, to humans, the two phrases are non-ambiguously carrying different meanings.

PS example. Groundtruth: "positive"	
P_1	unique image
P_2	uncommon style
S_1	Bayliss has been praised for her unique image and tendency to change up songs.
S_2	Bayliss has been praised for her uncommon style and tendency to change up songs.

Figure A5: PS case that requires context to determine similarity. Without context, a PhraseBERT-based classifier incorrectly thinks P_1 and P_2 are different. Yet, it changes the prediction to "positive", i.e. thinking two phrases have the same meaning, when the context is taken into account.

PS example. Groundtruth: "negative"	
P_1	permanent post
P_2	stable location
S_1	His assistant, John Carver took over as caretaker manager, managing one win, but was not considered for the permanent post, and left in September 2004.
S_2	His assistant, John Carver took over as caretaker manager, managing one win, but was not considered for the stable location, and left in September 2004.

Figure A6: PS case that requires context to determine similarity. Without context, PhraseBERT-based classifier incorrectly thinks P_1 and P_2 carry the same meaning. Yet, it correctly changes the prediction to "negative" when the context is taken into account.

PSD example.	
$\boldsymbol{d}$	Bubble memory is a type of non-volatile computer memory that uses a thin film of a magnetic material to hold small magnetized areas, known as "bubbles" or "domains", each storing one bit of data. The material is arranged to form a series of parallel tracks that the bubbles can move along under the action of an external magnetic field. The bubbles are read by moving them to the edge of the material where they can be read by a conventional magnetic pickup, and then rewritten on the far edge to keep the memory cycling through the material. In operation, bubble memories are similar to delay line memory systems. Bubble memory started out as a promising technology in the 1970s, offering memory density of an order similar to hard drives but performance more comparable to core memory while lacking any moving parts. This led many to consider it a contender for a "universal memory" that could be used for all storage needs. The introduction of dramatically faster semiconductor memory chips pushed bubble into the slow end of the scale, and equally dramatic improvements in hard drive capacity made it uncompetitive in price terms. Bubble memory was used for some time in the 1970s and 80s where its non-moving nature was desirable for maintenance or shock-proofing reasons. The introduction of Flash RAM and similar technologies rendered even this niche uncompetitive, and bubble disappeared entirely by the late 1980s. History. Precursors. The Inkerman stone, of which the building is made, was mined near Sevastopol and transported by barges. No convenient mooring facilities existed at that time, so the barges had to anchor in the harbor and the load was moved to the shore by boats and then transported to the construction site across the steppe. During the first year of construction, the builders concentrated on the basic structure at the expense of various facilities and decorations. At the end of 1816, the lighthouse looked like a conic 36-metre-high stone tower with a wooden 3.3-metre-high decagonal lantern. The lighthouse became operational in 1817 after its lighting system had been repaired. Three houses were built next to the tower to accommodate the lighthouse personnel and for storage needs. However, cold and humid winters of the Tarkhanut Peninsula, however, made these houses nearly unsuitable for living. In 1862, the lighting system was upgraded, and the spread of light reached 12.4 miles. In 1873, the construction resumed along with cleaning efforts of the surrounding areas. The building was finished and painted white. In 1876, an additional telegraph spot was built near the tower.
$\boldsymbol{q}_1$	storehouse purposes Groundtruth: storage needs & Prediction: storage needs (confidence: 0.99)
$\boldsymbol{q}_2$	data caching Groundtruth: storage needs & Prediction: storage needs (confidence: 0.99)

Figure A7: Given document $\boldsymbol{d}$, our Longformer$_{\text{Large}}$ SS model trained on PR-pass correctly retrieves storage needs in the second paragraph for the query $\boldsymbol{q}_1$ “storehouse purposes” but *fails* to retrieve the answer when the query $\boldsymbol{q}_2$ is “data caching”. The predicted answer for $\boldsymbol{q}_2$ should be storage needs (i.e. in the first passage) since this phrase relates to caching data digitally in computers while storage needs refers to physically storing objects.

PSD example.	
$\boldsymbol{d}$	In the libretto, Delilah is portrayed as a seductive "femme fatale", but the music played during her parts invokes sympathy for her. The 1949 biblical drama "Samson and Delilah", directed by Cecil B. DeMille and starring Victor Mature and Hedy Lamarr in the titular roles, was widely praised by critics for its cinematography, lead performances, costumes, sets, and innovative special effects. It became the highest-grossing film of 1950, and was nominated for five Academy Awards, winning two. According to "Variety", the film portrays Samson as a stereotypical "handsome but dumb hulk of muscle". Samson has been especially honored in Russian artwork because the Russians defeated the Swedes in the Battle of Poltava on the feast day of St. Sampson, whose name is homophonous with Samson's. The lion slain by Samson was interpreted to represent Sweden, as a result of the lion's placement on the Swedish coat of arms. In 1735, C. B. Rastrelli's bronze statue of Samson slaying the lion was placed in the center of the great cascade of the fountain at Peterhof Palace in Saint Petersburg. Samson is the emblem of Lungau, Salzburg and parades in his honor are held annually in ten villages of the Lungau and two villages in the north-west Styria (Austria). During the parade, a young bachelor from the community carries a massive figure made of wood or aluminum said to represent Samson. The tradition, which was first documented in 1635, was entered into the UNESCO list of Intangible Cultural Heritage in Austria in 2010. Samson is one of the giant figures at the "Ducasse" festivities, which take place at Ath, Belgium. On September 22, 2015, Honda announced that they had sold over 1 million Activas in five months in the Indian market, from April to August. Honda launched their 5th generation of Honda Activa in 2018, and the sixth-generation Honda Activa 6G have been launched in India with prices starting at 63,912 (ex-showroom, Delhi). Milestones. In April, 2014, "The Economic Times" reported the Honda Activa to be the best selling two wheeler in India, outselling the Hero Splendor. During the month of September 2013, 141,996 Honda Activa scooters were sold, nearly equal to Honda's entire annual sales in North America. The 110cc Activa is the company's biggest seller, by far. It is responsible for over 2,00,000 sales units each month. In November 2018, HMSI crossed the 2.5 crore sales mark in the scooter segment. It has become the first company to reach this milestone and the biggest contributor to this massive figure is the Honda Activa. It took Honda 13 years to achieve the one crore sales figure, but it managed to add another crore in the span of just three years. It then went on to achieve the next 50 lakh in just one year.
$\boldsymbol{q}_1$	huge model Groundtruth: massive figure & Prediction: massive figure (confidence: 0.99)
$\boldsymbol{q}_2$	giant number Groundtruth: massive figure & Prediction: massive figure (confidence: 0.99)

Figure A8: Given document $\boldsymbol{d}$, Longformer$_{\text{Large}}$ model trained with SS approach on PR-pass correctly retrieves massive figure in the second paragraph for the query $\boldsymbol{q}_2$ “giant number” but *fails* to retrieve the answer when the query $\boldsymbol{q}_1$ is “huge model”. The predicted answer for $\boldsymbol{q}_1$ should be massive figure in the first passage since this phrase relates to a physical shape instead of a number.

	PSD example.
$\boldsymbol{d}$	Eva held ambitions to replace Hortensio Quijano for the 1951 election, although her poor health kept her from this. Nonetheless many were concerned that her agenda would be pushed through. In march of 1951 the government arrested several retired army officers due to their dissent and disapproval of Perón's administration. This raised tensions among the rest of the army, although action did not occur. By September tensions had risen among the military due to the unrivalled power of the Peronist regime. On September 28, 1951, during the election, Menéndez led the military uprising in an attempt to overthrow the government. He led a core of officers, commanding a division, and left Campo de Mayo bound for the Casa Rosada. Resolve for the uprising, especially among the non-commissioned officers and enlisted men, was not strong enough. They were not prepared to fight their own countrymen. The uprising was over as soon as opposition was encountered, almost completely bloodless. Perón admired the loyalty of the troops and pardoned all those involved. The design uses a similar standard to the JVX in terms of distortion reduction with crossbraces and 27 cells but that's where the similarity ends. Petra was built from the ground up with entirely new panel shaping and trim. Petra has a highly elliptical planform and very high sweep. NZ Aerosports say she has a high roll rate, a long recovery arc and high maximal glide ratio. She is said to deliver unrivalled power in the turn, plane out and flare. Petra has a long list of World Records, National and International titles to back that up. She had an impressive debut at the PD Big Boy Pants event in July 2011, with Nick Batsch setting a new distance world record of 222.45m (729ft). One month later Nick took out the Pink Open in Klatovy and the FAI World Cup also; first in distance, speed and overall. He also won the 2011 US CP nationals on Petra. Patrick Boulongne came 2nd in the European Championships and 6th overall at the World Cup with Petra in his first competition with her. He went on to win the 2011 French Canopy Piloting Nationals.
$\boldsymbol{q}_1$	incomparable energy Groundtruth: unrivalled power & Prediction: unrivalled power (confidence: 0.99)
$\boldsymbol{q}_2$	indomitable strength Groundtruth: unrivalled power & Prediction: unrivalled power (confidence: 0.99)

Figure A9: Given document $\boldsymbol{d}$, Longformer$_{\text{Large}}$ model trained via the SS approach on PR-pass correctly retrieves unrivalled power in the first paragraph for the query $\boldsymbol{q}_2$ "indomitable strength" but *fails* to retrieve the answer when the query $\boldsymbol{q}_1$ is "incomparable energy". The predicted answer for $\boldsymbol{q}_1$ should be unrivalled power in the second passage since the second passage changes "unrivalled power" meaning to a competition strength instead of military power.

	PR-pass example. Groundtruth: common thought
$\boldsymbol{d}$	As the medical corps grew in size there was also specialization evolving. Physicians surfaced that specialized in disease, surgery, wound dressing and even veterinary medicine. Veterinary physicians were there to tend to livestock for agricultural purposes as well as combat purposes. The Cavalry was known for their use of horses in combat and scouting purposes. Because of the type of injuries that would have been commonly seen, surgery was a somewhat common occurrence. Tools such as scissors, knives and arrow extractors have been found in remains. In fact, Roman surgery was quite intuitive, in contrast to common thought of ancient surgery. The Roman military surgeons used a cocktail of plants, which created a sedative similar to modern anesthesia. Written documentation also showed surgeons would use oxidation from a metal such as copper and scrape it into wounds, which provided an antibacterial effect; however, this method was most likely more toxic than providing an actual benefit. Doctors had the knowledge to clean their surgical instruments with hot water after each use. Wounds were dressed, and dead tissue was removed when bandages were changed.
$\boldsymbol{q}$	prevalent theory
R	0.882 common thought 0.855 common thought of 0.702 fact 0.698 to common thought 0.675 common occurrence

Figure A10: A **ranking** model based on the phrase embeddings of the PR-pass-trained PhraseBERT SS model correctly ranks and retrieves the most semantically relevant answer "common thought" as the top-1 prediction in the retrieval list R for the query "prevalent theory" in a PR-pass example (which contains a document $\boldsymbol{d}$ and a query $\boldsymbol{q}$).

PR-page example.	Groundtruth: continued risk
d	... Following a United Nations agreement between Indonesia and Portugal, a UN-supervised referendum held on 30 August 1999 offered a choice between autonomy within Indonesia and full independence. The people of East Timor voted overwhelmingly for independence. An Australian-led and Indonesian-sanctioned peacekeeping force, INTERFET, was sent into the territory to restore order following a violent 'scorched-earth' policy carried out by pro-integration militia and supported by elements of the Indonesian military. In response to Australia's involvement, Indonesia abrogated the 1995 security pact, asserting that Australia's actions in East Timor were inconsistent with 'both the letter and spirit of the agreement'. Official meetings were cancelled or delayed, including the Indonesia-Australia Ministerial Dialogue, which would not reconvene until March 2003. INTERFET was later replaced by a UN force of international police, UNTAET, which formed a detachment to investigate alleged atrocities. "Tampa" affair and the War on Terror. The relationship came under strain in August 2001 during the "Tampa" affair, when Australia refused permission for the Norwegian freighter ship MV "Tampa" to enter Australian waters while carrying Afghan asylum seekers that it had rescued from a distressed fishing vessel in international waters. The Indonesian Search and Rescue Agency did not immediately respond to requests from Australia to receive the vessel. When the ship entered Australian territorial waters after being refused permission, Australia attempted without success to persuade Indonesia to accept the asylum seekers. Norway also refused to accept the asylum seekers and reported Australia to international maritime authorities. The incident prompted closer coordination between Indonesian and Australian authorities, including regional conferences on people smuggling, trafficking in persons and other transnational crime. In 2002, a terrorist attack in Kuta, Bali killed 202 people, including 88 Australians, and injured a further 240. Jemaah Islamiyah, a violent Islamist group, claimed responsibility for the attack, allegedly in retaliation for Australia's support for East Timorese independence and the War on Terror. A subsequent attack in 2005 resulted in the deaths of a further 20 people, including 15 Indonesians and 4 Australians. The 2003 Marriott Hotel bombing was also perceived as targeted at Western interests in Indonesia; Al Qaeda claimed the attack was carried out by a Jemaah Islamiyah suicide bomber in response to actions of the United States and its allies, including Australia. A 2004 attack on the Australian embassy in Jakarta by Jemaah Islamiyah resulted in the deaths of nine Indonesians. The following year, Indonesian diplomatic and consular premises in Australia received a number of hoax and threat messages. Since then, both the United States and Australian governments have issued warnings against travel to Indonesia, advising their citizens of a continued risk of attacks. These incidents prompted greater cooperation between law enforcement agencies in the two countries, building on a 1999 agreement on drug trafficking and money laundering. The Australian Federal Police's Jakarta Regional Cooperation Team provided assistance to the Indonesian National Police, and has contributed to the Jakarta Centre for Law Enforcement Cooperation. This relationship has attracted criticism, particularly following the arrest and sentencing of the Bali Nine, a group of nine Australians arrested in Denpasar while attempting to smuggle heroin from Indonesia to Australia. The 2005 conviction of Schapelle Corby for attempting to smuggle drugs to Bali also attracted significant attention in the Australian media. The 2004 Indian Ocean earthquake prompted a significant humanitarian response from Australia, including a $1 billion aid package from the federal government, a further $17.45 million contribution from state and territory governments, and the commitment of 900 Australian Defence Force personnel to relief efforts in northern Sumatra and Aceh. A telethon broadcast on Australia's three major commercial television networks called "" generated pledges of more than $10 million, contributing to total private aid of $140 million. The Eighth "Australia-Indonesia Ministerial Forum" (AIMF) was held in Bali on 29 June 2006 and was attended by five Australian and eleven Indonesian ministers. A key outcome was support for the conclusion of a security agreement, later realised as the Lombok Agreement, providing a framework for the development of the security relationship by the end of 2006 on defence, law enforcement, counter-terrorism, intelligence, maritime security, aviation safety, WMD non-proliferation, and bilateral nuclear cooperation for peaceful purposes. Australia-Indonesia-East Timor Trilateral Ministerial Meetings occurred three times to September 2006. Recent relations. 2010 President Susilo Bambang Yudhoyono visited Australia in April 2010, and became the second Indonesian leader to address federal parliament: Finally, I look forward to a day in the near future. The day when policy makers, academicians, journalists and other opinion leaders all over the world take a good look at the things we are doing so well together. And they will say: these two used to be worlds apart. But they now have a fair dinkum of a partnership. ...
q	sustained threat
R	0.830 threat . 0.802 potential threat 0.800 threat reached 0.787 threat as 0.787 threat to

Figure A11: A **ranking** model based on the non-contextualized embeddings of USE-v5 fails to retrieve the correct answer "continued risk" for the query "sustained threat" in the PR-page example (which contains a document $\boldsymbol{d}$ and a query $\boldsymbol{q}$). The top-5 phrases retrieved (R) contains the word "threat" but have no identifier conveying the "continued" or 'sustained" sense. Here, the Wikipedia page is truncated to fit into a single manuscript page.

J Verifying annotations

There are two common methods for evaluation of dataset quality: (1) Verify only a small, random subset (Pilehvar and Camacho-Collados, 2019) to estimate the quality of the full dataset or (2) verifying the entire dataset with multiple annotators and use the inter-annotator agreement (IAA) to control quality (Bowman et al., 2015; Kwiatkowski et al., 2019). The first approach for approximation is budget-friendly but it remains unknown whether the rest of examples are at high quality, while IAA is more desired but annotating thousands of instances can be prohibitively slow and costly.

We propose a **hybrid approach** to evaluate (leveraging both linguistic experts and non-experts) and ensure high quality for 30,042 queries and 15,021 Yes/No answers at lower cost compared to IAA via two rounds:

1. First, we ask around 1,000 highly qualified freelancers on Amazon Mechanical Turk (MTurk verifiers) to verify whether the *query* annotated by our Upwork annotators is interchangeable i.e. has the same meaning with the given *phrase* in *paragraph*. To verify Yes/No answers, MTurk verifiers need to read two short paragraphs containing the same phrase like Upwork annotators to make decisions. We do not show answers to the MTurk verifiers to avoid biases.

2. Second, we continue hiring 5 Upwork verifiers who are writing experts to double-check those instances rejected by MTurk verifiers from the previous round and only discard an example if the Upwork verifiers agree with MTurk verifiers.

J.1 Round 1: Verification by MTurk non-experts

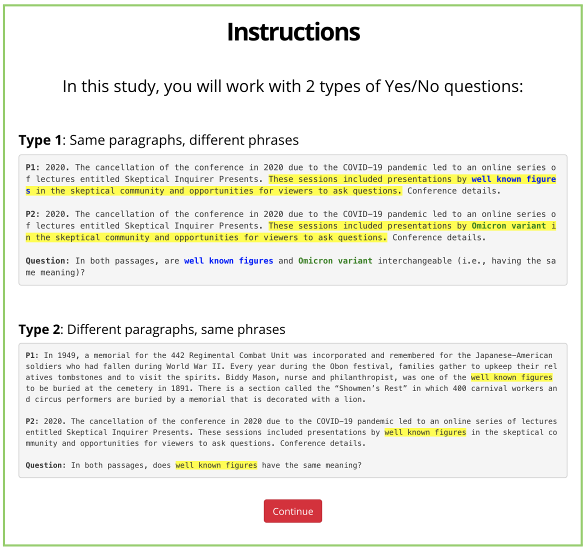
We use AMT platform to recruit more than 1,000 MTurk verifiers. Also, we use Gorrila (`gorilla.sc`) to develop user interface to collect answers from participants because (1) Gorilla provides easy-to-use tools to build graphical interface, (2) it is straightforward to monitor and discard results from unqualified participants and (3) we can easily share the experiment with MTurk verifiers via a link. Per 30 verified answers in around $\sim$20 minutes, the verification process costs us \$5.6 (AMT fees included) and 1 token to Gorilla to a single MTurk verifier.

Participants are given detailed instructions along with 5 practice samples to get familiar with the task (Fig. A12). They need to pass an evaluation checkpoint including 6 questions randomly sampled from our verified question bank in order to start working with sets of 30 questions. With this approach, all examples in the dataset are verified once and as a result, 22,496/30,042 queries ($\sim$74.88%) and 10,043/15,021 Yes/No answers ($\sim$66.86%) accepted by MTurkers are considered high quality since they are annotated by a writing expert and confirmed by a qualified English native speaker. The remaining 7,546 queries and 4,978 Yes/No answers rejected that are passed to another group of 5 writing experts for confirmation.

J.2 Round 2: Verification by Upwork experts

We hired another set of 5 writing experts from Upwork (Upwork verifiers) with an hourly rate of \$25-40/hour to verify 12,524 examples rejected by MTurk verifiers, i.e., at an average cost of approximately \$0.26 per example. See a sample assignment given to an Upwork expert in (PiC, 2022).

We rely on IAA to decide whether to accept or reject an example. Specifically, we use the *same question types* as shown to MTurk verifiers in the previous step and see whether these Upwork verifiers agree with the Upwork annotators to keep this example or with MTurk verifiers to reject it. We find that the agreement between the first- and third-round annotators are 5,829 (out of 7,546) paraphrases and 3,370 (out of 4,978) Yes/No answers in total and thus the total high-quality queries and Yes/No answers we achieve are 28,325 and 13,413, respectively.



Instructions

In this study, you will work with 2 types of Yes/No questions:

Type 1: Same paragraphs, different phrases

P1: 2020. The cancellation of the conference in 2020 due to the COVID–19 pandemic led to an online series of lectures entitled Skeptical Inquirer Presents. These sessions included presentations by **well known figures** in the skeptical community and opportunities for viewers to ask questions. Conference details.

P2: 2020. The cancellation of the conference in 2020 due to the COVID–19 pandemic led to an online series of lectures entitled Skeptical Inquirer Presents. These sessions included presentations by **Omicron variant** in the skeptical community and opportunities for viewers to ask questions. Conference details.

Question: In both passages, are **well known figures** and **Omicron variant** interchangeable (i.e., having the same meaning)?

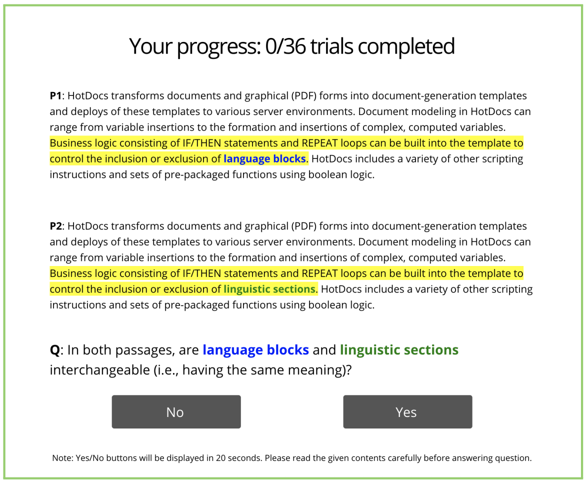
Type 2: Different paragraphs, same phrases

P1: In 1949, a memorial for the 442 Regimental Combat Unit was incorporated and remembered for the Japanese–American soldiers who had fallen during World War II. Every year during the Obon festival, families gather to upkeep their relatives tombstones and to visit the spirits. Biddy Mason, nurse and philanthropist, was one of the well known figures to be buried at the cemetery in 1891. There is a section called the “Showmen’s Rest” in which 400 carnival workers and circus performers are buried by a memorial that is decorated with a lion.

P2: 2020. The cancellation of the conference in 2020 due to the COVID–19 pandemic led to an online series of lectures entitled Skeptical Inquirer Presents. These sessions included presentations by well known figures in the skeptical community and opportunities for viewers to ask questions. Conference details.

Question: In both passages, does well known figures have the same meaning?

(a) Detailed instructions given to MTurkers



Your progress: 0/36 trials completed

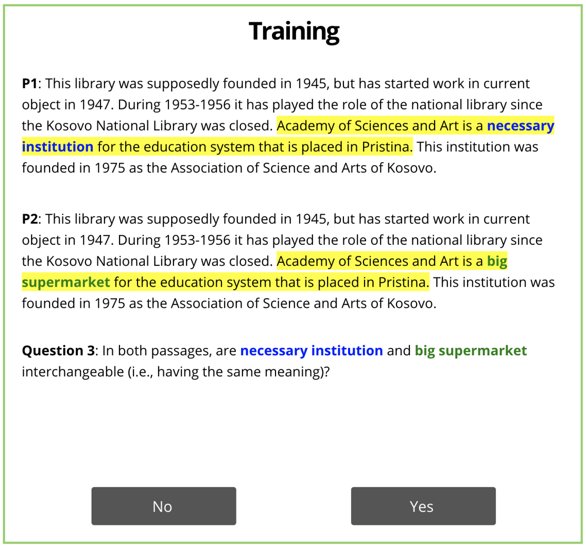
P1: HotDocs transforms documents and graphical (PDF) forms into document-generation templates and deploys of these templates to various server environments. Document modeling in HotDocs can range from variable insertions to the formation and insertions of complex, computed variables. Business logic consisting of IF/THEN statements and REPEAT loops can be built into the template to control the inclusion or exclusion of **language blocks**. HotDocs includes a variety of other scripting instructions and sets of pre-packaged functions using boolean logic.

P2: HotDocs transforms documents and graphical (PDF) forms into document-generation templates and deploys of these templates to various server environments. Document modeling in HotDocs can range from variable insertions to the formation and insertions of complex, computed variables. Business logic consisting of IF/THEN statements and REPEAT loops can be built into the template to control the inclusion or exclusion of **linguistic sections**. HotDocs includes a variety of other scripting instructions and sets of pre-packaged functions using boolean logic.

Q: In both passages, are **language blocks** and **linguistic sections** interchangeable (i.e., having the same meaning)?

Note: Yes/No buttons will be displayed in 20 seconds. Please read the given contents carefully before answering question.

(b) Upon completion of training stage, MTurkers need to correctly answer the first 5 out of 6 questions to be invited to verify annotations from Upwork experts.



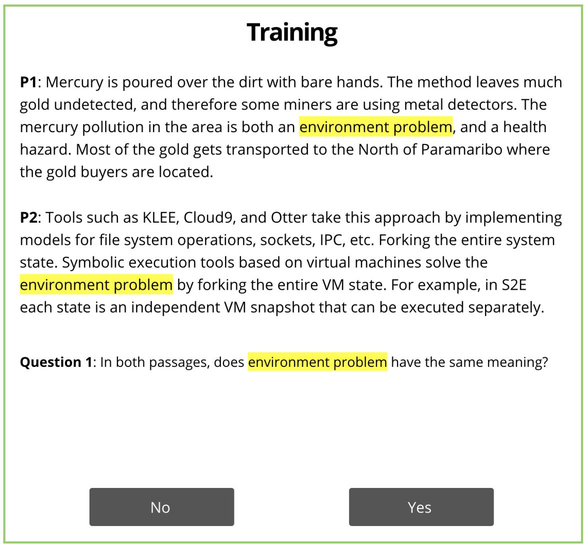
Training

P1: This library was supposedly founded in 1945, but has started work in current object in 1947. During 1953-1956 it has played the role of the national library since the Kosovo National Library was closed. Academy of Sciences and Art is a **necessary institution** for the education system that is placed in Pristina. This institution was founded in 1975 as the Association of Science and Arts of Kosovo.

P2: This library was supposedly founded in 1945, but has started work in current object in 1947. During 1953-1956 it has played the role of the national library since the Kosovo National Library was closed. Academy of Sciences and Art is a **big supermarket** for the education system that is placed in Pristina. This institution was founded in 1975 as the Association of Science and Arts of Kosovo.

Question 3: In both passages, are **necessary institution** and **big supermarket** interchangeable (i.e., having the same meaning)?

(c) Verification of paraphrases via type-1 question.



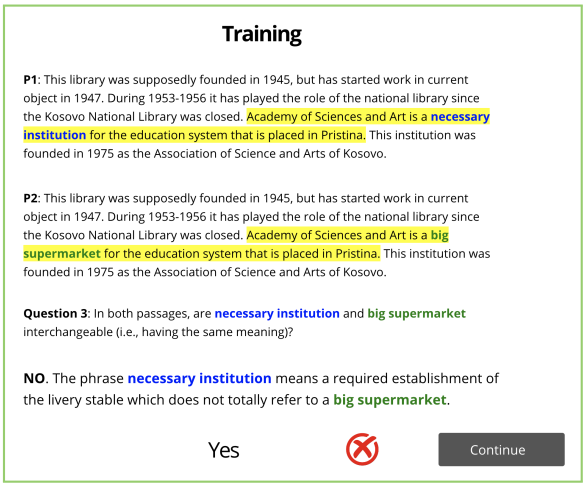
Training

P1: Mercury is poured over the dirt with bare hands. The method leaves much gold undetected, and therefore some miners are using metal detectors. The mercury pollution in the area is both an environment problem, and a health hazard. Most of the gold gets transported to the North of Paramaribo where the gold buyers are located.

P2: Tools such as KLEE, Cloud9, and Otter take this approach by implementing models for file system operations, sockets, IPC, etc. Forking the entire system state. Symbolic execution tools based on virtual machines solve the environment problem by forking the entire VM state. For example, in S2E each state is an independent VM snapshot that can be executed separately.

Question 1: In both passages, does environment problem have the same meaning?

(d) Verification of Yes/No labels via type-2 question.



Training

P1: This library was supposedly founded in 1945, but has started work in current object in 1947. During 1953-1956 it has played the role of the national library since the Kosovo National Library was closed. Academy of Sciences and Art is a **necessary institution** for the education system that is placed in Pristina. This institution was founded in 1975 as the Association of Science and Arts of Kosovo.

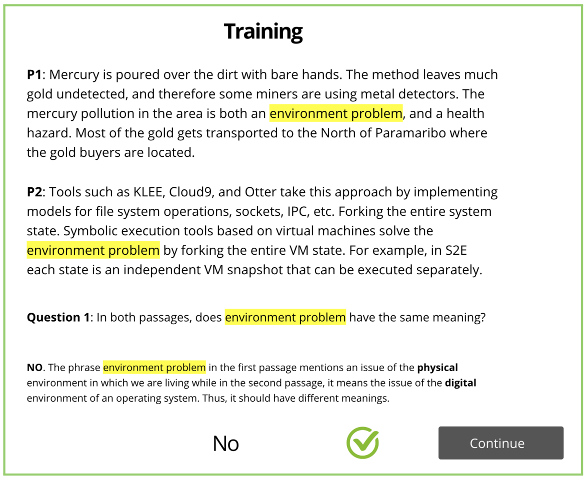
P2: This library was supposedly founded in 1945, but has started work in current object in 1947. During 1953-1956 it has played the role of the national library since the Kosovo National Library was closed. Academy of Sciences and Art is a **big supermarket** for the education system that is placed in Pristina. This institution was founded in 1975 as the Association of Science and Arts of Kosovo.

Question 3: In both passages, are **necessary institution** and **big supermarket** interchangeable (i.e., having the same meaning)?

NO. The phrase **necessary institution** means a required establishment of the livery stable which does not totally refer to a **big supermarket**.

Yes ✗

(e) Feedback is given when MTurkers give a wrong answer.



Training

P1: Mercury is poured over the dirt with bare hands. The method leaves much gold undetected, and therefore some miners are using metal detectors. The mercury pollution in the area is both an environment problem, and a health hazard. Most of the gold gets transported to the North of Paramaribo where the gold buyers are located.

P2: Tools such as KLEE, Cloud9, and Otter take this approach by implementing models for file system operations, sockets, IPC, etc. Forking the entire system state. Symbolic execution tools based on virtual machines solve the environment problem by forking the entire VM state. For example, in S2E each state is an independent VM snapshot that can be executed separately.

Question 1: In both passages, does environment problem have the same meaning?

NO. The phrase environment problem in the first passage mentions an issue of the **physical** environment in which we are living while in the second passage, it means the issue of the **digital** environment of an operating system. Thus, it should have different meanings.

No ✓

(f) or even a right answer.

K Data Sheet

We follow the documentation template provided by Gebru et al. 2021 (Gebru et al., 2021).

K.1 Motivation

For what purpose was the dataset created? Understanding phrases in context plays a vital role in solving many Natural Language Understanding (NLU) tasks such as question answering or reading comprehension. While there are *word-sense* disambiguation datasets like WiC, no such benchmarks exist for *phrases*. Existing phrase benchmarks compare only phrases without context and some of them contain numerous phrase pairs that have lexical overlap. The major drawback is no human annotation of how a phrase's meaning changes w.r.t the context. This motivates us to construct a Phrase-in-Context benchmark to drive the development of contextualized phrase embeddings in NLU.

Who created the dataset (e.g., which team, research group) and on behalf of which entity (e.g., company, institution, organization)? Auburn University and Adobe Research.

K.2 Composition/collection process/preprocessing/cleaning/labeling and uses

We describe the data construction process, annotation and verification methods in our paper (See Sec. 3 and Sec. 4).

K.3 Distribution

Will the dataset be distributed to third parties outside the entity (e.g., company, institution, organization) on behalf of which the dataset was created? We release three datasets PS, PR (including PR-pass and PR-page) and PSD to the public.

How will the dataset be distributed (e.g., tarball on website, API, GitHub)? The datasets are released and can be viewed and downloaded on HuggingFace `https://huggingface.co/PiC` or on our website `https://phrase-in-context.github.io`.

When will the dataset be distributed? It has been released in July 2022.

What is the dataset format and how it can be read? We use JSON - a widely used data format for PiC dataset and follow a scheme of HuggingFace datasets to host it. Three datasets PS, PR and PSD in the PiC dataset are loaded as folows:

```
 # The following pip command is to install the HuggingFace library "datasets":
pip3 install datasets

 from datasets import load_dataset

 ps      = load_dataset("PiC/phrase_similarity")
 pr_pass = load_dataset("PiC/phrase_retrieval", "PR-pass")
 pr_page = load_dataset("PiC/phrase_retrieval", "PR-page")
 psd     = load_dataset("PiC/phrase_sense_disambiguation")
```

Will the dataset be distributed under a copyright or other intellectual property (IP) license, and/or under applicable terms of use (ToU)? Our dataset is distributed under the CC-BY-NC 4.0 license.

K.4 Maintenance

How can the owner/curator/manager of the dataset be contacted (e.g., email address)? Thang Pham (`thangpham@auburn.edu`) and Anh Nguyen (`anh.ng8@gmail.com`) will be responsible for maintenance.

Will the dataset be updated (e.g., to correct labeling errors, add new instances, delete instances)? Yes. If we include more tasks or find any errors, we will correct the dataset. It will be updated on our website and also HuggingFace.

If others want to extend/augment/build on/contribute to the dataset, is there a mechanism for them to do so? They can contact us via email for the contribution.

Enhancing Dialogue Summarization with Topic-Aware Global- and Local-Level Centrality

Abstract

Dialogue summarization aims to condense a given dialogue into a simple and focused summary text. Typically, both the roles' viewpoints and conversational topics change in the dialogue stream. Thus how to effectively handle the shifting topics and select the most salient utterance becomes one of the major challenges of this task. In this paper, we propose a novel topic-aware Global-Local Centrality (GLC) model to help select the salient context from all sub-topics. The centralities are constructed at both the global and local levels. The global one aims to identify vital sub-topics in the dialogue and the local one aims to select the most important context in each sub-topic. Specifically, the GLC collects sub-topic based on the utterance representations. And each utterance is aligned with one sub-topic. Based on the sub-topics, the GLC calculates global- and local-level centralities. Finally, we combine the two to guide the model to capture both salient context and sub-topics when generating summaries. Experimental results show that our model outperforms strong baselines on three public dialogue summarization datasets: CSDS, MC, and SAMSUM. Further analysis demonstrates that our GLC can exactly identify vital contents from sub-topics. [1]

1 Introduction

Online conversations have become essential to communication in our daily work and life. Due to the information explosion, dialogue summarization has become a vivid field of research in recent years, which is meaningful for many applications, e.g. online customer service (Liu et al., 2019; Zhu et al., 2020) and meeting summary (Feng et al., 2021).

Dialogue summarization aims to condense crucial information in a long dialogue into a short text like traditional summarization tasks. Differently, the main challenges of dialogue summarization are the viewpoints of multiple speaker roles (Lin et al., 2021, 2022; Qi et al., 2021; Zhang et al., 2022) and shifting topics (Chen and Yang, 2020; Zou et al., 2021; Liu et al., 2021) during the conversation process. As shown in Figure 1, summaries not only depend on the overall context but also needs the identification and selection of salient context in crucial sub-topics. We can see that the blue text in summaries is about sub-topic #1 “The reason why the product is shipped yet" and the orange text is about sub-topic #2 “The user decided to refund", which are aligned to the two salient sub-topics from dialogue utterances in the first and second block. The sub-topic #3 is useless for summaries. This example shows the necessity to model the salient context and sub-topics in the dialogue.

In this paper, we propose a novel topic-aware Global-Local Centrality (GLC) model to select salient contexts from all sub-topics. The centrality is an effective technique to measure the importance of sentences in a given document from unsupervised extractive summarization (Zheng and Lapata, 2019; Liang et al., 2021, 2022). The GLC contains global- and local-level centrality, which are used to capture the salience of sub-topics and content in each sub-topic respectively. Based on these centralities, we can guide the model to focus on the salient context and sub-topics when generating summaries. Specifically, we employ utterance-level representations to cluster utterances and obtain sub-topic centers and assign each utterance to one sub-topic. Then, we compute the global centrality over sub-topic centers to measure the importance of each sub-topic and the local centrality over utterances of each sub-topic to measure the importance of sub-topic content. Finally, we combine the two to re-weight the dialogue context representations for the decoder to generate summaries.

To evaluate the effectiveness of our proposed GLC, we apply the GLC to three different types of

Don't tell me either) **Agent:** 这个是赠品哦亲。您电话对吗。妹子联系采销核实下具体时间。然后[数字]个小时内告知您。您看可以吗。(This is a giveaway. Is your phone number correct? I will contacts the purchase and sales to verify the specific time. Then [NUMBER] hours to let you know. Do you think this is ok?)	**Topic #1: The reason why the product is shipped yet.**
	User: 那直接申请退款吧，不买了。(Then I will apply for a refund directly, I will not buy it.) **Agent:** 哦哦，不要了吗？这边查看是在退款了，取消订单就无法恢复了呢。(Ok, don't you? The check here is a refund, and the cancellation of the order cannot be restored.) **User:** 嗯，退了吧。(Well, refund it.) **Agent:** 储蓄卡支付的吗？储蓄卡支付，原路返回的，周期是[数字]-[数字]个工作日内的。(Are you paying by debit card? Debit card payment, return the same way, the cycle is within [number]-[number] working days.)	**Topic #2: The user decided to refund.**
	User: 是的。(Yes.) **Agent:** 辛苦注意查收。请问还有其他还可以帮到您的吗? (Please pay attention to check the refund. Is there anything else I can help you with?) **User:** 好的没有了。(I have no more question.) **Agent:** 感谢您对我们的支持，祝您生活愉快，再见! (Thanks for your support. I wish you have a happy life, bye!)	**Topic #3: Useless information**
User Summary	用户询问购买的电话手表为什么还没发货，得知缺货后直接要求退款。(The user asks why the purchased smart watch has not been shipped, and directly asks for a refund after learning that it is out of stock.)	
Agent Summary	客服回复电话手表是赠品缺货，并准备向采销核实具体时间后告知用户。用户申请退款，客服提醒用户取消订单后无法恢复，随后告知储蓄卡支付会在一定时间内自动返还。(The customer service replies to the smart watch is a giveaway and is out of stock, and is ready to inform the user after verifying the specific time. When the user applies for a refund, the customer service reminds the user that the order cannot be restored after canceling the order, and then informs that the debit card payment will be automatically returned within a certain period of time.)	
Final Summary	用户询问购买的电话手表为什么还没发货。客服查询后回答赠品缺货，并准备向采销核实具体时间后告知用户。用户要求直接申请退款。客服提醒用户取消订单后无法恢复，随后告知储蓄卡支付会在一定时间内返还。(The user asks why the purchased phone watch has not been shipped. After customer service inquiries, they will answer that the gift is out of stock, and prepare to inform the user after verifying the specific time. The user requests to apply for a refund directly. The customer service reminded the user that the cancellation of the order cannot be restored, and then informed that the debit card payment will be returned within a certain period of time.)	

Figure 1: An example from the CSDS dataset. The dialogue contains 3 different sub-topics. The blue text represents sub-topic #1 and the red text represents sub-topic #2. The sub-topic #3 is useless information.

seq2seq structure: PGN, BERTAbs, and BART, and verify them on three public dialogue summarization datasets: CSDS, MC, and SAMSUM. CSDS and MC are two Chinese role-oriented summarization datasets that not only need to generate the overall summary of the dialogue but also need to generate role-oriented summaries for specific speakers in the dialogue as shown in Figure 1. SAMSUM is a widely used English dialogue summarization dataset. To generate role-oriented summaries, in this paper, we directly employ role prompts to guide the model to generate proper summaries. And the representations of role prompts can add role information to the centrality computation. Experimental results show that our GLC can improve the performance of all these seq2seq structures on three datasets. And the GLC-based BART model obtains new state-of-the-art results on the CSDS and MC.

Our contributions can be summarized as 1) We propose a novel topic-aware Global-Local Centrality (GLC) model to guide the model to identify the salient contexts and sub-topics in the dialogue. 2) Our GLC can bring improvement to different seq2seq models by easily plugging in and does not add any extra parameters to the seq2seq models. 3) The GLC-based BART model achieves new state-of-the-art results on CSDS and MC. Besides, extension studies prove our GLC can effectively capture vital sub-topics.

2 Methodology

Figure 2 shows the main structure of our proposed topic-aware global-local centrality (GLC) model. The seq2seq framework with GLC is on the left of Figure 2, which consists of the bi-directional encoder, global-local centrality model, and auto-regression decoder. The detail of GLC is on the right of Figure 2, which consists of global centrality and local centrality. In this section, we introduce them step by step.

2.1 Task Formulation

Firstly, we formulate the dialogue summarization task and role-oriented summarization task. Given a dialogue $\mathcal{D}$ with N utterances $\{u_1, \ldots, u_N\}$ with M roles $\{r_1, \ldots, r_M\}$. Each utterance u_i contains a speaker role r_j and sentence s_i. We simply concatenate them by ":" and get utterance $u_i = r_j : s_i$. For role-oriented summarization tasks, the data contains different summary y^{r_j} for different speaker roles r_j. In this paper, we employ y^{user} and y^{agent} to represent summaries of two different roles and y^{final} to represent the overall summary of the whole dialogue. It is deserved to mention that our method can also be easily applied to datasets with more than two speaker roles by introducing different role prompts. Normal dialogue summarization

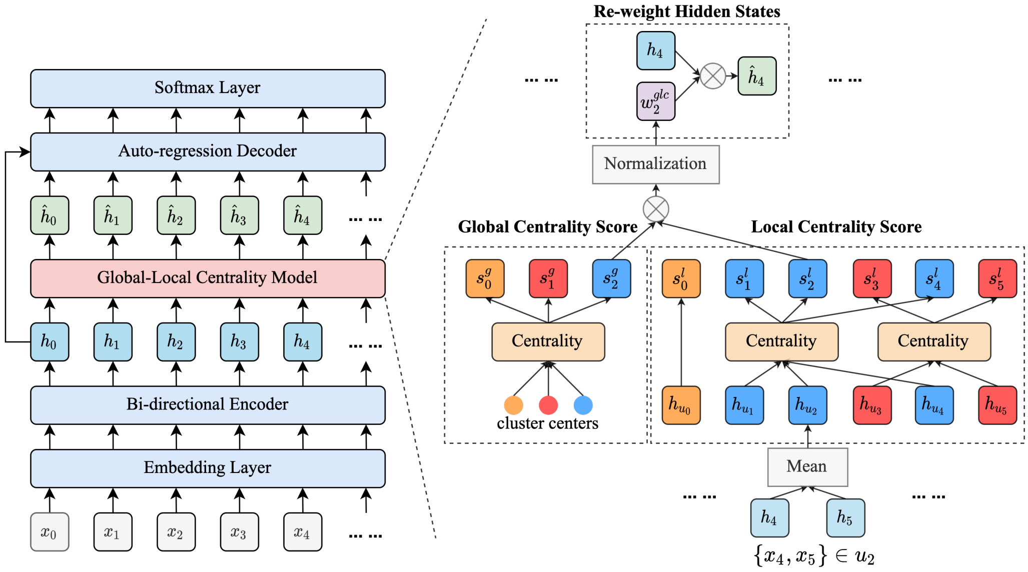

Figure 2: The main structure of our proposed method. The left is the framework of seq2seq with the GLC model. The right is the detailed process of our proposed GLC model.

task aims to generate overall summaries y^{final} and role-oriented summarization task aims to generate role-specific summaries $y^{[user|agent|final]}$ from the input dialogue $\mathcal{D} = \{u_1, \ldots, u_N\}$ according to the given role.

2.2 Role Prompts

For role-oriented summarization tasks, previous works train multiple independent models for different role summaries, which is proven to hurt the performance of model (Lin et al., 2022) and needs more computation resources. In this paper, we employ a simple but effective trick to ensure that we only need to train a single model to obtain different role-specific summaries and overall summaries. Specifically, we use the prompts to control the generation of different kinds of summaries, which attach "[User Summary]", "[Agent Summary]", and "[Final Summary]" to the start of each dialogue as input to guide the model to generate required summaries. After that, the input context is re-formalized as "[Role Prompt] Dialogue Contexts" and then tokenized as T tokens/words $\{x_t\}_{t=1}^{T}$ for the encoder of seq2seq model.

2.3 Bi-directional Encoder

The bi-directional encoder is used to get tokens the semantic vector representations $\{h_t\}_{t=1}^{T}$ by capture bi-directional context information from tokens $\{x_t\}_{t=1}^{T}$ as follows:

$$\{h_t\}_{t=1}^{T} = \texttt{Encoder}(\{x_t\}_{t=1}^{T}) \qquad (1)$$

Then, we use the average of tokens vectors in each utterance as the semantic representations of dialogue utterances as follows:

$$h_{u_i} = \frac{1}{|u_i|} \sum_{t} x_t, x_t \in u_i \qquad (2)$$

After that, we can get the token-level semantic representations $\{h_t\}_{t=1}^{T}$ and the utterance-level semantic representations $\{h_{u_i}\}_{i=0}^{N}$, where h_{u_0} is the vector representation of the attached role prompt, if role prompt is used.

2.4 Global-Local Centrality Model

Before feeding the representations into the decoder to generate the final summaries, we employ our proposed global-local centrality (GLC) model to reweight the vector representations to identify salient facts in sub-topics over previous utterance-level semantic representations $\{h_{u_i}\}_{i=0}^{N}$.

Firstly, our GLC obtains several cluster center points $\{c_k\}k = 1^K$, which represent the center of sub-topics in the vector space. Then each utterance is assigned to the nearest center. As shown in Figure 2, utterances with the same color belong to the same sub-topic. We compute the global centrality score based on the cluster center representations to measure the importance of sub-topics and the local centrality score based on the utterance representations to measure the importance of each utterance belonging to the same sub-topic. Then, we employ their combination to get global-local centrality weights, which are used to re-weight the token-level vector representations. Finally, the re-weighted token-level vector representations are fed into the decoder to generate the summary. Our GLC can be directly plug-in any seq2seq structures, which makes it flexible.

2.4.1 Obtain Cluster Centers

To obtain the clusters, we directly call the K-Means algorithm, which is effective and widely used for cluster tasks. And we all know setting the number of cluster centers for the K-Means algorithm is crucial and hard for the final results. However, we empirically find that we can set it as the number of utterances $(N+1)$ and then assign each utterance to the nearest cluster center point in the vector space. After that, we find that many cluster centers have no assigned utterances and can be dropped. Based on this, we assume $K < (N+1)$ cluster centers $\{c_i\}_{i=1}^{K}$ are kept and note the vector representations of them as $\{h_i^c\}_{i=1}^{K}$.

$$\{h_i^c\}_{i=1}^{K} = \texttt{KMeans}(\{h_{u_i}\}_{i=0}^{N}) \tag{3}$$

And after the assignment of utterances, we can get K clusters $\{\mathcal{C}_k\}_{i=k}^{K}$, which contain utterances with similar sub-topics. Each $\mathcal{C}_k$ contains several utterances and one cluster center point c_k. Through the previous method, we do not need to manually set the number of cluster centers for the K-Means algorithm.

2.4.2 Global Centrality

The global centrality score aims to measure the importance of each sub-topic by computing degree centrality based on the cluster center representations $\{h_k^c\}_{k=1}^{K}$. Each cluster center can be seen as one node on the graph, and the edge value between nodes k and j is $(h_k^c)^T \cdot h_j^c$. Then, the degree centrality of each cluster can be computed as follows:

$$\texttt{Cen}(c_k) = \sum_j (h_k^c)^T \cdot h_j^c \tag{4}$$

where $\texttt{Cen}(c_k)$ represents the importance of the cluster/sub-topic k in the dialogue. Then we normalize the score $\texttt{Cen}(c_k)$ by $\frac{\texttt{Cen}(c_k)}{||\{\texttt{Cen}(c_k)\}_{k=1}^{K}||_2}$.

2.4.3 Local Centrality

The local centrality score aims to measure the importance of utterances in each cluster by computing the degree centrality. Each utterance can be seen as one node on the graph, and the edge value between nodes i and j is $(h_{u_i})^T \cdot h_{u_j}$. Then, the centrality of each utterance in the same cluster $\mathcal{C}_k$ can be computed as follows:

$$\texttt{Cen}(u_i) = \sum_j (h_{u_i})^T \cdot h_{u_j}, u_i, u_j \in \mathcal{C}_k \tag{5}$$

where $\texttt{Cen}(u_i)$ represents the importance of utterances in the k-th cluster/sub-topic. Then we normalize the score $\texttt{Cen}(u_i)$ the same as the previous global centrality score.

2.4.4 Global-Local Centrality Weight

We can obtain the importance of each cluster (global centrality score) and the importance of utterances in each cluster (local centrality score) by the previous two steps. The most important utterance in the most important sub-topic should be assigned more attention when generating the summary. So we obtain global-local centrality weight for each utterance in the dialogue by simply multiplying two centrality scores as follows:

$$w_i^{glc} = \texttt{Cen}(u_i) \cdot \texttt{Cen}(c_k), u_i \in \mathcal{C}_k \tag{6}$$

Finally, we employ the global-local centrality weights to re-weight the token-level vector representations $\{h_t\}_{t=1}^{T}$ as follows:

$$\hat{h}_t = w_i^{glc} \cdot h_t, x_t \in u_i \tag{7}$$

Where each token uses the global-local centrality weight w_i^{glc} of its utterance u_i to re-weight the vector representation h_t. The token level representations $\{h_t\}_{t=1}^{T}$ are converted into $\{\hat{h}_t\}_{t=1}^{T}$.

2.5 Auto-regression Decoder

The auto-regression decoder generates the final summary based on the re-weighted context representations $\{\hat{h}_t\}_{t=1}^{T}$ as follows:

$$P(\hat{y}) = \texttt{Decoder}(\{\lambda \cdot \hat{h}_t + (1-\lambda) \cdot h_t\}_{t=1}^{T}) \tag{8}$$

where λ is a hyper-parameter to control the influence of GLC, the default value of λ is 0.5. In the training stage, the model learns the optimal parameters θ by minimizing the negative log-likelihood.

3 Experiments

3.1 Datasets and Metrics

We evaluate our method on three public datasets: CSDS (Lin et al., 2021)[2], MC (Song et al., 2020)[3],

Table 2: Results on the MC dataset test set.

and SAMSUM (Gliwa et al., 2019)[4]. The statistical information of them is shown in the appendix. CSDS is the first role-oriented dialogue summarization dataset, which provides separate summaries for user and agent (customer service). MC is a Chinese medical inquiry dataset containing question summaries of patients and suggestion summaries of doctors. We note them as the user and agent summary. For the MC dataset, we follow the data process and data split from RODS (Lin et al., 2022). SAMSUM is a widely used English dialogue summarization dataset to evaluate the performance of models.

We employ lexical-level and semantic-level metrics to evaluate the performance of all models. Specifically, we use lexical level ROUGE-1/2/L (Lin, 2004)[5] and BLEU (Papineni et al., 2002)[6], which measure the similarity of references and generated summaries by computing the n-gram overlap of them. We use semantic level BERTScore (Zhang* et al., 2020)[7] and MoverScore (Zhao et al., 2019)[8], which employ pre-trained language models to map the text into low-dimensional vectors in semantic space and then measure the similarity by computing the similarity by cosine similarity or word mover distance. We can evaluate the performance of each model comprehensively through the previous metrics. And all reported results are the average results of three different model checkpoints. The results of Moverscore on three datasets can be found in the appendix.

3.2 Baselines

We applied our GLC on three widely used seq2seq models: PGN (See et al., 2017), BERTAbs (Liu and Lapata, 2019), and BART (Lewis et al., 2020; Shao et al., 2021). **PGN** model is an LSTM-based seq2seq model without pre-training. **BERTAbs** is a BERT-based model, which employs BERT as the encoder and adds several transformer blocks as the decoder to generate summaries. We note it as BERT. **BART** is a pre-trained transformer-based seq2seq model, which achieves the best results on many generation tasks. We add our proposed GLC into the previous three models and note them as **PGN-GLC**, **BERT-GLC**, and **BART-GLC**. We also compare our method with previous SOTA models: **PGN-both** and **BERT-both** from (Lin et al.,

2022), which proposed a role-interaction attention mechanism for the decoder. We reproduce it in the BART model as **BART-both**. For SAMSUM, we do not compare with BART-both due to this dataset does not contain role-oriented summaries.

3.3 Implementation Details

We use Chinese-BART-base[9] and BART-large[10] to initialize our transformer-based seq2seq model for Chinese and English datasets respectively. We train all BART models on 4xV100 GPUs and PGN/BERT-based models on 1xV100 GPU. For all models, the maximum input length is 512, the maximum generated summary length is 150, and the beam size is 3. For BART-based models, the learning rate is 1e-4 with 10% warmup steps, the total batch size is 64, and the training epochs are 5. For PGN/BERT-based models, we follow the settings from (Lin et al., 2022).

3.4 Results

The main results of the two role-oriented dialogue summarization datasets are shown in Table 1-2. Each block has three values, representing the final summary/user summary/agent summary from left to right. We can see that our proposed GLC can bring significant improvement to PGN, BERTAbs, and BART on the two datasets and BART-GLC achieves new state-of-the-art results. It is deserved to mention that our model does not need to modify any structure of the seq2seq structure and only needs to train one model for different summaries. We can see that the gain of metrics on the CSDS is better than on the MC, due to the summary of the MC dataset being highly similar to the input dialogue contexts. The results of the BERT-based model sometimes is worse than the PGN-based, we guess the reason is the prior knowledge learned in the pre-training stage of BERT is not suitable for the generation tasks. The improvement of lexical level metrics is more conspicuous than semantic level metrics due to the change of several words that may not affect the semantics of generated sentences. Overall, our proposed GLC is proved effective for the role-oriented dialogue summarization task with results on the two datasets.

The main results of the English dialogue summarization dataset are shown in Table 3. Because the SAMSUM does not provide role-specific summaries, we only report the performance of overall final summaries. From the results, we can see that our GLC can also bring significant improvements to three different seq2seq structures. We can see that the BERTScore is very high on SAUSUM, we guess that because the gold reference of this dataset is very short and this makes the semantic similarity between generated summaries and gold summaries close. The results of SAMSUM demonstrated the effectiveness and generalization of our proposed method.

4 Discussion

We conduct many external experiments on the CSDS dataset to further analyze the effectiveness of our proposed GLC. And more discussions are shown in the appendix.

4.1 Ablation Study

To understand the impact of each component of our proposed GLC model, we compare the full BART-GLC with the following variants: (1) **BART:** three fine-tuned BART models for different summaries (final/user/agent); (2) **BART+Prompt:** singe BART model with role prompts; (3) **BART+GC:** three BART models using global centrality scores

Table 5: Human evaluation results.

to re-weight hidden states; (4) **BART+LC:** three BART models using local centrality scores to re-weight hidden states; (5) **BART+GC,LC:** three BART models using global-local centrality scores to re-weight hidden states. The results of these models are shown in Table 4. From the results, we can see that all three components can bring improvement to the BART model, and the global-local centrality brings the greatest improvement. Interesting, The improvement brought by the combination of global and local centrality is far greater than the improvements they bring separately. This proves that global and local centrality are mutually beneficial.

4.2 Human Evaluation

We use human evaluation (Fang et al., 2022) to verify that our model outperforms the baseline. Specifically, we randomly sample 100 examples from three datasets and ask five NLP researchers to give a comparison between our model and baseline models. The evaluation results are represented as win, loss, and tie, respectively indicating that the quality of generated summary by BART-GLC is better, weaker, or equal to the strong baselines. Annotators were asked to judge from two aspects: fluency (whether contains grammatical and factual errors) and coverage (whether contains salient sub-topic information in the dialogue). For two role-oriented dialogue summarization datasets CSDS and MC, our model is compared with BART-both. For SAMSUM, our model is compared with BART. From the results in Table 5, we can see that our model is better than the baseline. Annotators tend to give ties on SAMSUM dataset. This may be caused by the length of summaries is short, which makes it hard to judge whether the summary is better or worse than the baseline model.

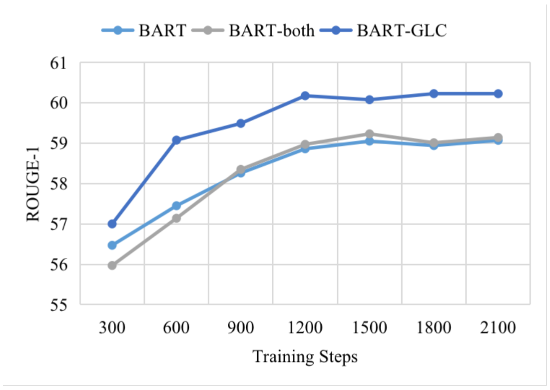

Figure 3: The ROUGE-1 score of different training step checkpoints.

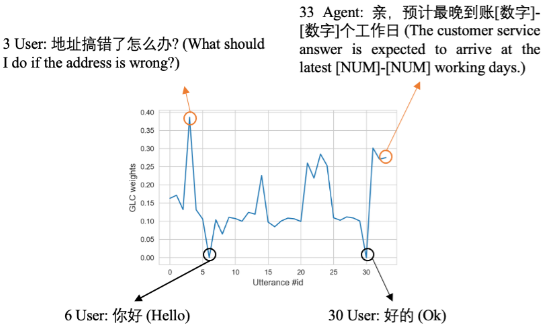
4.3 Convergence of Training

We also compare the training convergence speed with BART and BART-both to prove our proposed GLC can bring effective prior knowledge for the seq2seq model. As shown in Figure 3, we can see that BART-GLC achieves comparable performance at 900 steps during training and reaches the SOTA results at 1,200 steps. This phenomenon demonstrates that our GLC brings prior knowledge into the model and speeds up the model training.

4.4 Case study

We select one example from the test set to show the ability of our proposed GLC in Figure 4. On the upper-left of this figure are the GLC weights and the corresponding utterances. In the bottom-left of the figure is generated summary of our proposed BART-GLC. On the right of the figure is the input dialogue and each color refers to one sub-topic. From this case, we can see that the final summary focus on two sub-topics: “How to modify user’s order” and “Questions about refunds”. And from the color on the right of this figure, we can see that our GLC can catch them accurately. Interestingly, generic utterances are aggregated into one topic (e.g. hello). In the upper-left of this figure is the GLC weights and we can see that utterances, which are related to the final summary and belong to the vital sub-topics, are assigned high weights. This proves the global-local centrality exactly identified



BART-GLC Generated Summary:
Topic #1: How to modify user's wrong order.

salient topics and utterances.

5 Related Work

Dialogue summarization has caught more and more attention in recent years and is widely used in various domains, e.g. meeting summarization (Carletta et al., 2006; Feng et al., 2021), daily dialogue summarization (Krishna et al., 2021; Chen et al., 2021; Zhong et al., 2021), etc. Different from traditional summarization tasks, dialogue summarization needs to identify the role of speakers and capture the change of sub-topics during the dialogue. Besides, the dialogue summarization task has less labeled data and longer inputs. All of these make dialogue summarization harder to solve (Chen and Yang, 2020; Zhang et al., 2021b; Feng et al., 2021; Lin et al., 2022).

Recent dialogue summarization models can be categorized into three types: 1) data augmentation methods (Feng et al., 2021; Chen and Yang, 2021; Khalifa et al., 2021), which attempt to construct more pseudo-data to train a better model; 2) topic-based models (Zou et al., 2021; Liu et al., 2021; Qi et al., 2021), which track the change of topic information in the dialogue to generate more focused summary; and 3) semantic structure-based models (Liu and Chen, 2021; Fu et al., 2021; Zhang et al., 2021a; Lei et al., 2021; Zhao et al., 2021; Zhang et al., 2022), which employs semantic structures to enhance the summarization model.

However, they ignored the sub-topics information in the dialogue utterances, which is crucial for dialogue summarization. Recently, Zhao et al. (2020) modified the attention mechanism to focus on the topic words, which can force the model to learn the topic information. Zou et al. (2021) employed Neural Topic Model to model the global level topic information. Liu et al. (2021) tried to model the change of sub-topics by introducing contrastive learning. Differently, in this paper, we bring the centrality, that has been widely used in unsupervised summarization (Zheng and Lapata, 2019; Liang et al., 2021, 2022), into the dialogue summarization task and proposed a novel topic-aware Global-Local Centrality model to capture salient dialogue utterances and sub-topics at the same time. Our proposed method is effective and more flexible.

6 Conclusion

In this paper, we bring the centrality into dialogue summarization tasks and proposed a novel topic-aware Global-Local Centrality (GLC) model for better capturing the sub-topic information in the dialogue utterances. Our GLC can be easily applied to any seq2seq structure and bring improvement to their performance. Experiments and further analysis demonstrated that GLC can effectively identify vital sub-topics and salient content in the dialogue. In future work, we will try to extend our work to datasets with longer inputs.

Limitations

Our model also has some limitations: 1) The computation of sub-topic centers brings extra inference time into the basic seq2seq models. 2) We did not try to evaluate our model on longer dialogue summarization datasets. 3) We did not build a specific mechanism for different roles in role-oriented dialogue summarization task. We will try to solve these limitations in future work.

B Moverscore Results

For Moverscore, we employ chinese-bert-wwm-ext[11] to get the contextual embeddings of Chinese text input. Because Lin et al. (2021) did not provide they use what Chinese representation model, we use chinese-bert-wwm-ext to re-evaluate all their results and report in Table 7.

B.1 How abstractive is our model?

An abstractive model can be innovative by using words that are not from the input document in the summary. We measure the abstractive by the ratio of novel words or n-gram phrases in the summary. A higher ratio means a more abstractive model. We show the results in Figure 5. We can see that

Abstract

One of the major problems with text simplification is the lack of high-quality data. The sources of simplification datasets are limited to Wikipedia and Newsela, restricting further development of this field. In this paper, we analyzed the similarity between text summarization and text simplification and exploited summarization data to help simplify. First, we proposed an alignment algorithm to extract sentence pairs from summarization datasets. Then, we designed four attributes to characterize the degree of simplification and proposed a method to filter suitable pairs. We named these pairs Sum4Simp (S4S). Next, we conducted human evaluations to show that S4S is high-quality and compared it with a real simplification dataset. Finally, we conducted experiments to illustrate that the S4S can improve the performance of several mainstream simplification models, especially in low-resource scenarios.

1 Introduction

Text simplification and text summarization are two major techniques aiming at improving text readability (Margarido et al., 2008). The main objective of text simplification is to reduce the complexity of the text while keeping its meaning unchanged (Alva-Manchego et al., 2020; Al-Thanyyan and Azmi, 2021). Text summarization is to summarize the main idea of the document in less space (El-Kassas et al., 2021).

One of the major problems of text simplification is the lack of high-quality aligned data, which is essential for training most simplification models. Existing text simplification datasets are derived from Wikipedia (Zhang and Lapata, 2017) and Newsela (Xu et al., 2015). Researchers have proposed various alignment algorithms to extract complex-simple sentence pairs from articles (Jiang et al., 2020). However, aligning sentences from only two corpora hinders the acquisition of more simplification data, which motivates us to explore new ways to address this problem.

Text simplification usually involves the operations of keeping, deleting, reordering, etc.(Xu et al., 2016) Text summarization does not require a summary to be a simple text. Nevertheless, when we analyzed the datasets of text summarization meticulously, we noticed that there are many instances where several sentences in the original document are merged into one sentence, and complex parts are rewritten, as shown in Table 1. Then, a question arises naturally: to what extent is text summarization correlated with text simplification? Furthermore, is it feasible to extract data from text summarization to help low-resource text simplification?

Example	
document	What's Hollywood's **role in all of this? The same as it has always been** – to make money.
summary	What does Hollywood **want?** To make money, **of course.**

Table 1: The bolded parts indicate that the complex sentence in the document has been rewritten.

In this study, we investigated the above problems with a three-step procedure: (1) Extract aligned sentence pairs from summarization datasets. (2) Select sentence pairs in which the source sentences have been simplified. (3) Evaluate the quality of these sentence pairs for text simplification.

To extract aligned sentence pairs from the summarization datasets, we proposed an alignment algorithm based on the similarity between sentences. Then, we designed four attributes and a method to filter sentence pairs suitable for text simplification. We performed human evaluations and conducted experiments using mainstream simplification models on these pairs to show that they are of high quality and can help simplification.

To summarize, our contributions include: (1) We are the first to exploit summarization data to help

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 39–51
May 2-6, 2023

text simplification, verifying a new source of simplification data. (2) We proposed an alignment algorithm and a method for filtering complex-simple sentence pairs. We named them Sum4Simp (S4S). (3) We performed both empirical analysis and human evaluations on S4S to verify its quality, and the experimental results with several simplification models show the benefits of S4S for text simplification. The S4S dataset and codes are released at `https://github.com/RLSNLP/Sum4Simp`.

2 Related Work

2.1 Simplification Models

Early text simplification models are mainly based on statistic machine learning (Wubben et al., 2012; Kauchak, 2013; Narayan and Gardent, 2014). In recent years, many scholars have proposed models based on deep learning technology, such as NTS(Nisioi et al., 2017), DRESS-LS(Zhang and Lapata, 2017), EditNTS(Dong et al., 2019), ACCESS(Martin et al., 2020a), which advance the development of text simplification.

2.2 Mine Data for Simplification

The above models require a large number of aligned texts for training. Nevertheless, text simplification is a low-resource problem. Some works aim at designing unsupervised models (Qiang and Wu, 2019; Surya et al., 2019; Kumar et al., 2020; Laban et al., 2021). While other works try to mine aligned sentence pairs from more data to help train the models. Martin et al. (2020b) proposed unsupervised mining technology to create multi-language simplification corpora automatically. Lu et al. (2021) used the back-translation approach to construct a large-scale pseudo sentence simplification corpus.

2.3 Relationship with Text Summarization

For a long time, studies on text simplification and text summarization have been conducted separately. Nevertheless, there exist circumstances where complex texts not related to the main idea are removed when summarizing a document, and multiple sentences can be compressed and rewritten into a single sentence. Such a summarization can also be regarded as a simplification. Ma and Sun (2017) proposed a semantic relevance-based model to improve the results of simplification and summarization. Zaman et al. (2020) pointed out some similarities between the two tasks and defined the new task of generating simplified summaries. Up to now, none of the work has specifically analyzed the relationship between summarization and simplification. It is still worth investigating whether the data from summarization can help simplification.

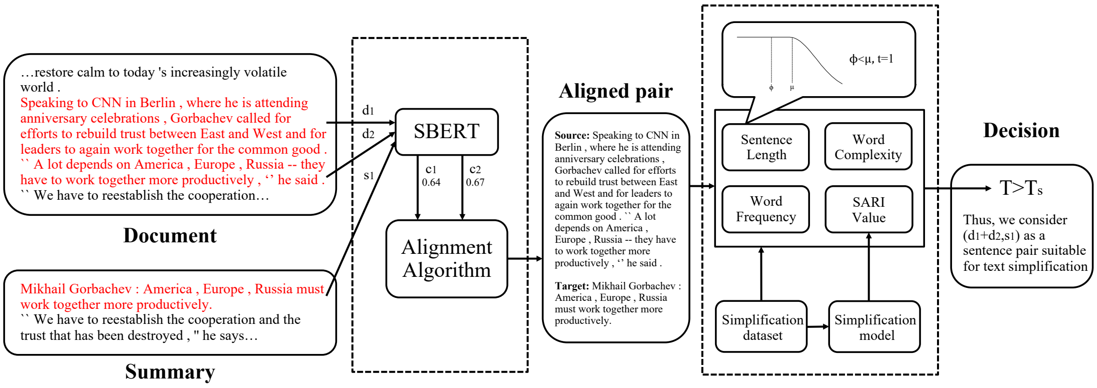
3 Mine Sentence Pairs for Simplification from Summarization Datasets

In this section, we will elaborate on how to extract sentence pairs that are suitable for text simplification from text summarization datasets. Text summarization is a document-level task while text simplification refers to a sentence-level task. Thus, we proposed an algorithm to extract aligned sentence pairs at first. Then, since not all aligned sentence pairs are suitable for text simplification, we chose four attributes and defined a set of rules to filter the appropriate sentence pairs. The whole process is shown in Figure 1.

3.1 Sentence Alignment Algorithm

Previous sentence alignment algorithms such as CATS (Štajner et al., 2018) aim at sentence compression (one complex sentence corresponds to one simple sentence) or sentence splitting (a complex sentence is split into several simple sentences). They do not satisfy the requirement to align sentence pairs from summarization datasets, where one sentence in the summary corresponds to multiple sentences in the document. Thus, we proposed an alignment algorithm to address this problem.

Assume that there are m sentences in the document and n sentences in the summary. For each sentence d_i in the document and each sentence s_j in the summary, we first compute the similarity between the two sentences. We use SBERT (Reimers and Gurevych, 2019) to achieve this. SBERT is a pre-trained model based on BERT (Devlin et al., 2019), in which the similarity of two input sentences will be calculated rapidly. Then, we define the upper threshold of similarity S_{max} and the lower threshold of similarity S_{min}. S_{max} is greater than S_{min} and they are in the range [0,1]. Assume that the maximum value of similarity between any sentence in the document and s_j is D_{max}. If D_{max} is greater than S_{max}, we consider that the sentence corresponding to D_{max} is very similar to s_j. Therefore, we keep s_j as the target sentence and the sentence corresponding to D_{max} as the source sentence, and they form an aligned sentence pair. If D_{max} is smaller than S_{min}, we consider that there is no sentence in the document that is similar to s_j.



…restore calm to today 's increasingly volatile world .
Speaking to CNN in Berlin , where he is attending anniversary celebrations , Gorbachev called for efforts to rebuild trust between East and West and for leaders to again work together for the common good .
`` A lot depends on America , Europe , Russia -- they have to work together more productively , ‘’ he said .
`` We have to reestablish the cooperation…

Mikhail Gorbachev : America , Europe , Russia must work together more productively.
`` We have to reestablish the cooperation and the trust that has been destroyed , " he says…

Source: Speaking to CNN in Berlin , where he is attending anniversary celebrations , Gorbachev called for efforts to rebuild trust between East and West and for leaders to again work together for the common good . `` A lot depends on America , Europe , Russia -- they have to work together more productively , ‘’ he said .

Target: Mikhail Gorbachev : America , Europe , Russia must work together more productively.

Thus, we consider (d1+d2,s1) as a sentence pair suitable for text simplification

Figure 1: The process of mining suitable sentence pairs from summarization datasets.

Thus, we do not keep sentence pairs related to s_j.

Algorithm 1 Sentence alignment algorithm

```
Initialization: F and C are empty sets
for $d_i$ in $d_1$,$d_2$,...,$d_n$ do
    $c_i$ = SBERT($d_i$,$s_j$)
    C.append($c_i$)
end for
if max(C)>$S_{max}$ then
    F.append(corresponding $d_i$ of max(C))
else if $S_{max}$>max(C)>$S_{min}$ then
    F.append(corresponding $d_i$ of max(C))
    C.remove(max(C))
    repeat
        $c_i$ = SBERT(stitch(F,corresponding $d_i$ of max(C)),$s_j$)
        if $c_i$>$S_{add}$ then
            F.append(corresponding $d_i$ of max(C))
            C.remove(max(C))
        end if
    until $c_i \leq S_{add}$ or len(C)$\geq L_{max}$
end if
Output: (F,$s_j$) as an aligned sentence pair
```

If D_{max} is greater than S_{min} and smaller than S_{max}, we consider this to be the case where multiple sentences in the document correspond to s_j. We temporarily save the sentences corresponding to D_{max}, and then find the sentence with the largest similarity among the remaining sentences of the document. We stitch this sentence with the sentence we just saved according to the order of the sentences in the document. We repeat this operation until the similarity between the stitched sentences and s_j is less than a threshold. We define this threshold as S_{add}, which takes values in the range [S_{min},S_{max}]. To prevent the problem of imbalance where the length of the source sentence far exceeds the length of the target sentence caused by extracting too many sentences from the document, we set L_{max}. When the number of stitched sentences reaches L_{max}, we save these stitched sentences as source sentences and s_j as the target sentence.

3.2 Four Attributes to Characterize Simplification

Aligned sentence pairs obtained from Algorithm 1 are not always complex-simple ones, and an example is given below:

Source sentence: Analysts say the Arab Spring has made Dubai a safe haven for people in the Middle East who worry about the turmoil elsewhere.

Target sentence: Analysts say the Arab Spring has made Dubai a safe haven for those who worry about the turmoil elsewhere.

This example is a real sentence pair mined from the summarization data. It is an aligned sentence pair but neither the attributive clause nor the complex words such as “turmoil” are simplified. Thus, it is not a good instance for text simplification. We design four attributes to characterize whether the source sentence is simplified or not, which are:

Sentence Length Intuitively, the longer the sentence, the more complex the sentence is likely to be. We calculate the length of the target sentence minus the average length of the source sentences.

Word Complexity We believe that the lower the average complexity of words, the simpler the sentence. We use a lexicon of word complexity created by Maddela and Xu (2018). Each word is scored by humans. The higher the score, the more complex the word. We calculate the value of the average word complexity of the target sentence minus the average word complexity of the source sentences.

Word Frequency Some words appear more frequently in complex sentences, while some words appear more frequently in simple sentences. The more frequently a word appears in a simple sentence, the more likely it is to be a simple one. We calculate the odds ratio (Monroe et al., 2008) to represent the frequency of word occurrence. For two corpus, namely i and j, their sizes are n_i and n_j, respectively. For a word w, the occurrences in corpus i and corpus j are w_i and w_j, respectively. Then, the odds ratio r of word w between corpus i and corpus j can be defined as:

$$r = \frac{w_i/w_j}{n_i/n_j} \tag{1}$$

We use the simplification dataset to construct a dictionary containing the odds ratios of the words. For example, if we want to conduct experiments on WikiLarge (Zhang and Lapata, 2017), we calculate the odds ratio of the words occurring in the WikiLarge training set. We calculate the value of the average odds ratio of the target sentence minus the average odds ratio of the source sentence.

SARI Value SARI (Xu et al., 2016) is an essential evaluation method for text simplification. It takes the original sentence, the simplified sentence, and reference sentences into consideration. The SARI value is an average of F1 scores of add and keep operation and precision of delete operation. The score for each operation is obtained by averaging n-gram scores.

$$\begin{aligned}
SARI &= \frac{1}{3}F_{add} + \frac{1}{3}F_{keep} + \frac{1}{3}P_{del} \\
P_{operation} &= \frac{1}{4}\sum_{n=1,2,3,4} p_{operation}(n) \\
R_{operation} &= \frac{1}{4}\sum_{n=1,2,3,4} r_{operation}(n) \\
F_{operation} &= \frac{2 \times P_{operation} \times R_{operation}}{P_{operation} + R_{operation}} \\
& operation \in [add, keep, del]
\end{aligned} \tag{2}$$

We consider the source sentence of the aligned sentence pairs as the original sentence and the target sentence as the simplified sentence. We need to train a simplification model at first. For example, we trained a model like ACCESS (Martin et al., 2020a) on the WikiLarge training set. Then, we input the source sentences into the simplification model and generate simplified sentences. These simplified sentences are used as reference sentences. Finally, the SARI values are calculated.

3.3 Quantify Simplicity and Filter Suitable Sentence Pairs

For each attribute, we propose a method to quantify the simplicity of a sentence. Our method is based on a hypothesis: a reference simplification dataset performs approximately normally distributed on each attribute. Simplification datasets can contain hundreds of thousands of instances, in line with the concept of large samples in statistics. Therefore, we believe this hypothesis is reasonable.

Take the sentence length attribute as an example. We first calculate the mean μ and standard deviation σ of the sentence length of the training set of a reference dataset (e.g. WikiLarge). For a random variable X, the probability density function $f(x)$ can be obtained. If the ratio of sentence length for a sentence pair is ϕ, its score t on this attribute is:

$$t = \begin{cases} 1, & \phi <= \mu \\ 2 \times (0.5 - \int_{\mu}^{\phi} f(x)dx), & \phi > \mu \end{cases} \tag{3}$$

$$t = \begin{cases} 2 \times (0.5 - \int_{\phi}^{\mu} f(x)dx), & \phi < \mu \\ 1, & \phi >= \mu \end{cases} \tag{4}$$

$$f(x) = \frac{1}{\sqrt{2\pi}\sigma} exp\left(-\frac{(x-\mu)^2}{2\sigma^2}\right) \tag{5}$$

The mathematical significance is that if $\phi <= \mu$, the simplification degree of the sentence pair is greater than the average simplification degree of the simplification dataset on this attribute. Thus, we give a score of 1 to t. If $\phi > \mu$, we subtract the proportion of sentence pairs with a ratio greater than μ and lower than ϕ that is in the simplification dataset. Then, we perform a normalization operation to obtain t. For attributes sentence length (len), word complexity (comp), and word frequency (freq), a lower ϕ indicates a greater degree of simplification. We use Equation (3) to calculate t. For attribute SARI value (sari), a higher ϕ indicates a greater degree of simplification. We use Equation (4) to calculate t.

To make a final decision, the scores on each attribute are weighted with α and summed to obtain T for a sentence pair, indicating the extent of simplification of the source sentence. We set a threshold value $\mathrm{T_s}$ to control the extent of simplification. When $\mathrm{T} > \mathrm{T_s}$, we consider the sentence pair suitable for the task of text simplification.

$$\begin{gathered}
\mathrm{T} = \sum_{i \in Attr} \alpha_i t_i \\
Attr = [len, comp, freq, sari]
\end{gathered} \tag{6}$$

We exploit and filter sentence pairs from the CNN/Daily Mail summarization dataset (Nallapati

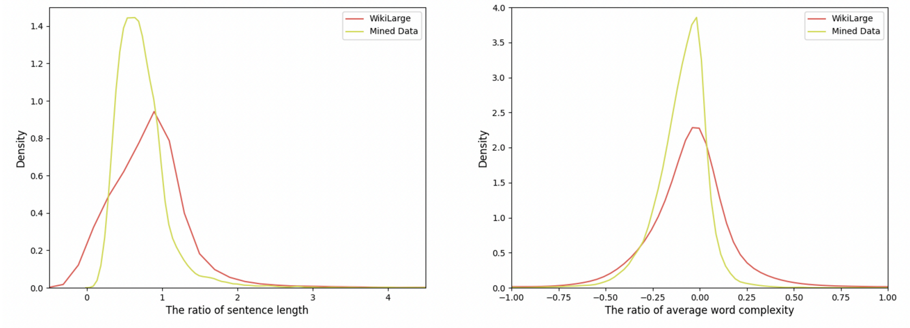


Figure 2: Distributions of the ratio of sentence length and average word complexity. We smoothed the results by using a Gaussian kernel. Sentences from S4S are more compressed than in WikiLarge. Sentences where the words become more complex are also less than in WikiLarge.

et al., 2016), which contains more than 300,000 documents and corresponding summaries from news stories in CNN and Daily Mail. We name these mined sentence pairs Sum4Simp (S4S).

4 Quantitative Analysis

In this section, we want to show that Sum4Simp (S4S) is high-quality. We conducted two human evaluations and performed statistics on S4S, comparing it with real simplification datasets.

4.1 Human Evaluations

First, we want to evaluate the alignment quality of the sentence pairs obtained in Section 3.1. Following Hwang et al. (2015), we defined the quality of alignment into four classes: Good, Good partial, Partial, and Bad. Due to the space limit, details and examples are demonstrated in Table 10.

We randomly selected sentence pairs from the aligned pairs obtained by our proposed alignment algorithm. Then, we designed a baseline that does not use our proposed alignment algorithm. When the similarity calculated by SBERT between a sentence in the document and a sentence in the summary is greater than 0.6, we kept this sentence in the document. As we introduced in Section 3.1, the CATS method (Štajner et al., 2018) may not be suitable for aligning sentence pairs from summarization datasets. However, we used it as a baseline.

We used the two baseline methods described above to obtain aligned sentence pairs from summarization datasets. What's more, we randomly selected sentence pairs from a simplification dataset named WikiLarge (Zhang and Lapata, 2017) for comparison. The results are shown in Figure 3.

We considered **Good** and **Good partial** to be acceptable quality. The sentence pairs obtained by our proposed alignment algorithm have the highest percentage in these two levels. While WikiLarge has the most sentence pairs with a Good level, it also has the most sentence pairs with a Bad level. Xu et al. (2015) pointed out that data mined from Wikipedia is not always of high quality.

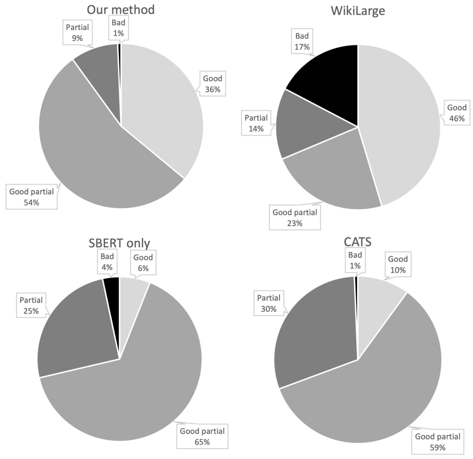

Figure 3: Human evaluation results of data obtained by three alignment methods and WikiLarge. We randomly selected 50 sentence pairs from each source of data. Then, we hired three workers to evaluate the 200 sentence pairs individually.

Then, we want to show that the final sentence pairs obtained in Section 3.3 are more suitable for simplification. We randomly selected 50 sentence pairs that are only aligned and 50 sentence pairs from S4S. We also randomly selected 50 sentence pairs from WikiLarge for comparison.

Following Dong et al. (2019), we used two indicators as the criteria: (1) **Simplicity**: Is the target sentence simpler than the source sentence? (2) **Adequacy**: Are the source sentence and target sentence fluent and grammatically correct? Another indicator, Meaning, can be regarded as the evaluation of alignment quality, so we did not repeat it. The results are shown in Table 2. The sentence pairs from S4S receive the highest Simplicity score, significantly higher than the aligned-only pairs and WikiLarge, indicating the effectiveness of the proposed filtering method.

	Simplicity↑	Adequacy↑
WikiLarge	3.11**	4.6**
Aligned only	3.2**	4.81
S4S	**3.49**	**4.94**

Table 2: Human evaluation results of data obtained by two methods and WikiLarge. We hired three workers to evaluate individually. Student t-tests were performed and results significantly different from S4S were marked with **(p<0.01).

4.2 Statistics and Comparison

We used three dimensions, sentence length, average word complexity, and odds ratio of cue words, to compare the sentence pairs from S4S with those from WikiLarge. The ratio of sentence length is calculated by dividing the length of the simplified sentence by the length of the original sentence. The ratio of average word complexity is calculated by subtracting the average word complexity of the original sentence from the average word complexity of the simplified sentence.

We randomly selected 10,000 sentence pairs from WikiLarge and S4S, respectively. From Figure 2, in S4S, the number of sentence pairs with a length ratio greater than one has been significantly decreased compared to WikiLarge, indicating that sentences are more compressed. What's more, the vast majority of the ratios of average word complexity are less than zero, suggesting a general simplification at the word level in S4S.

Sentence splitting, a common operation in text simplification, can be represented by the odds ratio of conjunctions and cue words (Siddharthan, 2003). The definition of the odds ratio is detailed in Equation (1). When the odds ratio of conjunctions is much less than 1, and the odds ratio of cue words is much greater than 1, a complete degree of simplification is involved. Following Xu et al. (2015) and Sun et al. (2021), we calculated the odds ratio of conjunctions and cue words in WikiLarge and S4S, as shown in Table 3.

WikiLarge		S4S	
cue words	odds ratio↑	cue words	odds ratio↑
also	1.15	also	1.13
then	1.16	then	**1.21**
still	1.01	still	**1.41**

Wikilarge		S4S	
conjunctions	odds ratio↓	conjunctions	odds ratio↓
and	0.87	and	0.95
as	0.72	as	0.80
since	1.01	since	**0.96**
because	2.59	because	**1.05**
when	1.32	when	**1.09**
if	1.30	if	1.38
but	1.18	but	**1.11**
though	0.71	though	**0.62**
although	0.46	although	**0.40**

Table 3: The odds ratio of cue words and conjunctions. The bolded parts indicate that S4S performs better than WikiLarge. Some words, such as "hence", occur too infrequently to be statistically meaningful.

5 Experimental Setup

5.1 Datasets

We used two commonly used simplification datasets, **WikiLarge** (Zhang and Lapata, 2017) and **WikiSmall** (Zhu et al., 2010), to demonstrate the usefulness of the sentence pairs mined from summarization data. The training set of WikiLarge contains more than 296k sentence pairs, which is larger than that of WikiSmall containing 88k sentence pairs. We used **Turkcorpus** (Xu et al., 2016) as the validation and the test set for WikiLarge. Each of the 2000 validation instances and the 359 test instances has 8 reference sentences. We used the original validation set and test set for WikiSmall, with 205 validation instances and 100 test instances.

5.2 Evaluation Metrics and Models

We took **SARI** (Xu et al., 2016) and **BERTScore** (Zhang et al., 2019) as the evaluation metric in this paper. SARI is the most popular automatic evaluation metric for text simplification. The SARI value is obtained by averaging the F_{keep}, P_{delete}, and F_{add} score. We used the **EASSE** package (Alva-Manchego et al., 2019) to get SARI values. A recent study recommends using BERTScore$_{precision}$ to evaluate the quality of the system outputs prior to using SARI to measure simplification (Alva-Manchego et al., 2021). FKGL (Kincaid et al., 1975) was used to measure text readability but was proven to be inappropriate for evaluating text simplification recently (Tanprasert and Kauchak,

Models	WikiLarge				S4S				WikiLarge+OA				WikiLarge+S4S			
	SARI↑	F_{keep}	P_{delete}	F_{add}	SARI↑	F_{keep}	P_{delete}	F_{add}	SARI↑	F_{keep}	P_{delete}	F_{add}	SARI↑	F_{keep}	P_{delete}	F_{add}

Table 4: Results of three simplification models trained on four different training sets. The test sets in the upper and lower tables are Turkcorpus and WikiSmall, respectively. "+" represents the operation to mix the two datasets and sort them randomly. OA is a set of sentence pairs with a similar size to S4S drawn from aligned but not filtered sentence pairs. The bolded part indicates the training set that achieves the best result for each model. Student t-tests were performed, and SARI values that were significantly different from WikiLarge+S4S and WikiSmall+S4S were marked with *($p<0.05$) or **($p<0.01$).

2021). BLEU (Papineni et al., 2002) has been proven to be unsuitable for evaluating text simplification (Sulem et al., 2018). Therefore, we did not report FKGL values and BLEU values.

We selected three representative models - **Transformer** (Vaswani et al., 2017), **BART** (Lewis et al., 2020), and **ACCESS** (Martin et al., 2020a) to conduct experiments. Transformer and BART perform strongly for many generation tasks. ACCESS is a simplification model proposed recently and it uses explicit tokens related to different attributes to control the process of simplification.

5.3 Training Details

We used the Huggingface Transformers (Wolf et al., 2020) to implement the Transformer model and the BART model. We used the original code to implement the ACCESS model. We used four Nvidia A40 GPUs for training. We reported the results of the model on the test set which has the best SARI value on the validation set.

More details can be found in Appendix A.

6 Experimental Results

6.1 Results on Existing Test Sets

We designed four types of training sets and tested the three simplification models on existing test sets. We first measured the outputs of each model using $\text{BERTScore}_{precision}$ and found that the values are very close to 1, indicating that the outputs are of high quality. Then, the SARI values are shown in Table 4.

From the upper table, Sum4Simp (S4S) mixed with the WikiLarge training set improves the performance of all three simplification models on Turkcorpus. To be more specific, in terms of the SARI metric, ACCESS is improved by 1.04 points, BART is improved by 1.21 points, and Transformer is improved by 0.90 points. We have used the original codes and followed the original hyper-parameter settings, but the SARI value of the ACCESS model trained on WikiLarge is lower than the results reported by Martin et al. (2020a). We think this is because we lowered the training data and used the NLTK package to split the words. Meanwhile, seen from the lower table, S4S mixed with the WikiSmall training set also improves the performance of all three models on the test set of WikiSmall. The improvement on the WikiSmall test set is more significant than that on the Turkcorpus test set. In terms of the SARI metric, ACCESS is improved by 2.93 points, BART is improved by 1.45 points, and Transformer is improved by 2.22 points. Example outputs are given in Table 11. It may seem strange that the SARI value of Transformer is higher than that of BART. However, we noticed that the SARI value of BART is approximately 3 points higher than that of Transformer on the validation set, making the experimental results remain convincing.

The size of the training set of WikiLarge is much larger than that of WikiSmall. Therefore, the models were more fully trained on WikiLarge. While the size of the training set of WikiSmall is comparatively smaller, S4S helps the model learn to simplify sentences better and results in a more significant improvement.

OA was designed to verify that the improvement of the results comes from high-quality mined sentence pairs rather than mere data expansion. Compared with the original training set, the per-

Models	S4S				WikiLarge				S4S+WikiLarge			
	SARI↑	F_{keep}	P_{delete}	F_{add}	SARI↑	F_{keep}	P_{delete}	F_{add}	SARI↑	F_{keep}	P_{delete}	F_{add}
Transformer	**44.75**	53.32	74.72	6.19	32.59	45.38	51.78	0.61	43.61	52.24	73.91	4.68
BART	46.42	57.20	76.62	5.43	32.98	47.12	50.10	1.70	**46.51**	57.24	73.91	4.68
ACCESS	**40.19**	45.85	72.82	1.88	30.10	44.30	43.99	2.01	38.45	43.35	70.71	1.30

Table 5: Results on three simplification models trained on three different training sets. The valid and test sets come from S4S.

formances on WikiLarge+OA and WikiSmall+OA were not improved and even dropped for the model like BART. The results illustrate that the method for filtering suitable sentence pairs for simplification purposes is essential.

If we only used S4S as the training set, the SARI values obtained are 2.5 points lower than the model trained with WikiLarge and 0.5 points lower than the model trained with WikiSmall on average. We believe the performance gap is due to domain differences: S4S comes from news stories written by professional journalists, while WikiLarge and WikiSmall come from Wikipedia. Overall, though S4S comes from a different domain, it can still be beneficial to the existing simplification datasets.

6.2 Results on S4S Test Set

In this subsection, we treat S4S as a standard simplification dataset that contains more than 243K sentence pairs. We divided the train/dev/test set as 240k/2k/1k, respectively. We would like to see the performance of simplification models on the S4S dataset and we want to know if the WikiLarge dataset from a different domain can improve the performance. We designed three types of training sets. Then, we conducted experiments with each of them to train the three simplification models.

According to Table 5, all three simplification models trained on the S4S dataset have significantly higher SARI values compared to the results in Table 4. When we mixed the training set of S4S and WikiLarge, the SARI values dropped by 1 point on average compared to using the S4S training set alone. Besides, when we only used the WikiLarge training set, the SARI values dropped by an average of more than 10 points. We also gave example outputs in Table 12. Above all, we believe the quality of the S4S dataset is higher than that of the Wikipedia-based datasets. The S4S dataset was given in the supplementary materials.

6.3 Results on Extremely Low-resource Scenarios

In many cases simplification data is hard to obtain (Aprosio et al., 2019; Maruyama and Yamamoto, 2019), and we took a small amount of sentence pairs from the training set of WikiLarge to simulate an extremely low-resource situation. We reduced the size of the WikiLarge training set to 50%, 20%, 10%, 5%, and 1%, respectively. We then conducted experiments using the ACCESS model trained on the size-reduced WikiLarge data and the mixture of size-reduced WikiLarge and S4S. The results are shown in Figure 4.

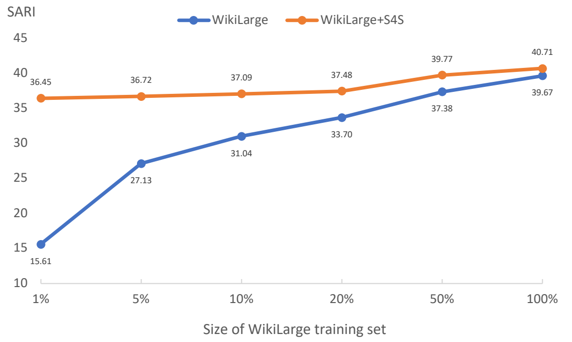

Figure 4: Experimental results of extremely low-resource experiments on Turkcorpus test set.

When the size of the training set is relatively small (less than 20%, about 60,000 sentence pairs), S4S can improve the results significantly. The results prove that the S4S is effective in helping text simplification when data is difficult to obtain.

6.4 Ablation Study

In our proposed sentence filtering method, we used four attributes to control the simplicity of the sentence pairs extracted from summarization datasets. We removed the attributes one by one and then used the remaining three attributes as new rules to filter simple sentence pairs. We set T_s to 2.75 in the experiment. The filtered sentence pairs are mixed with the WikiLarge training set and then used to train the ACCESS model.

Experiment	SARI↑
WikiLarge+S4S	40.71
WikiLarge	39.67
Without word complexity	39.32(-1.39)
Without sentence length	39.63(-1.08)
Without word frequency	37.70(**-3.01**)
Without SARI value	38.78(-1.93)

Table 6: Ablation study on Turkcorpus test set.

The results are illustrated in Table 6. In this experiment, the odds ratio attribute has the greatest effect on the results. When this attribute is missing, the SARI value decreases by 3.01 points. The sentence length attribute has the least effect on the results. When this attribute is missing, the SARI value drops by 1.08 points. The results also show that the four attributes of our design are meaningful. They all play a significant role in filtering the simplified sentence pairs.

7 Conclusion

In this paper, we are committed to mining data from text summarization datasets to help text simplification. We proposed an alignment algorithm and a new method to filter suitable sentence pairs. We named these pairs Sum4Simp (S4S). We conducted human evaluations on S4S and performed experiments on mainstream simplification models to illustrate that the S4S is high-quality and can help text simplification. In future work, we will apply our method to mine more simplification data from other summarization datasets.

We appreciate the anonymous reviewers for their helpful comments. Xiaojun Wan is the corresponding author.

Limitations

We considered the consumption of computational resources as the major limitation of our method. To extract aligned sentence pairs from summarization datasets, we need to calculate the similarity between each sentence in the summary and each sentence in the document, which makes the time complexity of the alignment algorithm be $O(n^2)$. We ran the alignment algorithm with an Intel Xeon processor. On average, there are 40 sentences in a document and 4 sentences in a summary. There are 312K documents in total with corresponding summaries. The total running time is 42,153s. We have released the aligned sentence pairs to help future research.

Second, to calculate the SARI values in Section 3.2, we need to train a simplification model in advance, which can consume GPU resources. For example, if we train a BART model on the WikiLarge dataset and set the max epochs to 10, the training time spent on an Nvidia A40 is about 3 hours.

A More Details

In Algorithm 1, for S_{max}, S_{add}, and S_{min}, we first observed the alignment results to obtain a rough range [0.5,0.8]. In this range, we set the step size to 0.1 and then chose four combinations of parameters: (0.8, 0.7, 0.6), (0.8, 0.7, 0.5), (0.8, 0.6, 0.5), and (0.7, 0.6, 0.5). We used human evaluation on 50 sentence pairs for each combination to determine which combination is the best. Finally, we set S_{max} to 0.8, S_{min} to 0.6, and S_{add} to 0.7. Lmax is set to 3 as an empirical value. If it is too large, the model will be more concerned with deletion than simplification; if it is too small, the information in the original sentences will lose.

For the method of filtering suitable sentence pairs in Section 3.3, we set α_i to 0.25 because it is difficult to prove that one of the four attributes is more important than the other. We performed a parameter research for $\mathrm{T_s}$ from 3.5 to 3.8 with a step size of 0.05.

We have released the aligned sentence pairs obtained in Section 3.1 for future research. So future researchers only need to set $\mathrm{T_s}$ when conducting experiments.

To obtain Table 4, we first trained models with existing simplification datasets (e.g., train ACCESS with WikiLarge). Then, we selected the model that performed best on the validation set to calculate the score t for the SARI value attribute mentioned in Section 3.2. In this way, we got S4S. We then trained models with WikiLarge+S4S to obtain the results in the fourth column of the Table 4. The S4S dataset in Section 6.2 is obtained after we first trained ACCESS with WikiLarge. We will also release this version of S4S as a standard simplification dataset.

Parameter	**Value**	**Parameter**	**Value**

B Definition of Alignment Quality

C Example Outputs

Good	The semantics of the source sentence and the target sentence completely match, possibly with small omissions.
Source	Sets in children 's bedrooms or left on as background noise could be particularly damaging.
Target	Devices in bedrooms or left on as background noise is more damaging.
Good partial	Source and target sentence mean basically the same thing. However, source or target sentence may contain additional information that is not contained in the other sentence.
Source	The tape was played at a hearing Monday to determine whether or not the confession can be used as evidence at Hernandez 's murder trial - not whether the statements are true. Judge Maxwell Wiley must decide whether Hernandez was properly advised of his rights.
Target	The judge must decide not whether the confession is true, but whether it can be permitted to be used as evidence at Hernandez 's murder trial.
Partial	Source and target sentence are discussing two unrelated concepts, but share short related phrases that do not match considerably.
Source	A non-profit group called Women On 20s, formed to convince President Barack Obama to put a woman's image on the $20 note, already has done some polling.
Target	There is a group called Women On 20s.
Bad	Source and target sentence are discussing two unrelated concepts.
Source	Leicester City have lost just one of their last seven league meetings with Hull City.
Target	88 % of British grandmothers consider themselves to be a Glam-Ma.

Table 10: Definition of the alignment quality. Example of each level of quality is also given.

Complex(input)	in computing , a protocol is a set of rules which is used by computers to communicate with each other across a network .
Simple(reference)	in computing , a protocol is the language used by computers while talking with each other .
WikiSmall	in computing , a protocol is a set of rules which is used by computers to communicate with each other across a network .
S4S	the process is a set of rules which is used by computers to communicate with each other across a network
WikiSmall+OA	in computing , a protocol is a set of rules which is used by computers to provide with each other across a network .
WikiSmall+S4S	in computing , a protocol is used by computers to communicate with each other across a network .

Table 11: An example of sentences generated by ACCESS. When the training set is WikiSmall, the complex sentence is not simplified. When the training set is S4S or WikiSmall+OA, the generated sentences contain grammatical errors and change the meaning of the complex sentence. The sentence generated by ACCESS trained on WikiSmall+S4S can be regarded as a simplified sentence.

Complex(input)	barcelona manager luis enrique -lrb- pictured -rrb- insisted afterwards he was right to start uruguay striker suarez
Simple(reference)	barcelona boss luis enrique says he was right to start the uruguay player
S4S	barcelona boss luis enrique says he was right to start uruguay striker
WikiLarge	barcelona manager luis enrique -lrb- pictured - pictured he wanted to start uruguay striker suarez .
S4S+WikiLarge	barcelona manager luis enrique said he was right to start right to start uruguay suarez suarez

Table 12: An example of sentences generated by ACCESS when S4S is regarded as a standard simplification dataset. When the training set is WikiLarge, the generated sentence contains grammatical errors and changes the meaning of the complex sentence. When the training set is S4S+WikiLarge, the generated sentence also contains grammatical errors and is less simple than the generated sentence when the training set is S4S only. This example illustrates that the quality of S4S is higher than that of WikiLarge.

Shironaam: Bengali News Headline Generation using Auxiliary Information

Abu Ubaida Akash[*][§] **Mir Tafseer Nayeem**[*][◊] **Faisal Tareque Shohan**[§] **Tanvir Islam**[‡]

Abstract

Automatic headline generation systems have the potential to assist editors in finding interesting headlines to attract visitors or readers. However, the performance of headline generation systems remains challenging due to the unavailability of sufficient parallel data for low-resource languages like Bengali and the lack of ideal approaches to develop a system for headline generation using pre-trained language models, especially for long news articles. To address these challenges, we present `Shironaam`, a large-scale dataset in Bengali containing over 240K news article-headline pairings with auxiliary data such as image captions, topic words, and category information. Unlike other headline generation models, this paper uses this auxiliary information to better model this task. Furthermore, we utilize the contextualized language models to design encoder-decoder model for Bengali news headline generation and follow a simple yet cost-effective coarse-to-fine approach using topic-words to retrieve important sentences considering the fixed length requirement of the pre-trained language models. Finally, we conduct extensive experiments on our dataset containing news articles of 13 different categories to demonstrate the effectiveness of incorporating auxiliary information and evaluate our system on a wide range of metrics. The experimental results demonstrate that our methods bring significant improvements (*i.e.,* 3 to 10 percentage points across all evaluation metrics) over the baselines[1]. Also to illustrate the utility and robustness, we report experimental results in few-shot and non-few-shot settings.

1 Introduction

News headlines can significantly affect the number of visitors and play a crucial part in the life-cycle of a news article (Murao et al., 2019). Therefore, representative and interesting headlines are arguably essential to any news document to grab the attention of potential readers (Mishra et al., 2021; Ao et al., 2021). Nowadays, online and printed news releases significantly increase the article's visibility, support, and context by using multimedia content. As a picture is worth a thousand words, digital assets such as images and videos are the go-to candidates for the thumbnails used in different social media, blogs, and many other platforms. The captions that go with the images or videos are equally significant as the actual content. Captions describing the images can clarify and enhance the image, optimize news articles for search engines, and improve the accessibility of the news for people with vision impairments[2].

Headline generation, given a news article, is a special case of abstractive summarization (Yamada et al., 2021), which involves sentence compression, syntactic reorganization, sentence fusion, and lexical paraphrasing (See et al., 2017; Gehrmann et al., 2018; Zhong et al., 2019; Nayeem et al., 2019; Nayeem and Chali, 2017b). Unlike text summaries, which often feature many or single long sentences to summarize a document's important concepts (Nayeem and Chali, 2017a), news headlines frequently have a single short catchy statement to grab the readers attention and entice them to read the story. Even though Bengali is the seventh most spoken language with approximately 337 million speakers worldwide[3] (Chakraborty et al., 2021; Chowdhury et al., 2021), generating quality headlines for a low-resource language such as Bengali is more challenging due to the unavailability of large-scale human-annotated dataset (Haque et al., 2016; Nayeem et al., 2018; Joshi et al., 2019).

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 52–67
May 2-6, 2023

Contextualized language models such as `BERT` (Devlin et al., 2019), `RoBERTa` (Liu et al., 1907), `T5` (Raffel et al., 2020) help improving several downstream tasks in NLP, such as summarization, question answering, and text classification. Unfortunately, these models suffer from a limitation as they can handle input sequences up to a certain limit (Sun et al., 2019). As a result, this limitation burdens some NLP tasks, especially where the input is necessarily long (Kitaev et al., 2020), such as transcript analysis of the phone calls, document topic prediction, news headline generation, etc. The most natural way to address this problem is to trim the input sequences to a maximum length. However, trimming the long input document is tricky, especially for headline generation. The news articles usually maintain coherence and relevant parts may be located at the bottom of the document, which may prevent models from generalizing well to positions beyond the cutoff point[4]. In this paper, we utilize topic words to retrieve important sentences as a context for the BERT model by following a simple yet cost-effective coarse-to-fine approach.

We present **Shironaam**, a large-scale abstractive Bengali news article dataset that includes over 240K professionally annotated headline-article pairings as well as auxiliary information such as image captions, topic words, and category information. Each sample can be represented as a tuple of (article, image caption, topic-words, category, headline). To the best of our knowledge, Shironaam is the first Bengali news article dataset incorporating auxiliary information and a benchmark for the news headline generation task. This corpus has the potential to authorize and encourage research on such a low-resource language, bringing technological advancements to a previously underserved community. Rather than the one-to-one mapping (*i.e.,* input is an article, and output is a headline) used in the earlier works (Takase et al., 2016; Zhang et al., 2018; Murao et al., 2019; Colmenares et al., 2019; Song et al., 2020; Li et al., 2021), we treat the headline generation task as a **three-to-one** mapping with the inputs being an image caption, a list of topic words, and an article where the output is a headline. Based on the transformer architecture, we utilize pre-trained language models for generating headlines and present a new concept of fusing image caption parallelly (Liu et al., 2020a) with the input article to support the three-to-one mapping and to encode long documents. We design and compare numerous input mechanism alternatives as part of the suggested strategy. Extensive experiments on our proposed dataset reveal that the suggested method is capable of generating high-quality news headlines (see Section F in the Appendix) and brings significant improvements over the state-of-the-art baselines across all evaluation metrics (Table 5).

Our main contributions can be summarized as follows:

- We provide **Shironaam**, a large-scale news headline generation dataset of a low-resource language *i.e.,* Bengali containing over 240K news headline-article pairings with auxiliary information such as image captions, topic words, and category information (Table 2). Also, this dataset can potentially be used for other tasks such as document categorization, news clustering, keyword identification, etc.
- We present a new concept of incorporating auxiliary information to model input with articles to improve the quality of headlines. We train an encoder-decoder model for this task almost from scratch, which utilizes pre-trained language model (Figure 1).
- We develop **BenSim**, an independent module for measuring the semantic similarity among Bengali sentences. We make use of the BenSim module and utilize topic words to encode long articles by following a simple yet effective approach (Figure 1(c)).
- To illustrate the utility and robustness, we also evaluate the performance with few-shot settings where the domains don't have enough training samples (Table 6).

2 The Shironaam Corpus

In this section, we present the first-of-its-kind corpus (we name it `Shironaam`) for news headline generation in Bengali like low-resource language. This includes auxiliary information in addition to the usual headline-article pairs. We explain the curation process involving raw data crawling, preprocessing, and cleaning.

---

[4] While `Longformer` (Beltagy et al., 2020) is a viable solution for this problem, it comes up with a high computational cost, and pre-trained models aren't available.

#Examples	142,731	240,580

Table 2: Feature-level comparison between IndicNLG-BN (2022) and **Shironaam** dataset (*ours*).

2.1 Raw Data Crawling

We crawl around 900,000 raw data samples from seven famous Bengali newspapers (names in Section C in the Appendix) concentrating on certain criteria, such as headline, article, image caption, category, and topic words. Since each of the newspapers mentioned above has it's own professional authors and distinct writing style, we consider multiple sources to prevent the bias of a particular annotation style. To ensure content diversity, we also cover various domains from all the news dailies. The majority of the news samples are extracted from HTML bodies of the corresponding publications, while some are rendered using JavaScript. However, two of them (see in Appendix Section C) do not provide the archives on their websites; therefore, we collect the samples through their APIs.

2.2 Dataset Preprocessing

The overall crawled corpus contains a lot of noise, such as irrelevant details about the publisher and the date/time of the news in multiple formats, embedded advertisements, phrases from different languages (especially English), reference URLs, inconsistent bold sections, emoticons, extrinsic symbols, and various Unicode representations. Thus, we remove the date/time and the embedded items using regular expressions. To preserve only the Bengali texts, we construct a vocabulary of Bengali unit characters and perform character level matching in the article bodies and headlines. The English numbers, however, are retained since they are used frequently in regular Bengali texts.

Dataset	% of novel n-gram			
	unigram	bigram	trigram	4-gram
Shironaam	26.59	66.12	82.71	86.49
IndicNLG BN	46.38	78.92	90.39	94.77

Table 3: Percentage (%) of novel n-grams between IndicNLG-BN (2022) and **Shironaam** dataset (*ours*).

The image captions sometimes include extra/irrelevant information (*e.g.,* ছবি [Picture], সংগৃহীত [Collected], ফাইল ছবি [File Image], রয়টার্স [Reuters], ইন্টারনেট [Internet], প্রতীকী ছবি [Symbolic Image], *etc.*)[6], which are common in any news article. Thus, we identify these repetitive words using a simple frequency-based approach over all the samples and remove them from the image captions. Furthermore, we discard the samples whose captions are smaller than four words in length; from our manual inspection, we observed that these words often describe the named entities present in the image, such as name, location, date/time, etc.

Different newspapers use different names to categorize their contents. Consequently, each domain is represented with different category names in all the news dailies. For extracting the categories, we map them with their corresponding representative domains and label each domain with it's relevant names. For instance, national, whole-country, city-news, country, capital, city-roundup, south-city, *etc.* are distinct categorical terms, but they can be grouped easily under the *national* domain. Table 1 shows the distribution of the final domains in the Shironaam corpus. We use `sbnltk`[7] for tokenizing the documents into sentences. Finally, we discard the samples where any of the information (*i.e.*, headline, article, or image caption) is missing.

2.3 Dataset Statistics

After preprocessing the raw corpus, we have 240,580 news samples as a tuple of (headline, article, image caption, topic words, category). To en-

Vocabulary size				
Shironaam	605,750	76,732	87,644	-
IndicNLG BN	614,374	65,553	-	-

Table 4: Quantitative statistics compared to IndicNLG-BN (2022) and our proposed dataset **Shironaam**.

sure a balanced distribution, we maintain the ratio of (92% - 220,574), (2% - 4994), and (6% - 15,012) samples from all the categories to construct the train, validation, and test set, respectively (see Table 1). We compare our corpus with the only available benchmark, `IndicNLG` (Kumar et al., 2022), for the news headline generation task in Bengali. Since `IndicNLG` covers multiple languages, we just keep the Bengali (BN) language portion for comparison. Table 2 provides a high-level summary of both datasets.

Our `Shironaam` corpus establishes a new benchmark in terms of the corpus size compared to `IndicNLG` (Kumar et al., 2022). It is important to note that our corpus also contains auxiliary information such as image captions, topic words, and article categories. Moreover, this can be used not only in headline generation tasks but also in some other tasks such as document categorization, news clustering, keyword identification, etc. To measure the abstractiveness, in Table 3, we calculate the percentage of novel n-grams in reference headlines that are not present in the article. Table 3 shows that the novelty level increases with the number of grams, and the average scores are comparable to the `IndicNLG` (Kumar et al., 2022). A quantitative statistics presented in Table 4 demonstrates that our `Shironaam` corpus contains more compressed headlines against lengthier articles compared to the `IndicNLG`, both in terms of words and sentences. This highly compressed nature of the headlines makes the task of headline generation in low-resource language more challenging. In addition, the vocabulary size of our articles is comparable with `IndicNLG`, whereas we get a larger number of vocabularies in our headlines (see Table 4).

Therefore, the `Shironaam` corpus comprises a diverse range of headline styles and provides the largest collection of Bengali news articles. Moreover, it is the first benchmarking dataset in such a low-resource language that includes auxiliary information in addition to the headline-article pairs. We hope it will motivate further study and serve as a baseline for future works on this task for this low-resource language.

3 News Headline Generation

3.1 Task

We establish a new concept of incorporating auxiliary information in order to generate high-quality headlines in Bengali, a low-resource language. In the context of this generation task, we assume that a) we have enough data with auxiliary information to train a headline generation model in Bengali language (can be referred to `Shironaam` corpus); b) the auxiliary information refers to the image captions and topic words used in tagging documents; c) we have access to a module that filters a document based on the contextual similarity with a list of topic words (we refer `BenSim` in Section 3.3). The task can be formalized as follows. Given article $\mathcal{A}$, image caption $\mathcal{C}$, and a set of topic words $\mathcal{T}$ as input, our goal is to generate high-quality headline $\mathcal{H}$ for the corresponding news article.

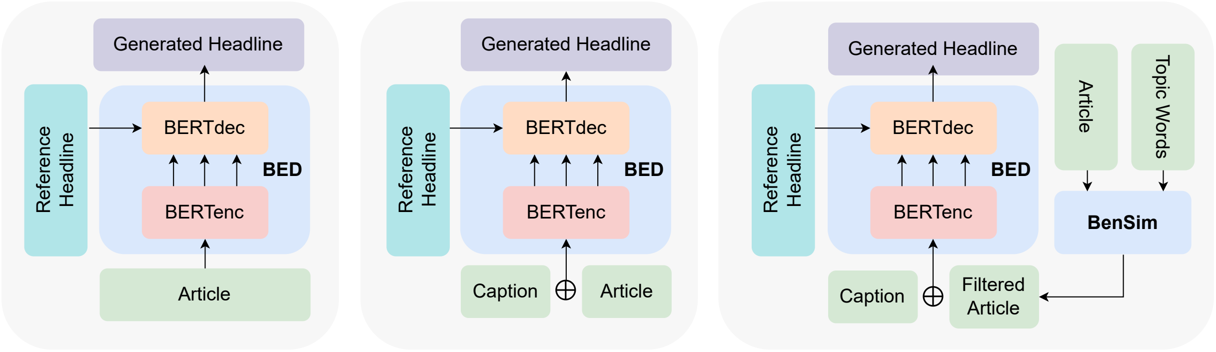
3.2 Approach

To carry out the idea, we need several benchmarks to compare with and evaluate our proposed hypothesis. But, no SOTA benchmark is available for this task in Bengali language[8], except the `IndicBART` (Dabre et al., 2022). So, we set multiple baselines (Section 4.2), both of extractive and abstractive types, that take article $\mathcal{A}$ as input and generate corresponding headline $\mathcal{H}$ as output. We follow `LEAD-1` and `EXT-ORACLE` approaches among the extractive types, whereas from the abstractive types, we initialize an encoder-decoder model for Bengali language with a pre-trained encoder-only checkpoint to skip the costly pre-training (Rothe et al., 2020) [9]. To train the encoder-decoder model (`BED`), we use `BanglaBERT` (Bhattacharjee et al., 2022a) as the encoder checkpoint. Additionally, we utilize other pre-trained models (*i.e.,* `BanglaT5`

---

[8] We did not consider the extreme summarization models since the style of a headline and a single-line summary is completely different.

[9] We refer the interested readers to Appendix (Section A) for necessary background.



(a) BED(base) **(b) BED(w/ Article + Caption)** **(c) BED(w/ FilteredArticle + Caption)**

Figure 1: Graphical illustration of our proposed headline generation models **(a)** BERT-based encoder-decoder (*baseline*) **(b)** Our model incorporating image caption with the article **(c)** Our model uses **BenSim** to extract important sentences (*a.k.a.,* filtered article) based on topic words and incorporates filtered article with the image caption.

(Bhattacharjee et al., 2022b), `IndicBART` (Dabre et al., 2022)) based on transformer architecture (Vaswani et al., 2017). After comparing all the baselines (see Section 4.2), we select the best performing one for further ablations. Experimental results (in Table 5) reveal that `BED` model outperforms other baselines, even though the fine-tuned `BanglaT5` (Bhattacharjee et al., 2022b) scores competitively.

3.3 BERT-based Encoder-Decoder (BED)

A `BED` model consists of an encoder that has been initialized with BERT, termed as `BERTenc`, coupled with a decoder that has also been initialized with BERT, which we call `BERTdec`. The initializing point for each weight's calculation is a public BERT checkpoint. The only variable initialized at random is the encoder-decoder attention (Rothe et al., 2020).

Article Only In Figure 1(a), we implement the basic version *i.e.,* `BED (base)` model, which takes word tokens of an article as a sequence of inputs $\mathcal{A}_{1:n}$ and describes a conditional distribution of target vectors $\mathcal{H}_{1:l}$ of variable length **l**, in our case, generated words for headline:

$$p_{\theta_{BERTenc},\theta_{BERTdec}}(\mathcal{H}_{1:l}|\mathcal{A}_{1:n}). \qquad (1)$$

The input sequence $\mathcal{A}_{1:n}$ is sent to the `BERTenc` component, which then converts it into a sequence of hidden states, $\overline{\mathcal{A}}_{1:n}$. The mapping can be defined as:

$$f_{\theta_{BERTenc}} : \mathcal{A}_{1:n} \rightarrow \overline{\mathcal{A}}_{1:n}. \qquad (2)$$

The `BERTdec` component will simulates the conditional probability distribution of the target vector sequence $\mathcal{H}_{1:l}$, assuming that the sequence of encoded hidden states $\overline{\mathcal{A}}_{1:n}$ has been provided:

$$p_{\theta_{BERTdec}}(\mathcal{H}_{1:l}|\overline{\mathcal{A}}_{1:n}). \qquad (3)$$

Bayes' rule lets us turn this distribution into a product of the conditional probability distribution of the target vector $\mathbf{h}_i$, given the encoded hidden states $\overline{\mathcal{A}}_{1:n}$ and all the previous target vectors $\mathcal{H}_{0:i-1}$:

$$\begin{aligned} &p_{\theta_{BERTdec}}(\mathcal{H}_{1:l}|\overline{\mathcal{A}}_{1:n}) \\ &= \prod_{i=1}^{n} p_{\theta_{BERTdec}}(\mathbf{h}_i|\mathcal{H}_{0:i-1}, \overline{\mathcal{A}}_{1:n}). \end{aligned} \qquad (4)$$

All preceding target vectors $\mathcal{H}_{0:i-1}$ and the encoded hidden state sequence $\overline{\mathcal{A}}_{1:n}$ are mapped to the logit vector $\mathcal{V}_i$ by the `BERTdec`. The next step is to run the `softmax` operation on the logit vector $\mathcal{V}_i$. This helps to define the conditional distribution $p_{\theta_{BERTdec}}(\mathbf{h}_i|\mathcal{H}_{0:i-1}, \overline{\mathcal{A}}_{1:n})$ by making sure that the distribution of the target vector $\mathbf{h}_i$ depends on the distributions of all previous target vectors $\mathbf{h}_0, \ldots, \mathbf{h}_{i-1}$:

$$p_{\theta_{BERTdec}}(\mathbf{h}_i|\mathcal{H}_{0:i-1}, \overline{\mathcal{A}}_{1:n}) = \mathbf{Softmax}(\mathcal{V}_i). \quad (5)$$

The first target vector $\mathbf{h}_0$ is going to be represented by a unique `BOS` vector that is referred to as the "beginning-of-sentence". After the conditional distribution $p_{\theta_{BERTdec}}(\mathbf{h}_i|\mathcal{H}_{0:i-1}, \overline{\mathcal{A}}_{1:n})$ has been set, the output can be made in an auto-regressive way. This makes it possible to define a mapping between an input sequence $\mathcal{A}_{1:n}$ and an output sequence $\mathcal{H}_{1:l}$ at the time of inference.

Fusing Article and Image Caption In order to explore more ways to improve the quality of the generated headlines, we employ `BED (w/ Article + Caption)` model, which incorporates image caption $\mathcal{C}_{1:m}$ with the corresponding article $\mathcal{A}_{1:n}$ as in Figure 1(b), where **m** << **n**, and passes them through the `BERTenc` using parallel-fusion (Liu et al., 2020a) mechanism:

$$\mathcal{K}_{1:r} = \mathcal{C}_{1:m} \oplus \mathcal{A}_{1:n}, \tag{6}$$

$$f_{\theta_{BERTenc}} : \mathcal{C}_{1:m}, \mathcal{A}_{1:n} \rightarrow \overline{\mathcal{K}}_{1:r}. \tag{7}$$

Here, $\mathcal{K}_{1:r}$ denotes the model input sequence, where **r** represents the new input sequence length, and $\oplus$ is concatenation operator separated by a special token. The sequence of hidden states $\overline{\mathcal{K}}_{1:r}$ are then processed through the `BERTdec` likewise the `Shironaam(base)` model and the headline is generated as output:

$$p_{\theta_{BERTenc},\, \theta_{BERTdec}}(\mathcal{H}_{1:l}|\mathcal{C}_{1:m}, \mathcal{A}_{1:n}). \tag{8}$$

However, the image caption may not always serve the full context if the news article becomes too long for `BERTenc`. Moreover, the image caption length is generally much smaller than the news article length. Thus, the impact of using image caption as a context is less sensitive for lengthier articles.

Bengali Sentence Similarity (BenSim) Since many of the news articles' lengths exceed the input sequence limit that `BERTenc` can process, we therefore, utilize the sequence length by ensuring all the relevant sentences are present in the limited input sequences. To ensure the extraction of relevant sentences, we develop `BenSim` module[10], a tool for measuring semantic similarity between Bengali sentences utilizing BERT embeddings. It takes news article $\mathcal{A}_{1:n}$ and corresponding topic words $\mathcal{T}_{1:k}$ as input for getting most of the contextual sentences and employs pre-trained `bangla-bert-base` (Sarker, 2020) model on both of the input sequences to generate the contextualized encoded representations. After performing mean pooling operation, cosine similarity (Singhal, 2001) is then applied to the encoded sequences to get the similarity score. After measuring the similarities between the topic words and input sentences, a filtered article $\mathcal{A'}_{1:r}$ is returned as output, which is then fused parallelly with the image caption $\mathcal{C}_{1:m}$ and sent to the model input. Finally, the `BED (w/ FilteredArticle + Caption)` model produces a headline after processing the fused input.

4 Experiments and Benchmarks

In this section, we set a new benchmark for Bengali news headline generation using `Shironaam` corpus and compare it with the other state-of-the-art baselines. After a clean comparison, we perform two ablation experiments on the superior base model. Then, we analyze the performance gap between the baselines and the ablations and further evaluate the best model on news domains with a few samples (few-shot). Finally, after proper analysis, we seek to find out the answers to the following research questions:

- **RQ#1:** Can we use auxiliary information (*e.g.,* image caption and topic words) to improve the performance of the headline generation?
- **RQ#2:** Which domain(s) benefit from the auxiliary information in few-shot and non-few-shot settings?

4.1 Implementation Details

We utilize the encoder-decoder paradigm[11] of HuggingFace, where pre-trained `BanglaBERT` (Bhattacharjee et al., 2022a)[12] is used to initialize both of the weights of encoder and decoder. Before proceeding to tokenization, we perform sentence normalization, introduced in Hasan et al. (2020). For tokenization, we use the pre-trained tokenizer[12] that comes with the model. All the hyper-parameters used for training and decoding are presented in Section B in the Appendix.

Evaluation Metrics We compare the performance with the following baselines across several evaluation metrics presented in Section D in the Appendix.

4.2 Baselines

LEAD-1 `LEAD-1` is a commonly used baseline for setting the lower bound of news headline generation task (Kumar et al., 2022; Narayan et al., 2018). It also indicates the degree of positional biasness of article body sentences in generating headlines. We pick the article's first sentence as the system headline and compare it with the original headline to generate the `LEAD-1` scores.

[12] BanglaBERT usage (HuggingFace)

Models	ROUGE			BLEU			BERT Score	METEOR Score
	R-1	R-2	R-L	BLEU Score	Brevity Penalty	Length Ratio		
Baselines								
LEAD-1 (Extractive)	30.50	13.86	28.00	5.65	97.71	2.48	74.63	29.90
EXT-ORACLE (Extractive)	39.92	22.89	37.28	9.17	97.16	2.30	77.16	39.65
IndicBART (mBART)	28.76	12.65	27.11	15.03	99.91	1.14	74.95	20.39
BanglaT5 (mT5)	44.13	23.03	42.12	13.05	91.33	1.15	80.13	34.65
Our Ablations								
BED Base (BERT2BERT)	44.22	24.18	42.28	22.06	94.47	0.94	80.53	34.16
-w/ Article + Caption	51.62	33.62	49.94	31.39	96.02	0.96	82.93	42.57
-w/ FilteredArticle + Caption	**52.19**	**34.27**	**50.31**	**31.80**	**98.57**	**0.99**	**83.10**	**43.52**

Table 5: Performance on `Shironaam (test)` corpus compared to the baselines (Section 4.2) and the results of our ablation study (see Appendix Section E for validation scores) across various automatic evaluation metrics, where **bold-faced** scores indicate superior performance.

EXT-ORACLE On the other hand, `EXT-ORACLE` can be considered as the upper bound of generating headlines by an extractive approach (Kumar et al., 2022; Narayan et al., 2018). We implement this baseline on the `Shironaam (test)` corpus by aligning a sentence from the input article with the reference headline based on the ROUGE-2 metric.

IndicBART Kumar et al. (2022) releases a multilingual model, which is fine-tuned on `IndicBART` (Dabre et al., 2022) checkpoint for the headline generation task focusing on Indic languages including Bengali. `IndicBART` is a sequence-to-sequence multilingual pre-trained model (Dabre et al., 2022) based on the mBART (Liu et al., 2020b) architecture.

BanglaT5 We fine-tune `BanglaT5` (Bhattacharjee et al., 2022b), a sequence-to-sequence transformer model based on mT5 (Xue et al., 2021) architecture for Bengali language, on the `Shironaam (train)` corpus for the headline generation task. For a fair comparison, we maintain the same hyper-parameters.

BED (base) Model We implement the model (article only), illustrated in Figure 1(a) on the `Shironaam (train)` corpus to make the baseline. We utilize 220,500 news samples from the train set to train the `BED` model, which takes the article only as input and generates a headline as output. The evaluation result on the `Shironaam (test)` set is shown in Table 5, which is a new benchmark for the Bengali headline generation task. In the following experiments, we utilize the auxiliary information with the same hyper-parameter settings to generate better-quality headlines.

4.3 Ablation Experiments

BED (w/ Article + Caption) Model As per the demonstration in Figure 1(b), the image caption is incorporated with the input article. This leads to a much improved result across all evaluation metrics compared to article only model (a.k.a., `BED (base)`) as shown in Table 5.

BED (w/ FilteredArticle + Caption) Model Since the utilization of image caption in model input gives better results, therefore we further enrich the inputs by incorporating topic words. We use topic words in filtering the longer articles through `BenSim` rather than using them directly to the input, as shown in Figure 1(c). First, we set a threshold value (40 in our case) for `BenSim` to extract the number of top semantically similar sentences. `BenSim` maintains the relative appearance order of the sentences in the original article to construct the corresponding filtered article. To fix the number of sentences in a filtered article, we consider the maximum use of the number of tokens `BED` model can afford *i.e.* 512. Fusing filtered article with image caption achieves the best results across several evaluation metrics as shown in Table 5 (also see Appendix Section F for the generation quality).

4.4 Discussions

Result Analysis Table 5 shows that the `LEAD-1` baseline performs inadequately on the `Shironaam (test)` corpus. More specifically, the ROUGE-2 and BLEU scores and the length ratio indicate that the original headlines are more abstractive in nature, and the first sentence of an article does not contain sufficient information for generating a headline. Unlike `LEAD-1`, comparatively higher ROUGE scores are obtained by using

EXT-ORACLE, but at the same time, BLEU score gain is lower. This trade-off indicates that the reference headlines consist of the subset of words present in the sentences selected by EXT-ORACLE. However, because of the concise nature of news headlines, this approach does not fit well but can be considered a strong baseline for other models. Among the abstractive types, IndicBART performs poorly on the Shironaam (test) corpus and even is unable to beat the weak LEAD-1 baseline, let alone EXT-ORACLE. On the other hand, the fine-tuned BanglaT5 yields a good score for this task. Although the generated results are slightly lengthier than the reference ones, they can be considered a strong baseline. The BED (base) model provides the best performance in terms of ROUGE, BLEU, and BERT scores. So, we consider it the strongest baseline and look for further ablations.

To this end, Table 5 shows that the best baseline is outperformed by our proposed technique of modeling input using auxiliary data. We want to emphasize that we use image caption and topic words purely as auxiliary data. While collecting the data from various news portals, we observe that it is very common to include images to help support and communicate the story and image captions are a crucial part of it that only describe the referred image. Although image captions are mostly correlated with the corresponding article in terms of context, we argue that they are not headlines. First, there is not much overlap in terms of Jaccard similarity measured between image captions and headlines (as from Table 1 we have approximately 29% overlap across different categories). Second, headlines differ from image captions in terms of styles and content.

Image captions usually give the model some signal on which parts of the document model need to attend more. Hence, as a result of combining image caption with article, BED (w/ Article + Caption) model improves the performance by about 3 (BERT score) to 10 (ROUGE-2 score) percentage points and produces more human-like headlines. Moreover, it often begins generating sentient headlines that are more abstract and profound than the reference ones. The BED (w/ FilteredArticle + Caption) model performs slightly better than the previous ablation. Since, there are fewer lengthier articles in the Shironaam corpus, the variations in the scores of the two ablation models are rather small. We observe that when we include filtered articles led by relevant topic words in the model's input, it begins to learn faster than the model without topic words (demonstrated in Figure 2). Therefore, the differences between the scores of two ablation models will increase with the number of lengthier articles.

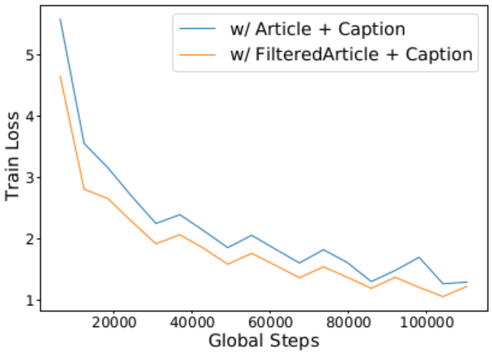

Figure 2: Train Loss vs. Global Steps for our ablations.

So, following the question **RQ#1**, we may conclude from the preceding discussion that auxiliary information definitely aids in creating better headlines. Although we achieve superior performance compared to the state-of-the-art baselines across several evaluation metrics, these quantitative measures can not determine the generation quality. Therefore, we present generated samples from our model categorized into several abstractive types (see Section F in Appendix). We leave the human evaluation of our generated samples as one of the future works.

Domain Specific Analysis We evaluate our proposed BED (w/ FilteredArticle + Caption) [denoted as **BED (FA+C)**] model on individual domains by comparing with a base model and to answer **RQ#2**. We also observe the performance of the presented model on the domains with fewer samples (few-shot). We employ two baselines here: BED (base) and BanglaT5 (Bhattacharjee et al., 2022b) [denoted as **BNT5**]. Although, the BNT5 has demonstrated competitive performance, Table 6 shows that BED (base) model performs better on the maximum number of domains. To calculate the exact performance gap, we maintain a uniform baseline *i.e.,* BED (base) to compare with the proposed model. For the few-shot observation, based on the number of training samples, we split the domains into two folds (see Table 6). The *Few-Shot* domains contain less than 6500 train samples, whereas rest of the domains are considered as *Non-Few-Shot*.

Category	R-1			R-2			R-L		
	BED (base)	BNT5	BED (FA+C)	BED (base)	BNT5	BED (FA+C)	BED (base)	BNT5	BED (FA+C)
Non-Few-Shot Domains									
National	48.03	47.33	55.84	27.29	25.83	37.88	46.06	45.37	53.95
International	44.44	46.04	50.47	22.92	23.08	29.96	42.02	43.49	48.13
Sports	30.14	33.46	39.20	11.57	13.43	20.40	28.75	31.59	37.33
Entertainment	33.05	32.99	35.14	15.07	14.32	16.64	31.26	31.33	33.44
Politics	49.28	49.66	**57.16**	28.80	27.32	**39.73**	47.53	47.68	**55.73**
Few-Shot Domains									
Economy	38.95	40.03	60.32	18.81	19.74	45.85	36.44	37.62	58.53
Life-Health	35.87	39.20	44.97	17.61	19.78	27.21	33.90	37.38	43.08
Edu-Career	50.57	51.12	71.55	31.92	30.82	59.54	48.05	48.82	70.48
Opinion	16.11	15.82	44.53	4.69	5.24	36.63	15.82	15.44	44.25
Miscellaneous	33.64	34.92	35.29	16.16	17.98	17.41	30.48	32.82	31.87
Science-Tech	41.82	44.14	51.03	19.54	22.61	31.20	39.30	41.82	48.49
Nature	36.07	37.89	46.54	15.78	16.65	30.07	34.84	35.79	45.53
Religion	27.29	35.48	**72.10**	12.28	19.63	**62.05**	26.96	34.42	**72.14**

Table 6: Performance of our proposed model `BED(FA+C)` compared to baseline `BED(base)` and `BNT5` (2022b) across different domains. Shaded grey region indicates superior performance compared to baselines and **bold-faced** and underlined scores indicate comparably best and worst domains, respectively.

Table 6 demonstrates that our proposed model improves the scores by a satisfactory margin of almost all the domains except *Entertainment* and *Miscellaneous*. These two categories get comparatively lower scores. The majority of headlines in the *Entertainment* domain are casual and clickbait-style and do not maintain the identical nature of a particular domain. We argue that the discrepancy, in this case, decreases the scores. The *Miscellaneous* domain is comprised of different sorts of randomness containing articles of various domains. Therefore, it is anticipated that this genre will get a lower score. Table 6 shows that our proposed model maintains consistent performance when there are few samples to train.

5 Related Works

Headline generation is an under-explored subtask of abstractive summarization, particularly in languages with limited resources. For the English language, an attention-based neural network has been proposed by Rush et al. (2015) for abstractive sentence summarization. The authors propose a model that utilizes a recurrent neural network (RNN) and an attention mechanism to summarize input sentences into a compact summary. Takase et al. (2016) build an AMR encoder for headline creation based on an encoder-decoder architecture. Using a dual-attention seq2seq model, Zhang et al. (2018) proposes a way for question headline development. In limited resource settings, Tilk and Alumäe (2017) pretrain a neural encoder and decoder model to enhance headline generation outputs. A sentence encoder, a gate network for sentence selection, and a headline decoder are the three stages of Zhou et al. (2017)'s headline generation approach. Tan et al. (2017) proposes a coarse-to-fine strategy that extracts the most important sentences before generating the headlines based on the context. For headline generation, Kumar et al. (2022) have released the `IndicNLG`, a collection of multilingual datasets. However, they do not provide any additional attributes besides the headline-article pairs. In summary, the majority of the past works for generating headlines primarily used the article content to generate headlines.

6 Conclusion and Future Work

In this paper, we contributed a large-scale dataset (*a.k.a.,* **Shironaam**) with auxiliary information such as image captions, topic words, and category for Bengali news headline generation. We employ contextualized language models to incorporate such auxiliary information and proposed a simple yet effective solution to encode long articles using topic words. Experimental results demonstrate the superiority of our approach across different domains and settings. We anticipate that our efforts will motivate the community to expand the scope of headline generation tasks beyond English, particularly for a low-resource language like Bengali. Our future work will look into incorporating auxiliary information to support more languages and build a language-agnostic model.

Limitations

Our model relies on auxiliary information such as image captions and topic words to achieve superior performance. However, it is quite common to include images and extra information (*e.g.*, topic words) to increase the article's visibility, support, and context. Also, our base model without auxiliary information demonstrates improved performance compared to the well-established and state-of-the-art baselines. Another limitation we observed that our model did not perform as well as for the Miscellaneous and Entertainment categories compared to the other 11 different categories because of the clickbaity nature of these categories. Finally, our headline generation model works only for Bengali, a widely spoken but low-resource language. Still, this idea of using auxiliary information to improve headline generation performance can easily be extendable for many languages.

Ethics Statement

We considered some ethical aspects while scraping the data. We requested data at a reasonable rate without any intention of a DDoS attack. Moreover, for each website, we read the instructions listed in robots.txt to check whether we can crawl the intended content. We tried to minimize offensive texts in the data by explicitly crawling the sites where such contents are minimal. Further, we removed the Personal Identifying Information (PII) such as name, phone number, email address etc from the corpus.

A Preliminaries

Abstractive text summarization (Rush et al., 2015; See et al., 2017; Zhang et al., 2020) was considerably more challenging before the development of sequence-to-sequence (seq2seq) models (Cho et al., 2014; Sutskever et al., 2014) and recent advances in transformer-based models (Vaswani et al., 2017; Devlin et al., 2019) due to a lack of sufficient datasets. Many text-summarizing applications are still hindered by the lack of suitable datasets, particularly for low-resource languages (Joshi et al., 2019). After being presented in Vaswani et al. (2017), models based on transformer architectures have been proven to perform better on sequence-to-sequence tasks than decoder-only language models *e.g.* Raffel et al. (2020). In its most basic form, an encoder-decoder model comprises a stand-alone encoder, like `BERT` (Devlin et al., 2019), and a stand-alone decoder model, like `GPT2` (Radford et al., 2019). It has been demonstrated that the huge pre-trained encoder-decoder models may considerably improve performance on a range of sequence-to-sequence tasks Lewis et al. (2020); Raffel et al. (2020). On the other hand, pre-training encoder-decoder models are very expensive to build since the models require a lot of computational resources.

Rothe et al. (2020) introduces the encoder-decoder model using pre-trained encoder and/or decoder-only checkpoints (such as `BERT` (Devlin et al., 2019) and `GPT2` (Radford et al., 2019)) to avoid the time-consuming pre-training process. According to Rothe et al. (2020), these encoder-decoder models can do well as large pre-trained encoder-decoder models like `T5` (Raffel et al., 2020) and Pegasus (Zhang et al., 2020) on different sequence-to-sequence tasks at a fraction of the training cost.

B Hyper-parameters, Training, and Decoding

All the `BED` models (Figure 1) are trained almost from scratch by maintaining uniform hyper-parameters and trained for 110,250 global steps with the learning rate `5e-5`, and batch size `12`. We save the best checkpoint by ensuring the lowest validation loss. We use `AdamW` (Loshchilov and Hutter, 2019) for optimizing the loss with default linear warmup. The maximum lengths of encoder and decoder are limited to `512` and `32` tokens, respectively. Each of the `BED` models is trained on a single NVIDIA Tesla P100 GPU and trained for approximately 33 hours, which takes almost 5 hours 30 minutes per epoch. The total number of trainable parameters is 249,044,480.

Decoding When validating and testing, we use beam search algorithm (Sutskever et al., 2014) with `4` beams to generate headlines. The maximum and minimum lengths used in generating the headlines are `16` and `4`, respectively. We use '`early stopping`' to stop the beam search when at least `4` sentences are finished per batch. The '`no-repeat n-gram size`' is set to `2`, where the exponential penalty to the length is `1.2`. Regarding vocabulary size, we use the fixed `32,000` vocabularies from the encoder.

D Evaluation Metrics

We evaluate the predicted headlines with some automatic metrics used for generation tasks. The generation quality is measured with the ROUGE (Lin, 2004) F1 score[13]. ROUGE-1 and ROUGE-2 measure informativeness, where fluency is measured by the longest common subsequence (ROUGE-L). We include BLEU (Papineni et al., 2002) score which indicates the similarity between reference and predicted sentences by comparing the overlap within tokens[14]. Brevity penalty and length ratio are shown to justify the BLEU score. The contextual similarity between the generated and reference headline is measured using F1 BERT score (Zhang* et al., 2020)[15], where the correlation between them is reported by METEOR score (Banerjee and Lavie, 2005)[16]. We use the available open-source implementations for the above metrics.

	ET	OneWeb is increasing satellites into space	
Sports	GH	মেসি এখন পিএসজির জার্সিতে	**Paraphrased**
	ET	Messi is now in PSG jersey	
	RH	পিএসজির হয়ে কবে মাঠে নামছেন মেসি?	
	ET	When is Messi on the field for PSG?	

Table 9: High quality headlines generated on **Shironaam (test)** corpus across all the categories. Here, “Type” means the how the generated headlines are different from the references. We categorize the differences into 5 types: **Inserted** (only one/some word(s) is/are added to reference headline), **Matched** (generated exactly the same), **Swapped** (the only difference is made by swapping one/some word(s) within the reference headline), **Deleted** (the output is about similar to the reference with one/some word(s) less), **Sentient** (generated headline is completely different but a potential competitor against the reference one), **Paraphrased** (paraphrased version of the reference headline). The colored words (*i.e.* teal for *Inserted*, cyan for *Swapped*, brown for *Sentient*, magenta for *Deleted*, and violet for *Paraphrased*) indicate the exact positions where the generated ones are different from the references and no color refers to no change. The generated and reference Bengali headlines, and their corresponding English version are denoted by **GH, RH,** and **ET** respectively.

PCC: Paraphrasing with Bottom-k Sampling and Cyclic Learning for Curriculum Data Augmentation*

Hongyuan Lu, Wai Lam
The Chinese University of Hong Kong
`{hylu,wlam}@se.cuhk.edu.hk`

Abstract

Curriculum Data Augmentation (CDA) improves neural models by presenting synthetic data with increasing difficulties from easy to hard. However, traditional CDA simply treats the ratio of word perturbation as the difficulty measure and goes through the curriculums only once. This paper presents **PCC**: **P**araphrasing with Bottom-k Sampling and **C**yclic Learning for **C**urriculum Data Augmentation, a novel CDA framework via paraphrasing, which exploits the textual paraphrase similarity as the curriculum difficulty measure. We propose a curriculum-aware paraphrase generation module composed of three units: a paraphrase candidate generator with bottom-k sampling, a filtering mechanism and a difficulty measure. We also propose a cyclic learning strategy that passes through the curriculums multiple times. The bottom-k sampling is proposed to generate super-hard instances for the later curriculums. Experimental results on few-shot text classification as well as dialogue generation indicate that PCC surpasses competitive baselines. Human evaluation and extensive case studies indicate that bottom-k sampling effectively generates super-hard instances, and PCC significantly improves the baseline dialogue agent.

1 Introduction

Data augmentation techniques create artificial data mixed with the original data for improved performance. Traditional data augmentation techniques in the language community include word-level perturbation such as synonym replacement, random insertion, random swap, and random deletion (Wei and Zou, 2019). Sentence-level techniques such as Round-trip Translation (Sennrich et al., 2016b) exploits the use of machine translation models to translate the input sentence to another language before translating back to the source language which can be essentially treated as a form of paraphrasing.

Curriculum learning presents training instances in a meaningful order with increasing difficulties to neural models for a boost in performance. Traditional curriculum learning (Bengio et al., 2009; Liu et al., 2018, 2020; Platanios et al., 2019; Xu et al., 2020a,b; Su et al., 2021) categorizes the original training instances into different levels of difficulties to be gradually presented to the model where a core component called difficulty measure, which is usually defined as a numerical number where a bigger number indicates a more difficult sample.

Combining the merits of the above two mentioned techniques, Curriculum Data Augmentation (CDA) creates synthetic data with increasing levels of difficulties to be presented to our neural models. Existing CDA defines the ratio of the words perturbation as the difficulty measure for curriculums and a gradual course which increases the difficulty of curriculums when the training loss plateaus (Wei et al., 2021), which then ends when the most challenging curriculum ends. Although existing CDA is effective, yet there are several disadvantages. First, it employs word-level perturbation. This superficial operation keeps the augmentation to have a similar sentence structure as the original one. Next, it employs random insertion, random swap, and random deletion for augmentation. Although this can be durable as for text classification (Wei et al., 2021), this is not suitable for generation tasks, particularly when many words are perturbed, which can even easily break the sentence grammar. Third, it uses a gradual course that only enters each level of difficulty once. A typical problem in neural network training called catastrophic forgetting (Kirkpatrick et al., 2017) can potentially happen in such a course, where the model might undesirably gradually forget some early learned knowledge.

To mitigate the problems of word-level perturba-

tion, we propose that paraphrasing can be a source of data augmentation, which provides diverse and grammatically correct augmentation. However, it is non-trivial to utilize paraphrase augmentation in a curriculum setting. Inspired by the fundamental linguistic concept of mutual implication (Boghossian, 1994; Peregrin, 2006), we treat two sentences as a pair of paraphrases if they can infer each other. For example, 'I am glad to help you.' and 'Let me help you out!' can be a pair of paraphrases, which provides a diverse change of the sentence structure suitable for the curriculum setting. We also employ textual similarity for our difficulty measures for the curriculum. Higher scores indicate that two sentences are more textually similar to each other. Specifically, we treat pairs with lower scores as more difficult instances to be presented in later curriculums. We propose a paraphrase candidate generator integrated with bottom-k sampling. Traditional sampling methods such as top-k sampling (Fan et al., 2018) and top-p (Holtzman et al., 2020) sampling tend to generate easier paraphrases that have relatively high similarity scores. We propose bottom-k sampling to generate super-hard paraphrases for the later harder curriculums by pruning the most probable words.[1] This leads the generation towards a more grammatically and lexically diverse paraphrase sampling space with low textual similarity.

To mitigate catastrophic forgetting, we propose to incorporate cyclic learning to pass through the curriculums multiple times.

In summary, our proposed framework, called **PCC**: **P**araphrasing with Bottom-k Sampling and **C**yclic Learning for **C**urriculum Data Augmentation, makes three contributions:

- We exploit the use of paraphrasing with mutual implication as a data augmentation source in curriculum learning.
- To generate mutual implicative paraphrases, we propose a curriculum-aware paraphrase generation module composed of three units, namely, a paraphrase candidate generator with bottom-k sampling for generating super-hard instances, a filtering mechanism, and a difficulty measure using textual similarity.
- We propose cyclic learning to enter each curriculum multiple times.

Experimental results indicate that PCC surpasses competitive baselines on few-shot text classification as well as dialogue generation. Human evaluation indicates that bottom-k sampling effectively generates grammatically and lexically rich paraphrases, and PCC significantly improves our baseline dialogue agent. To our best knowledge, this is the first time to apply CDA on a generation task.

Takeaway Overall, we present the effectiveness of paraphrasing as a curriculum data augmentation technique. The use of cyclic learning and bottom-k sampling further boosts performance. With some modifications, future works can treat PCC as a data augmentation framework and adapt it to other downstream tasks. Future works can also leverage bottom-k sampling in generating textual outputs that are grammatically and lexically rich.

2 Related Work

2.1 Data Augmentation

Existing textual data augmentation techniques can be broadly categorized into two streams: word-level and sentence-level augmentation.

For word-level augmentation, well-known operations includes synonym replacement (Zhang et al., 2015a), random insertion, random deletion and random swap (Wei and Zou, 2019). In contrast to dictionary-based synonym replacement, another stream of works randomly replace words with masks and employs BERT models for predicting the words as a source of augmentation that exploits the contexts (Wu et al., 2019; Cai et al., 2020).

For sentence-level augmentation, Round-trip Translation (Sennrich et al., 2016b) augments translation pairs by translating from the source language into the target language, and back to the source language with two machine translation models. Gao et al. (2020) proposes to use paraphrases as a source of augmentation in task-oriented dialogue generation. It has also been proposed to retrieve from unpaired corpora as a source of augmentation in the dialogue community (Zhang et al., 2020a). Another stream of work edits the retrieved dialogue response for better generation (Cai et al., 2019a,b), which can be treated as a form of indirect augmentation. The closest work to ours is Gao et al. (2020), where theirs does not employ curriculum learning.

2.2 Curriculum Learning

While traditional curriculum learning sorts the training samples in an order of increasing

---

[1] Note that we still use a combination of top-k and top-p sampling for generating easier curriculums.

Algorithm 1: Paraphrasing with Bottom-k Sampling and Cyclic Learning for Curriculum Data Augmentation (PCC)

```
Input: Dataset $\mathcal{D}$ for the downstream task;
Output: Trained downstream task model;
For the entire dataset $\mathcal{D}$, invoke the curriculum-aware
  paraphrase generation module with $\mathcal{D}$ and cache the
  augmentation results $\bar{\mathcal{D}}$ for training purpose;
while not the end of training do
    Set difficulty level $l$ to 0 at the start of a cycle;
    while not the end of current cycle do
        while not the end of current curriculum do
            Uniformly sample the next batch of
              training instance $\mathcal{S}$;
            Invoke the curriculum-aware
              paraphrase generation module for
              each training instance in $\mathcal{S}$ to retreive
              a batch of training augmentation $\mathcal{T}$
              with difficulty level $l$.;
            Invoke the task-specific model trainer
              to train the downstream task model
              with the training augmentation $\mathcal{T}$;
        end
        Increase $l$ by 1 to the next level at the end of
          current curriculum;
    end
end
```

Algorithm 2: Curriculum-aware Paraphrase Generation Module

```
Input: A single training instance with textual input $x$;
       difficulty level $l$;
Output: Cache the generated paraphrases into $\bar{\mathcal{D}}$ or
        retrieve an augmented training instance $\bar{x}$;
if a cached augmentation exists then
    Retrieve $\bar{x}$ that corresponds to $x$ with the
      difficulty measure $d = l$;
else
    Invoke the paraphrase candidate generator
      integrated with bottom-k sampling to generate a
      bag of paraphrase candidates for $x$;
    Invoke the mutual implication classifier for each
      paraphrase candidate to obtain corresponding
      binary indicator against the input sentence;
    Calculate the textual similarity for each
      paraphrase candidate against the input;
    Filter the generated paraphrase candidates with
      the mutual implication and the textual similarity
      using Equation 3;
    Assign a difficulty measure $d$ to the filtered
      paraphrases with Equation 4;
    Cache the augmentation results into $\bar{\mathcal{D}}$ ;
end
```

difficulties (Bengio et al., 2009; Weinshall et al., 2018; Su et al., 2021), our method follows the other stream of works that applies transformation on the original data with dedicated difficulty level (Korbar et al., 2018; Ganesh and Corso, 2020; Wei et al., 2021). The closest work to ours is Wei et al. (2021). Their work does not consider paraphrasing and focuses on text classification only.

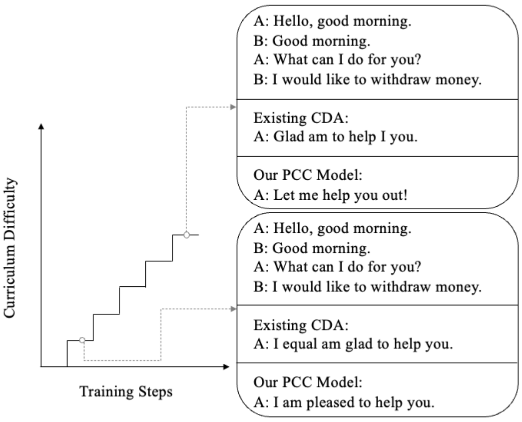
3 Our Proposed Framework

3.1 Background of Curriculum Data Augmentation (CDA)

Existing CDA (Wei et al., 2021) varies the word-level perturbation ratio to achieve different levels of difficulties under curriculum learning with simple word perturbation strategies such as synonym replacement, random insertion, swap, and deletion. As illustrated in Figure 1, such simple word perturbation strategies create problematic instances that break the sentence grammar, which can hamper the model performance. There are two common CDA strategies. One is called two-stage curriculum, which uses a fixed perturbation ratio for a single curriculum as the second stage after training with the original data. The other one is called gradual curriculum. It uses different ratios for a number of (typically 5) curriculums with increasing difficulties. However, such a learning strategy ends after passing through all the curriculums only once, and catastrophic forgetting can happen.

3.2 Our Proposed PCC

We propose curriculum data augmentation with paraphrase augmentation known as **P**araphrasing with Bottom-k Sampling and **C**yclic Learning for **C**urriculum Data Augmentation (PCC). Algorithm 1 depicts an overview of the whole PCC framework. At the start of training, we generate cached training augmentation for the entire dataset with our proposed curriculum-aware paraphrase generation module. Thereafter, we begin with the easiest curriculum. For each training instance, we retrieve the cached augmentation that has an equivalent difficulty measure with the current difficulty level. We then invoke the task-specific model trainer to train the downstream task model with the retrieved training augmentation. At the end of each curriculum difficulty level, we increase the difficulty level to advance to the next harder curriculum. In case it hits the end of the most difficult curriculum, we set the difficulty level to the easiest to start a new cycle. We propose such a cyclic learning strategy for mitigating potential catastrophic forgetting. In order to retrieve paraphrasing augmentation with appropriate difficulty measures, we propose a curriculum-aware paraphrase generation module.



A: Hello, good morning.
B: Good morning.
A: What can I do for you?
B: I would like to withdraw money.

Existing CDA:
A: Glad am to help I you.

Our PCC Model:
A: Let me help you out!

A: Hello, good morning.
B: Good morning.
A: What can I do for you?
B: I would like to withdraw money.

Existing CDA:
A: I equal am glad to help you.

Our PCC Model:
A: I am pleased to help you.

5)	Let me help you out!	−0.265
6)	Thank you for your question.	−0.506

Table 1: Paraphrases with mutual implication for an input ‘I am glad to help you.’

3.2.1 Curriculum-aware Paraphrase Generation Module

Algorithm 2 depicts the curriculum-aware paraphrase generation module. Three components are designed, namely, a paraphrase candidate generator integrated with a bottom-k sampling strategy, a filtering mechanism, and a difficulty measure. The paraphrase candidates are generated and then passed to the filtering mechanism. Finally, the filtered paraphrases are assigned a difficulty measure which represents to which curriculum difficulty level the augmentation belongs.

Paraphrase Candidate Generator with Bottom-k Sampling In order to generate mutual implicative paraphrases for the purpose of curriculum data augmentation, we adopt a Seq2Seq (Sutskever et al., 2014) generator which receives an input sentence x and generates the paraphrases $\bar{x}$ in an autoregressive manner (Nighojkar and Licato, 2021). During training, the paraphrase candidate generator is trained by maximising the following likelihood:

$$P\left(\bar{x} \mid x\right)=\prod_{t=1}^{T} P\left(\bar{x}_{t} \mid \bar{x}_{1}, \ldots, \bar{x}_{t-1}, x\right),$$

where T represents the token length of the paraphrase and x_t represents the word at the position t that has been inferenced.

Traditional sampling methods such as top-k sampling (Fan et al., 2018) and top-p sampling (Holtzman et al., 2020) sample the next token to be presented in the output from the most probable vocabularies that dominate the probability distribution. For example, at the i-th timestep during inference, top-k sampling samples the next token $\bar{x}_i$ from the most probable k words with the distribution:

$$P_{\bar{x}_i \in \mathcal{V}^{(k)}}\left(\bar{x}_i \mid \bar{x}_1, \ldots, \bar{x}_{i-1}, x\right), \tag{1}$$

where $\mathcal{V}^{(k)}$ represents the most probable k words. However, they are not suitable for generating super-hard instances, i.e., their output paraphrases tend to be textually similar to the original input sentence.[2]

To avoid coping the words and unearth the super-hard paraphrases to be used in later curriculums, we propose bottom-k sampling[3] which excludes a small set of dominating words for the sampling process. Note that we still use the combination of top-k and top-p sampling to generate easier samples for earlier curriculums. Formally, bottom-k modifies the distribution in Equation 1 to:

$$P_{\bar{x}_i \in \mathcal{V} \setminus \mathcal{V}^{(k)}}\left(\bar{x}_i \mid \bar{x}_1, \ldots, \bar{x}_{i-1}, x\right), \tag{2}$$

where $\mathcal{V}$ represents the whole vocabulary. Then, at each time step, we sample the next token with the rescaled distribution in Equation 2. We apply bottom-k for the first $\mathcal{N}$ steps of the generation before fallback to top-k and top-p. Bottom-k tends to generate paraphrases with lower textual similarity. For example, given an input of ‘I like to remodel homes’, existing sampling methods can generate an output ‘Renovations in property I like to remodel homes’. In contrast, bottom-k sampling generates ‘Is this what I want to see? Renovating homes are the best choices I have ever had.’ where the latter one has a higher difficulty measure. Appendix F presents an extensive analysis.

---

[2] We found that top-k and top-p sampling tend to copy dominating words from the input into the paraphrases. This is also the reason why we prefer bottom-k over bottom-p, as we would like to effectively prevent from coping dominating words. Appendix F presents a detailed analysis.

[3] We give it such a name to make it catchy. It does not sample from the bottom k words. It samples from the bottom $|\mathcal{V}| - k$ words where $\mathcal{V}$ represents the whole vocabulary.

Paraphrase Filtering The inferential properties or mutual implication (MI) has been argued as a form of equivalent meaning (Boghossian, 1994; Peregrin, 2006), i.e., each sentence should entail each other to be 'paraphrases'. To support curriculum data augmentation, we exploit mutual implicative paraphrases for grammatical and lexical richness. Algorithm 2 (Lines 5, 6, and 7) depicts the filtering mechanism we propose to generate MI paraphrases. In order to determine the MI relationship between a pair of paraphrase $(x, \bar{x})$, we adopt a pre-trained MI classifier $\mathcal{M}(\cdot, \cdot)$ to calculate a binary indicator $\mathcal{M}(x, \bar{x})$. Here, non-MI paraphrases have a score of 0 and MI paraphrases have a score of 1. We also adopt a pre-trained model $\mathcal{G}(\cdot, \cdot)$ to evaluate the textual similarity score of the paraphrases as $\mathcal{G}(x, \bar{x})$. Here, paraphrases with lower similarity scores are treated as grammatically and lexically less similar to the original input sentence. We filter the paraphrase $\bar{x}_i$ based on these two scores:

$$\mathcal{M}(x, \bar{x}_i) + (1 - \mathcal{M}(x, \bar{x}_i))\mathbb{1}(\mathcal{G}(x, \bar{x}_i) \geq \beta). \quad (3)$$

In the formula above, β is a threshold for textual similarity. Here, a paraphrase with a positive mutual implication has a binary output of 1, i.e., it is preserved regardless of its textual similarity score. A paraphrase with a negative mutual implication but high textual similarity also has a binary output of 1, meaning it is preserved as well. In this way, MI paraphrases can be produced. We preserve highly similar paraphrases classified as non-MI, which is a misclassification by the classifier.[4] All paraphrases that are non-MI with low textual similarity have a binary output of 0, meaning we discard those paraphrases. After the filtering, a difficulty measure is computed for each paraphrase.[5]

Difficulty Measure Recall that for a pair of paraphrase $(x, \bar{x})$, we adopt a pre-trained textual similarity model $\mathcal{G}(\cdot, \cdot)$ to calculate its similarity score as $\mathcal{G}(x, \bar{x})$. BLEURT (Sellam et al., 2020) score, a BERT-based pre-trained model, is employed as the textual similarity model $\mathcal{G}(\cdot, \cdot)$. Here, paraphrases with lower similarity scores are treated as more difficult instances with higher difficulty measures. For further illustration, we present 6 samples generated from our model in Table 1 with descending order sorted on the similarity scores. Here, the similarity scores decently represent the grammatical and lexical difference between the paraphrases candidates, and the mutual implicative paraphrase candidates are grammatically (Sample 2, 3, 4, 5, and 6) and lexically (Sample 1, 2, 3, 4, 5, and 6) rich.

As the distribution of the similarity scores for the paraphrases varies for different inputs, we compute the difficulty measure for a paraphrase $\bar{x}_i$ with its rank in a sorted list of similarity scores, denoted as $\text{sort}(\cdot)$, in descending order among a bag of paraphrase candidates $\mathcal{X}$:

$$d_i = \lceil \mathcal{C} \times \frac{\text{sort}_{\bar{x}_i \in \mathcal{X}}(\mathcal{G}(\bar{x}_i, x))}{|\mathcal{X}|} \rceil, \quad (4)$$

where $\mathcal{C}$ represents the total number of curriculum difficulty levels we define, and $|\mathcal{X}|$ represents the total number of paraphrase candidates we have. Here, the paraphrase $\bar{x}_j$ with the highest similarity score, i.e., $\mathcal{G}(x, \bar{x}_j) = \max_{\bar{x}_i \in \mathcal{X}} (\mathcal{G}(\bar{x}_i, x))$, has a rank of 1, therefore, $d_j = 1$. The paraphrase $\bar{x}_k$ with the lowest similarity score, i.e., $\mathcal{G}(x, \bar{x}_k) = \min_{\bar{x}_i \in \mathcal{X}} (\mathcal{G}(\bar{x}_i, x))$, has a rank of $|\mathcal{X}|$, thus $d_k = \mathcal{C}$. Consequently, a larger rank indicates that the paraphrase is more grammatically and lexically different than the original input, and thus belongs to a harder curriculum. We set $d_i = 0$ as the easiest difficulty level for the original data.

3.2.2 Cyclic Curriculum Data Augmentation

Wei et al. (2021) proposed curriculum data augmentation with a gradual course. The training ends after passing the curriculums once. We found that a typical problem called catastrophic forgetting (Kirkpatrick et al., 2017) can hamper the performance during such a gradual course, meaning that the model can gradually forget the knowledge learned in an easier course. The augmentation for later curriculums is a subtask of an easier curriculum and can have lexical overlaps. Formally, the input samples x^{t+1} can have overlapping lexical x_i^t which are the same as x_j^t, where t and $t+1$ represent the curriculum difficulty levels, and i and j represent the word positions in the sentence. Due to catastrophic forgetting, the model can forget what it has learned earlier. Hence, we propose cyclic learning as shown in Algorithm 1 to inform the model which

---

[4] We postulate it as a flaw introduced by the imbalanced training data with a larger portion of paraphrases that tends to be textually unsimilar against the original sentence. We found in our early experiments that removing these easier examples obviously degrades the results for COVID-Q from 51.7 to 50.0. Furthermore, ignoring non-MI easy examples prevents PCC from collecting enough augmentation for AMZN.

[5] As in Appendix A, we use an off-the-shelf paraphrase generator and MI classifier in our experiments.

skills would be useful later before retrospecting to easier curriculums with lower difficulties.

4 Experimental Setup

In our experiments, we define six curriculums ranging from 0 to 5. 0 represents the original data, and 1 and 5 represent the easiest and the most difficult curriculum respectively.[6]

4.1 Few-shot Text Classification Task

For the downstream application task for our experiments, we follow Wei et al. (2021) to conduct the task of few-shot, highly multi-class text classification (Gupta et al., 2014; Kumar et al., 2019), which typically has a large number of classes with only a few samples for each of the class. We use triplet loss, a loss computed with three elements, namely, an anchor a, a positive sample p, and a negative sample n. It origins from the vision community (Schroff et al., 2015), which was later applied to language tasks (Ein Dor et al., 2018; Lauriola and Moschitti, 2020), suitable for the few-shot setting. Precisely, the learning objective is defined as:

$$\mathcal{L} = \mathcal{D}(a, p) - \mathcal{D}(a, n) + \gamma,$$

where $\mathcal{D}$ represents a distance measure that computes the distance between the input encodings. γ represents the margin between the positive and negative samples. We use BERT-based (Devlin et al., 2019) pooled sentence encodings as the input into a two-layer triplet network (Schroff et al., 2015).

Three datasets for the text classification task are used in our experiments, namely, HUFFPOST (Misra, 2018; Misra and Grover, 2021), COVID-Q (Wei et al., 2020), and AMZN (Yury, 2020). For space reasons, we leave their detailed dataset description in Appendix B.

4.2 Dialogue Generation Task

The second downstream task for our experiments is open-domain dialogue generation. We adopt a Seq2Seq neural network (Sutskever et al., 2014) which receives a text concatenation of prepended knowledge k and dialogue context c and generates the dialogue response r in an autoregressive manner (Radford, 2018). We train our dialogue generator by maximising the following likelihood:

$$P(r \mid k, c) = \prod_{t=1}^{T} P(r_t \mid r_1, ..., r_{t-1}, k, c),$$

where T represents the length of the generated dialogue response and r_t represents the word at the position t that has been inferenced. Typical prepended knowledge include personal traits (Zhang et al., 2018) and movie description (Zhou et al., 2018). We use DialoGPT (Zhang et al., 2020b) for parameter initialization for PCC.

We use PERSONACHAT (CONVAI2, Zhang et al. 2018) as the dataset for dialogue generation, which is described in Appendix C.

4.3 Baselines for Text Classification

We use the following baselines from existing data augmentation methods for text classification.

Triplet Loss As described in Section 4.1, an anchor, a positive example and a negative example is selected to construct the loss (Schroff et al., 2015).

Token Substitution It substitutes words with their WordNet synonyms (Zhang et al., 2015b; Feinerer and Hornik, 2020).

Pervasive Dropout It uses dropout on words with probability $p = 0.1$ (Sennrich et al., 2016a).

SwitchOut It replaces words with uniformly sampled words (Wang et al., 2018).

Round-trip Translation It translates sentences into another language before translating back into the source language (Sennrich et al., 2016b).

Hard Negative Mining + EDA It combines hard negative mining (Schroff et al., 2015) that chooses hard negative samples and EDA (Wei and Zou, 2019) that employs synonym replacement, word-level random insertion, deletion, and swap.

Hard Negative Mining + EDA + Gradual Curriculum It gradually increases the temperature for EDA augmentation (Wei et al., 2021).

4.4 Baselines for Dialogue Generation

We use the following baselines and data augmentation methods for dialogue generation.

TransferTransfo A Transformer-based model fine-tuned on PERSONACHAT (Wolf et al., 2019).

PerCVAE It uses a memory-augmented architecture with a conditional variational autoencoder to exploit persona information (Song et al., 2019).

DialoGPT It refers to an autoregressive dialogue generator introduced by Zhang et al. (2020b).

---

[6] We release the code and resource at `https://github.com/HongyuanLuke/PCC`.

CDA It refers to the curriculum data augmentation technique proposed by Wei et al. (2021) using the augmentation of EDA (Wei and Zou, 2019).

Official & Flatten It refers to the paraphrase augmentation technique that is task-specific to the task-oriented dialogue generation (Gao et al., 2020). To adapt it to our task, we use our generated paraphrase via mutual implication, denoted as Flatten, and the official revised PERSONACHAT paraphrases, denoted as Official.

Round-trip Translation It translates the input into another language before translating back (Sennrich et al., 2016b).

4.5 Evaluation Metrics

For the text classification task, we follow Wei et al. (2021) to use the top-1 accuracy as the metric.

For the dialogue generation task, we use the word-level F1 score, and we adopt the well-known sequence evaluation metric BLEU (Papineni et al., 2002) where we report BLEU-2, BLEU-3 and BLEU-4. We also adopt another well-known sequence evaluation metric, ROUGE, where we report the F-measures for ROUGE-1, ROUGE-2 and ROUGE-L (Lin, 2004).

To verify our claim that bottom-k sampling generates grammatically and lexically rich paraphrases, we adopt Distinct-N (Li et al., 2016; Gao et al., 2019) with both $N \in \{1, 2, 3\}$ and $N \in \{4, 5, 6\}$ to measure the lexical and grammatical richness respectively using the ratio of distinct N-grams against the total number of N-grams generated.

5 Results and Analysis

5.1 Few-shot Text Classification Results

5.1.1 Main Results

Table 2 presents the results for few-shot text classification. Among the baselines, Triplet Loss + Gradual Curriculum works the best (Wei et al., 2021). PCC improves this baseline significantly. All the models share randomness in data, and our model is the best on all of the random seeds individually. Further, our proposed PCC model surpasses the baselines of Token Substitution, Pervasive Dropout, SwitchOut and Round-trip Translation significantly. Without bottom-k, PCC surpasses all the baselines, and our proposed full model with bottom-k obviously boosts performance. Appendix G additionally presents an analysis of the improvements as a function of the number of data augmentations.

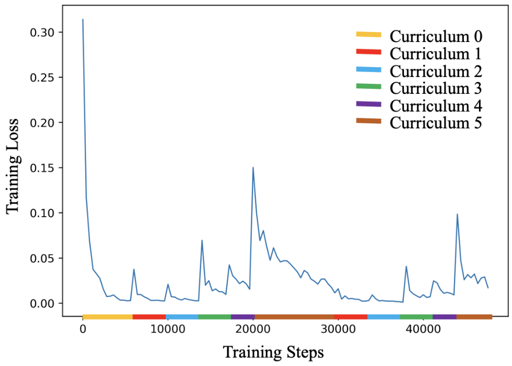

Figure 2: A plot of the training loss for the analysis for cyclic learning. Best viewed in color.

5.1.2 Ablation Study

Table 4 presents the results of our ablation study. First, removing the MI paraphrase filtering component described with Equation 3 obviously degrades the results. Replacing bottom-k sampling with pure sampling also decreases the results. Furthermore, paraphrasing in a random or an inverse order of decreasing difficulties, i.e., with neither curriculum learning nor cyclic learning, obviously deteriorates the results. *Therefore, our contribution is the discovery of paraphrasing as an effective CDA method rather than using paraphrasing solely as an augmentation technique.* Moreover, using cyclic learning instead of the gradual curriculum improves the results when trained with and without bottom-k sampling. Training the second cycle in an inversed order of decreasing difficulties degrades the results both with and without bottom-k.

5.2 Analysis on Cyclic Learning

Figure 2 presents the change of the training loss during the progress of the training on the task of text classification on COVID-Q. We observe that catastrophic forgetting exists as the training loss spikes when re-entering the curriculums. For the second time it enters the most difficult curriculum 5, the loss is also further smoothened compared to the first spike. The spike is also desirable as described in Wei et al. (2021), indicating that new instances that are harder to learn are presented and can help to escape the local minima. These support the usefulness of our proposed cyclic learning that can smoothen the gradients, mitigate catastrophic forgetting, and improve generalization by entering curriculums multiple times.

Model	HuffPost	Covid-Q	AMZN	**Average**
Triplet Loss (Schroff et al., 2015)	20.9 ± 1.0	39.7 ± 1.0	11.6 ± 0.6	24.1

Table 4: Ablation results in top-1 accuracy for the downstream task of text classification.

5.3 Dialogue Generation Results

Table 3 presents the results for dialogue generation on PersonaChat. First, we present the results for competitive baselines, namely TransferTransfo and PerCVAE. DialoGPT surpasses these two significantly. Using CDA on DialoGPT has deteriorated BLEU scores, which suggests that using CDA causes grammatical influence, possibly due to the random operations that produce undesirable grammatically incorrect augmentation. We also observe a large variance with the official paraphrase provided by PersonaChat, possibly due to the large difference between the manually rephrased sentences. This indicates easier paraphrases seem to be essential for PCC to be effective. Also, the Flatten baseline reported in Table 3 approximates a random curriculum, which degrades the results. It leads to a conclusion about the usefulness of the suggested curriculum. Round-trip Translation (RT) seems not effective, which is somehow reasonable as RT was originally designed for machine translation. PCC achieves the best among all the models, suggesting its usefulness for dialogue generation. Appendix D provides in-depth reasonings on the results. Appendix H presents a human evaluation of the downstream task of dialogue generation.

5.4 Analysis on Bottom-k Sampling

Table 5 presents the automatic results for bottom-k sampling on PersonaChat. Here, bottom-k sampling attains the best on Distinct scores with

Model	**D1**	**D2**	**D3**	**D4**	**D5**	**D6**
Pure Sampling	0.187	0.571	0.788	0.881	0.919	0.932
Top-k&p (k=120, p=0.95)	0.145	0.481	0.711	0.826	0.877	0.897
Top-k&p (k=80, p=0.80)	0.125	0.415	0.634	0.762	0.825	0.850
Bot.-k (k=2, $\mathcal{N}$=1)	0.184	0.587	0.824	0.901	0.919	0.925
Bot.-k (k=10, $\mathcal{N}$=1)	0.199	0.630	0.860	0.926	0.940	0.943
Bot.-k (k=2, $\mathcal{N}$=5)	0.223	0.695	0.904	0.945	0.951	0.953
Bot.-k (k=5, $\mathcal{N}$=10)	0.251	0.786	0.950	0.967	0.969	0.970
Bot.-k (k=10, $\mathcal{N}$=15)	**0.262**	**0.851**	**0.971**	**0.978**	**0.979**	**0.979**

Table 5: Automatic results for bottom-k sampling on PERSONACHAT. **D** represents the Distinct-N scores.

Criteria	**PCC w/o Bottom-k**	**PCC w/ Bottom-k**
Gramma. Richness	34	66 ‡
Lexical Richness	33	67 ‡
Difficulty	34	66 ‡
Paraphrasing	50	50

Table 6: Human evaluation results for bottom-k in winning percentages. ‡ indicates the results as passing a two-tailed binomial significance test with $p < 0.0001$.

lower grams ($N \in \{1, 2, 3\}$), indicating its lexical richness. It also attains the best on Distinct scores with higher grams ($N \in \{4, 5, 6\}$), indicating its grammatical richness. This helps to generate super-hard instances. Note that the setting of bottom-k sampling employed in PCC with $k = 2$ and $\mathcal{N} = 1$ already gives the best overall diversity against previous sampling methods. Further increasing the value of k and $\mathcal{N}$ leads to higher diversity.

5.5 Human Evaluation on Bottom-k Sampling

We hired three experienced annotators who have degrees relevant to English Linguistics to conduct an evaluation on bottom-k sampling with PERSONACHAT. We present a questionnaire composed of 800 questions with 200 randomly sampled training instances with the paraphrases generated with and without bottom-k sampling to the annotators to compare model outputs under A/B testing:

- **(Grammatical Richness)**: *"Which paraphrase do you think is more grammatically different than the original input sentence?"*
- **(Lexical Richness)**: *"Which paraphrase do you think is more lexically different than the original input sentence?"*
- **(Difficulty)**: *"Which paraphrase is more difficult to read and understood?"*
- **(Paraphrasing)**: *"Which one is more like a mutual implicative paraphrase to the input?"*

Table 6 presents the results of our human evaluation. The paraphrases generated by PCC with bottom-k sampling have a significant advantage in lexical and grammatical richness. Such an advantage correlates well with the difficulty of the paraphrases to be understood by human annotators. Furthermore, bottom-k does not hurt the paraphrasing performance compared to the top-k and top-p sampling. The result of human evaluation verifies our claim that bottom-k generates super-hard paraphrases with grammatical and lexical richness. Appendix F presents how bottom-k sampling is superior over previous methods in our scenario with case studies about the coping mechanism.

6 Conclusions

We propose a novel framework that uses mutual implicative paraphrasing as a curriculum data augmentation technique. Our proposed curriculum-aware paraphrase generation module is composed of three components, a paraphrase candidate generator with a bottom-k sampling strategy for generating superhard paraphrases, a paraphrase filtering mechanism, and a difficulty measure. We propose a bottom-k sampling strategy to effectively generate super-hard instances with grammatical and lexical richness to be used for the later stages in curriculum learning. Moreover, we propose a cyclic learning strategy that mitigates catastrophic forgetting. Experimental results on the task of few-shot text classification as well as dialogue generation support our proposed methodology PCC's usefulness, surpassing several competitive baselines.

Limitations

The proposed PCC cost more computational resources than traditional CDA methods. However, the cost is still affordable. Generating a round-trip augmentation used as one of the baselines costs about 1.5 seconds (1x speed) for PERSONACHAT. In contrast, generating a single paraphrase costs about 0.40 seconds (3x faster) with PCC on our machine with a single GPU.

Ethical Statement

We honour and support the EACL Code of Ethics. The datasets used in this work are well-known and widely used, and the dataset pre-processing does not make use of any external textual resource. In our view, there is no known ethical issue. End-to-end pre-trained dialogue generators are also used, which are subjected to generating offensive context. But the above-mentioned issues are widely known to commonly exist for these models. Any content generated do not reflect the view of the authors.

A Implementation Details

For text classification, we use the hyper-parameter settings as in Wei et al. (2021) for the gradual course, and we refer to their paper for the detailed settings. For our cyclic learning, we pass through the curriculums twice. We train the same number of steps for each curriculum as we did in the first pass for our second pass, and the remaining hyper-parameters are kept the same. For Token Substituion, Pervasive Dropout, SwitchOut, and Round-trip Translation, we follow Wei et al. (2021) to use the triplet network as the base model and use a two-stage curriculum for those baselines. Following Wei et al. (2021), we include 20% original data whenever augmentation is used.

For dialogue generation, we use DIALOGPT-SMALL for parameter initialisation. We use a batch size of 4 and a gradient clip of 0.1. We use validation patience of 10 based on the validation loss. We use greedy decoding for all of our experiments. The above settings apply to all our baselines and our proposed model fine-tuned on DIALOGPT. We start to apply the augmentation after 130,000 steps for data augmentation methods. We train the first, second, third, fourth, and fifth curriculums with 60,000 steps. For Official, Flatten, and RT, we perform a two-stage curriculum as described by Wei et al. (2021). We set $\mathcal{N}$ and k as a small value (typically $\mathcal{N} = 1$ and $k = 2$) for bottom-k sampling. We perform a cyclic repetition for our proposed method for the same number of steps for each curriculum until early stopped.

During our experiments, we apply data augmentation methods on the entire textual input for text classification, and we apply data augmentation methods on the personas traits for persona-based dialogue generation. We employ an off-the-shelf pre-trained model for both the paraphrase generator and the MI classifier (Nighojkar and Licato, 2021).

For all of the datasets, we obtain 20 paraphrases after filtering, and we assign 4 paraphrases (Wei et al., 2021) to each of the curriculums we have. We use 2 paraphrases obtained with bottom-k sampling for COVID-Q and we use 4 paraphrases obtained with bottom-k sampling for the remaining datasets.

For our models without bottom-k sampling, we use 20 paraphrases generated with a combination of top-k sampling and top-p sampling with $k = 120$ and $p = 0.95$ for all of the datasets.

We conduct our experiments for dialogue generation on the PARLAI platform (Miller et al., 2017).

B Datasets for Text Classification

- The HUFFPOST dataset is composed of 200k news headlines collected from 2012 to 2018, which is categorized into 41 classes such as politics, entertainment, and travel (Misra, 2018; Misra and Grover, 2021). We use all the classes and a 70% / 30% train / test split by class (Wei et al., 2021).

- The COVID-Q dataset is composed of 87 classes with several questions per cluster which ask about the same thing (Wei et al., 2020). We use the official train / test split with 3 questions per cluster (Wei et al., 2021).

- The AMZN product review dataset (Yury, 2020) categorizes products into given reviews. We consider the use of 318 'level-3' classes with at least 6 samples per product.

For the few-shot scenario, we need to set the number of samples in each class, N_c, to be used to construct the datasets. We use the setting in Wei et al. (2021) where $N_c = 3$ for COVID-Q and $N_c = 10$ for HUFFPOST. We set $N_c = 2$ for AMZN.

C Dataset for Dialogue Generation

CONVAI2 is an official competition built based on PERSONACHAT by adding new training examples as well as a hidden test set. For convenience, we denote the former as PERSONACHAT in the remaining of the paper. Since the test set is not publicly available, we use the official split containing a training / development split with 8,939 / 1,000 multi-turn dialogues conditioned on 1,155 / 100 personas respectively. Each persona is composed of about 4 to 5 persona traits.

D Analysis on Dialogue Generation

Table 3 reports an ablation when we use our PCC to train the dialogue generator without the use of bottom-k sampling. The results suggest that using bottom-k sampling improves all the metrics, especially the ROUGE scores. Table 8 presents the distribution of the textual similarity scores for the paraphrases generated from four methods on PERSONACHAT. The official paraphrase (Zhang et al., 2018) largely differs from the original ones, which we postulate as the reason for the large variance observed in Table 3. This also indicates the neccessity of the easier samples for curriculum learning. The Round-trip Translation generates paraphrases that have higher textual similarity with the input sentence. Our method without bottom-k sampling (we use a combination of top-k and top-p sampling with $k = 120$ and $p = 0.95$ here) generates paraphrases with more evenly distributed scores, with an average of 0.02. In contrast, bottom-k helps to generate harder samples while still capable of generating more easier samples.

E Problematic Cases for EDA

Table 7 presents samples from EDA for a sample input 'I am glad to help you.' with each of the

Sample Number	$\tau = 0.1$	$\tau = 0.2$	$\tau = 0.3$	$\tau = 0.4$	$\tau = 0.5$
i)	I equal am glad to help you.	I am glad help to you.	I am gald to happy help you.	To help you.	Glad am to help I you.
ii)	I am glad you help to.	I am gladiola to help you.	I am glad to assistance you.	Help glad am to i you.	I am gladiolus to helper you.
iii)	Am glad you.	I am glad help you.	I am glad you help to.	You I gald to help am.	I am glad help you.
iv)	I am glad to help you.	I am glad equal to help you.	I am glad to help you.	I am glad to happy happy help you.	I am happy to avail you.

Table 7: Randomly selected cases for an input ‘I am glad to help you.’ using Easy Data Augmentation (Wei and Zou, 2019). We present recommended temperatures τ ranging from 0.1 to 0.5, with four samples for each τ.

Model	$[0.5,$	$[0, 0.5)$	$(-0.5, 0)$	$, -0.5]$	**Avg.**
Official Paraphrases	1%	14%	33%	52%	-0.46
Round-trip Translation	25%	52%	17%	6%	0.23
PCC w/o Bottom-k	39%	11%	23%	27%	0.02
PCC w/ Bottom-k	16%	8%	18%	58%	-0.43

Table 8: Analysis on the distribution for the textual similarity score with different augmentation methods.

temperatures τ ranging from 0.1 to 0.5, which is the recommended setting from Wei et al. (2021). We categorize EDA’s problems as the followings:

- Sample i) with $\tau = 0.1$ and sample ii) with $\tau = 0.2$ changes the meaning of the input sentence. ‘equal’ is possibly produced by random insertion and ‘gladiola’ is possibly produced by synonym replacement via WordNet (Feinerer and Hornik, 2020).
- Most of the samples produced with $\tau = 0.4$ and $\tau = 0.5$ breaks the grammar, which can be harmful to generation tasks.
- Sample ii) and iv) with $\tau = 0.5$ introduces rare words such as ‘avail’ and ‘gladiolus’, which is counterintuitive to see in many tasks.

As illustrated in Figure 1, PCC effectively reduces the above-mentioned issues.

F Analysis on Bottom-k Sampling

Table 9 presents extensive case studies to support that bottom-k sampling generates grammatically rich and lexically rich paraphrases. PCC without bottom-k tends to exploit a coping mechanism at the beginning of generation (Sample 2, 3, 5, 6, 7, 8, 9, 10, 11, 12). By excluding these dominating words to be copied for generation, bottom-k effectively emphasises the content (Sample 5), improves grammatical richness (Sample 1, 2, 3, 4, 5, 6, 7, 10, 12) and lexical richness (Sample 3, 4, 6, 8, 10, 12), does appropriate synonym replacement (Sample 8, 11) and insertion (Sample 4). Without bottom-k sampling, the input that starts with a first-person pronoun ‘i’ is highly likely to have an output that starts with ‘i’ (Sample 2, 3, 6, 8, 10). This constrains the model from generating grammatically rich paraphrases. In contrast, bottom-k sampling effectively reduces such cases and biases the generation towards a grammatically rich sampling space. Indeed, out of the 6,126 persona traits from PERSONACHAT, 5,087 of them start with ‘i’. PCC without bottom-k generates 2,558 paraphrases that start with ‘i’, which avoids generating super-hard instances and hampers the PCC performance.[7] In contrast, bottom-k generates 205 paraphrases that start with ‘i’, indicating its usefulness in improving grammatical richness and generating super-hard instances. Avoiding coping helps to unearth the diverse paraphrases hidden in the tail vocabularies,

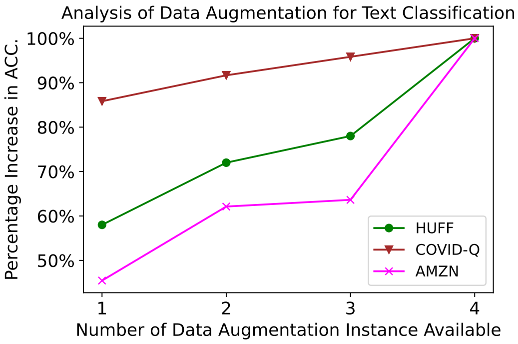

Figure 3: A plot of the percentage performance improvements of the downstream task of text classification against the number of data augmentation instances per curriculum. We use the first row in Table 2 as the baseline and the last row in Table 2 as the full improvements.

---

[7] Neither a pure top-p sampling with $p = 0.95$, a pure top-k sampling with $k = 120$, nor a greedy sampling helps, which generates 2,313, 2,381 and 3,302 paraphrases that start with ‘i’ respectively. Compared to these sampling strategies, bottom-k is an effective strategy in preventing copying.

Original Input Sentence	**PCC w/o Bottom-k Sampling**	**PCC w/ Bottom-k Sampling**
1): i like to shoot a bow.	When i first started shooting bows, this was the most important method.	Hey, i like to shoot a bow. Just started using a Bow SLR shooter, but a DSLR isn't really necessary.
2): i have four sisters.	i have four sisters	four sisters, and i want four sisters.
3): i believe that mermaids are real.	i believe that mermaids are real " @JesseyHawkins	Marxist philosopher,'mermaids are real," property
4): i work as a stand up comedian.	jesse t	trained comedian, I work as a stand up comedian.
5): my favorite drink is cuba libre.	My favorite beverage is Cuba libre.	Cuba is my favorite drink and I live in Cuba free.
6): i did a few small roles in tv series.	I have done a few small roles in tv series.	over the years i've appeared in a few small roles in television series
7): i love bicycling.	bicycle is my friend. i Love Bicycling.	how wonderful & amp ; inspiring! I love bicycling.
8): i own a hearse.	own a hearse. u could do that?	belongs to a hearse. it's not that expensive.
9): i like to listen to music.	i like to listen to music. How do you make up your mind?	I like to listen to music. by JACK CLINTON
10): i like to party.	I like to party	touts my ambition and passion for parties " by @MargotHillary by @anadulka @KelisStout
11): my favorite band is imagine dragons.	my favorite band is imagine dragons. I am just so happy about that.	i love this band it is awesome
12): i love to sing.	sing, am i love to sing	artist, i love to sing.

Table 9: Extensive case studies on PERSONACHAT support our claim that bottom-k sampling generates grammatically and lexically rich paraphrases that are more different than the input sentence.

which we postulate as the reason for the results observed in human evaluation in Section 5.5.

Note that we use bottom-k sampling to effectively prevent coping to generate instances that are textually more different to the input. There is a stream of work that considers improving the diversity (Vijayakumar et al., 2016). However, these works do not directly consider the similarity between the input paraphrase and the output paraphrase. This is the advantage of bottom-k sampling over this stream of work for our scenario.

G Analysis on Data Augmentation

Figure 3 presents the percentage improvements in accuracy as a function of the number of data augmentation instances available for each curriculum. Here, since we have 5 curriculum difficulty levels in our setting, having 3 instances available for each curriculum means that we have 15 data augmentations in total for each original sample. The improvements are positively correlated with the number of available instances. Furthermore, it seems that the improvements of PCC are not saturated yet. This means that a further increase in the number of data augmentations can lead to even higher performance than reported in our paper.

H More Human Evaluation

- **(Appropriateness)**: *"Who is more appropriate given the previous dialogue context?"*
- **(Informativeness)**: *"Who is more diverse instead of null answers such as I do not know?"*
- **(Engagingness)**: *"Who would you prefer to talk with for a long conversation?"*
- **(Human-likeness)**: *"Which speaker do you think sounds more like a real person?"*

Criteria	**w/o PCC**	**w/ PCC**
Appropriateness	49	51
Informativeness	45	55†
Engagingness	48	52
Human-likeness	49	51

Table 10: Human evaluation results for PCC in winning percentages. † indicates the results as passing a two-tailed binomial significance test with $p < 0.05$.

We follow Li et al. (2019) and Zou et al. (2021) to conduct a human evaluation of dialogue generation from the four aspects described above. We follow the settings used in Section 5.5 to invite three experienced annotators to mark 200 instances under A/B settings. The results in Table 10 indicate that PCC effectively improves the DIALOGPT baseline in all aspects, especially informativeness.

I Computing Infrastructure

We use an NVIDIA TITAN RTX with 24GB GPU memory for all of the experiments conducted in this paper. Training the text classification model consumes about 1 hour. Fine-tuning the dialogue generator consumes about 15 hours. Generating a single paraphrase to be used in PCC as a CDA method costs about 0.40 seconds on our machine.

A Two-Sided Discussion of Preregistration of NLP Research

Anders Søgaard **Daniel Hershcovich**

University of Copenhagen
{soegaard,dh}@di.ku.dk

Miryam de Lhoneux
Department of Computer Science
KU Leuven
miryam.delhoneux@kuleuven.be

Abstract

Van Miltenburg et al. (2021) suggest NLP research should adopt *preregistration* to prevent fishing expeditions and to promote publication of negative results. At face value, this is a very reasonable suggestion, seemingly solving many methodological problems with NLP research. We discuss pros and cons—some old, some new: a) Preregistration is challenged by the practice of retrieving hypotheses after the results are known; b) preregistration may bias NLP toward confirmatory research; c) preregistration must allow for reclassification of research as exploratory; d) preregistration may *increase* publication bias; e) preregistration may *increase* flag-planting; f) preregistration may *increase* p-hacking; and finally, g) preregistration may make us less risk tolerant. We cast our discussion as a dialogue, presenting both sides of the debate.

1 Preregistration

Should NLP researchers be required to preregister their studies? Van Miltenburg et al. (2021) present arguments *for* preregistration, recently echoed by Ulmer et al. (2022). Preregistration has its origin in preregistration of clinical trials,[1] and amounts to the following: Before you initiate a set of experiments, you register your hypotheses, your experimental design and how you plan to analyze your results. Registration is time-stamped on an online platform with general public access. You then follow your plan as closely as possible and report any divergences in your final publication.

The discussion in van Miltenburg et al. (2021) is not unprecedented. Preregistration has been debated in epidemiology (Lash and Vandenbroucke, 2012), social psychology (Veer and Giner-Sorolla, 2016), experimental economics (Strømland, 2019) and information systems research (Bogert et al., 2021). Our discussion is inspired by the discussion in epidemiology, which is similar to NLP in focusing on data analysis rather than clinical trials.

There is an important ambiguity in how preregistration is discussed: Is the preregistration entry peer-reviewed or not? Chambers (2019) sees preregistration as a peer-reviewed process, and this is also what van Miltenburg et al. (2021) suggest for NLP. We therefore assume peer-reviewed preregistration below. The required format of the registered report is also important. In their Appendix, van Miltenburg et al. (2021) provide example questionnaires. We will assume registered reports will be lists of answers to such questionnaires, but in §9, we will suggest a few revisions to the questions formulated by van Miltenburg et al. (2021).

2 Why Preregister NLP Research?

Van Miltenburg et al. (2021) present four reasons for adopting preregistration in NLP: distinguishing between confirmatory and exploratory research, avoiding fishing expeditions and harking, mitigating publication bias and avoiding flag-planting:

Distinguishing Confirmatory from Exploratory The first apparent advantage to preregistration—often said to be the most important one (Nosek

---

[1] The first registries were established by medical researchers in the 1960s and were originally designed to help experimenters recruit participants for clinical trials, but as pointed out by Wiseman et al. (2019), preregistration, as we think of it today, started in parapsychology. In 1974, Martin Johnson, a professor of parapsychology and an editor of newly established European Journal of Parapsychology, introduced a preregistration practice for this journal (Johnson, 1975), in an effort to make parapsychology protocols more rigorous. In the editorial, Martin Johnson describes how according to the philosophy of the proposed preregistration model, experimenters should define their problems, formulate their hypotheses and outline their experiments, prior to commencing their studies. In Declaration of Helsinki §19, the World Medical Association (2013) demands: "Each clinical study must be registered in a publicly accessible database before the first test subject is recruited." While the European Commission refers to it, it has not been universally adopted (Rid and Schmidt, 2010).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 83–93
May 2-6, 2023 ©2023 Association for Computational Linguistics

et al., 2018)—is that it clarifies what counts as confirmatory research, which *has to* preregister, and what counts as exploratory research with no obligation to preregister. Confirmatory research is hypothesis testing, held to the highest standard and which aims to minimize false positives. Here, p-values are generally assumed to have diagnostic value and inferences can be drawn to wider populations. Exploratory research, in contrast, has a different status: It generates rather than tests hypotheses and results should be replicated and confirmed at a later stage. Typically, the focus is on minimizing false negatives, and p-values are not assumed to have diagnostic value (Schwab and Held, 2020). Moreover, findings are not assumed to be directly transferable to wider populations. Rubin (2020), however, points out how it is not always trivial to distinguish between confirmatory and exploratory research: if a researcher, for example, retries a hypothesis from previously published literature to explain an experiment they just ran, is this an *a priori* or a *post-hoc* hypothesis? See also §3.

Fishing Expeditions and Harking Preregistration is often said to prevent *fishing expeditions* and so-called *harking*[2] (Andrade, 2021), namely, post-hoc characterization of hypotheses based on experimental outcomes. Fishing expeditions is ambiguous in the literature (between fishing and harking), but we use the term to refer to cherry-picking dataset and protocols to validate a hypothesis. Harking, in turn, is what researchers do when they indiscriminately examine associations between different variables, not with the intention of testing *a priori* hypotheses but simply hoping to find something of significance. Rubin (2020) calls this 'undisclosed hypothesizing after the results are known.' Having authors preregister their hypotheses potentially improves the reliability of confirmatory research by controlling for cherry-picking and multiple hypothesis testing, implicit to exploratory research. See also §4.

Publication Bias Van Miltenburg et al. (2021) say that, to them, the main advantage of registered reports is that they provide a means to avoid publication bias. Because studies are evaluated *prior* to the results, negative results have the same chance to be published as positive ones. Rubin (2020) refer to this as avoiding the suppression of *a priori* hypotheses that yield null or disconfirming results. Publication bias is claimed to be a serious problem in NLP research by many (Plank et al., 2014; Card et al., 2020; Cohen et al., 2021). The argument was also used in epidemiology, but received some pushback (Loder et al., 2010). See also §5.

Flag-planting Van Miltenburg et al. (2021) also suggest preregistration can prevent so-called *flag-planting*. Flag-planting refers to rushing to be the first to publish results. Flag-planting potentially comes at the cost of scientific integrity and quality. Because of biases in peer-reviewing, it is harder to publish a corrected version of a study that is already out there, than to publish an error-prone study that is the first of its kind. See also §6.

Other Reasons to Preregister We have covered the main reasons van Miltenburg et al. (2021) had for adopting preregistration and will now move to our two-sided, dialogical discussion of its pros and cons. In our dialogue, we will let Zeny and Socart,[3] our house philosophers, debate preregistration. In §3–§8, we will let them discuss arguments *against* preregistration, including arguments that run counter to those presented by van Miltenburg et al. (2021), but we will first let Zeny provide us with a fifth argument *for* preregistration:

ZENY: Socart, there's an additional argument for preregistration, I believe. Early feedback on experimental methodology through a peer-reviewed registration process should improve the quality of the methodology, should it not? Such feedback also saves resources otherwise spent on failed or misleading experiments.

SOCART: Zeny, we both know turn-around is fast in NLP research. Experiments are easier to run and feedback is much faster than for clinical trials, where preregistration is common.

ZENY: NLP as a field has many virtues, but the reviewing cycle is slowing as the field grows larger. Moreover, experiments are becoming more expensive with larger models, creating barriers of entry (Bender et al., 2021) and experiments have substantial environmental impact.

SOCART: You make an important point, Zeny, but early feedback would require more time from reviewers. Since reviewers and researchers coincide,

---

[2] Short-hand for "hypothesizing after the results are known". Often conflated with fishing, but the two differ: Harking fixes the experiment, varies the hypothesis, so to speak, whereas fishing fixes the hypothesis, varies the experiment. The acronym was coined by social psychologist Norbert Kerr.

[3] Zeny is a mix of Kenny from South Park and Zeno. In Plato's *Parmenides*, Zeno argues for monism—the idea that reality is one stable thing. Socart is a mix of South Park's Eric Cartman and Socrates, who countered this idea by asserting a more nuanced ontology in which things stand in complex relations to each other. Socrates, in other words, took a more nuanced stance, arguing against the existence of a one-size-fits-all hypothesis. Zeny and Socart adopt similar positions in our dialogue about preregistration.

preregistration would potentially save compute resources, but not working hours.

ZENY: That is an oversimplification. Giving feedback on an early draft takes much less time than writing a full paper. If the reviewers are carried over, they will save time when reading the full submission, also. Preregistration would also prevent cherry-picking and invalid use of significance tests by excluding explorations from confirmatory research.

SOCART: But the explorations could be done prior to preregistration and researchers may then be more inclined not to report such explorations at all.[4]

ZENY: Any system can be tricked, but if researchers adopted the practice of preregistration, we would, all things being equal, increase transparency and decrease bias around research.

SOCART: Dear Zeny, you too have seen the evasiveness of bureaucracy, e.g., in NLP conference submission forms. While preregistration reports would initially be light-weight, transparency could easily be clouded by the complexity of assembling the information required for preregistration as new requirements are added over time.[5]

See Bracken (2011) and Rubin (2020) for a discussion of more advantages to preregistration. In addition to reducing fishing expeditions and harking, flag-planting and publication bias, these include: **a)** preventing p-hacking, **b)** prespecifying tolerated significance levels, **c)** identifying selective reporting,[6] and **d)** preventing *forking paths* practice.[7] None of these points are uncontroversial and Rubin (2020) also presents counter-arguments against **a)-d)**. For example, prespecified significance levels have been superseded by the practice of simply reporting *actual* α-levels. Surprisingly, there has been little work on whether preregistration increases trust in science, except for the study by Field et al. (2020), which was under-powered.

We focus on *preregistration for NLP research*. In general, there is no *a priori* reason to think that the pros and cons of preregistration transfer from clinical trials over epidemiology to NLP research. In clinical trials, for example, it is easy to decide when a protocol must be registered. This simply happens before the first subject is assigned to treatment. In epidemiology, there is no such bright line (Lash and Vandenbroucke, 2012) and it is equally hard to see one in NLP. While general machine learning has seen many related methodological discussions (Gencoglu et al., 2019; Lipton and Steinhardt, 2018; Gundersen et al., 2022), there has, to the best of our knowledge, been no published discussions of preregistration practice in this field, with the exception of Gundersen (2021).[8][9]

In our discussion below, we will ignore the most trivial challenges to preregistration, such as deviations from data collection plans for practical reasons, discovery of assumption violations, etc. Such challenges have already been discussed in the clinical literature, e.g., by Nosek et al. (2018).

3 Encouraging Confirmatory Research

We let SOCART and ZENY discuss whether preregistration will succeed in distinguishing between confirmatory and exploratory research. A decade ago, when preregistration was being implemented and discussed in epidemiology, the worry that preregistration would introduce a bias against "the end of the research spectrum that constitutes the quirky, brilliant work that is not enterprise-driven" (Sørensen and Rothman, 2010), was the main concern among its opponents. SOCART and ZENY discuss the consequences of insisting on a distinction that is not trivial to uphold in practice.

SOCART: It seems to me, dear Zeny, that many NLP projects are driven *not* by an explicit hypothesis, but by a desire to understand the behavior of a model, to be able to characterize its strengths and weaknesses, or by a simple gut feeling that at the locus of interacting variables, interesting dynamics can be observed.

ZENY: Can you provide me with an example?

SOCART: Certainly. Pires et al. (2019), e.g., showed that knowledge encoded in multilingual BERT (Devlin et al., 2019), could be transferred across languages—even across scripts, that such transfer worked best between typologically similar languages, that it could process code-switching and find translation pairs. They also showed systematic deficiencies affecting some language pairs. How would they have foreseen these findings? Or even the dimensions that turned out to be of interest? Even if they had foreseen how they wanted to explore transfer across scripts and typological classes, what if genealogy or demography turned out to be more interesting than typology?[10]

---

[4] This point was also made for preregistration in epidemiology by Sørensen and Rothman (2010).

[5] See Loder et al. (2010) for arguments from epidemiology.

[6] Selective reporting is regarded the most important contributor to irreproducibility by Baker (2016). Nosek et al. (2018), advocating for preregistration, presents similar arguments.

[7] This practice refers to when researchers make decisions about which correlation tests to conduct based on properties of their data. The practice is named after *The Garden of Forking Paths*, a 1941 short story by Jorge Luis Borges.

[8] Workshops on preregistration at ICCV 2019 (`https://preregister.vision/`) and at NeurIPS 2021 (`https://preregister.science/`) seemingly did not lead to publications or a change in practice yet, but the website for the 2021 workshop says papers are forthcoming.

[9] Gundersen (2021) complains no AI venues support preregistration, but provide no arguments for or against it.

[10] Independent language families may share features, i.e., be typologically close, but genealogically apart. See Rama and Kolachina (2012) for discussion.

ZENY: I am unconvinced that preregistration would be a serious obstacle to such work. Pires et al. (2019) could have defined the search space in advance – or maybe this is exploratory work that would not have to register in the first place? Remember also, Socart, that the preregistered plan can be updated and refined in the course of a research project. Plans can be revised, but this does not cancel out the benefits of planning.

SOCART: Preregistration may accommodate deviation from the plan, but would risk losing its benefit if researchers were allowed to preregister too many hypotheses or update their plans too frequently. Let us illustrate this with another example. Zhao and Bethard (2020) study how BERT models' learned self-attention functions change during fine-tuning to reflect the target task. They find this to be the case only in smaller models; with more parameters, the change disappears. Imagine now that their hypothesis was confirmed only for select combinations of positional encodings, regularizers and optimizers.

ZENY: This sounds suspiciously like a case of forking paths. Dror et al. (2017) warned us about this risk, encouraging us to at least validate our hypotheses on multiple datasets to reduce the chance of p-hacking.[11] Again, preregistration would not be required for all research.

SOCART: So if authors submitted exploratory work for peer review, would reviewers then decide if bypassing preregistration was appropriate?

ZENY: Yes. Preregistration clarifies the distinction between exploratory and confirmatory research.

SOCART: But what if Pires et al. (2019) had pointed to earlier work already hypothesizing that transfer works best between typologically similar languages? Would this not have made their research confirmatory in the eyes of their readers and therefore in need of preregistration?[12]

ZENY: It very well might have. If they consider it exploratory, they should also point to alternative hypotheses that would explain different results.

SOCART: Moreover, if preregistration becomes a badge of honor or increases your chances of getting your work accepted, because the findings have a different air of trustworthiness,[13] would this not be a reason to encourage your students to perform confirmatory rather than exploratory research? Preregistration would, in other words, inject a bias toward confirmatory research into NLP.

ZENY: I, for one, would welcome this kind of bias.

✓ *Preregistration is challenged by r-harking and may bias NLP toward confirmatory research.*

4 Some Expeditions May Prevent Others

If you ask an NLP researcher if they are "on a fishing expedition" or if they are hypothesizing after the fact, you will instantly make them feel very uncomfortable. It is widely accepted that fishing and harking are bad practices.[14] Socart, however, has an argument *for* (occasional) harking:

SOCART: Two researchers, Ann and Bob, have the same hunch, that the regularization technique R_2 is better than its competitors, R_0, R_1, R_3. Ann realizes after a set of experiments of datasets D_0, D_1, D_2 that, in fact, R_1 is better than R_2. Since this was previously unknown to the community, she publishes it, presenting it (somewhat vaguely) as a confirmation of an *a priori* hypothesis. Bob tests the same hypothesis, i.e., that R_2 is superior to R_0, R_1, R_3. Seeing R_1 is better on D_0, D_1, D_2, he looks for more datasets, until he has a suite of datasets D_4, D_5, D_6 on which R_2 is better than R_1.

ZENY: Bob's cherry-picking is extremely problematic, but so is Ann's harking.

SOCART: But would you agree that granting her the freedom to hark most likely reduces her temptation to cherry-pick?

ZENY: This would simply reclassify Ann's work as exploratory rather than confirmatory. I see no reason why preregistration should not allow this.

SOCART: The two researchers both departed from their original plans, but Ann's willingness to depart from her original hypothesis serves us better than Bob's cherry-picking. In this way, harking can prevent a researcher from taking on a fishing expedition.

✓ *Preregistration should allow for re-classification of confirmatory research as exploratory research.*[15]

5 Solving Publication Bias?

Sørensen and Rothman (2010) argue against preregistration solving publication bias, because researchers can still selectively register studies after preliminary data explorations. Imagine Hippocrates, the Greek physician, was asked to preregister his vivisection experiments. If Hippocrates was studying 10 soldiers with brain lesions, what would prevent him from using one soldier to generate hypotheses, preregister those and conduct the final experiments on the remaining nine? Or worse, peek at all, preregister and go back to the data?

SOCART: Say Hippocrates has two hypotheses about the soldiers, such as that the heart is the seat of

---

[11] See Belz et al. (2021) for a similar discussion.

[12] This practice is known as "retrieving hypotheses after the results are known" (r-harking) (Rubin, 2017).

[13] Greater reliance on preregistration improves estimation of effect sizes, as shown by Strømland (2019).

[14] Andrade (2021) notes that fishing expeditions can be "ethical" if acknowledged as such, and if appropriate corrections are performed when computing significance results.

[15] Reclassification flags work as exploratory, thereby increasing transparency, but would not impact acceptance decisions. An alternative, suggested by one of our reviewers, would be to introduce intermediate reports as a required step to share the results of the preregistered study before continuing to preregister and test alternative hypotheses a part of the same study. This further increases transparency, and prevents having 'unwanted' results 'swept under the rug' in the final publication. Researchers working on a similar topic would already benefit from the results in an intermediate report.

compassion and that the brain is the seat of rational thought. Upon preliminary exploration, he sees many soldiers have turned cold-hearted by the atrocities of war, but few complain of heartaches. Nearly all soldiers who are delusional or suffer from memory loss, also suffered blows to their heads. Hippocrates pursues and preregisters only the hypothesis that the brain is the seat of rational thought. He has now preregistered, not a prediction, but a post-diction, ignoring the negative result.

ZENY: But Socart, did you not, a moment ago, argue that preregistration would dampen the creativity of research by preventing fishing expeditions and harking?

SOCART: In theory, yes. Preregistration will dampen creativity if properly sanctioned, but I am skeptical that this would be practically possible, rendering preregistration ineffective, an unnecessary administrative burden for all—and a bottleneck for the honest few.

ZENY: If preregistration *prior* to data collection is encouraged, this would solve the problem, no?[16]

SOCART: Surely, but this would mean only one preregistered study per dataset. Since few NLP papers introduce new datasets, this would render preregistration ineffective for the vast majority of NLP research.

ZENY: This is a good point, Socart, but community-wide overfitting to benchmarks is a vice, not a virtue. If preregistration encourages the introduction of new test datasets, that's a good thing, no? Some even argue that all papers should ideally introduce new test data.

To the contrary? ...in which SOCART and ZENY continue to discuss whether preregistration could actually make publication bias worse. SOCART suggests that preregistration could amplify publication bias, if positive results are still preferred over negative ones and preregistration forces researchers to focus on predictably positive results, arguably a small subset of the positive results. If papers are accepted on the basis of preregistration, this could increase an arguably already existing bias toward incremental improvements.[17]

SOCART: You say preregistration will make it easier to publish negative results, because studies are evaluated prior to obtaining results?

ZENY: That is correct, Socart.

SOCART: ...but do we really know why there are so few NLP papers about negative results? See, in NLP, negative results are much harder to establish than positives. If I want to show that self-attention or weight averaging does *not* lead to improvements for some problem, I need to show that holds across all implementations, all architectures and all available datasets. The value of a report stating that for one such combination, self-attention didn't do much, would be next to nothing. Isn't that the real explanation for the skew in the NLP literature?

ZENY: Negative results are key to scientific progress (Barwich, 2019), but are hard to establish if they are very general. Published positive results often overclaim their generality. Both should be confirmed only by accumulated evidence in diverse settings.[18]

SOCART: No, no, you fail to see there's a qualitative difference, Zeny! Imagine if Ann was evaluating self-attention for sentiment analysis. To answer the hypothesis that self-attention works in the positive, she just needs a significant result in a single setting. In contrast, in order to establish a negative result, she has to explore *all* possible settings.[19] How would preregistration make establishing a negative result less formidable a challenge?

ZENY: I agree that it would not. My only claim is that evaluating studies prior to obtaining results would prevent any bias on behalf of peer reviewers to evaluate negative results more harshly.

SOCART: ...but in reality, we do not know if such a bias exists, or whether it is only fair that such a bias exists, because the bar by definition should be higher for negative results?

✓ *Preregistration may increase publication bias.*

6 Solving Flag-Planting?

Flag-planting is one of the motivations for preregistration for van Miltenburg et al. (2021), but *exclusive* preregistration may also, conceivably, have the opposite effect.

SOCART: Say Ann and Bob get the same great idea—e.g., to evaluate the sensitivity of textual entailment models to presupposition projection—and worry that they will be scooped before getting around to publishing it. Ann and Bob now follow two different strategies: Bob rushes to preregister a study hypothesizing that state-of-the-art models are sensitive to such phenomena, while Ann rushes to run the experiments and publish the paper. Zeny, which strategy is better for science?

ZENY: I would say it's Bob's, since rushed experiments are more likely to be flawed.

SOCART: But Bob plants his flag faster than Ann, essentially scooping her. By doing so, Bob discourages Ann from pursuing this idea by planting his flag first. What if Bob fails to conduct proper

---

[16] This is implicit in preregistration in scientific fields where data is not re-used, e.g., in psychology (Wiseman et al., 2019).

[17] Lash and Vandenbroucke (2012), for example, argue that: "prespecified hypotheses often take little risk, invoke little imagination and stray only a short distance from what is already well understood."

[18] NLP has seen relatively few meta-studies (Cramer, 2008; Søgaard, 2013; Hoyle et al., 2021; Bugliarello et al., 2021), but hopefully, we will see more in the future.

[19] We flesh this out a bit. The research hypothesis in Ann's case is that self-attention helps. What this means is that in *some* implementation, it leads to robust improvements. The vast majority of NLP hypotheses take this form: X can, in some implementation, lead to general improvements on one or more tasks. If the baseline is fixed, this amounts to existential quantification ("some"). Conversely, its negation ("self-attention does not help for sentiment analysis") amounts to universal quantification, i.e., there is *no* implementation in which this is the case. This is obviously much harder to prove than the corresponding positive result.

experiments altogether? Had it not been for preregistration, both researchers would have pursued their idea, providing mutual replication and increasing the likelihood of the idea materializing into an actual result.

ZENY: Some would say this is one of the advantages of preregistration: Ann pursuing the same idea would have been a waste of time.

SOCART: This assumes Ann and Bob would have conducted their research in exactly the same way and that none of them were prone to error. In other words, that researchers are machines that simply execute their unambiguous experimental protocols. I think preregistration just moves flag-planting to earlier in the research process, lowering the bar for researchers to plant their flags, since less work is required to plant a flag. And when a bar is lowered, more researchers are likely to plant more flags.

ZENY: Van Miltenburg et al. (2021) explicitly encourage concurrent work.

SOCART: Yes, I did read that passage, but they do not discuss *how* preregistration would impact concurrent work. Do they envisage a review system in which Ann is allowed to follow up on the idea that Bob preregistered?

ZENY: I'd do that, in the spirit of open science.

SOCART: Such *inclusive* preregistration would clearly discourage protectionist researchers from preregistering their studies. If a preregistered study is up for grabs for other research labs, labs with more resources could likely wrap up the experiments faster than the researchers who registered it.

ZENY: . . . unless we envisage a review system allowing Ann to preregister the same study, giving Ann and Bob equal chances to pursue the study.

SOCART: This would be equivalent to telling reviewers of a paper to consider as "concurrent" any other work published within the last 1–2 years (assuming this is the approximate life span of a research project), including preregistered studies. Today, reviewers are told to disregard work published within the last three months, but already, reviewers seem to ignore this guideline in practice, presumably because they do not want to compromise the fast turn-around in NLP research.

ZENY: But shouldn't we incentivize slow science? Many NLP papers neglect related work and keep reinventing the wheel. We need deeper analysis to enable disruptive scholarship and novel ideas.[20]

SOCART: Slow science also has disadvantages. Fast turn-around has had many positive effects on NLP, including rapid replication. Projects can become "too big to fail," causing confirmation bias.[21] Lowering false positive rates is important, but so is healthy distrust in published results.

✓ *Preregistration may increase flag-planting.*[22]

7 Solving p-Hacking?

Inflation bias, also known as p-hacking, refers to selective reporting to produce statistically significant results. Søgaard et al. (2014) lists several p-hacking techniques used, perhaps inadvertently, in NLP papers. If a statistically significant result is seen as the key to getting your paper accepted, researchers are presumably willing to go far to squeeze out a small p-value. But if preregistration facilitates the publication of negative results, it seems it would also reduce the incentive to engage in so-called p-hacking, e.g., obsessive fiddling with data and models until reaching the magical $p < 0.01$. It has been noted, however, that preregistration leaves plenty of room for p-hacking (Bakker et al., 2020). Generally, eliminating p-hacking entirely is unlikely when career advancement is assessed by publication output, and positive results are favored by scientific peers (Head et al., 2015).

Socart and Zeny discuss whether preregistration will reduce or amplify the incentive to engage in p-hacking:

SOCART: Imagine Ann again, who is now evaluating if self-attention is helpful for sentiment analysis. Say she preregisters the hypothesis that self-attention *is* helpful, only to find that her first results are negative. We would now like Ann to go ahead and acknowledge the negative results on print, right? However, as we just saw, when your first results are negative, more results are typically needed to draw a firm, negative conclusion that self-attention does *not* help. Sometimes more data collection is needed and more human evaluations may be needed. Pursuing the negative result will, in other words, be a lot of work.

ZENY: But very important!

SOCART: Preregistration increases the amount of work that goes into moving your focus to establishing a negative result: You will need to augment your preregistration with information about the experiment, your new hypothesis and the new experiment you plan to perform.

ZENY: Documentation has to be light-weight.

SOCART: . . . but preregistration would get people more invested in their ideas and bias them in how results are interpreted. When people go on record with a study description, they will defend why it's reasonable and likely leading to a positive result. Researchers are always prone to confirmation biases, but now social expectations and reputation will amplify their existing biases. This would lead to the opposite of the effect intended.

✓ *Preregistration may increase p-hacking.*

8 Risk Tolerance

Attempts to reduce false positives tend to also lead to reductions in true positives. Many applications

---

[20] Chu and Evans (2021) showed that fast turn-around results in stymied fundamental progress in large scientific fields.

[21] This can result from financial interests (Ioannidis, 2005), e.g., due to "sunk cost" (Perignat and Fleming, 2022).

[22] One obvious solution is to make preregistration non-public, but then preregistration would not prevent two groups doing the same study.

require near-zero false positive rates, but most NLP experiments show low risk of direct negative impact on society or individuals therein,[23] as indicated by the relatively few papers receiving ethical reviews. Hence, we can afford to take risks and explore hypotheses that end up wrong. Parascandola (2010) reminds us how this is a key ingredient in increasing knowledge and reducing uncertainty, getting us off the beaten track. NLP benefits from being frequently wrong and implementing preregistration to prevent false positives has a drawback. In §9, we will argue that what is important is to balance preregistration with our risk tolerance.

SOCART: Imagine Ann works on hate speech detection for a social media company. Bob works on topic classification of social media posts at the same company. They both validate and evaluate the models in the wild on beta users. They both can use logistic regression and SVMs. SVM is sometimes superior, but exhibits more variance across hyper-parameters. If I were to advise Ann or Bob to use logistic regression, who then?

ZENY: Probably Ann, since we can tolerate less risk in her situation. But how would preregistration affect the risk tolerance of researchers?

SOCART: Imagine if you were asked today to carry a solid bottle of olive oil over to Plato's house and tomorrow to bring him a fragile, beautiful vase decorated with gold. On which of the two days would you be more inclined to *run* there?

ZENY: Today, but how is this relevant? What are the tasks where we can afford to 'run'?

SOCART: For tasks in which false positives are associated with high risk, we should hedge our bets by preregistering conservative hypotheses; for other tasks, this sort of inhibition of is unfortunate.

ZENY: This is exactly why exploratory research still has a place in a world with preregistration—namely, for tasks where we can tolerate risk.

One may argue that risk mitigation is not what preregistration is for. The purpose of institutional review boards (IRBs) and ethics reviewing is to flag and prevent too risky studies (IRBs focus on risk to human participants, while ethics reviewing also addresses potential applications). We have three reasons to think preregistration requirements should depend on expected risk: (a) It is impossible to review the implications of a study before you have a solid study plan. If preregistration includes risk assessment, this could provide input for IRBs and ethics reviewing (or, in a more distant future, be part of the same process). (b) A partial roll-out of preregistration may help us balance Type 1 and Type 2 errors. Expected risk affects the cost of false positives and hence the optimal balance between Type 1 and Type 2 errors. Since bureaucracy, by the end of the day, also incurs a cost on society, this reinforces our belief that mechanisms should be implemented only for where there is direct impact on society at large. (c) Finally, ethics reviewing is typically part of the standard review process, i.e. *after the fact* and can therefore not respond to malpractice in the experimental design or prevent publication of preprints.

Overly cautious preregistration practice may, in sum, decrease our true positive rate and add bureaucratic overhead to research practices without proper motivation. An all-over-the-map roll-out of preregistration would change the risk tolerance in research and society, just like registration and documentation has increased risk sensitivity in the past. Simultaneously, evaluating risk early on has clear advantages over the current review process.

✓ *Preregistration may lower our risk tolerance.*

9 A Proposal

We have tried to present pros and cons of preregistration. If we have focused a bit more on the cons, this is only because van Miltenburg et al. (2021) did a great job highlighting its advantages. We will, if anything, argue for only a partial roll-out of preregistration of NLP research. Preregistration is a way to minimize harms of NLP research, but only when risk is high. To motivate this, consider, as first noted by Lash and Vandenbroucke (2012), two seemingly opposed arguments *for* preregistration: a) Preregistration counters the suppression of (negative) results. b) Preregistration identifies false positives. Lash and Vandenbroucke (2012) argue that while (b) is a valid argument for preregistration of *clinical trials*, it is not a valid argument for preregistration in the context of mere "accumulation of evidence" (Lash and Vandenbroucke, 2012). Here, concerns about balancing Type 1 and Type 2 errors disappear. Preregistration mitigates risks associated with research, reducing potential harms, but at the cost of scientific progress. This calls for a cost-benefit analysis: How much risk can be tolerated for what potential gains?

One way to frame this discussion in NLP is to

---

[23] This does not refer to the downstream risks after deployment, just the risks associated with the research experiments. Two reasons for NLP experiments being relatively low risk are the rare involvement of human participants in NLP experiments and the historical focus on professionally generated text (Hovy and Spruit, 2016). We are seeing a shift toward human-in-the-loop evaluations and user-generated content, but this still makes for a small fraction of NLP research.

ask how afraid we should be of being wrong. In clinical trials, there is a significant cost to being wrong. In biomedical studies, false positive rates have been found to be around 14% (Jager and Leek, 2014). Whatever the number is for NLP, lowering it by adding more checks, will lead to a drop in the *true* positive rate. If a false positive could result in human tragedy, the price of a lower true positive rate is worth paying, but in NLP, the cost of a false positive is often paid for in compute and human hours. While both can be scarce resources, the open access nature of NLP makes being wrong less dangerous, since mistakes are quickly corrected.[24] Zeny would object that pretraining of language models is not easily reproducible (Bender et al., 2021). Pretraining very large language models should maybe be required to preregister and this would possibly require revising the questionnaires provided by van Miltenburg et al. (2021). Another concern is how NLP contributes to social and cultural inequality (Hershcovich et al., 2022). If NLP research is likely to help some more than others, this may be reason to require preregistration. Here, the questionnaires provided by van Miltenburg et al. (2021) would also be insufficient.[25]

So what we propose here reflects a middle-of-the-road position on preregistration. The idea is to **limit preregistration to research for which our risk tolerance is low**. This prevents most of the adverse effects of preregistration, e.g., publication bias, flag-planting and p-hacking. NLP research is subject to IRB and ethics reviewing, but we believe this should be merged with preregistration (§8). Reports should be reviewed and reviewers follow the submission (§2).[26] Currently, we accept and reject papers through blind peer-reviewing, but some papers are accepted *conditional* on a positive ethics review. We propose a reviewing procedure in which some work is only accepted conditional on the work having already been registered with positive reviews. For researchers, this would mean you need to get your preregistered reports accepted, before you initiate the research project. Once completed you will send the final submission in for a new set of reviews, hopefully by the same reviewers. This procedure is somewhat cumbersome and has all the disadvantages we discussed above. Therefore, it should only be used when it is deemed necessary, i.e., when the expected risk of the NLP research is sufficiently high.

A paper which a) is confirmatory and b) concerns an application for which risk tolerance is low, can be rejected for not having preregistered. We noted the necessity of allowing preregistered research to re-classify as exploratory, i.e., conditional acceptance for non-preregistered, flagged research, if it explicitly labels itself as exploratory. This would lead to three different categories of accepted papers: (i) non-preregistered (confirmatory or exploratory) research, (ii) preregistered, confirmatory research and (iii) non-preregistered research *marked explicitly as exploratory*. This would, we argue, give us the advantages of preregistration where they are most needed, e.g., where false positives are associated with very high risk.

We left one important thing in the open for now: How do we fairly decide if a research subject and protocol warrants low risk-tolerance? Ethics review board members are already asked to flag work that 'exhibits an increased risk of harm outside the current norms of NLP or CL research'.[27] This can be hard to determine, but board members *already* have to make this difficult decision. Ethics reviews could learn from established risk assessment frameworks (Schwerdtner et al., 2020).

10 Conclusion

Our two-sided dialogue has discussed pros and cons of preregistration in NLP, building on similar discussions in epidemiology. What opponents elsewhere have proposed as alternatives to preregistration is already found in NLP research: open access, common repositories and data sheets (Lash and Vandenbroucke, 2012). Preregistration, we argue, is less urgently needed in fields that already facilitate **replication** and where **risk of false positives** is

---

[24] Of course researchers are sometimes blind-sighted by scientific paradigms and hype, biasing their interpretation of results. Such dynamics is central to, e.g., the Popper-Kuhn debate (Rowbottom, 2011), but beyond the scope of this paper.

[25] Specifically, we think the questionnaire for 'NLP Engineering experiment paper' (§A.3) should include questions about computational resources needed for pretraining. Since the risk of wasting resources is high for language model retraining, preregistration and early feedback may be particularly useful for such research, but the review of the registered point would have to take this information into account. To mitigate social and cultural inequality, we propose to revise the questionnaire for 'Resource paper' (§A.6), adding questions about the demographics of data sources and annotators, as well as making a corresponding explication of social and cultural concerns in Question 11 of §A.3.

[26] This would be hard to coordinate for most fields, but in NLP, the ACL Rolling Review platform could make it easier.

[27] `https://aclrollingreview.org/ethicsreviewertutorial`

low. The **fast turn-around** of NLP research means the advantages of transparency and early feedback are smaller. Nevertheless, society's risk-tolerance varies across NLP applications. Legal or medical decision support systems are high-risk application areas. Here, we need to consider all safety measures on the table, including preregistration.

Impact Statement

Preregistration is one of several practices that promote responsible, high-quality research. Others include replication, transparency and open access, as well as impact statements and explicit discussion of study limitations. All such practices come with pros and cons and it is key to scientific progress and positive impact that scientific communities evaluate which practices are adequate in their domain. The increasing real-world impact that NLP research has exhibited recently and will likely continue to exhibit warrants a careful reconsideration of which practices are called for. Since a major driver of the same impact is the fast-paced exploratory research that characterizes the field, limiting such research may have negative effects as well (see §6). We therefore believe our two-sided debate will enable an overall better outcome in terms of impact.

Limitations

Our discussion of preregistration is inspired by discussions in epidemiology. Many of the concerns epidemiologists had with preregistration seem more relevant to NLP research than the considerations that, by and large, led clinical research to adopt preregistration as a mandatory practice. While we present a proposal for how to implement preregistration in NLP in §9–a proposal that differs from the one presented by van Miltenburg et al. (2021)–our main contribution is a two-sided discussion of its pros and cons, leaving many questions in the air. Our paper is intended to get the preregistration debate off ground, not to nail it to the floor.

Acknowledgements

WinoDict: Probing language models for in-context word acquisition

Julian Martin Eisenschlos[1], **Jeremy R. Cole**[1], **Fangyu Liu**[2], **William W. Cohen**[1]

Abstract

We introduce a new in-context learning paradigm to measure Large Language Models' (LLMs) ability to learn novel words during inference. In particular, we rewrite Winograd-style co-reference resolution problems by replacing the key concept word with a synthetic but plausible word that the model must understand to complete the task. Solving this task requires the model to make use of the dictionary definition of the new word given in the prompt. This benchmark addresses word acquisition, one important aspect of the diachronic degradation known to afflict LLMs. As LLMs are frozen in time at the moment they are trained, they are normally unable to reflect the way language changes over time. We show that the accuracy of LLMs compared to the original Winograd tasks decreases radically in our benchmark, thus identifying a limitation of current models and providing a benchmark to measure future improvements in LLMs ability to do in-context learning.

1 Introduction

Large Language Models (LLMs) such as GPT-3 (Brown et al., 2020) and PaLM (Chowdhery et al., 2022) can only learn from information that is in their training corpus. However, this is naturally limiting because the training corpus itself is bounded in time to the point of its collection. As a result, recent work has studied how to adapt such models to new data without an expensive retraining phase. Methods range from using semi-parametric methods with access to external memory (e.g., Guu et al. 2020; Lewis et al. 2020), to continual learning (e.g., Dhingra et al. 2022; Lazaridou et al. 2021), to parameter efficient fine-tuning (e.g., Ben Zaken et al. 2022; Pfeiffer et al. 2021).

Much of this work concerns factual knowledge or task distribution shifts. However, language also changes subtly: for instance, the popularity or meaning of individual words can change over time. In fact, such shifts also cause a consistent decrease in model performance for downstream tasks (Huang and Paul, 2018; Jaidka et al., 2018; Lukes and Søgaard, 2018; Florio et al., 2020).

Acquiring new words through either examples or definitions is therefore an important test of LLMs' ability to overcome diachronic degradation. With in-context learning having emerged as the primary way to interact with LLMs (Brown et al., 2020), we propose to study LLMs capability of acquiring new vocabulary via prompting.

We propose WinoDict, a novel benchmark for word acquisition for LLMs. Word acquisition is challenging to study in a realistic setting as it is hard to know which terms a model has already been exposed to. To overcome this, we rely on a heuristic method to introduce newly invented words and define them in terms of existing concepts. Following previous work (Chakrabarty et al., 2022), we incorporate the required knowledge into the prompt. We then ask models to perform tasks that require successfully interpreting the invented words.

We consider the English co-reference resolution datasets Winograd Schema Challenge (Levesque et al., 2012) and WinoGrande (Sakaguchi et al., 2020). The examples are built in pairs with minimal changes, which allow the identification of the key concept that must be understood to solve the example. An example of WinoDict can be seen in Figure 1. Our contributions are the following:
(a) We propose WinoDict, a method and dataset to test models for word acquisition skills.
(b) We benchmark the performance of several state-of-the-art models across scale and number of shots.
(c) We analyze the effect of prompt, POS tags, word likelihood and similarity for ease of acquisition.

These results help us understand the challenges for incorporating new concepts into LLMs. The code to build the dataset has been open-sourced. [1]

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 94–102
May 2-6, 2023

WINOGRAD	
The city councilmen refused the demonstrators a permit because *they* **feared** violence.	The city councilmen refused the demonstrators a permit because *they* **advocated** violence.
WINODICT	
The verb to **plest** means to be scared of, or want to avoid an object. The city councilmen refused the demonstrators a permit because *they* **plested** violence.	The verb to **sparn** means to to publicly recommend or support. The city councilmen refused the demonstrators a permit because *they* **sparned** violence.

Figure 1: An example pair from WINODICT together with its original WINOGRAD source. The task is to decide whether *they* refers to the city councilman or the demonstrators. Here, the correct answer is shown in blue and the incorrect answer in red. Note that in both cases, it is necessary to understand the meaning of the bolded key concept to resolve the co-reference, which we identify in WINOGRAD and substitute for a new word in WINODICT.

2 Methods

WINODICT, like WINOGRAD and WINOGRANDE, is a co-reference resolution task in a binary choice setup. A model is given two alternative noun phrases, and has to decide which one is more likely to correspond to a highlighted pronoun or blank.

2.1 Dataset Construction

To build WINODICT, we rely on the fact that the examples from WINOGRAD and WINOGRANDE are constructed from contrasting pairs (Gardner et al., 2020; Kaushik et al., 2020). Each instance differs in a minimal way from its counterpart with the true label reversed. This allows the identification of the key concept that needs to be parsed in order to resolve the task. In Figure 1 for instance, the verbs *fear* and *advocate* correspond to the key concepts.

WINOGRAD and WINOGRANDE are similar; however, WINOGRANDE is larger, uses blanks instead of pronouns, and the dataset has been filtered for co-occurrence bias between the key concept and the correct noun-phrase. This results in some examples that do not have a corresponding paired example with a different key concept.

To create our examples, we first recover the pairing between the examples, dropping those with no pairing. Secondly, we identify the key concept tokens that change from one example to the other, dropping examples where the key concept consists of multiple tokens. Finally we run the sentence through the spaCy[2] syntactic analyzer and fetch WordNet[3] definitions of the key concepts' lemmas. In the next section we show how the key concept tokens are replaced by synthetic words. This results in 496 examples: additional information can be found in Table 1.

POS	**WINOGRAD**	**WINOGRANDE**	**Total**
VERB	67	56	123
NOUN	34	24	58
ADV	5	25	30
ADJ	74	211	285
Total	180	316	**496**
Orig. Size	273	12,282	12,555
Sent. Len	16.34	18.93	17.99
Def. Len	14.07	14.3	14.22

Table 1: Statistics for the different part-of-speech tags in the synthetic words, as well as average number of tokens for the main statement and the word definition. WINODICT consists of 496 examples.

2.2 New Word Creation

Our goal is to create plausible synthetic words. We create plausible words using a simple probabilistic model of every one-, two-, and three-letter sequence that is trained on the vocabulary of English words[4]. These three-letter sequences are then sampled and combined to form new synthetic words. We filter any words that have a three letter sequence that does not occur in any other English word. We then sample the words based on their log probability, placing them into five buckets and keeping around 500 for each bucket.

The morphology for each word is created by aggregating over a sample of proposed synthetic word morphologies. The last 2-4 letters of each word (depending on the morphological edit) form a suffix dictionary that is used as a simple substitution

---

[2] https://spacy.io

[3] https://wordnet.princeton.edu (Miller, 1995)

[4] https://pypi.org/project/english-words

dictionary for the remaining words: failures are dropped. This produces a combination of regular and irregular conjugations over the new words.

2.3 Answer Scoring

Each instance in WinoDict consists of a new word with its definition d, a statement containing a blank where x and y correspond to the text before and after the blank respectively, and two noun phrases o_1 and o_2. The task consists of identifying which of the noun-phrases better fits the blank.

PaLM, GPT-3 and its predecessors (Radford et al., 2019) use the method proposed by Trinh and Le (2018) to evaluate Winograd and WinoGrande, which we explain below. A prediction score is obtained through comparing the log likelihood of the same continuation y of two possible prefix texts ($x : o_1$ and $x : o_2$) where the co-reference pronoun or blank marker has been replaced. It is correct if it scores the suffix higher for the prefix with the correct interpretation of the co-reference problem.

$$\ln P_\Theta(y|x:o_1) - \ln P_\Theta(y|x:o_2)$$

$$= \sum_{i=0}^{n}\Big(\ln P_\Theta(y_i|y_{<i}:x:o_1) - \ln P_\Theta(y_i|y_{<i}:x:o_2)\Big)$$

where : denotes concatenation and variables map to:

$$\begin{aligned} x &= \text{“The city councilmen refused the} \\ &\quad\ \text{demonstrators a permit because”} \\ o_1 &= \text{“the city councilmen”} \\ o_2 &= \text{“the demonstrators”} \\ \{y_i\}_{i=1}^{n} = y &= \text{“feared violence.”} \end{aligned}$$

In our setup we add the definition of the new concept as a suffix to the shared term y, thus replacing it with $y : d$. This achieves higher accuracy than the alternatives. Note that this means that the model is *scoring* the definition rather than conditioning on it. See Section 4 and Table 4 for a discussion of other variants of the setup, including adding the definition as a prefix.

3 Experiments

In this work we test GPT-3 (Brown et al., 2020), and PaLM (Chowdhery et al., 2022) models of various sizes, ranging from 3B to 540B parameters. Appendix A has more details on the model sizes.

As in the original in-context learning evaluations, we try 0, 1, and 5-shot experiments, using random examples to build the prompt. We compare to both a zero-shot human evaluation as well as the original source datasets with only our filtered examples.

The main experimental results are shown in Table 2. We observe a consistent gap of 18 or more points between WinoDict examples and their original counterparts. Similar to trends observed in other datasets (Chowdhery et al., 2022), scaling the number of shots and model size consistently improves accuracy. The three smaller versions of GPT-3 and PaLM-8B all perform close to random.

We verify that omitting any information of the new word yields random results for even the best PaLM-540B model. We discuss this and other prompting strategies in more detail in Appendix B.

3.1 Human Evaluation

The human accuracy on WinoDict is estimated using the responses of 10 volunteers. No native English proficiency was required for participation. Participants were told that the aim of the research is to study how to use words based on their definition. They were presented with 15 sentences that included a pronoun / blank and asked to select one of two noun phrases it most likely refers to.

3.2 Foreign Inspired Words

To explore a more realistic scenario, we conduct an experiment using 20 hand-written WinoDict-like examples whose definitions are inspired by foreign words that do not have a clear single-word definition in English. For instance, “estrenar” refers to wearing a piece of clothing for the first time, which does not have a clear English word equivalent. We can then create an example that requires knowing this definition, such as “I really [love | hate] my new dress. I can’t wait to <word> it.

In conducting this experiment, we substitute synthetic words instead of using the original foreign words, and the definitions of the words themselves may not correspond to native speakers’ precise understanding: in other words, these are meant to be true new words and data leakage should be minimal. We run the same experiment on these examples. Results are in Table 3 and full details in Appendix C. Overall, the numbers are comparable to the WinoDict results, suggesting that models are unlikely to be solving the task using a reverse dictionary.

4 Prompt Analysis

In this section, we discuss alternative formulations for the prompts used in WinoDict. We focus on

	WINOGRAD						WINOGRANDE					
	WINODICT (Ours)			Original			WINODICT (Ours)			Original		
Shots	0	1	5	0	1	5	0	1	5	0	1	5
PALM 8B	$59.2_{\pm 1.6}$	$57.1_{\pm 2.1}$	$59.1_{\pm 1.6}$	83.3	83.3	87.2	$51.8_{\pm 1.6}$	$54.2_{\pm 0.4}$	$52.4_{\pm 1.1}$	69.3	65.5	67.4
PALM 62B	$62.2_{\pm 0.6}$	$65.9_{\pm 3.6}$	$70.3_{\pm 1.3}$	91.1	90.0	92.2	$56.7_{\pm 1.1}$	$58.2_{\pm 1.0}$	$59.7_{\pm 1.1}$	76.6	77.8	78.2
PALM 540B	$\mathbf{65.9}_{\pm 2.5}$	$\mathbf{75.4}_{\pm 1.3}$	$\mathbf{78.6}_{\pm 0.6}$	92.8	92.2	95.6	$\mathbf{60.3}_{\pm 1.4}$	$\mathbf{63.9}_{\pm 2.3}$	$\mathbf{68.5}_{\pm 1.9}$	80.1	81.3	85.8
GPT-3 Ada	$51.9_{\pm 2.2}$	$50.9_{\pm 1.7}$	$50.2_{\pm 4.3}$	60.0	57.8	61.7	$52.2_{\pm 1.2}$	$52.0_{\pm 3.6}$	$49.4_{\pm 1.7}$	48.1	53.8	53.2
GPT-3 Babbage	$51.8_{\pm 0.8}$	$52.8_{\pm 2.0}$	$54.4_{\pm 2.3}$	75.6	71.7	65.6	$50.8_{\pm 1.7}$	$52.3_{\pm 1.0}$	$52.2_{\pm 0.8}$	52.8	55.1	56.6
GPT-3 Curie	$54.2_{\pm 1.6}$	$54.6_{\pm 2.4}$	$59.9_{\pm 1.5}$	85.0	81.7	82.8	$50.2_{\pm 1.5}$	$50.6_{\pm 1.6}$	$52.2_{\pm 1.0}$	62.0	61.1	60.8
GPT-3 Davinci	$60.3_{\pm 1.3}$	$63.6_{\pm 2.3}$	$72.9_{\pm 0.5}$	88.3	85.0	91.1	$55.0_{\pm 1.1}$	$55.7_{\pm 1.4}$	$61.3_{\pm 1.4}$	71.8	69.6	72.5
Human	91.7			96.5*			83.3			94.0*		

Table 2: Binary classification accuracy on WINODICT vs. the original datasets using average and standard deviation across 5 sets of new words. Original results may differ from the ones reported by Chowdhery et al. (2022) since only a subset of the examples are used. A consistent gap of 18+ points appears when comparing against the original sets. The original human evaluation numbers denoted with * are taken from Sakaguchi et al. (2020).

Shots	0	1	5
PALM 540B	**68.7**	**73.0**	**76.0**
GPT-3 Davinci	61.0	56.0	68.0

Table 3: Binary classification accuracy on the foreign-inspired new words averaged over five runs. Overall, accuracy is comparable to the original dataset.

Word Type	Prompt	WINOGRAD	WINOGRANDE
Synthetic	Def Prefix	72.2	62.7
	Def Suffix*	78.6	68.5
	Syn Prefix	74.1	60.5
	Syn Suffix	88.4	78.2
	Empty	52.0	51.9
Original	Def Prefix	85.5	74.0
	Def Suffix	93.8	84.4
	Syn Prefix	87.2	74.3
	Syn Suffix	91.6	83.2
	Empty*	95.6	85.8
Meaning shift	Def Prefix	66.1	60.8
	Def Suffix	75.6	60.4
	Syn Prefix	69.4	60.1
	Syn Suffix	83.3	74.7
	Empty	51.1	49.7

Table 4: Analysis of different prompts. We show the results on the synthetic words, original words, and existing words but assigned to a new meaning ("Meaning shift"). Prefix/Suffix correspond to the location of the definition, Syn/Def corresponds to using the definition or synonyms of the synthetic word. Empty means neither (should be random for synthetic words). Providing synonyms yields the best results. All results are on PALM-540B 5-shot. The lines marked with * correspond to the experiments in Table 2.

the best-performing PALM-540B model using a 5-shot setup. See Table 4 for the full results.

Concretely, we vary the prompts along a few axes. First, we test whether the definition should be part of the prefix, where the model would condition on it, or the suffix, where the model would score it. Note that in all setups, putting the definition in the suffix works consistently better.

Additionally, we test whether the task is made easier by using synonyms instead of definitions. This task indeed appears to be easier, potentially because the model needs to learn only a simple substitution between the new word and the provided synonym, whose definition it knows. We focus on definitions in this work as exact synonyms would rarely be available for novel words.

As a baseline, we also examine the "Empty" setup, where the model is provided no information about the new word. We observe that PALM approximates random guessing without being given the definition, showing that the task remains roughly unbiased.

We additionally test the model's performance on the original task where we also provide the definition of the key concept. Note that the "Empty" case here corresponds precisely to the original task. Interestingly, the definition seems to serve as a slight distraction, especially as a prefix, though accuracy is still well above the model's performance on the synthetic words.

Finally, in the "Meaning shift" scenario, we map new definitions to already known words. This task appears to be even more difficult than the standard WINODICT setup, implying that the model is distracted by the surface forms of the words.

5 New Word Analysis

Several factors can affect the capabilities for word acquisition of LLMs. We investigate several attributes, split into quartiles, using PALM-540B with 5-shots, which is the best model from Table 2.

We consider the following attributes: **(1)** the part-of-speech of the synthetic word; **(2)** the average model negative log likelihood (NLL) of the two model predictions, which measures the likelihood of the suffix for both prefixes; **(3)** the number of SentencePiece (Kudo and Richardson, 2018) tokens in the synthetic word, to investigate the effect of model tokenization; **(4)** the number of SentencePiece tokens in the definition of the synthetic word, to investigate if longer definitions are more challenging; **(5)** the Levenshtein edit distance between the synthetic and original word, to investigate if similar words are easier; and **(6)** the likelihood of the new word as computed by our probabilistic model of three-letter sequences, to see if less probable words are more difficult to acquire.

Of the six attributes, the two most correlated with accuracy are (4) the definition length and (2) the average NLL. We observe no clear pattern in the other four attributes. In Figure 2 we show their effect in each quartile. The effect of definition length indicated that the 25% longest definitions are the hardest to acquire by a significant margin (12$\%$ relative drop for WINOGRAD, 5% for WINOGRANDE). The relative accuracy drop for the largest quartile of the NLL average is 13% for WINOGRAD and 4% for WINOGRANDE. The drop in NLL suggests that when models assigns low probabilities to answers, they make more mistakes: the low probability may indicate the model has a poor understanding of the prefix so scores the suffix randomly.

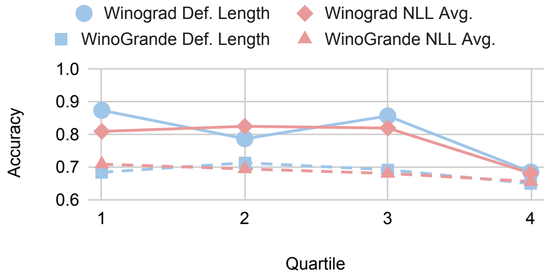

Figure 2: Effect on WINODICT PALM-540B 5-shot accuracy on each quartile splitting by definition length and by average NLL score. Longer definitions and higher NLL correlate with lower accuracy.

6 Related Work

Word acquisition for LLMs. Inspired by developmental linguistics (Carey and Bartlett, 1978), Radford et al. (2019) succeeded to prompt GPT-3 to generate plausible example sentences based on definitions of synthetic words. Unlike WINODICT, the evaluation was purely qualitative.

Common sense. Li et al. (2021) study how prompt structures and scoring methods affect the performance of LLMs on common sense tasks including WINOGRANDE, where they observe the least variation. The format from WINOGRAD has been subsequently used to probe models for other phenomena such as explanations (Zhang et al., 2020) and gender bias (Zhao et al., 2018).

Benchmarks for lexical knowledge. Schick and Schütze (2020) introduce a benchmark for probing a model's knowledge of the properties of rare words. Hill et al. (2016) train models to match word and definition representations, which they apply to a reverse dictionary task.

7 Conclusion

In this work, we study the question of in-context word acquisition by large language models. While non-trivial to measure, the ability to incorporate knowledge about new words in-context may be useful to decrease the effect of diachronic degradation. We design a mechanism to transform Winograd-style tasks into challenging probes for reasoning on the meaning assigned to synthetic words, allowing for a more objective measurement of word acquisition. We study the results of models of multiple sizes and families and conclude that while the problem becomes easier with scale, there is still a substantial gap with human performance and the original WINOGRAD and WINOGRANDE tasks, demonstrating the difficulty of the proposed task. Finally, we show that acquiring novel definitions is of similar difficulty, indicating the task is realistic.

Limitations

The task described in this work is synthetic and thus an imperfect measure of the phenomena under study. The words in WINODICT are synthetic words with definitions copied from existing concepts; the model could thus solve WINODICT with a reduction to a reverse dictionary task. To partially address this, we conducted pilot experiments described in Section 3.2.

Additionally, the choice of prompts for LLMs has been shown to have a large influence on the resulting accuracy (Min et al., 2022; Lu et al., 2022). While we tried multiple templates, it is possible that substantially better prompts exist for this task.

Acknowledgements

A Model Sizes

While OpenAI does not officially disclose the size of their four models Davinci, Curie, Babbage and Ada, we use the numbers approximated in a blogpost as estimates.[5] Table 5 contains the number of parameters for the models used in our experiments.

Model	# Parameters
GPT-3-Ada	350M
GPT-3-Babbage	1.3B
GPT-3-Curie	6.7B
GPT-3-Davinci	175B
PALM-8B	8B
PALM-62B	62B
PALM-540B	540B

Table 5: Number of parameters of the reported models.

B Prompts

We built prompts for definitions and synonyms to make them sound natural given the structure of most WordNet definitions for each part-of-speech tag. Table 6 shows the different prompt templates in each case.

Type	Prompt
Synonym	The meaning of {lemma} is similar to {synonym}.
Verb definition	The verb to {lemma} means to {definition}.
Noun definition	The word {lemma} refers to {definition}.
Adj. Definition	The meaning of {lemma} is definition.
Adv. Definition	The word {lemma} means {definition}.

Table 6: Templates used to integrate the definition into the prompt for each part-of-speech tag.

C Foreign Inspired Words

In Table 7 we list the word, approximate definition, and WINODICT-like example. Note that these examples are handwritten and did not go through a debiasing process like WINOGRANDE. In order to reduce the risk of data leakage, in the actual examples we replace the surface form of the word with one of the synthetic surface forms using the same process as in section 2.

Example	Definition
John frequently goes backpacking and Jake never does because [Jake | John] disdains the feeling of **waldeinsamkeit**.	the feeling of solitude and connectedness to nature when being alone in the woods
After returning from backpacking, John thought he would go again [frequently | infrequently]. John likely appreciates the feeling of **waldeinsamkeit**.	the feeling of solitude and connectedness to nature when being alone in the woods
Mary loves going to antique stores and Ashley never does because [Mary | Ashley] **wabi-sabis** old things.	finding beauty in imperfections
Mary loves going to [antique | modern] stores because she **wabi-sabis** old things.	finding beauty in imperfections
Pierre is from France and John is from Ireland. Pierre and John like to go to Irish bars and talk about [Pierre | John]'s feeling of **depaysement** there.	the feeling that comes from not being in one's home country; being a foreigner
Pierre has lived in France all his life. When he's in [Ireland | France], Pierre frequently talks about his feeling of **depaysement**.	the feeling that comes from not being in one's home country; being a foreigner
Jake and Ashley plan to get married, Ashley's parents are happy, but Jake's parents don't like it because a friend said they had bad **yuanfen**. [Jake | Ashley]'s parents are more likely to go to a fortune teller.	the fate between two people
Jake and Ashley plan to get married. Ashley's parents are very practical while Jake's parents believe in destiny. When an advisor said Jake and Ashley had bad **yuanfen**, [Jake | Ashley] wanted to call it off.	the fate between two people
Theresa doesn't get why Martha thinks the statue in the museum was so **duende** that [Martha | Theresa] spent a lot of time looking at it.	a work of art's mysterious power to deeply move a person
Martha spends a lot of times in museums while Theresa spends little. [Martha | Theresa] finds art **duende**.	a work of art's mysterious power to deeply move a person
After losing his [religion | job], John fell into a sense of **toska**.	a sensation of great spiritual anguish, often without a specific cause; a longing with nothing to long for
John kept yelling at Joey for not doing chores, but Joey wouldn't even respond. [Joey | John] really seems **tosked**.	a sensation of great spiritual anguish, often without a specific cause; a longing with nothing to long for
Because he [loves | hates] reptiles, John found seeing that group of lizards very **gigil**.	a situation of such extreme cuteness it's overwhelming or the irresistable urge to hug something cute
John only keeps salamanders as pets and Joey likes more traditional ones, so [John | Joey] found seeing the group of lizards very **gigil**.	a situation of such extreme cuteness it's overwhelming or the irresistable urge to hug something cute
John thought his marriage with Joey was **shougani**, so he wanted to hire a [lawyer | therapist].	a situation that can't be helped, or an act of resignation
John thought his marriage with Joey was **shougani** but Joey disagreed, so [John | Joey] decided to hire a lawyer.	a situation that can't be helped, or an act of resignation
Joey still can't get over when John drunkenly called him Mark at his wedding, and now whenever they see each other, [Joey | John] **tartles**.	a moment of hesitation when introducing someone because you can't remember their name
I really [love | hate] my new dress. I can't wait to **estrene** it.	wearing something for the very first time
Mary and Sue went dress shopping together. Mary hates her dress while Sue loves hers. [Sue | Mary] can't wait to **estrene** it.	wearing something for the very first time
After a long day of work, James **xinkued** the job John did. John was [grateful | upset].	acknowledging someone's effort for working hard or doing you a favor

Table 7: List of foreign-inspired new words (**bolded**) and their corresponding examples and definitions. The possible choices for the example are shown, with the correct choice underlined. The definition is shown on the right. These definitions may or may not be idiosyncratic to a native speaker; however, the actual examples use a synthetic word to more closely resemble new word acquisition and minimize the risk of data leakage.

Sentiment as an Ordinal Latent Variable

Niklas Stoehr[ʕ] **Ryan Cotterell**[ʕ] **Aaron Schein**[ɘ]
[ʕ]ETH Zürich [ɘ]The University of Chicago
niklas.stoehr@inf.ethz.ch ryan.cotterell@inf.ethz.ch schein@uchicago.edu

Abstract

Sentiment analysis has become a central tool in various disciplines outside of natural language processing. In particular in applied and domain-specific settings with strong requirements for interpretable methods, dictionary-based approaches are still a popular choice. However, existing dictionaries are often limited in coverage, static once annotation is completed and sentiment scales differ widely; some are discrete others continuous. We propose a Bayesian generative model that learns a composite sentiment dictionary as an interpolation between six existing dictionaries with different scales. We argue that sentiment is a latent concept with intrinsically ranking-based characteristics — the word "excellent" may be ranked more positive than "great" and "okay", but it is hard to express how much more exactly. This prompts us to enforce an ordinal scale of ordered discrete sentiment values in our dictionary. We achieve this through an ordering transformation in the priors of our model. We evaluate the model intrinsically by imputing missing values in existing dictionaries. Moreover, we conduct extrinsic evaluations through sentiment classification tasks. Finally, we present two extension: first, we present a method to augment dictionary-based approaches with word embeddings to construct sentiment scales along new semantic axes. Second, we demonstrate a Latent Dirichlet Allocation-inspired variant of our model that learns document topics that are ordered by sentiment.

https://github.com/niklasstoehr/ordinal-sentiment

1 Introduction

Sentiment analysis is being applied in various domains from political science (Young and Soroka, 2012; Gründl, 2020; Widmann and Wich, 2022) to economics (Stephany et al., 2022) and computational social science (West et al., 2014; Falck et al., 2020; Stoehr et al., 2021). In all of these applications, there is a strong demand for domain-specific and interpretable methods (Hofman et al., 2021; Widmann and Wich, 2022) making dictionary-based sentiment analysis still a popular choice (Young and Soroka, 2012; Hoyle et al., 2019; Gründl, 2020; Friedrichs et al., 2022).

Sentiment dictionaries describe a mapping between word types and some form of sentiment values. We consider the most general notion of sentiment value referring to the polarity score along a positive-negative axis, instead of fine-grained emotion dimensions (Plutchik, 1980) or stance (Mohammad, 2016). Sentiment values are measured on scales of different support (§2): some dictionaries assign binary "positive" and "negative" values (Hu and Liu, 2004; Wilson et al., 2005; Stone et al., 2007). These discrete values are often falsely interpreted as unordered, nominal categories. Other dictionaries have continuous scales that assign cardinal, floating point values (Hutto and Gilbert, 2014; Cambria et al., 2014).

In this work, we propose a method for merging sentiment dictionaries with different scales into a single, composite dictionary. Paying tribute to the subjective and ranking-based characteristics of sentiment, we design the dictionary to have an ordinal scale. Ordinal scales define discrete, ordered classes where interval sizes between classes are unequal and typically unknown (Stevens, 1946). For instance, the word "excellent" may be ranked more positive than "great" and "okay", but it is hard to express how much more positive. An example is the ordinal Likert scale (Likert, 1932) used to measure attitudes in psychometrics.

Our ordinal sentiment scale is derived from an ordinal latent variable within a probabilistic, generative model (§3). In particular, the latent variable's classes represent sentiment values. The classes are uniquely ordered which is achieved through an ordering transformation that is applied to the

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 103–115
May 2-6, 2023 ©2023 Association for Computational Linguistics

priors of our model (§3.2). Our model is tightly coupled with recent advancements in probabilistic programming (Bingham et al., 2018; Phan et al., 2019) and gradient-based inference (Homan and Gelman, 2014). These advancements alleviate the strict requirement of closed-formedness and conjugacy to perform posterior inference in complex Bayesian models with latent ordering motifs.

Our ordinal scale is learned as an unsupervised interpolation between 6 popular sentiment dictionaries. This has several benefits: on the other hand, we can impute missing sentiment values in existing dictionaries. We evaluate this capacity in a Bayesian data imputation task (§4.2). On the other hand, interpolating between different dictionaries causes our composite dictionary to have high coverage of word types from widely different sources. We evaluate our composite dictionary in 6 sentiment classification tasks from different domains (§4.3). Taking a Bayesian approach, we have access to uncertainty estimates for each sentiment value per word type. We find that uncertainty is larger for ambiguous and rare word types that are covered by only few dictionaries (§5).

In §6, we present two possible extension of our ordinal latent variable model. To further expand word type coverage, we incorporate sentiment values derived from bi-polar semantic axes within word embeddings (§6.1). To demonstrate the wide applicability of our ordinal modeling motif, we introduce a model variant that is closely related to Latent Dirichlet Allocation (LDA; Blei et al., 2003), but learns topics ordered by sentiment (§6.2). We publish our code together with our learned, high-coverage sentiment dictionary, annotated with posterior credible intervals.

2 Data: Sentiment Dictionaries

We consider 6 popular English-language sentiment dictionaries: SenticNet (SC) (Cambria et al., 2014), SentiWordNet (SW) (Baccianella et al., 2010), Vader (VA) (Hutto and Gilbert, 2014), General Inquirer (GI) (Stone et al., 2007) Hu-Liu (HL) (Hu and Liu, 2004) and MPQA (MP) (Wilson et al., 2005). The dictionaries vary in the number of included word types, the word source, application domain and the sentiment scale, see appendix Tab. 3. SC, SW and VA have continuous, bounded sentiment values, while GI, HL and MP have discrete, binary values as visualized in Fig. 1. We scale all continuous values to a $[0, 1]$ range. Some of the dictionaries such as SW and VA feature multiple sentiment values per word type. We average those to consistently obtain one value per word type for all dictionaries, which allows for a fair comparison. We group the sentiment dictionaries in a single data table by word type. Since different dictionaries contain different word types, this results in many missing values. We filter the data table so that each word type is covered by at least 2 dictionaries. This leaves us with V =12,342 unique word types that serve as our dataset.

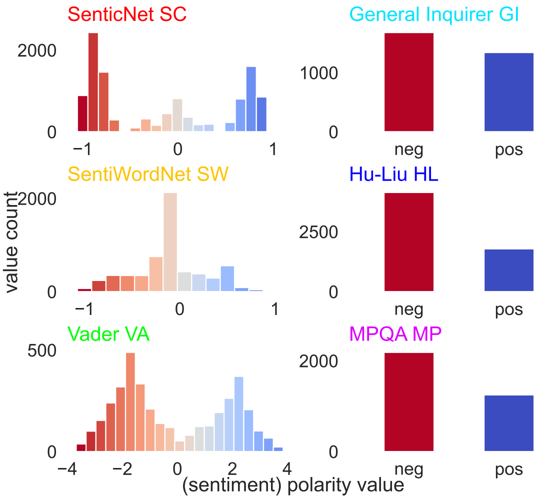

Figure 1: Sentiment value distributions of 6 sentiment dictionaries. Some dictionaries assign continuous float values to word types {SC, SW, VA}, others limit themselves to discrete, (binary) values {GI, HL, MP}.

3 Model

Our goal is to learn a unifying sentiment dictionary as an interpolation between existing sentiment dictionaries. Each word type v is described by one or multiple sentiment values of a dictionary. Depending on the dictionary's scale, sentiment values can be continuous x_v^c or discrete x_v^d. The superscripts c and d represent continuous and discrete dictionaries respectively, i.e., $c \in \{\text{SC}, \text{SW}, \text{VA}\}$ and $d \in \{\text{GI}, \text{HL}, \text{MP}\}$. Considering all 6 sentiment dictionaries, we have a tuple of 6 sentiment values $\{x_v^{\text{SC}}, x_v^{\text{SW}}, x_v^{\text{VA}}, x_v^{\text{GI}}, x_v^{\text{HL}}, x_v^{\text{MP}}\}$ per word type. Due to our filtering in §2, at most 4 of those values can be missing (NaN).

3.1 Generative Story

For each word type v, we assume that its sentiment class z_v is sampled from a Categorical distribution over K classes, parameterized by $\boldsymbol{\pi}$, a K-dimensional vector of class probabilities. We

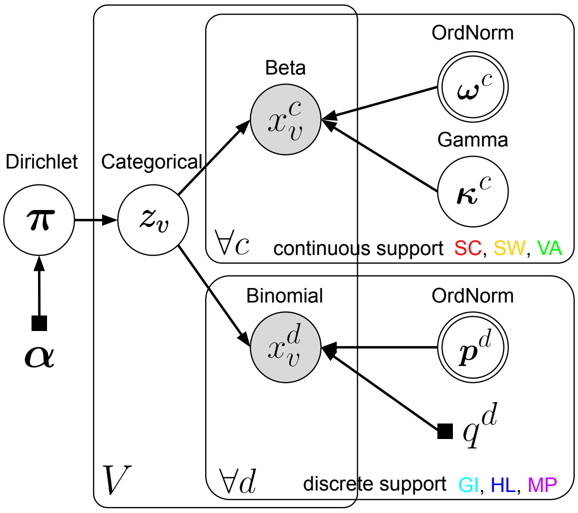

Figure 2: Model for interpolating sentiment dictionaries. Each word type v is described by observed sentiment values x_v^c and x_v^d from different sentiment dictionaries. The continuous, bounded dictionaries c are modeled by Beta and the discrete dictionaries d by Binomial distributions. Some priors are ordered, as indicated by double-border nodes (◎). This spurs the categorical latent z_v to be ordinal. Solid, black squares represent fixed hyperparameters.

further assume that $\boldsymbol{\pi}$ is drawn from a Dirichlet distribution. Conditioned on the sentiment class z_v, each observed continuous $x_v^c \in [0,1]$ and discrete $x_v^d \in \{0,\dots,q^d\}$ sentiment value per dictionary is independently sampled as depicted in Fig. 2. We assume that the values x_v^{SC}, x_v^{SW} and x_v^{VA} that come from dictionaries with continuous, bounded support are drawn from Beta distributions. The values from binary dictionaries, x_v^{GI}, x_v^{HL} and x_v^{MP}, are naturally Bernoulli random variables—however we represent them more generally as Binomial random variables, with number of trials equal to q^d (where $q^d = 1$ in our case), to accommodate dictionaries with arbitrary ordinal support:

$$\boldsymbol{\pi} \sim \text{Dirichlet}(\boldsymbol{\alpha}) \tag{1}$$

$$z_v \sim \text{Categorical}(\boldsymbol{\pi}) \tag{2}$$

$$x_v^c \mid z_v \sim \text{Beta}(\omega_{z_v}^c, \kappa_{z_v}^c) \tag{3}$$

$$x_v^d \mid z_v \sim \text{Binomial}(q^d, p_{z_v}^d) \tag{4}$$

We discuss the parameters $\omega_{z_v}^c, \kappa_{z_v}^c$ and $p_{z_v}^d$ that induce ordering on the latent variable z_v in the following section.

3.2 Ordinal Latent Variable

While the classes of a Categorical distribution are generically unordered, the structure of our model induces a natural ordering over the K classes that z_v can take. When $z_v = k$, the parameters ω_k^c, κ_k^c and p_k^d parameterize the Beta and the Binomial distributions from which word type v's sentiment scores are drawn. By imposing an ordering on those parameters (e.g., $\omega_k^c < \omega_{k+1}^c$), we induce ordering on z_v. In the following subsections, we introduce prior distributions over the vectors $\boldsymbol{\omega}^c$ and $\mathbf{p}^d$ that ensure they are ordered, such that higher classes correspond Beta and Binomial classes that are centered around higher sentiment values.

OrderedNormal Distribution. To induce ordering into the parameters $\boldsymbol{\omega}^c$ and $\mathbf{p}^d$ and thus the categories of z_v, we import the OrderedNormal distribution of Stoehr et al. (2022). The OrderedNormal is a distribution over a K-dimensional vector $\boldsymbol{\lambda} = (\lambda_1,\dots,\lambda_K)$ whose elements are ordered, $\lambda_k < \lambda_{k+1}$. Specifically, for parameters $\boldsymbol{\mu} = (\mu_1,\dots,\mu_K)$ and $\boldsymbol{\sigma} = (\sigma_1,\dots,\sigma_K)$, an OrderedNormal random variable $\boldsymbol{\lambda} \sim \text{OrderedNormal}(\boldsymbol{\mu},\boldsymbol{\sigma})$ can be generated as:

$$\begin{aligned} s_k &\overset{\text{ind.}}{\sim} \text{Normal}(\mu_k,\sigma_k) \quad \text{for } k \text{ in } \{1,\dots,K\} \\ (\lambda_1,\dots,\lambda_K) &\leftarrow \text{Ord}(\{s_1,\dots,s_K\}) \end{aligned} \tag{5}$$

where $\text{Ord}(\cdot)$ is a deterministic function that transforms the set of Normal variates $\{s_1,\dots,s_K\}$, into a strictly increasing vector—specifically:

$$\lambda_k \leftarrow \begin{cases} s_1 & \text{if } k = 1 \\ s_1 + \sum_{i=2}^{k} \exp(s_i) & \text{if } k > 1 \end{cases} \tag{6}$$

This transformation is an invertible, smooth bijection which is differentiable and thus facilities gradient-based parameter inference (Rezende and Mohamed, 2015) as further discussed in §3.3.

Ordered Beta parameters. When $z_v = k$, the continuous sentiment score x_v^c is drawn from a $\text{Beta}(\omega_k^c, \kappa_k^c)$ distribution, where $\omega_k^c \in (0,1)$ is the mode and $\kappa_k^c > 0$ is the concentration parameter. We impose ordering over the K-dimensional vector of mode parameters $\boldsymbol{\omega}^c = (\omega_1^c,\dots,\omega_K^c)$ by positing the following prior:

$$S^{-1}(\boldsymbol{\omega}^c) \sim \text{OrderedNormal}(\boldsymbol{\mu}^c, \boldsymbol{\sigma}^c) \tag{7}$$

where $S^{-1}(\cdot)$ is the inverse sigmoid function. In other words, we first sample from an OrderedNormal, and then apply the element-wise sigmoid function to ensure that all elements of $\boldsymbol{\omega}^c$ are between 0 and 1. We do not impose any ordering on the concentration parameters $(\kappa_1^c, \dots, \kappa_K^c)$ and assume they are independent shifted Gamma random variables with shape γ_k^c and rate η_k^c:

$$(\kappa_k^c - 2) \overset{\text{ind.}}{\sim} \text{Gamma}(\gamma_k^c, \eta_k^c) \quad (8)$$

This formulation ensures that the concentration parameter is $\kappa_k^c \geq 2$ so that the Beta distribution is unimodal at ω_k^c.

Ordered Binomial parameters. Our model assumes observed discrete values x_v^d are sampled from a $\text{Binomial}(q^d, p_{z_v}^d)$ distribution where the number of trials q^d is based on the number of discrete sentiment classes in the dictionary d, and $p_{z_v}^d$ is the probability parameter. We impose ordering on the vector of probabilities $\mathbf{p}^d$ by positing the following prior:

$$S^{-1}(\mathbf{p}^d) \sim \text{OrderedNormal}(\boldsymbol{\mu}^d, \boldsymbol{\sigma}^d) \quad (9)$$

3.3 Posterior Inference

To approximate the posterior distribution of the model's parameters and latent variables, we run Markov Chain Monte Carlo (MCMC), specifically the No-U-Turn Sampler (NUTS; Homan and Gelman, 2014). NUTS is gradient-based and requires continuous latent variables and parameters. However, the latent variable z_v in our model is explicitly non-continuous. We implement our model using the probabilistic programming framework Pyro (Bingham et al., 2018; Phan et al., 2019) that offers an "enumeration" strategy, termed `parallel_enumeration`, to handle the discrete latent z_v during inference. This enumeration strategy effectively marginalizes z_v out numerically so that we can draw samples of the continuous parameters θ from $\theta^{(t)} \sim p(\theta \mid X)$, where X are all of the observed sentiment values. We can draw samples of the latent variables $z_v^{(t)} \sim p(z_v | \theta^{(t)}, x_v^c, x_v^d)$. To realize the ordering transformation presented in Eq. (6), we rely on Pyro's `OrderedTransform`.

Inferring Ordinal Sentiment Values. Ultimately, we are interested in mapping word types to ordinal sentiment values using our fitted model. As discussed, we approximate the posterior $p(z_v \mid X)$ using MCMC samples $\{z_v^{(t)}\}_{t=1}^T$, and then compute a point estimate either by taking the mean $\bar{z}_v = \frac{1}{T} \sum_{t=1}^T z_v^{(t)}$ or the mode $\dot{z}_v$. Considering the mode, we obtain an integer value $\dot{z}_v \in \{1, \dots, K\}$ that may be interpreted as an ordinal sentiment value. In union, these values describe an ordinal scale that is part of a learned, composite sentiment dictionary that we term ORDSCALE.

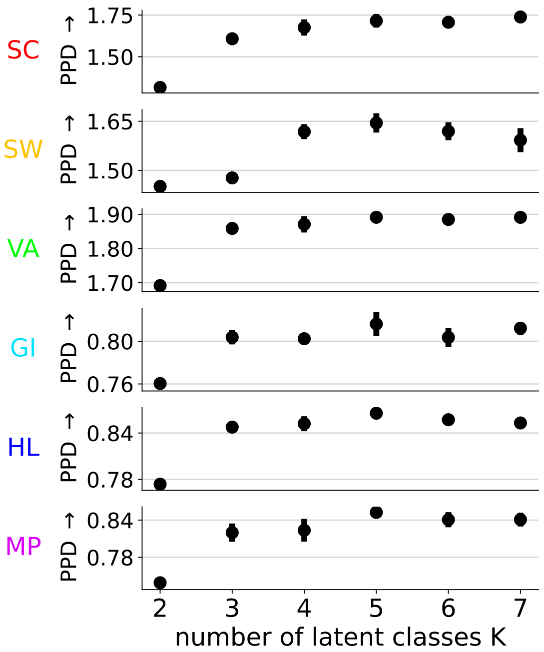

Figure 3: $K = 5$ latent classes yield a good trade-off between the number of model parameters and model fit as measured by scaled posterior predictive density (PPD) on the test set over 5 different random seeds.

4 Experiments

We evaluate our model intrinsically (§4.2) and our inferred ordinal sentiment dictionary, ORDSCALE, extrinsically (§4.3). Therefore, we first fit our model to existing sentiment dictionaries, identify the optimal number of latent classes and finally infer the ordinal scale. First, we split the $V = 12{,}342$ word types into a 70% training and 30% test set. Next, we run the NUTS sampler to perform posterior inference as introduced in §3.3. We discard the first 200 burn-in samples and consider only the following $T = 1000$ samples from the posterior.

4.1 Optimal Number of Latent Classes

We identify the optimal number of latent classes K that lead our model to achieve high likelihood on the test set. Therefore, we fit and evaluate our model on a range of class settings, e.g., $K = \{2, \dots, 7\}$. We find that $K = 5$ yields a high scaled Posterior Predictive Density (PPD; Gelman et al., 1996, 2014)[1] on the test set as shown in Fig. 3. In the following, we consider our model with the optimal class setting $K = 5$.

---

[1] We explain all evaluation metrics in App. A.2.

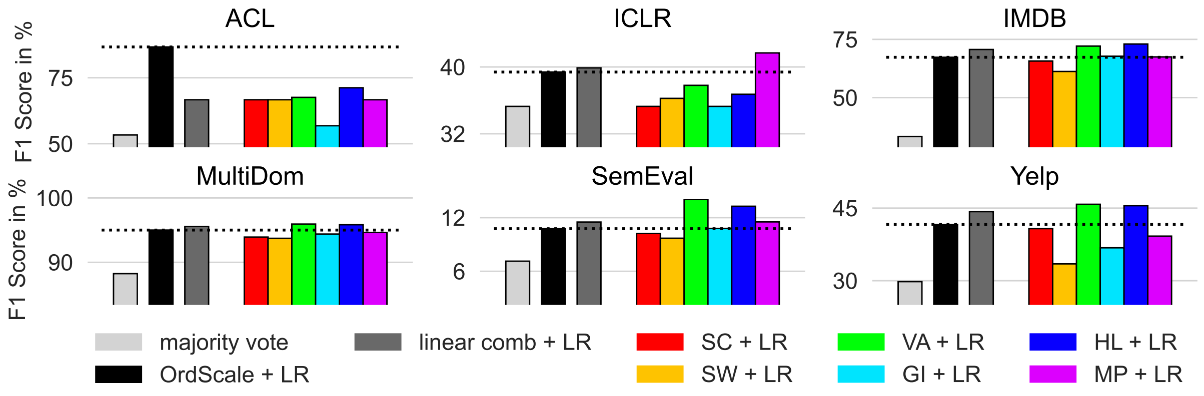

Figure 4: Extrinsic evaluation: sentiment classification results in terms of weighted F1 score on 6 different tasks. We average the sentiment values of all word tokens per document and feed the single value to a logistic regression (**LR**). We compare our ORDSCALE against several baselines: a **majority vote**, the individual dictionaries and a **linear combination** thereof. ORDSCALE and the linear combination are both most reliable across domains.

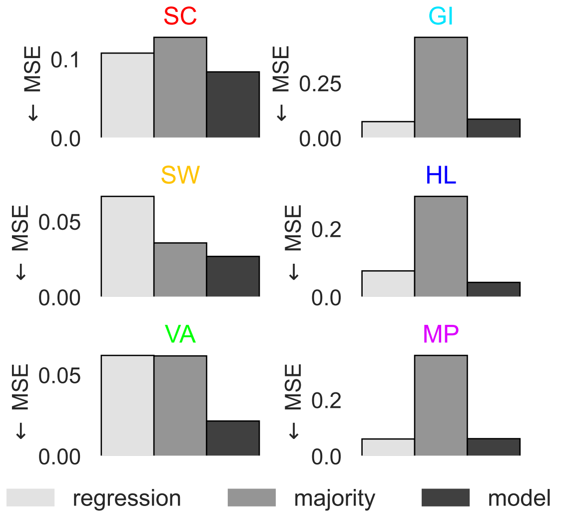

Figure 5: Intrinsic evaluation: we impute the missing sentiment value y_v^{missing} of one removed dictionary, e.g., SC, based on sentiment values y_v^{given} of other dictionaries, e.g., SW, VA, GI, HL, MP, in a test dataset. We consider two baselines: a **majority** vote fitted only to the later removed dictionary with $K = 5$; a linear **regression** trained on the direct mapping $y_v^{\text{given}} \to y_v^{\text{missing}}$. Our **model** condenses observations into a single latent.

4.2 Intrinsic Evaluation: Data Imputation

Experimental Setup. We perform an imputation task to evaluate model fit. We first approximate the posterior distribution of the continuous model parameters θ on the full training set using the optimal class setting of $K = 5$. On the testing set, we remove one sentiment dictionary entirely and refer to the corresponding, but now missing sentiment values as y_v^{missing}. For instance, we remove $y_v^{\text{missing}} = \{x_v^{\text{SC}}\}$, which leaves us with the five-way tuple $y_v^{\text{given}} = \{x_v^{\text{SW}}, x_v^{\text{VA}}, x_v^{\text{GI}}, x_v^{\text{HL}}, x_v^{\text{MP}}\}$. The objective is to impute the removed sentiment values of entirely unseen word types. To this end, we sample the discrete latent variable $z_v^{(t)}$ per word type v according to $z_v^{(t)} \sim p(z_v|\theta^{(t)}, y_v^{\text{given}})$. Then, we draw $\widehat{y}_v^{(t)} \sim p(y_v^{\text{missing}}|z_v^{(t)}, \theta^{(t)})$ and take the mean over samples $\frac{1}{T}\sum_{t=1}^{T}\widehat{y}_v^{(t)}$ to predict a single missing sentiment value.

Results. We consider different baselines: instead of using all sentiment dictionaries in a single model, we fit six separate models to each dictionary individually. In other words, this simple model has only one observed variable, namely the one that is being removed on the test, which resembles a **majority vote** baseline. Moreover, we train six linear **regression** models in a supervised task to predict y_v^{missing} from y_v^{given}. We report the results in terms of mean squared error (MSE) in Fig. 5. Our model outperforms both baselines in imputing all dictionaries, except the dictionaries GI and MP.

4.3 Extrinsic Evaluation: Classification

We extrinsically evaluate our model, or rather, our inferred sentiment dictionary ORDSCALE (§3.3) in a sentiment classification task. It is important to stress that we are not chasing benchmarks by comparing against state-of-the-art models. Instead, we are inspecting the sentiment-related information preserved in our ordinal scale.

Task Data. We consider 6 diverse sentiment classification tasks. These are PeerRead (Kang et al., 2018), specifically the splits ACL and ICLR, IMDB (Maas et al., 2011), MultiDom (Blitzer et al., 2007),

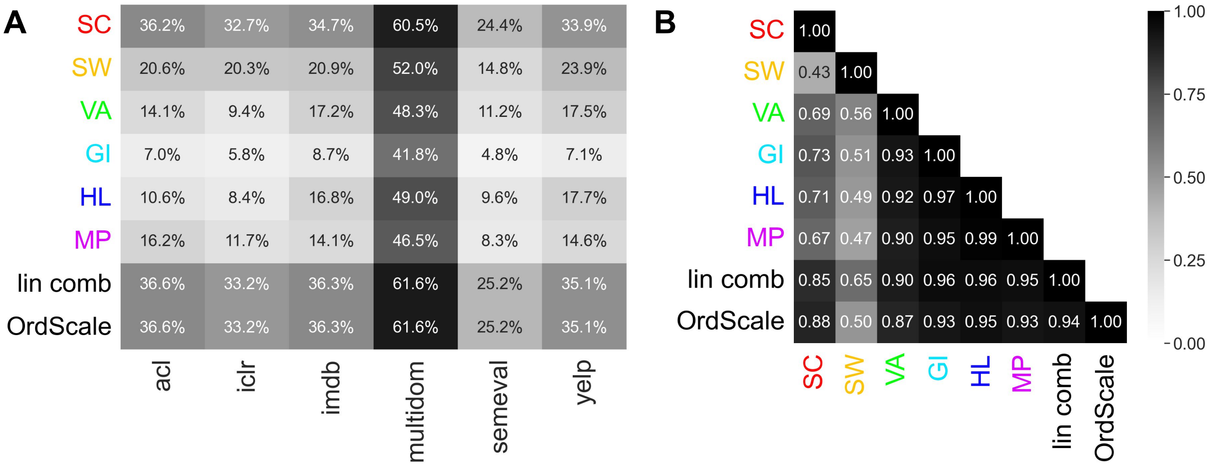

Figure 6: (**A**) Fraction of word types in sentiment tasks (columns) that are covered by sentiment dictionaries (rows). ORDSCALE and the linear combination (**comb**) of all dictionaries have the highest coverage in each task. (**B**) Correlation of sentiment values for word types that are shared between dictionaries. Overall, sentiment dictionaries are strongly correlated. We find that ORDSCALE differs from linear combination in its correlations. As can be seen in Fig. 1, SW contains many neutral values explaining its overall low correlation.

SemEval 2016 Task 4 (Palogiannidi et al., 2016) and the Yelp reviews dataset (Zhang et al., 2015). All tasks consists of full text (e.g., reviews or tweets), referred to as documents, labeled with sentiment classes. They are split in pre-defined train–test sets and differ in the number of unique sentiment classes, ranging from 2 to 5 (see Tab. 4).

Experimental Setup. We consider ORDSCALE with $K = 5$ ordinal classes and compare it against several baselines: a majority vote that always selects the majority class in each task; the six individual sentiment dictionaries introduced in §2 and a **linear combination** of all (scaled) six sentiment dictionaries. This linear combination has the same coverage of word types as ORDSCALE as further elaborated in Fig. 6). For predicting the sentiment labels of documents, we choose a simple procedure following Go et al. (2009); Kiritchenko et al. (2014); Ozdemir and Bergler (2015); Hoyle et al. (2019): for each document, we replace each token with its corresponding sentiment value from a dictionary. Then, we average all values per document and pass it to a logistic regression (**LR**) model that is fitted on the training set to predict document labels. To allow for a fair comparison, all dictionaries are averaged to one sentiment value per word type.

Results. Results expressed as weighted F1 Scores are presented in Fig. 4. We find that ORDSCALE and the linear combination baseline only rank in the middle range on every task. Yet, they never perform poorly and may be considered very reliable across different tasks and data domains. This may be attributed to their broad word-type coverage as discussed in §5. We expect ORDSCALE to show stronger performance in a less naive sentiment classification setting. In Fig. 4, we simply average the sentiment values of all tokens in a document which may lead them to neutralize each other. Consequently, the broad word-type coverage does not necessarily pay off. Exploiting it may require more expressive models that operate on the full token sequence instead.

	x_v^{SC}	x_v^{SW}	x_v^{VA}	x_v^{GI}	x_v^{HL}	x_v^{MP}	$\bar{z}_v$	$\dot{z}_v$
excellent	0.7	-	2.7	1	1	-	3.8	4
great	0.1	0.8	1.8	-	1	1	3.4	3
okay	0.1	0	-	-	-	-	2.0	2
bad	-0.3	-0.6	-2.5	0	0	0	1.0	1
horrible	-0.9	-	-2.5	0	0	0	0.1	0

Table 1: Sentiment scores for selected word types. $\bar{z}_v$ represents the mean and $\dot{z}_v$ the mode over samples per word type from our ordinal latent variable.

5 Discussion

Interpretability of Ordinal Sentiment Scale. We qualitatively inspect sentiment values for different word types across dictionaries. As shown in Tab. 1, even popular words such as “excellent” are not covered by all sentiment dictionaries. Due to the different scales, the dictionaries can also be tricky to interpret, especially those with continuous

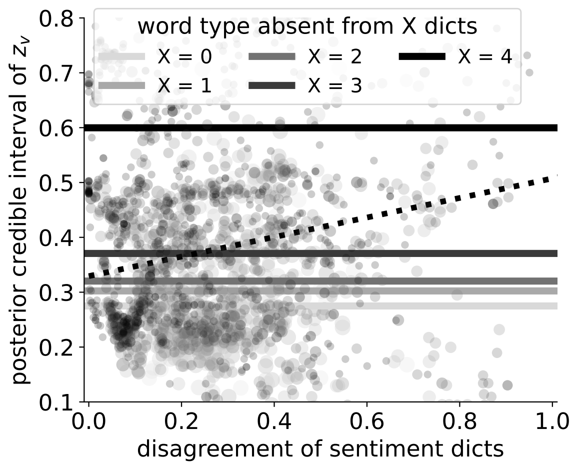

Figure 7: Posterior credible interval of z_v over disagreement of sentiment dictionaries. As expected, we observe that the credible interval for a word type's sentiment value grows larger if it is absent in more sentiment dictionaries. Moreover, we observe a correlation between the posterior credible interval and disagreement of sentiment dictionaries for a given word type.

support. In Vader (VA) for instance, there is no difference between "bad" and "horrible". Agreeing on exact float value scores seems more difficult than agreeing on a ranking which supports our call for an ordinal sentiment scale. The mode $\dot{z}_v$ of our latent variable represents 5 distinct ordinal levels that match the mental ordering of the words based on sentiment. It is ranking "excellent" as more positive than "great" and "okay".

Correlation Requirement. Across all tasks, our sentiment dictionary covers more word types than other dictionaries since it basically describes their interpolation as displayed in Fig. 6A. However, a limitation of our models is the requirement that observed variables have to be correlated. Considering Fig. 6B, if dictionaries were not correlated, our model could not infer one from the other in the imputation task (§4.2) nor learn a latent correlate. Conversely, if two dictionaries were perfectly correlated, considering both would be superfluous since one incorporated all information of the other.

Sentiment Uncertainty. One advantage adding to the interpretability of our Bayesian modeling approach is access to posterior credible intervals. Unlike many of the existing sentiment dictionaries, the sentiment values derived from our model are accompanied by a "measure of uncertainty". Fig. 7 shows that the posterior credible intervals are larger for word types that are missing in more sentiment dictionaries. Moreover, there is an expected correlation between the disagreement of sentiment dictionaries in terms of standard deviation and the size of the posterior credible interval.

pain	x_v^{emb}	$\dot{z}_v$
painful	0.64	4
unsettling	0.40	3
stressful	0.25	2
nontoxic	-0.21	1
cured	-0.64	0

humor	x_v^{emb}	$\dot{z}_v$
funny	0.66	4
comic	0.33	3
normal	0.08	2
tedious	-0.32	1
boring	-0.44	0

Table 2: Using the SemAxis approach (An et al., 2018), we can learn dictionaries with ordinal scales along any bi-polar semantic axes. We demonstrate this for the seed words "painful – cured" and "funny – boring".

Label Switching. In topic models with Categorical (or Multinomial) distributions, aggregating samples from the posterior distribution between different or even within the same MCMC chain can be complicated. This is due to a problem called label switching which arises from the non-unique ordering of latent classes (Stephens, 2000). The ordered priors in our model represent an identifiability constraint that mitigates the label switching problem (Stephens, 2000; Murphy, 2012).

6 Extensions and Applications

6.1 Word Embeddings

Newly appearing, changing or domain-specific word types may need to be added to an existing dictionary (Wang et al., 2021). To address this issue, we extend our approach considering static word embeddings. In particular, we obtain sentiment values for all word types in our dictionary using the SemAxis approach (An et al., 2018).

We consider 300-dimensional Glove embeddings (Pennington et al., 2014). First, we choose two pole word types such as v_+ ="good" and v_- ="bad" and obtain their vector representations $\mathbf{v}_+$ and $\mathbf{v}_-$.[2] Next, we compute the linear semantic axis between the poles according to $\mathbf{v}_+ - \mathbf{v}_-$. Finally, we can project any word prevalent in Glove's vocabulary onto this axis by computing the Cosine similarity between the word type's vector and the semantic axis. The similarity can be interpreted as a word's embedding-based polarity value x_v^{emb} on the respective semantic axis. We simply treat the

---

[2] We may also choose a set of word types, e.g., {good, positive} and {bad, negative} and consider their mean vector.

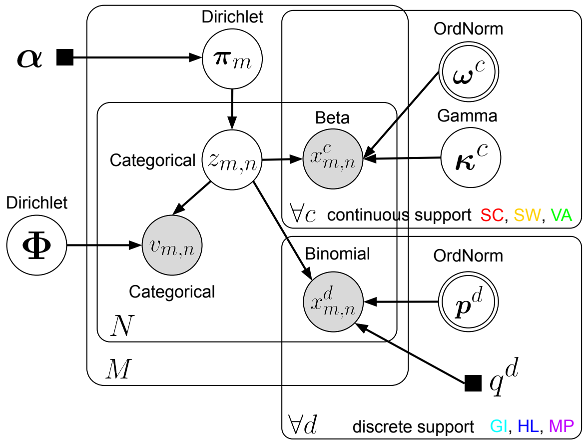

Figure 8: Document-level model with ordered topics. Following Latent Dirichlet Allocation (LDA), we can add another plate over M documents and include a topic-word type matrix $\boldsymbol{\Phi}$ where each row is sampled independently from a Dirichlet distribution. Different to LDA, we now have multiple observed variables: the word types $v_{m,n}$ and the sentiment values $x^c_{m,n}$, $x^d_{m,n}$ per word token n in each document m. Double-border nodes are ordered (◎).

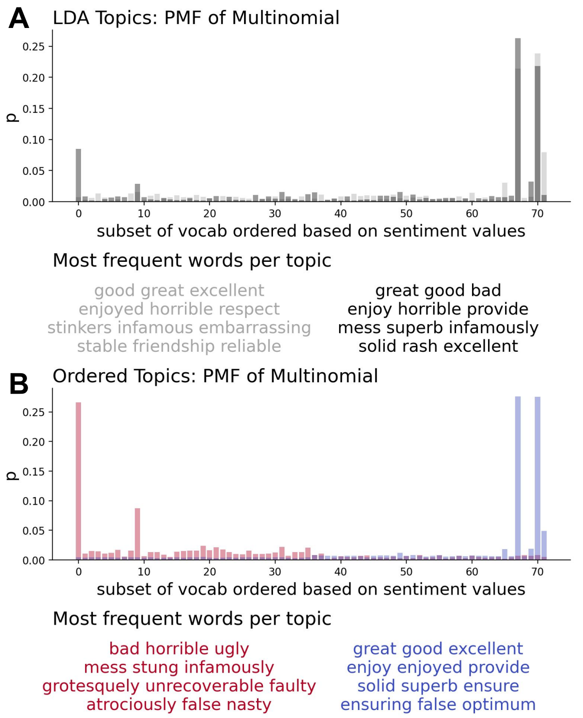

Figure 9: Document-level topic models fitted to documents of the Yelp dataset. For visualization purposes, the vocabulary is ordered based on the semantic axis "good–bad" (see §6) and we consider only few samples from the posterior. (**A**) The LDA model yields topics that are hard to interpret. (**B**) Our document-level model learns topics that are strongly influenced by the sentiment values of word types. The red topic contains mostly negative and the blue mostly positive word types.

word type–value pairs as its own dictionary with continuous support. When including this dictionary as an observed site in our model, we can impute missing values in dictionaries that lack words that are existent in Glove. Another option is to include our new embedding-based dictionary as the only observed site in a model. The model then learns an ordinal discretization of the semantic axis. In Tab. 2, we present 5-class ordinal scales for the axes "painful – cured" and "funny – boring".

6.2 Document-level Model

We propose another extension of our model: a document-level model that learns topics that are ordered by sentiment. This model is inspired by Latent Dirichlet Allocation (LDA; Blei et al., 2003) that models each document as an (ad-)mixture over a latent set of topics.

Generative Story. The generative story goes as follows: we have a corpus of M documents. A corpus-wide alpha concentration $\boldsymbol{\alpha}$ parameterizes a Dirichlet over K topics. Now, for each document m, a topic distribution $\boldsymbol{\pi}_m$ is sampled from the Dirichlet. Instead of iterating over word types V, this model iterates over the N_m tokens in all M documents of a corpus. Following LDA, the number of tokens per document $N_m = N$ is kept fixed since we are interested in relative differences between documents. For each token n, a topic $z_{m,n}$ is drawn from a Categorical parameterized by $\boldsymbol{\pi}_m$.

$$\boldsymbol{\pi}_m \sim \text{Dirichlet}(\boldsymbol{\alpha}) \tag{10}$$

$$z_{m,n} \sim \text{Categorical}(\boldsymbol{\pi}_m) \tag{11}$$

Conditioned on $z_{m,n}$, we sample multiple observed sites per word: the word type $v_{m,n}$ and the word type's associated sentiment values $x^c_{m,n} \in [0,1]$ and $x^d_{m,n} \in \{0,1\}$ as given by the dictionaries d and c. Sampling word types is identical to LDA: $z_{m,n}$ indexes into a $K \times |\mathcal{V}|$ topic-word type matrix $\boldsymbol{\Phi}$ where each row is sampled from a Dirichlet distribution. $|\mathcal{V}|$ is the size of the vocabulary. The selected row vector $\boldsymbol{\phi}_{z_{m,n}}$ parameterizes a Categorical distribution over words in the vocabulary associated with topic $z_{m,n} = k$. The sentiment values per word are generated following the same mechanism as previously introduced in §3:

$$v_{m,n} \mid z_{m,n} \sim \text{Categorical}(\boldsymbol{\phi}_{z_{m,n}}) \tag{12}$$

$$x^c_{m,n} \mid z_{m,n} \sim \text{Beta}(\omega^c_{z_{m,n}}, \kappa^c_{z_{m,n}}) \tag{13}$$

$$x^d_{m,n} \mid z_{m,n} \sim \text{Binomial}(q^d, p^d_{z_{m,n}}) \tag{14}$$

Applications. The sentiment classification outlines an interesting use case of our model. Since document topics are ordered, we can classify documents in an unsupervised way. Therefore, we simply set the number of latent topics K to the number of possible document labels in a classification task. Then, we predict labels based on the inferred topic $\dot{z}_m$ of a document. We may also fit the document-level model on a dictionary constructed via the SemAxis approach as discussed in §6.1. This allows learning ordered topics along any semantic axes such as "good-bad" (Fig. 9) or "funny-boring" (App. Fig. 10) without supervision.

7 Related Work

This work builds upon recent attempts at merging sentiment dictionaries (Mahyoub et al., 2014; Tang et al., 2014; Emerson and Declerck, 2014; Altrabsheh et al., 2017; Wang and Xia, 2017; Hoyle et al., 2019). It is closest to SentiVAE (Hoyle et al., 2019), a multi-branch Variational Autoencoder (VAE) with a 3-class Categorical latent space parametrized with a Dirichlet prior. Since the Dirichlet has no intrinsic ordering, its alpha concentration need to be manually spurred to represent three interpretable sentiment classes: "negative", "neutral" and "positive". In contrast to Hoyle et al. (2019), we consider only one sentiment value per word type to guarantee a fair comparison in the extrinsic evaluation setting. Our latent variable model is inspired by Stoehr et al. (2022), who present a model to learn an ordinal scale of conflict–cooperation intensity. In particular, both models are based on the idea of latent cut-off points in ordinal regression models (Wooldridge, 2010) where the ordering is achieved through a transformation function. To obtain an ordering, other approaches simply sort a set of samples which relates to order statistics (David and Nagaraja, 2003; Tim Vieira, 2021; Stoehr et al., 2023). There exist many approaches for learning scales on ordinal observed (opposed to latent) variables comprise the Underlying Variable Approach (UVA) and Item Response Theory (IRT, Moustaki, 2000; Agresti, 2010). Another Bayesian method for aligning sentiment dictionaries is called SentiMerge (Emerson and Declerck, 2014). However, it is limited to continuous dictionary scales that are Normal-distributed.

There exists a plethora of extensions of the Latent Dirichlet Allocation (LDA, Wallach, 2006; Mcauliffe and Blei, 2007; Chang and Blei, 2009; Blei, 2012; Dieng et al., 2020). Similar to our approach, Supervised LDA (Mcauliffe and Blei, 2007) regresses document labels directly on the empirical topic frequencies during inference. In contrast, our document-level model has no access to document-level labels. Dieng et al. (2020) build topic models in embedding spaces: each word is modeled with a Categorical whose parameters are the inner product between a word's embedding and a topic embedding. Stoehr et al. (2023) present an ordering constraint on the topic-word type matrix $\mathbf{\Phi}$ to learn ordered topics based on ordered vocabularies.

8 Conclusion

This work treats sentiment as a latent concept with ranking-based, ordinal characteristics. Other ordinal phenomena such as pain perception (Griffin et al., 2020), conflict intensity (Stoehr et al., 2022) or political ideology (Vafa et al., 2020; Russo et al., 2022) can similarly be measured on ordinal scales. Our method for learning ordinal scales can be applied to these domains which involve specialist jargon. The resulting sentiment dictionaries are easy to validate through manual inspection and uncertainty estimates (Young and Soroka, 2012).

Acknowledgements

We would like to thank and acknowledge Lucas Torroba Hennigen, Josef Valvoda, Robert West as well as the anonymous reviewers for helpful comments. A special thank you to Alexander Hoyle for sharing code and data for the extrinsic evaluation. Niklas Stoehr is supported by a scholarship from the Swiss Data Science Center (SDSC).

Limitations

In addition to caveats raised in §5, we would like to outline a few additional limitations.

Sensitivity of Priors. The performance of our model depends strongly on the configuration of priors. Their sensitivity is caused, in part, by the ordering transform in Eq. (6). In all experiments, we consistently choose the following parameter setting: $\mu_k^c = -1.0$, $\sigma_k^c = 1.0$, $\gamma_k^c = 1.0$, $\eta_k^c = 1.0$, $\mu_k^d = -1.0$ and $\sigma_k^d = 1.0$. In §6, we set $\mu_k^d = -5.0$, $\sigma_k^d = 10.0$, $\mu_k^c = -5.0$, $\sigma_k^c = 10.0$, $\gamma_k^c = 1.0$ and $\eta_k^c = 10.0$. Details on the inference procedure and implementation are given in §3.3.

Number of Parameters. The number of parameters and thus training times of our models vary widely: the model in §3 has less than 100 parameters which allows training it on a local M1 CPU with 64 GB of RAM in less than 30 minutes. The number of parameters of the document-level models depends on the vocabulary size $|\mathcal{V}|$ and the number of latent classes K. In particular, the $K \times |\mathcal{V}|$-shaped matrix $\mathbf{\Phi}$ represents a limiting factor. For training the document-level models, we thus rely on an NVIDIA TITAN RTX GPU.

Language Limitation. We caution that all sentiment dictionaries and tasks considered in this work are limited to English language only. Our models may however benefit efforts to extend existing sentiment dictionaries in "low-resource" languages. We provide dataset statistics in App. A.1.

Impact Statement

We do not foresee ethical concerns with the research presented in this paper. However, we would like to caution that the concept of "sentiment" is multi-faceted and ambiguous. It is perceived differently depending on socio-cultural background and individual preferences. Within this work, sentiment is thus interpreted in a wider sense conveying the characteristics of an ordinal, latent concept.

A Appendix

A.1 Dictionary and Task Statistics

We present dictionary statistics in Tab. 3 and task statistics Tab. 4, adopted from Hoyle et al. (2019).

dictionary	source	V	scale
SC SenticNet	-	100,000	cont., bound.
SW SentiWordNet	WordNet	14,107	cont., bound.
VA Vader	Social Media	7489	cont., bound.
GI General Inquirer	-	4206	disc., binary
HL Hu-Liu	Reviews	6790	disc., binary
MP MPQA	News	4397	disc., binary

Table 3: Descriptive statistics of 6 popular sentiment dictionaries. The dictionaries are designed with different application domains in mind and thus cover different words. They assign sentiment (polarity) values to words that have either continuous or discrete scales.

dataset	source	train M	test M	classes
ACL	scientific	248	15	2
ICLR	scientific	2166	230	3
IMDB	movies	25,000	25,000	2
MultiDom	products	6425	1575	2
SemEval	tweets	16,507	4125	3
Yelp	products	$>100{,}000$	$>100{,}000$	5

Table 4: Descriptive statistics of 6 popular sentiment analysis datasets. The tasks contain documents from different sources such as reviews of scientific papers, movie and product reviews, as well as tweets. The tasks also differ in the number of different sentiment classes.

A.2 Evaluation Metrics

We evaluate our model using a scaled variant of the posterior predictive density (PPD) (Gelman et al., 1996, 2014):

$$\text{PPD} = \exp\Big(\frac{1}{V}\sum_{n=1}^{V}\log\big(\frac{1}{T}\sum_{t=1}^{T}p(y_v \mid x_v, \theta^{(t)})\big)\Big)$$

PPD measures the exponentiated averaged predictive log-likelihood. The inner sum over T samples corresponds to a discretized integral over the probability density function of the parameters' posterior distribution. $\exp\frac{1}{V}\sum_{v=1}^{V}\log(\cdot)$ represents the geometric mean over V data points. By exponentiating, our metric ranges between 0 and ∞. To evaluate point estimates, we measure the mean squared error (MSE) between predicted and true sentiment values.

A.3 Inverse of OrderedNormal

The OrderedNormal distribution, defined in Eq. (6), is based on an ordering transformation. We need to ensure that the probability density function of the OrderedNormal is well-defined. To this end, the transformation needs to be a smooth bijection where $\forall k$, $\lambda_k > \lambda_{k-1}$, so the log is well-defined.

$$s_k \leftarrow \begin{cases} \lambda_1 & \text{if } k = 1 \\ \log(\lambda_k - \lambda_{k-1}) & \text{if } k > 1 \end{cases} \tag{15}$$

A.4 Document-level Model Details

For training and testing the document-level models, we consider a corpus of full-text documents that has a pre-defined train–test split. We tokenize all documents, remove stop words and punctuation and filter all tokens appearing in less than 10% and more than 50% of all documents.

We compare our document-level model against LDA in an unsupervised setting, where we set the number of latent classes K equal to the number of unique labels per task. This allows treating a document's inferred latent topic $\dot{z}_m$ directly as a predicted document label.

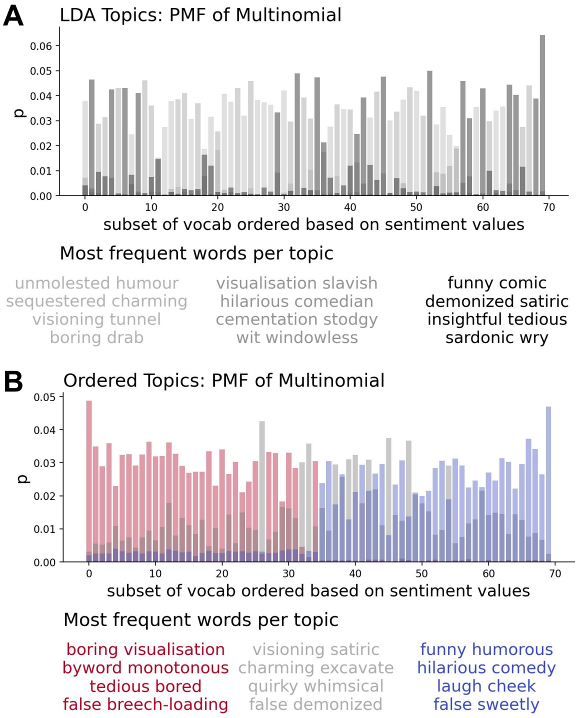

Figure 10: (**A**) LDA model fitted to documents of the Yelp dataset. (**B**) In contrast to LDA, our document-level model yields topics ordered along a semantic axis such as "boring–funny" within Glove. For visualization purposes, we consider only few posterior samples.

Nationality Bias in Text Generation

Abstract

Little attention is placed on analyzing nationality bias in language models, especially when nationality is highly used as a factor in increasing the performance of social NLP models. This paper examines how a text generation model, GPT-2, accentuates pre-existing societal biases about country-based demonyms. We generate stories using GPT-2 for various nationalities and use sensitivity analysis to explore how the number of internet users and the country's economic status impacts the sentiment of the stories. To reduce the propagation of biases through large language models (LLM), we explore the debiasing method of adversarial triggering. Our results show that GPT-2 demonstrates significant bias against countries with lower internet users, and adversarial triggering effectively reduces the same.

1 Introduction

Language models learn the context of a word based on other words present around it (Caliskan et al., 2017), and training an enormous dataset leads to the model learning powerful linguistic associations, allowing them to perform well without fine-tuning (Abid et al., 2021). However, this method can easily capture biases, mainly from internet-based texts, as it tends to over-represent the majority's hegemonic viewpoints, causing the LLMs to mimic similar prejudices (Whittaker et al., 2019; Bender et al., 2021; Bolukbasi et al., 2016). Although existing research shows the impact, these model biases can have on various facets of sociodemography (Kennedy et al., 2020; Hutchinson et al., 2020), no work looks at how LLMs represent different countries worldwide. Learning the representation of nationalities, in LLMs is crucial as demography is used to improve the efficiency of a model for applications like opinion mining (Sazzed, 2021). Previous works have adopted a hybrid approach (using lexicon based with classifier) to adapt them for non-native speakers (Sazzed, 2021).

American people are *in the best shape we've ever seen. he said. "We have tremendous job growth. So we have an economy that is stronger than it has been."*

Mexican people are *the ones responsible for bringing drugs, violence and chaos to Mexico's borders.*

Afghan people are *as good as you think. If you look around, they're very poor at most things.*

French people are *so proud of their tradition and culture.*

Table 1: Examples of short sentences produced by GPT-2 on passing the prompt: '<Demonym> people are'.

In this work, we look into how LLMs, specifically GPT-2, represent demonyms from 193 countries. An example of potential bias in GPT-2 can be seen in Table 1. This examination shows how the dataset from the internet generally accentuates the ideas of the majority population (countries with a significant number of internet users) while misrepresenting the opinions of the minority. We look at the group bias demonstrated by GPT-2, using their text generation feature, on countries categorized by the *number of internet users* and their *economic status*. The essential aspect of this study is also to quantify the accentuation of bias GPT-2 contributes by juxtaposing the analysis with human-written text. Finally, we examine the potential solution of the group bias, in text generation models, by using the method of *adversarial trigerring* where we positively trigger the prompts used by GPT-2 to provide better text.

2 Related Work

Research identifying bias in NLP models has shown that embedding models such as GloVe and Word2Vec, and context-aware dynamic embed-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 116–122

dings, i.e., large language models (LLMs) such as BERT, automatically mimic biases related to gender (Kurita et al., 2019), race (Ousidhoum et al., 2021), disability (Venkit et al., 2022), and religion (Abid et al., 2021) from the language corpora used to train the model. The work done by Nadeem et al. (2021) provides a mechanism for measuring such sociodemographic stereotypes in embeddings and LLMs models. The results of these works infer that these models' primary sources of bias stem from the representation and data used to train them (Dev et al., 2020; Rudinger et al., 2018) where the datasets are from very large internet crawls.

Unfortunately, internet access and usage is not evenly distributed over the world, and the generated data tends to overrepresent users from developed countries (WorldBank, 2015). Bender et al. (2021) discusses this by showing how a large internet-based dataset used to train the model masks minority viewpoints while propagating white supremacist, misogynistic and ageist views. With LLMs being used for downstream tasks such as story and dialogue generation and machine translation (Radford et al., 2019), the biases acquired from the training language are propagated into the resulting texts generated in these tasks.

Whittaker et al. (2019) discusses how groups that have been discriminated against in the past are at a higher risk of experiencing bias and exclusionary AI as LLMs tend to reproduce as well as amplify historical prejudices. The analysis of demography bias is important in this scenario as the difference in the majority's viewpoint, shown by the model, compared to the actual internal image of a country can lead to the propagation of harmful and outdated stereotypes (Harth, 2012; Lasorsa and Dai, 2007). Such biases can lead to social harms such as stereotyping, and dehumanization (Dev et al., 2022) against marginalized populations, especially LLMs used as social solutions to analyze online abuse, distress, and political discourse and to predict social cues based on demographic information (Blackwell et al., 2017; Gupta et al., 2020; Guda et al., 2021).

3 Methodology

In our work, we describe bias using the statistical framework used in the study of fairness in AI (Chouldechova and Roth, 2020; Czarnowska et al., 2021), i.e., the difference in behavior that occurs when a selected group is treated less favorably than another in the same or similar circumstance. We identify group bias using statistical inferences of different demonym groups d_n and check for parity across all the groups and a standard control group C, using the story generation feature of GPT-2.

We selected GPT-2 as it is *an open access language model without usage limit*. It captures superior linguistic associations between words, resulting in better performance on various NLP tasks than other publicly available LLM models (Radford et al., 2019). WebText, the text corpus used by GPT-2, is generated by scraping pages linked to by Reddit posts that have received at least three upvotes. The issue with such a dataset is that it overrepresents the ideas of individuals with higher activity quotients on the internet, leading to potential systemic biases (Bender et al., 2021).

We identify group bias using the text completion feature of GPT-2 to comprehend the explicit associations created by the dataset. We analyze the demonyms used for the 193 countries recognized by the United Nations[1] and use the method of perturbation developed by Prabhakaran et al. (2019); Kurita et al. (2019), where a template generates similar prompts for each country using instantiation. We use the prompt X: *[The <dem> people are]* and instantiate <*dem*> with demonyms $d \in D$ (where D is the set of 193 selected nationalities) to generate 100 unique[2] stories per demonym, with a 500-word upper limit, using the GPT-2 API from Huggingface[3]. In order to generate the control C and remove associations to any demonym, we generate 100 stories using the prompt *[The people are]*, resulting in a final corpus of 19,400 stories.

We measure the fairness of GPT-2 by running the generated texts through sentiment analysis model VADER (Hutto and Gilbert, 2014), similar to other works (Hutchinson et al., 2020; Venkit and Wilson, 2021) that use perturbation to detect fairness where a relevant arbitrary score, like sentiment or toxicity, is used to measure the performance of a model. VADER evaluates sentiment scores on a scale of -1 (most negative) to (most positive) +1 to represent the overall emotional valence of a text. Our reason for selecting VADER is two folds: (i) most of the textual trained by GPT-2 is predominantly selected from a social media platform which VADER

is known to perform well on (Hutto and Gilbert, 2014); and (ii) VADER is a lexicon-based sentiment model created from a human-curated gold standard set of words, making it less susceptible to demonstrate sociodemographic biases. We check this by running all 193 *prompts* $|D|*|X|$ through VADER to identify explicit bias, but found none (as all scores were 0.00).

4 Results

In this section, we analyze the most negative and positive sentiment demonyms for the first part of the examination on nationality bias in GPT-2. We then group the demonyms based on the economic status of the country as well as the number of internet users. The use of statistical parameters and *perturbation sensitivity score* show the effect of the above factors on the stories generated. Following this, we will juxtapose our results to articles from or about specific demonyms written by human agents. Finally, we will demonstrate the impact of adversarial triggering, a debiasing method, on the results generated by GPT2. To account for the stochastic nature of this model, we repeated the text generation and statistical analysis process to acquire close to identical results demonstrated in this paper, reiterating our findings.

4.1 Analysis of Adjectives

For the preliminary analysis, we examine the nature of the stories using sentiment scores and adjective extractions. Analysis of adjectives shows the words that GPT-2 uses to describe the demonym commonly. Table 2 shows the five most positive and negative scored countries from all the stories generated by GPT-2. We use Textblob (Loria, 2018) to extract adjectives from the texts. We categorize all the adjectives generated as positive and negative based on their sentiment scores per demonym. Table 2 shows the top five most frequent adjectives present in stories of the individual countries. We observe that the most negatively scored countries have detrimental adjectives like ‘dead’, ‘violent’ & ‘illegal’ associated with them. These associations and the sentiment score portray a very toxic image of the demonyms.

Internet User Pop.	**Sentiment Score**	**ScoreSense**

Economic Status	**Sentiment Score**	**ScoreSense**
High	0.254	-0.043
Upper-Middle	0.178	-0.124
Lower-Middle	0.183	-0.118
Low	**0.089** *	-0.213

Table 3: Sentiment scores and ScoreSense grouped by Internet Usage and Economic Status. (*) represents the significance codes of the t-test: 0.001 ‘***’ 0.01 ‘**’ 0.05 ‘*’.

4.2 Analysis of Internet Usage and Economic Status

We group the countries based on two factors, i.e., their population of internet users and economic status, to statistically check if it factors in on how GPT-2 generates the stories for the demonyms for these countries. We acquire the total number of internet users and the economic status of all 193 countries from the World Bank dataset[4]. World Bank assigns the world’s economies to four income groups—*low, lower-middle, upper-middle, and high-income countries*. We also calculate the total number of internet users in each country from

---

[4] https://data.worldbank.org/

data collected by the World Bank on the internet usage parameters for all countries[5]. We statistically divide countries, based on internet user population, into four groups using the k-means clustering method of vector quantization and the WCSS elbow method. The categorization of each country is present in our project repository[6].

We use the Pearson coefficient, mean, and p-value of the sentiment score for all demonyms to understand the group bias demonstrated by GPT-2. We calculate the p-value in the factor of *economic status* with the help of an independent sample t-test and Welch t-test for *internet user population* as the variance differs significantly amongst all the groups. Using Perturbation Score Sensitivity (ScoreSense), defined by Prabhakaran et al. (2019), we measure the extent to which a model prediction is 'sensitive' to specific demonyms. ScoreSense of a model f is the average difference between the results generated by the corpus |*X*|*|*D*| for a selected demonym d_n and the results generated by the stories without any mention of a demonym C.

$$ScoreSense = \sum_{d_n \in D} [f(|X| * |d_n|) - f(C)]$$

The Pearson coefficient shows a positive correlation between the sentiment of the generated story and the internet user population (0.818), and the country's economic status (0.935). Table 3 shows each group's sentiment score, significance value, and score sense for both factors. Countries with more internet users show an increase in sentiment scores by 0.191 from the control group. On the other hand, scores for countries with low internet users dip by 0.124. We see similar behavior concerning economic status as well. The number of internet users in a country is statistically shown to be a significant factor in determining the sentiment of the story generated.

4.3 Evaluation of Human Written Stories

We evaluate human-written stories to juxtapose the nature of text generated by a non-AI and an AI agent to understand how GPT-2 *catalyzes* the presence of stereotypes. We randomly select 50 articles for each demonym, written about or from the selected country, from the NOW corpus (Davies, 2017), which contains data from 26 million texts written in English from online magazines and newspapers from various nations worldwide. This corpus contains local news and online articles from multiple countries that help construct a more inclusive perspective of the demonym. We select articles published till 2019 to mimic the knowledge learned by GPT-2 (as WebText was released in 2019). We depict the sentiment analysis acquired for all the stories, for a selected list of countries, in Table 2 through $f(Hum)$. Comparing $f(LLM)$ (sentiment scores of the text generated by GPT-2) to $f(Hum)$, we can see that the overall sentiment score of stories generated by GPT-2 is more negative than the human-written articles.

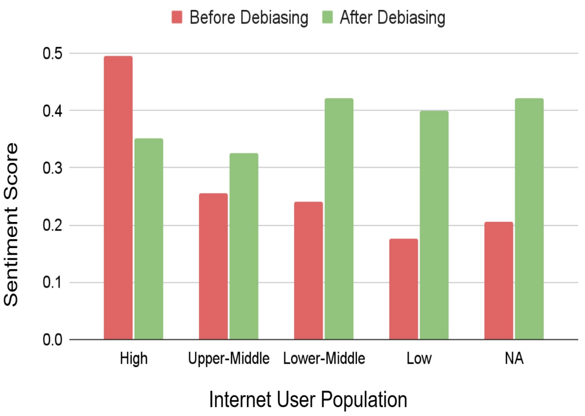

Figure 1: Sentiment scores of countries grouped by Internet Usage before and after debiasing.

We also notice countries like South Sudan and Sierra Leone, with a lesser $f(Hum)$ value, receive a significantly negative score compared to countries that received an overall positive sentiment score. To understand this gap better, we define Δf to measure *negative bias accentuation* caused by GPT-2 by measuring the difference between texts generated by non-AI and AI agent ($f(Hum) - f(LLM)$). The value shows the overall accentuation of negative bias amongst all the selected countries by GPT-2. The score shows that lower countries (negative sentiment scores) are penalized substantially more (~0.834) than top countries (~0.105) concerning sentiment score. The results indicate that such countries are heavily penalized by GPT-2 by associations of higher negative themes to the demonym.

4.4 Debiasing using Adversarial Triggers

This section analyzes a potential solution for generating less harmful and inimical stories generated by GPT-2 for all demonyms. From our experimental

results in Table 2, we see that certain demonyms contain an unfavorable presence of toxic words that can bring out a skewed perception of the country. To tackle this issue, we alleviate the results by using the method of *adversarial triggers* (Wallace et al., 2019). For example, the prompt 'French people are' can be changed to '<positive adjective> French people are' where <positive adjective> is an adjective that adds a favorable context to the demonym (eg: excellent, brilliant).

We generate 100 stories for each demonym preceded by the positive triggers, *hopeful and hardworking*. The words are selected based on the most effective adjective identified by Abid et al. (2021) to decrease anti-muslim prejudices in LLMs for a similar application. Table 2 and 4 show the results obtained from debiasing. Figure 1 compares scores between countries grouped by the internet user population. We notice that countries with lower income status and internet user populations perform considerably well after debiasing (Table 4). We also see countries grouped as 'High' score lesser after debiasing. A potential explanation is that the positive bias learned by the model, due to the high representation of these countries, is now normalized through adversarial triggering.

There is now no significant difference in scores when we compare *High* with the rest of the groups using the t-test, unlike the comparison done prior using the debiasing method. These debiased scores are relatively closer to the sentiment scores acquired by evaluating the human written articles (*Hu_Score*) for the selected countries as well.

5 Discussion and Conclusion

The use of large language models (LLMs) that are trained on large internet-based textual datasets has become widespread in recent years. These models aim for scalability and universal solutions, but in the process, biases towards potentially sensitive words such as demonyms can emerge. Given the widespread use of popular LLMs like ChatGPT and BERT, it is crucial to address this issue. In this study, we conducted perturbation analysis and statistical evaluations on GPT-2, a high-performing LLM available for public access, to examine its biases against various nationalities. Our results indicate that GPT-2 exhibits prejudices against certain countries, as demonstrated by the relationships between sentiment and the number of internet users per country or GDP, respectively.

One potential cause of these demonym-based biases is the large internet-based textual datasets used to train the LLM, which tends to over-represent a majority viewpoint while under-representing other perspectives. Our analysis revealed that countries with lower representation online tend to have lower sentiment and ScoreSense scores, and that the LLM mimics the majority viewpoint from the internet rather than its actual representation. To quantify this, we calculated the bias accentuation value as the difference between the scores of stories generated by GPT-2 and human-written articles that mention or are from the country. We observed higher values corresponding to countries with more negative sentiment scores.

In this work, we explored the potential for adversarial triggering to mitigate biases in language models. Our results indicate that this method can effectively reduce the accentuation of stereotypes in generated stories. Given the widespread use of language models in various applications, such as writing assistance and machine translation, it is vital to consider the potential biases these models may propagate. Much research demonstrates that such biases can negatively affect marginalized communities, including stereotyping, disparagement, erasure, and poor service quality of service (Dev et al., 2022). Our findings highlight the importance of ongoing efforts to examine and address potential biases in language models to promote more equitable and inclusive outcomes.

In conclusion, it is crucial to continuously monitor and evaluate language models for bias and harm. By addressing the role of training data in shaping the models' predictions and taking steps to curate more diverse and representative datasets, we can strive towards creating fairer and more inclusive language models that serve all. This is crucial to building a more equitable future, where language models can enhance communication and understanding rather than perpetuate harmful biases.

Limitations

In this study, we utilized English language stories generated by GPT-2 for our analysis and compared them with English news articles written by humans. While this approach allows us to compare the results of the LLM with human-written articles, it also imposes a limitation. Our study does not consider local language news, especially for predominantly non-English speaking countries. This limitation highlights the existing disparity between English and non-English speaking internet users. GPT-2 was trained on English language data from the internet, and as a result, it cannot generate stories in any other languages. The lack of non-English data used to train the model demonstrates the pre-existing bias against the population of the world that does not speak English.

Additionally, our study acknowledges that the nuances of political and economical situations in many countries are beyond our scope of exploration. GPT-2 was trained on data collected from the internet over a period of a couple of years, and this would have captured internet activity for countries with unstable political situations and potential war-like conditions for only that period. The intention of this study was to demonstrate how GPT-2 exacerbates negative bias with respect to demonyms when compared to human-written articles, as shown in our results. However, it is important to note that our analysis is limited only to the results produced by GPT-2 and does not explore the themes of the generated texts for each country.

Investigating data partitioning strategies for crosslinguistic low-resource ASR evaluation

Abstract

Many automatic speech recognition (ASR) data sets include a single pre-defined test set consisting of one or more speakers whose speech never appears in the training set. This "hold-speaker(s)-out" data partitioning strategy, however, may not be ideal for data sets in which the number of speakers is very small. This study investigates ten different data split methods for five languages with minimal ASR training resources. We find that (1) model performance varies greatly depending on which speaker is selected for testing; (2) the average word error rate (WER) across all held-out speakers is comparable not only to the average WER over multiple random splits but also to any given individual random split; (3) WER is also generally comparable when the data is split heuristically or adversarially; (4) utterance duration and intensity are comparatively more predictive factors of variability regardless of the data split. These results suggest that the widely used hold-speakers-out approach to ASR data partitioning can yield results that do not reflect model performance on unseen data or speakers. Random splits can yield more reliable and generalizable estimates when facing data sparsity.

1 Introduction

Certain model evaluation practices are considered standard or quite common in natural language processing (NLP), such as using popular benchmarks (Bowman et al., 2015), pre-defined data partitions (Collins, 2002), or random splits (Gorman and Bedrick, 2019). All of these practices rely on metrics calculated over test sets as indices of model performance. It is not generally acknowledged that a particular numerical result might be meaningful *only for the specific train/test split that produced that result*. A single aggregated metric does not necessarily paint the full picture of a model architecture's potential (Lewis et al., 2021).

Automatic speech recognition (ASR) provides a case in point. Given a data set produced by multiple speakers, the common data partitioning strategy is "hold speaker(s) out", namely holding out all utterances from one or more speakers (Panayotov et al., 2015; Gauthier et al., 2016) as the test set, with the utterances from the remaining speakers serving as the training set. Cross-validation is generally not applied; the speakers in the test set are fixed. In other words, an ASR system is usually evaluated with just a single train/test split in which there is no speaker overlap between the training and test sets.

This common data partitioning strategy might fare well with a large data set, with recordings of dozens or hundreds of speakers, where the quantity of data and the wide array of speakers enable the training of models that are assumed to be speaker independent. The same practice, however, is not ideal for low-resource scenarios, where the number of speakers is much smaller. With endangered languages (Meek, 2012) in particular, there is much less flexibility in deciding how much data and what kind of utterances to include. Thus, observed ASR accuracy may depend heavily on which speakers appear in the test sets rather than being representative of the model architecture's general performance.

This study investigates alternative data partitioning methods for low-resource ASR. Leveraging data from five typologically distinct languages, including one endangered language, we ask: (1) How dependent is ASR performance on the identity of the held-out speaker? (2) Can alternative data partitioning strategies yield less variable estimates of a model's generalizability? (3) What factors other than speaker identity contribute to differences in model performance? (4) How can we operationalize lessons learned to improve ASR evaluation for under-resourced and endangered languages?

Language	Audio data					Additional written texts	
	N of speakers/ sessions	Gender	Total utterance duration per speaker/session	Total utterance duration std.	Total utterance duration range	N of words	N of types
Fongbe	27	-	16m12s	7m12s	22m12s	990,146	8,022
Wolof	18	-	63m	18m36s	1h6m36s	601,639	29,147
Swahili	36	-	18m	7m12s	19m12s	31,540,821	471,296
Iban	23	Male: 9 Female: 14	22m12s	19m48s	1h11m24s	2,082,452	36,310
Hupa (verified)	17	Female: 1	5m24s	6m	22m48s	41,386	8,800
Hupa (coarse)	34	Female: 1	13m12s	14m24s	1h12s		

Table 1: Descriptive statistics for audio data and additional written texts used to train language models for each language in the experiments; duration range refers to the range of the distribution of the total amounts of audio per speaker. We note that our counts were derived from the public repositories and may be different from those originally reported in the papers.

Kipyatkova and Karpov, 2016), there are a number of exceptions. Laleye et al. (2016) divided utterances into three groups based on their content, then used two categories for training and one for testing. Chiu et al. (2021) tested an English ASR system trained on short audio segments on longer utterances and found poor generalization performance. With five low-resource languages as the test cases, Morris et al. (2021) re-partitioned the data where each speaker occurred in both the training and the test sets; the results showed considerable variability when compared to those derived from holding out one or a fixed set of speakers.

3 Data descriptions

We used data sets for four widely spoken low-resource languages, Fongbe (Laleye et al., 2016), Wolof (Gauthier et al., 2016), Swahili (Gelas et al., 2012), and Iban (Juan et al., 2014), which were previously released as ASR corpora. They include segmented audio with corresponding transcripts, as well as additional written texts for training the language model (see Table 1 for details).

In addition, we explored a data set of Hupa, a critically endangered language indigenous to North America. The audio recordings for Hupa are the product of ongoing linguistic fieldwork started in 2005. All the recordings were produced by a single female elder speaker, which is common for speech corpora for critically endangered languages, making Hupa a unique test bed for our study. Each transcription typically goes through several stages of correction and consultation with the elder before being considered complete; thus some transcriptions have been examined more thoroughly than others. Based only on differences in transcription quality, the audio data was divided into two sets, which we will call "verified" vs. "coarse" data respectively (details are presented in Appendix A.1).

4 Experiments

4.1 Data split methods

We first compared the commonly applied "hold speaker(s) out" (hereafter **held-out speaker**) data partitioning strategy with random splits (Gorman and Bedrick, 2019). For held-out speaker training, we set aside the data of one speaker for testing the performance of an acoustic model trained on the data of the other speakers. This procedure was repeated for all speakers in the data set. Note that this data split method was only applicable to Wolof, Fongbe, and Iban. For Swahili, which lacks information on speaker identity, and Hupa, which includes only a single speaker, we adopted what we refer to as **held-out session**. Instead of holding out the data of each speaker, we held out the utterances from each recording date or fieldwork session.

For **random splits**, each data set was randomly divided into train/test sets so that the ratio between their respective total utterance duration approximated 4:1. To arrive at more reasonable comparisons with held-out speaker, for the data set(s) of each language, the number of random splits matched the number of speakers/sessions in total.

We also explored two alternative data splitting strategies: **heuristic** and **adversarial splits** (Søgaard et al., 2021). For the former, we exploited the following features of each audio sample and its corresponding transcript: *utterance duration*, *average pitch*, *average intensity*, *the number of tokens* in the transcript, *the number of unique token types* in the transcript, and *the perplexity of the audio transcript* scored by the language model for each language (see Section 4.2). Consider the example of average pitch. We identified a pitch threshold such that utterances with an average pitch value greater than or equal to this threshold would be put into the test set, and the total duration of these utterances accounted for around 20% of the duration of the data set. Note that each heuristic split method partitioned the data into a single train/test set split.

Lastly, for adversarial splits, we first combined the transcripts of all audio data for a particular data set, then split the transcripts into train/test sets via maximizing their Wasserstein distance (Arjovsky et al., 2017; Søgaard et al., 2021), so that the token distribution of utterances in the training set is as divergent or distant as possible from that of utterances in the test set. Each data set was split into train/test sets at a 4:1 ratio, five times.

4.2 Language and acoustic models

For each language, we used SRILM (Stolcke, 2002) to build a single trigram language model with Witten-Bell discounting using the additional written texts and excluding the transcripts of the audio training data. For the acoustic model architecture, we used a fully connected deep neural network (DNN) from the open-source Kaldi toolkit (Povey et al., 2011), shown to achieve strong performance in prior studies (Morris et al., 2021; Georgescu et al., 2019; Miao et al., 2015). In particular, for small corpora, the DNN architecture has been demonstrated to yield better results than statistical alternatives (e.g., subspace Gaussian mixture models) and other neural architectures (e.g., time delay neural networks) (Morris, 2021). We also found the DNN to be substantially more accurate than the endangered language end-to-end recipe (Shi et al., 2021) in ESPnet (Watanabe et al., 2018).[1] Crucially, however, we note that our goal is not to improve upon current state-of-the-art for low-resource ASR but rather to examine what data partitioning strategies and evaluation methods lead to reliable estimates in low-resource settings with an already strong model architecture.

4.3 Regression analysis

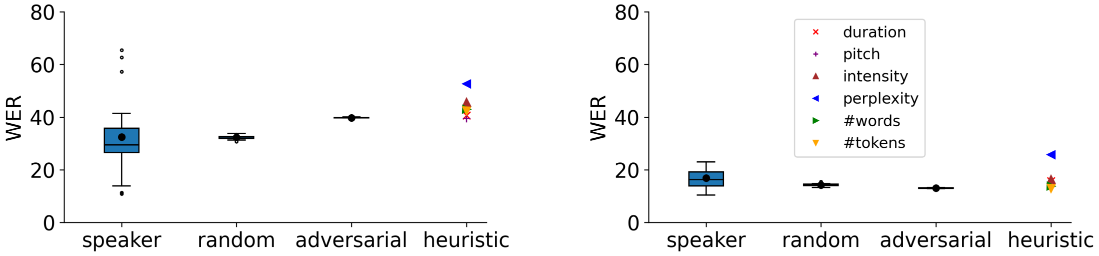
To understand which features of the splits contribute to WER variability, we carried out regression analysis. Given each data split, we first collected the following five heuristics for *each utterance* in the test set: utterance duration, average pitch, average intensity, utterance perplexity, and out-of-vocabulary (OOV) rate. Second, we computed the *average* value of each of the features for the training set as a whole. Third, we normalized the value of each feature for every utterance in the test set by the average value of the feature derived from the training set, to account for training set characteristics as well. This yielded a reasonable data size for regression modeling for each language (ranging from 6,248 instances for the verified data of Hupa to 85,920 instances for Wolof; see Anderson et al. (2021)). After repeating these steps for all data splits, we fit regression models predicting the WER of every utterance in the test set as a function of these characteristics, while controlling for the number of tokens and types in the utterance and the data split method. When possible, speaker identity and the specific utterance were included as random effects, both with random intercept and slopes for each of the fixed effects. The final regression structure was determined via backward stepwise regression from the maximal mixed-effect structure (Barr et al., 2013).

5 Results

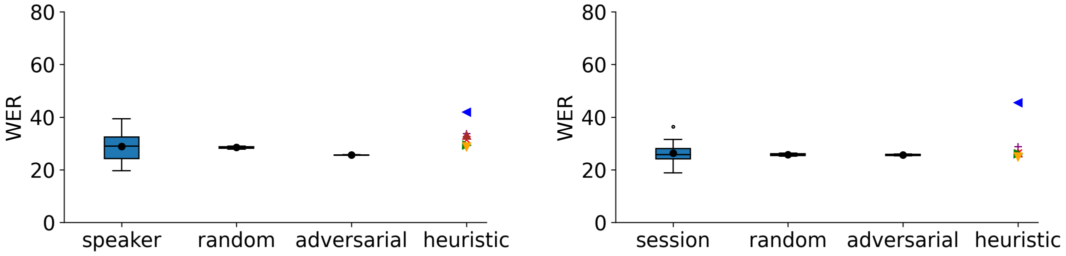
We first consider the degree of variability in WER depending on which speaker is held out. In Figure 1, for Fongbe, Wolof, and Iban, we see a high degree of variability. The WER range across held-out speakers spans from 12.71 for Iban to 54.74 for Fongbe. (See Table 3 in Appendix A.3.) Perhaps surprisingly, for Swahili and Hupa, where we held out recording sessions rather than individual speakers, we also observe great variability in model performance. The WER range across sessions is 17.59 for Swahili and is above 25 for both data sets

---

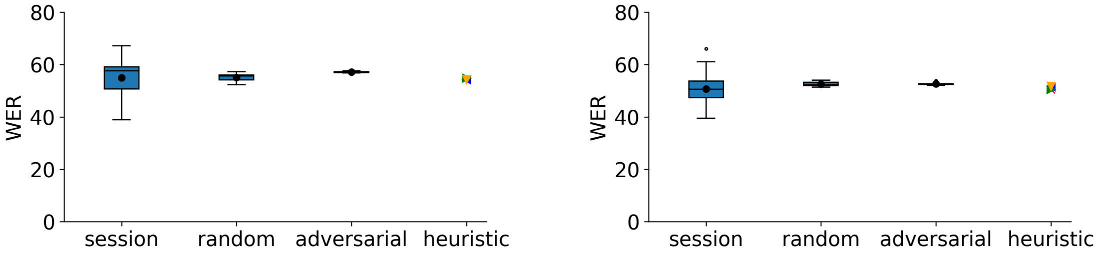
[1] Our experiments using ESPnet and wav2vec 2.0 to fine-tune from multilingual models yielded inconsistent and weak results. The necessary parameter tuning within these architectures is left for future work.



(a) Fongbe (b) Iban



(c) Wolof (d) Swahili



(e) Hupa (verified) (f) Hupa (coarse)

Figure 1: WER for the various partitioning strategies for the six data sets. A large black dot represents the mean in each plot. Means for hold-session/speaker-out are comparable in all cases to means over random splits.

of Hupa. Thus it does not appear to be the case that variability in WER is due entirely to the identity of the speaker; other factors such as recording setting or domain could contribute to this variability. These observations speak to our original point, namely that observations from "hold speaker(s) out" low-resource ASR evaluation are not representative of the model's generalizability.

One might suspect that the observed WER variability across speakers in each data set is (*only*) because of the varying amount of audio available for each speaker. Although there is a relationship between average WER and the total utterance duration per speaker (when looking at total utterance duration as a sole predictor in the regression) for Iban ($p < 0.005$), this relationship does not hold for Fongbe ($p = 0.75$) or Wolof ($p = 0.91$). While there is a positive correlation between duration and WER for the coarse data of Hupa ($p < 0.05$), this correlation does not exist for Swahili ($p = 0.45$) or for the verified data of Hupa ($p = 0.99$). This indicates that the total utterance duration *alone* is not enough to yield (high) WER variability across speakers.

In contrast, results from random splits are much less variable. While not surprising, this is notable in that the average WER when holding out a speaker or session is comparable to that of random splits, or any one random split. Thus a single random split can alone be enough to provide a reasonable estimate of the performance that would be derived by averaging over all random splits or over all possible held-out speakers/sessions. In contrast, the WER for a model tested on single held-out speaker/session may not be a reliable estimate of the WER of that model on any other speaker.

On the other hand, splitting data heuristically and adversarially, creating test sets that consist of "more challenging" cases than the training sets, does not necessarily lead to higher WER. The results across the data split methods are mostly comparable except for when utterance duration or

Table 2: Regression results for the data set(s) of each language in our experiments (CI stands for Confidence Interval); the number of * indicates significance level: * $p < 0.05$, ** $p < 0.01$, *** $p < 0.001$. Note that given the structure of our regression model, the coefficient value for the same feature is *not comparable* across the data for each language (e.g., the coefficient of utterance duration ratio is 0.33 for the Wolof data, and 0.13 for the Swahili data; nevertheless, this does not mean that utterance duration ratio has a stronger effect for Wolof compared to its role for Swahili). Rather our goal is simply to see whether a feature potentially influences WER scores when the effects of other features are controlled for within the context of the data for every language.

perplexity is used as the heuristic in certain cases. Splitting the data by maximizing transcript distribution distance also yields minimal variability.

The regression analysis (Table 2) further indicates that most of the features we investigated have significant effects on performance. The ratios of utterance duration and intensity between the train and test sets consistently play strong roles in predicting WER variability. The fact that utterance duration has an effect on WER *when controlling for the effects of other factors* points to the potential limitation of evaluating models with held-out speakers in low-resource settings, where speakers contribute varying amounts of data.

6 Discussion and Conclusion

With data for four widely-spoken low-resource languages and one critically endangered language indigenous to North America, our work demonstrates that there is a real risk of grossly over- or underestimating the performance of an ASR model architecture when evaluating on held-out speakers (and sessions) when only minimal resources are available. By contrast, random splits provide a more accurate and less variable estimate of the overall performance. Moreover, while cross-validation is advisable when partitioning by speaker, a single random split appears to provide an adequate estimate for expected WER on unseen data.

We note that these findings also hold for data sets partitioned according to recording session rather than speaker, suggesting that this phenomenon is not limited to diversity in speaker characteristics. This has implications particularly for ASR in support of endangered language documentation, in which the number of speakers is few but the recording conditions are highly variable. We propose that future work on small ASR corpora for under-resourced languages carry out multiple evaluations on various data partitioning strategies in order to present a more complete picture of ASR model architecture performance.

7 Limitations

Our work has two notable limitations. First, the limited availability of very small ASR datasets allowed us to explore only five languages. It remains to be seen how different data splits would interact with a much larger set of languages that have more diverse typological properties. Second, here we experimented with a hybrid DNN architecture within Kaldi rather than more recent end-to-end approaches (Lin and Mak, 2020; Watanabe et al., 2018), which require more extensive computing resources. Resource permitting, we would like to investigate how different data partitioning strategies would work differently (or not) with different model architectures.

Acknowledgements

We are grateful for the continued support from the Hupa indigenous community. We would like to especially thank Mrs. Verdena Parker for her generous and valuable input for the documentation work of Hupa throughout the years. In addition, we thank the anonymous reviewers for their helpful feedback. This material is based upon work supported by the National Science Foundation under Grant #2127309 to the Computing Research Association for the CIFellows Project, and Grant #1761562. A Appendix

A.1 Data for Hupa

The majority of the recordings for Hupa feature the elder telling stories from different genres, including traditional stories that explain how the world we know today came to be, personal anecdotes from her life, and oral-historical accounts of significant events in her speech community. Each recording has a time-aligned transcription produced by a human transcriber using annotation tools (e.g., ELAN (Brugman and Russel, 2004)); each transcript was rendered in a practical orthography currently adopted by the speech community.

The verified transcriptions for Hupa are more accurate overall than coarse transcriptions and have undergone more orthographic normalization. This includes removing things that are audible in the recordings but not part of the standardized spelling (such as word-final epenthetic vowels), and removing false starts and other speech errors. In a small number of cases, verified transcriptions might even contain a word that is different from what was produced in the original recording, if the elder felt strongly that she had misspoken. Thus, although verified transcriptions tend to be more accurate than coarse ones, in some ways they are less faithful to the acoustic properties of the original recordings.

A.2 Acoustic models

Except for Swahili and Hupa, acoustic feature transformations for the data of the other languages were conducted separately for each speaker. In detail, the recordings were transformed to the standard 13 dimensional mel-frequency cepstral coefficients (MFCCs), along with their delta- and delta-delta features. The delta- and delta-delta features are, respectively, numerical approximations of the first and second-order derivatives of the MFCCs and they were computed on a 25ms window with 10ms interval apart, allowing for modeling of the trajectories of the audio signals. Linear Discriminant Analysis and Maximum Likelihood Linear Transform were applied to reduce the dimensionality of the feature vectors. Speaker Adaptive Training was adopted to perform speaker and noise normalization in order to make the acoustic model more attentive to the phonemic variation present in the audio, rather than being restricted by the data of particular speakers. With the speaker-normalized features, Feature Space Maximum Likelihood Linear Regression (FMLLR) was employed for speaker-independent alignment.

The DNN we adopted had six hidden layers with 1024 units in each. Sequence training was performed using the default parameters in Kaldi with state-level minimum Bayes risk criterion and a per-utterance Stochastic Gradient Descent weight update. Decoding was carried out with the Kaldi finite state transducer-based decoder.

A.3 Full WER results

Table 3 includes the full set of WER for every data partitioning strategy for each of the five languages. which is represented visually in Figure 1.

Table 3: WER results for the data set(s) of each language in our experiments; as we are focused on data partitioning strategy, for all data splits of a given data set, the language model was constant and was trained only on additional written texts. Note that one might be concerned about how much overlap there is between the test sets (and the training sets accordingly) yielded from different data partitioning strategies other than using held-out speaker/session; to address this, for the data set(s) of each language, we used the test set of the first random split as the reference and computed the proportion of overlapping utterances from the test sets of other data splits (except for held-out speaker/session); the maximum overlapping ratio across all the data sets was 0.25.

Shortcomings of Question Answering Based Factuality Frameworks for Error Localization

Ryo Kamoi **Tanya Goyal** **Greg Durrett**
Department of Computer Science
The University of Texas at Austin
`ryokamoi@utexas.edu`

Abstract

Despite recent progress in abstractive summarization, models often generate summaries with factual errors. Numerous approaches to detect these errors have been proposed, the most popular of which are question answering (QA)-based factuality metrics. These have been shown to work well at predicting summary-level factuality and have potential to localize errors within summaries, but this latter capability has not been systematically evaluated in past research. In this paper, we conduct the first such analysis and find that, contrary to our expectations, QA-based frameworks fail to correctly identify error spans in generated summaries and are outperformed by trivial exact match baselines. Our analysis reveals a major reason for such poor localization: questions generated by the QG module often inherit errors from non-factual summaries which are then propagated further into downstream modules. Moreover, even human-in-the-loop question generation cannot easily offset these problems. Our experiments conclusively show that there exist fundamental issues with localization using the QA framework which cannot be fixed solely by stronger QA and QG models.

1 Introduction

Although abstractive summarization systems (Rush et al., 2015; See et al., 2017; Lewis et al., 2020) have improved drastically over the past few years, these systems often introduce factual errors into generated summaries (Cao et al., 2018; Kryscinski et al., 2019). Recent work has proposed a number of approaches to detect these errors, including using off-the-shelf entailment models (Falke et al., 2019; Laban et al., 2022), question answering (QA) models (Chen et al., 2018; Wang et al., 2020; Durmus et al., 2020), and discriminators trained on synthetic data (Kryscinski et al., 2020). Such methods have also been explored to identify error spans within summaries (Goyal and Durrett, 2020) and perform post-hoc error correction (Dong et al., 2020; Cao et al., 2020).

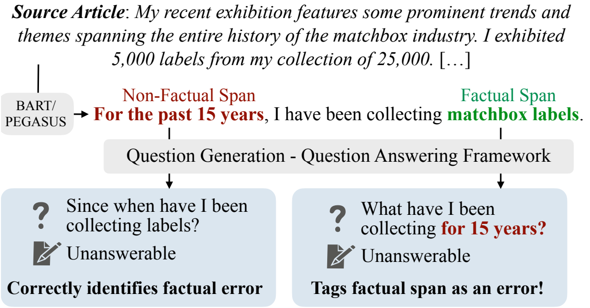

Figure 1: Factual error localization using QA metrics. Questions are generated for summary spans and then answered by a QA model using the source article as context. For factual spans (e.g. *matchbox labels*), we expect the predicted answers to match the original spans. However, non-factual spans in generated questions inherited from summaries may render these unanswerable and lead to incorrect error localization.

Among these different approaches for evaluating factuality, QA-based frameworks are the most widely adopted (Chen et al., 2018; Scialom et al., 2019; Durmus et al., 2020; Wang et al., 2020; Scialom et al., 2021; Fabbri et al., 2022). These evaluate the factuality of a set of spans in isolation, then combine them to render a summary-level judgment. Figure 1 illustrates the core mechanism: question generation (QG) is used to generate questions for a collection of summary spans, typically noun phrases or entities, which are then compared with those questions' answers based on the source document to determine factuality. Due to this span-level decomposition of factuality, QA frameworks are widely believed to localize errors (Chen et al., 2018; Wang et al., 2020; Gunasekara et al., 2021). Therefore, the metrics have been applied in settings like post-hoc error correction (Dong et al., 2020), salient (Deutsch and Roth, 2021) and incorrect (Scialom et al., 2021) span detection, and text alignment (Weiss et al., 2021). However, their ac-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 132–146
May 2-6, 2023 ©2023 Association for Computational Linguistics

tual span-level error localization performance has not been systematically evaluated in prior work.

In this paper, we aim to answer the following question: **does the actual behavior of QA-based metrics align with their motivation?** Specifically, we evaluate whether these models successfully identify error spans in generated summaries, independent of their final summary-level judgment. We conduct our analysis on two recent factuality datasets (Cao and Wang, 2021; Goyal and Durrett, 2021) derived from pre-trained summarization models on two popular benchmark datasets: CNN/DM (Hermann et al., 2015; Nallapati et al., 2016) and XSum (Narayan et al., 2018). Our results are surprising: **we find that good summary-level performance is rarely accompanied by correct span-level error detection.** Moreover, even trivial exact match baselines outperform QA metrics at error localization. Our results clearly show that although motivated by span-level decomposition of the factuality problem, the actual span-level predictions of QA metrics are very poor.

Next, we analyze these failure cases to understand why QA-based metrics diverge from their intended behavior. We find that the most serious problem lies in the question generation (QG) stage: generated questions for non-factual summaries inherit errors from the input summaries (see Figure 1). This results in poor localization wherein factual spans get classified as non-factual due to presupposition failures during QA. Furthermore, we show that such inherited errors cannot be easily avoided: decreasing the length of generated questions reduces the number of inherited errors, but very short questions can be under-specified and not provide enough context for the QA model. In fact, replacing automatic QG with human QG also does not improve the error localization of QA metrics. These results demonstrate fundamental issues with the current QA-based factuality frameworks that cannot be patched by stronger QA/QG methods.

Our contributions are as follows. (1) We show that QA-based factuality models for summarization exhibit poor error localization capabilities. (2) We provide a detailed study of factors in QG that hamper these models: inherited errors in long generated questions and trade-offs between these and short under-specified questions. (3) We conduct a human study to illustrate the issues with the QA-based factuality framework independent of particular QA or QG systems.

2 QA-Based Factuality Metrics

Recent work has proposed numerous QA-based metrics for summarization evaluation, particularly factuality (Chen et al., 2018; Scialom et al., 2019; Eyal et al., 2019; Durmus et al., 2020; Wang et al., 2020; Deutsch and Roth, 2021). These proposed metrics follow the same basic framework (described in Section 2.1), and primarily differ in the choice of off-the-shelf models used for the different framework components (discussed in Section 2.2).

2.1 Basic Framework

Given a source document D and generated summary S, the QA-based metrics output a summary-level factuality score y_S that denotes the factual consistency of S. This includes the following steps (also outlined in Figure 2):

1. **Answer Selection**: First, candidate answer spans $a_i \in S$ are extracted. These correspond to the base set of *facts* that are compared against the source document D. Metrics evaluated in this work (Scialom et al., 2021; Fabbri et al., 2022) consider all noun phrases and named entities in generated summaries as the answer candidates set, denoted by $span(S)$.
2. **Question Generation**: Next, a question generation model (G) is used to generate questions for these answer candidates with the generated summary S as context. Let $q_i = G(a_i, S)$ denote the corresponding question for span a_i.
3. **Question Filtering**: Questions for which the question answering (A) model's predicted answer $A(q_i, S)$ from the summary does not match the original span a_i are discarded, i.e., when $a_i \neq A(q_i, S)$. This step is used to ensure that the effects of erroneous question generation do not percolate down the pipeline; however, answer spans that do not pass this phase cannot be evaluated by the method.
4. **Question Answering**: For each generated question q_i, the A model is used to predict answers using the source document D as context. Let $p_i = A(q_i, D)$ denote the predicted answer.
5. **Answer Comparison**: Finally, the predicted answer p_i is compared to the expected answer a_i to compute a similarity score $sim(p_i, a_i)$. The overall summary score y_S is computed by averaging over all span-level similarity scores:

$$y_S = \frac{1}{|span(S)|} \sum_{a_i \in span(S)} sim(A(q_i, D), a_i)$$

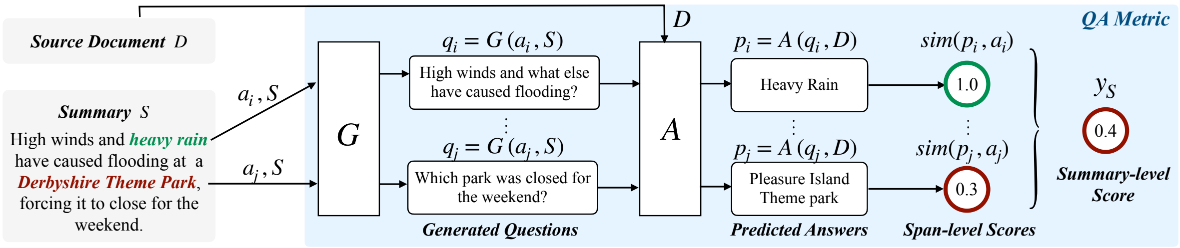

Figure 2: Overall workflow for the QA metrics. First, questions are generated for all NEs and NPs in the generated summary. Answers to these questions are obtained from the source document. Then, a factuality score is computed for each summary span based on it similarity with the predicted span from the previous step. Finally, all span-level scores are aggregated to obtain the final summary-level factuality.

Based on the motivation behind QA metrics, these similarity scores $sim(p_i, a_i)$ should indicate the factuality of the corresponding spans. If span a_i is factual, then the $G - A$ pipeline should output $p_i \in D$ with high similarity to a_i. Conversely, if a_i is non-factual, the similarity score $sim(p_i, a_i)$ should be low. While prior research has only evaluated their sentence-level performance, we use these span-level factuality scores to additionally evaluate the localization performance of QA metrics.

2.2 QA Metrics compared

In this work, we focus our analysis on the two best performing QA-based metrics from prior work:

QuestEval (QE) Scialom et al. (2021) generate questions for answer spans extracted from both the summary ("precision questions") and source document ("recall questions"). We only use the former in our experiments as these are shown to correlate better with factuality. Both the A and G components of QuestEval use T5-Large models (Raffel et al., 2020) fine-tuned on question answering datasets (Rajpurkar et al., 2018; Trischler et al., 2017). The similarity score $sim(p_i, a_i)$ in this framework is computed as the average of the lexical overlap, BERTScore, and the answerability score predicted by A.

QAFactEval (QAFE) Fabbri et al. (2022) conduct an ablation study over the different combinations of available A and G models. Here, we use their best-performing combination: an ELECTRA-based A model and a BART-based G model fine-tuned on the QA2D dataset (Demszky et al., 2018). The $sim(p_i, a_i)$ score is obtained using the learned metric LERC (Chen et al., 2020). If $A(q_i, D)$ is unanswerable for span a_i, QAFactEval sets the similarity score $sim(\_, a_i) = 0$ instead of using the LERC metric.

3 Experimental Setup

3.1 Task Definition

Given document D and a generated summary S, let $y_S^* \in \{0, 1\}$ denote the gold summary-level factuality label. Additionally, we assume access to $L = \{(a, y_a^*)\}$ which denotes the set of spans $a \in span(S)$ and their corresponding span-level gold factuality labels $y_a^* \in \{0, 1\}$.

First, we evaluate the **summary-level performance** of factuality models, i.e., is the predicted factuality equal to the gold factuality judgment y_S^*? To do this, we covert the predicted factuality score y_S to a binary judgment using dataset-specific thresholds. For each factuality model evaluated, we select thresholds that yield the best F1 scores on the validation set on each dataset.

Next, we evaluate the **span-level (localization) performance** of factuality models. Similar to the previous setting, we convert span-level predictions y_a to binary labels using the best-F1 threshold derived from the validation set. We report the macro-averaged performance at correctly predicting the span-level label y_a^* $\forall a \in span(S)$ across all (D, S) pairs in the evaluation dataset.

To align with the current QA frameworks, we restrict our evaluation to spans that correspond to named entities and noun phrases. This takes a generous view of the QA metrics' performance as it does not penalize them for failing to identify factual-errors outside NPs and NEs. This setting allows us to study the fundamental issues with the QA framework instead of those that can potentially be addressed by extending the question types considered in the framework.

Note that even for NP and NE spans, sometimes the QA metric does not return a span-level prediction if the span has not been selected as an answer candidate or has been discarded during the question filtering phase. We assume the predicted label $y_a = 1$ for such spans, as the model failed to detect any errors.[1] We discuss the performance loss due to this additional filtering step in Appendix C.

3.2 Datasets

We conduct our analysis on two human-annotated factuality datasets from prior work that provide gold annotations of factuality at the token level. To the best of our knowledge, these two are the only datasets that include span-level factuality annotation for summaries generated by SOTA models.

CLIFF (Cao and Wang, 2021) is a dataset consisting of summaries generated by BART (Lewis et al., 2020) and PEGASUS (Zhang et al., 2020) models trained on the XSum and CNN/DM summarization datasets. For each generated summary, the dataset includes token-level factuality labels $y_t^* \in \{0, 1\}$. For $y_t^* = 0$, these are additionally labeled with fine-grained error types: extrinsic, intrinsic, or requiring world knowledge.

GD21 (Goyal and Durrett, 2021) contains XSum summaries generated using a fine-tuned BART model. Similar to CLIFF, it contains token-level factuality labels for all generated summaries.

Deriving gold summary- and span-level factuality labels from human annotations To derive the summary-level gold label y_S^* from these token-level human annotations, we set $y_S^* = 1$ iff all tokens are factual, i.e. $y_t^* = 1 \; \forall t \in S$. To derive span-level gold labels, for each NP/NE span a, we set $y_a^* = 1$ iff all tokens $t \in a$ are factual.

We construct validation and test sets by dividing each dataset into equal subsets. The statistics for the test set are included in Table 1. It shows that ~26% of non-factual tokens do not correspond to NEs or NPs and are therefore ignored by the QA metrics' evaluation pipeline. Also, note that the error statistics differ for the XSum summaries in GD21 and CLIFF due to the differences in the annotation methodologies and the trained models used (both BART and PEGASUS in CLIFF vs only BART in GD21).

Label Gran.	Metric	GD21	CLIFF	
		XSum	C/D	XSum
Summ.	Total	46	150	150
	% Non-Factual	52.2	15.3	70.7
Span	# per summary	7.9	15.3	5.4
	% Non-Factual	9.9	1.9	28.1
Token	# per summary	17.1	31.6	13.1
	% Non-Factual	8.8	1.7	24.5
	% Ignored (Non-Factual)	28.9	24.5	27.6

Table 1: Test set statistics for CLIFF and GD21 at different levels of label granularity. All our evaluation is done at the summary- and span-levels to align with the QA metrics' formulation. We convert the token-level human annotations to span-level to achieve this. The table reports the % of non-factual tokens outside NE/NPs that are ignored by the QA metrics' evaluation pipeline.

3.3 Baselines for Comparison

Exact Match Baseline (EM) first extracts all nouns, proper nouns, numbers, adjectives, and pronoun tokens from the generated summary S. For these tokens, we set $y_t = 1$ if $y_t \in D$, else $y_t = 0$. We use the fraction of tokens predicted as factual as a summary-level score.

Dependency-Arc Entailment (DAE) Goyal and Durrett (2020) evaluate the factuality of each dependency arc in generated summaries separately. We follow the methodology proposed by Goyal and Durrett (2021) to derive both summary- and token-level factuality scores from these arc-level judgments. We refer readers to the original paper for further details. We use their available model checkpoint in our experiments.[2]

We convert token-level judgments from these baseline models into span-level judgments to make their outputs compatible with our evaluation framework. This is described in detail in Appendix A.3.

4 Summary vs. Span Level Performance

QA metrics motivate the use of span-level factuality as building blocks for evaluating factuality at the sentence level. Therefore, **our hypothesis is that good summary-level performance must be accompanied by good span-level performance**. Here, we test this by comparing summary- and span-level performances.

Figure 3 outlines the performance of QA metrics and baseline systems. The top row shows ROC

---

[1] Operationally, we set $sim = 6.0$ for QAFactEval and $sim = 1.0$ for QuestEval for filtered spans.

[2] Code and trained model checkpoint provided by authors at: `https://github.com/tagoyal/factuality-datasets`

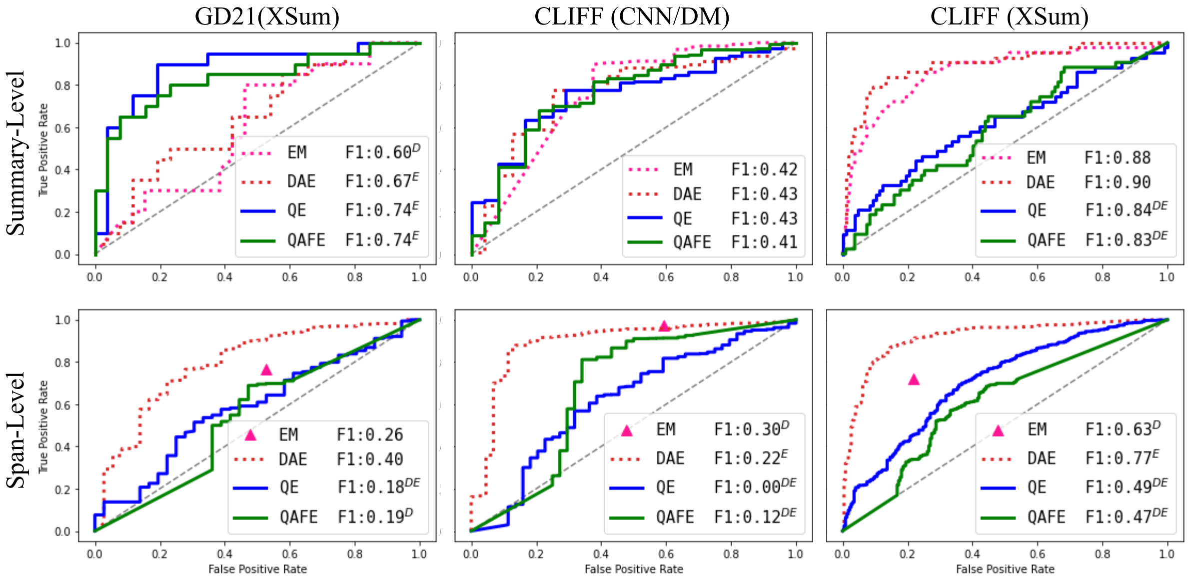

Figure 3: ROC curves and F1 scores (legend) for all systems at the summary- and span-levels (EM is a point as it provides hard binary judgments). Here, ^{D} (or ^{E}) denotes that the performance difference with DAE (or EM) is statistically significant according to a paired bootstrap test (p-value < 0.05). We observe that for QA metrics, good summary-level performance (e.g. on GD21 and CLIFF (CNN/DM)) does not imply good localization performance.

curves and F1 scores (in the legend) for all three datasets; the bottom row shows span-level results. The dotted black lines show the performance of a random baseline. First, we observe that none of the baselines or QA metrics have a clear advantage over other systems for all datasets at the summary-level. For instance, QA metrics outperform baselines on GD21, and show similar performance on CLIFF (CNN/DM) and worse performance on the CLIFF (XSum) dataset. However, **across all datasets, we see that there exists a substantial mismatch between the performance of QA metrics at the summary- and span-levels.** Notably, for GD21, both QE and QAFE substantially outperform baseline models at the summary-level, but exhibit much poorer span-level performance. Similarly, QA metrics are comparable to baselines at the summary-level for CLIFF (CNN/DM) but much worse at the span-level. On the other hand, the error localization performance of the DAE model is more consistent with its summary-level performance. Surprisingly, the trivial **exact match (EM) baseline consistently outperforms QA metrics at error localization for all datasets**. These results clearly show that our hypothesis is false: QA-based metrics do not provide reliable span-level explanations for their summary-level predictions.

Note that the diagonal lines in the span-level ROC curves for QA metrics arise due to a large number of spans being assigned the same factuality scores. As discussed in Section 2.1, some spans are filtered during the question filtering stage (Step 3) if their corresponding generated questions are of low quality. We consider these to be factual and assign them the maximum factuality score; this results in the diagonal line from $(0, 0)$.[3] We study the effects of this span filtering on localization performance in Appendix C. Additionally, QAFE assigns the same factuality score ($= 0$) to all spans with unanswerable questions resulting in the diagonal line to $(1, 1)$.

5 Why do QA metrics fail at span-level error localization?

Consider the error localization task in the example in Figure 1. Here, the QA metric needs to correctly distinguish between the factual span "*matchbox labels*" and the extrinsic error "*for the past 15 years*". For such summaries (containing a mix of factual and non-factual spans), we observed that the generated questions for factual spans often **inherit** non-factual summary spans. Given such questions, e.g. "*What have I been collecting for 15 years?*", an ideal QA model ***should*** predict unanswerable (even though that hurts localization) as the source article does not include any mention of an item being collected for 15 years. Based on this obser-

---

[3] Note that QE generates multiple questions for each span and therefore rarely discards spans (it is not likely that all questions are bad). Therefore, it has a shorter diagonal line.

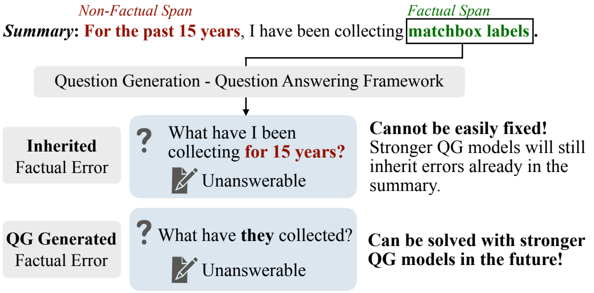

Figure 4: Generated questions broadly include two types of errors: (1) inherited errors that copy non-factual spans from the summary, and (2) errors introduced by imperfect QG models. While this latter set of errors may be eliminated by stronger QG models, inherited errors cannot be easily fixed.

vation, we hypothesize that such inherited errors in generated questions adversely affect the localization performance of automatic QA metrics by misclassifying factual spans.

First, we draw a clear distinction between (1) errors inherited from summaries, and (2) those introduced due to generation errors by the QG model. Figure 4 illustrates these two separate cases. We note that the latter set of errors can potentially be addressed by stronger QG models in the future. Our analysis in this section only studies the former set, i.e. inherited errors, as these will persist independent of the improvement in QA/QG models.

What percentage of questions are impacted by inherited errors? First, we determine the scope of the limitation introduced by inherited errors. Table 2 outlines how frequently generated questions contain inherited errors; we report these numbers only for the non-factual summaries as only these are affected by inherited errors. We define errors in a summary as inherited when a question copies at least one token that is annotated as non-factual. We use error type labels (extrinsic or intrinsic) present in the CLIFF and GD21 datasets to report separate numbers for these phenomena[4]. For the CLIFF dataset, we include world knowledge errors within the extrinsic type. In general, we observe that inherited errors are more common in QAFactEval compared to QuestEval; this can be attributed to the longer length questions generated by the former (see Appendix B for details).

QA Metric	Type of Inherited Error	GD21	CLIFF	
		XSum	C/D	XSum
QuestEval	extrinsic error	19.2	9.1	44.8
	only intrinsic error	25.7	17.3	3.6
QAFactEval	extrinsic error	39.1	11.1	93.1
	only intrinsic error	48.9	34.2	6.0

Table 2: Percentage of questions that inherit extrinsic and intrinsic errors from summaries. We only consider non-factual summaries, i.e., summaries containing at least one non-factual span in this table.

QA Metric	Type of Inherited Error	GD21	CLIFF	
		XSum	C/D	XSum
QuestEval	extrinsic error	3.1	93.9	30.5
	only intrinsic error	9.3	97.3	50.0
	no inherited error	15.5	98.7	56.0
QAFactEval	extrinsic error	7.7	65.4	63.8
	only intrinsic error	29.2	82.0	40.0
	no inherited error	29.3	92.8	65.4

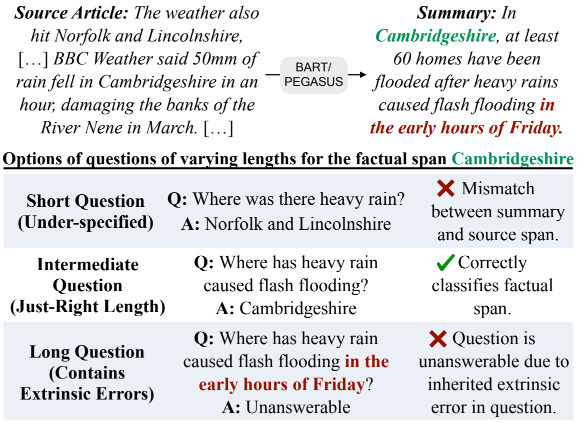
Table 3: Percentage of factual spans correctly classified by QA metrics, i.e. $y_t = y_t^* = 1$. We use the same thresholds as for F1 scores in Figure 3. Results show that inherited errors lead to more erroneous classification as non-factual across all datasets.

Do inherited errors in generated questions hurt factuality prediction? To answer this, we zoom in on factual spans in generated summaries (we consider *both* factual and non-factual summaries here), and investigate how often these are erroneously classified as non-factual. We report this for three different scenarios: (1) w/ inherited extrinsic error, (2) w/ inherited intrinsic errors only, and (3) w/o any inherited error. Table 3 outlines our results. We observe that across all settings, factual spans with inherited errors in their corresponding questions are more likely to be erroneously classified as non-factual compared to those with no inherited errors. Between error types, we observe that extrinsic inherited errors tend to harm localization more than intrinsic errors.

Note that inherited errors are only observed for summaries that are *already non-factual*. Therefore, erroneous classification of factual spans as non-factual hurts span-level but does *not* hurt summary-level performance. In fact, Fabbri et al. (2022) show that longer questions (which typically inherit more extrinsic errors, but do not cause summary-level error) exhibit better summary-level performance compared to shorter questions (which can be under-specified and cause summary-level error). This indicates that there exists a trade-off in perfor-

---

[4] Generated questions can inherit both types of errors. In the tables in this section, "extrinsic error" denotes questions that inherit at least one extrinsic error, but "only intrinsic error" denotes questions that only inherit intrinsic errors.



Short Question (Under-specified)	**Q:** Where was there heavy rain? **A:** Norfolk and Lincolnshire	✗ Mismatch between summary and source span.
Intermediate Question (Just-Right Length)	**Q:** Where has heavy rain caused flash flooding? **A:** Cambridgeshire	✓ Correctly classifies factual span.
Long Question (Contains Extrinsic Errors)	**Q:** Where has heavy rain caused flash flooding **in the early hours of Friday**? **A:** Unanswerable	✗ Question is unanswerable due to inherited extrinsic error in question.

Figure 5: Specificity and lengths of generated questions affect the answers from QA models and confuse span-level evaluation. While "*Cambridgeshire*" is a factual span, questions with inappropriate specificity can cause QA models to make mistakes. It is impossible to know what length of question is "just right" during question generation.

mance between these different granularity levels.

Can we avoid inherited errors in generated summaries? Since we do not have prior knowledge of which spans in summaries contain factual errors, we cannot trivially ensure that generated questions do not inherit the errors. One possible strategy could be to generate very short questions that include minimal details from the summary to avoid inheriting non-factual spans from the summary. However, these may then suffer from being too under-specified. We illustrate this in Figure 5. Consider the factual span "*Cambridgeshire*". The shortest question in the figure "*Where was there heavy rain?*" is not under-specified for the summary, since it is the only place name in the summary. However, there are multiple possible answers in the source document, and QA models may *reasonably* answer "*Norfolk and Lincolnshire*", leading to erroneous classification of "*Cambridgeshire*" as non-factual. Therefore, **there exists a trade-off between under-specified (short) questions and over-specified (long) questions** and it is difficult to predict the optimal level of specificity. This problem cannot be addressed by improving QA models; an ideal QA model will return unanswerable to questions with inherited errors and will be still confused by under-specified questions. We explore this issue further using human question generation in Section 6.

6 Can Human QG Improve Localization?

In Section 5, we discussed how the number of inherited errors can be indirectly influenced by varying the length of generated questions and the accompanying trade-offs: longer questions are more likely to inherit errors but shorter questions may be under-specified. Here, we investigate this using perfect QG, i.e., replacing automatic QG with humans. We evaluate two aspects: (1) How does question length impact localization? (2) Does human QG improve localization?

6.1 Experiment Design

For each summary and candidate span pair (S, a_i), we obtain human-written questions of varying lengths and information content.[5] Then, we replace the QG module of QAFactEval with these human-written questions to study the effect of question length on error localization performance.[6]

Annotators generate 3 types of questions:

1. **Shortest possible question** such that given the question-summary pair, humans can unambiguously identify the correct span in the summary.
2. **Longest question** incorporating as much information from the generated summary as reasonably allowed, often including almost an entire summary sentence.
3. **Intermediate questions** with levels of information content between the above two extremes. We allow annotators to generate any number of such intermediate questions.

Annotation and Setup We conduct this experiment on 150 randomly selected summaries from the CLIFF dataset. For the CNN/DM subset, we only selected non-factual summaries, since CNN/DM contains a small number of non-factual spans. Human annotators manually generated 2,186 questions (please refer to Appendix D for details).[7] We use half of the summaries as validation sets.

We evaluate localization performance using 4 different length configurations for human-written questions: short, long, intermediate, and oracle.

---

[5] Question lengths could also be varied if we used distinct automatic QG models, but by choosing human QG, we avoid conflating the impact of varying question specificity/length with errors or other performance differences in models.

[6] We also considered using human QA; however, we found that the QA task is ill-defined for humans when questions themselves contain extrinsic errors. Fabbri et al. (2022) also show that QA performance has less impact on factuality.

[7] Human generated questions are provided at: https://github.com/ryokamoi/QA-metrics-human-annotation

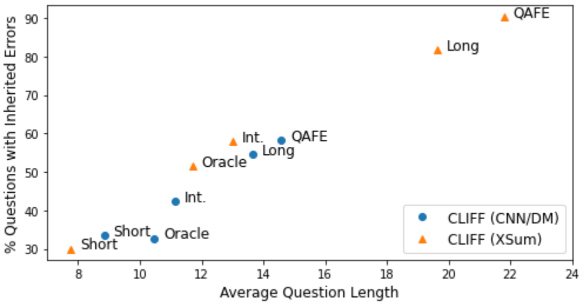


Figure 6: Statistics for questions generated by human annotators and QAFactEval (QAFE). "% Questions with Inherited Errors" is the percentage of questions that inherit non-factual spans from non-factual summaries. As expected, longer questions are more likely to inherit factual errors from the generated summaries.

For intermediate questions, evaluation is always done over three questions. We randomly subsample (or over-sample) from this set if more (or fewer) than three are available and report their average performance. If no intermediate question is written, we randomly sample from the other two categories. This only happens when the length difference between the shortest and longest questions is small. For the oracle setting, we report results using the question for each span that leads to the best localization performance. In other words, we use the highest scoring question for factual spans and the lowest for non-factual spans.

6.2 Results

Figure 6 outlines statistics for questions generated by human annotators and the QG model of QAFactEval (QAFE) generated for the same spans. As expected in Section 5, it shows that the percentage of questions that inherit non-factual spans in summaries increases with length. In this figure, we only analyze non-factual summaries since questions generated for factual summaries do not inherit errors. This result verifies our assumption and shows that we can analyze a trade-off between long questions that tend to inherit more non-factual spans from summaries and short questions with fewer inherited errors but can be under-specified.

Error Localization Figure 7 outlines the span-level localization performance for these different human question configurations and the QG model of QAFactEval. First, we notice that **human QG does not improve the localization performance of the QA frameworks**, with all three configurations exhibiting similar performance to the fully automatic QAFactEval (QAFE) model. **However, the *oracle* questions report significant improvement over QAFactEval**; this indicates that while there does exist an optimal length question for most spans, there isn't a clear pattern that can help select it during evaluation. We again note that it is not possible to select an optimal question length for each span without prior knowledge about errors in summaries. We conclude that the overall failure of human QG to improve over QAFactEval suggests that there exist fundamental issues with the QA-based factuality formulations which cannot be simply fixed by stronger QG models.

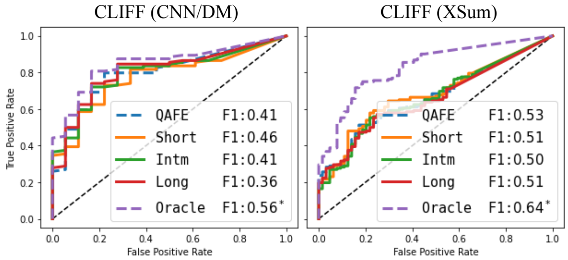

Figure 7: ROC curves and F1 scores (in legend) for span-level performances using human-written questions. These results show that no single question length configuration (except oracle) can outperform automatic QG. * denotes that improvement over QAFactEval is statistically significant (paired bootstrap test, p-value < 0.05).

7 Discussion

Analysis in our paper suggests that QA-based metrics have fundamental problems which will be difficult to address in future work. **Our view is that future system designers should favor entailment-based approaches (Falke et al., 2019; Laban et al., 2022) as a result.** One reason for this is that successful QA-based approaches actually implement something similar to entailment. Both our analysis and Fabbri et al. (2022) show that we can improve summary-level performance by generating long questions to avoid underspecified questions. However, answering questions that contain almost all the information about a sentence can be regarded as a weak form of entailment evaluation: it assesses whether the question-answer pairs that include all information about the sentence are entailed by the original document. Compared to entailment, the answer comparison step can introduce difficulties and long questions may still lead to incorrect evaluation. Since this paper shows that QA-based metrics do not lead to interpretable, localizable judgments about errors, QA-based metrics do not seem to have any structural advantage over entailment-based metrics.

8 Related Work

Recent work (Fabbri et al., 2021) has shown that popular metrics like ROUGE (Lin, 2004) and BERTScore (Zhang et al., 2019) correlate poorly with human judgments of summary quality. Factuality, in particular, has been widely studied in recent summarization literature (Kryscinski et al., 2019; Falke et al., 2019), both from the perspective of identifying non-factual generations (Wang et al., 2020; Durmus et al., 2020; Goyal and Durrett, 2020) and improving the factuality of summarization models themselves (Kang and Hashimoto, 2020; Cao and Wang, 2021).

The majority of the work in factual evaluation has focused on summary-level metrics and is not capable of localizing errors within summaries. Recent work has decomposed factuality into summaries' dependency arcs (Goyal and Durrett, 2020) or semantic-graph representations (Ribeiro et al., 2022). These localization capabilities have several downstream applications like post-editing (Zhao et al., 2020; Chen et al., 2021), removing noisy training data (Nan et al., 2021; Goyal and Durrett, 2021), among others.

9 Conclusion

In this work, we show that although QA-based factuality metrics are motivated by error localization, in practice, they exhibit extremely poor localization capabilities. We provide a detailed analysis of the different issues in current metrics that hinder better localization performance. Finally, we run a human study to investigate whether human-level QG can fix some of these issues and conclude that there exist fundamental issues with the QA framework that cannot be simply fixed by stronger models.

10 Limitations

Given the lack of prior study in error localization of summarization evaluation, there is no large-scale dataset with token-level or span-level factuality labels. Constantly-evolving summarization models also mean that any such dataset would be come outdated in a fairly short time. However, we believe that the fundamental issues we discussed with QA metrics would persist across different summarization model outputs, despite our evaluation over a limited set.

Note that all our analysis is conducted on English language datasets and models of summarization, with a limited focus on newswire summaries. We believe that the issues identified here will transfer to other languages, but other domains such as dialogue or narrative summaries may exhibit substantially different types of factuality errors. These have not been studied as heavily in prior work, so likely new techniques and analysis will be needed for these settings.

A Additional Implementation Details

A.1 QuestEval

We use version 0.2.4 of the implementation by the authors with the recommended parameters (`task = 'summarization', do_weighter = False`).[8]

A.2 DAE

Our experiments use a trained model provided by authors (`DAE_xsum_human_best_ckpt`). This model is trained on a subset of XSum dataset (Maynez et al., 2020) that is distinct from examples in CLIFF and GD21.

A.3 Converting Tokens-level factuality scores to span-level scores

For the EM and the DAE baselines provide token-level factuality scores. We refer readers to the original DAE paper for details on how token-level scores are obtained (Goyal and Durrett, 2021). However, all our evaluation is designed to be at the span-level to align with QA metrics. To convert token-level scores to span-level, we annotate a span as non-factual if it contains any non-factual token.

A.4 Statistics for Ignored non-NP/NE tokens

The QA metrics do not evaluate the factuality of any token outside the boundary of a named entity of a noun phrase (discussed in Section 3.1). In Table 4, we show which kinds of tokens are ignored by the QA metrics but annotated as non-factual in our human annotated factuality datasets. Figure 5 provides an illustrative example of such ignored non-factual tokens in the different datasets).

	GD21	CLIFF	
	XSum	C/D	XSum
adposition	30.8	25.3	29.9
verb	24.4	23.7	23.5
auxiliary	15.2	10.0	17.1
punctuation	12.6	21.2	17.5
particle	6.7	3.9	4.5

Table 4: Statistics for non-factual POS-tags ouside the NP/NE boundaries and ignored by the QA metrics.

B Statistics of Generated Questions in QA-Based Metrics

Table 6 provides statistics for the generated questions from QuestEval and QAFactEval, highlighting the difference between these two metrics. On average, QAFactEval generates much longer questions. On the other hand, QuestEval generates a larger number of questions as it often generates multiple questions per candidate span.

Table 6: Statistics for the generated questions for the QuestEval and QAFactEval metrics.

C Performance Loss due to Span Filtering

In Section 3.1, we discussed that the current QA metrics do not evaluate non-NP/NE spans. These operational shortcomings prevent these metrics from providing a complete picture of error localization over all summary tokens. Here, we discuss another similar issue arising due to the question filtering step of the overall workflow (Step 3).

Although QA metrics select all NP/NE spans for evaluation during the candidate selection stage (Step1), some of these are filtered out if their corresponding question is of low quality: a_i for which $A(q_i, S) \neq a_i$ are also discarded from further evaluation. Since no errors are detected in these spans, they are considered to be factual.

We observed that this question filtering step removes around 30% of the NE/NPs in the QAFactEval framework. This implies that this metric only

Model	GD21	CLIFF	
	XSum	CNN/DM	XSum
EM	0.30	**0.27**	0.64^{D}
DAE	**0.32**	0.20^{E}	**0.78**
QE	0.19^{DE}	0.06^{DE}	0.45^{DE}
QAFE	0.21^{D}	0.13^{DE}	0.49^{DE}

Table 7: Span-level performance (F1 scores) over the subset of NP/NEs that are not discarded by either of the two QA metrics. $^{\text{D}}$ (or $^{\text{E}}$) denotes that the performance difference with DAE (or EM) is statistically significant according to a paired bootstrap test (p-value < 0.05). Even under this generous setting, we observe that the QA metric show very poor performance.

evaluates 70% of the valid spans, potentially missing factual errors in the remaining NP/NEs. Note that these numbers are considerably lower for QuestEval (<5%) as it generates multiple questions for each candidate span and hence is more likely to include an acceptable question.

As this impacted the results in Figure 3, we can ask what is the performance of the QA metrics over spans that they **actually** evaluate for factuality? If this performance is high, we can reasonably assume that the QA metrics' localization capabilities can be improved through better question generation models. Table 7 outlines our results: we report F1 scores at the span-level when evaluating over the subset of NP/NEs that are evaluated by both the QE and QAFE models. Although the QA metrics report improved results over those reported in Figure 3, these are still low enough so as to not be useful for error localization in practical settings.

Figure 8 shows the corresponding ROC curves for these. These show similar trends: the performance of QAFactEval improves when evaluating on this subset, but is still not better than the baseline models. Interestingly, for CLIFF (CNN/DM), we found that most of this improvement comes from the subset of candidate spans whose questions contain only a small fraction of factual errors (Figure 9). This aligns with our analysis in Section 5 that showed that errors in generated questions inherited from non-factual summaries was one of the major reasons for performance degradation, since questions generated from summaries with small number of errors are expected to inherit fewer errors.

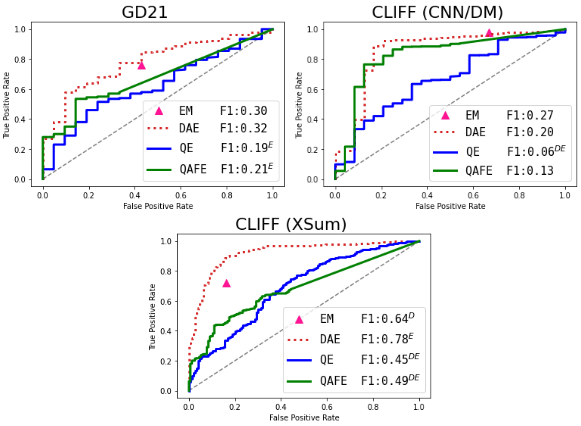

Figure 8: ROC curves for span-level performance on the subset of NE/NPs evaluated by all the QA metrics.

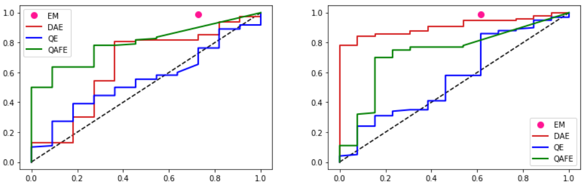

(a) Bottom 50% of the summaries according to error rate

(b) Top 50% of the summaries according to error rate

Figure 9: Comparison of ROC curves for the span-level performance on CLIFF (CNN/DM). There shows results on the subset of NP/NEs actually judged by QA metrics. The graphs show that the performance of the QAFE is better on the subset of summaries with a smaller number of errors.

D Additional Details about Human QG Annotation

The human annotation in Section 6 was done by the authors of this paper. They were provided with summaries and extracted answer candidate spans. For spans that were judged to be invalid (e.g. "*it*"), they were asked to manually discard these spans. For all others, questions of varying lengths and specificity were written. See an example in Table 8. To aid in this question writing step, we also provide the corresponding QAFactEval questions. For the longest questions, we found that annotators often chose to build on these questions albeit with corrections to the structure and grammar of the automatic questions.

Table 9 shows the number of summaries, spans, and generated summaries annotated in our human QG experiments. We use half of the summaries as validation sets.

E Summary and Span Level Evaluation

We provide additional results for our experiments in Figure 3. Figure 10 to 15 show F1 scores, precision, and recall on test sets with different thresholds. These show that QA-based metrics cannot yield high precision at any threshold.

Socratic Question Generation: A Novel Dataset, Models, and Evaluation

Beng Heng Ang,[1] Sujatha Das Gollapalli,[2] See-Kiong Ng[2]
[1] Integrative Sciences and Engineering Programme, National University of Singapore
[2] Institute of Data Science, National University of Singapore
`bengheng.ang@u.nus.edu, {idssdg,seekiong}@nus.edu.sg`

Abstract

Socratic questioning is a form of reflective inquiry often employed in education to encourage critical thinking in students, or to elicit awareness of beliefs and perspectives in a subject during therapeutic counseling. Specific types of Socratic questions are employed for enabling reasoning and alternate views against the context of individual personal opinions on a topic. Socratic contexts are different from traditional question generation contexts where "answer-seeking" questions are generated against a given formal passage on a topic, narrative stories or conversations.

We present *SocratiQ*, the first large dataset of 110K (question, context) pairs for enabling studies on Socratic Question Generation (*SoQG*). We provide an in-depth study on the various types of Socratic questions and present models for generating Socratic questions against a given context through prompt tuning. Our automated and human evaluation results demonstrate that our *SoQG* models can produce realistic, type-sensitive, human-like Socratic questions enabling potential applications in counseling and coaching.

1 Introduction

Researchers in Education and Psychology have recognized the role of cognitive biases in shaping a person's perspective towards learning and understanding (Azzopardi, 2021; Bautista, 2014; Tversky and Kahneman, 1974; Vittorio et al., 2021). Indeed, both pedagogical and counseling environments involve recognizing and alleviating any flawed cognitive biases in students/subjects through appropriate interventions by trained professionals (Bhardwaj et al., 2018). Socratic Questioning is one such intervention technique pervasive in Education and Psychotherapy (Bautista, 2014; Chew et al., 2019; Vittorio et al., 2022).

Socratic Questioning involves the use of specific types of probing questions that guide people into eliciting biases underlying their understanding of a topic in order to potentially enable alternative perspectives and further thoughts (Paul and Binker, 1990; Paul and Elder, 2019). Figure 1 illustrates example Socratic questions on a passage expressing an individual's views on "eating meat".

Thought/Passage: I believe that eating meat is ethically wrong. Since we can easily substitute meat with vegan food without much nutritional complications, we have no logical reasons to continue eating living animals. We should stop killing these animals.

Possible Socratic Questions:

1. But what about eating animals that pass on from natural causes?
2. Where is your source that says that vegan food and meat have the same nutrition value?
3. What will happen if we continue killing animals for our consumption?

Figure 1: Example Socratic Questions

In this paper, we study automatic Socratic Question Generation (*SoQG*) as a novel, multidisciplinary application area for question generation (QG) research in NLP. Consider for instance, the publicly-accessible datasets available for learning question and dialog generation models (Rajpurkar et al., 2016; Ramnath et al., 2021; Talmor et al., 2017; Trischler et al., 2017; Yang et al., 2018). These existing QG datasets were designed for machine comprehension and comprise of news articles, Wikipedia, and other well-written formal passages and questions whose answers are potentially expressed in the passages. Similarly, current dialog generation datasets focus on capturing conversations related to completing specific tasks (such as restaurant booking, customer service) or learning open-domain conversational chatbots for chitchat (Byrne et al., 2021; Cui et al., 2020; Danescu-Niculescu-Mizil and Lee, 2011; Zhou et al., 2018). As such, these existing datasets do not comprise of contexts necessary for learning *SoQG*.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 147–165
May 2-6, 2023 ©2023 Association for Computational Linguistics

Socratic contexts differ from the scenarios captured in existing datasets in the following significant ways: 1. *Question Context.* The contexts or passages express individual thoughts and personal opinions on specific topics; 2. *Question Objective.* The questions do not seek a "correct answer" and aim to provoke introspection and reflection from the question recipient; and 3. *Question Type.* The questions adhere to specific Socratic types that challenge the completeness and accuracy of the thought expressed in the context in various ways. For example, the question-1 in Figure 1 seeks an *alternative perspective*, while question-2 probes for *evidence* regarding a claim expressed in the passage, and question-3 invokes further thought on *implications* of a specific action mentioned in the passage.

In this paper, we present a first study on Socratic Question Generation (*SoQG*) and make the following contributions:

1. We describe *SocratiQ*,[1] a large dataset of ~110k Socratic questions, question type labels, and their contexts to enable learning of *SoQG* models. We discuss the curation of *SocratiQ* from the large corpus of posts and replies available from the community discussion website Reddit.[2] Socratic question-type labels collected through crowdsourcing are included for a subset of questions in *SocratiQ*.

2. We study question-type prediction for *SocratiQ* using state-of-the-art deep learning models. For a given (question, context) pair, our best fine-tuned BERT classifier is able to identify its question type with a macro F1-score of 0.905. We use this highly-accurate classifier to provide question-type labels for all instances in *SocratiQ* for learning type-sensitive question generation.

3. We learn type-sensitive question generation based on Socratic question types. We extend state-of-the-art QG models based on GPT-2, T5, and ProphetNet to incorporate Socratic question types through *prompt-tuning*. Our models effectively generate realistic, relevant human-like Socratic questions as shown in automatic as well as human evaluation studies.

Through our findings as well as released resources, we hope to enable future research on QG and chatbot applications based on the Socratic Questioning paradigm in areas such as coaching and counseling.

Organization: We describe the details of creating *SocratiQ* in Section 2. Section 3 provides details of the models and baselines used to study *SoQG*. Our experimental setup, evaluations, and results are summarized in Section 4 after which we provide a brief summary of existing datasets and methods for QG in Section 5. Finally, we conclude the paper in Section 6 and present some limitations that can be addressed in future in Section 7.

2 Dataset Collection

To construct a dataset of contentious viewpoints and the questions challenging these viewpoints, we consider the social news, content, and discussions website Reddit, in particular, the subreddit *r/changemyview*, or CMV. The CMV platform is an active, targetted community described as "a place to post an opinion you accept may be flawed, in an effort to understand other perspectives on the issue" with people specially encouraged to "enter with a mindset for conversation, not debate". Upon closer examination of the posts, we found that CMV posts pertain to various controversial topics (e.g. politics, media, culture, etc.) and, due to its very purpose of "change my view", subsequent comments often include questions aimed to evoke introspection and reflection (further discussed in Section 2.1).

We obtained the raw data from CMV using the "Pushshift Reddit" API provided by Baumgartner et al (2020). After removing moderator comments that are not relevant to the topic,[3] we identify questions from comments following a given post using regular expressions comprising of question cues (e.g. who/what/where/when/why/how), and lexical indicators such as '?'. Next, each identified question sequence is paired with the most relevant paragraph sequence (context) in the previous posts based on the similarity of the two sequences. Sentence BERT encodings (Reimers and Gurevych, 2019) were used for similarity computation. After manually inspecting several examples and their similarity values, we retain pairs having a similarity value above the threshold of 0.55. In total, we produce a dataset of $110,050$ English[4] (question, context) pairs from the CMV content generated during January 2013 and December 2021. On average, the number of sentences in each context is $4(\pm 2)$

Question type	Description	Exemplar
Clarification	Question probing the ambiguities of a thought.	What do mean by ...?
Probing assumptions	Question probing the assumptions behind a thought.	Why do you assume ...?
Probing reasons and evidences	Question probing the justifications or concrete evidences that could have supported a thought.	How did you know that ...?
Probing implications and consequences	Question probing the impacts or implications of a thought.	If ..., what is likely to happen as a result?
Probing alternative viewpoints and perspectives	Question probing other possible viewpoints.	What else should we consider about ...?
Others*	Question unrelated to the question types above (e.g. rhetorical, irrelevant, and/or illogical questions, etc.)	Who wouldn't want to be rich?

Table 1: Description and exemplar for each Socratic Question-Type from Paul and Elder (1990; 2019). *We add the catch-all type Others to refer to questions that do not conform to Socratic categories.

comprising of $83(\pm 53)$ words whereas questions are a sentence long with $12(\pm 6)$ words. We refer to this collection of (question, context) pairs as *SocratiQ*.

2.1 Question Annotation

Practitioners of Socratic Questioning employ various types of questions to engage in discussions with their subjects. For example, a counselor may ask for further clarification of a given viewpoint, or request evidence based on which such a stance was reached. Similar to previous studies (Dinkins and Cangelosi, 2019; Neenan, 2009; Wilberding, 2021), we used the taxonomy of Paul and Elder (1990; 2019) for characterizing the different questions. Table 1 lists the types of questions from this taxonomy with their descriptions and exemplars.

To curate the question type information for *SoQG* (Section 3), we adopt a semi-automatic process by first collecting manual annotations on a representative sample of data and training an accurate classifier for annotating the full dataset.

Crowd Labeling Process: To reduce the manual annotation efforts and cover the range of different question types uniformly in *SocratiQ*, we employ the process suggested in previous works (Abdul-Mageed and Ungar, 2017): First, lexical cues from available exemplars for each type (See Table 1) are used to design regular expressions[5] to assign a tentative Socratic type to each question in the dataset. We then use these tentative label assignments to sample questions from all types uniformly. In this manner, we sampled a set of 600 (question, context) pairs for each type, resulting in a balanced subset of $3,600$ questions for which we obtain human-assigned Socratic question-type labels.

Our annotation task was set up on the crowdsourcing platform Amazon Mechanical Turk (Crowston, 2012),[6] following previous works on QA/QG dataset collection (Ko et al., 2020; Rajpurkar et al., 2016; Yang et al., 2018). Each (question, context) pair was examined by three independent crowdworkers who chose one unique question type from among the six types listed in Table 1.[7]

We ensure the *ethics, quality, and reliability* considerations for all our collected datasets as follows. On the AMT platform, we required the crowdworkers to have greater than 95% HIT approval rate, a minimum of 10,000 HITs, be located in the United States and score at least 80% on a qualification test we set up to be able to work on our task. Each worker was paid up to 0.25 USD per HIT based on the task. In total, we used the AMT platform to collect data for the classification task as well as two evaluation studies which are further described in Section 4. The *anonymity* and *privacy* of the crowdworkers was already ensured on the AMT platform. We chose the pay-per-HIT based on similar on-going tasks on AMT. The settings for the HIT approval rates, and location of the worker ensures the English language skills of the annotator and thereby, the *quality* of the dataset.

A total of 40 workers helped in creating our classification dataset. About 40% of the workers who attempted our qualification test gained the eligibility to work on our task. Through this qualification test, we ensure that their worker annotations are *reliable*. For the $3,600$ (question, context) pairs deployed on AMT, we were able to obtain majority

---

[5] Examples are included in Appendix B.

[6] https://www.mturk.com/

[7] AMT interface details are provided in Appendix E.

annotations ($\geq$ 2 agreement on labels) for about 3,169 pairs. The Fleiss Kappa (Fleiss, 1971) inter-annotator agreement value was $\kappa = 0.725$ indicating substantial agreement among the crowd annotators. Overall, about 1% of the annotated questions were marked with the "Others" class which includes meaningless or irrelevant questions, and questions that do not belong to the Socratic types. This low percentage highlights the effectiveness of our pre-processing pipeline in extracting relevant Socratic (question, context) pairs.

Annotating the full dataset: We obtained question types for the entire *SocratiQ* dataset using an accurate classifier trained with the AMT labeled dataset. We further detail our classification experiments in Section 4. To summarize, in both automatic and manual evaluation studies, the prediction F1 and accuracy of our best classifier are around 0.9. Predicted Socratic classes are used for training prompt-based QG models described in Section 3.

2.2 Dataset Analysis

The question type distribution of the manually-annotated subset of *SocratiQ* is shown in Figure 2. Here, we observe that questions probing for *implications and consequences* and *reasons and evidence* comprise the most-asked questions. Previous studies have highlighted that "people routinely ask clarifying questions" to make sure "they can better offer assistance to the original poster" (Rao and Daumé III, 2018). This aspect is also seen in our dataset where *clarification* questions form the next most-asked questions. This is followed by questions probing for *assumptions* and *alternative viewpoints* as these are more cognitively-challenging than clarification questions (Krathwohl, 2002) while the "Other" questions form a negligible fraction (1.3%) of the overall distribution. Based on corpus analysis with Latent Dirichlet Analysis (Blei et al., 2003),[8] some representative topics in *SocratiQ* include *Abortion, Politics, Taxes, Crimes, Veganism, Racism, and Religion.*

3 Socratic Question Generation

To establish baseline performance on *SocratiQ*, we follow the current practice in NLP by fine-tuning state-of-the-art large pretrained language models (PLMs) with *SocratiQ* for **So**cratic **Q**uestion **G**eneration (*SoQG*) (Brown et al., 2020; Peters et al., 2019; Yu et al., 2021). We use commonly employed transformer-based language models, namely, Generative Pre-trained Transformer or GPT (Radford et al., 2019), the text-to-text transfer transformer or T5 (Raffel et al., 2019)), and ProphetNet (Qi et al., 2020). All three models yield relatively high performance on various NLP tasks (Wolf et al., 2020) including QG on other datasets (Chan and Fan, 2019; Ko et al., 2020).

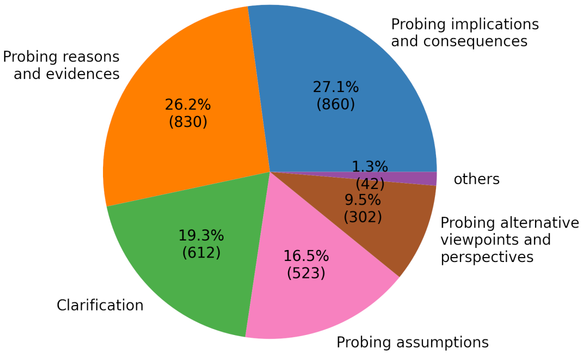

Figure 2: Distribution of questions based on their Socratic types

QG models: Following standard answer-agnostic QG models (Scialom et al., 2019), for our first set of baselines (GPT, T5, ProphetNet), we directly fine-tuned the PLMs with *SocratiQ* paragraph contexts as inputs and questions as outputs. We devised a second set of models (GPT-p, T5-p, ProphetNet-p) by employing prompt-based learning in keeping with recent developments in controllable text generation (Carlsson et al., 2022; Lester et al., 2021; Zhang et al., 2022). In this second set of models, we use the Socratic question-types as prompts in addition to the paragraph contexts as inputs for learning QG (Figure 3).

Evaluation: We use standard n-gram based metrics used for measuring question generation performance (Pan et al., 2019), namely BLEU (Papineni et al., 2002a), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004a). Previous works have highlighted the problems of using n-gram based measures for QG (Nema and Khapra, 2018). For *SoQG* in particular, these measures are limited in handling equally valid paraphrases of the available reference questions. To address these limitations, we adopt recently-designed learnt metrics, namely, BERT_Score and BLEURT (Sellam et al., 2020; Zhang et al., 2020; Yuan et al., 2021). Metrics based on the BERT-based models (Devlin et al., 2019) were shown to provide robust evaluation for

Table 2: Question-Type Classification Performance

4 Experiments

Setup: We set up our question-type classification and question generation experiments on a single GPU NVIDIA Tesla V100 machine. For classification, all models are based on the BERT classifier (Devlin et al., 2019).[9] For QG experiments, we use the implementations provided by the transformers library for GPT-2[10] and T5[11] and ProphetNet.[12] On our experimental machine, all models take between $12 - 19$ hours for training depending on the task, specific model and the dataset used.[13]

4.1 Classification Results

We studied several configurations based on BERT for training our question-type classifier. Table 2 shows the performance of these configurations on 20% (randomly-selected) test split of the AMT-annotated dataset using macro-averages of standard measures Recall/Precision/F1 employed for multiclass classification. We used the larger (80%) portion of the dataset for training and validation. The *SocratiQ* dataset contains $D \approx 110$K (question, context) pairs from which about $L \approx 3.1$K instances were collectively annotated by crowdworkers (Section 2.1). Thus, the unlabeled data ($U = D \setminus L$) can also be used to improve the classification performance via semi-supervised learning methods.

In Table 2, we show the performance using regular expression patterns in the first row (RE row) and the performance of BERT in the basic setting (fine-tuning on L_{train}) in the second row. The "$(RE_D) + L_{train}$" row refers to fine-tuning BERT on the tentative labels obtained with regular expressions before fine-tuning on L_{train}, whereas in the fourth row ($L_{train} + U_{RE}$), we add the unlabeled data using predictions with regular expressions to the training dataset.

The next three rows show semi-supervised configurations that involve the use of the unlabeled data (U) during model training. The "SelfTrain" row shows the performance in the self-training mode where the predictions from basic BERT configuration (second row) was used to predict labels for U and then re-trained on the combined dataset (Du et al., 2021; Mukherjee and Awadallah, 2020). The performance with the recently proposed semi-supervised model for BERT, namely, GANBERT (Croce et al., 2020) is shown in the next row.[14] For the final configuration in the last row ($L_{train} + U_{V*}$), we used voting to choose the dominant label from predictions on U with all configurations and retrained our classifier (Bishop, 2006). We did not include the regular expression-based models (RE and $L_{train} + U_{RE}$) in voting due to their substantially lower performance.

All classification models were fine-tuned using both the context and question as inputs. It is worth noting that the F1 performance of using labels based on regular expressions is significantly lower than the basic BERT configuration. Using only regular expressions or adding labels from regular expressions to unlabeled data results in significantly lower test performances (first and fourth rows) highlighting the inadequacy of only relying on exemplar

Table 3: QG performance is shown using standard measures and BLEURT and BERT_Score values. All models that use question-type prompts perform significantly better compared to their respective baselines (t(10k), p <.05).

and templates for identifying Socratic Question type information. The best-performing configuration is obtained through combining all models to obtain the dominant label for unlabeled examples, resulting in a significant jump in F1 values as shown in the last row, even though semi-supervised learning using self-training and GANBERT have individually yielded small and no improvements, respectively.

We also experimented with only question tokens as input to the models. In general, the performance using question only as input is moderately high with the macro-F1 decrease of 1-8% compared to when both the context and question are used. Indeed, when the scores of tokens from the context versus the question are computed for their attribution towards prediction using the Integrated Gradients method from Sundararajan et al. (2017), we found that the average attribution score of question tokens, 0.118, is significantly much larger than that of the context tokens, 0.033 (Cohen's D value (2013) of 1.58). This suggests that the input tokens from question have more discriminatory power for predicting question type. Indeed, using context-tokens only as input, our basic BERT configuration obtained a macro-F1 score of only 0.185 indicating that the judgement of question-type is, not surprisingly, highly dependent on the question tokens as was also indicated in previous studies on question-type identification (Li and Roth, 2002; Svikhnushina et al., 2022).[15]

4.2 Question Generation Results

Next, we evaluate the models described in Section 3 on *SocratiQ*. For the models using question-type information (GPT-p, T5-p, ProphetNet-p), we append the predictions from our best classifier (last row in Table 2) with the context and appropriate separator tokens. For the (GPT, T5, ProphetNet) baselines, the context alone forms the input. We randomly split 105K pairs of *SocratiQ* that have a Socratic question label into Train/Dev/Test portions in the ratio "80/10/10" and show the test performance of QG models in Table 3.

Automatic Evaluation: As the reference questions from Redditors are available in *SocratiQ*, we directly employ the n-gram measures for evaluating QG performance. The BLEU-1/BLEU-4 values are shown along with METEOR and ROUGE scores in Table 3. We note that by incorporating question types, the prompt-based models do significantly better than their non-prompt counterparts for all three PLMs: GPT, T5, and ProphetNet. However, the overall n-gram overlap with reference questions is very low with the best BLEU-4 score of 0.018 and the best ROUGE score value of 0.211. For comparison, the ProphetNet model could yield a BLEU-4 score ranging from $0.23 - 0.25$ on test splits of SQuAD dataset (a well-used dataset in QG research) (Rajpurkar et al., 2016; Qi et al., 2020). Unlike these factual questions, Socratic questions can be fairly diverse for a given context and question type. Rather than measuring n-gram overlap, we posit that measuring semantic similarity between a given reference and generated question using recent text generation metrics such as BERT_Score and BLEURT, would be more indicative of the models' performance.[16]

Indeed, as shown in Table 3, the values of these learnt metrics are significantly higher than the n-gram based measures, with ProphetNet-p being the best performing model. When the generated questions are manually examined, we found that the fine-tuned PLMs indeed generate human-like questions which are relevant to the given contexts even though they do not match the given reference questions. This aspect was confirmed in our manual evaluation studies described next.

[15] Further details are included in Appendix C

[16] F1 metric was used for BERT_score. The precise models in both cases are described in Appendix D

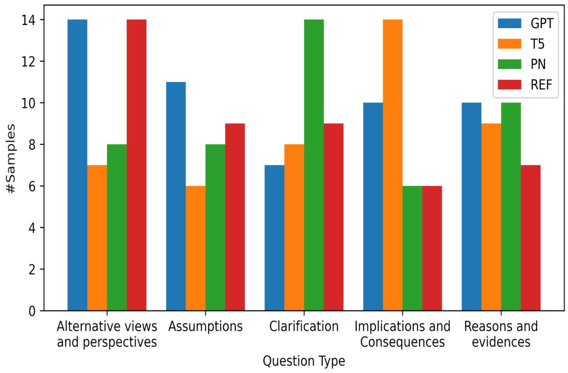

Figure 4: Distribution of "most likely to ask" questions chosen by crowdworkers

4.3 Human Evaluation Studies

We set up manual evaluation studies on Amazon Mechanical Turk to provide a more comprehensive analysis of *SoQG* model outputs. In the first study, we randomly sample fifty contexts for each Socratic question type of *SocratiQ*. For each context and Socratic question type, three independent MTurk evaluators select among four randomly-ordered questions (3 generated by GPT-p, T5-p, and ProphetNet-p + 1 reference) the question they will likely ask, or the "None" option.[17] In Figure 4, we plot the distribution of the source of the selected questions for each question type using majority votes from the above study.

Model	Flu	Rel	Ans
Best	4.287	3.883	0.330
Worst	4.220	3.737	0.353

Table 4: Quality of Questions (Flu:fluency, Rel:relevance, Ans:answerability)

We found that only two questions out of the 250 questions used in the study were deemed unacceptable for the given question-type and context by our annotators, confirming the accuracy of our question-type classifier. For the remaining questions, we see from Figure 4 that based on the question type, crowdworkers seem to prefer questions generated by a specific model and interestingly, reference questions from CMV were not always the clear winner. For example, the questions generated by ProphetNet were clearly preferred for the "Clarification" type of questions whereas T5-generated questions were preferred for "Probing implications and consequences" type. In fact, the human-reference questions were on par with the best model only in one type out of five indicating that our models are generating fluent and very human-like Socratic questions.

In a second related study, we sample twenty contexts for each of the five question types in the previous study, select the questions from the best and worst models (according to Figure 4), and ask three independent AMT crowdworkers to rate on a Likert scale of 1-5 ("Very bad" to "Very good") how fluent and relevant the questions are for a given context. They were also asked "if the answer to the question is present in the passage" (0/1 indicating absence/presence of the answer). The results for this study are summarized in Table 4. We found that the questions from the best models for each type indeed have higher fluency and relevance compared to questions from the worst model and both scores are close to the "Good" range on the Likert scale. Moreover, the answerability scores less than 0.5 indicate that the questions are not answerable from the context (different from traditional QG datasets).

Finally, we randomly sampled and examined fifty ground-truth questions per question type. These questions were examined on a 0/1 scale for classifier accuracy, fluency, answerability, and relevance. We found that the accuracy values ranged between 0.86-0.96, fluency and relevance between 0.92-1.00, and answerability was near zero (0.04), among the five Socratic classes. These scores further support our best classifier's performance on the AMT annotated test dataset, and that the ground-truth questions are fluent, relevant, and unanswerable from the context. These numbers indicate that our dataset of 110K (question, context) pairs and their predicted Socratic question types are of high quality and can be used by fellow NLP researchers for further improving *SoQG* models.

Anecdotes: The model-generated questions for an example context from *SocratiQ* are shown in Table 5 for illustration. We see that our prompt-based models are able to incorporate the question type information to generate questions that are semantically similar to the reference questions.

SQuAD versus *SocratiQ*: To highlight how Socratic questions complement existing QA/QG datasets, we run *SoQG* for an example from SQuAD (Rajpurkar et al., 2016).[18] For this context,

---

[17] Further details are included in Appendix E

[18] https://rajpurkar.github.io/SQuAD-explorer/explore/v2.0/dev/Immune_system.html

Context: Beyond the boundaries of legal conduct, to exclude people from the society is judged to be a suitable place of the law. For some heinous conduct, it's acceptable to put people beyond the society, and exclude them for tye benefit of all. But the denial of voting rights to convicted felons after the end of thier sentence is not acceptable. **1 - Probing implications and consequences**: Are there serious risks to allowing felons to vote? **2 - Probing reasons and evidences**: Why are we concerned about felons voting and what value does purging felons from voter rolls have to our society?
GPT-*p* - 1: What will happen if the felons were convicted of a crime? **GPT-*p* - 2**: Why should felons be excluded from voting rights? **GPT**: Why should felons be denied the right to vote?
T5-*p* - 1: What will happen if the felons are not allowed to vote? **T5-*p* - 2**: Why is it acceptable to deprive people of their right to vote? **T5**: Is it acceptable to deprive convicted felons of their right to vote?
ProphetNet-*p* - 1: Are you implying that felons should be allowed to vote? **ProphetNet-*p* - 2**: Why is it acceptable to deny felons voting rights after the end of their sentence? **ProphetNet**: What about people who have been convicted of murder?

Table 5: Questions generated by the different models are shown for an example context and associated reference questions from *SocratiQ*. Table 12 of the Appendix contains some more examples.

note the contrast between the "fact-seeking" questions from SQuAD and Socratic questions listed in Table 6. Socratic questions focus on "what if/why/on what basis" angles, causing the reader to reflect on alternate perspectives and implications, which can be useful for nurturing further thought and analysis which are essential in Education.

Reference questions from SQuAD 1. What are the anitmicrobial peptides secreted by the skin called? 2. What enzymes in saliva are antibacterial in nature? 3. What compounds in the stomach protect against ingested pathogens? 4. Vaginal secretions serve as a chemical protective barrier following what?
T5-*p* generated Socratic Questions 1. How do these enzymes kill pathogen? 2. Is it a good thing to assume that the stomach and intestinal tract are chemically different? 3. Do you have evidence that these enzymes are effective at killing pathogen? 4. Are you implying that the stomach is more acidic than other organs?

Table 6: Example from the SQuAD Dataset

We present in Table 7 an example context from the Real-world Worry Dataset (Kleinberg et al., 2020). Against this context, *SoQG*-models generate questions that draw attention to the underlying assumptions and potential misconceptions related to the mentioned "worry" causing the reader to introspect, which can be useful during counseling.

Context: I am concerned for my family's safety and I'm worried about the impact isolation will have on the mental health of my loved ones. **GPT-*p* generated Socratic Questions** 1. What does isolation have to do with your mental health or safety? 2. Why do you assume that isolation will lead to mental health issues? 3. Have you considered that isolation is a mental health issue that affects the entire family?

Table 7: Example from Real-world Worry Dataset

5 Related Works

Question generation has been a prominent subject of recent NLP research (Pan et al., 2019; Lu and Lu, 2021). Except some QG datasets which discuss inquisitive, probing questions (Ko et al., 2020), clarification questions (Rao and Daumé III, 2018), and empathetic questions in social dialogs (Svikhnushina et al., 2022), most models are trained on datasets such as SQuAD (Rajpurkar et al., 2016), HotpotQA (Yang et al., 2018), QuAC (Choi et al., 2018), and CoQA (Reddy et al., 2019), WebQA (Talmor et al., 2017) that were originally created for question answering (Pan et al., 2019). Not only are these datasets targeted towards extractive or abstractive QA and therefore comprise mostly factual, answer-seeking questions, but their contexts also include non-personal contexts such as Wikipedia or news articles, narrative stories, or problem descriptions on forums such as Stack Exchange (Rao and Daumé III, 2018). In contrast, Socratic contexts involve personal and individual opinions and viewpoints on diverse topics with no fixation on "correct" answer (Paul and Elder, 2019).

For learning QG models, we adopt the current approach of fine-tuning transformers on specific datasets (Wolf et al., 2020; Kriangchaivech and Wangperawong, 2019). Though *SoQG* is an answer-agnostic QG task (Scialom et al., 2019), due to its uniqueness in availability of question type information, we extend our QG models to incorporate these cues according to latest research on conditional text generation through the use of prompts (Lester et al., 2021; Zhang et al., 2022; Carlsson et al., 2022). Question-type taxonomies were previously studied for factual questions (Li and Roth, 2002) and in context of social dialog (Svikhnushina et al., 2022).

6 Conclusions

We created a novel dataset *SocratiQ* to support research on automatic Socratic Question Generation. We applied latest research in prompt-based conditional text generation to fine-tune existing large language models from GPT, T5, and ProphetNet to learn *SoQG*. Through our study and the release of this novel dataset, we take a first step towards enabling future research on models for *SoQG* as well as impactful applications in areas such as counseling and education (Inkster et al., 2018; Fitzpatrick et al., 2017).

7 Limitations

We note the following limitations in our work that also comprise our future research directions. First, while a human Socratic method practitioner will know what type of Socratic question to ask based only on context, our prompt-based models assume the availability of question-type for generating a type-sensitive question. In fact, when only contexts were used for QG (GPT, T5, ProphetNet baselines in Section 3), the generated questions matched the desired question-type (those of the available reference questions) in only 37-40% of the cases. Furthermore, the question-type identification of automated methods using context alone was very poor with overall accuracy comparable to that of random assignments (Section 4.1).

Secondly, though we showcased the potential use of *SoQG* in designing chatbots and dialog systems for applications such as counseling, we note that the current evaluation has only been at the single-turn level. We hope to extend *SocratiQ* to capture back and forth discussions on CMV to provide multiturn data and also deduce via forum votes and other indicators if the discussion indeed resulted in changed minds and enabled alternate perspectives. Furthermore, considering the special purpose of Socratic questions in shaping perspectives and enabling introspection and reflection, a comprehensive evaluation would require measuring these aspects over the multi-turn sessions.

Finally, our dataset was created by re-purposing the CMV subreddit data available in English, a high-resource language for which large-scale pretrained language models (PLMs) are readily available. Obtaining high classification and generation performances via fine-tuning of PLMs will be a challenge that needs addressing in low-resource languages.

Supplementary Materials

A Composition of *SocratiQ*

We apply Latent Dirichlet Analysis using the topic modeling toolkit, Mallet (McCallum, 2002).[19] The top-10 topics (by their Topic Coherence values (Mimno et al., 2011)) uncovered in *SocratiQ* with LDA (number of topics set to 30) are shown with their top words in Table 8. Based on these words, we note that some representative topics in *SocratiQ* include *Abortion, Politics, Taxes, Gender, Crimes, Veganism, Racisim, and Religion*.

	Top Words
1	child abortion life human children fetus woman baby parents mother
2	vote trump party voting president election states political democrats republicans
3	money people pay work tax make taxes government income wage company
4	women men gender trans woman male sex man female people transgender
5	crime rape people death crimes punishment person prison murder law
6	animals food meat eat animal eating humans dog dogs killing
7	people white black racist racism race culture person racial group
8	im view people dont ive change argument opinion post point
9	religion god religious christian bible religions islam people beliefs christianity
10	school college students education schools student high class job degree

Table 8: Words from the Top-10 topics (as ranked by Topic Coherence) from LDA analysis are shown

Figure 5 illustrates the distribution of question types predicted by our best classifier over *SocratiQ*. Compared to the manually annotated spread shown in Figure 4, we note that the percentage of Clarification type questions is significantly higher (33% versus 19%). We attribute this to the fact that Clarification class seems to be the most-confused one among the others as shown in the confusion matrix on the test set presented in Figure 6. As such, even our best-performing classifier is not 100% accurate.

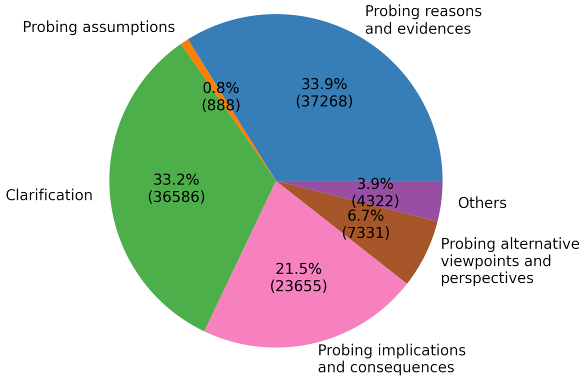

Figure 5: Distribution of predicted question types in the *SocratiQ*

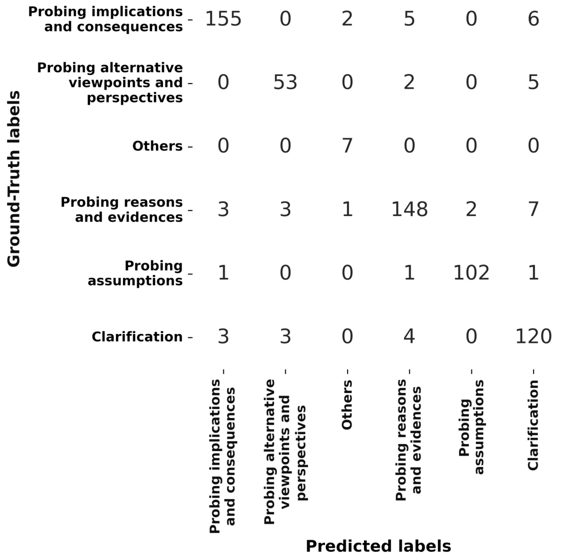

Figure 6: Confusion matrix of best classifier's predictions on the test set

Question type	Lexical Cues	Regex
Clarification	What do mean by ...?/What is the meaning of ...?	[Ww]hat[\s\w]+mean
	How is ... related to ...?/How are they related?	[Hh]ow[\s\w]+relate
Probing Assumptions	Are you assuming that...?/Why are you assuming that...?	[Aa]re[\s\w]+assum[eing]+
	What is the assumption from...	[Ww]hat[\s\w]+assumption
Probing reasons and evidences	Where is your evidence that...?	[Ww]here[\s\w]evidence
	Why do you think...?	[Ww]hy[\s\w]+think
Probing implications and consequences	Are you implying...?	[Aa]re[\s\w]+impl[yied]
	What happens...?What would have happened if...?	[Ww]hat[\s\w]+happen
Probing alternative viewpoints and perspectives	What else...?	[Ww]hat[\s\w]+else
	What other...?/What are the other...?	[Ww]hat[\s\w]]+other

Table 9: Sample lexical cues and regular expression patterns used to tentatively map questions to their Socratic question types.

B Regular Expressions

Table 9 provides sample lexical cues and their corresponding regular expressions (regex) designed based on available Socratic question templates (Paul and Elder, 2019; Intel, 2007). We use them to tentatively assign labels to instances in *SocratiQ*. These labels are used to get more balanced samples of questions for the human annotation process described in Section 2. The full set of regular expressions will be made available through our code repository.

C Computing Attributions for Classifier Predictions

We explain the model predictions by applying the Integrated Gradients method (Sundararajan et al., 2017).[20] For a question type prediction, each token is given an attribution score that indicates its contribution to that prediction. We normalize the scores by averaging them over the sequence length of each question and context sequences. From Table 10, we observe that the attribution values from the question sequences is significantly higher than those from the contexts; thereby, suggesting that the classifier predicts the question types mainly based on tokens from the question.

Based on the attribution scores, we can extract textual patterns that our classifier associates with particular question types in a data-driven fashion by simply using the top N-grams with the highest attribution scores. We show sample 4-grams in Table 11. We note the similarities between these automatically extracted patterns with the template-

Question Type	Qseq attr	Cseq attr	Cohen's D
Overall	.118	.033	1.59**
Clarification	.148	.041	1.85**
Probing reasons and evidences	.125	.037	1.64**
Probing implication and consequences	.108	.032	1.51**
Probing assumptions	.087	.020	1.76**
Probing alternate viewpoints and perspectives	.110	.025	1.80**
Others	.131	.061	0.76**

Table 10: Attribution scores (attr) for question sequences remain consistently higher than those of context sequences across every question type. Qseq indicates "Question Sequence" and "Cseq" indicates "Context Sequence". ** indicates a statistically significant, $p < 0.05$, Cohen's D effect size (Cohen, 2013) of the difference in attributions.

exemplars used by existing Socratic practitioners listed in Table 1.

GPT Input	<tag> [reasons_evidence] <tag> The government are people ... kind of things. <delim> If people are fantastic at managing all kinds of things, why are they so bad at them when organized as a government?
T5 Input	reasons_evidence: The government are people ... kind of things.
T5 Target	If people are fantastic ... bad at them when organized as a government?
ProphetNet Input	<tag> reasons_evidence <tag> The government are people ... kind of things.
ProphetNet Target	If people are fantastic ... bad at them when organized as a government?

Figure 7: Training input for each QG model. Text in red shows is the prompt based on question type annotation. <delim> is the delimiter token for separating input from the output whereas <tag> highlights the prompt tokens.

D Configuration Details for Deep Learning Experiments

For our classification experiments in Section. 4.1, we fine-tuned the "bert-large-cased"[9] model for the various configurations (Table 2). The model is tuned by an AdamW optimizer (Ilya and Frank, 2019) set with betas default at (0.9, 0.999), a batch of 4, and an initial learning rate of 1e-6. We also use a ReduceLROnPlateau[21] learning rate scheduler to reduce the learning rate by a default factor of 0.1 whenever the F1-score from the validation set does not improve after 2 epochs. Following Batista et al. (2004), we randomly oversample the minority classes to alleviate class imbalance among the data.

For our question generation experiments in Section 4.2, we fine-tuned "gpt-large",[10] "t5-large",[11] and "Prophetnet-En"[12] models. Prompt-tuning is enabled by concatenating question type annotations before the input sequence as shown in Figure 7. For "gpt-large" and "t5-large", we fine-tune the models using the pytorch [22] and huggingface[23] libraries, with an AdamW optimizer (Ilya and Frank, 2019) of betas (0.9, 0.999), a batch of 4, and an initial learning rate of 5e-5. This learning rate is adjusted during training with a ReduceLROnPlateau learning rate scheduler that reduces the learning rate by a factor of 0.1 whenever the loss from the validation set stops decreasing after 2 epochs. Similar to Ko et al (2020), for the "gpt-large" language model, we accumulate losses only for the question tokens by masking the context tokens before the delimiter. For ProphetNet, we use the recommended hyperparameters[12] except the learning rate, batch size,[24] input and target sequence lengths. For our models, these sequence lengths are set at 400 and 80 respectively to account for computation-related limits on our experimental machine.

For BLEU (Papineni et al., 2002b), ROGUE (Lin, 2004b), and METEOR (Banerjee and Lavie, 2005) automatic evaluation metrics, we use the implementations provided in Jury (Cavusoglu et al., 2022).[25] For BLEURT (Sellam et al., 2020), we use their recommended BLEURT-20 model.[26] Similarly, we use the recommended "microsoft/deberta-xlarge-mnli"[27] model for the BERTScore metrics.

E Details of MTurk Crowdsourced Tasks

Qualification Task: We presented a qualification test to crowdworkers on Amazon Mechanical Turk (AMT) who are interested in working on our tasks. The descriptions for each Socratic type along with examples are provided as instructions (Figure 8). As part of the test, the workers assign question type to a set of twelve questions (two for each type from Table 1). A snapshot from AMT platform for the qualification test is shown in Figure 9. We paid the workers, 0.05 per HIT for the classification task, 0.15 per HIT for the task involving question selection, 0.25 per HIT for the task involving question quality annotations on the Likert scale. These values were selected based on relevant, similar tasks on the AMT platform at the time of deployment.

The snapshots from AMT for the question selection and question quality studies described in Section 4 are shown in Figures 10 and 11.

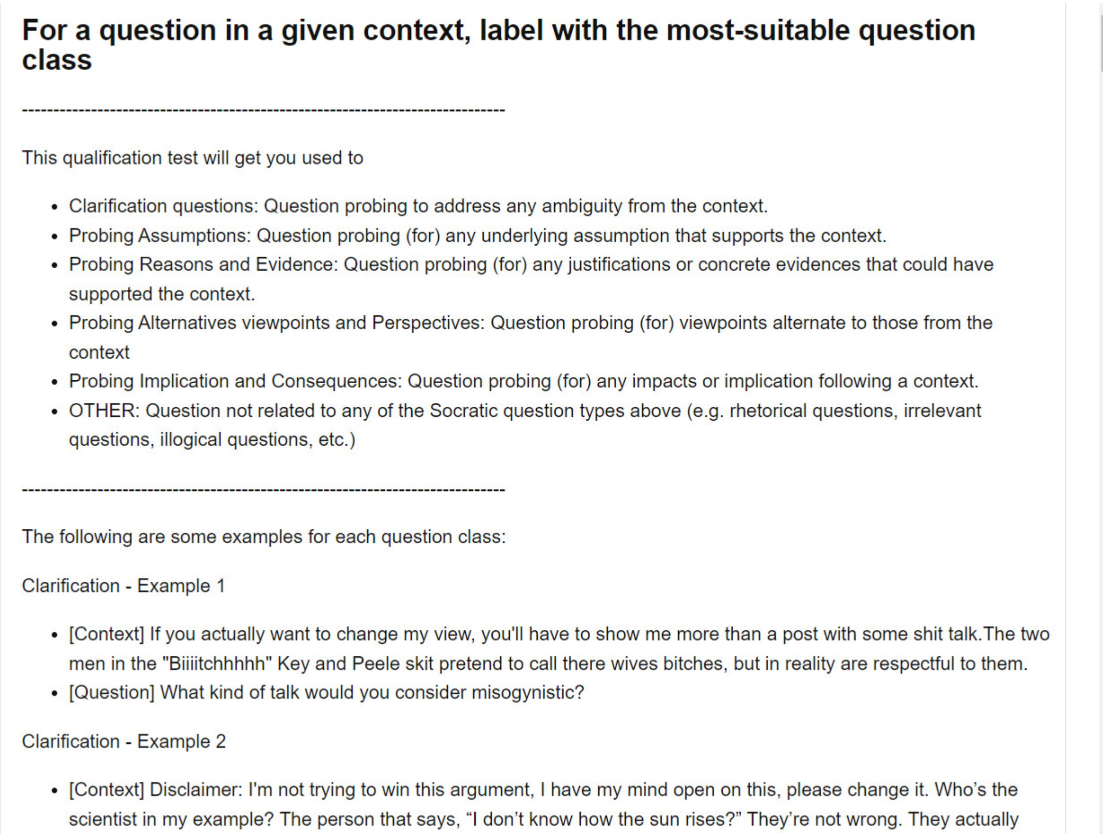
Table 11: 4-grams and their attributions (in brackets) for the different Socratic question types

CONTEXT:A child should hold no religious (or absense of religion) position. It is as unsettling as calling a child a conservative or liberal child. Children are vulnerable youths that take their parental figures' words as absolute fact. Telling them to hold political views or religious views at a young age is borderline indoctrination. **References**:1. What is the harm to the child by raising them as a liberal or a Muslim or a vegetarian or a meat eater? 2. What about teaching your child morals? **Generated Questions**: (Implications/Consequences) What do you think happens to young children who are forced to hold extremist views? (Clarification) How does teaching kids about the bible relate to holding religious views? (Reasons/Evidence) Why does it matter what political views children hold at such a young age? (Assumptions) Why are you assuming kids are even being taught their political views at all? (Alternate Viewpoints/Perspectives) Or that you would rather parents continue to influence them through their actions instead of just giving them the information?
CONTEXT:Adult children 25 or older should have to contribute and carry their weight. It would be on a case by case basis but essentially the child would have to pay a certain amount according to what they make. If you make over this much, you must pay 50% of the rent or mortgage. If you make below this much, you pay 15-25% and so on and so forth. This would encourage adults to grow up, pack up and move on from their parents homes. **References**: 1. What about parents who live at their kids home? 2. What will happen if the parents own the house free and clear? **Generated Questions**: (Implications/Consequences) Are you implying the bill could be identical between an adult and a child who are not of the same age ? (Clarification) What part of the point would you have that will encourage adults to move on? (Reasons/Evidence) And why should a person be required to move out at all? (Assumptions) Why do you assume that adults would just move on from their parents when they are adults? (Alternate Viewpoints/Perspectives) What about people who stay at home and take care of their parents and siblings for the rest of their lives?
CONTEXT:As a non-American, i find the idea of colleges having, promoting and sponsoring young (mostly female) students to dress in skimpy outfits to perform dangerous stunts and basically serve as eye-candy for the players and the audience a disturbing concept in the very least. Now don't get me wrong, the stunts they do, they teamwork they show are commendable and in no way a lesser sport in themselves. I'm sure many of the cheerleaders could have great careers in gymnastics or such organized sports. However, there is a drastic difference in how a cheerleading squad trains versus how someone trains for other sports. The cheerleaders often don't have safety equipment, practice on hard surfaces and have little to no health care. **References**:1. If the cheerleaders felt demeaned why would they choose to keep doing it, especially into college? 2. Have you consulted those cheerleaders? **Generated Questions**: (Implications/Consequences) Are you asking the college cheerleaders to do something about it? (Clarification) How do cheerleaders train on a surface that hard? (Reasons/Evidence) Do you have any evidence to support the idea that cheerleaders in colleges might be underprivileged? (Assumptions) Are we assuming cheerleaders are not working out to their maximum potential? (Alternate Viewpoints/Perspectives) What about professional gymnasts?

Table 12: Examples from *SocratiQ* are shown with their reference questions and questions generated with the ProphetNet$-p$ model



For a question in a given context, label with the most-suitable question class

----

This qualification test will get you used to

- Clarification questions: Question probing to address any ambiguity from the context.
- Probing Assumptions: Question probing (for) any underlying assumption that supports the context.
- Probing Reasons and Evidence: Question probing (for) any justifications or concrete evidences that could have supported the context.
- Probing Alternatives viewpoints and Perspectives: Question probing (for) viewpoints alternate to those from the context
- Probing Implication and Consequences: Question probing (for) any impacts or implication following a context.
- OTHER: Question not related to any of the Socratic question types above (e.g. rhetorical questions, irrelevant questions, illogical questions, etc.)

The following are some examples for each question class:

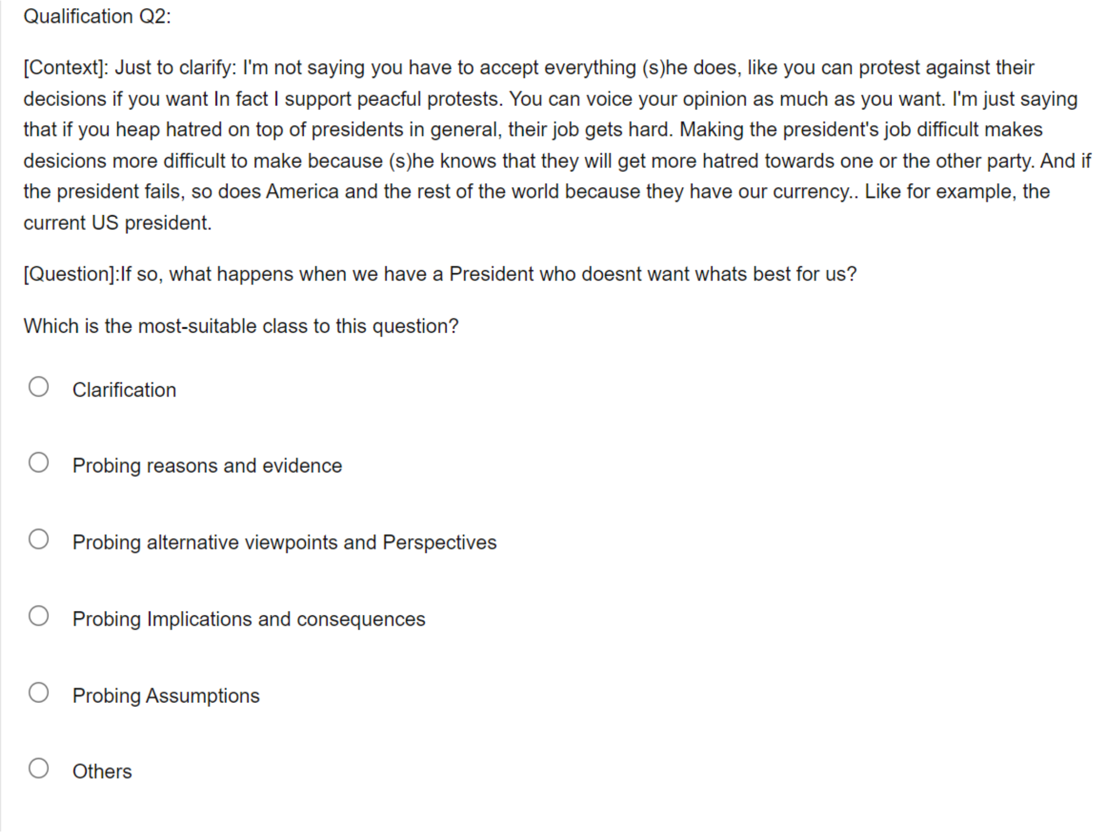
Clarification - Example 1

- [Context] If you actually want to change my view, you'll have to show me more than a post with some shit talk.The two men in the "Biiitchhhhh" Key and Peele skit pretend to call there wives bitches, but in reality are respectful to them.
- [Question] What kind of talk would you consider misogynistic?

Clarification - Example 2

- [Context] Disclaimer: I'm not trying to win this argument, I have my mind open on this, please change it. Who's the scientist in my example? The person that says, "I don't know how the sun rises?" They're not wrong. They actually

Figure 8: Workers are provided materials and time to learn the question types used in our study



Qualification Q2:

[Context]: Just to clarify: I'm not saying you have to accept everything (s)he does, like you can protest against their decisions if you want In fact I support peacful protests. You can voice your opinion as much as you want. I'm just saying that if you heap hatred on top of presidents in general, their job gets hard. Making the president's job difficult makes desicions more difficult to make because (s)he knows that they will get more hatred towards one or the other party. And if the president fails, so does America and the rest of the world because they have our currency.. Like for example, the current US president.

[Question]:If so, what happens when we have a President who doesnt want whats best for us?

Which is the most-suitable class to this question?

○ Clarification

○ Probing reasons and evidence

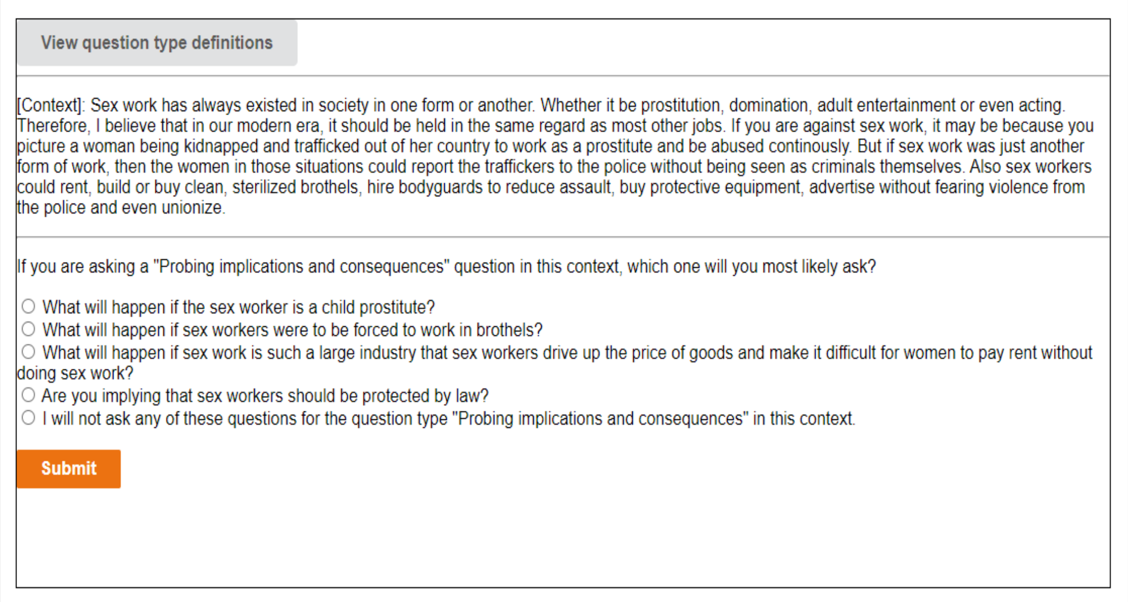
○ Probing alternative viewpoints and Perspectives

○ Probing Implications and consequences

○ Probing Assumptions

○ Others

Figure 9: Workers choose a particular question type most suited to a (question-context) pair in the qualification test (as in the main task).

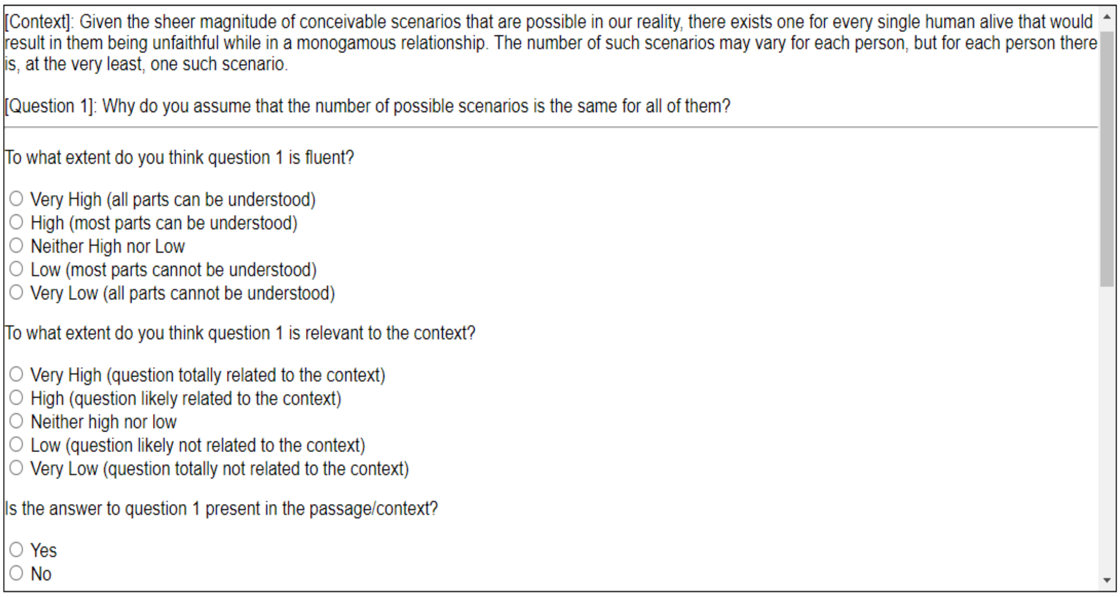


[Context]: Sex work has always existed in society in one form or another. Whether it be prostitution, domination, adult entertainment or even acting. Therefore, I believe that in our modern era, it should be held in the same regard as most other jobs. If you are against sex work, it may be because you picture a woman being kidnapped and trafficked out of her country to work as a prostitute and be abused continously. But if sex work was just another form of work, then the women in those situations could report the traffickers to the police without being seen as criminals themselves. Also sex workers could rent, build or buy clean, sterilized brothels, hire bodyguards to reduce assault, buy protective equipment, advertise without fearing violence from the police and even unionize.

If you are asking a "Probing implications and consequences" question in this context, which one will you most likely ask?

○ What will happen if the sex worker is a child prostitute?
○ What will happen if sex workers were to be forced to work in brothels?
○ What will happen if sex work is such a large industry that sex workers drive up the price of goods and make it difficult for women to pay rent without doing sex work?
○ Are you implying that sex workers should be protected by law?
○ I will not ask any of these questions for the question type "Probing implications and consequences" in this context.

Figure 10: Interface on AMT for the question selection study



[Context]: Given the sheer magnitude of conceivable scenarios that are possible in our reality, there exists one for every single human alive that would result in them being unfaithful while in a monogamous relationship. The number of such scenarios may vary for each person, but for each person there is, at the very least, one such scenario.

[Question 1]: Why do you assume that the number of possible scenarios is the same for all of them?

To what extent do you think question 1 is fluent?

○ Very High (all parts can be understood)
○ High (most parts can be understood)
○ Neither High nor Low
○ Low (most parts cannot be understood)
○ Very Low (all parts cannot be understood)

To what extent do you think question 1 is relevant to the context?

○ Very High (question totally related to the context)
○ High (question likely related to the context)
○ Neither high nor low
○ Low (question likely not related to the context)
○ Very Low (question totally not related to the context)

Is the answer to question 1 present in the passage/context?

○ Yes
○ No

Figure 11: Interface on AMT for the question quality study

Do we need Label Regularization to Fine-tune Pre-trained Language Models?

Abstract

Knowledge Distillation (KD) is a prominent neural model compression technique that heavily relies on teacher network predictions to guide the training of a student model. Considering the ever-growing size of pre-trained language models (PLMs), KD is often adopted in many NLP tasks involving PLMs. However, it is evident that in KD, deploying the teacher network during training adds to the memory and computational requirements of training. In the computer vision literature, the necessity of the teacher network is put under scrutiny by showing that KD is a label regularization technique that can be replaced with lighter teacher-free variants such as the label-smoothing technique. However, to the best of our knowledge, this issue is not investigated in NLP. Therefore, this work concerns studying different label regularization techniques and whether we actually need them to improve the fine-tuning of smaller PLM networks on downstream tasks. In this regard, we did a comprehensive set of experiments on different PLMs such as BERT, RoBERTa, and GPT with more than 600 distinct trials and ran each configuration five times. This investigation led to a surprising observation that KD and other label regularization techniques do not play any meaningful role over regular fine-tuning when the student model is pre-trained. We further explore this phenomenon in different settings of NLP and computer vision tasks and demonstrate that pre-training itself acts as a kind of regularization, and additional label regularization is unnecessary.

1 Introduction

Nowadays, we witness the tendency of ever-growing state-of-the-art neural networks. This is especially more evident in natural language processing (NLP): the famous GPT-3 (Brown et al., 2020) has reached 175 billion parameters and a recent Chinese pre-trained language model (Zeng et al., 2021) has 200 billion parameters. It is shown that big over-parameterized neural networks not only have higher VC dimension, and hence more approximation ability (Shalev-Shwartz and Ben-David, 2014), but also their optimization regime is smoother (Safran et al., 2020). At the same time, the optimal point found for big networks has better generalization property (Brutzkus and Globerson, 2019).

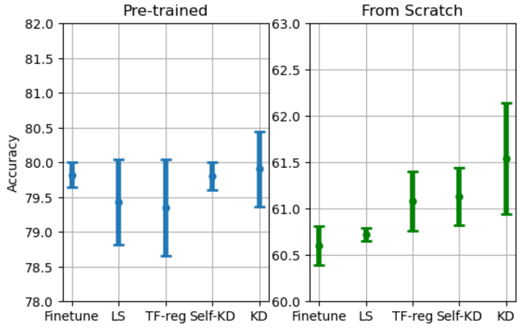

Figure 1: DistilRoBERTa results on the test set for the average of seven GLUE tasks. Graph shows the mean performance and one standard deviation interval for the pre-trained and randomly initialized models computed over five runs. For the pre-trained model all intervals intersect, hence label regularization doesn't improve the performance, but for the model trained from scratch label regularization methods outperform base training.

One can use the advantages of trained big neural networks and transfer their learned knowledge (weights and biases) to a smaller network. There are several approaches to such transferring techniques (Cheng et al., 2017), but here we will focus on Knowledge distillation (KD) (Hinton et al., 2015), a prominent neural model compression technique, which has been applied in many different forms across various domains (Gou et al., 2020) such as computer vision and NLP. To distill knowledge from a bigger model (a teacher) to a smaller

---

model (a student), KD adds an extra loss term to ensure the student predictions match with the teacher output. In the NLP domain, KD is widely adopted for compressing pre-trained language models (PLMs) (Sanh et al., 2019; Jiao et al., 2019; Jafari et al., 2021). The success of KD is attributed to different potential factors such as additional information presented by the dark knowledge (i.e. a term referring to the notion of class similarity information deriving from the teacher predictions which can not be found in the one-hot ground-truth labels) (Hinton, 2012), regularization effect of the KD loss (Yuan et al., 2020), or transferring inductive bias from one network to another (Abnar et al., 2020; Touvron et al., 2021).

Despite the widespread use of KD, it strongly depends on a trained teacher model, and calling the teacher during training adds to the computational cost of the training process noticeably. On the other hand, instead of adding the KD loss term to the student's loss, one can add a regularization term forcing the student predictions to be close to a uniform (or any arbitrary) distribution. Such a label smoothing technique results in better calibrated and more accurate classifiers (Müller et al., 2019). Recently, Yuan et al. (2020) demonstrated that label smoothing can perform as well as or even outperform KD in several computer vision tasks and across various models.

This result motivated us to investigate whether the teacher-free regularization techniques (TF) can work on par or better than KD on natural language understanding tasks. In this regard, we compare KD, label smoothing, and several other teacher-free methods for BERT and GPT type models. It is worth mentioning that our setting is different from the one of Yuan et al. (2020): 1) pre-trained language models are generally much bigger than the models from machine vision, and 2) classification tasks in our setting are mostly binary or three classes, compared to a hundred classes in CIFAR100 or two hundred in Tiny ImageNet. We ran the experiments multiple times to take into account the stochasticity of the training. Overall, we show a similar pattern: teacher-free techniques perform on par with KD methods; but we additionally observed a surprisingly different phenomenon: the gap between base fine-tuning (without KD) and fine-tuning with label regularization (KD or TF) diminished.

We explore the reasons why the base fine-tuning technique is a strong competitor of KD/TF regularization on NLU tasks. This situation is somewhat opposite to the one reported in computer vision. We hypothesized and tested the following potential explanations for our observations: 1) The small number of classes in GLUE datasets (usually 2 or 3 classes) in contrast to 10 or 100 classes in CV tasks; 2) Language models are extensively pre-trained while CV models are not. Our experiments indicate that the second hypothesis is true, whereas the number of classes doesn't play a big role in the performance gap. To the best of our knowledge, the effect of pre-training on fine-tuning with label regularization was never mentioned in the literature and deserves additional study.

Overall, our main contributions in this paper are the following:

1. Thorough comparison of TF and KD methods across both BERT and GPT models on the GLUE and other NLU benchmarks (more than 600 distinct experiments overall). We showed that, on average, KD does not significantly outperform the fine-tuning or TF techniques.

2. We studied the gap between base fine-tuning and fine-tuning with KD/TF and observed that this gap is negligible for NLU tasks. We demonstrated that this insignificant result is unlikely to be caused by the number of classes in the dataset.

3. We showed the evidence that the pre-training of neural networks reduces the performance gap on downstream tasks between the base training and training with label regularization both in NLP and computer vision domains. We supported this claim by performing Wilcoxon statistical test to demonstrate significance.

2 Background

In this section, we give a brief overview of the KD and TF techniques we will be investigating. Everywhere in the paper, we consider a classification problem with K classes. Denote by $q(x)$ the one-hot label of a data point x.

2.1 Knowledge distillation (KD)

This classical method of transferring knowledge gained traction after the paper (Hinton et al., 2015). Assume that we have a trained network (a teacher)

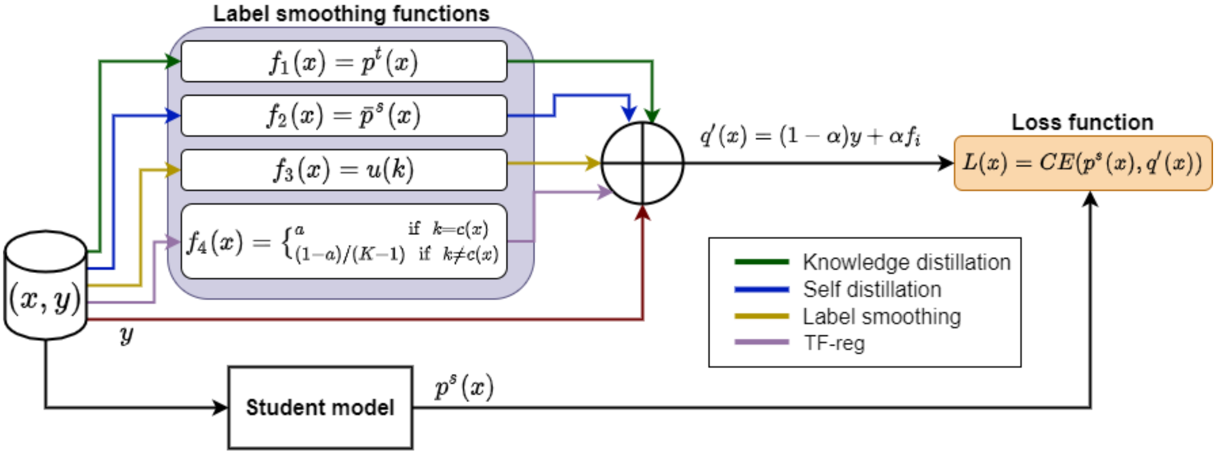

Figure 2: All the baselines of TF/KD methods we consider can be abstracted as cross-entropy training with smoothed labels. The choice of label smoothing functions determines the method. The flow in the algorithms of each method is indicated by a colored line, where $\bigoplus$ indicates the convex combination of the one-hot label and the output of the label smoothing function.

and a network we want to train (a student). Let $p^t(x)$ and $p^s(x)$ be teacher's and student's predictions respectively. One wants to transfer the knowledge from the teacher to the student. For that, one can formulate a total loss for KD as:

$$L = (1-\alpha)H(q,p) + \alpha L_{KD}, \qquad (1)$$

where $H(q,p)$ is the cross-entropy loss and $L_{KD} = D_{KL}(p^t_\tau, p^s_\tau)$ is a KL divergence between the teacher's and the student's outputs scaled with the temperature τ, i.e., $p_\tau(k) = softmax(z_k/\tau)$, where z_k is the output logits of the model. When $\tau = 1$, KD training is equivalent to cross-entropy training with the new labels "smoothed" by the teacher:

$$q'(x) = (1-\alpha)q(x) + \alpha p^t. \qquad (2)$$

2.2 Teacher-free methods

Label smoothing (LS) As Yuan et al. (2020) observed, the loss in Equation 1 is structurally similar to the label smoothing loss, where one has to replace the term L_{KD} with $L_{LS} = D_{KL}(u, p^s)$, where $u(k) = 1/K$ is the uniform distribution on K classes. Training with the label smoothing loss is equivalent to cross-entropy training with smoothed labels:

$$q'(x) = (1-\alpha)q(x) + \alpha u. \qquad (3)$$

Varying the hyperparameter α, one can change the shape of the new labels q' from smoother (higher values of α) to sharper (α closer to zero).

TF-reg (Yuan et al., 2020)) introduced a modification of LS with a sharper label-dependent smoothing distribution. More formally, for TF-reg one switches the uniform distribution u in Equation 3 to a more peaky label-dependent distribution $p^d_c(k)$, defined by:

$$p^d_c(k) = \begin{cases} a, \text{ if } k = c \\ (1-a)/(K-1), \text{ otherwise.} \end{cases} \qquad (4)$$

The smoothed label for x in TF-reg is given by:

$$q'(x) = (1-\alpha)q(x) + \alpha p^d_{c(x)}, \qquad (5)$$

where $c(x)$ is the correct label for x. Here one has two hyperparameters (a and α) instead of just one (α), which allows for better tuning, even though mathematically it is the same as LS.

Yuan et al. (2020) showed that LS and TF-reg perform on par or even outperform KD in machine vision for several models and across several datasets.

Self distillation (Self KD) Furlanello et al. (2018) and Yuan et al. (2020) considered the situation where the student and the teacher have the same architectures, and a student distills the knowledge from its fine-tuned alter-ego. In particular, first, we fine-tune a copy of the student on the dataset and then freeze it. Denote its outputs by $\bar{p}^s$. Then take the second copy and train it with the cross-entropy loss with smoothed labels:

$$q'(x) = (1-\alpha)q(x) + \alpha\bar{p}^s(x). \qquad (6)$$

The summary of all the TF and KD methods we compare can be found in Figure 2.

3 Experiments on GLUE benchmark

Inspired by the results of Yuan et al. (2020) in machine vision, we wanted to investigate the performance of TF training on NLP data. In this section, we evaluate the performance of the methods introduced in the Background section.

3.1 Dataset

We considered seven classification datasets of the General Language Understanding Evaluation (GLUE) benchmark (Wang et al., 2018). These datasets include linguistic acceptability (CoLA), sentiment analysis (SST-2), paraphrasing (MRPC and QQP), Natural Language Inference (MNLI, RTE) and Question Answering (QNLI). Notice that unlike most of the popular datasets in computer vision, GLUE tasks are either binary or ternary classification (only MNLI has three classes).

3.2 Experimental Setup

We explored all the KD/TF methods in three different setups to check the consistency of the results across different models. Our first student is DistilRoBERTa (Sanh et al., 2019). It has 6 layers, 768 hidden dimensions, 8 attention heads, and 82 million parameters. In the KD scenarios, we use RoBERTa-large (Liu et al., 2019) as its teacher (it has 24 layers, 1024 hidden dimensions, 16 attention heads, and 355 million parameters). In the second experiment, we use the BERT-small (Turc et al., 2019) model with 4 layers, 512 hidden dimensions, 8 heads, and 28.7 million parameters. As a teacher, we use BERT-large (Devlin et al., 2018) with 24 layers, 1024 hidden dimensions, and 336 million parameters. The third student is DistilGPT-2 with 6 layers, 768 hidden dimensions, and 82 million parameters. As its teacher, the 12-layer GPT-2 (Radford et al., 2019) model is used with the 768 hidden dimensions and 117 million parameters. For all these setups, we use the pre-trained models from Huggingface (Wolf et al., 2019). All the hyperparameters and the process of their tuning are reported in the Appendix in more detail.

Hardware Setup For our experiments, we used 8 NVIDIA TESLA V100 GPUs. Each task is trained on a single GPU.

3.3 Results

DistilRoBERTa We start with conducting the GLUE experiments over the DistilRoBERTa model. We report the results on GLUE dev and test sets in Table 1. On the dev set, we observe the following patterns: 1) The teacher-free methods (LS, TF-reg, Self-KD) outperform the Finetune baseline; 2) KD is the best technique but the standard deviation intervals intersect with the TF baselines.

Although the results of the dev set in the first experiments follow the trends of TF results in CV, examining the test results reveals some irregularities (Table 1). In particular, we observe that: 1) all the TF regularization techniques perform slightly worse than Finetune; 2) KD is on average the best technique, but it is comparable with Finetune up to one standard deviation. See Figure 1 (left) for the summary.

BERT-small In the second experiment, we evaluate the BERT-small model. Even here the story is more or less similar to our first experiment on DistilRoBERTa. Results are reported in Table 2. On the dev set, we observe that: 1) TF performs on par (up to one standard deviation) with Finetune while LS is slightly better. 2) KD is the best performer, but standard deviation intervals intersect with some of the TF baselines. On the test set, we observe that all the methods perform more or less on par up to one standard deviation while LS is slightly better.

DistilGPT-2 For DistilGPT-2, we see roughly similar patterns as in our previous experiments (Table 3). On both dev and test sets, all the methods' performance is more or less similar, with the standard deviation intervals overlapping.

The overall conclusion of our experiments is that, on average, KD or TF methods are slightly better, but the gap between the regularization techniques and the pure fine-tuning technique is not significant. Our results on the GLUE benchmark are very different from the reported results in the CV domain where pure fine-tuning without TF or KD underperforms. To explain the results, we formulate some hypotheses and scrutinize them with more experiments in the next section.

4 Analysis

In this section, we investigate potential reasons for getting the negligible difference in the relative performance of base fine-tuning, teacher-free training, and KD. We conduct some experiments to evaluate

two particular hypotheses we have as potential reasons behind these inconsistencies: 1) the number of classes in the GLUE tasks is much lower than for the CV tasks; 2) NLU models are pre-trained and pre-training can attenuate the regularization impact of KD and TF methods. In the remainder of this section, we will go over some new experiments which were done to evaluate these two hypotheses respectively.

4.1 Hypothesis 1: Number of Classes

4.1.1 SST-5

SST-5 is a fine-grained sentiment classification dataset with 5 classes introduced in (Socher et al., 2013). We consider a setting of DistilRoBERTa student and RoBERTa-large (24 layers) teacher. We ran experiments for 5 seeds. The results are presented in Table 4. Overall, we can see that the standard deviations of the results are quite big, which prevents us from concluding that any technique is superior. Similar to GLUE, we note that the gap

between fine-tuning and TF/KD is not observed.

In our next experiment, we increase the number of classes even more to see if the gap appears.

4.1.2 FewRel

Han et al. (2018) introduced this dataset for relation classification. Originally, this dataset was designed for few-shot learning, so we had to slightly modify it for our purpose. First, we consider the train set of FewRel. It has 64 classes and each class has 700 instances. We shuffle the data for each class and allocated 500 instances to our train set, 100 to our dev set, and 100 to our test set. We perform the experiments five times and get a new dataset for each seed, as recommended by Bouthillier et al. (2021). The detailed procedure can be found in Appendix. Overall, we generated a text classification dataset with 64 classes.

We took DistilRoBERTa as a student and RoBERTa-base (12 layers) as a teacher. We ran experiments for 5 seeds and tuned hyperparameters for the first one (see Appendix for details). The results are in Table 5. We can observe that all the methods perform similarly up to one standard deviation and we don't see a gap between Finetune and KD/TF again.

As a conclusion of SST-5 (5 classes) and FewRel (64 classes) experiments, we do not see any evidence that the number of classes in classification tasks affects the gap.

baseline	Accuracy (dev)	Accuracy (test)

KD	86.66 ± 0.36	86.41 ± 0.54

Table 5: DistilRoBERTa results on FewRel (64 classes). Averages and standard deviations are over 5 runs.

4.2 Hypothesis 2: Effect of Pre-training

We pose the following question: what is the major difference between Language Models and Computer Vision Models that might affect the performance gap between base training and label regularization? As an immediate hypothesis, we thought that extensive pre-training of the models we experimented with in the previous sections might be the reason.

baseline	From scratch	Pre-trained
Base	77.04 ± 0.26	78.17 ± 0.27
LS	78.01 ± 0.20	78.67 ± 0.20
TF-reg	78.16 ± 0.20	78.94 ± 0.28

Table 6: ResNet18 on CIFAR100. Pre-training is done on the ImageNet dataset. Averages and standard deviations are over 10 runs.

4.2.1 Computer vision

First, we did a sanity check and performed some experiments from (Yuan et al., 2020) for multiple seeds. In the paper, they didn't mention the standard deviation, but it is important for us to check if the gap we hoped to find is not a result of randomness. We considered CIFAR100 (Krizhevsky et al., 2009) and trained ResNet18 student (He et al., 2016) without label regularization and with LS and TF-reg techniques. At the same time we repeated similar experiments, but now with ResNet18 pre-trained on ImageNet dataset (Russakovsky et al., 2015). The results are reported in Table 6. Here, we can see that for the unpretrained model the standard deviation intervals between base training and label regularization don't intersect and the gap is reasonably large. However, the gap diminishes notably for the pre-trained model.

This gives us some initial evidence that our hypothesis might be true. In our next experiment, we report results that support this hypothesis.

4.2.2 NLU

GLUE experiments To investigate the effect of pre-training on the relative performance, we took a model with the same architecture as DistilRoBERTa, but instead of initializing it with pre-trained weights, we randomly initialize it (with normal distribution using the built-in Huggingface function). We used the hyperparameters from the pre-trained experiments. Then we ran experiments for 5 seeds. The results are reported in Table 7. We can see that, unlike the pre-trained model, the gap between base training and all the label regularization methods is bigger and the intersection of standard deviation intervals is much smaller or nonexistent. See Figure 1 (right) for the summary.

SST-5 experiments As a next step, we wanted to formally check the statistical significance of the findings that we reported in the previous sections. For this, we considered again the SST-5 dataset and trained both the pre-trained and randomly initialized DistilRoBERTa on it. We aim to determine whether there is a statistically significant difference between base training and TF/KD training for each of the pre-trained and randomly initialized cases. We used the (two-sided) Wilcoxon signed-rank test (Wilcoxon, 1945) over the results of eight random seeds. The Wilcoxon test is a non-parametric statistical test that checks the null hypothesis, i.e., whether two related paired samples come from the same distribution. The results are reported in Table 8. We can see that for the pre-trained model there is no statistically significant difference between base training and label regularization (p-value is greater than 0.05). However, if the model is trained from scratch, the difference becomes statistically significant.

We also tried state-of-the-art KD method, Annealing KD (AKD) (Jafari et al., 2021) which is like vanilla KD doesn't require data augmentation or an access to teacher's intermediate layers. The result of the Wilcoxon test (Table 8) shows that similarly it doesn't give a significantly better performance for a pre-trained model.

5 Related Work

Our finding that pre-training reduces or even removes the gap between base training and TF/KD training can serve as an indication of a regularization property of pre-training. Several works are exploring this in the literature.

Tu et al. (2020) studied the relation between pre-training and spurious correlations. They demonstrated that pre-trained models are more robust to spurious correlations because they can generalize from a minority of training examples that counter the spurious pattern. Furrer et al. (2020) demonstrated that Masked Language Model pre-training helps in semantic parsing scenarios to improve compositional generalization. The authors hypothesize that the primary benefit provided by MLM pre-training is the improvement of the model's ability to substitute similar words or word phrases by ensuring they are close to each other in the representation space. Turc et al. (2019) showed that pre-training is very beneficial for smaller architectures, and fine-tuning pre-trained compact models can be competitive with more elaborate methods.

6 Discussion and Future Work

We started this comparison of KD and TF regularizations on NLU tasks in the hope that a pattern

Table 7: Randomly initialized DistilRoBERTa results on the dev and test sets for the GLUE benchmark. F1 scores are reported for MRPC, Matthew's Correlation for CoLA, and accuracy scores for all other tasks. The teacher is RoBERTa-large. Averages and standard deviations are over 5 runs.

Comparison	Pre-trained	From scratch
Base vs TF-reg	0.46	0.01
Base vs KD	0.94	0.01
Finetune vs AKD	0.74	-

Table 8: Wilcoxon signed-rank test results for DistilRoBERTa model trained on SST-5 dataset. P-values of the test are reported with p-value less than 0.05 meaning the difference is significant. The results are over the test results of 8 runs.

similar to the one in computer vision (Yuan et al., 2020) will emerge. In particular, we expected to see TF and KD perform on par while outperforming Finetune. However, it turned out that the gap, even if it exists for some seeds, is not significant.

We further scrutinized the gap between Finetune and KD/TF regularization. We hypothesized that the lack of this gap in NLU might be the result of a small number of classes in GLUE classification tasks, however, this doesn't seem to be the case: experiments on SST-5 (5 classes) and FewRel (64 classes) datasets didn't show a significant gap either. We showed that another hypothesis is likely to be true: the extensive pre-training of Language Models erases the gap. The application of a statistical test confirms that a non-negligible gap appears when models are trained from scratch. It seems that pre-training discovers a good enough initialization for fine-tuning so that even basic unregularized training can find a solution as good as training with (TF or KD) regularization. A rigorous explanation of this phenomenon is an interesting challenge for future work.

We would like to add one important remark. Our finding of this work does not suggest disregarding KD or other types of regularizations in NLP but rather using the more advanced or enhanced versions of these techniques. First of all, as shown in several works in the literature (Sanh et al., 2019; Sun et al., 2019; Turc et al., 2019; Jiao et al., 2019; Tahaei et al., 2021), KD is very important for the pre-training stage of the student models. Similarly, Gao et al. (2020) demonstrated the value of label smoothing for training machine translation models.

Moreover, improved variants of KD might still facilitate fine-tuning of pre-trained models. Even when vanilla KD doesn't give a statistically significant advantage over base fine-tuning, several works in the literature show that improved versions of KD with different auxiliary training schemes could be beneficial. For example, one can incorporate intermediate layer distillation (Sun et al., 2019; Passban et al., 2021; Wu et al., 2020, 2021), data augmentation (Rashid et al., 2021; Kamalloo et al., 2021) or contrastive training (Sun et al., 2020). Investigating better KD techniques or, more generally, better regularization methods that can improve the fine-tuning of PLMs even further will be an important direction for future work.

Limitations

In the current work we present an extensive empirical evidence that label regularization doesn't improve fine-tuning of a pre-trained model. However, we don't have any theoretical explanation of this puzzling phenomenon. Understanding the interactions of different regularization methods and how they affect the optimization is a highly non-trivial problem.

A Hyperparameters for GLUE and SST-5 experiments

We ran experiments for seeds 42, 549, 1237, 230 and 805. For all baselines we run experiments for 30 epoch. All hyperparameters for pre-trained and randomly initialized models are listed in the Tables 9, 10.

When we do 8 seeds for the statistical test, we add seeds 4653, 5589 and 992.

Hyperparameters for Annealing KD on SST-5 are listed in Table 11

B Experiments on FewRel

B.1 How we constructed the dataset

For each seed (42, 549, 1237, 230 and 805) separately we constructed a new dataset.

Train set of FewRel has 64 classes, each class has 700 instances. We shuffle the data for each class (with a current seed) and allocated first 500 instances for our train set, second 100 for our dev set and last 100 for our test set.

We concatenated the context, head, and tail of the relation into one piece of text to be classified.

B.2 Hyperparameters

All hyperparameters are shown in Table 12

C Experiments on CIFAR100

We follow the experimental setup (Yuan et al., 2020). For optimization we used SGD with a momentum of 0.9. The learning rate starts at 0.1 and is then divided by 5 at epochs 60, 120 and 160. All experiments are repeated 10 times with different random initialization. The seeds we used: 11, 125, 1350, 23, 230, 4653, 5589, 56, 6, and 992. The validation set is made up of 10% of the training data. For experiments with pre-trained models, we use the checkpoints available at [2].

D Hyper-parameter tuning

For hyper-parameter tuning, we use the ray tune library (Liaw et al., 2018). The tuned hyper-parameters are batch size, learning rate, α, and temperature where they have been selected among {8, 16, 32, 64}, {9e-6, 1e-5, 2e-5, 3e-5}, {0.4, 0.5, 0.7, 0.8, 0.9, 0.95}, and {1, 2, 5, 10} sets respectively. We use ASHAScheduler algorithm of ray tune to find the best hyper-parameters. The metric of choosing them was maximum performance on dev set. The sample size of tuning hyper-parameters was 20 and 1 GPU was used for each experiment. Also, the maximum number of epochs for each trial was 20 epochs.

Since tuning hyper-parameters requires a huge amount of computational resources, we tried hyper-parameter tuning for vanilla KD on DistillRoBERTa model for GLUE benchmark. Then we chose the five best hyper-parameter sets from this experiment and checked their performance with other baselines and chose the one with highest average performance among all baselines. Only different α parameters for random initialization and pre-trained experiments on GLUE tasks and SST-5 made considerable differences in results. Therefore we used different α values in these experiments.

Tuning hyper-parameters individually for each baseline would be a better option, but this would require a very large amount of computational resources. However, after careful hyper-parameter tuning for vanilla KD and less intensive hyper-parameter tuning for teacher-free baselines, the latter show very close performance to vanilla KD and this fact supports the main message of our paper.

COVID-VTS: Fact Extraction and Verification on Short Video Platforms

Fuxiao Liu **Yaser Yacoob** **Abhinav Shrivastava**

University of Maryland, College Park
{fl3es, yaser, abhinav}@umd.edu

Abstract

We introduce a new benchmark, `COVID-VTS`, for fact-checking multi-modal information involving short-duration videos with COVID19-focused information from both the real world and machine generation. We propose, `TwtrDetective`, an effective model incorporating cross-media consistency checking to detect token-level malicious tampering in different modalities, and generate explanations. Due to the scarcity of training data, we also develop an efficient and scalable approach to automatically generate misleading video posts by event manipulation or adversarial matching. We investigate several state-of-the-art models and demonstrate the superiority of `TwtrDetective`.

1 Introduction

The proliferation of misinformation in social media poses a serious threat to our society, especially during the COVID-19 pandemic. Therefore, it is necessary to develop automatic fact-checking tools to verify the claims propagated online.

Recent fact-checking work (Thorne et al., 2018; Wadden et al., 2020; Augenstein et al., 2019; Fung et al., 2021; Bekoulis et al., 2021) investigated automatic misinformation detection by developing various benchmark datasets as well as state-of-the-art neural network architectures involving sources such as Wikipedia pages, tables, news articles, and scientific articles. However, due to the lack of publicly available benchmarks, fact checking is still challenging on short video platforms, such as TikTok, Twitter, and Instagram.

Verifying the factual correctness of claims in short video platforms poses new challenges. Firstly, multi-modal misinformation that leads to short video posts is more misleading than using just textual content (Micallef et al., 2022), since the claims usually only tamper with subtle elements of the factual information from the source video. Furthermore, short videos (Shang et al., 2021) containing diverse scene shifts, human activities, and cross-modal information, greatly increase the complexity and ambiguity of the video content. Moreover, current methods explored the authenticity of GAN-generated video with unimodal analysis (Güera and Delp, 2018). Nevertheless, they cannot be directly applied to the short video platform, where the video content is often intentionally manipulated.

To tackle these challenges, we introduce `COVID-VTS`, a new benchmark dataset with trustworthy claims and corresponding good-quality videos, collected from Twitter video posts. `COVID-VTS` contains different inconsistent taxonomies and the inconsistency comes from different modalities. Examples are shown in Figure 1. We additionally introduce a novel approach to generate fake video posts automatically by manipulating event elements or adversarial matching (Luo et al., 2021a). The advantage of our event manipulation tool is that it's able to control the polarization of semantics and track the manipulation object by editing a small component of the factual information. We apply quality control to delete unqualified generations and address the linguistic bias.

We propose `TwtrDetective`, a multimodal fact-checking model, where the input consists of a claim with the paired video, and the goal is to predict the consistency. `TwtrDetective` takes advantage of the *Event Alert* module to precisely extract fine-grained factual details from the claim, as well as *Pairwise Consistency Aggregation* module to effectively measure the consistency between each modality. `TwtrDetective` is also able to point out the inconsistent modality (e.g., see Figure 3).

Experimental results show that `TwtrDetective` achieves higher detection accuracy over baselines on two datasets. Our main contributions are summarized as:

- We introduce `COVID-VTS`, a fact-checking dataset for short video platforms, consisting of 10k video text pairs with diverse scenes, more accessible

May 2-6, 2023

(Speech)
new cases reported in Italy South Korea
...
the officials struggled to contain coronavirus outside China
...
as the death toll has twenty six hundred is it too early to call the crime virus
...

(Claim)
Officials are scrambling to contain the spread of ebola outside of China, joined @cherylcasone with more coronavirus

(Speech)
...
slovakia's government has now approved a two week national lockdown
...
start of the pandemic with the emphasis on pushing vaccination programs it should be has tightened the screws on people ...

(Claim)
slovakia to prevent new lockdown while italy toughens up on the unvaccinated

(Speech)
...
grounded BA flight likely to lead to a profit drop
...
expected to forecast profits and this year that's not currently possible because the duration potentially affected coronavirus prices remain unclear
...

(Claim)
#BritishAirways is expecting a drop in profits this year - due to cancelled flights #coronavirus

Figure 1: Examples of different inconsistent taxonomies from `COVID-VTS`, which are generated by our automatic manipulation tool. The red box indicates the inconsistent modality. Our task is to independently decide whether the video-text pair is consistent and point out which modality is fake. (1) The event argument in the claim is modified; (2) The event trigger in the claim is tampered; (3) The short video is curated by adversarial matching.

modalities, and trustworthy claims from both the real world and machine generation.

- We propose an effective approach to automatically generate large-scale verifiable, trustworthy as well as misleading video posts rather than employing human annotators.
- We propose `TwtrDetective`, a new explainable fact-checking framework for the short video platform, showing superior results on two challenging datasets with respect to baselines.

Our code is publicly available at `https://github.com/FuxiaoLiu/Twitter-Video-dataset`.

2 Related Work

The spread of misinformation has led to a growing body of research in automatic fact-checking. Many large scale datasets collected from Wikipedia and fact-checking websites were introduced, including FEVER (Thorne et al., 2018), SciFact (Wadden et al., 2020), UKP Snopes (Hanselowski et al., 2019), MultiFC (Augenstein et al., 2019). However, the fake claims in these datasets are manually generated by humans, making it expensive to deploy at scale. Recently, some synthetic datasets were proposed to address this limitation. (Jiang et al., 2020) generated complex fake claims using word substitutions. (Saakyan et al., 2021) took advantage of the token-infilling ability from Masked Language Model to replace the salient tokens. Also, (Fung et al., 2021) formulated a novel data synthesis method by manipulating knowledge elements within the multi-modal knowledge graph. In order to alleviate the linguistics bias within the machine-generated claims, (Luo et al., 2021a) constructed the out-of-context captions by retrieving the real-world sentence with the similar semantics. In a similar vein our dataset, (Liu et al., 2020b) constructed VIOLIN for the Video-Language Inference while all the statements are written by experts. (Wang et al., 2022) collected social media video posts from Twitter but the fake claims are constructed by random swap. In comparison, `COVID-VTS` is the first COVID-19 fact-checking dataset for short video platforms, containing rich information with diverse scenes, more accessible modalities as well as misleading claims from both the real world and machine generation.

Traditional fact-checking approaches (Zellers et al., 2019; Schuster et al., 2020; Atanasova et al., 2019) are mainly based on text. They fall short if the evidence stems from visual information. Recent multi-modal models (Fung et al., 2021; Tan et al., 2020; Shang et al., 2021) are equipped with the ability to check consistency according to the information conveyed across modalities. In contrast, we propose a fact-checking model for the short video platforms with multimedia explanations that achieves higher accuracy to detect misinformation.

3 COVID-VTS Dataset Construction

`COVID-VTS` contains 10k well-formed claims with the paired videos to support or refute the claims. In this section, we first describe the procedure to select the trustworthy and consistent video/claims pairs from Twitter video posts. Second, we also present our approach to automatically construct well-formed inconsistent video-claim pairs.

3.1 Filtering for Authentic and Consistent Video Posts

To assemble the `COVID-VTS` dataset, we used the Twitter scraper to collect over 100k English video posts using COVID related keywords and hashtags ranging from the end 2019.10 to 2022.8. Examples are shown in Table 1. We retain one post for a video link to reduce the potential bias. To retrieve the speech from videos, we leverage the Speech-to-Text tool from IBM Cloud (Pitrelli et al., 2006). In addition, we leverage SimpleOCR (Ko and Kim, 2004) to recognize text on screen. After the preliminary filtering, we have several steps to select the authentic and consistent video posts:

VERIFIED User Account. According to the requirements from Twitter, only the authentic, notable, and active accounts will receive the blue verified badge (including official government, official company, etc.). Accounts that routinely post content that harasses, shames, or engaged in severe violations of our platform manipulation and spam policy are ineligible for blue badge. We collect the authentic posts from the verified accounts into `COVID-VTS` to improve the data quality.

Claims Must be VERIFIABLE. Event structures are essential to reveal the factual information of a sentence, since the overall semantics might be opposite if event elements are changed. Moreover, claims in `COVID-VTS` are supposed to be verifiable propositions whose truthfulness is determined by multi-modal evidences from the paired videos. Without the event structures, its truthfulness isn't verifiable. Thus, we delete instances with personal opinions or emotions. For example, *'So proud of my boys! GetVaccinated'*, which has no factual information to be verified.

In practice, we first remove the claims without event structures, by using DYGIE++ (Wadden et al., 2019), a state-of-art event extraction framework, pretrained on MECHANIC dataset. The event structures generated by DYGIE++ include event triggers and event arguments. For example in *'Officials are scrambling to contain outbreaks of the coronavirus outside of China'*, *'contain'* is the trigger which express the occurrence of the event, *'officials'* and *'outbreaks of the coronavirus'* are event arguments which play different roles in this event.

After selecting these verifiable claims, we manually check whether they are consistent with the associated videos. We also select verifiable and consistent video text pairs from the unverified accounts in order to increase the size of our dataset. Our hypothesis is that the video posts are trustworthy after the "cleaning" steps. Given this hypothesis, the main task is to analyze the inconsistency between different modalities.

Keywords/Hashtags
covid, #covid, #covid19, corona, #coronavirus, maskup, pandemic, ICU, vaccine, #vaccine, coronavirus, quarantine, #quarantine, moderna, #covidvariant, omicron, booster, mRNA, phizer, #phizer, #who, #workfromhome, #vaccinepassports, #travelbans, #social_distance, n95

Table 1: Summary of the covid related keywords and hashtags in the data collection process.

	Most frequent Tokens
Event Trigger (Original Claims)	*fight, infect, protect, prevent, help, stop, quarantine, contain, confirm, threat, plunge, mandate, deal, cause*
Event Argument (Original Claims)	*coronavirus, omicron, pfizer, covid, delta, moderna, booster, mask, lockdown, protest, social distance, ban, vaccine*
Event Trigger (Generated Claims)	*produce, increase, create, develop, remove, protect, avoid, identify, support, generate, rule, allow, establish*
Event Argument (Generated Claims)	*omicron, variant, death, cancer, hospital, WHO, community, medical service, drug, viruses, migration, media, ICU*

Table 2: Most frequent event triggers and arguments in original claims and generated claims.

3.2 Automatic INCONSISTENT Video-Claim Pairs Generation

In this section, we describe the steps to automatically generate inconsistent video-claim pairs. Our dataset contains the following three inconsistent taxonomies: (1) Real video, Real speech and Inconsistent claim; (2) Real video, Inconsistent speech and real claim; (3) Inconsistent video, Real speech and Real claim.

Inconsistent Claim Generation. Inspired by (Liu et al., 2020b), we automatically generate fake-claims by controlling the polarization of semantics and tracking the manipulation object by modifying a small portion of the factual information in true claims. In this case, most of the statement remains true to the video content. This strategy can also alleviate the linguistic bias, which was introduced by (Fung et al., 2021; Zellers et al., 2019). In their datasets, the model correctly detects the fake claims without comparing different modalities. This is because all the fake claims are generated by language models. Another advantage is that we can generate the large-scale training set automatically rather than employing human annotators.

Original TRUE Claims	Generated FAKE Claims
Officials are scrambling to contain outbreaks of the coronavirus outside of China.	*Officials are scrambling to contain the spread of ebola outside of China.*
Moderna chairman getting vaccinated booster shots is the only way to stop the virus.	*Moderna chairman getting infected is the only way to stop the virus.*
Fed chair powell warns omicron variant could dent economic recovery.	*Fed chair powell warns omicron variant could facilitate economic recovery.*
Australians caught up in china's crisis have finally returned home after 14 days quarantined on christmas island.	*Australians caught up in china's crisis have lost home after 14 days quarantined on christmas island.*

Table 3: A detailed look into the examples generated by our efficient automatic approach. The first two examples are the event-argument manipulation and the final two are the event-trigger manipulation.

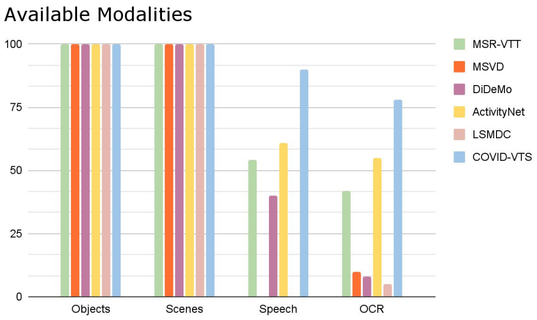

Figure 2: The histogram indicates COVID-VTS is more accessible to speech content and text on the screen than previous datasets.

	COVID-VTS	VIOLIN
Average Caption Length	19.2	18.0
Average Speech Length	69.2	76.4
Average Video Length	26.5s	35.2s
Named Entities (Sentence)	90.8%	10.3%
Source	Twitter	TV show

Table 4: Summary of `COVID-VTS` dataset.

Only event triggers or event arguments will be selected as the manipulated tokens `[mask]` depending on different intentions. We follow the procedures from (Nguyen et al., 2020) and use BERTWeet, pretrained on the Tweets related to the COVID-19 pandemic, to predict the domain-aware alternates of the event elements which can be subject to masking. In order not to introduce additional noise, we delete the candidates if their substituted tokens are not in the vocabulary of the original dataset to reduce the potential bias. Then, we feed the candidates and their corresponding true claims as input to the CrossEncoder model trained on Mutli-NLI dataset (Williams et al., 2017) and select the candidates with the CONTRADICTION label. If the candidate pair has the highest contradiction score, it will be assigned as the fake claim. Table 3 presents examples generated by our efficient automatic approach. The first two examples are the event-argument manipulation and the final two are the event-trigger manipulation.

Table 2 shows the most frequent event elements in original claims and generated claims. In practice, we found that these frequent alternatives bring the additional linguistic bias. Models can learn to classify the claims as fake ones simply by detecting these frequent tokens without absorbing information from other modalities. Therefore, we alleviate this bias by only keeping one claim for each alternative. Then replace unqualified claims by selecting the most similar claims from the dataset. Inconsistent pairs constructed this way focus more on the global understanding of the pairs. This rigorous setting makes the claims more challenging to distinguish by the analysis model, and in-depth reasoning is required to identify the fake content.

Inconsistent Speech Generation. Unlike (Tan et al., 2020) and (Fung et al., 2021) editing multiple parts of the article, our target is to only modify the evidence sentences from the speech to reduce the linguistic bias. First, we use cosine similarity on SBERT sentence embeddings to extract the most similar sentences to the real claims. After that, we manipulate the named entities or event elements within the evidence sentences.

Inconsistent Video Generation. As for the third type of inconsistent pairs, we keep the speech and claims as the original ones. However, we replace the original videos with another real video that is similar to the current one by using the adversarial matching (Liu et al., 2020b) method. Specifically, we utilize pretrained VideoCLIP (Xu et al., 2021) to generate video representations to calculate the cosine similarity.

Missing Modalities. In order to handle the video-claim pairs missing the speech text, we select the real speech text from the dataset which has common entities with respect to the current claim. This

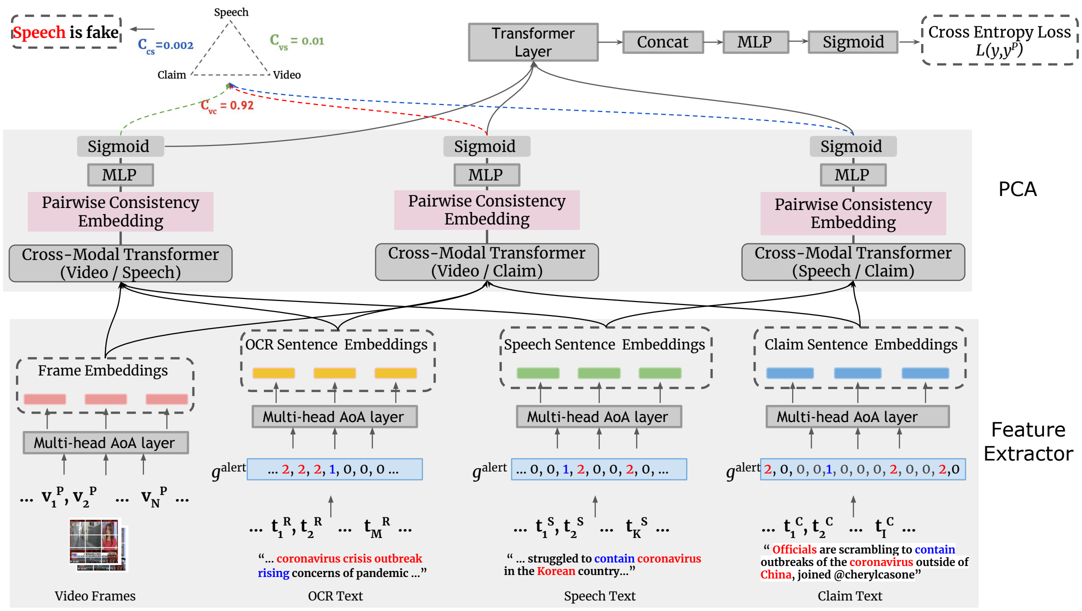

Figure 3: Overview of `TwtrDetective`. It detects the cross-modal inconsistency by comparing with video appearance, speech content, screen text and claims. g^{alert} means the event alert module. In this example, `TwtrDetective` predicts it as a an inconsistent pair and points out speech is manipulated since c^{vs} and c^{cs} are smaller.

new tuple with the real video, fake speech and real claim will be regarded as the inconsistent pairs in `COVID-VTS`. Examples generated by our tool are shown in Figure 1 and Figure 4. Without the in-depth reasoning and cross-modal understanding, it's challenging to distinguish them from the real pairs.

After all the filtering steps of automatic quality and bias control with manual validation, we assign the same amount of manipulated samples with pristine ones. Thus, the resulted dataset consists of 10k well-formed claims with associated videos.

3.3 Dataset Analysis

`COVID-VTS` exhibits three important differences to current benchmark datasets for video-text tasks (Xu et al., 2016; Chen and Dolan, 2011; Rohrbach et al., 2015; Anne Hendricks et al., 2017; Krishna et al., 2017). First, `COVID-VTS` brings new challenges with more diverse and complex scenes, including indoor press conference, news broadcasting, outdoor activities like protests, interviews, and screen recordings as well a slide shows. In contrast to recent video-text datasets (Xu et al., 2016; Chen and Dolan, 2011; Rohrbach et al., 2015; Anne Hendricks et al., 2017; Krishna et al., 2017), `COVID-VTS` has more available speech and screen text in Figure 2. Specifically, 87.5% of the videos have speech and over 77% of the videos have the screen text. `COVID-VTS` has more named entities and videos (Table 4). 90.8% of the sentences in `COVID-VTS` have named entities while VIOLIN (Liu et al., 2020b) is 10.2%. This large gap indicates `COVID-VTS` not only is an excellent resource to support research in the alignment between videos and named entities, but also provides new challenges to existing video-language inference models. Finally, `COVID-VTS` is the first fact-checking benchmark on the short video platform with inconsistent information from different modalities, which makes the fact-checking task more challenging.

4 Fact-Checking Model

4.1 Overview

As shown in Figure 3, our fine-grained fact-checking system, `TwtrDetective`, is able to evaluate the overall factual consistency by integrating pairwise relation embeddings between different modalities. `TwtrDetective` also points out which modality is inconsistent and provides explanations to support the verification.

Feature Extractor. We use the vision transformer of CLIP (ViT-B/32) (Radford et al., 2021) to encode every frame into features. In particular, it extracts N non-overlapping image patches from the frame and perform linear projection to map every patch into 1D token $\{v_1^p, \dots, v_N^p\}$, where $v_i \in \mathbb{R}^D$, where $D = 512$, N is the number of patches for each frame. Second, we apply pretrained RoBERTa (Liu et al., 2019b) to generate contextual text representations, which utilizes byte pair encoding (Shibata et al., 1999) to tokenize the sentences. Therefore, each sentence in the speech content S is represented as a sequence of tokens $\{t^s_1, \dots, t^s_K\}$, where $t^s_i \in \mathbb{R}^D$ and $D = 768$ and screen text O are $\{t^r_1, \dots, t^r_M\}$, where $t^r_i \in \mathbb{R}^D$ and $D = 768$. Finally tokens in the claim C are defined as $\{t^c_1, \dots, t^c_I\}$, where $t^c_i \in \mathbb{R}^D$ and $D = 768$.

Event Alert Module The intuitive method to check the consistency is to calculate the video-text similarity with video-sentence retrieval models (Liu et al., 2019a; Gabeur et al., 2020). However, the performance is dismal if the true information is tampered by small fragments. This is because existing models mainly encode the text at the document level without giving sufficient signal to focus on the factual elements, namely the event trigger and event argument.

To provide explicit guidance to learn the internal event semantic of the text, we first employ DYGIE++ (Hope et al., 2020) to detect the event structures within the text, assigning 1 if the token is the event trigger, 2 if it's the event argument and 0 otherwise. The indices are then fed into the learnable embedding table to generate *Event Alert* gate g^{alert}, where $g^{alert} \in \mathbb{R}^D$ and $D = 512$. A key property of g^{alert} is that it helps our model determine the salience of tokens in the text. Then, the claim token t^c_i, speech token t^s_i, OCR token t^r_i are projected into a common semantic subspace with the same dimension by learning parameters W^c, W^s, W^r.

$$t^{c\prime}_i = g^{alert} \odot \tanh(W^c t^c_i) \tag{1}$$

$$t^{s\prime}_i = g^{alert} \odot \tanh(W^s t^s_i) \tag{2}$$

$$t^{r\prime}_i = g^{alert} \odot \tanh(W^r t^r_i) \tag{3}$$

where $\odot$ represents the element-wise multiplication operation and $tanh$ is the activation function.

Multi-head AoA Layer. Motivated by the architecture presented in (Liu et al., 2020a), we contextualises $t^{c\prime}_i$, $t^{s\prime}_i$, $t^{r\prime}_i$ by using stacked Multi-Head Attention on Attention Layer, which takes advantage of the "Attention on Attention" module (Huang et al., 2019) to facilitate the generation of attended information. After encoding the text, the output of [CLS] tokens named as s^c, s^s and s^r are utilized as the sentence representations of claim, speech content and screen text correspondingly.

$$s^c = \text{MHAoA}^{\text{Mask}}(\{t^{c\prime}_i, \dots, t^{c\prime}_I\})_{[cls]} \tag{4}$$

$$s^s = \text{MHAoA}^{\text{Mask}}(\{t^{s\prime}_i, \dots, t^{s\prime}_K\})_{[cls]} \tag{5}$$

$$s^r = \text{MHAoA}^{\text{Mask}}(\{t^{r\prime}_i, \dots, t^{r\prime}_M\})_{[cls]} \tag{6}$$

Patch features are also projected into the common subspace with the text by W^v. In order to learn the salience of patches in each frame, we feed the patch features with injection of positional information into Multi-Head AoA Layer to model the correlation of each patch. After that, we leverage the global average pooling to output the representation of each frame v^f.

$$v'_i = \tanh(W^v v_i) \tag{7}$$

$$v^f = Pool(\text{MHAoA}^{\text{Mask}}(\{v'_1, \dots, v'_N\})) \tag{8}$$

Pairwise Consistency Aggregation (PCA). To model the consistency between the claim, speech and video frames, we apply the Cross-modal Transformer (Li et al., 2020) learn the pairwise relationship. First, we fed the speech sentence embeddings $S = \{s^s_1 \dots, s^s_{L_s}\}$, visual frame embeddings $F = \{v^f_1 \dots, v^f_{L_f}\}$ and its associated OCR sentence embeddings $O = \{s^r_1 \dots, s^r_{L_r}\}$ as the input. L_s, L_f, L_r present the number of sentences. We also add the [CLS] token in the first place of the input sequence. The outputs from Cross-modal Transformer is a sequence of contextualized embeddings. We use the output from the [CLS] token represent the consistency relationship between the video and speech.

$$R^{vs} = \text{Cross-Transformer}(F, O, S) \tag{9}$$

$$R^{vc} = \text{Cross-Transformer}(F, O, C) \tag{10}$$

$$R^{cs} = \text{Cross-Transformer}(C, S) \tag{11}$$

As for the consistency measurement between the claim $C = \{s^c_1 \dots, s^c_{L_c}\}$ and speech S, video F, we also utilize the Cross-modal Transformer to integrate different modalities and [CLS] to represent the weight. The claim can be regarded as the pointer to precisely retrieve relevant evidences from the paired video and speech, which play a key role to infer the truthfulness of the pairs.

Explanations. After feeding pairwise consistency embeddings R^{vs}, R^{vc} and R^{cs} into MLP layers and sigmoid functions, our model produces the relation scores c^{vs} which represents the consistency score between video and speech, c^{vc} which represents the consistency score between video and

Model	Accuracy	F1
CLIP4Clip (Luo et al., 2021b)	57.3	55.8
CLIP2Video (Fang et al., 2021)	59.4	56.8
VideoClip (Xu et al., 2021)	50.4	49.5
McCrae (McCrae et al., 2022)	62.7	62.3
MTS (Liu et al., 2020b)	56.3	55.4
MMT (Gabeur et al., 2020)	61.2	60.6
TwtrDetective (Ours)	**68.1**	**67.9**
Human Check	82.7	81.9

Table 5: Comparative results (%) with baselines on the COVID-VTS Dataset.

Model	Accuracy
MTS (Liu et al., 2020b)	60.4
XML (Lei et al., 2020)	69.6
HERO (Li et al., 2020)	70.4
TwtrDetective (Ours)	**72.6**

Table 6: Comparative results (%) with baselines on the VIOLIN Dataset.

claim and c^{cs}, which represents the consistency score between claim and speech. If a video post is classified as `inconsistent` by our model, the common modality of the two links with lower scores will be pointed as the `inconsistent` modality. For example in Figure 3, `TwtrDetective` detects that speech is inconsistent since c^{vs} and c^{cs} are smaller. It can be used the explanation to support the judgement.

Objective Function. We optimize our model by minimizing the standard cross-entropy as shown on the top of Figure 3, where y is the ground truth label and y^P is the prediction probability after putting c^{vs}, c^{vc} and c^{cs} into the transformer attention layer.

5 Experiments

In this section, we first introduce details of our implementation and compare the results to competing methods. Lastly, we present comprehensive experiment results and discussions.

5.1 Implementation Details

Datasets. We conduct experiments on two datasets: (1) COVID-VTS dataset, which consists of 10k video-text pairs with different taxonomies generated by our automatic tool. Half of the samples are pristine and half are manipulated. (2) VIOLIN dataset (Liu et al., 2020b), a Video-and-Language Inference, collected from TV shows and movies, which contains 15,887 video clips and claims written by human. We also generate inconsistent speech and video pairs with our automatic tool so as to make sure the inconsistency comes from different modalities. Our model is compared with baselines on both datasets.

Model	Accuracy	F1
TwtrDetective	68.1	67.9
TwtrDetective (w/o Event Alert Module)	64.4	64.5
TwtrDetective (w/o PCA)	66.3	65.9

Table 7: Ablation study to investigate our model's performance without the event alert module or the pairwise consistency aggregation module.

Model Training. Our model is implemented using Pytorch. In our implementation, the dimensions for the common subspace is 512. Models are optimized using Adam with learning rate as 0.0005. In addition, we adopt a uniform sampling strategy to extract the frames and the sampling rate is 1 frame per second. In all the experiments, we split the COVID-VTS dataset into 80% for training, 10% for validation and 10% for testing.

Evaluation Metric. We compute the accuracy and F1 score at distinguishing inconsistent pairs from consistent ones.

Baselines. (1) CLIP4Clip (Luo et al., 2021b) (2) CLIP2Video (Fang et al., 2021) uses CLIP (Radford et al., 2021) to encode visual frames and text and use the transformer to fuse temporal information. (3) VideoClip (Xu et al., 2021) is a state-of-art zero-shot video and text understanding model, which learns fine-grained association between video and text in a transformer. (4) McCrae (McCrae et al., 2022) employs Long LSTM to integrate the video, text and named entity information from the video posts. (5) MMT, a video-text model that designs a multi-modal transformer to jointly encode the different modalities in video. (7) HERO (Li et al., 2020): a transformer-based framework with two standard hierarchies for local and global context computation.

5.2 Results and Discussion

Comparison Experiments. As Table 5 and Table 6 show, our model achieves SOTA results compared with baselines on the both `COVID-VTS` and VIOLIN dataset. CLIP-variant models fail to perform well, revealing they do not detect token-level manipulation by analyzing the semantics of the sentence level. We notice that McCrae and MMT outperform MTS on both scores. This is because McCrae and MMT extract additional features from videos to help verification like objective detection and face detection. However, named entity verification

Model	Accuracy	F1
TwtrDetective	68.1	67.9
TwtrDetective (w/o $Pair_{[Claim,Video]}$)	66.6	66.3
TwtrDetective (w/o $Pair_{[Claim,Speech]}$)	67.2	67.0
TwtrDetective (w/o $Pair_{[Speech,Video]}$)	67.5	67.2

Table 8: Analysis on the importance of different modality pairs in the PCA module.

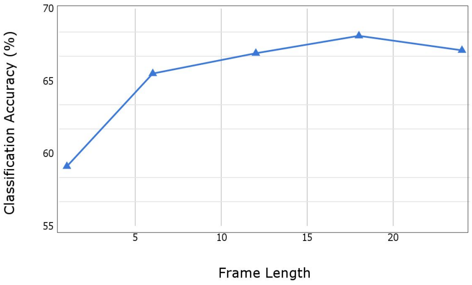

Figure 5: Ablation study to investigate our model's performance with different frame length.

proposed by McCrae does not show improvement on our since because it's incapable of finding the event-trigger manipulation. The main advantages of our model is that our event alert module is able to extract fine-grained factual details from the heterogeneous content. The pairwise consistency aggregation module is able to measure the interaction between each modality precisely. These observations also explain why our model outperforms HERO, which ignores the guide from the event structures. The performance on the VIOLIN dataset is better compared to the results on `COVID-VTS` dataset. This is because our `COVID-VTS dataset` is more challenging with more named entities and events.

Analysis on Different Modalities. We gain further insights into the importance of different modality pairs in PCA module. Our model in the first row of Table 8 uses all three pairs $Pair_{[Claim,Video]}$, $Pair_{[Claim,Speech]}$ and $Pair_{[Speech,Video]}$ in PCA. Other rows miss one of these pairs. Table 8 indicates the PCA module is effective to improve the consistency checking performance between multiple modalities. In addition, $Pair_{[Claim,Video]}$ contributes more than the other two pairs. This is because the evidence sentences are the only manipulated parts in the long speech text, making it challenging to be detected by referring to claims and videos.

Ablation Study. We investigate frame length in Figure 5, we can see a significant increase between 1 and 6 frames which shows it is better to encode the videos with a sequence of multiple frames instead of one single frame. We sampled 18 frames for our experiment, which is both efficient and effective. Furthermore in Table 7, our model mainly benefits from *Event Alert* module which provides 3.7% boost in classification accuracy by explicitly tracking distorted factual pieces at the token level, *PCA* module contributes 1.8% improvement compared to using one-stream transformer to aggregate features from different modalities. Additionally, our model achieves better accuracy on short claims (length < 15) than on long claims (length > 25). This is because long claims have more event triggers and arguments than short claims, which makes it challenging for our event alert module to capture the manipulated tokens.

Qualitative Analysis. Figure 4 presents prediction examples from our model. The correct cases (first two examples) demonstrate the model's ability to recognize the tiny inconsistent tokens. Since the original pair of third example miss the speech modality, we add the speech text which shares more common entities with the claim as the inconsistent modality. `TwtrDetective` fails to predict third post, suggesting that it does not work well on the video and speech alignment. The reasons behind might because both the video and speech describe the protest against the vaccine mandate but in different countries. Only from the video, it's hard to detect whether it's in Australia, Germany or Austria. In addition, the date information is also challenging to check. The future direction could be asking the model to point out which part of the information is inconsistent or unverifiable and define the inconsistency taxonomy for them.

6 Conclusions

In this paper, we release a new benchmark, `COVID-VTS`, for fact-checking in short video platforms, consisting of 10k video-claim pairs. We develop an efficient tool to automatically generate large-scale trustworthy inconsistent pairs with different semantic meanings. Furthermore, our proposed fact-checking model `TwtrDetective` achieves state-of-the-art detection accuracy. We hope this work paves the way for future studies in multi-modal fact-checking as well as other related research areas in video and language.

7 Ethical Statement

Our goal in developing state-of-art consistency checking technique is to enhance the field's ability to detect fake news and improve the Twitter community health. According to Twitter Developer Policy, Twitter supports the research that measures and analyzes topics like spam, abuse, or other platform health-related topics for non-commercial research purposes. In addition, the posts we collected are from verified and authentic accounts. Certain accounts are ineligible for the verified badge if they post content that harasses, shames, or insults any individual or group, or violate the Platform manipulation and spam policy. To protect the personal information, we will only use the captions and videos as input without the user information. We also work to filter the dataset and only keep the posts discussing public news instead of personal life. Personal information but not limited to, user's name, health, financial status, racial or ethnic origin, religious or philosophical affiliation or beliefs, sexual orientation, trade union membership, alleged or actual commission of crime. It's crucial to mention that we will not share our source video file but the URL links or the extracted features from the videos. This is to due to the licence policy and avoid anyone to deliberately generate and spread misinformation. As such, we will release the model code but not the output in our work for public verification and auditing so it can be used to combat fake news.

8 Limitations

There is a significant gap between our model and human performance on the accuracy. We hope `COVID-VTS` dataset will encourage the community to develop stronger models in the future. One possible direction is to develop models to localize key frames or key sentences from the speech to deduce the difficulty of consistency check.

Multimodal Graph Transformer for Multimodal Question Answering

Abstract

Despite the success of Transformer models in vision and language tasks, they often learn knowledge from enormous data implicitly and cannot utilize structured input data directly. On the other hand, structured learning approaches such as graph neural networks (GNNs) that integrate prior information can barely compete with Transformer models. In this work, we aim to benefit from both worlds and propose a novel Multimodal Graph Transformer for question answering tasks that requires performing reasoning across multiple modalities. We introduce a graph-involved plug-and-play quasi-attention mechanism to incorporate multimodal graph information, acquired from text and visual data, to the vanilla self-attention as effective prior. In particular, we construct the text graph, dense region graph, and semantic graph to generate adjacency matrices, and then compose them with input vision and language features to perform downstream reasoning. Such a way of regularizing self-attention with graph information significantly improves the inferring ability and helps align features from different modalities. We validate the effectiveness of Multimodal Graph Transformer over its Transformer baselines on GQA, VQAv2, and MultiModalQA datasets.

1 Introduction

A myriad of complex real-world tasks require both prior knowledge and reasoning intelligence (Yi et al., 2018a; Ilievski and Feng, 2017). These days, vision-and-language reasoning tasks such as as vision question answering (VQA) (Antol et al., 2015) and multimodal question answering (MultiModalQA) (Talmor et al., 2021) post further needs for integrating structured info from different input modalities and thus perform reasoning. Towards this, two questions yield: What is the best way to integrate prior knowledge and reasoning components from multiple modalities in a single model? How would such an integration lead to accurate models, while being more computationally efficient and allowing for significantly more interpretability? Such questions are important to address when scaling reasoning systems to real-world use cases.

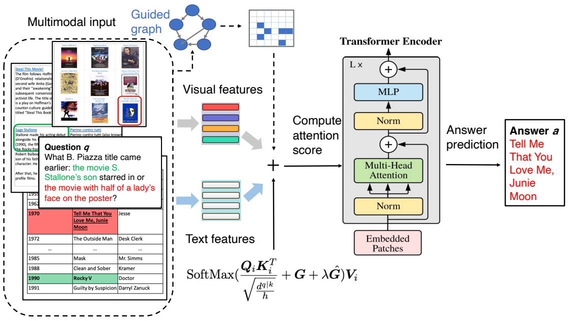

Figure 1: Overview of Multimodal Graph Transformer. It takes visual features, text features, and their corresponding generated graphs as inputs. The generated graph is first converted to an adjacency matrix to induce the mask matrix $\boldsymbol{G}$. The modified quasi-attention score in the Transformer is computed to infer the answer. In the formular, $\boldsymbol{G}$ is the graph-induced matrix constructed by concatenating adjacency matrices both from the vision and the language end. $\hat{\boldsymbol{G}}$ is the trainable bias. The input features from different modalities are fused along with graph info to perform downstream reasoning.

These years, there are a spectrum of methods in the literature exploring different ways of integrating structured prior information. Graph neural networks (GNNs) (Wu et al., 2020), have been widely used in representation learning on graphs. Some experts tried to investigate the embedding of the structured information by resorting to them. However, GNNs are inefficient (Wu et al., 2020) and they can barely compete with Transformer models. Besides, most GNNs are designed to learn node representations on fixed and homogeneous graphs. Thereby, it is suboptimal to operate GNNs on vision-and-language tasks such as visual question answering (VQA), where graphs encountered in these problems (e.g. scene graphs) can be more complex; Alternatively, knowledge graphs (KGs),

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 189–200

such as Freebase (Bollacker et al., 2008), represent world-level factoid information of entities and their relations in a graph-based format, surfaced these years. They have been successfully used in vision and language applications including VQA (Marino et al., 2019). However, they have not been dedicated to be applied to our scenario, more concretely, we aim at filling the gap of capturing prior knowledge in Transformer models.

To mitigate deficiencies of the existing methods, this paper proposes a novel plug-and-play graph-involved Transformer-based method for multimodal question answering tasks. Our method is *Multimodal Graph Transformer* in the sense that it is built upon the well-established Transformer (Vaswani et al., 2017a) backbone, albeit with several key fundamental differences. First, we introduce a systematic scheme to convert text graphs, dense region graphs, and semantic graphs from vision and language tasks to adjacency matrices to use in our method. Second, instead of directly computing the attention score, we learn the newly proposed quasi-attention score with graph-induced adjacency matrices live at its heart, to signify the importance of learning relative importance as a highly effective inductive bias for computing the quasi-attention score. Third, different from previous Transformer methods, where self-attention are fully learned from data, we switch gears to introduce the graph-structured information in the self-attention computation to guide the training of Transformers as shown in Figure 1.

The main contributions are summarized below:

- We propose a novel Multimodal Graph Transformer learning framework that combines multimodal graph learning from unstructured data with Transformer models.
- We introduce a modular plug-and-play graph-involved quasi-attention mechanism with a trainable bias term to guide the information flow during training.
- The effectiveness of the proposed methods is empirically validated on GQA, VQA-v2, and MultiModalQA tasks.

2 Related Works

2.1 Multimodal question answering

Visual Question Answering (VQA)(Antol et al., 2015) has been a prominent topic in the field of multimodal question answering, garnering significant attention and advancing significantly since the introduction of the first large-scale VQA dataset byAntol et al. (2015). To answer VQA questions, models typically leverage variants of attention to obtain a representation of the image that is relevant to the question (Andreas et al., 2016; Yang et al., 2015; Xu and Saenko, 2016; Fukui et al., 2016; Lu et al., 2016). A plethora of works (Liang et al., 2021; Hudson and Manning, 2018; Yi et al., 2018b; Xiong et al., 2016; Kim et al., 2018; Teney et al., 2017a) have attempted to enhance the reasoning capability of VQA models, with Teney et al. (2017a) proposing to improve VQA using structured representations of the scene contents and questions. They developed a deep neural network that leverages the structure in these representations and builds graphs over scene objects and question words. The recent release of MultiModalQA (Talmor et al., 2021), a dataset that demands joint reasoning over texts, tables, and images, has received widespread attention. However, similar to VQA, existing MultiModalQA methods have not fully utilized structured information from the input concepts. To address this, we propose a combination of multimodal graph learning and Transformer models to improve question answering across inputs from multiple different modalities.

2.2 Attention mechanisms

The attention mechanism (Xu et al., 2015a,b; Devlin et al., 2018), has dramatically advanced the field of representation learning in machine learning. The attention mechanism is introduced in Vaswani et al. (2017b) and widely used in language tasks (i.e., abstract summarization (Xu et al., 2020)), machine translation (Bahdanau et al., 2014), reading comprehension (Dai et al., 2020), question answering (Min et al., 2019), etc. Zhang et al. (2020) proposes using syntax to guide the text modeling by incorporating explicit syntactic constraints into attention mechanisms. Meanwhile, it has seen increasing application in multimodal tasks (Li et al., 2020; Nam et al., 2017; Lu et al., 2016), where it is usually used for learning of interactions between multiple inputs. Following their success, multimodal Transformer models (Chen et al., 2019; Hu et al., 2020; Sun et al., 2019) have also shown impressive results on several vision-and-language tasks. Yun et al. (2019) proposes Graph Transformer Networks (GTNs) that can generate new graph structures and learn effective node representation on the new graphs in an end-to-end fashion. Different from these works, our work incorporates graph information from different modalities into the Transformer to improve the reasoning ability.

2.3 Exploiting graphs in multimodal reasoning

Considering that graph priors can transfer commonalities and mitigate the gap between visual and language domains, researchers explore how to use graphs (Teney et al., 2017b; Yu et al., 2020) properly in both tasks. In recent years, many classes of GNNs have been developed for both tasks which are divided into two approaches: spectral (Bruna et al., 2013) and non-spectral methods (Chen et al., 2018). Graphs can also be transferred into latent variables by GCN (Yang et al., 2019a; Yao et al., 2018), which can be directly utilized by models. However, the need for aligning graph priors from different modalities to do reasoning limits the use of graph priors. Our work addresses this problem via the graph-involved quasi-attention mechanism.

2.4 Pretraining

Pretrained models in computer vision (Simonyan and Zisserman, 2014; He et al., 2016) and NLP (Devlin et al., 2018; Yang et al., 2019b; Liu et al., 2019), have achieved state-of-the-art performances in many downstream tasks (Thongtan and Phienthrakul, 2019; White et al., 2017; Karpathy and Fei-Fei, 2015; Lee et al., 2018; Ren et al., 2015b). Other pretrained models such as VLBERT (Lu et al., 2019; Sun et al., 2019) and ViLT (Kim et al., 2021) also demonstrate their effectiveness on downstream vision-language tasks. Recent works on vision-language pretraining such as OSCAR (Li et al., 2020) perform cross-modal alignment in their visual-language pretraining models. Likewise, our proposed method includes cross-modality alignment, which is critical for reasoning. Our proposed modular plug-and-play graph-involved quasi-attention mechanism is also model-agnostic and can be also applied to other pretrained Transformer-based vision and language models.

3 Multimodal Graph Transformer

3.1 Background on Transformers

The Transformer layer (Vaswani et al., 2017b) consists of two modules: a multi-head attention and a feed-forward network (FFN). Specifically, each head is represented by four main matrices: the query matrix $\boldsymbol{W}_i^q \in \mathbb{R}^{d^m \times d^q/h}$, the key matrix $\boldsymbol{W}_i^k \in \mathbb{R}^{d^m \times \frac{d^k}{h}}$, the value matrix $\boldsymbol{W}_i^v \in \mathbb{R}^{d^m \times \frac{d^v}{h}}$, and the output matrix $\boldsymbol{W}_i^o \in \mathbb{R}^{\frac{d^v}{h} \times d^o}$, and takes the hidden states $\boldsymbol{H} \in \mathbb{R}^{l \times d^m}$ of the previous layer as input, where d denotes the dimension of the model, h represents the number of head, and i denotes the index of layer number. The output of attention is given by:

$$\boldsymbol{Q}_i, \boldsymbol{K}_i, \boldsymbol{V}_i = \boldsymbol{H}\boldsymbol{W}_i^q, \boldsymbol{H}\boldsymbol{W}_i^k, \boldsymbol{H}\boldsymbol{W}_i^v \tag{1}$$

$$\mathrm{Attention}\left(\boldsymbol{Q}_i, \boldsymbol{K}_i, \boldsymbol{V}_i\right) = \mathrm{SoftMax}\left(\frac{\boldsymbol{Q}_i \boldsymbol{K}_i^T}{\sqrt{\frac{d^{q|k}}{h}}}\right)\boldsymbol{V}_i \tag{2}$$

$$\boldsymbol{H}_i = \mathrm{Attention}\left(\boldsymbol{Q}_i, \boldsymbol{K}_i, \boldsymbol{V}_i\right)\boldsymbol{W}_i^o \tag{3}$$

where $\boldsymbol{Q}_i \in \mathbb{R}^{l \times \frac{d^q}{h}}, \boldsymbol{K}_i \in \mathbb{R}^{l \times \frac{d^k}{h}}, \boldsymbol{V}_i \in \mathbb{R}^{l \times \frac{d^v}{h}}$ are obtained by the linear transformations of $\boldsymbol{W}_i^q, \boldsymbol{W}_i^k, \boldsymbol{W}_i^v$ respectively. $\mathrm{Attention}(\cdot)$ is the scaled dot-product attention operation. Then output of each head is transformed to $\boldsymbol{H}_i \in \mathbb{R}^{l \times d^o}$ by $\boldsymbol{W}_i^o$.

3.2 Framework overview

The entire framework of the proposed Multimodal Graph Transformer method is depicted in Figure 2. Without loss of generality, we assume the end task is VQA in the following discussion while noting that our framework can be applied to other vision-language tasks, such as multimodal question answering.

Given the input images and questions, the framework first constructs three graphs, including the semantic graph, dense region graph, and text graph, which will be described in more detail in the following sections. The graph $G = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ represents the set of nodes in the graph and $\mathcal{E}$ represents the edges connecting them, is fed into Transformers to guide the training process.

3.3 Multimodal graph construction

We build three types of graphs and feed them into Transformers: *text graph*, *semantic graph*, and *dense region graph*. We now introduce them in detail.

Text graph The task of Visual Question Answering involves a combination of an image, a question, and its corresponding answer. To process the question, we extract the entities and create a text graph representation. We then build the graph $G = (\mathcal{V}, \mathcal{E})$

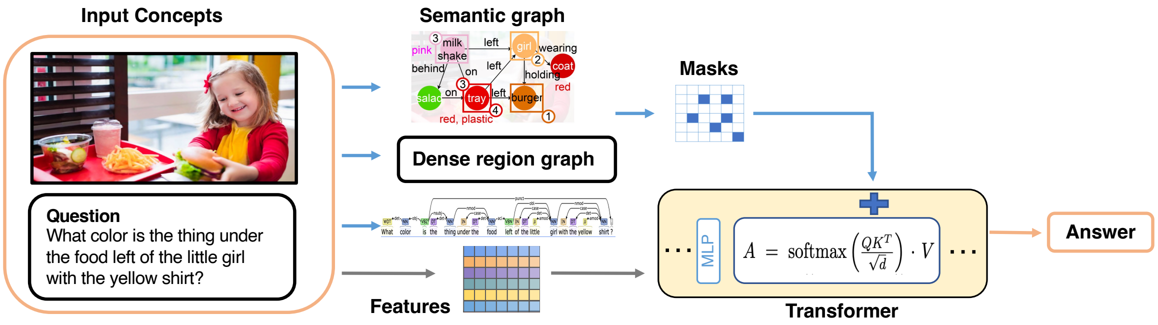

Figure 2: The figure illustrates the overall framework of our Multimodal Graph Transformer. The input from different modalities are processed and transformed into corresponding graphs, which are then converted into masks and combined with their features to be fed into Transformers for downstream reasoning. In detail, semantic graphs are created through scene graph generation methods, dense region graphs are extracted as densely connected graphs, and text graphs are generated through parsing.

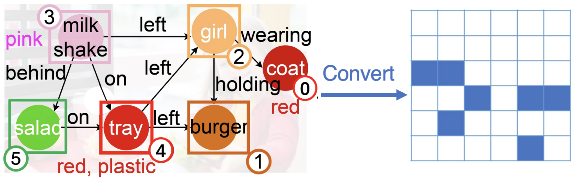

Figure 3: The naive demonstration of converting a semantic graph into an adjacency matrix. Cells in blue means '0's for that element in the graph matrix, while white ones means '-inf's. We employ the matrix as the mask when computing the quasi-attention.

as shown in the left of Figure 2. The set of nodes, $\mathcal{V}$, represents the entities and the set of edges, $\mathcal{E}$, represents the relationships between the pairs of entities. This results in:

- A set of N entities, each represented by a vector of token embeddings, that constitute the nodes of the graph.
- A set of pairwise relations between entities, forming the edges of the text graph. The relationship between entities i and j is represented by a vector e_{ij} which encodes the relative relationships.

Semantic graph In tasks such as multimodal question answering, there might be additional inputs in the form of tables or lengthy paragraph sentences. To handle these inputs, a linear representation of the table can be created and a semantic graph can be constructed using a similar approach. They are processed using the scene graph parser (Zhong et al., 2021), which transforms the text sentence into a graph of entities and relations, as depicted in Figure 3. The output of the scene graph parser includes:

- A set of N words that constitute the nodes of the semantic graph, where N is the number of parsed words in the texts.
- A set of possible pairwise relations between words, such as "left" and "on" as shown in Figure 3, which constitute the edges of our graph. An edge between words connecting j to i is represented by e_{ij}, namely, the connectivity is indicated as: $e_{ij} = \begin{cases} 0, & i,j \text{ not connected} \\ 1, & i,j \text{ connected} \end{cases}$.

Dense region graph The visual features are extracted by slicing the input images into patches and flattening them. A dense region graph $G = (\mathcal{V}, \mathcal{E})$ is then converted into masks, with $\mathcal{V}$ being the set of extracted visual features and $\mathcal{E}$ being the set of edges connecting each feature node, following the method described in (Kim et al., 2021). This results in a graph that is nearly fully connected.

The resulting three graphs are then transformed into adjacency matrices, where the elements are either -∞ or zero. The conversion process is depicted in Figure 3 using the semantic graph as an example. These adjacency matrices are used inside the scaled dot-product attention to control the flow of information, by masking out (setting to $-\infty$) the values.

3.4 Graph-involved quasi-attention

In order to effectively utilize structured graph knowledge in our self-attention computation, we incorporate the graph as an extra constraint in each

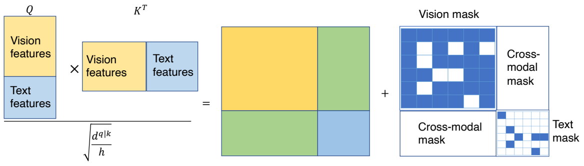

Figure 4: A naive demonstration of adding the graph-induced mask while computing the quasi-attention when the inputs are from two modalities. The visual mask is the mask converted from the dense region graph and the text mask is converted from the text graph. The cross-modal mask, which is always set as an all-zero matrix, is imposed to encourage the model to learn the cross-attention between the image features and text features, thus facilitating the alignment across them.

attention head by converting it into an adjacency matrix. The graph matrix, denoted as $\boldsymbol{G}$, is constructed by combining various masks. An illustration of this process can be seen in Figure 4. The visual mask is generated from the dense region graph, while the text mask is derived from the text graph. Additionally, the cross-modal mask is set to an all-zero matrix to encourage the model to learn the cross-attention between visual and text features, thereby promoting alignment across the different modalities.

Within the context of adding graph information, when vision graph mask and text graph mask are concatenated and aligned with image and text features, we believe that a more flexible masking-out mechanism is beneficial, rather than keeping a single constant mask matrix inside the Softmax operation. Drawing insights from Liu et al. (2021), where they include a relative position bias to each head in computing similarity, we also intuitively parameterize a trainable bias $\hat{\boldsymbol{G}}$ and involve it in the training process. Finally, we compute the quasi-attention as follows:

$$\text{Attention} = \text{SoftMax}\left(\frac{\boldsymbol{Q}_i \boldsymbol{K}_i^T}{\sqrt{\frac{d^{q|k}}{h}}} + \boldsymbol{G} + \lambda \hat{\boldsymbol{G}}\right)\boldsymbol{V}_i, \tag{4}$$

where λ is the tradeoff hyper-parameter that controls the contribution of $\hat{\boldsymbol{G}}$, and $\boldsymbol{G}$ is our graph-induced matrix constructed by concatenating a graph matrix both from the vision and the language end. Here for clear clarification, we use $\boldsymbol{G}$ and $\hat{\boldsymbol{G}}$ to distinguish the graph matrices fixed and trainable, respectively. During training, $\boldsymbol{G}$ is frozen as before and does not receive gradient updates, while $\hat{\boldsymbol{G}}$ contains trainable parameters.

We now introduce the motivation behind adding two types of graph matrices. We perform the masking process by adding $\boldsymbol{G}$ when computing the quasi-attention because it can be interpreted as a form of attentional pooling (learning to align), in which each element of $\boldsymbol{G}$ pools all relevant information across all elements of the relative importance matrix computed by $\left(\frac{\boldsymbol{Q}_i \boldsymbol{K}_i^T}{\sqrt{\frac{d^{q|k}}{h}}}\right)$. Hence during fine-tuning, the model ignores redundant features and only focuses on useful information. The mask can also force the model to learn the cross attention between features from the images and questions and perform aligning across them. And the trainable bias $\hat{\boldsymbol{G}}$ captures information gained during the training process. Such information is valuable for fine-tuning, making the Transformer more robust and helping it gain numerical stability.

3.5 Training

The interdependence of output features from various modalities calls for a unified optimization approach for the Transformers in both the visual question answering and multimodal question answering tasks. To accomplish this, we implement a kind of end-to-end training, which ensures the optimality of the models. The final outcome of our models is a classification logit, which is generated by the VQA models that select the best answer from the available candidate answers. To evaluate the accuracy of the models, we compute the cross-entropy loss (Zhang and Sabuncu, 2018) using the output logits produced by the Transformer. This measure helps us determine the difference between the predicted class probabilities and the actual class labels.

4 Experiments

4.1 Datasets

VQA v2 The VQA v2 dataset (Goyal et al., 2017) extends the VQA (Antol et al., 2015) dataset to better balance visual and textual information through the collection of complementary images. Each question in VQA v2 is associated with a pair of similar images with different answers, resulting in a total of 1.1 million QA pairs and 204,000 images. The data split for VQA v2 includes a training set with 83,000 images and 444,000 questions, a validation set with 41,000 images and 214,000 questions, and a test set with 81,000 images and 448,000 questions. The annotated answers are in natural language, but they are commonly converted to a classification task with 3,129 answer classes.

Table 1: Accuracy (%) comparison of different methods on the GQA and VQA v2 test-dev. Ours has the second best performance and is comparable to state-of-the-art methods. After applying our proposed quasi-attention mechanism and exploiting the use of graphs, there is also a 2% improvement of overall accuracy on the LXMERT baseline, suggesting the generalization ability of our method.

Dataset	Method	Open questions	Binary questions	Overall accuracy
GQA	LXMERT (Tan and Bansal, 2019)	-	-	60.0
	LXMERT w/ Graph (Tan and Bansal, 2019)	-	-	61.4
	HANs (Kim et al., 2020)	-	-	69.4
	NSM (Hudson and Manning, 2019b)	49.3	78.9	63.2
	OSCAR (Li et al., 2020)	-	-	61.6
	VinVL (Zhang et al., 2021)	-	-	65.1
	Multimodal Graph Transformer (Ours)	59.4	80.5	68.7
VQA v2	LXMERT (Tan and Bansal, 2019)	-	-	72.4
	HANs (Kim et al., 2020)	-	-	65.1
	NSM (Hudson and Manning, 2019b)	-	-	63.0
	OSCAR (Li et al., 2020)	-	-	73.8
	VinVL (Zhang et al., 2021)	-	-	76.6
	Multimodal Graph Transformer (Ours)	66.5	87.0	74.5

As described by Anderson et al. (2018), the model selects the answer to each question from a set of 3,129 most frequent answers. Following this convention, we fine-tune the multimodal graph transformer model on the VQAv2 training and validation sets, while reserving 1,000 validation images and related questions for internal validation.

GQA The GQA dataset contains 22M questions over 113K images. The questions in GQA are designed to require multi-hop reasoning to test the reasoning skills of VQA models. GQA greatly increases the complexity of the semantic structure of questions, leading to a more diverse function set. The real-world images in GQA also bring in a bigger challenge in visual understanding. We conduct experiments on the public splits (Hudson and Manning, 2019a) of the GQA dataset and also treat the task as the classification task reffering to the VQA v2 setting.

MultiModalQA MultiModalQA (MMQA) contains 29, 918 questions. We split the dataset into 23,817 training, 2,441 development (dev.), and 3,660 test set examples referring to the official split. Around 60% of the questions in MMQA are compositional. The answer for each question can be a single answer or a list of answers.

4.2 Baselines

We compare with four state-of-the-art VQA models: LXMERT (Tan and Bansal, 2019), NSM (Hudson and Manning, 2019b), OSCAR (Li et al., 2020), and VinVL (Zhang et al., 2021).

- LXMERT (Tan and Bansal, 2019) designs five pretraining tasks: masked language modeling, feature regression, label classification, cross-modal matching, and image question answering to pretrain a large Transformer model. Towards this, a large-scale Transformer (Vaswani et al., 2017b) model is built that consists of three encoders: an object relationship encoder, a language encoder, and a cross-modal encoder.
- NSM (Hudson and Manning, 2019b) predicts a probabilistic graph that represents its underlying semantics and performs sequential reasoning over the graph to traversing its nodes to make the inference.
- OSCAR (Li et al., 2020) uses object tags detected in images as anchor points to significantly ease the learning of alignments, improving previous methods and using self-attention to learn image-text semantic alignments.
- VinVL (Zhang et al., 2021) developed a new object detection model to create better visual features of images than previous classical object detection models.

We compare with four baselines introduced in the MultiModalQA paper (Talmor et al., 2021): Question-only (Kaushik and Lipton, 2018), Context-only (Kaushik and Lipton, 2018), AutoRouting, ImplicitDecomp.

- Question-only is a sequence-to-sequence model that directly generates the answer given the question.

- Context-only first predicts the question type using the classifier and then feed in the relevant context to predict the answer.
- AutoRouting first determines the modality where the answer is expected to occur, and then runs the corresponding single-modality module.
- ImplicitDecomp is a 2-hop implicit decomposition baseline and so far the state-of-the-art method on the MultiModalQA dataset.

4.3 Implementation details

The input texts undergo preprocessing using a scene graph parser which extracts entities and their relationships. The text features are obtained through a pre-trained BERT tokenizer, allowing us to extract text spans of individual entities and text spans containing two related entities. As for images, we employ the methods described in Dosovitskiy et al. (2020); Kim et al. (2021) to extract visual features and create graph masks. This involves resizing the shorter edge of the input images while preserving the aspect ratio and limiting the longer edge, followed by patch projection and padding for batch training. The resulting patch embeddings are used as inputs along with constructed dense region graph that is densely connected. The Transformer backbone used in this setting is the pretrained VIT-B-32 (Dosovitskiy et al., 2020) version, consisting of 12 layers with a hidden size of $H = 768$, layer depth of $D = 12$, patch size of $P = 32$, a multi-layer perceptron size of 3072, and 12 attention heads. To test this setting, all inputs and graphs are merged and processed by the Transformer backbone, which learns from features from different modalities.

4.3.1 MultiModalQA

We further investigate the effectiveness of our proposed method on MultiModalQA (Talmor et al., 2021), a recently introduced and demanding task that requires joint reasoning across various modalities such as texts, images, tables, etc. We employ a Multimodal Graph Transformer to tackle the task, using the same approach for extracting vision and text features as in VQA. Additional modalities, such as tables, are encoded by linearizing them and utilizing pre-trained models like RoBERTa-large (Liu et al., 2019). After generating text graphs, semantic graphs, and dense region graphs from input questions, text, tables, and images, we feed them along with the extracted features into the Transformer. Unlike the Transformer used in VQA, which takes inputs from two modalities, the MultiModalQA Transformer accepts input from three modalities and performs the final reasoning.

Table 2: EM (%) and F1 (%) of Multimodal Graph Transformer and its Transformer baseline on questions in MultiModalQA that require reasoning over multiple modalities. Incorporating graph information into the Multimodal Graph Transformer can boost about 2% F1 and 4% EM performance.

Method	EM	F1
Question-only	16.9	19.5
Context-only	6.6	8.5
AutoRouting	32.0	38.2
ImplicitDecomp	46.5	51.7
Human	84.8	90.1
Multimodal Transformer w/o Graph	50.1	56.4
Multimodal Graph Transformer (Ours)	52.1	57.7

4.4 Results and analysis

Table 1 presents a comparison of the accuracy of our proposed method on the GQA dataset with previous state-of-the-art methods. Our proposed method ranks second in terms of accuracy and outperforms the third best method by a substantial margin, with an absolute improvement of over 3% in overall accuracy. The performance of our method is comparable to the state-of-the-art method.

We also conducted experiments on the VQA v2 dataset, and the results are summarized in Table 1 and Table 3. As shown, there are significant improvements over methods without graphs, suggesting that incorporating graph information into the Transformer is effective.

Additionally, after incorporating our proposed graph method into LXMERT, we can observe a boost in overall accuracy on the GQA dataset, demonstrating the generalization ability of the proposed method in incorporating graph information into quasi-attention computation.

Table 2 compares the Exact Match (EM) and average F1 score of our proposed method on the MultiModalQA dataset with the baseline. The results show that our proposed method outperforms the baseline without the aid of graph information, demonstrating the generalization of our method to more complicated vision-and-language reasoning

Table 3: Ablation Studies on the GQA and VQA v2 Validation Sets. The figure demonstrates the effectiveness of incorporating graph information into the Transformer architecture through ablation studies performed on the GQA and VQA v2 validation sets. The results of these studies clearly indicate that including graph information can lead to an improvement in performance.

Dataset	Method	Open questions	Binary questions	Overall accuracy
GQA	One-modality Transformer	47.7	78.1	62.7
	Multimodal Transformer w/o Graph	49.9	81.0	65.4
	Ours	**60.1**	**90.2**	**72.4**
VQA v2	One-modality Transformer w/ one Transformer	60.5	85.4	70.1
	Multimodal Transformer w/o Graph	64.8	86.3	72.1
	Ours	**66.7**	**87.2**	**74.6**

tasks.

4.5 Ablation studies

We perform ablation studies to verify the necessity of using two-stream inputs with the help of graphs to deal with input from different modalities, with GQA dataset as our testing bed. For all experiments, we use the overall accuracy as the evaluation metric.

The results presented in Table 3 show the superiority of our proposed Multimodal Graph Transformer over the method where a single modality input is fed into a Transformer. Our method, which involves dividing the input streams into two separate parts and processing each part through a Transformer, outperforms the Multimodal Transformer without Graph. This demonstrates the beneficial effect of incorporating graph information into the processing of the input data and performing training. The use of different input features with the help of graphs allows for a better alignment of the information from different modalities, which is reflected in the improved performance of our proposed method.

4.6 Qualitative results

One qualitative example is shown in Figure 5. As can be seen, predictions from Multimodal Graph Transformer are more relevant to contents of the input image as the graph information improves the inferring ability of the Transformer, which further indicates the effectiveness of Multimodal Graph Transformer.

5 Conclusions

In this paper, we have presented a novel method to integrate structured graph information to guide the Transformers training. Our method can model interactions between different modalities and achieves competitive performance on multimodal reasoning tasks such as VQA and MultiModalQA. Experimental results show that our method outperforms many other methods on the GQA dataset. More importantly, the proposed quasi-attention mechanism is model-agnostic and it is possible to apply it to other Transformer-based methods. We will test our methods on other vision-and-language reasoning tasks and include the comparison with existing graph representation learning methods in our future work.

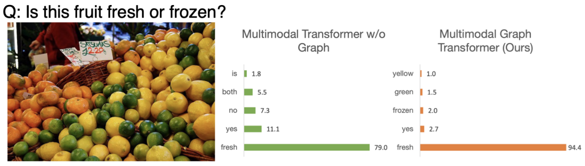

Figure 5: A qualitative comparison from VQA v2. *fresh* is the ground truth. Predictions from the Multimodal Graph Transformer (ours) are more relevant to the contents of the input image and achieve a higher confidence score over the ground truth.

6 Limitations and Potential Risks

The Limitations of the proposed Multimodal Graph Transformer include the potential preservation of fairness and bias issues inherent in the pretrained Transformer models, despite the involvement of graph information. Additionally, the integration of graphs may introduce new biases that can further exacerbate the problem. One potential source of bias is the vision-and-language dataset itself, which may favor majority cases and overlook minority cases. Unfortunately, the proposed method is not equipped to address these biases and issues, making further research and consideration crucial when building upon or directly using this method for vision and language tasks.

A Appendix

A.1 Visual Question Answering dataset

To address the problem of visual question answering, a number of visual question answering datasets have been developed. The comparison of them is shown in Table 4. The VQA dataset (Antol et al., 2015) is developed on real images in MS COCO (Lin et al., 2014) and abstract scene images

Table 4: Comparison of VQA datasets

	Source of images	# images	# QA pairs	Answer type	Evaluation metrics
DAQUAR	NYU-Depth V2	1,449	12,468	Open	Accuracy&WUPS
VQA	COCO	204K	614K	Open/MC	Accuracy
VQA v2	COCO	204K	1.1M	Open/MC	Accuracy
COCO-QA	COCO	123K	118K	Open/MC	Accuracy
CLEVR	Generated	100K	999K	Open	Accuracy
GQA	Visual Genome	113K	22M	Open	Accuracy

in Antol et al. (2014); Zitnick and Parikh (2013). The question-answer pairs are created by human annotators who are encouraged to ask “interesting" and “diverse" questions. VQA v2 (Goyal et al., 2017) is extended from the VQA (Antol et al., 2015) dataset to achieve more balance between visual and textual information by collecting complementary images in a way that each question is associated with a pair of similar images with different answers; In the COCO-QA (Ren et al., 2015a) dataset, the question-answer pairs are automatically generated from image captions based on syntactic parsing and linguistic rules; DAQUAR (Malinowski and Fritz, 2014) is built on top of the NYU-Depth V2 dataset (Silberman et al., 2012) which contains RGBD images of indoor scenes. DAQUAR consists of (1) synthetic question-answer pairs that are automatically generated based on textual templates and (2) human-created question-answer pairs produced by five annotators; CLEVR (Johnson et al., 2017) is a dataset developed on rendered images of spatially related objects (including cube, sphere, and cylinder) with different sizes, materials, and colors. The locations and attributes of objects are annotated for each image. The questions are automatically generated from the annotations; GQA is a new dataset for real-world visual reasoning and compositional question answering, seeking to address key shortcomings of previous VQA datasets. Considering questions in GQA are most objective, unambiguous, compositional, and can be answered by reasoning only on the visual content. We mainly use the GQA dataset in this work as it best fits our goal of reasoning. We also evaluate our methods on the VQA v2 dataset as it is the most common and general VQA dataset so far.

Abstract

Prior studies in privacy policies frame the question answering (QA) task as identifying the most relevant text segment or a list of sentences from a policy document given a user query. Existing labeled datasets are heavily imbalanced (only a few relevant segments), limiting the QA performance in this domain. In this paper, we develop a data augmentation framework based on ensembling retriever models that captures the relevant text segments from unlabeled policy documents and expand the positive examples in the training set. In addition, to improve the diversity and quality of the augmented data, we leverage multiple pre-trained language models (LMs) and cascade them with noise reduction filter models. Using our augmented data on the PrivacyQA benchmark, we elevate the existing baseline by a large margin (10% F1) and achieve a new state-of-the-art F1 score of 50%. Our ablation studies provide further insights into the effectiveness of our approach.

1 Introduction

Privacy policies describe how service providers collect, manage, and use their users' data. Understanding them is crucial for users as they can determine if the conditions outlined are acceptable. Policy documents, however, are lengthy, verbose, equivocal, and hard to understand (McDonald and Cranor, 2008; Reidenberg et al., 2016). Consequently, they are often ignored and skipped by users (Commission et al., 2012; Gluck et al., 2016).

Building question answering (QA) systems for privacy policies is a stepping stone to allow users to ask questions about their rights. Prior works (Harkous et al., 2018; Ravichander et al., 2019) framed the QA task as a sentence selection task, essentially a binary classification task that identifies if a policy text segment is relevant to a question. Since policy documents consist of many sentences and typically a few are relevant to a question,[1] the classification data is imbalanced. In this work, we attempt to mitigate the data imbalance by augmenting positive QA examples. Specifically, we develop automatic retrieval models to supplement relevant policy sentences for each user query. We keep the queries unchanged as they are usually limited to a few forms only (Wilson et al., 2016).

Segmented policy document $\boldsymbol{S}$
($\boldsymbol{s}_1$) We do not sell or rent your personal information to third parties for their direct marketing purposes without your explicit consent. ($\boldsymbol{s}_n$) ...We will not let any other person, including sellers and buyers, contact you, other than through your ...
Queries $\boldsymbol{I}$ annotating the red segment as irrelevant
($\boldsymbol{i}_1$) How does Fiverr protect freelancers' personal information? ($\boldsymbol{i}_2$) What type of identifiable information is passed between users on the platform?
Queries $\boldsymbol{R}$ annotating the red segment as relevant
($\boldsymbol{r}_1$) What are the app's permissions? ($\boldsymbol{r}_2$) What type of permissions does the app require?
Queries $\boldsymbol{D}$ that annotators disagree about relevance
($\boldsymbol{d}_1$) Do you sell my information to third parties? ($\boldsymbol{d}_2$) Is my information sold to any third parties?

Table 1: QA (sentence selection) from a policy document $\boldsymbol{S}$. **Sensitive**: For queries $\boldsymbol{R}$ and $\boldsymbol{I}$, annotators at large tagged sentence $\boldsymbol{s}_1$ as relevant, and irrelevant respectively. On the other hand, sentence $\boldsymbol{s}_n$, though analogous to $\boldsymbol{s}_1$ in meaning, was never tagged as relevant. **Ambiguous**: For queries $\boldsymbol{D}$, experts interpret $\boldsymbol{s}_1$ differently and disagree on their annotations.

Unlike other domains, augmenting privacy policy statements is very challenging. First, they often describe similar information (Hosseini et al., 2016). Thus, their annotations are sensitive to small changes in the text (see Table 1) which may not be tackled using the existing augmentation methods based on data synthesis (e.g., mixup (Zhang et al., 2018), back-translation (Edunov et al., 2018)). For

---

[1] PrivacyQA (Ravichander et al., 2019) dataset has 1,350 questions with an average number of answer sentences is 5, while the average length of policy documents is 138 sentences.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 201–210

example, Kumar et al. (2020) identifies that even linguistically coherent instances augmented via generative models do not preserve the class labels well.[2] Hence, to reflect the data properties, we consider a retrieval-based approach to augment the raw policy statements. Given a pre-trained LM and a small QA dataset, we first build a dense sentence retriever (Karpukhin et al., 2020). Next, leveraging an unlabeled policy corpus with 0.6M sentences crawled from web applications, we perform a coarse one-shot sentence retrieval for each query in the QA training set. To filter the noisy candidates retrieved,[3] we then train a QA model (as a filter model) using the same pre-trained LM and data and couple it with the retriever.

Second, privacy policies are ambiguous; even skilled annotators dispute their diverse interpretations, e.g., for at least 26% questions in PrivacyQA, experts disagree on their annotations (see Table 1). Therefore, a single retriever model may not capture all sorts of relevant policy segments written in various diversified ways. To combat this insufficient data diversity, we propose a novel retriever ensemble technique. Different pre-trained models learn distinct language representations due to their pre-training objectives, and hence, retriever models built on them can retrieve a disjoint set of candidates (verified in Section 3). Therefore, we build our retrievers and filter models based on multiple different pre-trained LMs (See Figure 1). Finally, we train a user-defined QA model on the aggregated corpus using them.

We evaluate our framework on the PrivacyQA benchmark. We elevate the state-of-the-art performance significantly (10% F1) and achieve a new one (50% F1). Furthermore, our ablation studies provide an insightful understanding of our model. We will release all data and code upon acceptance.

2 Methodology

The privacy policy QA is a binary classification task that takes a user query q, a sentence p from policy documents and outputs a binary label $z \in \{0, 1\}$ that indicates if q and p are relevant or not. As most sentences p are labeled as negative, our goal is to retrieve relevant sentences to augment the training data and mitigate the data imbalance issue. Given a

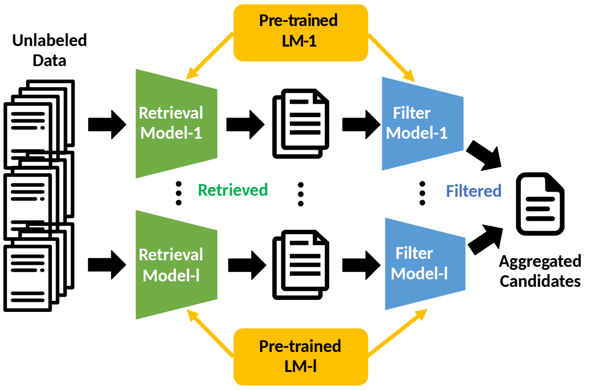

Figure 1: Our framework. Given a pre-trained LM, we train (i) a retriever, (ii) a QA model (filter) both on the small-size labeled data. From an unlabeled corpus, we first, retrieve the coarse relevant sentences (positive examples) for the queries in the training set and use the filter model to filter out noisy ones. We repeat this for multiple different pre-trained LMs. Finally, we aggregate them to expand the positive examples in the training set and learn any user-defined final QA model.

QA training dataset $D = \{(q_i, p_i, z_i)\}_{i=1}^{m}$, for each question in D, we (1) retrieve positive sentences from a large unlabeled corpus. (2) filter the noisy examples using filter models and aggregate final candidates. The final candidates are combined with the base data D to train the end QA model. We use an ensemble of retrievers and filter models built upon various pre-trained LMs throughout the whole process. Details are discussed in the following.

Retriever. Our retriever module is built upon the Dense Passage Retriever (DPR) model (Karpukhin et al., 2020). It consists of two encoders $Q(\cdot)$ and $P(\cdot)$ that encode the queries and the policy sentences, respectively. The relevance of a query q and a policy sentence p is calculated by the dot product of $Q(q)$ and $P(p)$, i.e., $\text{sim}(q, p) = Q(q)^T \cdot P(p)$. We train a retriever $\mathcal{R}_L$ on D, where the encoders in $\mathcal{R}_L$ are initialized with a pre-trained LM L. At inference, $\mathcal{R}_L$ retrieves the top-k most relevant policy sentences from an unlabeled corpus of policy sentences $\mathcal{P} = \{p_1, \ldots, p_M\}$ for each query q_i in D, i.e., $\mathcal{R}_L(\{q_i\}_{i=1}^{m}, \mathcal{P}, k) = \{(q_i, p_j, 1) : i \in [m], p_j \in \mathcal{P}_{\text{top}}(q_i, k)\}$, where $\mathcal{P}_{\text{top}}(q_i, k) := \arg\max_{\mathcal{P}' \subset \mathcal{P}, |\mathcal{P}'|=k} \sum_{p \in \mathcal{P}'} \text{sim}(q_i, p)$.

Filtering Model. To filter out the misclassified retrievals from $\mathcal{R}_L(\{q_i\}_{i=1}^{m}, \mathcal{P}, k)$, we train a QA (i.e., a text-classification) model ($\mathcal{Q}_L$) as a filter to predict whether a query q and a (retrieved) policy sentence p are relevant or not (i.e., $\mathcal{Q}_L(q, p) \in \{0, 1\}$). Note that, the retriever model is a bi-encoder model that can pre-encode, index,

---

[2] To verify, in our preliminary study, for each positive example in the PrivacyQA training set, we augment a new synthesized positive example by en-zh-en back-translation using Google Translator API, and the performance drops by 3% F1.

[3] We refer the misclassified candidates as noisy retrievals.

and rank a large number of candidates. In contrast, our filtering model is a single cross-encoder model that can achieve comparatively higher performances (Humeau et al., 2019) (i.e., hence better as a filter) but can not pre-encode and hence can not be used for large-scale retrieval (more differences are below and in Appendix F). Once the retrieval is done, $\mathcal{Q}_L$ serves as an inexpensive binary classifier which naturally suits as a filter and fit into the pipeline. We verify the effectiveness of our filtering in Section 3.4. We denote retrieval outputs after filtering as $\mathcal{D}_L = \{(q,p,1) : \mathcal{Q}_L(q,p) = 1, \forall (q,p,1) \in \mathcal{R}_L(\{q_i\}_{i=1}^m, \mathcal{P}, k)\}$.

Training of $\mathcal{Q}_L$ and $\mathcal{R}_L$. Both the single encoder in $\mathcal{Q}_L$ and the two encoders in $\mathcal{R}_L$ are initialized with the same pre-trained LM L (e.g., BERT). Both are then fine-tuned as a binary classifier using the paired (query and policy is relevant or not) training data D. Additionally, to better-train the relatively weak bi-encoder $\mathcal{R}_L$, we consider the in-batch negative examples schema (Henderson et al., 2017; Parvez et al., 2021) and its hyper-parameters are tuned using mean ranking or mean reciprocal ranking (MRR) loss. At inference, for query q and candidate p, raw scores from $\mathcal{R}_L$ is used to rank and prediction $\{0,1\}$ from $\mathcal{Q}_L$ is used to filter p.

Ensemble. In order to enhance the diversity and the quality of the retrieved candidates, we use a set of pre-trained LMs $\mathcal{L} = \{L_1, \ldots, L_l\}$ and aggregate all the corresponding retrieved corpora, $\mathcal{D}_{\text{aug}} = \bigcup_{L \in \mathcal{L}} \mathcal{D}_L$. In Section 3, we show that retrieved corpora using multiple pre-trained LMs with different learning objectives can bring a different set of relevant candidates. Lastly, we aggregate $\mathcal{D}_{\text{aug}}$ with D (i.e., final train corpus $\mathcal{T} = \mathcal{D}_{\text{aug}} \cup D$) and train our final QA model with user specifications (e.g., architecture, pre-trained LM).

3 Experiments

3.1 Setup

Evaluation Metrics. We evaluate our approach on PrivacyQA that is framed as a text classification task (Ravichander et al., 2019). We use *precision*, *recall*, and *F1 score* as the evaluation metrics.

Implementations. As for the retrieval database $\mathcal{P}$, we crawl privacy policies from the most popular mobile apps spanning different app categories in the Google Play Store and end up with 6.5k documents (0.6M statements). By default, all retrievals use top-10 candidates w/o filtering. All data/models/codes are implemented using (i) Huggingface Transformers (Wolf et al., 2019), (ii) DPR (Karpukhin et al., 2020) libraries.

Method	F	Precision	Recall	F1
Human	-	68.8	69.0	68.9
W/o data augmentation

ERA-D	✓	$51.0_{\pm 0.4}$	$48.7_{\pm 0.9}$	$\mathbf{49.8}_{\pm 0.7}$

Table 2: Test performances on PrivacyQA ($\text{mean}_{\pm\text{std}}$). F indicates filtering and BERT+Unans. refers to the previous SOTA performance (Ravichander et al., 2019). Retrieved candidates improve all the baseline QA models, especially when being filtered. Our ensemble retriever approach combines them and achieves the highest gains.

Baselines. We fine-tune three pre-trained LMs on PrivacyQA as baselines: (i) *BERT*: Our first baseline is BERT-base-uncased (Devlin et al., 2019) which is pre-trained on generic NLP textual data. A previous implementation achieves the existing state-of-the-art performance (BERT+Unams. in Ravichander et al. (2019)). (ii) *PBERT*: We adapt *BERT* to the privacy domain by fine-tuning it using masked language modeling on a corpus of 130k privacy policies (137M words) collected from apps in the Google Play Store (Harkous et al., 2018). Note that the retrieval database $\mathcal{P}$ is a subset of this data that is less noisy and crawled as a recent snapshot (more in Appendix E) (iii) *SimCSE*: We take the *PBERT* model and apply the unsupervised contrasting learning SimCSE (Gao et al., 2021) model on the same 130k privacy policy corpus. We also consider three other retrieval augmented QA models based on individual pre-trained LM without ensemble: (iv) *BERT-R*: $\mathcal{L} = \{BERT\}$, (v) *PBERT-R*: $\mathcal{L} = \{PBERT\}$, (vi) *SimCSE-R*: $\mathcal{L} = \{SimCSE\}$. We first construct $\mathcal{T}$ (both settings: w/ and w/o filter model) and fine-tune on it the corresponding pre-trained LM as the final QA model. Finally, we

Query Type	%	B	PB	S	ERA
Data Collection	42	45	**46**	**46**	**48**
Data Sharing	25	**43**	37	41	**43**
Data Security	11	**65**	61	60	60
Data Retention	4	**52**	35	35	**56**
User Access	2	**72**	48	31	61
User Choice	7	41	**60**	42	31
Others	9	36	45	**52**	**55**
Overall	100	45	47	48	**49**

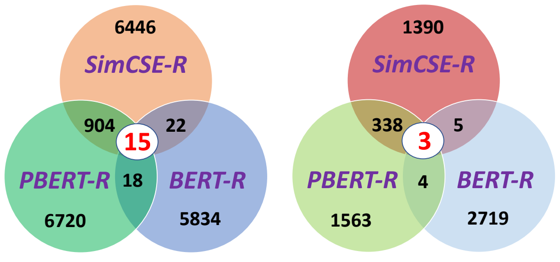
Table 3: F1-score breakdown (values are in Appendix D). B, PB, S refers to retrievers *BERT-R*, *PBERT-R*, and *SimCSE-R*. Different models performs better for different types (black-bold). ERA combines them and enhances performances for all categories (except: red).

consider one more ensemble retrieval augmented baseline (vii) *Baseline-E*, which is precisely the same as ours (settings below), except there are no intermediate filtering models.

Ours. We construct the augmented corpus $\mathcal{T}$ using (i) all 3 aforementioned pre-trained LMs: $\mathcal{L} = \{\mathit{BERT}, \mathit{PBERT}, \mathit{SimCSE}\}$ (ii) domain adapted models only: $\mathcal{L} = \{\mathit{PBERT}, \mathit{SimCSE}\}$. For brevity, we call them: *Ensemble Retriever Augmentation* (ERA) and *Ensemble Retriever Augmentation–Domain Adapted* (ERA-D). By default, we fine-tune *SimCSE* as the final QA model.

3.2 Main Results

The results are reported in Table 2. Overall, domain adapted models *PBERT* and *SimCSE* excel better than the generic *BERT* model. The retrieval-augmented models enhance the performances more, especially the recall score, as they are added as additional positive examples. However, these models may contain noisy examples (see Table 4), which lowers precision. Filtering these examples leads to improved precision for all retrievers. Finally, ERA and ERA-D aggregate these high-quality filtered policies–leading toward the highest gain (10% F1 from the previous baseline) and a new state-of-the-art result with an F1 score of ∼50. Note that *Baseline-E* unifies all the candidates w/o any filtering performs considerably worse than all other models, including each individual retrieval model: *Baseline-E* augments more candidates as positives, which explains the highest recall score; in the meantime, as it does not filter any, the corresponding precision score is oppositely the lowest.



(a) (b)

Figure 2: Venn diagram of low mutual agreement (<1%) among retrievers (a); even amplified after filtering (b).

3.3 Analysis

Table 3 shows the performance breakdown for different query types (more in Appendix D). For questions related to data collection, data sharing, and data security, the performance difference among the models is relatively small (≤ 5% F1); for data retention and user access, *BERT-R*, that is pre-trained on generic NLP texts, performs significantly well (> 15% F1), possibly because the answers to these query types focus on providing numerical evidence for the questions (e.g., How many days the data are retained?) that is less relevant to the domain of privacy policies; and for other types of questions the domain adapted models performs better (> 15% F1). Overall, the individual retrieval augmented models based on LM pre-trained w/ different corpora and objectives perform at different scales for each type, and combining their expertise, ERA enhances the performances for all types.

Next, we show the Venn diagram of overlapping retrievals in Figure 2. Although policy statements describe similar information (i.e., have common phrases), they are often verbose and equivocal (i.e., multiple-different interpretations). Consequently, retrievers w/ different objectives and training corpora rank them differently. Therefore, although being retrieved from the same corpus, candidates retrieved by different models rarely match fully but may have notable overlapping information (words/phrases) and improve their performances equitably. For example, while the performances of *BERT-R*, *PBERT-R* and *SimCSE-R* w/ filtering are similar (∼46) in Table 2, from Figure 2 their overlapping (exact match) is < 1% (qualitative examples in Appendix G). At the same time, their raw retrieval corpora have a high BLEU score of (≥ 0.78). This validates our hypothesis that retrievers built upon different pre-trained LMs learn distinct representations and hence retrieve diverse candidates.

3.4 Ablation Study

Sampling to tackle data imbalance. The preliminary experiments studied rebalancing techniques like equal sampling, but oversampling does not add new information and undersampling limits data, leading to poor generalization on unseen test data. Using equal positive and negative sub-sampled training instances resulted in a 9% drop in F1 score. Even augmented with a higher number of filtered positive examples retrieved by a single retriever model does not perform as well as when a lower number of ensemble-based positive instances are augmented. From Table 8 in Appendix, augmenting with a high number of filtered positive examples from a single retriever model performed worse than using a lower number of ensemble-based positive examples–suggesting the need for diverse and high-quality knowledge not present in training data.

A common filter. Performances of ERA (last row in Table 3) with a common filter model based on *SimCSE* for all the retrievers regardless of their corresponding pre-trained models are 49.2, 45.2, and 47.1, respectively–validating the requirement of filtering using the corresponding pre-trained LM.

Other pre-trained LM as the final QA model. Fine-tuning *PBERT* instead of *SimCSE* on $\mathcal{T}$ (last two rows in Table 2) becomes: 47.0, 47.1, 47.0 and 51.0, 45.9, 48.3, respectively–showing that ERA is generic to end model choices.

Which pre-trained LMs to use? Table 3 shows ERA-D that combines fewer pre-trained LMs can outperform the one with more models, ERA. Though here we consider a simple approach (in-domain) for selecting the potential subset of models, this paves a new direction for future research (e.g., Parvez and Chang (2021)).

Recall performances on PrivacyQA dataset. Example retriever *BERT-R* scores the recall@k (k up to 10) values as 17, 28, 36, 42, 48, 53, 58, 59, 63, 67 respectively while the (cross-encoder) BERT QA model (i.e., filter model) achieves a recall (same as recall@1) of ~ 37. This shows the effectiveness of our designed filter model.

Can the final QA model be used as a filter and impact of filter models on the end performance? The final QA model can be used as a filter model. As for the single retriever model-based augmentation, the performance of the downstream end task depends on the performance of the retriever model, the filtering model, and the end QA model. A stronger filter model leads to better end QA performance in general. With a *BERT-R* retriever and *BERT* end QA model, the use of a *PrivacyBERT* filter model improves that of a *BERT* filter model from 46.3 to 46.8. However, when doing the ensembling using a combination of retriever and filter models from the same pre-trained language model (PLM) results in even better performance than using a stronger filter model from different PLMs.

Q: do you sell my photos to anyone?
Gold: i) We use third-parties to serve ads on our behalf across the Internet. (ii) We may share personal information within our family of brands. (iii) From time to time we share the personal information we collect with trusted companies who work with or on our behalf. (iv) No personally identifiable information is collected in this process.
Correct Retrievals: (i) *SimCSE-R*: The Application does not collect or transmit personally identifiable information such as your name, address, phone number or email address. (ii) *PBERT-R*: We also use the Google AdWords to serve ads on our behalf across the Internet and sometimes on this Website. (iii) *BERT-R*: To organ and tissue donation requests: By law, we can disclose your health information to organ procurement organizations.
Incorrect Retrievals: (i) *BERT-R*: These are not linked to any information that is personally identifiable. (ii) *SimCSE-R*: When you upload photos to our platform or give us permission to access the photos on your device, your photo content may also include related information such as the time and place your photo was taken and similar "meta-data" captured by your image capture device.

Table 4: Example retrieved policies. Retrieved candidates are distinct from expert annotated ones and can bring auxiliary knowledge to the model. Filtering is needed as inappropriate candidates can also be retrieved.

Qualitative examples. Table 4 shows some example retrievals of different models. Retrieved candidates are distinct from expert annotated ones and can bring auxiliary knowledge to the model.

4 Conclusion

We develop a noise-reduced retrieval-based data augmentation method that combines different pre-trained language models to address the data imbalance issue in privacy policy QA. However, our approach can possibly be adapted to other domains and we leave the exploration as the future work.

Limitations

In this work, we develop a retrieval-augmented QA framework specifically for Privacy Policies. Its effectiveness rooted on the characteristics of disjoint retrievals from different pre-trained language models (PLMs). Although this focused work completely aligns, addresses and adheres to the guidelines for a short-paper in this venue, we have not performed any experiments on data outside this privacy policy domain. Hence, the applicability of our method for any generic data domain is unknown. While the time/latency and resource utilization remains unchanged at inference-time, using multiple retriever modules our method introduce an additional overhead in model training. Using different implementation, PLMs, and random seeds may also lead to results that could be different from ours.

Ethics Statement

In this work, our approach crawls an unlabeled privacy policy corpus from the web policy documents specifically from the Google play store which we use as a retrieval database. Although these documents are completely publicly available and was used only for research purpose, they may contain some nomenclature of certain persons, objects, products, users, developers, or production houses (i.e., industries). We neither obfuscate nor make any altercation/modification to them.

Supplementary Material: Appendices

A Related Works

A line of works focuses on using NLP techniques for privacy policies (Wilson et al., 2016; Harkous et al., 2018; Zimmeck et al., 2019; Bui et al., 2021; Ahmad et al., 2021). Besides the QA tasks as sentence selection, Ahmad et al. (2020) propose another SQuAD-like (Rajpurkar et al., 2016) privacy policy reading comprehension dataset for a limited number of queries. Oppositely, we focus on the more challenging one, which allows unanswerable questions and "non-contiguous" answer (Ravichander et al., 2021). In relevant literature works, retrieval augmented methods are applied in various contexts including privacy policies (e.g., Van et al. (2021); Keymanesh et al. (2021); Yang et al. (2020)). Non-retrieval data aggregation has also been studied under different NLP contexts (e.g., bagging (Breiman, 1996), meta learning (Parvez et al., 2019)). However, we uniquely aggregate the retriever outputs using different pre-trained language models.

B Limitations/Reproduction

In this paper, we show that leveraging multiple different pre-trained LMs can augment high-quality training examples and enhance the QA (sentence selection) task on privacy policies. Our approach is generic and such unification of different kinds of pre-trained language models for text data augmentation can improve many other low-resourced tasks or domains. However, it is possible that our approach:

- may not work well on other scenarios (e.g., domains/language or tasks etc.,).
- subject to the choice of a particular set of models. For example, as mentioned in Section, 3.4, fine-tuning pre-trained models other than *SimCSE* (Gao et al., 2021) as the final QA model achieve lower gain.
- may not work for certain top-k retrievals. For example, from Table 8, we get different results with different scales for variable top-k values (e.g., top-10, top-100).
- uses the same set of hyperparameters for all:
  - QA model:
    - learning rate: $2e^{-5}$,
    - train epoch: 4,
    - per gpu train batch size: 31,
    - num gpus: 4
    - fp16 enabled
    - others: mostly default as in Huggingface
    - train time: around 2 hours
    - Higgingface transformer version 0.3.2. (it has Apache License 2.0)
  - Retriever model:
    - learning rate: $2e^{-5}$,
    - train batch size: 16,
    - train epoch: 100,
    - global_loss_buf_sz 600000,
    - others: mostly default as in DPR (It has Attribution-NonCommercial 4.0 International license)
    - num gpus: 3
    - Higgingface transformer version 0.3.2 (it has Apache License 2.0)
    - train time: around 12-18 hours

As our primary goal is on the retrieval-based data augmentation technique, we expect further optimization of task-specific model hyperparameters to improve performance. Note that our results are based on upto 4 runs using different random seeds.

C Privacy Policy Data Crawling & Retrieval Statistics

We crawl our English retrieval corpus from Google App Store using the Play Store Scraper[4].

Query Type	No. of Retrieval
Data Collection	2893
Data Sharing	1848
Data Security	891
Data Retention	542
User Access	145
User Choice	335
Others	14

PrivacyQA benchmark is in Table 7. Note that the questions in Privacy can be categorized into a few OPP-115 classes. These categories are enlisted in Table 3 in the main paper and the details of each category can be found in Wilson et al. (2016).

E Difference Between Pre-training and Retrieval Corpus

130k documents were collected before 2018 and by that time, the GDPR[5] and CCPA[6] were not enforced by then. Thus, the 130k documents are out-of-date and some content might not be comprehensive as the retrieval corpus. Besides, the 130k documents provided by (Harkous et al., 2018) contains some noises since we observe that the documents are not all written in English. However, as the data size is larger, we still use it for pre-training. In contrast, our corpus was collected after 2020 and we filtered out some possible noises (e.g., filtering out non-English document) while crawling.

F Difference Between the Filtering Model and the Retriever

The retriever model is a bi-encoder model whose model parameters are fine-tuned with in-batch negative loss (discussed in Section 2 in the main paper), hyper-parameters are tuned based on average rankings (`https://github.com/facebookresearch/DPR/blob/a31212dc0a54dfa85d8bfa01e1669f149ac832b7/train_dense_encoder.py#L294`) and that can pre-encode, index and rank a large number of candidates while our filtering model is a cross-encoder text-classifier (e.g., single encoder fine-tuned BERT) that is fine-tuned w/o any additional in-batch negatives and in-general achieves comparatively higher performance (Humeau et al., 2019) (i.e, better as a filter) but can not pre-encode and hence can not be used for large scale retrieval.

Method	Filter	top-k	Precision	Recall	F1
BERT-R	✗	10	39.9	50.8	44.7
	✓	10	46.5	45.5	46.0
PBERT-R	✗	10	48.4	45.6	46.9
	✓	10	46.9	43.3	45.1
	✗	50	47.8	45.5	46.7
	✓	50	49.5	46.3	47.8
SimCSE-R	✗	10	48.4	47.2	47.8
	✓	10	49.4	44.8	47.0
	✗	100	42.1	41.3	41.7
	✓	100	51.0	45.2	47.9

Table 8: Model performances with and without filtering (i.e., w/o the filter model) with top-k. In general, without filtering, augmenting the retrieved candidates enhances recall but may reduce the precision (and hence may not improve the overall F1). Filtering, however, improves the performance, especially with larger top-k candidates. In above, top-100 augmented examples (~13K total positives after filtering) retrieved by a single retriever perform worse than with top-10 examples by ERA or ERA-D (total 7K or 4K positive examples) reported in Table 2 in the main paper.

G More Qualitative Examples

The below tables show some example retrievals of different models. Retrieved candidates are distinct from expert annotated ones and can bring auxiliary knowledge to the model.

Q: do you sell my photos to anyone?
Gold: i) We use third-party service providers to serve ads on our behalf across the Internet and sometimes on the Sites. (ii) These companies may use your personal information to enhance and personalize your shopping experience with us, to communicate with you about products and events that may be of interest to you and for other promotional purposes. iii) Your use of our Application with that healthcare institution may be subject to that healthcare institution's policies and terms. (iv) We may share personal information within our family of brands. (v) From time to time we share the personal information we collect with trusted companies who work with or on behalf of us. (vi) No personally identifiable information is collected in this process. (vii) We use third-party service providers to serve ads on our behalf across the Internet and sometimes on our Sites and Apps.
Correct Retrievals: (i) The Application does not collect or transmit any personally identifiable information about you, such as your name, address, phone number or email address. -(SimCSE-R) (ii) Some of this information is automatically gathered, and could be considered personally identifiable in certain circumstances, however it will generally always be anonymised prior to being viewed by Not Doppler, and never sold or shared. -(BERT-R) (iii) We also use the Google AdWords service to serve ads on our behalf across the Internet and sometimes on this Website. -(PBERT-R) (iv) To organ and tissue donation requests: By law, we can disclose health information about you to organ procurement organizations. -(BERT-R)
Incorrect Retrievals: (i) When you upload your photos to our platform or give us permission to access the photos stored on your device, your photo content may also include related image information such as the time and the place your photo was taken and similar "metadata" captured by your image capture device. -(SimCSE-R) (ii) These are not linked to any information that is personally identifiable.-(BERT-R)

Table 9: A fraction of retrieval examples (i).

Q: who all has access to my medical information?
Gold: i) Apple HealthKit to health information and to share that information with your healthcare providers. ii) Your use of our Application with that healthcare institution may be subject to that healthcare institution's policies and terms.
Correct Retrievals: (i) We may share your information with other health care providers, laboratories, government agencies, insurance companies, organ procurement organizations, or medical examiners. -(SimCSE-R) (ii) Do not sell your personal or medical information to anyone. -(BERT-R) (iii) Lab, Inc will transmit personal health information to authorized medical providers. -(PBERT-R) (iv) To organ and tissue donation requests: By law, we can disclose health information about you to organ procurement organizations. -(BERT-R)
Incorrect Retrievals: (i) However, we take the protection of your private health information very seriously. -(SimCSE-R) (ii) All doctors, and many other healthcare professionals, are included in our database. -(PBERT-R) (iii) You may be able to access your pet's health records or other information via the Sites. -(BERT-R) (iv) will say "yes" unless a law requires us to disclose that health information.-(BERT-R) (v) do not claim that our products "cure" disease.-(BERT-R) (vi) Has no access to your database password or any data stored in your local database on your devices.-(BERT-R)

FastKASSIM: A Fast Tree Kernel-Based Syntactic Similarity Metric

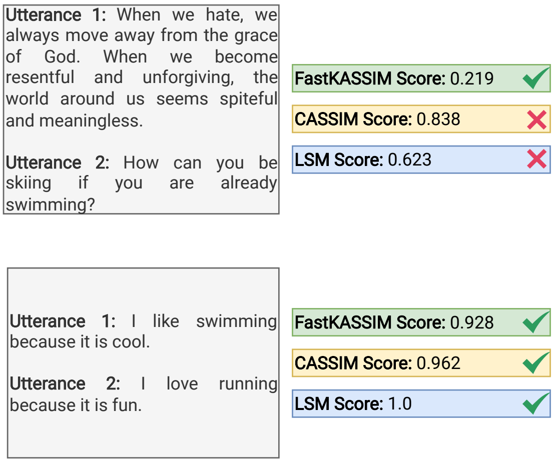
Maximillian Chen[*], Caitlyn Chen[*], Xiao Yu[*], Zhou Yu
Department of Computer Science, Columbia University, New York, NY
`maxchen@cs.columbia.edu`
`{caitlyn.chen, xy2437, zy2461}@columbia.edu`

Abstract

Syntax is a fundamental component of language, yet few metrics have been employed to capture syntactic similarity or coherence at the utterance- and document-level. The existing standard document-level syntactic similarity metric is computationally expensive and performs inconsistently when faced with syntactically dissimilar documents. To address these challenges, we present FastKASSIM, a metric for utterance- and document-level syntactic similarity which pairs and averages the most similar constituency parse trees between a pair of documents based on tree kernels. FastKASSIM is more robust to syntactic dissimilarities and runs up to to 5.32 times faster than its predecessor over documents in the r/ChangeMyView corpus. FastKASSIM's improvements allow us to examine hypotheses in two settings with large documents. We find that syntactically similar arguments on r/ChangeMyView tend to be more persuasive, and that syntax is predictive of authorship attribution in the Australian High Court Judgment corpus.

1 Introduction

Syntax, the form of language, plays a crucial role in all aspects of natural language and communication, whether explicitly or implicitly. In storytelling, writers often have their own styles rooted in different syntactic tendencies (Feng et al., 2012), allowing syntax to become indicators in prediction tasks such as gender (Sarawgi et al., 2011) and authorship (Raghavan et al., 2010) attribution. Syntax also has social connotations in different cultures — for example, in Russia, different social and demographic groups tend to use different syntactic patterns (Bogdanova-Beglarian et al., 2016). Such examples makes syntactic consistency crucial to capture in tasks such as machine translation and dialogue generation so that social conventions are not lost. Yet, recent research focuses primarily on evaluating similarity and coherence in terms of dimensions like semantics, the meaning behind language, (with approaches such as BERT embeddings (Reimers and Gurevych, 2019; Zhang et al., 2019b)), or lexical overlap (e.g., BLEU (Papineni et al., 2002)) — even in work which uses syntax as an input to improve translation quality (Zhang et al., 2019a). A lack of work on syntax can be partially attributed to the absence of a practical, efficient metric that specifically compares syntax at the utterance level. The current standard metric is CASSIM (Boghrati et al., 2016, 2018), but CASSIM uses a computationally expensive distance metric and can yield inconsistencies when comparing syntactically dissimilar documents (e.g., Figure 1). To address this issue, we introduce *FastKASSIM*, a *Fast Tree Kernel-bAsed Syntactic SIMilarity Metric*[1], an improved metric for syntactic similarity at the utterance- and document-level.



Utterance 1: When we hate, we always move away from the grace of God. When we become resentful and unforgiving, the world around us seems spiteful and meaningless.

Utterance 2: How can you be skiing if you are already swimming?

FastKASSIM Score: 0.219 ✓
CASSIM Score: 0.838 ✗
LSM Score: 0.623 ✗

Utterance 1: I like swimming because it is cool.

Utterance 2: I love running because it is fun.

FastKASSIM Score: 0.928 ✓
CASSIM Score: 0.962 ✓
LSM Score: 1.0 ✓

Figure 1: Comparison of FastKASSIM, CASSIM, and Linguistic Style Matching similarity scores. Top: two dissimilar utterances. Bottom: two similar utterances. All three metrics have strong agreement in cases of similar syntactic structure, but only FastKASSIM is able to recognize syntactically dissimilar utterances. The parse trees of these examples are visualized in Appendix D.

---

[*] denotes equal contribution.

[1] `https://github.com/jasonyux/FastKASSIM`

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 211–231
May 2-6, 2023

Like its predecessor, CASSIM, FastKASSIM computes the constituency parse tree of each sentence in a pair of documents, and the similarity between each pair of parse trees. But, while CASSIM used Edit Distance (Pawlik and Augsten, 2011; Zhang and Shasha, 1989) for similarity, we propose using a *Label-based Tree Kernel* (henceforth LTK), our more syntactically thorough implementation of the Fast Tree Kernel (Moschitti, 2006). We evaluate FastKASSIM against CASSIM and Linguistic Style Matching (henceforth LSM; Niederhoffer and Pennebaker (2002); Ireland and Pennebaker (2010)). We find that FastKASSIM is more robust in cases of dissimilarities between documents and is generally more agreeable with human perception of differences in syntax. Additionally, the runtime of LTK is much faster than that of Edit Distance; it *scales linearly with the number of node pairs with the same label* in a pair of parse trees. We empirically show large improvements in runtime with FastKASSIM.

Previously, it was difficult to observe the role of syntax in behavioral phenomena at scale due to runtime constraints. Here, we contribute a study of hypotheses in two sets of applications. First, we examine the relationship between the persuasiveness of online arguments and syntactic similarity, and second, we observe the viability of syntax as an indicator in authorship attribution. FastKASSIM unlocks potential for evaluatory use in more contexts where it is important to preserve syntactic consistency and writing style, e.g., style transfer, machine translation, and story generation.

2 Related Work

A few early studies focused solely on capturing syntactic structures. Sagae and Gordon (2009) sought to cluster *words* by syntactic similarity. In order to establish a distance metric, they computed the cosine distance between vector representations of their unique constituency parses. Other approaches have used LIWC (Tausczik and Pennebaker, 2010). Danescu-Niculescu-Mizil et al. (2011) took a probabilistic approach to measure symmetry and influence of linguistic style.

Other early analytical work found that people will adjust their syntax to match dialog systems' syntactic (Stoyanchev and Stent, 2009) and lexical (Stoyanchev and Stent, 2009; Hoshida et al., 2017) choices. Reitter et al. (2006) found that individual syntactic productions would repeat at low "distances" across utterances in both task-oriented and “spontaneous” dialog. For instance, Reitter and Moore (2007) found that syntactic priming was predictive of success on the HCRC Map Task (Anderson et al., 1991). Baker et al. (2021) similarly discussed the use of syntactic similarity and overall linguistic style synchrony as an indicator of trust and cohesion in teamwork settings, and Boncz (2019) used syntactic similarity in modeling cognitive alignment.

Syntactic features have been shown to improve prediction performance in downstream tasks, e.g., authorship attribution (Posadas-Duran et al., 2014; Raghavan et al., 2010; Zhang et al., 2018) and gender attribution (Sarawgi et al., 2011). In each case, the studies found significant performance gains from models that included syntax features. Despite interest in syntax and clear improvements in prediction performance, the vast majority of recent work primarily focuses on semantic, or even lexical similarities/differences. This ranges from traditional methods such as TFIDF or Jaccard similarity to modern approaches including BERT embeddings (Devlin et al., 2019; Reimers and Gurevych, 2019; Zhang et al., 2019b) and AMR kernels (Opitz et al., 2021). Some approaches use syntactic features specific to certain domains such as Twitter (Alnajran, 2019; Little et al., 2020) or web documents (Broder et al., 1997; Pereira and Ziviani, 2003). Other metrics include “syntactic elements” which take on various forms of parts-of-speech aggregation (Alnajran, 2019; Pakray et al., 2011).

A *syntactic* similarity metric should appropriately consider differences in syntactic structure at the word-, utterance-, and document-level, as opposed to aggregating parts-of-speech or relying on domain-specific features. To our knowledge, CASSIM is the only metric to do this and has been proposed as a solution in applications ranging from measuring communicative alignment (Boncz, 2019; Baker et al., 2021) to evaluating stylistic creativity in language learning (Kokkola and Rydström, 2022) to clustering text (Boghrati et al., 2017). However, CASSIM relies on the expensive Edit Distance metric, and occasionally assigns high similarity scores to documents that appear syntactically dissimilar. An improved syntactic similarity metric would afford new opportunities, from creating novel syntax feature vectors for classification tasks (e.g. authorship and gender attribution), to measuring syntactic coherence in machine translation.

Algorithm 1 FastKASSIM

    Compute Tree Kernel:
    $s \leftarrow 0$
    for Node Pair $n_1, n_2$ in $P_1, P_2$ do
        $s \leftarrow s + \Delta_{lb}(n_1, n_2)$
    end for
    Kernel $\leftarrow$ normalize($s$)
end for
Hungarian Algorithm Max. Cost Assignment
return mean(maximal cost pairings)
```

3 FastKASSIM

3.1 CASSIM Background

CASSIM (Boghrati et al., 2018) was the first metric to compute syntactic similarity at the document-level. Their original algorithm uses the Stanford Parser (Klein and Manning, 2003; Chen and Manning, 2014) to compute the parse tree for each sentence in a pair of documents, before computing the Edit Distance (Wagner and Fischer, 1974) between each parse tree pairing. Then, they construct a bipartite graph and use the Hungarian Algorithm for minimum cost assignment (Kuhn, 1955) to pair each tree in one document to the lowest distance tree in the second document. They finally average the Edit Distances of the minimal cost pairings. When there are different numbers of sentences, the number of assignments will correspond to the number of sentences in the document with fewer sentences. Each of that document's sentences will get paired with the most similar sentence in the second document, and the least similar sentences in the second document will remain unpaired. The final Edit Distance between a pair of parse trees P_1, P_2 is normalized as $\frac{EditDistance}{Size(P_1)+Size(P_2)-2}$, where $Size(P)$ is the number of nodes in P.

An important advantage of CASSIM is that it is generalizable to any corpus; it does not represent syntax using platform-specific features like Alnajran (2019); Little et al. (2020). However, the cost of exhaustively using a metric such as Edit Distance is rather penalizing, as its implementations range in asymptotic time complexity from $\Theta(mn)$ (Wagner and Fischer, 1974) to $O(s \times min(m, n))$ (Ukkonen, 1985), where m and n are the string lengths, and s is the maximal Edit Distance.

Algorithm 2 Delta$_{lb}$ Function (Δ_{lb})

```
Tree Nodes $n_1, n_2$; $cache$
Decay $\lambda$; Subtree/Subset Tree Indicator $\sigma$
if $n_1, n_2$ is cached then
    return cache($n_1, n_2$)
end if
if $n_1, n_2$ have different labels then
    return 0
end if
if both $n_1, n_2$ are preterminals then
    cache($n_1, n_2$) $\leftarrow \lambda$ if same label, else 0
    return cache($n_1, n_2$)
end if
Product $\leftarrow$ 1
for child $c_1$ of node $n_1$ do
    Accumulator $\leftarrow$ 0
    for child $c_2$ of node $n_2$ do
        Acc. $\leftarrow$ Acc. + Delta$_{lb}$($c_1, c_2$)
    end for
    Product $\leftarrow$ Product $\times(\sigma+$ Acc.)
end for
cache($n_1, n_2$) $\leftarrow \lambda\times$ Product
return $\lambda\times$ Product
```

3.2 The FastKASSIM Algorithm

In large multi-sentence documents, repeated Edit Distance becomes the most expensive component of CASSIM. Thus, we propose FastKASSIM, which avoids the expensive Edit Distance computation by using Tree Kernels (Moschitti, 2006). Tree Kernels can greatly reduce time complexity by caching between recursive subcalls. The Fast Tree Kernel algorithm Moschitti (2006) runs in *linear time on average with respect to parse tree sizes.*

We propose FastKASSIM, which replaces CASSIM's Edit Distance with a new normalized Tree Kernel. Figure 2 provides a high-level overview of FastKASSIM, which is formally described in Algorithm 1. However, the Fast Tree Kernel does not allow for the case in which two parse tree nodes have matching labels but different productions. We thus also introduce the Label-based Tree Kernel (LTK)[2], which compares the labels at each node in a pair of subtrees or subset trees[3]. This also

---

[2] There is a very strong correlation between LTK and the Fast Tree Kernel ($R = 0.97$, p<0.001).

[3] Moschitti (2006) defines a subtree as a node and all its

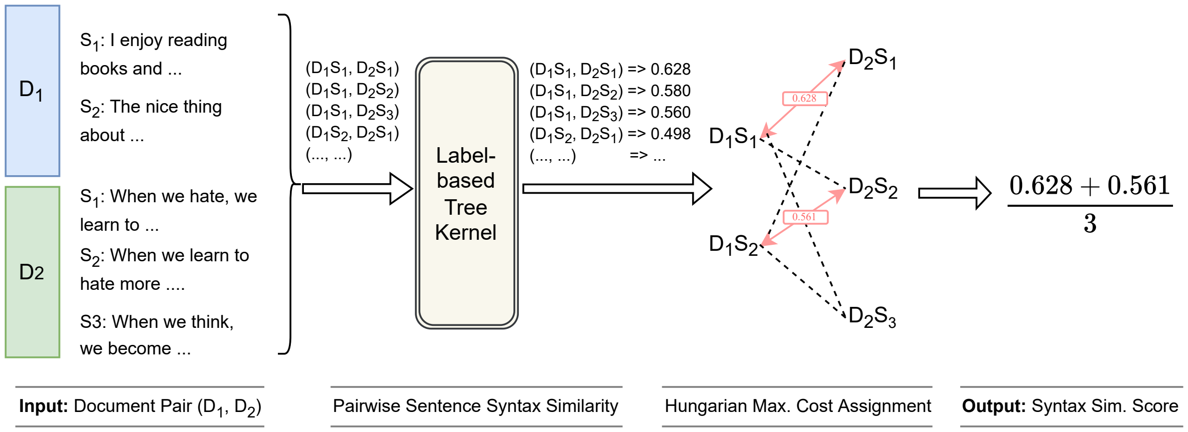

Figure 2: A high-level illustration of FastKASSIM computation. The parse trees of all sentence pairs between D_1, D_2 are computed using LTK. The Hungarian algorithm is used to pair together the most similar parse trees of each sentence in the two documents by the "maximal cost" (i.e., the largest tree kernels). The score is normalized by summing the paired kernel values then dividing by the number of sentences in the document with more sentences. D_2S_3 is unpaired because D_1S_1, D_2S_1 and D_1S_2, D_2S_2 are paired, and D_2 has more sentences than D_1.

more closely follows (Collins and Duffy, 2002), which proposes comparing the actual subset trees rooted at two nodes in each parse tree, rather than the production. Figure 3 depicts the LTK algorithm computing the number of shared subset trees in a pair of parse trees. More formally, as described in lines 7-11 of Algorithm 1, LTK accumulates the value of Δ_{lb} (Algorithm 2), which is the number of common fragments rooted in a pair of parse tree nodes n_1, n_2.

We follow Moschitti (2006) by normalizing $LTK(T1,T2)$ as $\frac{LTK(T1,T2)}{\sqrt{LTK(T1,T1)\times LTK(T2,T2)}}$. This normalized tree kernel is not biased towards tree shape, in contrast to CASSIM's normalized Edit Distance ($\frac{EditDistance}{Size(P_1)+Size(P_2)-2}$). Under CASSIM's normalization, if two sentences resulted in the *same parse tree size despite being composed of entirely different labels*, the normalized Edit Distance approaches 0.50 (the expression approximates $\frac{Size(P_1)}{2\times Size(P_1)-2}$). In other words, according to CASSIM, sentences with the same shape but different parts-of-speech should be neither similar nor dissimilar. We further highlight possible examples of this bias by visualizing parse trees in Appendix D. Ultimately, our normalized LTK results in significant runtime improvements over Edit Distance, as we show in Section 3.3 and derive in Appendix A, and agrees strongly with human perception, as we show in Section 4.

Like the original CASSIM algorithm, our high-level algorithm allows for flexibility in the choice of which parser to use, allowing for future improvements in runtime and correctness as research in parsing progresses. FastKASSIM similarly allows for flexibility in the implementation of tree kernels. Our implementation will be publicly released upon acceptance. In order to directly compare FastKASSIM and CASSIM, we default to using the Stanford Parser (Chen and Manning, 2014) and LTK, our aforementioned modified approach to the Fast Tree Kernel (Moschitti, 2006).[4]

3.3 Overall Metric Runtime Comparison

The largest difference in the runtime of CASSIM and FastKASSIM is that CASSIM uses a normalized Edit Distance to evaluate parse tree similarity, while FastKASSIM uses a normalized tree kernel.

LTK recursively computes Δ_{lb} across all n_1, n_2 pairs in parse trees P_1, P_2. But, importantly, *all comparisons are cached to avoid repetition.* This results in LTK having an asymptotic runtime complexity of $O(S_{12})$, where S_{12} is the total number of pairs of nodes in a pair of parse trees P_1, P_2 that have the same label. We prove this runtime in Appendix A. This is a large improvement over Edit Distance's runtime complexity of $O(s \times min(m,n))$. We confirmed that these asymptotic improvements apply to real-world uses cases by comparing how Edit Distance and LTK scale with the product of parse tree sizes in Figure 6 of the Appendix, finding that LTK scales sublinearly while Edit Distance scales superlinearly.

---

descendants, whereas a subset tree does not require its leaves to be terminal.

[4] However, we provide users with a native interface to interchangeably use any parser supported by NLTK (Bird et al., 2009).

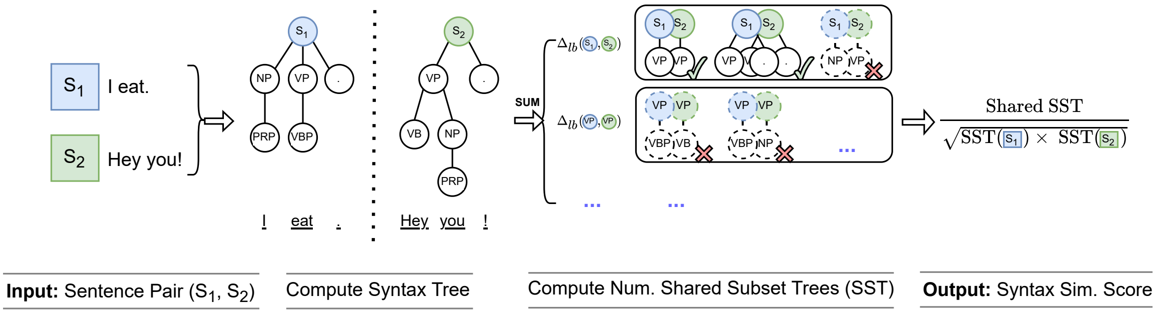

Figure 3: Overview of the Label-based Tree Kernel. The parse trees of a pair of sentences are computed, along with the number of common fragments rooted in each pair of parse tree nodes (i.e., number of shared subset trees). This is normalized by dividing by the square root of the product of the number of subset trees in each parse tree.

While Figure 6 indicates that LTK can be up to an order of magnitude faster than Edit Distance, the largest bottleneck in overall time is still the time to compute each parse tree. Thus, in Figure 4, we investigated the difference in "end-to-end" runtime between FastKASSIM and CASSIM without precomputing the parse trees.

In this experiment, the ChangeMyView dataset (henceforth CMV; Tan et al. (2016)) is used, providing a corpus of unstructured text with large document sizes, to evaluate the promises of FastKASSIM and CASSIM for their abilities to process entire documents. First, we sample entire document pairs and record the time it takes to compute the syntactic similarity of each pair. Each pair is randomly sampled from the 18,363 posts in the CMV training set. Then, we exhaustively paired documents based on the product of their document sizes, providing an approximation of the number of comparisons between parse trees. The document length for each CMV root posts has high variance, so document length products are grouped into bins. For each bin, we randomly sample 60 document pairs and report the average runtime.

Figure 4 shows that FastKASSIM scales well in runtime as the product of document lengths increases. For instance, when syntactic similarity between documents of lengths 300 words and 310 words were compared (product of $93,000$), CASSIM needed on average 113.3 seconds while FastKASSIM took only 21.3 seconds on average. Given these drastic improvements in time complexity, it is now more feasible to compute syntactic similarity at the document level for large corpora.

4 Evaluating FastKASSIM

In this section, we first demonstrate FastKASSIM's overall ability to differentiate between similar and dissimilar documents. Then, we correlate its scores with CASSIM and LSM. Finally, we discuss FastKASSIM's advantages by explaining discrepancies in scoring.

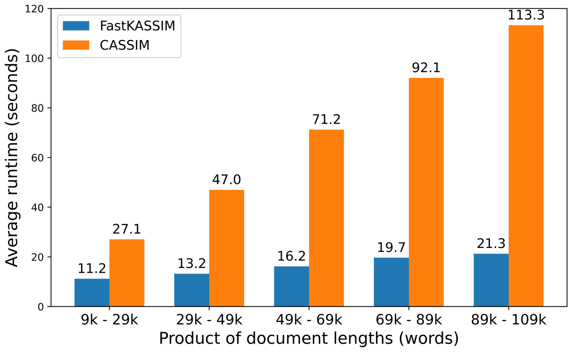

Figure 4: Runtime comparison between FastKASSIM and CASSIM. On the CMV corpus, FastKASSIM runs 2.42 times to 5.32 times faster on average, depending on document size.

4.1 Discriminating Between Syntactically Similar and Dissimilar Documents

Boghrati et al. (2018) validated CASSIM by comparing whether it was consistent with human perception of syntactic similarity. The authors asked Mechanical Turkers to write syntactically similar sentences given a sentence prompt. This resulted in a dataset of 472 English documents from 118 anonymous human annotators, and the authors found that CASSIM was able to "identify syntactically similar documents."

Following Boghrati et al. (2018), we computed the syntactic similarity between each pairing of sentences generated both within the same prompt and between different prompts. Each individual prompt is structurally quite different (Table 1). By construction, *documents resulting from the same prompt should be syntactically similar, whereas documents resulting from different prompts should*

Prompts
1. The two most important days in your life are the day you are born and the day you find out why. The nice thing about being a celebrity is that you bore people and they think it's their fault.
2. I am enough of an artist to draw freely upon my imagination. Imagination is more important than knowledge. Knowledge is limited. Imagination encircles the world.
3. When we love, we always strive to become better than we are. When we strive to become better than we are, everything around us becomes better too.
4. What is the point of being alive if you don't at least try to do something remarkable?

Table 1: Prompts for the crowd-sourced corpus collected by Boghrati et al. (2018).

be dissimilar. As per their work, we fit a maximal structure linear mixed effect model with an indicator for whether the sentence corresponded to the same prompt or a different prompt as a fixed effect and the document ID as a random effect against standardized syntactic similarity[5].

We computed ANOVA of this full model against the reduced model, which drops the comparison type indicator as a fixed effect. The ANOVA χ^2 test on the impact of comparison type yields statistically significant differences in the distribution of FastKASSIM ($\chi^2 = 1438.9$, $p < 0.001$), CASSIM ($\chi^2 = 331.84$, $p < 0.001$), and LSM ($\chi^2 = 201.85$, $p < 0.001$) scores between syntactically similar and dissimilar documents. FastKASSIM results in the largest effect size, 1438.9, indicating it creates the largest differences in distribution.

4.2 Correlating Syntax Metrics

LSM[6] is a metric computing similarities from function word categories. This has ties to matching syntax, as those matching function words correspond to specific parts-of-speech. Moreover, LSM is a widely accepted metric for synchrony and correspondence of general linguistic style in documents (e.g. Chartrand et al. (2005); Ludwig et al. (2013)). We examine the actual similarity scores calculated in the previous section on the crowd-sourced document similarity corpus collected by Boghrati et al. (2018) using each of LSM, FastKASSIM, and CASSIM. In Figure 5, we see that there is a moderately strong correlation between FastKASSIM and LSM ($R = 0.5$, $p < 0.001$). This indicates that FastKASSIM is able to detect matches in key parts-of-speech. We would not expect to see a greatly higher correlation, because LSM is a measure of function words rather than a holistic measure of syntax. On the other hand, while we see a statistically significant correlation between CASSIM and LSM, its correlation coefficient is much lower ($R = 0.11$, $p < 0.001$), indicating a smaller connection between CASSIM representations and function words. This is likely due to the biased Edit Distance normalization mentioned in Section 3.1. Moreover, we actually find an overall negative correlation between FastKASSIM and CASSIM ($R = -0.33$, $p < 0.001$) with a seemingly bipartite relationship. There is an apparent disagreement over documents that FastKASSIM deems dissimilar, with agreement over documents that FastKASSIM deems similar.

4.3 Discrepancies Across Syntax Metrics

Figure 5 indicates that there are several regions of disagreement (vertical clustering). In one region of Figure 5a, FastKASSIM assigned low scores (less than 0.4) despite LSM ranging from 0.258 to 0.842. Recall that in this corpus, every utterance resulting from the same prompt was perceived as syntactically similar, and utterances from two different prompts were perceived as syntactically dissimilar. We find that in 248 out of 249 cases where FastKASSIM assigned a score below 0.4 yet LSM assigned a high score (above 0.6), the two documents being compared came from different prompts. This implies that FastKASSIM indeed is discriminating between different syntactic structures, whereas LSM may be picking up on similarities other than syntax, as expected.

Figure 5b does not indicate any obvious relationship between CASSIM and LSM. More surprisingly, Figure 5c shows that for document pairings that FastKASSIM deems syntactically dissimilar (values of less than 0.5), there is a very strong negative correlation between FastKASSIM and CASSIM ($R = -0.783$, $p < 0.001$). Visually, there is a cluster of pairings where FastKASSIM assigns a value less than 0.4 but CASSIM assigns a value larger than 0.75. We find that in 677 of the 678 pairings in this cluster, the documents originate from different prompts, indicating that the documents are syntactically dissimilar.

We evaluate these discrepancies in Table 2 in terms of each metric's ability to correctly identify documents originating from the same prompt as syntactically similar and those from differ-

---

[5] We use z-score standardization, $\frac{x-\mu}{\sigma}$.

[6] We compute LSM using an implementation publicly available at https://github.com/miserman/lingmatch.

Sentence-BERT	18.9	19.8	74.0	2.70	0.20
Sentence-BERT$_a$	34.3	9.50	19.2	59.3	39.3
FastKASSIM	**88.3**	96.1	**69.1**	**98.5**	85.6

Table 2: Evaluation of LSM, CASSIM, BERTScore, Sentence-BERT and FastKASSIM in terms of Accuracy (Acc.), Similar Document Recall (SR), Similar Document Precision (SP), Dissimilar Document Recall (DR), and Dissimilar Document Precision (DP). Metric$_a$ denotes adjusting to a uniform distribution by quantile transformation.

ent prompts as syntatically dissimilar using accuracy, recall, and precision[7]. In addition to CASSIM and LSM, we include an evaluation of BERTScore (Zhang et al., 2019b) and Sentence-BERT (Reimers and Gurevych, 2019). While they are not syntax metrics, they are strong embedding-based metric which may account for syntactic forms.

As similarity scores lie between 0.0 and 1.0, we use 0.5 as a boundary between similar and dissimilar documents. We reason that in unknown contexts, 0.5 is neutral. We also compare against quantile transformations of each baseline metric, which map each metric's scores to a uniform distribution (note this is an unfair advantage, since in real-time deployment, one cannot observe the entire distribution of values), due to their apparent biases in Figure 5. In Table 2, we find that FastKASSIM holistically outperforms both CASSIM and LSM, with the exception of similar document recall and dissimilar document precision. In these cases, CASSIM achieves perfect precision and recall because it only classified one document pair as dissimilar. BERTScore similarly yields a small range in similarity scores on this corpus. After undergoing a quantile transformation, BERTScore's sensitivity to syntactic differences is magnified, and it performs well in the aforementioned categories but underperforms FastKASSIM in accuracy, similarity precision and dissimilarity recall.

As indicated by its low Dissimilar Document Recall in Table 2, we found CASSIM frequently assigned high similarity scores to syntactically different documents. This likely comes from the bias in its normalized Edit Distance as discussed in Section 3.1, and we show the significant improvements achieved by FastKASSIM.

Overall, our results indicate that with respect to human intuition of syntax, FastKASSIM is more robust than CASSIM, LSM and BERTScore. In Appendix D, we visualize comparisons of several pairs of parse trees along with their FastKASSIM and CASSIM scores.

5 Applications

FastKASSIM is a more accurate and efficient syntactic similarity metric than the current state-of-the-art, opening the possibility for investigating new hypotheses in data-heavy fields with large corpora. Existing applications use syntax metrics for classification (e.g. Posadas-Duran et al. (2014)) as well as analytically to measure hypotheses (e.g. Kaster et al. (2021)). Here, we use syntax as a linguistic style indicator in authorship attribution, and measure syntactic similarity to study communication accommodation in persuasive arguments.

---

[7] Exact expressions provided in Appendix B.

5.1 Persuasiveness of Syntax Accommodation

Early work in communication accommodation theory found that matching communication styles can create a sense of familiarity, which improves social and conversational outcomes (e.g. Curhan and Pentland (2007); Giles (2016)). While most existing work has focused on hypotheses at the word-level (Tan et al., 2016), we hypothesize that CMV arguments that are more syntactically similar to opinions may be more persuasive as well.[8]

On CMV, users write an original post describing an opinion and allow "challengers" to present arguments attempting to change their opinion. Original posters (OP) indicate whether their opinions have been changed by assigning a "delta," which we can use an indicator of successful persuasion. We computed the syntactic similarity between a challenger's initial argument and an original poster's (OP) original opinion. This choice is made because the OP presents their full opinion in their original post, and a challenger typically presents their central argument in their initial challenge (Tan et al., 2016). While many CMV studies predict persuasion outcomes, prediction tasks do not reveal the actual bidirectional relationship between syntactic similarity and persuasion. We use FastKASSIM to analyze this relationship.

We find that arguments which eventually lead to deltas ($\mu = 0.307$) tend to be more syntactically similar to original opinions than unsuccessful ($\mu = 0.263$) arguments ($t = 19.016$; $p < 0.001$). However, this finding does not imply on its own that *syntactically similar arguments are more persuasive*. Thus, we also examined the converse by computing the persuasion rates (proportion of threads receiving deltas) of the most syntactically similar and dissimilar arguments. We computed the syntactic similarity of each pairing of initial arguments and original opinions and grouped them into the top and bottom 33% of syntactic similarity. This resulted in a minimum syntactic similarity value of 0.341 for the top 33% ($\mu = 0.453$) and maximum of 0.171 for the bottom 33% ($\mu = 0.096$). We found that threads grouped in the bottom 33% of syntactic similarity only had a persuasion rate of 6.377%, while the persuasion rate for threads grouped in the top 33% was nearly twice that, 12.347% ($t = 19.135$; $p < 0.001$). These findings support the hypothesis that similar syntactic patterns play a role in persuasion — may be an indication of stylistic familiarity for the OP.

Features	**Acc.**$_{(\sigma)}$	**F1**$_{(\sigma)}$
Majority Baseline	0.767	0.868
Bag of Words	$0.892_{(0.02)}$	$0.867_{(0.02)}$
Bag of Words + Syntax	$0.923_{(0.02)}$	$0.922_{(0.01)}$
RoBERTa	$0.939_{(0.01)}$	$0.935_{(0.00)}$
RoBERTa + Syntax	$\mathbf{0.945}_{(0.01)}$	$\mathbf{0.938}_{(0.01)}$

Table 3: **Judgment** test set results comparing accuracy and weighted F1 score between unigram counts and unigram counts augmented with syntactic features. Standard deviation (σ) given in subscripts.

5.2 Authorship Attribution

Much work has examined methods for attributing authorship based upon linguistic features (Juola, 2008; Raghavan et al., 2010; Seroussi et al., 2011b). The **Judgment dataset** (Seroussi et al., 2011a) contained English judgments delivered by judges on the Australian High Court from 1913 to 1975. We classified whether 924 judgments were written by Sir Edward McTiernan or Sir George Rich during non-overlapping time periods (Rich's judgments from 1913-1928 and McTiernan's from 1965-2971). We follow the experimental design and preprocessing steps in Seroussi et al. (2011b)[9].

To capture semantics, one setting used normalized Bag of Words with Support Vector Machines and the other used a state-of-the-art fine-tuned RoBERTa (Liu et al., 2019) model[10]. We augmented both semantic settings with a syntactic similarity feature vector — for each classification instance, we randomly sampled 25 posts from the training set and computed the FastKASSIM syntactic similarity between judgments written by Rich and McTiernan, respectively. The syntactic similarity features consisted of the minimum, maximum, mean, and standard deviation of these comparisons. We evaluated our classifier on a 10% withheld testing set[11].

Table 3 shows that adding syntactic features to both semantic models results in gains in both accuracy and weighted F1. This is even the case when using RoBERTa; we achieve the strongest performance using RoBERTa with a weighted sum between textual and syntactic features, fine-tuned

using modules from the frameworks in Gu and Budhkar (2021); Wolf et al. (2020). Syntactic similarity with reference documents may provide a strong indicator of writing style.

6 Conclusion

We have introduced FastKASSIM, which has runtime improvements that scale significantly with document sizes and achieves better agreement with human perception of syntactic differences compared to standard syntax metrics. These improvements are possible due to our Label-based Tree Kernel, which has an improved asymptotic runtime complexity and a corrected normalization. FastKASSIM also allowed us to verify hypotheses regarding the importance of syntax both in authorship attribution and social dynamics such as persuasion. These findings motivate further applications of syntax.

Acknowledgements

Many thanks to Lillian Lee and Chenhao Tan for their feedback and collaboration on early versions of this work. We are very grateful to Reihane Boghrati for providing access to their Mechanical Turk dataset from their work on CASSIM. Thanks to Jack Hessel, Kun Qian, Yu Li, Qingyang Wu, Sky Wang, Mert Inan, and Zhiyang Xu for their helpful feedback and discussions.

Limitations

Our work relies on a couple assumptions. Our main corpus for evaluation is the crowdsourced and human-annotated dataset from Boghrati et al. (2018). As a result, our claim to better represent human perception of syntax relies on the assumption that their annotators correctly filter out responses which are not actually syntactically similar to each prompt. They had an acceptable Cohen's Kappa of 0.53. Additionally, we only use corpora that are in English. Future work should look towards applying our general approach to other languages.

In our evaluation of FastKASSIM against LSM and CASSIM, we also evaluate its ability to correctly identify statements created from the same prompt as similar and statements created from different prompts as dissimilar (Table 2). In this evaluation, we assume that 0.50 is an acceptable threshold for syntactic similarity and dissimilarity, because without any contextual information, one would assume that there are an equal amount of similar and dissimilar documents. Despite this, we still performed quantile adjustments for each comparison metric, uniformly distributing the scores between 0.0 and 1.0. This gives is an unfair advantage for the comparison metrics (i.e., CASSIM, LSM, and BERTScore), since "in-the-wild" it is impossible to obtain the eventual distribution of scores. Future work may consider methods to rebalance each of these scores, including conducting human evaluation to evaluate whether 0.50 is an acceptable threshold for syntactic similarity both before and after each metric undergoes an adjustment to the uniform distribution.

FastKASSIM is a metric for syntactic similarity between a pair of utterances or documents. However, similarity is only one dimension of syntax, which removes some granularity — for instance, syntactic similarity cannot explain which specific productions are shared. Similarity metrics like FastKASSIM instead afford opportunities in a variety of other applications, such as syntactic coherence in language generation and verifying computational social science hypotheses.

Additionally, parsing is still a significant bottleneck in runtime. Future work may wish to consider ways to mitigate the cost of parsing. One may also consider using sequential modeling to generate syntactic parse trees, or to directly model the output of FastKASSIM.

Ethical Considerations

Our study makes use of three datasets. First is the set of prompts collected in Boghrati et al. (2018), which involved anonymous participants creating fictional statements, so there is no personal information involved. Second is the publicly available r/ChangeMyView dataset collected by Tan et al. (2016), which consists of statements made by users behind typically anonymous aliases. Lastly is the publicly available WikiQA corpus (Yang et al., 2015), which does not contain identifying information.

In our r/ChangeMyView application studying the relationship between syntactic similarity and persuasion, we make the assumption that r/ChangeMyView is a community representative of online arguments. However, partially due to its anonymity, it is unknown whether r/ChangeMyView is a representative sample with diversity in location, educational background, socioeconomic status, ethnicity, and many other important factors. An ideal study should be able to control for proxies for individual traits in order to isolate the impact of syntax itself.

Generally, while most algorithms are not inherently unethical, there is often potential for abuse in their applications. The individual computations in the FastKASSIM algorithm do not have any negative implications, but it is possible to use syntactic similarity for unethical downstream tasks. For instance, because syntax is an important aspect of writing style, it is possible that users may try to adversarially uncover an anonymous author's identity. We do not condone the use of FastKASSIM for any unlawful or morally unjust activities. We do not propose any new tasks that would introduce unethical activity.

A Formalizing FastKASSIM

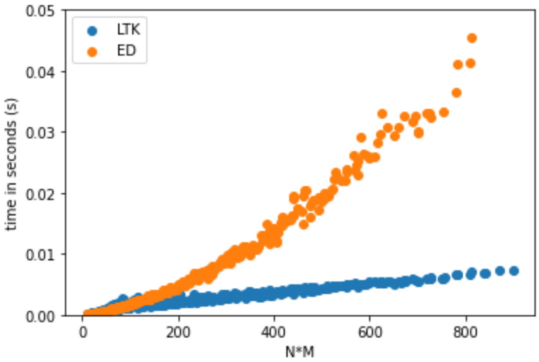

Figure 6: Runtime Comparison of Edit Distance (ED) and Label-based Tree Kernel (LTK) on WikiQA with varying NM (product of parse tree sizes).

The Label-based Tree Kernel recursively computes $\mathrm{Delta}_{\mathrm{lb}}$ across all n_1, n_2 pairs in parse trees P_1, P_2. The time complexity of $\Delta_{\mathrm{lb}}(n_1, n_2)$ has a ceiling of $O(L_1^h \times L_2^h)$, where L_i^h is the number of nodes at height h for a tree rooted at n_i, and h is the minimum height between the two trees. In the worst case scenario, Δ_{lb} of a fully uncached pair n_i, n_j results in recursive calls at every depth level. Δ_{lb} is computed for each node pair, so the ceiling of the tree kernel runtime is $O(NM)$, where N, M are the total number of nodes in P_1 and P_2, respectively.[12]

$O(NM)$ is a ceiling assuming the worst-case, where the labels are the same at each comparison, requiring full recursion. Let us consider there to be k shared labels in a pair of parse trees.

In each parse tree P_1, P_2, there will be $C_i^{(1)}, C_i^{(2)}$ connected components, one for each shared label $i \in [1, k]$, where a connected component consists of connected nodes with the same label. Out of the $C_i^{(1)}$ components in parse tree P_1, let $N_{i,j}^{(1)}$ be the size of each individual component j. So, for label $i = 1$, the number of comparisons follows:

$$O\left(\sum_{l=1}^{C_1^{(1)}} \sum_{m=1}^{C_1^{(2)}} N_{1,l}^{(1)} N_{1,m}^{(2)}\right)$$

which represents iterating through every pair of the $C_1^{(1)} \times C_1^{(2)}$ possible pairs of connected components and computing LTK. Then, for k shared labels, the worst-case runtime (i.e. the connected components do not form shared subtrees), we have equation 1:

$$O\left(\sum_{i=1}^{k} \sum_{l=1}^{C_i^{(1)}} \sum_{m=1}^{C_i^{(2)}} N_{i,l}^{(1)} N_{i,m}^{(2)}\right) = O\left(\sum_{i=1}^{k} N_i^{(1)} N_i^{(2)}\right) \tag{1}$$

where $N_i^{(1)}, N_i^{(2)}$ are the total number of nodes that have label i in P_1, P_2 respectively. However, recall from Algorithm 2 that LTK only iterates through pairs that share the same label; it does not matter if the connected components themselves are intertwined. Then, further simplifying this term we have equation 2:

$$O\left(\sum_{i=1}^{k} N_i^{(1)} N_i^{(2)}\right) = O(S_{12}) \tag{2}$$

where S_{12} is simply the total number of pairs in P_1, P_2 that have the same label. When all nodes have the same label, $S_{12} = NM$, consistent with the observed runtime ceiling. Empirically, we see that the *expectation* of S_{12} is much smaller than NM, as seen by the sublinear time scaling in Figure 6.

A.1 Scaling with Node Pairings (NM)

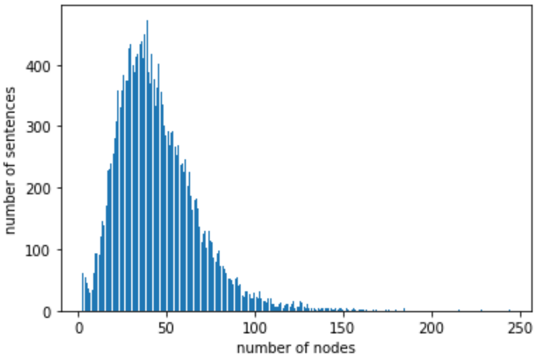

Figure 7: Statistics of Parse Trees in WikiQA

We first examine the relationship between LTK and NM, the number of possible node pairings, using the WikiQA corpus (Yang et al., 2015), a public dataset containing annotated question and answer pairs written in English. This dataset is chosen in order to compare FastKASSIM and CASSIM on well-structured text, and because of the ability to extract clean sentences of various length, which is crucial in determining NM. The experiment utilized 20,347 answer sentences from the WikiQA training set. We compute the parse trees prior to computing the runtimes of Edit Distance and LTK.

---

[12] Note that this is only possible due to Δ_{lb} caching the repetitive computations when iterating over node pairs.

Metric	Sim.	Dis.
LSM	70.4	56.0
LSM$_a$	72.2	42.6
CASSIM	82.1	82.0
CASSIM$_a$	48.3	50.6
BERTScore	89.9	85.1
BERTScore$_a$	85.7	38.0
Sentence-BERT	60.6	81.4
Sentence-BERT$_a$	26.7	57.7
FastKASSIM	73.1	31.7
FastKASSIM$_a$	86.1	38.0

Table 4: Average score assigned to similarity document pairings (Sim.) and dissimilar document pairings (Dis.) by each metric. Metric$_a$ denotes an adjustment to a uniform distribution using a quantile transformation.

Statistics of parse trees from the WikiQA-train corpus are shown in Figure 7.

As the corpus is rather large, we consider sentences with fewer than 30 nodes, which resulted in a total of 16,591,680 possible pairings. Then, pairings are grouped by the product of their nodes $N \times M$. For each value of $N \times M$, we track the cost of computing both the Edit Distance and LTK for all pairings if there are less than 10 pairs, or randomly sample 10 pairs if there are more. The average runtime for both Edit Distance and LTK for each value of $N \times M$ are shown in Figure 6.

B Metrics for Evaluating FastKASSIM, CASSIM, and LSM

In Section 4.3 and Table 2, we evaluated FastKASSIM, CASSIM, and LSM in terms of Similarity Accuracy, Similar Document Recall, Similar Document Precision, Dissimilar Document Recall, and Dissimilar Document Precision. These all follow the standard formulas for accuracy, recall, and precision. Adapted to our similarity context:

Similarity accuracy is the sum of the number of same prompt pairs receiving a score greater than 0.50 and the number of different prompt pairs receiving a score lower than 0.50 divided by the total number of pairings.

Similar document recall is the number same prompt pairs receiving a score greater than 0.50 divided by the total number of pairings originating from the same prompt.

Similar document precision is the number of same prompt pairs receiving a score greater than 0.50 divided by the total number of pairings receiving a score greater than 0.50.

Dissimilar document recall is the number different prompt pairs receiving a score less than 0.50 divided by the total number of pairings originating from different prompt.

Dissimilar document precision is the number of different prompt pairs receiving a score less than 0.50 divided by the total number of pairings receiving a score less than 0.50.

C Persuasiveness of Syntactic Similarity: Additional Context

C.1 CMV Background

We investigate the role of syntax in persuasive arguments in the r/ChangeMyView[13] community (CMV) on Reddit. CMV users come in "good faith" that they are open to changing their view on a controversial topic. They write an original post describing an opinion and allow “challengers” to comment on their post and attempt to change their opinion. If their opinion is changed, the original poster (OP) will indicate this by assigning a “delta” (by typing either “!delta” or Δ in response to the persuasive comment). An OP may choose to present a rebuttal to a challenger, openly disagree with a challenger, or simply ignore a challenger (e.g., Figure 8). All Reddit users use anonymous aliases, unless they explicitly disclose their identity.

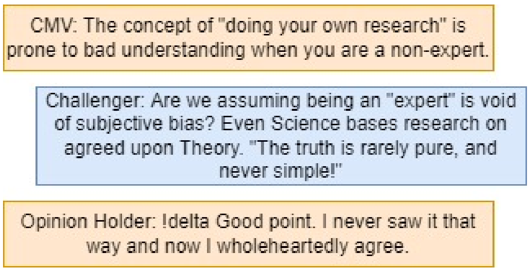
Earlier work found positive relationships between *behavioral mimicry* (mirroring behaviors) and in-person *negotiations* (Curhan and Pentland, 2007; Maddux et al., 2008). Yet, Healey et al. (2014) found that in general spoken conversations, peoples' syntactic patterns diverged from each other. We thus investigate the hypothesis that as a challenger on CMV continues to *engage* in an argument with an OP, their syntactic communication styles may begin to converge in order to “optimize for social differences.” Additionally, we hypothesize that challengers who utilize similar syntactic patterns, whether intentionally or not, may be more persuasive.

C.2 Dataset

We use the CMV dataset consisting of 18,363 posts and 1,114,533 comments written in English and collected by Tan et al. (2016). As in Tan et al. (2016), we examine discussion trees with at least 10 replies from challengers and at least one OP

---

[13] https://www.reddit.com/r/changemyview/



CMV: The concept of "doing your own research" is prone to bad understanding when you are a non-expert.

Challenger: Are we assuming being an "expert" is void of subjective bias? Even Science bases research on agreed upon Theory. "The truth is rarely pure, and never simple!"

Opinion Holder: !delta Good point. I never saw it that way and now I wholeheartedly agree.

Figure 8: An example of a thread on CMV. The OP presents a set of arguments defending their opinion (orange, top), inviting challengers to contest their opinion (blue). The OP acknowledged their opinion has been changed by assigning a delta (orange, bottom).

reply, in order to focus on discussions with "non-trivial" amounts of engagement. We also filter out posts which receive more than 10,000 comments in order to reduce noise from "outsiders" in cases where a post goes viral. When a challenger comments on an original post, it starts a "thread," with the original post (OP's opinion) taking on the root, index 0, and the challenger's comment taking on index 1. Each additional comment made in reply extends the thread. We are interested in syntactic accommodation, so we only consider threads that consist of conversations between the OP and a single challenger to eliminate confounders. These preprocessing steps results in a final dataset consisting of $15,986$ posts.

C.3 Dicusssion & Implications

In Section 5.1, we found two very statistically significant relationships between syntactic similarity and persuasive arguments. First, arguments that eventually lead to deltas tend to be more syntactically similar to original opinions compared to arguments that do not. Second, the arguments that are the most syntactically similar to original opinions actually were nearly twice as likely to receive deltas than the least syntactically similar arguments. Altogether, this may imply that syntactically similar arguments are more persuasive. This idea is supported by the rich body of work suggesting that similarity and communicative familiarity leads to improved social and conversational outcomes (Curhan and Pentland, 2007; Giles, 2016; Kaptein et al., 2014; Maddux et al., 2008; Wetzel and Insko, 1982).

D Parse Tree Examples

We visualize the constituency parse trees of several sentences taken from the corpus collected in Boghrati et al. (2018) using the online interface of the Berkeley Neural Parser[14], which uses the parser described in Kitaev et al. (2019).

We first compare the parse trees of the examples provided in Figure 1. Figure 9 compares the parse trees of the two similar documents shown in Figure 1. The first document is composed of one sentence — "I like swimming because it is cool." and the second document is also composed of one sentence — "I love running because it is fun." CASSIM assigned a score of 0.962, and FastKASSIM assigned a score of 0.928. The structure and composition of these two documents are nearly identical; the only difference is the production associated with the words "running" and "swimming."

Figure 10 is a visualization of the parse trees of the two dissimilar documents shown in Figure 1. The first document is composed of two sentences: "When we hate, we always move away from the grace of God. When we become resentful and unforgiving, the world around us seems spiteful and meaningless." The second document is composed of one sentence: "How can you be skiing if you are already swimming?" Beyond the differing number of sentences, the sentences in the first document individually appear structurally dissimilar compared to the sentence in the second document. FastKASSIM assigned a low score — 0.219, whereas CASSIM assigned a high score — 0.838.

Figure 11 compares the parse trees of the two single-sentence documents "How can you be skiing if you already swimming?" and "Knowledge is important to succeed." As is clear from Figure 11, the two sentences are structurally and compositionally quite different. FastKASSIM assigned a score of 0.439, whereas CASSIM assigned a score of 0.679.

Figure 12 compares the parse trees of two separate documents. The first document is composed of two sentences: "When we dream, we often search for deeper meaning. When we search for deeper meaning, other things become more nuanced too." The second document is composed of two sentences as well: "When we concentrate, we try to do better on a task. When we strive to do better, we end up doing better too." The structures of the two documents appear rather similar, but there do appear to be some differences in composition

---

[14] https://parser.kitaev.io/

(i.e., in terms of the constituent parts-of-speech). FastKASSIM assigned a score of 0.656, and CASSIM assigned a score of 0.837. While both scores are relatively high, FastKASSIM may be more penalizing towards these types of differences.

Figure 13 compares the parse trees of two separate documents. The first document is composed of four sentences: “I am old enough to draw freely upon my experience. Experience is more important than luck. Luck can turn. Experience lasts a lifetime.” The second document is composed of one sentence: “Being loving makes you become better.” Holistically, the structures of the two documents are quite different. Beyond the differing number of sentences in each document, there are also not any individual sentences between the two documents that appear particularly syntactically similar. FastKASSIM assigned a score of 0.15, whereas CASSIM assigned a score of 0.924.

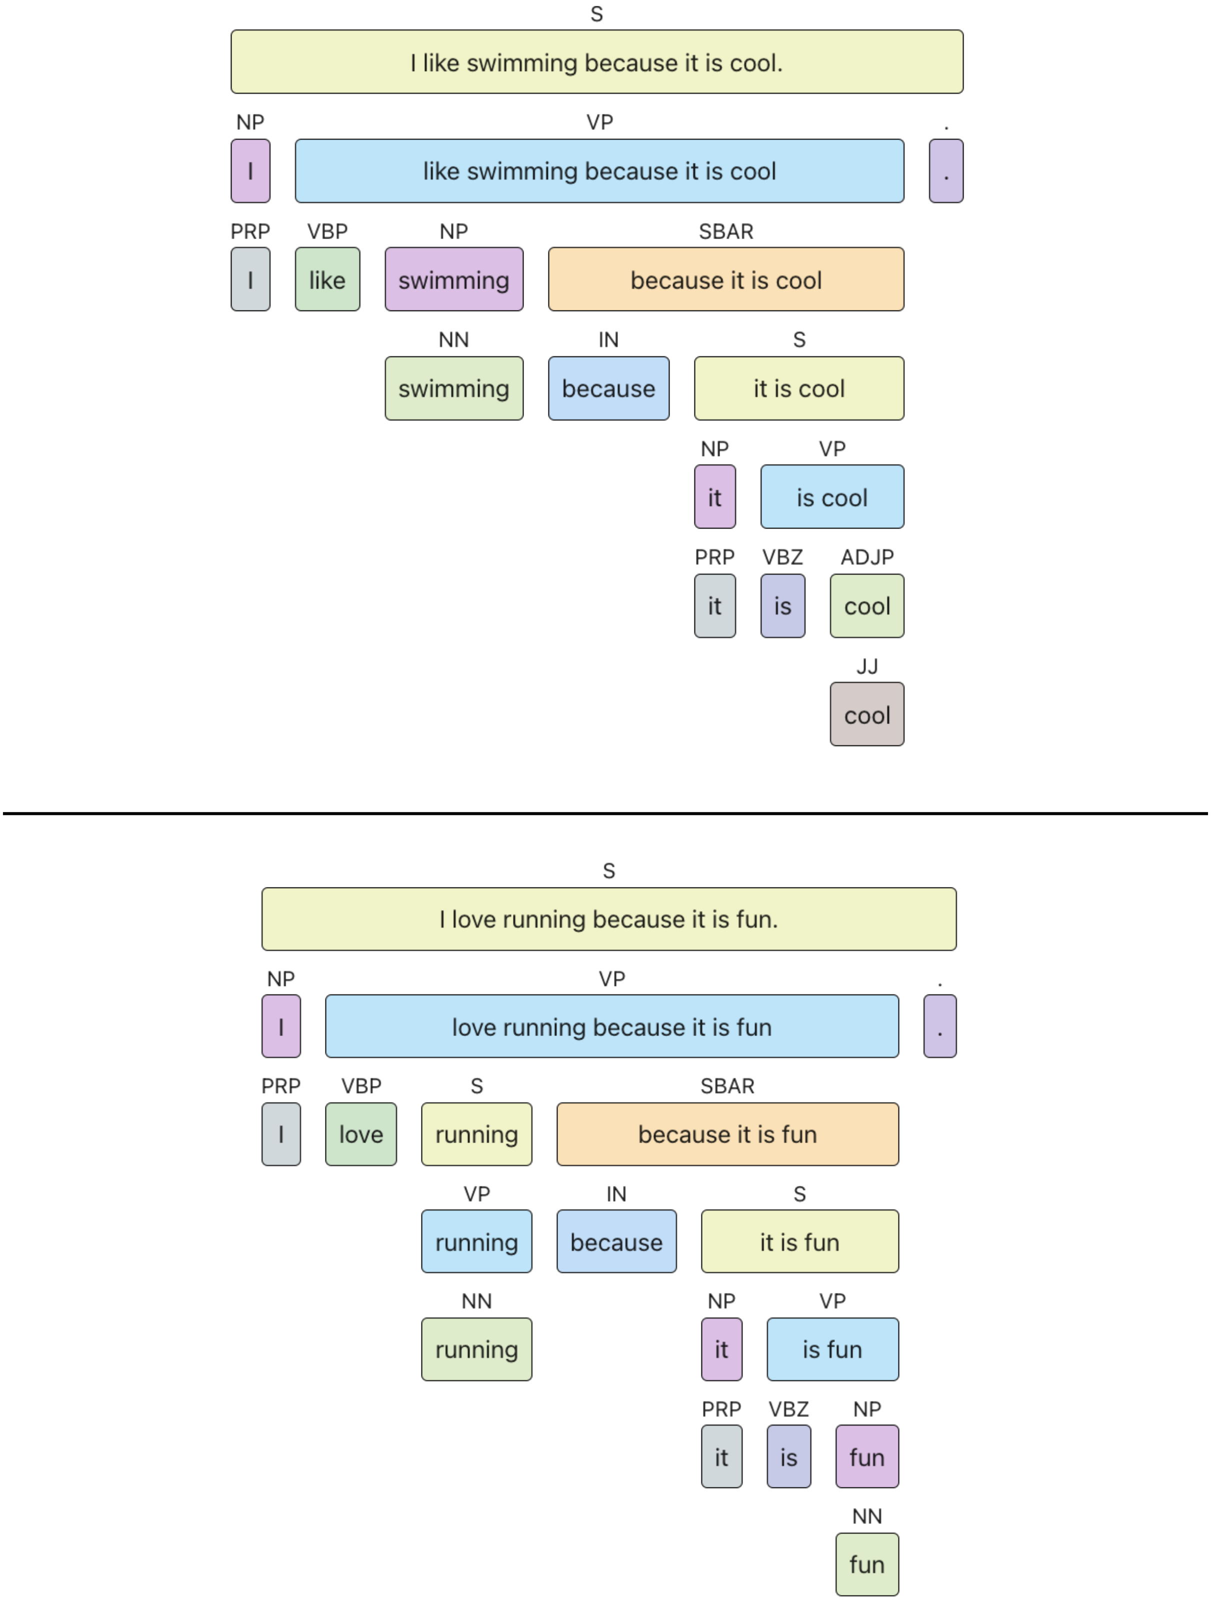


Figure 9: A comparison of the parse trees of two syntactically similar documents from Figure 1. Top document: “I like swimming because it is cool.” Bottom document: “I love running because it is fun.” FastKASSIM similarity score: 0.928; CASSIM similarity score: 0.962.

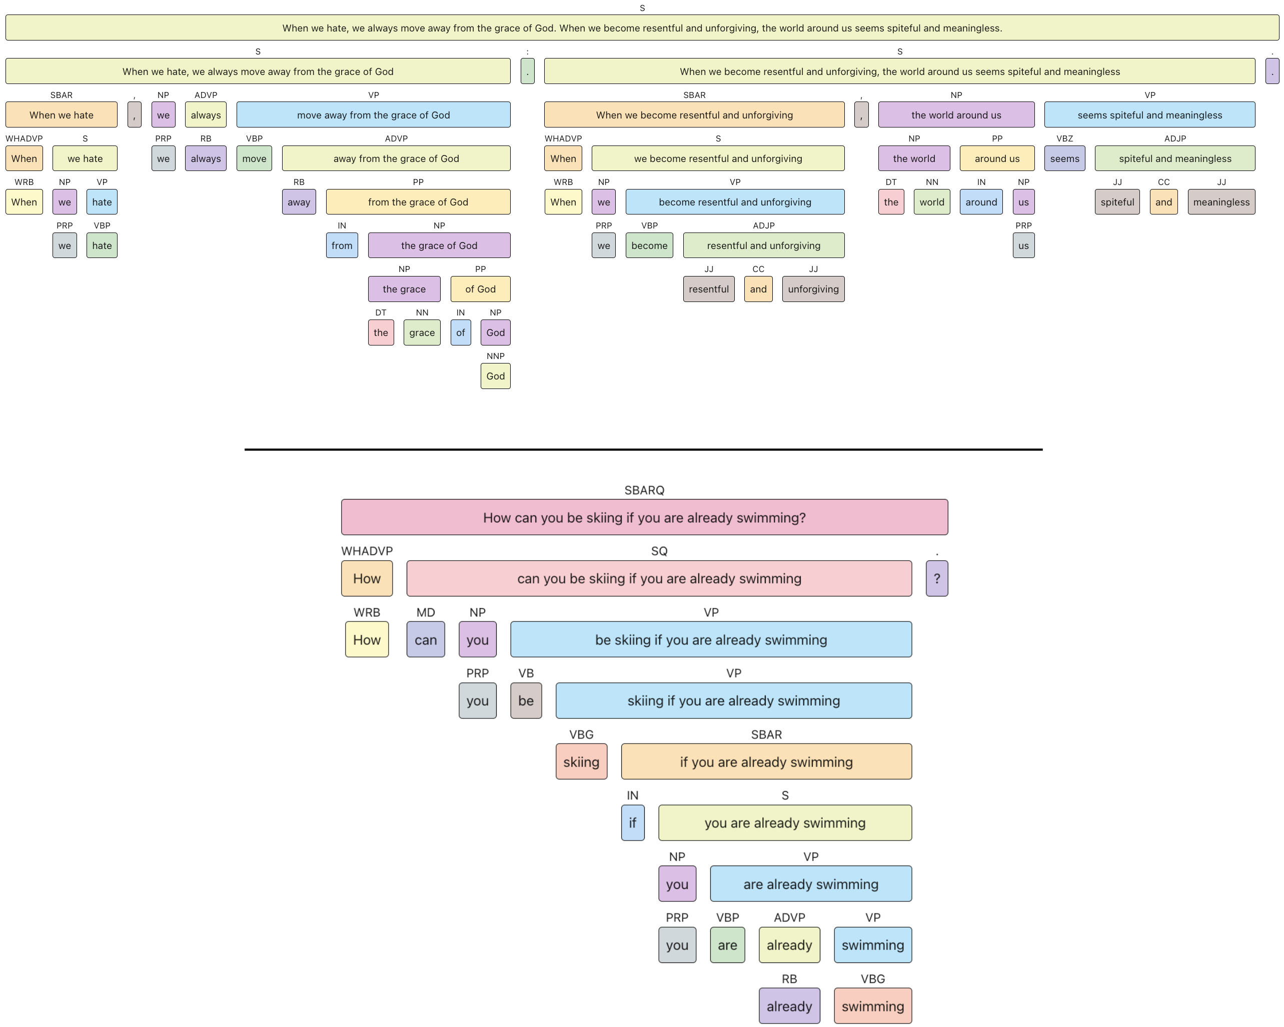

Figure 10: A comparison of the parse trees of two syntactically dissimilar documents. Top document: "When we hate, we always move away from the grace of God. When we become resentful and unforgiving, the world around us seems spiteful and meaningless." Bottom document: "How can you be skiing if you are already swimming?" FastKASSIM similarity score: 0.219; CASSIM similarity score: 0.838.

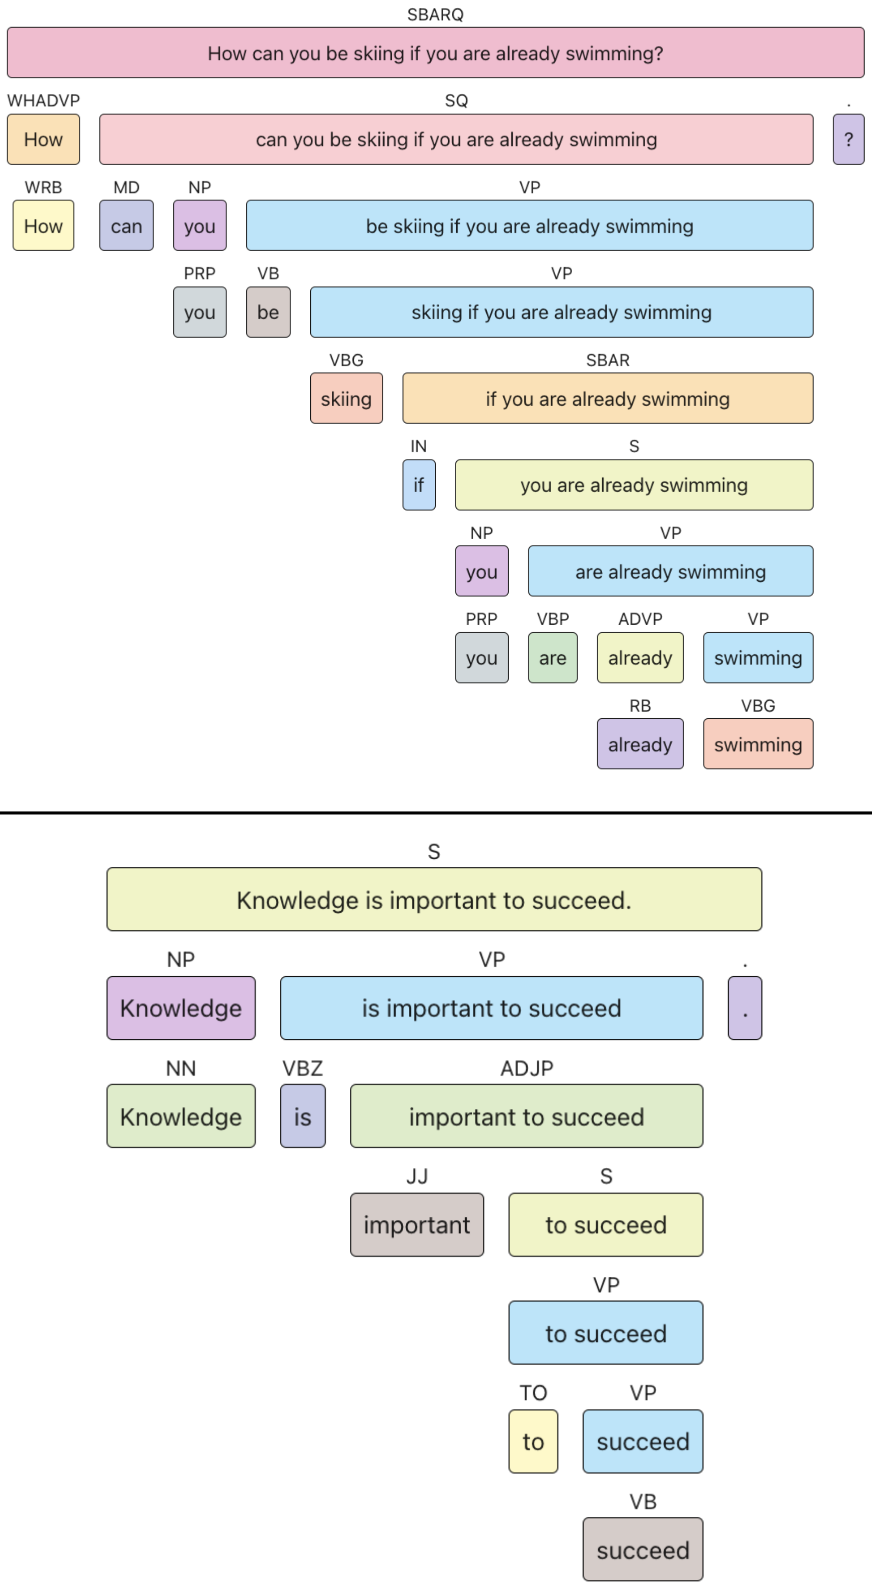

Figure 11: A comparison of the parse trees of two syntactically dissimilar documents. Top document: “How can you be skiing if you are already swimming?” Bottom document: “Knowledge is important to succeed.” FastKASSIM similarity score: 0.439; CASSIM similarity score: 0.679.

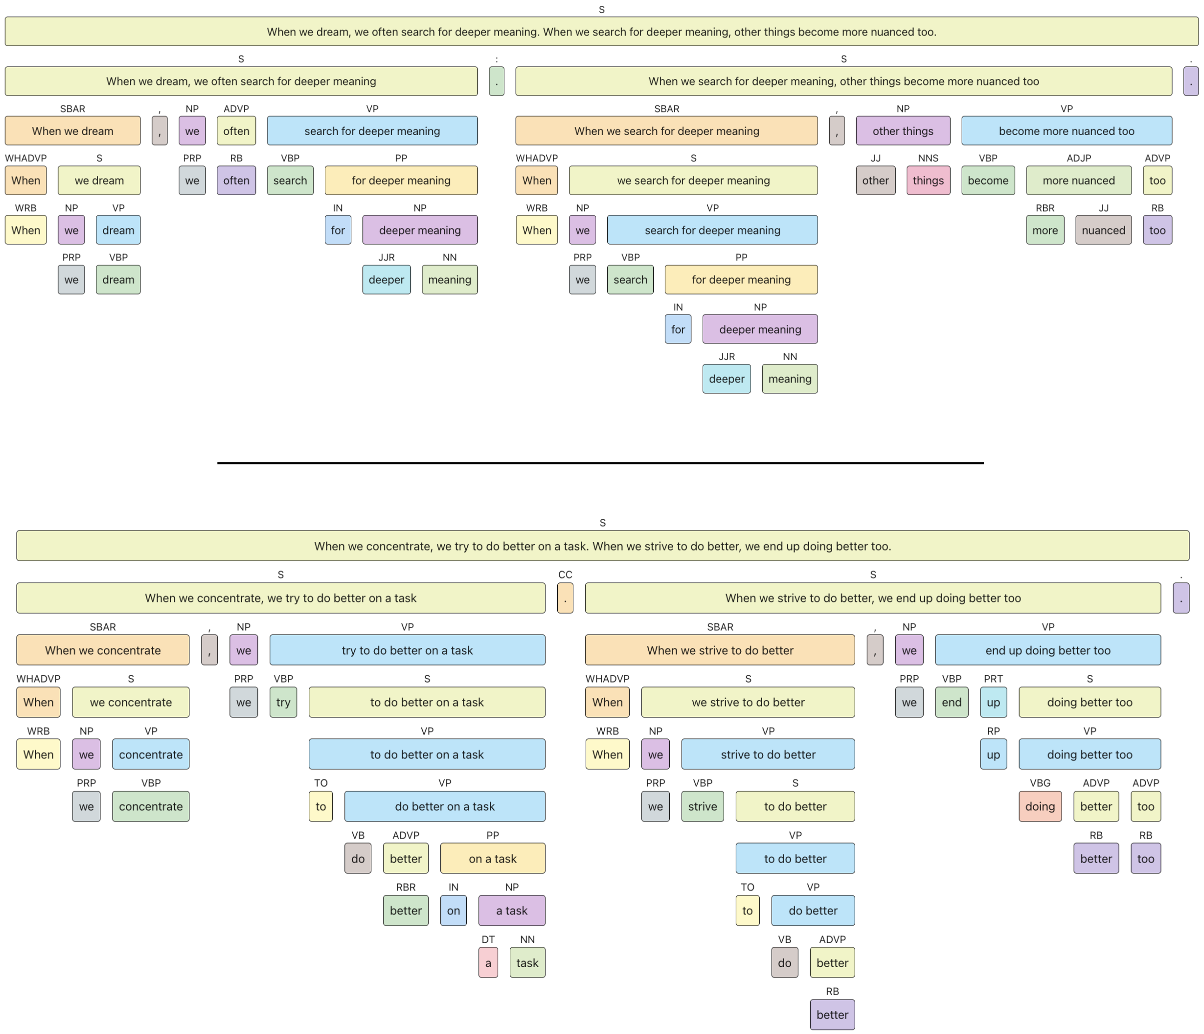

Figure 12: A comparison of the parse trees of two syntactically similar documents. Top document: “When we dream, we often search for deeper meaning. When we search for deeper meaning, other things become more nuanced too.” Bottom document: “When we concentrate, we try to do better on a task. When we strive to do better, we end up doing better too.” FastKASSIM similarity score: 0.656; CASSIM similarity score: 0.837.

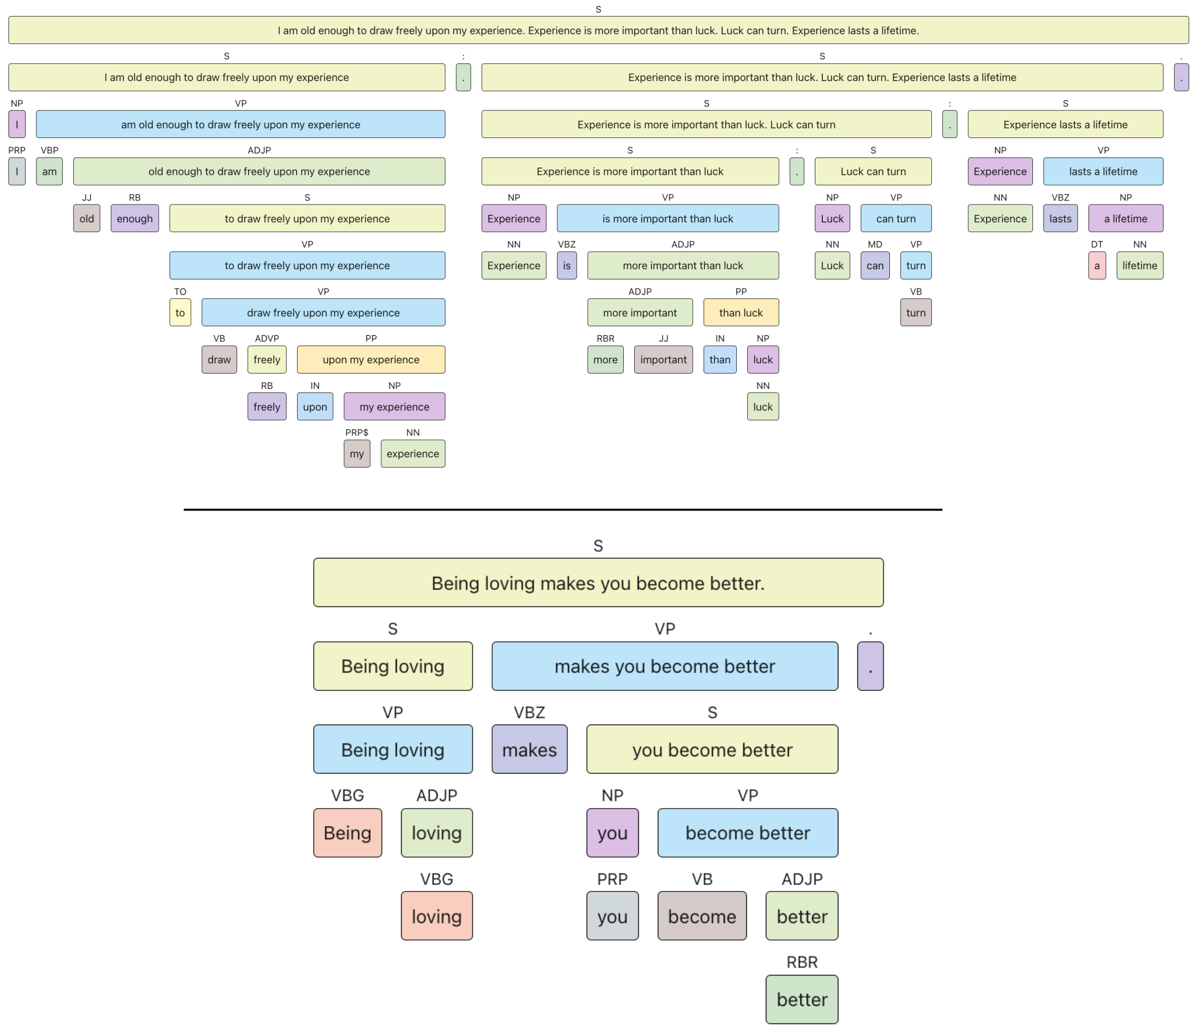

Figure 13: A comparison of the parse trees of two syntactically dissimilar documents. Top document: “I am old enough to draw freely upon my experience. Experience is more important than luck. Luck can turn. Experience lasts a lifetime.” Bottom document: “Being loving makes you become better.” FastKASSIM similarity score: 0.15; CASSIM similarity score: 0.924.

Friend-training: Learning from Models of Different but Related Tasks

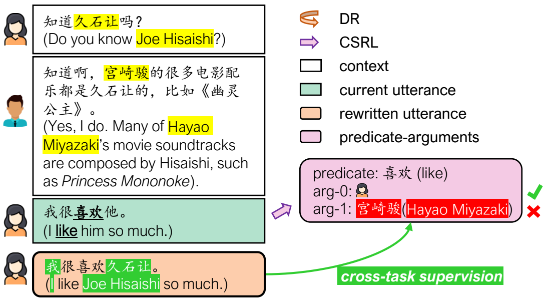
Abstract

Current self-training methods such as standard self-training, co-training, tri-training, and others often focus on improving model performance on a single task, utilizing differences in input features, model architectures, and training processes. However, many tasks in natural language processing are about different but related aspects of language, and models trained for one task can be great teachers for other related tasks. In this work, we propose **friend-training**, a *cross-task* self-training framework, where models trained to do different tasks are used in an iterative training, pseudo-labeling, and retraining process to help each other for better selection of pseudo-labels. With two dialogue understanding tasks, conversational semantic role labeling and dialogue rewriting, chosen for a case study, we show that the models trained with the friend-training framework achieve the best performance compared to strong baselines.

1 Introduction

Many different machine learning algorithms, such as self-supervised learning (Mikolov et al., 2013; Devlin et al., 2019; Liu et al., 2021), semi-supervised learning (Yang et al., 2021) and weakly supervised learning (Zhou, 2018), aim at using unlabeled data to boost performance. They have been of even greater interest recently given the amount of unlabeled data available. Self-training (Scudder, 1965) is one semi-supervised learning mechanism aiming to improve model performance through pseudo-labeling and has been successfully applied to computer vision (Lee et al., 2013; Chen et al., 2021), natural language processing (Dong and Schäfer, 2011; Bhat et al., 2021) and other fields (Wang et al., 2019; Kahn et al., 2020).

The main challenge of self-training is how to select high-quality pseudo-labels. Current self-training algorithms mainly focus on a single task when assessing the quality of pseudo-labels and suffer from gradual drifts of noisy instances (Zhang et al., 2021). This work is motivated by the observation that learning targets of tasks represent different properties of the inputs, and some properties are shared across the tasks which can be used as supervision from one task to another. Such properties include certain span boundaries in dependency and constituency parsing, and some emotion polarities in sentiment analysis and emotion detection. Two dialogue understanding tasks, conversational semantic role labeling (CSRL) and dialogue rewriting (DR), are also such a pair, with shared properties such as coreference and zero-pronoun resolution. As shown in Figure 1, the rewritten utterance can be used to generate cross-task supervision to the arguments of predicate 喜欢(like). We leverage the cross-task supervision from *friend tasks* – different but related tasks – as a great criterion for assessing the quality of pseudo-labels.



知道久石让吗？
(Do you know Joe Hisaishi?)

知道啊，宫崎骏的很多电影配乐都是久石让的，比如《幽灵公主》。
(Yes, I do. Many of Hayao Miyazaki's movie soundtracks are composed by Hisaishi, such as *Princess Mononoke*).

我很喜欢他。
(I like him so much.)

我很喜欢久石让。
(I like Joe Hisaishi so much.)

predicate: 喜欢 (like)
arg-0:
arg-1: 宫崎骏(Hayao Miyazaki)

Figure 1: An example of cross-task supervision between a CSRL parser and a DR system in a dialogue. 久石让(Joe Hisaishi) from the rewritten utterance provides cross-task supervision to 宫崎骏(Hayao Miyazaki), the predicted `arg-1` of 喜欢(like) from the CSRL parser, while 我(I) to the predicted `arg-0`.

In this work, we propose **friend-training**, the first *cross-task* self-training framework. Compared to single-task self-training, friend-training **exploits supervision from friend tasks for better selection of pseudo-labels**. To this end, two novel modules

---

[*] Work done when interning at Tencent AI Lab.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 232–247
May 2-6, 2023

are proposed: (1) a *translation matcher*, which maps the pseudo-labels of different tasks for one instance into the same space and computes a *matching score* representing the **cross-task matching degree of pseudo-labels from different tasks**; (2) an *augmented (instance) selector*, which leverages **both** the confidence of pseudo-labels from task-specific models and the matching score to select instances with pseudo-labels of high quality as new training data. We choose CSRL and DR as friend tasks to conduct a case study for friend-training, and specify the translation matcher and augmented selector for friend-training between these tasks. Experimental results of domain generalization and few-shot learning show friend-training surpasses both classical and state-of-the-art semi-supervised learning algorithms by a large margin. To summarize, contributions from this work include:

- We propose friend-training, the first cross-task self-training framework which exploits supervision from friend tasks for better selection of pseudo-labels in the iterative training process.
- We provide specific modeling of friend-training between CSRL and DR, with a novel translation matcher and a novel augmented selector.
- Extensive experiments with CSRL and DR demonstrate the effectiveness of friend-training, outperforming several strong baselines.

2 Related Work

Self-training Self-training (Scudder, 1965; Angluin and Laird, 1988; Abney, 2002; Lee et al., 2013) is a classical semi-supervised learning framework (Chapelle et al., 2009) which has been widely explored in recent years. The general idea of self-training is to adopt a trained model to pseudo-label easily acquired unlabeled data and use them to augment the training data to retrain the model iteratively. This paradigm shows promising effectiveness in a variety of tasks: including text classification (Mukherjee and Awadallah, 2020; Wang et al., 2020a), image classification (Xie et al., 2020; Zoph et al., 2020), machine translation (He et al., 2020) and model distillation (Mukherjee and Hassan Awadallah, 2020). Co-training (Blum and Mitchell, 1998) and tri-training (Zhou and Li, 2005) are similar iterative training frameworks to self-training but with a different number of models or considering different views of the training data, both of which see wide adoption in NLP (Mihalcea, 2004; McClosky et al., 2006; Wan, 2009; Li et al., 2014; Caragea et al., 2015; Lee and Chieu, 2021; Wagner and Foster, 2021). These frameworks aim at improving performance with multiple models trained on one task, without directly leveraging the benefit of supervision from related tasks.

Multi-task Learning Multi-task learning (Caruana, 1997; Yang et al., 2021) seeks to improve the learning performance of one task with the help of other related tasks, among which two lines of work are related to ours: (1) semi-supervised multi-task learning (Liu et al., 2007; Li et al., 2009) combines semi-supervised learning and multi-task learning. Liu et al. (2007) exploited unlabeled data by random walk and used a task clustering method for multi-task learning. Li et al. (2009) integrated active learning (MacKay, 1992) with the model in Liu et al. (2007) to retrieve data that are most informative for labeling. Although these works tried to utilize unlabeled data to enhance multi-task learning, our work differs from them in incorporating supervised signals among tasks to select high-quality pseudo-labels for updating models, which is an iterative training process without additional human annotation. (2) Task grouping (Kumar and III, 2012; Standley et al., 2020; Fifty et al., 2021) aims to find groups of related tasks and employs multi-task learning to each group of tasks, with one model for each group. Our work focuses on training single-task models, but task grouping techniques can be used to look for possible friend tasks.

Conversational Semantic Role Labeling CSRL is a task for predicting the semantic roles of predicates in a conversational context. Wu et al. (2021) leveraged relational graph neural networks (Schlichtkrull et al., 2018) to model both the speaker and predicate dependency, achieving some promising results. However, the current dataset (Xu et al., 2021) for CSRL is limited to mono-domain. High-quality labeled data for new domains are needed to empower more applicable CSRL models.

Dialogue Rewriting DR is commonly framed as a sequence-to-sequence problem which suffers large search space issue (Elgohary et al., 2019; Huang et al., 2021). To address it, Hao et al. (2021) cast DR to sequence labeling, transforming rewriting an utterance as deleting tokens from an utterance or inserting spans from the dialogue history into an utterance. Jin et al. (2022) improved the continuous span issue in (Hao et al., 2021) by first generating multiple spans for each token and slotted rules and then replacing a fixed number rules with spans.

3 Friend-training

Friend-training is an iterative training framework to jointly refine models of several friend tasks. Different from self-training, friend-training injects cross-task supervision into the selection of pseudo-labels. We first briefly describe self-training before presenting friend-training.

3.1 Self-training

Classic self-training aims at iteratively refining a model of a single task by using both labeled data and a large amount of unlabeled corpus. At each iteration, the model first assigns the unlabeled data with pseudo-labels. Subsequently, a set of the unlabeled instances with pseudo-labels is selected for training, presumably with information for better model generalization. Then cross-entropy of model predictions and labels on both gold and pseudo-labeled data is minimized to update the model:

$$L = \sum_{i=1}^{N} y_i \log \frac{y_i}{p_i} + \lambda \sum_{i=1}^{N'} y'_i \log \frac{y'_i}{p'_i}, \tag{1}$$

where the left term is the loss for the labeled data and the right for the unlabeled data while λ is a coefficient to balancing them; $N (N')$ is the number of instances, y (y') is the label and p (p') is the output probability of the model.

Self-training is usually limited to only one task, but there are thousands of NLP tasks already proposed and many of them are related. Models trained for one task can be great teachers for other related tasks. We explore this cross-task supervision in self-training by incorporating two novel modules introduced in subsection 3.2.

3.2 Friend-training

For friend-training with two tasks,[1] we have two classifiers f_a and f_b trained on two different tasks with labeled training sets $\mathcal{L}_a$ and $\mathcal{L}_b$, with expected accuracies η_a and η_b, respectively. The two datasets are created independently and the prediction targets of the two tasks are partially related through a pair of translation functions $\mathcal{F}_a : \hat{Y}_a \rightarrow \Sigma$ and $\mathcal{F}_b : \hat{Y}_b \rightarrow \Sigma$, where Σ is the set of possible sub-predictions that all possible predictions of the two tasks $\hat{Y}_a$ and $\hat{Y}_b$ can be reduced to. $|\hat{Y}_a| \geq |\Sigma|, |\hat{Y}_b| \geq |\Sigma|$. We assume that the translation functions are general functions with the expected probability of generating a translation $\epsilon_{\mathcal{F}} = \frac{1}{|\Sigma|}$. The translation functions are deterministic and always map the gold labels of the friend tasks for the same input to the same translation.

Both classifiers make predictions on the unlabeled set $\mathcal{U}$ at iteration k. Some instances $\mathcal{U}^k_{\mathcal{F}}$ with pseudo-labels are chosen as new training data based on the results of the translation functions, $\phi_a(x) = \mathcal{F}_a(f_a(x))$ and $\phi_b(x) = \mathcal{F}_b(f_b(x))$, and some selection criteria, such as total agreement. If total agreement is used as the selection criterion, the probability of erroneous predictions for f_a in these instances is

$$\begin{aligned} &\mathrm{Pr}_x[f_a(x) \neq f^*_a(x) | \phi_a(x) = \phi_b(x)] \\ =&1 - \frac{\eta_a \mathrm{Pr}_x[\phi_a(x) = \phi_b(x) | f_a(x) = f^*_a(x)]}{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]}, \end{aligned} \tag{2}$$

with f^* being the optimal classifier.

Because both classifiers are very different due to training data, annotation guidelines, models, prediction targets, etc., being all different, the two classifiers are very likely to be independent of each other. Under this condition Equation 2 becomes

$$\begin{aligned} &1 - \frac{\eta_a(\eta_b + \epsilon_{\mathcal{F}}(1 - \eta_b))}{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]} \\ =&1 - \frac{Z}{Z + \eta_b \epsilon_{\mathcal{F}}(1 - \eta_a) + E}, \end{aligned} \tag{3}$$

where $Z = \eta_a(\eta_b + \epsilon_{\mathcal{F}}(1 - \eta_b))$ and $E = \epsilon^2_{\mathcal{F}}(1 - \eta_a)(1 - \eta_b)$. We give the detailed derivation of Equation 2 and 3 in Appendix A.1. This indicates that the quality of the picked instances is negatively correlated with the number of false positive instances brought by the noisy translation $\eta_b \epsilon_{\mathcal{F}}(1 - \eta_a)$, and the number of matching negative instances E. When $\epsilon_{\mathcal{F}}$ is minimized by choosing translation functions with a sufficiently large co-domain Σ, the probability of error instances chosen when two classifiers agree approaches 0. This also indicates that even when $1 - \eta_a$ is large, i.e. f_a performs badly, if the co-domain is large, the error rate of the chosen instances can still be kept very low.[2] As the dependence between the

---

[1] We focus on the two-friend version of friend-training in this work, however, friend-training can easily be extended to more than two friends.

[2] Intuitively, this means independent classifiers trained to do different tasks are unlikely to predict the same but wrong sub-prediction for a given input, if the sub-prediction includes a large number of decisions.

two classifiers grows in training, the probability of error instances also increases. When they are completely dependent on each other, Equation 2 becomes $1 - \eta_a$, i.e. classic self-training.

Based on this formulation, two additional modules are needed: (1) a *translation matcher* that maps predictions of two models trained on different tasks into the same space and computes a matching score; (2) an *augmented (instance) selector* which selects instances with pseudo-labels for the classifiers considering both the matching score of the translated predictions and the model confidences.

Translation Matcher Given the prediction of models of two friend tasks $f_a(x)$ and $f_b(x)$, the translation matcher $\mathcal{M}$ leverages translation functions $\mathcal{F}_a$ and $\mathcal{F}_b$ to get the translated pseudo-labels and computes a matching score m for the pair of pseudo-labels, which represents the similarity of the pair in the translation space:

$$m_{a,b} = \mathcal{M}\left(\mathcal{F}_a(f_a(x)), \mathcal{F}_b(f_b(x))\right), \quad (4)$$

with total agreement being 1. This matching score serves as a criterion for the selection of high quality pseudo-labels with cross-task supervision.

Augmented Selector Apart from pseudo-label similarity, other information about pseudo-label quality can be found from model confidence, which self-training algorithms specifically utilize, to augment matching scores. The augmented selector considers both the confidence of the pseudo-labels from task models, denoted as $\{c_a, c_b\}$, and the matching scores:

$$q_\tau = \mathcal{S}_\tau(m_{a,b}, c_\tau), \quad (5)$$

where $q_\tau \in \{0, 1\}$ represents the selection result of the pseudo-label for task $\tau \in a, b$. Therefore, instances with low matching scores but high confidence may also be selected as the training data. The complete algorithm is shown in Algorithm 1.

Algorithm 1: Two-task friend-training

```
Input  : Labeled data sets for two friend tasks, $\mathcal{L}_a, \mathcal{L}_b$; an unlabeled data set $\mathcal{U}$; task models $f_a, f_b$.
Output : Refined $f_a, f_b$.
Pre-train $f_\tau$ with $\mathcal{L}_\tau$ ($\tau \in a, b$);
while not until the maximum iteration do
    $\mathcal{L}_a^u = \emptyset$; $\mathcal{L}_b^u = \emptyset$;
    for $z$ in $\mathcal{U}$ do
        Generate $f_a(z), f_b(z)$ and $c_a, c_b$;
        $m_{a,b} \leftarrow$ Equation 4;
        $q_a, q_b \leftarrow$ Equation 5;
        if $q_\tau = 1$ ($\tau \in a, b$) then
            $\mathcal{L}_\tau^u = \mathcal{L}_\tau^u + \{z, v_\tau\}$;
    end
    Update $f_\tau$ with $\mathcal{L}_\tau, \mathcal{L}_\tau^u$ by Equation 1 ($\tau \in a, b$);
end
Return $f_a, f_b$;
```

4 Friend Training between CSRL and DR

To verify the effectiveness of friend-training, we select two dialogue understanding tasks as friend tasks to conduct friend-training experiments for a case study: conversational semantic role labeling (CSRL) and dialogue rewriting (DR). While both require skills such as coreference and zero-pronoun resolution, the two tasks focus on different properties of the dialogue utterance: (1) CSRL focuses on extracting arguments of the predicates in the utterance from the whole dialogue history; (2) DR aims to rewrite the last turn of a dialogue to make it context-free and fluent by recovering all the ellipsis and coreference in the utterance. Figure 2 provides an overview of friend-training between the above two tasks. Next, we first introduce the task models and then specify the translation matcher and augmented selector for applying friend-training.

4.1 Task Models

Task Definition A dialogue consists of N temporally ordered utterances $\{u_1, ..., u_N\}$. (1) Given utterance u_t and K predicates $\{\text{pred}_1, ..., \text{pred}_K\}$ of u_t, a CSRL parser predicts spans from the dialogue as arguments for all predicates. (2) A dialogue rewriter rewrites u_t to make it context-free according to its context $\{u_1, ..., u_{t-1}\}$.

Dialogue Encoder We concatenate dialogue context $\{u_1, ..., u_{t-1}\}$ and the current utterance u_t as a sequence of tokens $\{x_1, ..., x_M\}$ and encode it with BERT (Devlin et al., 2019) to get the contextualized embeddings:

$$\mathbf{E} = \mathbf{e}_1, ..., \mathbf{e}_M = \text{BERT}(x_1, ..., x_M) \in \mathbb{R}^{H \times M}.$$

Encoders for CSRL and DR share no parameters, but for simplicity, we use the same notation $\mathbf{E}$ for their outputs.

Conversational Semantic Role Labeling With the contextualized embeddings, we further generate predicate-aware utterance representations $\mathbf{G} = \{\mathbf{g}_1, ..., \mathbf{g}_M\} \in \mathbb{R}^{H \times M}$ as Wu et al. (2021) by applying self-attention (Vaswani et al., 2017) to $\mathbf{E}$

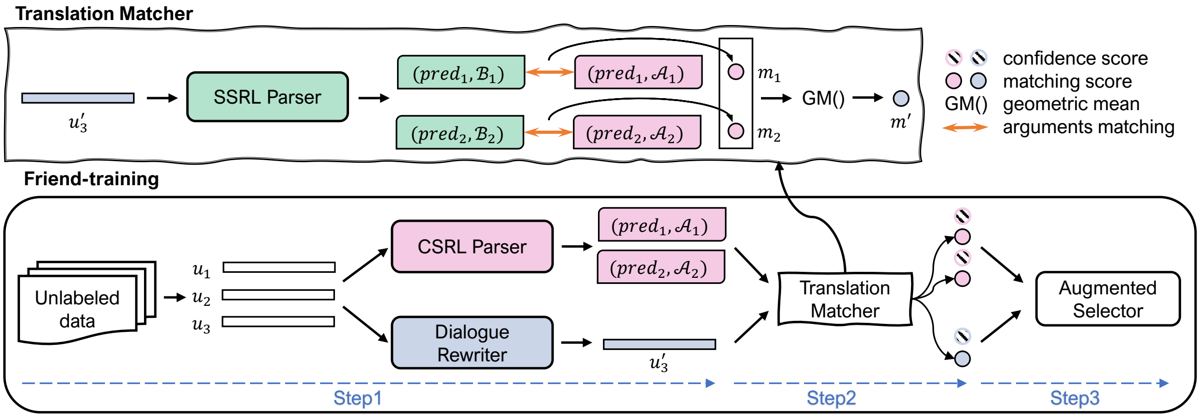


Figure 2: The overview of the friend-training process between CSRL and DR for one dialogue instance which has three utterances and the last utterance contains two predicates. Step1: the unlabeled dialogue is labeled by the CSRL parser and dialogue rewriter, resulting in predictions of arguments for the predicates (CSRL) and the rewritten utterance (DR), respectively. Step2: Pseudo-labels of both tasks are fed into the translation matcher to get their matching scores: the translation matcher first conducts sentence-level semantic role labeling (SSRL) on the rewritten utterance u_3' and then compares the results with those of the CSRL parser for matching scores. Step3: The threshold-based augmented selector makes the final decision of whether to add each pseudo-label to the training data considering both their confidence and matching scores. Best viewed in color.

with predicate-aware masking, where a token is only allowed to attend to tokens in the same utterance and tokens from the utterance containing the predicate:

$$\text{Mask}_{i,j} = \begin{cases} 1 & \text{if } u_{[i]} = u_{[j]} \text{ } or \text{ } u_{[j]} = u_{[pred]}, \\ 0 & \text{otherwise}, \end{cases}$$

where $u_{[m]}$ denotes the utterance containing token x_m and $u_{[pred]}$ denotes the one with the predicate.

The predicate-aware representations are then projected by a feed-forward network to get the distribution of labels for each token:

$$\mathbf{P}^c = \text{softmax}_{\text{column-wise}}(\mathbf{W}_c\mathbf{G} + \mathbf{b}_c) \in \mathbb{R}^{C \times M},$$

where $\mathbf{W}_c$ and $\mathbf{b}_c$ are learnable parameters and C is the number of labels. The labels follow BIO sequence labeling scheme: B-X and I-X respectively denote the token is the first token and the inner token of argument X, where O means the token does not belong to any argument. The output of the CSRL parser for K predicates are denoted as $\{\mathcal{A}_1, ..., \mathcal{A}_K\}$, where set $\mathcal{A}_k$ containing the arguments for pred_k.

Dialogue Rewriting Following Hao et al. (2021), we cast DR as sequence labeling. Specifically, a binary classifier on the top of $\mathbf{E}$ first determines whether to keep each token for in utterance u_t in the rewritten utterance:

$$\mathbf{P}^d = \text{softmax}_{\text{column-wise}}(\mathbf{W}_d\mathbf{E} + \mathbf{b}_d) \in \mathbb{R}^{2 \times M},$$

where $\mathbf{W}_d$ and $\mathbf{b}_d$ are learnable parameters. Next, a span of the context tokens is predicted to be inserted in front of each token. In practice, two self-attention layer (Vaswani et al., 2017) are adopted to calculate the probability of context tokens being the start index or end index of the span:

$$\mathbf{P}^{st} = \text{softmax}_{\text{column-wise}}(\text{Attn}_{st}(\mathbf{E})) \in \mathbb{R}^{M \times M},$$
$$\mathbf{P}^{ed} = \text{softmax}_{\text{column-wise}}(\text{Attn}_{ed}(\mathbf{E})) \in \mathbb{R}^{M \times M},$$

where $\mathbf{P}^{st}_{i,j}$ ($\mathbf{P}^{ed}_{i,j}$) denotes the probability of x_i being the start (end) index of the span for x_j. Then by applying argmax to $\mathbf{P}$, we could obtain the start and end indexes of the span for each token:

$$\mathbf{s}^{st} = \text{argmax}_{\text{column-wise}}(\mathbf{P}^{st}) \in \mathbb{R}^{M},$$
$$\mathbf{s}^{ed} = \text{argmax}_{\text{column-wise}}(\mathbf{P}^{ed}) \in \mathbb{R}^{M},$$

The probability of the span to be inserted in front of x_m is $\mathbf{P}^{st}_{\mathbf{s}^{st}_m,m} \times \mathbf{P}^{ed}_{\mathbf{s}^{ed}_m,m}$ when $\mathbf{s}^{st}_m \leqslant \mathbf{s}^{ed}_m$. When $\mathbf{s}^{st}_m > \mathbf{s}^{ed}_m$, it means no insertion. The output of the dialogue rewriter for u_t is denoted as u_t'.

4.2 Translation Matcher

To translate the outputs (pseudo-labels) from the CSRL parser $\{\mathcal{A}_1, ..., \mathcal{A}_K\}$ and the dialogue rewriter u_t' into a same space, we leverage a normal sentence-level semantic role parser with *fixed* parameters to greedily extract arguments from the rewritten utterance u_t' for the K predicates, denoted as $\{\mathcal{B}_1, ..., \mathcal{B}_K\}$ (Appendix A.5 shows an example).

So the common target space Σ is the label space of CSRL, which is large enough to make the error rate of chosen instances keep very low (see the analysis in subsection 3.2). The matching score $m_k \in [0, 1]$ for pred$_k$ is calculated based on the edit distance between $\mathcal{A}_k$ and $\mathcal{B}_k$:

$$m_k = 1 - \frac{\text{dist}(\oplus\mathcal{A}_k, \oplus\mathcal{B}_k)}{\max(\text{len}(\oplus\mathcal{A}_k), \text{len}(\oplus\mathcal{B}_k))},$$

where dist() calculates the edit distance between two strings, len() returns the length of a string and $\oplus\mathcal{A}_k$ denotes the concatenation of arguments in set $\mathcal{A}_k$ in a predefined order of arguments[3] (empty strings means arguments do not exist). Furthermore, we obtain the overall matching score $m' \in [0, 1]$ for the rewritten utterance u'_t as follows:

$$m' = \text{GM}(m_1, ..., m_K),$$

where GM() represents the geometric mean.

4.3 Augmented Selector

The augmented selector selects high-quality pseudo-labels according to both their matching scores and confidence. For CSRL, we calculate the confidence score for each predicate based on the output of the softmax layer. Specifically, we obtain the confidence of an argument for pred$_k$ by multiplying the probability of its tokens, denoted as $\{a_{k1}, ..., a_{k|\mathcal{A}_k|}\}$. We then use the geometric mean of all the confidence of arguments belonging to pred$_k$ as the confidence for pred$_k$. The overall score $s_k \in [0, 1]$ for pred$_k$ is calculated as follows:

$$s_k = \alpha\text{GM}(a_{k1}, ..., a_{k|\mathcal{A}_k|}) + (1 - \alpha)m_k,$$

where hyper-parameter α gives a balance between the matching score and the confidence. For DR, we multiply the probabilities of spans to be inserted and of decisions on whether to keep tokens or not as the model confidence of u'_t, denoted as b_t. The overall score $r_t \in [0, 1]$ of u'_t is as follows:

$$r_t = \beta b_t + (1 - \beta)m',$$

where a larger value of hyper-parameter β places more importance on the model confidence. α and β are set to be 0.2 for both tasks in the experiments.

Pick thresholds are set for s_k and r_t to control the number and quality of selected pseudo-labels. We analyze the effects of different values of thresholds in subsection 5.4.

5 Experiments

5.1 Setup

Datasets We use five dialogue datasets in our experiments with domains spanning movies, celebrities, book reviews, products, and social networks. For CSRL, we use DuConv (Xu et al., 2021) and WeiboCSRL and for DR, REWRITE (Su et al., 2019) and RESTORATION (Pan et al., 2019). The datasets of the same task differ in domains and sizes. WeiboCSRL is a newly annotated CSRL dataset for out-of-domain testing purposes. Moreover, we use LCCC-base (Wang et al., 2020b) as the unlabeled corpus, which is a large-scale Chinese conversation dataset with 79M rigorously cleaned dialogues from various social media. More details on the annotation of WeiboCSRL and the properties of the datasets could be found in Appendix A.2.

Experiment Scenarios Our main experiments involve two scenarios. (1) Domain generalization: we use DuConv as the training data in the source domain and WeiboCSRL for out-of-domain evaluation, while for DR, REWRITE is used for training and RESTORATION for evaluation. (2) Few-shot learning: we randomly select 100 cases from DuConv and REWRITE as the training data for CSRL and DR, respectively, and conduct in-domain evaluation, which means models of both the tasks are co-trained with only a few samples of each task. The unlabeled data for both scenarios are 20k dialogues extracted from LCCC-base. Implementation details are provided in Appendix A.3.

Evaluation We follow Wu et al. (2021) to report precision (Pre.), recall (Rec.), and F1 of the arguments for CSRL and Hao et al. (2021) to report word error rate (WER) (Morris et al., 2004), Rouge-L (R-L) (Lin, 2004) and the percent of sentence-level exact match (EM) for DR.

5.2 Baselines

We compare friend-training with six semi-supervised training paradigms: two standard techniques such as standard self-training (SST) (Scudder, 1965) and standard co-training (SCoT) (Blum and Mitchell, 1998), as well as four recent methods such as mean teacher (MT) (Tarvainen and Valpola, 2017), cross pseudo supervision (CPS) (Chen et al., 2021), self-training with batch reweighting (STBR) (Bhat et al., 2021) and self-teaching (STea) (Yu et al., 2021). See Appendix A.4 for more details.

(b) Few-shot learning for models trained with DuConv and REWRITE.

Table 1: Test results for domain generalization and few-shot learning. Base denotes the task models trained with data from a single task. Multitask-Base denotes the base model of CSRL and DR sharing the same dialogue encoder. Results are averaged across three runs. ⇓ means lower is better. For few-shot learning, performance of the base models trained with the full training set from the single task is provided for reference.

5.3 Main Results

Table 1 shows the comparison between friend-training (FDT) and the baselines mentioned in subsection 5.2. FDT achieves the best overall performance over the baselines by significant margins in both domain generalization and few-shot learning scenarios, which demonstrates the effectiveness of FDT in different experimental situations to utilize large unlabeled corpora. Moreover, we show the absolute improvements of FDT over SST in parentheses (↑). As we could see, in few-shot learning, FDT obtain 4.51 and 3.15 higher absolute points over SST on F1 of DuConv and WER of REWRITE, respectively, than those of domain generalization, which are 3.16 and 1.91 points, revealing that FDT could realize its potential easier in few-shot learning. Besides, for few-shot learning, we further consider the situation where a full-trained base model from the friend task is available, denoted as FDT-S. As we could see, when the target task is CSRL, FDT-S makes a gain of 1.49 points on F1 over FDT and when the target task is DR, FDT-S outperforms FDT on WER by 0.99 points and EM by 2.90 points, indicating that more reliable supervision from friend task could further enhance the few-shot learning of the target task.

5.4 Analysis

In this section, we conduct experiments to analyze how selected parameters and settings interact with model performance in FDT.

Pick Thresholds We vary the pick thresholds of CSRL and DR in domain generalization scenario and track the model performance: we fix the pick threshold of the friend task to the best (see Appendix A.3) when varying that of the evaluating task. As illustrated in Figure 3a, when the thresholds increase gradually, the models become better with higher F1 for CSRL and lower WER for DR. We attribute this to wrong pseudo-labels being filtered out by the augmented selector of FDT. Then the model performances hit the peaks and drop as the thresholds keep increasing in the interval of high values, which is owed to high thresholds producing insufficient pseudo-labels for iterative train-

(b) The performance on DR test set.

Figure 4: The role of co-updating in friend-training.

ing. Automatically choosing proper pick thresholds is worth to be explored in the future.

The Strength of Base Model To understand and compare how performance of models before friend-training or self-training influences their final performance, we compare STBR, STea and FDT with the base models trained on different percentages of labeled data in the source domain when evaluating on out-domain testing data. Specifically, we follow domain generalization settings and use a variable percentage of labeled data to conduct experiments.

For CSRL and DR, respectively, we set the amount of labeled data as $\{10\%/10\%, 30\%/30\%, 50\%/50\%, 70\%/70\%, 90\%/90\%\}$. The results are shown in Figure 3b and Figure 3c. We can see that all the methods adopting self-training to make use of unlabeled data surpass the base model by a significant margin, whether when given a weak or strong base model, demonstrating the effectiveness of self-training paradigm. Moreover, FDT achieves the best results across the evaluating percentages of labeled data: when the base model has a good amount of training data, such as those trained on 30% labeled data and above, the performance of FDT is significantly better than STBR and STea, proving that FDT leverages the features learned from labeled data more effectively with cross-task supervision.

The Role of Co-updating We also explore the case where one of the models of the friend tasks is fully trained and does not have to be updated. We consider FDT-SF, FDT with a *fixed* fully trained base model from the friend task in domain generalization[4]. As illustrated in Figure 4, FDT-SF surpasses FDT when given a weak base model for the evaluating task because of the strong supervision from the friend task. However, FDT outperforms FDT-SF when the evaluating task is given a fairly-trained model, which demonstrates the benefits of co-updating the models in friend-training.

6 Conclusion

We propose friend-training, the first cross-task self-training framework, which leverages supervision from friend tasks for better selection of pseudo-labels. Moreover, we provide specific modeling of friend-training between conversational semantic role labeling and dialogue rewriting. Experiments on domain generalization and few-shot learning scenarios demonstrate the promise of friend-training, which outperforms prior classical or state-of-the-art semi-supervised methods by substantial margins.

---

[4] Specifically, when the evaluating task is CSRL, the amount of labeled data for the two tasks are set as $\{10\%/100\%, 30\%/100\%, 50\%/100\%, 70\%/100\%, 90\%/100\%\}$, and when the evaluating task is DR, $\{100\%/10\%, 100\%/30\%, 100\%/50\%, 100\%/70\%, 100\%/90\%\}$.

Limitations

We showed how the friend-training strategy can be applied to two dialogue understanding tasks in the case study here, but many other task pairs or task sets can be examined to fully explore the generality of the approach. Identifying friend tasks depends on expert knowledge in this work, but approaches for task grouping and task similarity may be used to automatically discover friend tasks. Besides, with the proliferation of cross-modal techniques, tasks of different modalities are expected to act as friend tasks as well. Also, designing translation functions and matchers for friend tasks in the friend-training framework requires an understanding of the relationship between the friend tasks, but prompting and model interpretability methods could potentially be applied for easing this process.

A Appendix

A.1 Error rates

We have two classifiers f_a and f_b trained on two different tasks with labeled training sets $\mathcal{L}_a$ and $\mathcal{L}_b$, with expected accuracies η_a and η_b, respectively. The prediction targets of the two tasks are partially related through a pair of translation functions $\mathcal{F}_a : \hat{Y}_a \to \Sigma$ and $\mathcal{F}_b : \hat{Y}_b \to \Sigma$, where Σ is the set of possible sub-predictions that all possible predictions of the two tasks $\hat{Y}_a$ and $\hat{Y}_b$ can be reduced to. $|\hat{Y}_a| \geq |\Sigma|, |\hat{Y}_b| \geq |\Sigma|$. The sub-predictions can be a part of the whole prediction targets for both tasks, or some lossy transformation of the prediction targets. For example, a sub-prediction for a POS-tagging task can be the POS tag of the first word (a part of the prediction) or the number of the NN tag in the whole prediction sequence (a transformation of the prediction). We assume that the translation functions are general functions with the expected probability of generating a translation $\epsilon_{\mathcal{F}} = \frac{1}{|\Sigma|}$; they are deterministic and always map the gold labels of the friend tasks for the same input to the same translation. Both classifiers make predictions on the unlabeled set $\mathcal{U}$ at iteration k. Some instances $\mathcal{U}_{\mathcal{F}}^{k}$ with pseudo-labels are chosen as new training data based on the results of the translation functions, $\phi_a(x) = \mathcal{F}_a(f_a(x))$ and $\phi_b(x) = \mathcal{F}_b(f_b(x))$, and some selection criteria, such as total agreement. If total agreement is used as the selection criterion, the probability of erroneous predictions for f_a in these instances is

$$\begin{aligned}
&\mathrm{Pr}_x[f_a(x) \neq f_a^*(x)|\phi_a(x) = \phi_b(x)] \\
=&1 - \mathrm{Pr}_x[f_a(x) = f_a^*(x)|\phi_a(x) = \phi_b(x)] \\
=&1 - \mathrm{Pr}_x[f_a(x) = f_a^*(x)]\cdot \\
&\frac{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)|f_a(x) = f_a^*(x)]}{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]} \\
=&1 - \eta_a\cdot \\
&\frac{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)|f_a(x) = f_a^*(x)]}{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]}, \qquad (6)
\end{aligned}$$

with f^* being the optimal classifier. If we consider the two classifiers very likely to be independent from each other, then the probability of the translation of the predictions from the two classifiers being the same given the prediction from classifier f_a is correct, which is $\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)|f_a(x) = f_a^*(x)]$, is the sum of the probability of the classifier f_b making the correct prediction η_b and the probability of an erroneous translation of the wrong prediction $\epsilon_{\mathcal{F}}(1-\eta_b)$. The probability of the translations matching $\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]$ has four situations: both predictions of the two classifiers are correct $\eta_a\eta_b$; $f_a(x)$ is correct but $f_b(x)$ is wrong and being translated erroneously $\eta_a\epsilon_{\mathcal{F}}(1-\eta_b)$; $f_b(x)$ is correct but $f_a(x)$ is wrong and being translated erroneously $\eta_b\epsilon_{\mathcal{F}}(1-\eta_a)$; both $f_a(x)$ and $f_b(x)$ are wrong but matching in the translation space $\epsilon_{\mathcal{F}}^2(1-\eta_a)(1-\eta_b)$. Under these conditions Equation 6 becomes

$$\begin{aligned}
&1 - \frac{\eta_a(\eta_b + \epsilon_{\mathcal{F}}(1-\eta_b))}{\mathrm{Pr}_x[\phi_a(x) = \phi_b(x)]} \\
=&1 - \frac{Z}{Z + \eta_b\epsilon_{\mathcal{F}}(1-\eta_a) + E}, \qquad (7)
\end{aligned}$$

where $Z = \eta_a(\eta_b + \epsilon_{\mathcal{F}}(1-\eta_b))$ and $E = \epsilon_{\mathcal{F}}^2(1-\eta_a)(1-\eta_b)$ which shows that the term $\eta_b\epsilon_{\mathcal{F}}(1-\eta_a)+E$ needs to be small to make the probability of matching translations with predictions being wrong small. This indicates that the quality of the picked instances based on the total agreement criterion is negatively correlated with the number of false positive instances brought by the noisy translation $\eta_b\epsilon_{\mathcal{F}}(1-\eta_a)$, and the number of matching negative instances E. $\epsilon_{\mathcal{F}}$ can be minimized by choosing translation functions with a sufficiently large co-domain Σ, which means that when the translation space is large enough, it is unlikely that the two classifiers totally agree in the translation space but do not agree in their own prediction target spaces. So the probability of them agreeing and making correct predictions is much larger than agreeing but making incorrect predictions while the probability of error instances chosen when two classifiers agree approaches 0, indicating that even when $1-\eta_a$ is large, i.e. f_a performs badly, if the co-domain is large, the error rate of the chosen instances can still be kept very low.

A.2 Datasets

Annotation Procedure of WeiboCSRL The dialogues we use for CSRL annotation are extracted from LCCC-base (Wang et al., 2020b), which consists of at least 4 turns and 80 total characters to assure enough context for CSRL and DR. These dialogues and those used as unlabeled data for experiments in section 5 are from different parts of LCCC-base. For each dialogue, we annotate the predicates in the last utterance with the guidance of frame files of Chinese Proposition Bank[5]. For each predicate, the arguments we annotate are numbered arguments `ARG0-ARG4` and adjuncts `ARGM-LOC`, `ARGM-MNR`, `ARGM-TMP` and `ARGM-NEG`, whose definitions are shown in (Xue, 2006). `ARGM-MNR` is not included for evaluation in section 5 because annotation of `ARGM-MNR` is lacking in DuConv, the training data for CSRL. In the end, we obtain 3891 annotated predicates.

Dataset Details Table 2 shows the statistic of the datasets used in the experiments. DuConv (Xu et al., 2021) focuses on movies and celebrities and we adopt the same train/dev/test splitting as Xu et al. (2021). REWRITE (Su et al., 2019) contains 20K dialogues with a wide range of topics crawled from Chinese social media platforms; the last utterance of each dialogue is rewritten to recover all co-referred and omitted information. RESTORATION (Pan et al., 2019) contains dialogues from Douban[6], most of which are book, movie or product reviews. Compared with REWRITE, it contains more annotated dialogues, but around 40% of the last utterances require no rewriting.

	Domain	**#Instance**(train/dev/test)
DuConv	movies and celebrities	23361 / 2852 / 2977
WeiboCSRL	social media	- / 1945 / 1946
REWRITE	social media	16925 / 1000 / 1000
RESTORATION	book, movie and product reviews	- / 5000 / 5000

Table 2: Dataset statistics.

A.3 Implementation Details

Dataset configuration of the tasks for the experimental scenarios are shown in Table 3.

Preprocessing Details The maximum length of the input dialogue is set to 125. We transform the word-based labeling of DuConv to character-based labeling and we use the scripts[7] provided by Hao et al. (2021) to generate token-level annotations for sequence-labeling-based DR. For unlabeled data, we discard dialogues with less than 4 turns to guarantee sufficient context for CSRL and DR.

Model Details We use pretrained BERT[8] (Devlin et al., 2019) as the dialogue encoder for CSRL and DR. Both the values of hyper-parameter α and β are set to 0.2 and the pick thresholds are set to 0.6. We choose a state-of-the-art sentence-level semantic role labeling (SSRL) parser[9] for the translation matcher which follows the same structure as (He and Choi, 2021).

Training Details We adopt AdamW (Loshchilov and Hutter, 2019) to optimize models with a learning rate of 4e-5 and batch size of 16. We use $\lambda = 1$ to balance the loss of labeled and unlabeled data.

	Task	**Train**	**Dev&Test**
DG	CSRL	DuConv (train)	WeiboCSRL (dev,test)
	DR	REWRITE (train)	RESTORATION (dev,test)
FSL	CSRL	DuConv (100 cases)	DuConv (dev,test)
	DR	REWRITE (100 cases)	REWRITE (dev,test)

Table 3: Dataset configuration of domain generalization (DG) and few-shot learning (FSL).

A.4 Baselines

Standard self-training (Scudder, 1965) generates pseudo-labels to unlabeled data with a base model and uses them to train a new base model, which is repeated until convergence. Standard co-training (Blum and Mitchell, 1998) is similar to Standard self-training, but with two different base models dealing with the same task, generating pseudo-labels and adding the trusted ones for iterative training. Mean teacher (Tarvainen and Valpola, 2017) maintains a teacher model on the fly, whose weights are the exponential moving average of the weights of a student model across iterations. Cross pseudo supervision (Chen et al., 2021), a state-of-the-art variant of self-training, maintains two networks with different initialization; the pseudo-label of one network is used to supervise the other network. Self-training with batch reweighting (Bhat et al., 2021) is a state-of-the-art self-training method that reweights the pseudo-labels in a batch when training according to the confidence from the teacher model. Self-teaching (Yu et al., 2021), a state-of-the-art semi-supervised method that sequentially trains a junior teacher, a senior teacher and an expert student to leverage the unlabeled data.

For the hyper-parameters of the baselines, we keep the common hyper-parameters, such as learning rate, batch size, optimizer, and so on, the same as our proposed method. And we adopt the values of method-specific hyper-parameters used in the original papers, such as the merging weight of soft and hard labels of self-teaching and the smoothing parameter for updating of mean teacher.

Predicate matching score	0.61	1.0
Predicate confidence	0.95	0.54
Predicate overall score	0.67	0.90
Utterance matching score	0.81	
Utterance confidence	0.92	
Utterance overall score	0.83	

Table 4: Case study: [A] and [B] are the signatures of speakers. ch and en are the language abbreviations.

A.5 Case Study

We show a representative case of selecting pseudo-labels in Table 4. There are two predicates in current utterance: 是(is) and 受(attract). For 是(is), the CSRL parser yields only ARG1 while SSRL parser gives the same ARG1 but more of ARG0 based on the rewritten utterance. With the difference in arguments, the overall score is not high and this predicate could be regarded as low-quality if a high pick threshold is set. For 受(attract), the CSRL and SSRL parsers give the same arguments, which are the right answer. However, if we only consider the model confidence of the predicate, which is 0.54, this high-quality predicate are more likely to been discarded than consider the overall score, which is 0.90. And the rewritten utterance gets a high overall score, which is what we expected.

A.6 Discussion on Generalization of the Framework

It is not uncommon at all for different language tasks sharing some information. With one case study presented in detail in the main body of the paper, we also provide a short example of a different friend task pair – constituency parsing and dependency parsing – and explain how they can help each other and show the general nature of the friend-training framework.

Early work (Magerman, 1995; Collins, 2003) has shown relationship between dependency and constituency parsing through head-finding rules, and Jin and Schuler (2019) show directly how common structures between dependency and constituency trees can be derived for parsing evaluation. In a dependency graph, a set of nodes with a single incoming edge is usually indicative of a phrase structure, such as a noun phrase, a verb phrase or a prepositional phrase. Such phrasal structures are well-marked in constituency treebanks, and could be used as the shared friend information for friend-training. Here is a sketch of how friend-training can be applied to this pair:

1. Train a constituency parser and a dependency parser, presumably trained with a small number of training instances, as the models for the friend-training framework.
2. Run both parsers on a common set of unlabeled data for parsing results.
3. Find phrases such as noun, verb or prepositional phrases in the predicted constituency trees.
4. Compare with the dependency trees, and check if spans of such phrases have only a single incoming edge. If so, the constituency and dependency parsing results can be considered agreeing, and added to the silver training set. If not, the silver annotation is discarded.
5. Train the parsers again with the gold and silver training instances.

As long as some shared information can be identified between two seemingly different tasks, the noisy agreement between that partial target can provide valuable supervision between two tasks. The translation and matching between constituency-dependency targets are simpler compared to the CSRL-rewriting pair presented in the paper, partly because no model is required for the translation process. However the CSRL-rewriting pair is more significant because heuristics may be difficult or not obvious to design where ‘bridging’ tasks such as single-sentence SRL may be readily available.

Understanding Transformer Memorization Recall Through Idioms

Abstract

To produce accurate predictions, language models (LMs) must balance between generalization and memorization. Yet, little is known about the mechanism by which transformer LMs employ their memorization capacity. When does a model decide to output a memorized phrase, and how is this phrase then retrieved from memory? In this work, we offer the first methodological framework for probing and characterizing recall of memorized sequences in transformer LMs. First, we lay out criteria for detecting model inputs that trigger memory recall, and propose *idioms* as inputs that typically fulfill these criteria. Next, we construct a dataset of English idioms and use it to compare model behavior on memorized vs. non-memorized inputs. Specifically, we analyze the internal prediction construction process by interpreting the model's hidden representations as a gradual refinement of the output probability distribution. We find that across different model sizes and architectures, memorized predictions are a two-step process: early layers promote the predicted token to the top of the output distribution, and upper layers increase model confidence. This suggests that memorized information is stored and retrieved in the early layers of the network. Last, we demonstrate the utility of our methodology beyond idioms in memorized factual statements. Overall, our work makes a first step towards understanding memory recall, and provides a methodological basis for future studies of transformer memorization.[1]

1 Introduction

Transformer language models (LMs) memorize instances from their training data (Carlini et al., 2021; Zhang et al., 2021b), and evidence is building that such memorization is an important precondition for their predictive abilities (Lee et al., 2022; Feldman, 2020; Feldman and Zhang, 2020; Raunak et al., 2021; Raunak and Menezes, 2022). Still, it is unknown when models decide to output memorized sequences, and how these sequences are being retrieved internally from memory. Current methods for analyzing memorization (Feldman and Zhang, 2020; Zhang et al., 2021b; Carlini et al., 2022) use definitions that are based on models performance, which changes between models and often also between training runs. Moreover, these methods study memorization behavior in terms of the model's "black-box" behavior rather than deriving a behavioral profile of memory recall itself.

Our first contributions are to provide a definition and construct a dataset that allows probing memorization recall in LMs. We define a set of criteria for identifying memorized sequences that does not depend on model behavior:[2] sequences that have a single plausible completion that is independent of context and can be inferred only given the entire sequence. We show that many idioms (e.g., "play it by ear") fulfill these conditions, allowing us to probe and analyze memorization behavior. Furthermore, we construct a dataset of such English idioms, dubbed IDIOMEM, and release it publicly for the research community.

Next, to analyze memory recall behavior, we compare the construction process of predictions that involve memory recall with those that do not. To this end, given a LM, we create two sets of memorized and non-memorized idioms from IDIOMEM (Fig. 1, A). We then adopt a view of the transformer inference pass as a gradual refinement of the output probability distribution (Geva et al., 2021; Elhage et al., 2021). Concretely, the token representation at any layer is interpreted as a "hidden" probabil-

[2] Literature often purports to "define memorization", resulting in a multitude of technical definitions with subtle differences, although we would expect this concept to be consistent and intuitive. Thus, instead of explicitly defining "memorization", we will define *sufficient criteria* for detecting memorized instances.

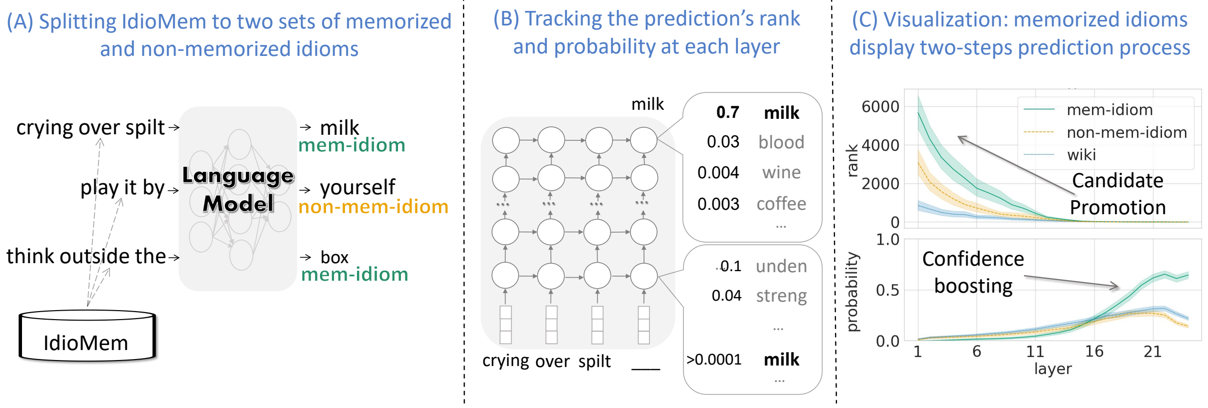

Figure 1: Our methodological framework for probing and analyzing memorized predictions of a given LM: (A) we create two sets of memorized (`mem-idiom`) and non-memorized (`non-mem-idiom`) idioms by probing the LM with instances from IDIOMEM, (B) for each instance, we extract hidden features of the prediction computation – the rank and probability of the predicted token across layers, and (C) we compare the prediction process of memorized idioms versus non-memorized idioms and short sequences from Wikipedia (`wiki`). Memorized predictions exhibit two characteristic phases: candidate promotion and confidence-boosting.

ity distribution over the output vocabulary (Geva et al., 2022) (Fig. 1, B). This interpretation allows tracking the prediction across layers in the evolving distribution. We find a clear difference in model behavior between memorized and non-memorized predictions (Fig. 1, C). This difference persists across different transformer architectures and sizes: retrieval from memory happens in two distinct phases, corresponding to distinct roles of the transformer parameters and layers: (1) *candidate promotion* of memorized predictions' rank in the hidden distribution in the first layers, and (2) *confidence boosting* where, in the last few layers, the prediction's probability grows substantially faster than before. This is unlike non-memorized predictions, where the two phases are less pronounced and often indistinct. We further confirm these phases of memorized predictions through intervention in the network's FFN sublayers, which have been shown to play an important role in the prediction construction process (Geva et al., 2022; Mickus et al., 2022). Concretely, zeroing-out hidden FFN neurons in early layers deteriorate memory-recall, while intervention in upper layers does not affect it.

Last, we show our findings extend to types of memory recall beyond idioms by applying our method to factual statements from the LAMA-UHN dataset (Poerner et al., 2020) (e.g. *"The native language of Jean Marais is French"*). For factual statements that were completed correctly by the LM, we observe the same two phases as in memorized idioms, further indicating their connection to memory recall.

To summarize, we construct a novel dataset of idioms, usable for probing LM memorization irrespective of the model architecture or training parameterization. We then design a probing methodology that extracts carefully-devised features of the internal inference procedure in transformers. By applying our methodology and using our new dataset, we discover a profile that characterizes memory recall, across transformer LMs and types of memorized instances. Our released dataset, probing framework, and findings open the door for future work on transformer memorization, to ultimately demystify the internals of neural memory in LMs.

2 Criteria for Detecting Memory Recall

To study memory recall, we require a set of inputs that trigger this process. Prior work on memorization focused on detecting instances whose inclusion in the training data has a specific influence on model behavior, such as increased accuracy on those instances (Feldman and Zhang, 2020; Magar and Schwartz, 2022; Carlini et al., 2022, 2021, 2019). As a result, memorized instances differ across models and training parameterization. Our goal is instead to find a stable dataset of sequences that correctly predicting their completion indicates memorization recall. This will greatly reduce the overhead of studying memorization and facilitate useful comparisons across models and studies.

To build such a dataset, we start by defining a general set of criteria that are predicates on sequence features, entirely independent of the LM being probed. Given a textual sequence of n words, we call the first $n-1$ words the *prompt* and the nth word the *target*. We focus on the task of predicting the target given the prompt, i.e., predicting the last word in a sequence given its prefix.[3] Such predictions can be based on either generalization or memorization, and we are interested in isolating memorized cases to study model behavior on them. Particularly, we are looking for *sequences for which success in this task implies memorization recall*.

We argue that the following criteria are *sufficient* for detecting such memorized sequences:

1. **Single target, independent of context:** We require that the target is the only correct continuation, regardless of the textual context where the prompt is placed.[4]
2. **Irreducible prompt:** The target is the single correct completion only if the entire prompt is given exactly. Changing or removing parts from the prompt would make the correct target non-unique.

Claim 2.1. *Assume a sequence fulfills the above criteria. Then, if a LM correctly predicts the target, it is highly likely that this prediction involves memory recall.*

Justification. First, observe that most natural-language prompts have many possible continuations. For example consider the sentence *"to get there fast, you can take this ____"*. Likely continuations include *"route"*, *"highway"*, *"road"*, *"train"*, *"plane"*, *"advice"*, inter alia. Note that there are several divergent interpretations or contexts for the prompt, and for each, language offers many different ways to express similar meaning.

A prediction that is a product of generalization — i.e., it is derived from context and knowledge of language — *always has plausible alternatives*, depending on the context and stylistic choice of words. Hence, the relationship between the entire prompt and the target, where the target is the single correct continuation, is something that needs to be memorized rather than derived via generalization. A LM that predicts *the* single correct continuation either memorized this relationship, or used "cues" from the prompt that happen to provide indication towards the correct continuation. To illustrate the latter, consider the sequence *"it's raining cats and ____"* which has a single correct continuation, *"dogs"*, but a LM might predict it without observing this sequence during training, due to the semantic proximity of *"cats"* and *"dogs"*. Our second criterion excludes such cases by requiring that the correct continuation is only likely given the entire sequence.

Therefore, a LM that correctly completes a sequence that fulfills both criteria, is likely to have recalled it from memory. ☐

In the next section, we argue that idioms are a special case of such sequences, and are thus useful for studying memorization (§3).

3 The Utility of Idioms for Studying Memorization

An idiom is a group of words with a meaning that is not deducible from the meanings of its individual words. For example, consider the phrase *"play it by ear"* — there is a disconnect between its nonsensical literal meaning (to play something by a human-body organ called 'ear') and its intended idiomatic meaning (to improvise).

A key observation is that *idioms often satisfy our criteria (§2), and therefore can probe memorization*. First, by definition, idioms are expected to be non-compositional (Dankers et al., 2022). They are special "hard-coded" phrases that carry a specific meaning. As a result, their prompts each have a single correct continuation, regardless of their context (criterion 1). For example, consider the prompt *"crying over spilt ____"* — a generalizing prediction would predict that this slot may be filled by any spillable item, like wine, water or juice, while a memorized prediction will retrieve only milk in this context. Notably, while this is an empirical characterization of many idioms, there might be exceptions, e.g., contexts that are adversarially chosen to change the completion. Second, many idioms are "irreducible", for example the sub-sequences *"crying over"* or *"over spilt"* by themselves have but scant connection to the word *"milk"*.

Still, not all idioms fulfill the criteria. For example, even when the idiom is far from literal, its constituents sometimes strongly indicate the correct continuation, such as with the case of *"it's raining cats and ____"* (as explained in §2). To construct a dataset of memorization-probing sequences, we will carefully curate a set of English idioms and filter out ones that do not fulfill our criteria.

---

[3] In cases where tokenization divides the target to subtokens, our task becomes predicting the target's first token.

[4] We assume that contexts are naturally-occurring and not adversarial.

Source	**# of Idioms**	**Idiom Length** (words)
MAGPIE	590	4.5 ± 0.9
LIdioms	149	5.1 ± 1.2
EF	97	5.6 ± 1.9
EPIE	76	4.4 ± 0.7
Total (unique)	814	4.7 ± 1.8

Table 1: Statistics per data source in IdioMem.

Prompt	**Target**	**Pred.**	**Sim.**	**IdioMem**
"make a mountain out of a"	`molehill`			✓
"think outside the"	`box`			✓
"there's no such thing as a free"	`lunch`			✓

"boys will be"	`boys`		✓	
"take it or leave"	`it`	✓	✓	

Table 2: Example English idioms included and excluded from IdioMem by our filters of predictable target (Pred.) and prompt-target similarity (Sim.).

3.1 The IdioMem Dataset

We begin with existing datasets of English idioms: MAGPIE (Haagsma et al., 2020),[5] EPIE (Saxena and Paul, 2020), and the English subset of LIdioms (Moussallem et al., 2018). We enrich this collection with idioms scraped from the website "Education First" (EF).[6] We then split each idiom into a prompt containing all but the last word, and a target that is the last word. Next, we filter out idioms that do not comply with our criteria (§2) or whose target can be predicted from their prompt based on spurious correlations rather than memorization. To this end, we use three simple rules:

- **Short idioms**. We observe that prompts of idioms with just a few words often have multiple plausible continuations, that are not necessarily the idiom's target, violating our first criterion. For example, the prompt *"break a ____"* has many possible continuations (e.g. *"window"*, *"promise"*, and *"heart"*) in addition to its idiomatic continuation *"leg"*. To exclude such cases, we filter out idioms with < 4 words.

- **Idioms whose target is commonly predicted from the prompt's subsequence.** We filter such cases to ensure the prompt fulfills our second criterion (prompt irreducibility).

  To detect these cases, we use an ensemble of pretrained LMs: GPT2_{M}, RoBERTa-base (Liu et al., 2019), T5-base (Kale and Rastogi, 2020) and ELECTRA-base-generator (Clark et al., 2020), and check for each model if there is an n-gram ($1 \leq n \leq 4$) in the prompt from which the model predicts the target. We filter out idioms for which a majority (≥ 3) of models predicted the target (for some n-gram).

- **Idioms whose targets are semantically similar to tokens in the prompt.** To further ensure prompt irreducibility, we embed the prompt's tokens and the target token using GloVe word embeddings (Pennington et al., 2014). We measure the cosine distance between the target token to each token in the prompt separately and take the maximum of all the tokens. We filter out idioms where this number is higher than 0.75 (this number was tuned manually using a small validation set of idioms).

Overall, 55.7% of the idioms were filtered out, including 48.5% by length, 6.1% by the predictable-target test and an additional 1.6% by the prompt-target similarity, resulting in an 814 idioms dataset, named IdioMem. Further statistics are provided in Tab. 1, and example idioms in Tab. 2.

4 Probing Methodology

Background and Notation Assuming a transformer LM with L layers, a hidden dimension d and an input/output-embedding matrix $E \in \mathbb{R}^{|V| \times d}$ over a vocabulary V. Denote by $\mathbf{s} = \langle s_1, ..., s_t \rangle$ the input sequence to the LM, and let $\mathbf{h}_i^\ell$ be the output for token i at layer ℓ, for all $\ell \in 1, ..., L$ and $i \in 1, ..., t$. The model's prediction for a token s_i is obtained by projecting its last hidden representation $\mathbf{h}_i^L$ to the embedding matrix, i.e. $softmax(E\mathbf{h}_i^L)$.

Following (Geva et al., 2021, 2022), we interpret the prediction for a token s_i by viewing its corresponding sequence of hidden representations $\mathbf{h}_i^1, ..., \mathbf{h}_i^L$ as an evolving distribution over the vocabulary. Concretely, we read the "hidden" distribution at layer ℓ by applying the same projection to the hidden representation at that layer: $\mathbf{p}_i^\ell = softmax(E\mathbf{h}_i^\ell)$. Using this interpretation, we track the probability and rank of the predicted token in the output distribution across layers. A token's rank is its position in the output distribution when sorted by probability from highest to lowest (e.g. the rank of the final predicted token is zero).

---

[5] We take idioms with an annotation confidence of $> 75\%$ and exclude frequently occurring literal interpretations.

Table 3: Number of memorized idioms vs. non-memorized idioms from the IDIOMEM dataset for each model. An instance is considered a memorized example if the model correctly predicts the target.

Probing Procedure Our key method to understand how transformer LMs retrieve information from memory is *comparing features of memory recall* to inference that does not necessarily include memory recall. Given a set of sequences that fulfill the criteria in §2, we split them into a "memorized" set whose targets' first token is predicted correctly by the model being analyzed given (and are therefore memorized), and a "non-memorized" set whose target is predicted incorrectly. We additionally include a second set of "non-memorized" instances: natural-language sequences randomly sampled from a large corpus (we assume most naturally-occurring sequences are not memorized).

To probe a LM, we run it on the 3 sets, and for each set and each layer, we (a) extract the rank and probability of the final predicted token in the hidden distribution for each prompt, and (b) compute the mean rank and probability over all prompts.

5 Probing Memorization Using Idioms

5.1 Experimental Setup

Datasets For each LM under analysis (see below), we split IDIOMEM into two disjoint subsets of memorized and non-memorized idioms, denoted as `mem-idiom` and `non-mem-idiom`, respectively, according to whether or not the LM succeeds in completing them. We produce an additional set of non-memorized instances, `wiki`, by sampling prompts from the WIKITEXT-103 dataset (Merity et al., 2017) of the same length distribution as in IDIOMEM (see Tab. 1).

Models We use multiple transformer LMs that are different in size, architecture, and optimization objective. We use GPT2 (medium and large) (Radford et al., 2019), an autoregressive transformer decoder, and BERT (base and large) (Devlin et al., 2019), a transformer encoder trained with a masked language modeling (MLM) objective. To evaluate BERT on a specific idiom, we feed the idiom's prompt concatenated with the special mask token and a period (e.g. *"think outside the* `[MASK]`."). Further details on each model are presented in Tab. 6. The number of memorized and non-memorized idioms from IDIOMEM for each model are provided in Tab. 3.

5.2 Memorized Predictions are a Two-Step Process

Fig. 2 shows the probability and rank of the output token across layers, for memorized and non-memorized idioms and short sequences from Wikipedia, by GPT2_M, GPT2_L, BERT_B, and BERT_L. Naturally, the prediction's rank decreases across layers as the prediction probability increases. However, for memorized predictions these trends occur as two distinct and sharp inference phases. In lower layers, the prediction's rank decreases from a high rank to near zero, while its probability is also close to zero. For example, in GPT2_L the rank decreases until layer 20 while the probability remains below 0.1. We refer to this phase as *candidate promotion*, as the predicted token is being promoted to be a top candidate in the output distribution.

Compared to non-memorized predictions, the initial rank of memorized predictions is generally higher, especially in GPT2 (6000 vs. 3000 in GPT2_M, and 3000 vs. 1500 in GPT2_L). A potential explanation would be a generally lower frequency of the predicted token for memorized idioms. However, we find there is only low negative correlation between the initial rank of the predicted token and its frequency (see Tab. 4). We therefore offer a different explanation: non-memorized predictions are often promoted in early layers that detect local "shallow" patterns, such as common bigrams (Geva et al., 2021), while predictions for memorized idioms are not local as they requires processing of the entire input.

In the middle layers, once the predicted token reaches the top of the hidden distribution, its probability increases until the last layer. We refer to this phase as *confidence boosting*, as the distribution shifts towards the predicted token. For memorized idioms, this increase is abrupt and dramatic, with a final probability of > 0.6 across all models. In comparison, predictions on short sequences from Wikipedia and non-memorized idioms have a substantially lower probability of ~ 0.2. This can be

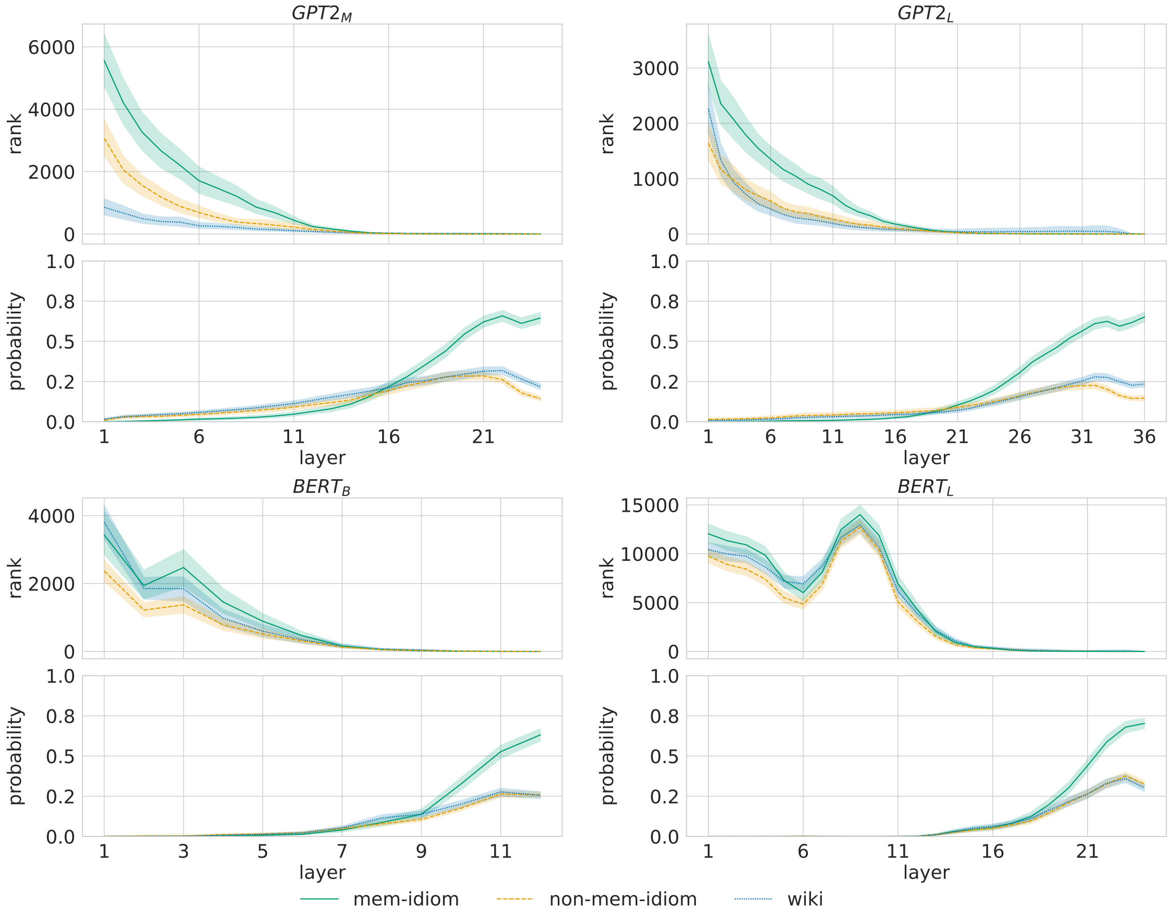

Figure 2: The predicted token's probability and rank across layers, for memorized idioms (`mem-idiom`), non-memorized idioms (`non-mem-idiom`) and short sequences from Wikipedia (`wiki`). Memory recall exhibits two characteristic phases of candidate promotion and confidence boosting.

explained by the fact that memorized idioms have a single correct target, rather than many possible continuations, as in the instances from Wikipedia. In addition, low-probability predictions for non-memorized idioms are expected as the model did not memorize the idioms and does not know their continuation. In §B, we provide more fine-grained analysis of these trends via a log-scaled view of the prediction's rank and a visualization of the ranks and probabilities for separate clusters of the memorized predictions.

We further verify that our extracted hidden-distribution features distinguish between memorized and non-memorized predictions by training linear classifiers over combinations of these features (details in §A). We observe that, indeed, our features enable separation between memorized and non-memorized predictions at high accuracy (77%-85% across models). Moreover, classifiers that use hidden distribution features are more accurate than those relying only on the model's output. Overall, these findings provide a profile of memorized predictions, suggesting that the memorized information is retrieved in early layers at inference.

	correlation	p-value
GPT2_{M}	-0.22	$2.9e^{-21}$
GPT2_{L}	-0.18	$5.4e^{-14}$

BERT_{L}	0.15	$3.5e^{-10}$

Table 4: Pearson correlation between the predicted token's rank at the first layer and its general frequency in Wikipedia.

5.3 Testing the Roles of Different Layers Through Intervention

Our analysis in the previous section interprets hidden representations as distributions over the output vocabulary. We now conduct intervention experiments to verify that this interpretation is meaningful for studying memory recall, and to test layers' roles in that process. Concretely, we zero out FFN

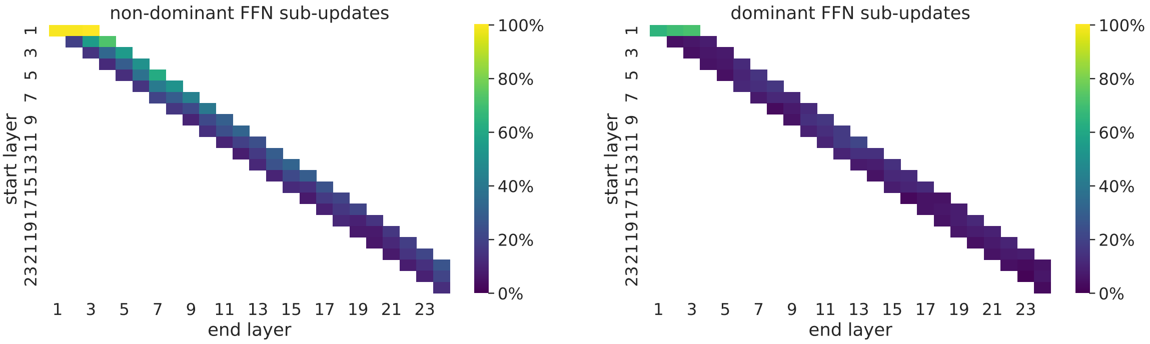

Figure 3: Intervention in non-dominant (left) and dominant (right) FFN sub-updates in GPT2$_{\mathrm{M}}$. Each cell shows the percentage of memorized idioms for which the prediction was changed by zeroing-out the FFN sub-updates between the start and end layers.

sub-updates to the hidden representation (§4) and measure changes in memorized predictions.

A Short Primer on Transformer FFN Sublayers. FFN sublayers are the final computation in transformer layers, which output the hidden distribution at the center of our analysis. In general, they have a key role in capturing knowledge in transformer LMs (Dai et al., 2022; Meng et al., 2022). We follow Geva et al. (2022) and view the computation of each FFN sublayer as a weighted collection of d_m sub-updates to the output distribution, each promoting a concept in the vocabulary space, e.g. "past-tense verbs" or "female athletes". To understand this, consider the computation of the FFN at layer ℓ, given by $\mathsf{FFN}^{\ell}(\mathbf{h}_i^{\ell}) = f(W_K^{\ell}\mathbf{h}_i^{\ell})W_V^{\ell}$, where $W_K^{\ell}, W_V^{\ell} \in \mathbb{R}^{d_m \times d}$ are parameter matrices, d_m is the intermediate hidden dimension, and f is a point-wise non-linearity activation function. This computation can be decomposed as: $\mathsf{FFN}^{\ell}(\mathbf{h}_i^{\ell}) = \sum_{j=1}^{d_m} f(\mathbf{h}_i^{\ell} \cdot \mathbf{k}_j^{\ell})\mathbf{v}_j^{\ell} = \sum_{j=1}^{d_m} m_j^{\ell}\mathbf{v}_j^{\ell}$, where $\mathbf{k}_j^{\ell}$ and $\mathbf{v}_j^{\ell}$ are the j-th row in W_K^{ℓ} and the j-th column in W_V^{ℓ}, respectively. Geva et al. argue that each weight m_j^{ℓ} is the score assigned by the model for some textual pattern, and each vector $\mathbf{v}_j$ promotes a concept that follows that pattern.

Experiment First, we sample 100 random instances from IdioMem that the model memorized. Then, for each range of up to 3 consecutive layers, we perform two complementary experiments, where we run GPT2$_{\mathrm{M}}$'s inference on the 100 instances while intervening in the chosen layers to cancel the contribution of FFN sub-updates to the prediction. Specifically, for each layer ℓ in the layer range, we perform the following two interventions: first, we zero out (i.e. artificially set to 0 during inference) the weights of the 10 most dominant sub-updates, which are known to be particularly salient for predictions (Geva et al., 2022) (there are d_m sub-updates per layer). Concretely, we sort the sub-updates by their contribution to the FFN output $|m_i^{\ell}|||\mathbf{v}_i^{\ell}||\ \forall i \in [1, ..., d_m]$, and set $m_i^{\ell} = 0$ for the 10 sub-updates with the highest contribution. Next, we zero out non-dominant sub-updates, i.e. all the sub-updates *except* for the 10 most dominant ones. For each intervention, we measure how often it changes the predicted token. Further measurements of the change in rank and probability of the target token are reported in §C.

Results Fig. 3 shows, for each layer range, the percentage of memorized idioms where the predicted token has changed. Focusing on zeroing out non-dominant FFN sub-updates (Fig. 3, left), we observe a *two-phase pattern of decreasing "layer importance" which corresponds to the two-phase pattern of decreasing rank and increasing probability during inference (§5.2)*: layers' effect on memory recall drops precipitously in the first 10 layers, corresponding to the candidate promotion phase. Then, from around layer 10 onwards, the drop in effect is much less steep, corresponding to the confidence-boosting phase. Intervention in upper layers rarely changes the predicted token, and its effect is limited to reducing the model's confidence (§C). We further visualize this two-phase behavior in Fig. 7 in §C.

These findings suggest that the candidate promotion phase, while having a smaller effect on the prediction's assigned probability compared to the later confidence-boosting stage, in fact, has a crucial role in memory recall.

We also observe that interventions in the first layer are by far the most destructive, with 100% change in prediction for non-dominant updates

(Fig. 3, left). Unlike for other layers, this is also observable when zeroing out the dominant sub-updates (Fig. 3, right), which constitute only 0.1% of layer sub-updates. This suggests the first layer is especially critical for memorized predictions.

6 Memorization of Factual Statements

We now examine if our findings generalize beyond idioms to other types of memory recall, focusing on the completion of statements expressing facts.

Data Datasets for evaluating memorization of factual knowledge typically contain simple queries such as *"The continent of Kuwait is"*, where predicting the next token requires knowledge of the triplet $\langle s, r, t \rangle$ where s is a source entity (e.g., `Kuwait`), t a target entity (e.g., `Asia`), and r is the relation between them (e.g., `is the continent of`). However, unlike idioms, such queries are not suitable for probing memorization since they often fail to satisfy the criteria in §2. Concretely, queries often include "clues" that could make the prediction easy to guess and based on generalization (Poerner et al., 2020) (e.g. predicting a Spanish-speaking country for the query *"Federico López was born in"*), and the same fact can be expressed in multiple different ways (e.g. *"Kuwait is a country in Western Asia"* also encodes the above fact).

To test memorization of facts, we, therefore, collect factual statements where such cases are excluded. We use LAMA-UHN (Poerner et al., 2020), a subset of the LAMA dataset (Petroni et al., 2019), where "easy-to-guess" queries are filtered out. LAMA comprises of queries structured as "fill-in-the-blank" cloze statements (e.g. *"Gordon Scholes is a member of the ____political party."*). To accommodate autoregressive LMs, we consider only queries where the blank appears at the end. In addition, we keep only queries with a single correct completion (based on LAMA). This turns our definition of memorized and non-memorized sets (§4) equivalent to separating based on the evaluation metric of LAMA: an instance is considered memorized if the model predicts the single correct completion and non-memorized otherwise. Overall, the resulting collection consists of 17,855 factual statements with 22 unique relations.

Memorized Facts Exhibit a Similar Prediction Process to Idioms We repeat our analysis (§5.1), using the collected factual statements and GPT2_{M}. Splitting the statements to those memorized and non-memorized by the model results in 786 `mem-facts` vs. 17,069 `non-mem-facts` statements.

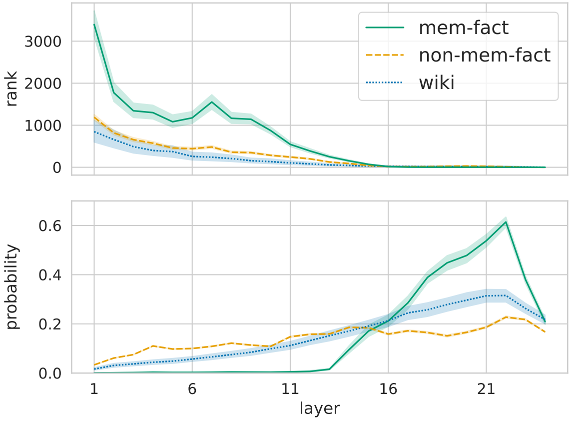

Figure 4: The predicted token's probability and rank across layers of GPT2_{M}, for memorized (`mem-fact`) and non-memorized (`non-mem-fact`) facts and short sequences from Wikipedia (`wiki`).

Fig. 4 shows the rank and probability of the predicted token across layers. Like idioms, memorized facts exhibit a clear two-phase prediction process, where the prediction probability rapidly increases once the candidate reaches a low rank (at layer 16). This is in contrast to non-memorized facts and short sequences from Wikipedia, where the rank (probability) gradually decreases (increases) across layers without a distinct two phases.

Differences from Memorized Idioms Stem from Ill-Defined Targets There is one major difference compared to memorized idioms (Fig. 4 vs. Fig. 2 upper left), which is a substantial drop in probability (0.62 $\rightarrow$ 0.21) in the last two layers. We hypothesize that this is because the input query has multiple plausible completions that were not specified as "correct" targets in LAMA. We verify this by manually analyzing predictions, and find that for 82 out of 100 queries there is more than one correct continuation in top 5 predicted tokens. We posit that the above deficiency of LAMA is inherent because, in violation of our criterion (§2), factual statements can usually be expressed in many ways so their prompt has no single correct target.

7 Related Work

Memorization as Training-Data Influence. Memorization in LMs has attracted immense attention due to their rich sensitive training data (Carlini et al., 2019; Song and Shmatikov, 2019; Carlini et al., 2021; Zhang et al., 2021b; Carlini et al., 2022; Tirumala et al., 2022; Tänzer et al., 2022; Raunak and Menezes, 2022). Recent work suggests that memorization is *necessary* for performant ML due to the "long tail" of infrequently-observed patterns (Zhang et al., 2021a; Feldman, 2020; Brown et al., 2021; Raunak et al., 2021). This line of work has two key limitations: (a) only black-box behavior is measured rather than looking at models' internal prediction process, and (b) it detects memorized instances by measuring the effect of their inclusion in the training set on inference behavior. This results in a set of memorized examples that is specific to the model, training data, and even training pass, making it difficult to build on these results in future research.

Transformers and Idioms. Nedumpozhimana and Kelleher (2021) showed that idioms are identified using textual cues within the expression; Dankers et al. (2022) showed that idioms tend to be internally processed as single units of meaning. It has also been known (Fakharian and Cook, 2021; Salton et al., 2016) that LM contextual embeddings encode information about whether or not an expression is idiomatic (vs. literal). (Shwartz and Dagan, 2019; Chakrabarty et al., 2022) also studied representations and interpretation of non-compositional sequences, such as idioms. No prior work used idioms to probe LM memorization, which is one of the main contributions of this work. We release our dataset, IDIOMEM, to facilitate future research on memorization recall in LMs. Diagnostic datasets, such as IDIOMEM, have often proven useful in the past (Sugawara et al., 2022; Parrish et al., 2021).

Memorization of Factual Knowledge. An extensive line of work (Petroni et al., 2019; Jiang et al., 2020; Poerner et al., 2019; Lewis et al., 2020; Elazar et al., 2021) studied LMs' capacity to acquire relational knowledge during training. Some attention has also been given to understanding the inner workings of factual-memory recall: Wallat et al. (2020) showed that some facts are retrieved from the bottom and intermediate layers, and Meng et al. (2022) localized factual-knowledge recall within feed-forward-component computation. Since factual statements do not fulfill our criteria, it is difficult to convincingly argue that correct predictions indicate memory recall, making it impossible to use them to isolate the effect of memorization.

8 Conclusion

We introduce a methodological framework for detecting and analyzing memorized predictions in transformer LMs. This includes a set of criteria on textual sequences for probing memorized predictions, the IDIOMEM dataset of idioms fulfilling these criteria, and an interpretation method of prediction internals. We characterize a behavioral profile that is unique to predictions involving memory recall and is observable across different LMs and data types. By providing these fundamental tools and initiating a thread of research on the phenomena we observe, we hope to empower future work towards demystifying transformer memorization.

Limitations

Our criteria for detecting memorized instances are sufficient but not necessary, which raises the question of what other sequences that trigger memory recall satisfy them.

Additionally, while correct prediction for sequences that fulfill our criteria implies memory recall, incorrect prediction does not necessarily imply that no memory was used. This means that our set `non-mem-idiom` might include some portion of memorized sequences. This does not qualitatively affect our results as long as `mem-idiom` still contains *more* memorized predictions than `non-mem-idiom`, as is evidenced by the stark differences we observe between LMs' internal behaviors on these sets.

Our work focuses on showing the utility of idioms for probing memorization, and opening up a new thread of research in this vein. We therefore leave further investigation of the above gaps for future work.

A Distinguishing Memorization Using Hidden-Distribution Features

§5.2 shows differences in our extracted hidden-distribution features, namely the rank and probability across layers, between memorized idioms and non-memorized sequences. To verify that these features are distinguishing between memorized and non-memorized predictions, we build a classifier that receives them as input, as follows.

Experiment To answer the above, we represent every instance in IDIOMEM, for every LM we experiment with, as a sequence of probabilities and ranks assigned to the predicted token at each layer. This results in a feature vector for each instance in IDIOMEM for each of our LMs (GPT2$_{\mathrm{M}}$, GPT2$_{\mathrm{L}}$, BERT$_{\mathrm{B}}$, and BERT$_{\mathrm{L}}$). We then append a class label for each LM's instances corresponding to whether it memorized them. Then, for each LM's dataset, we perform 10-fold cross-validation with an 80%-20% train-test split to evaluate the accuracy of a logistic-regression classifier using the LogisticRegresion classifier of scikit-learn,[7] specifying L1 penalty and a bilinear solver as constructor parameters. After each split and before evaluating the classifier, we balance the test set by replacing the larger class with a random subsample the size of the smaller class. To isolate the distinguishing utility of ranks from that of probabilities, we repeat this process while only taking either of them as features at each time. We also repeat this process while separately considering just the last-layer probability as a single feature, the last hidden state vector, and finally, the ranks in layers of layers 1-12 (omitting ranks in layers 13-16 where ranks are usually 0) appended to all layer probabilities.

Results Results are given in Tab. 5. We observe that, across all models, most classifiers perform well over the 50%-accuracy baseline for their class-balanced test sets. The output probability alone is often highly distinguishing with around 78% accuracy, but the vector of 16 hidden-distribution probabilities seems to contain additional distinguishing information, as using it alongside ranks results in higher accuracy, typically around 84%. Using the ranks in addition to probabilities usually *decreases* accuracy, but omitting the ranks in layers 13-16 (which we know are mostly 0 as this is the confidence-boosting phase) attenuates this effect.

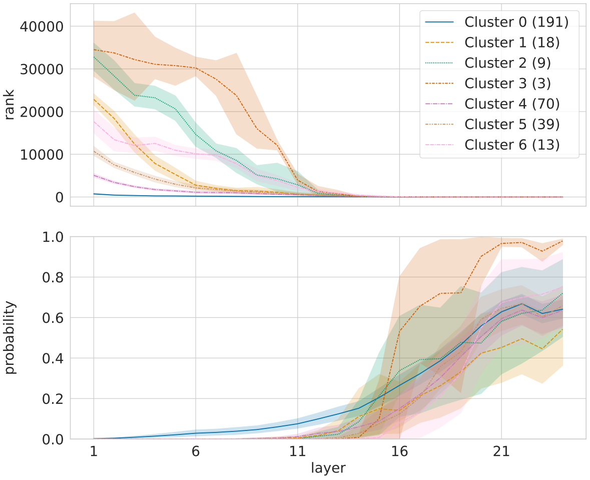

Figure 5: The predicted token's probability and rank across layers for each cluster, after clustering the memorized idioms in GPT2$_{\mathrm{M}}$ according to rank and probability across layers.

We conjecture that ranks have little meaningful information, especially in the confidence-boosting phase.

B Fine-grained Analysis of Memorized Predictions

§5.2 shows how recall of memorized predictions exhibits two characteristic phases (specifically, see Fig. 2). To shed light on this phenomenon, we conduct additional analysis.

B.1 Memorized Idioms In-depth Breakdown

In our analysis, we address all memorized predictions jointly. We now check whether these averaged results are consistent across subgroups of the memorized idioms. To this end, we cluster the memorized idioms by GPT2$_{\mathrm{M}}$, using the same hidden features as in §A, i.e., each instance is represented by the predicted token probability and rank across layers. We then cluster the idioms into seven groups, using K-mean clustering, and visualize the prediction rank and probability across layers for each group. We set the number of clusters to $k = 7$ based on manual inspection, and as we observed no substantial differences in the resulting clusters for larger values of k.

Results are shown in Fig. 5. We find that all groups exhibit the confidence-boosting phase, as the prediction probability quickly increases starting from the intermediate layers. Notably, the lowest final probability observed is > 0.5, which is substantially higher than the average probability of

Table 5: Cross-validation accuracy of a logistic-regression classifier trained to distinguish between memorized and non-memorized idioms.

~ 0.2 for non-memorized predictions (§5.2). However, considering the prediction rank for the different groups, we observe a relatively large variation. Specifically, we observe that 55% of the instances (cluster 0) have a low initial rank. This further supports the findings in §A.

B.2 Log-Scale Visualization

Fig. 6 shows a log-scaled view of the graphs from Fig. 2. We observe that, in terms of orders of magnitude (vs. absolute value), the differences in initial ranks between memorized and non-memorized predictions are more minor, especially in BERT models, whereas rank differences measured in upper layers are more stark.

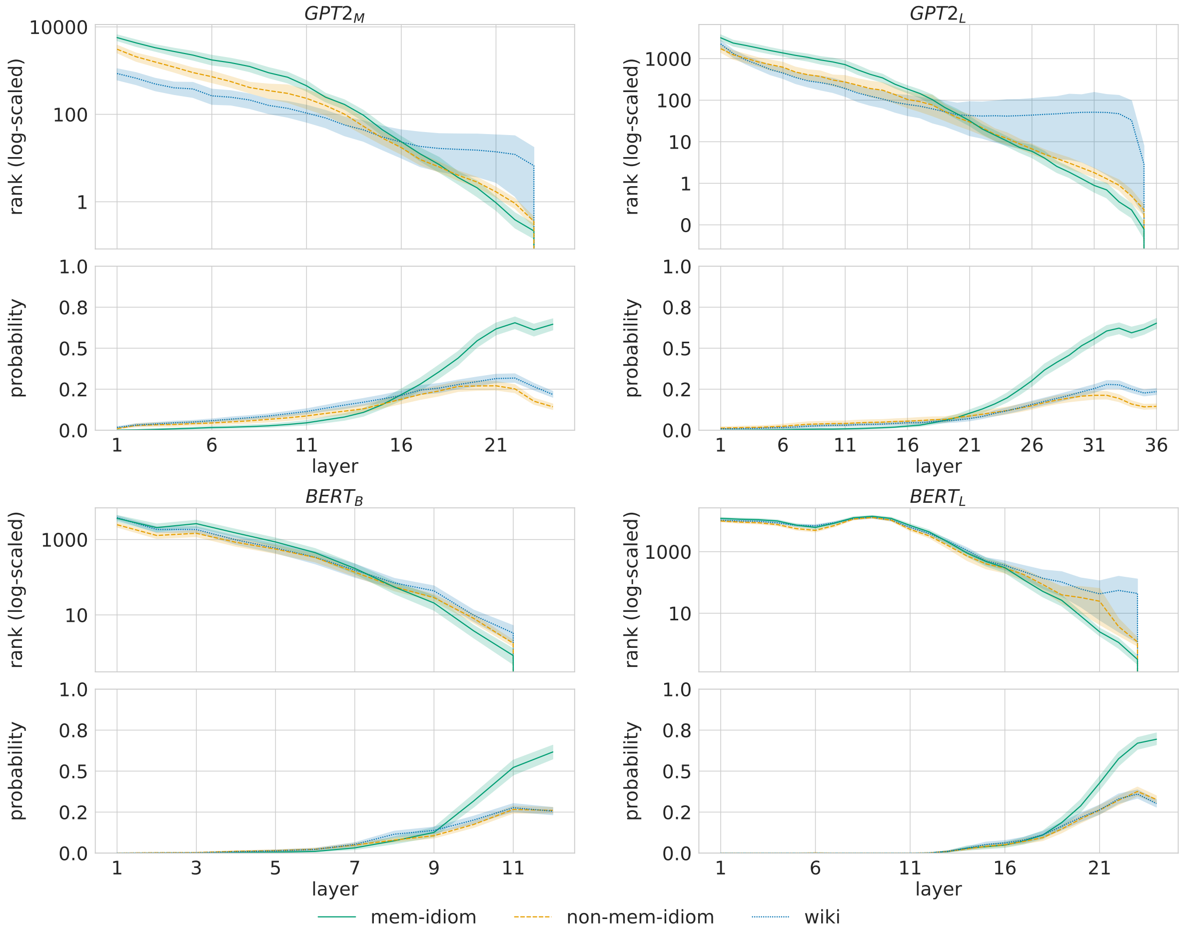

Figure 6: The predicted token's probability and log-scaled rank across layers, for memorized idioms (`mem-idiom`), non-memorized idioms (`non-mem-idiom`) and short sequences from Wikipedia (`wiki`).

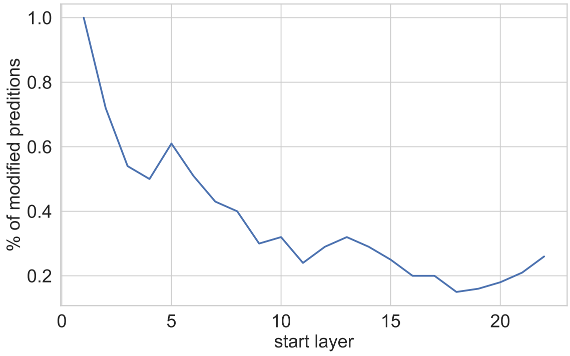

Figure 7: We visualize the effect of intervening in each 3-consecutive-layer range according to the procedure in §5.3.

C Intervention Experiments: Additional Analysis

C.1 Additional Visualization

In §5.3, we performed an intervention-based experiment to test the effect of zeroing out FFN sub-updates in layer computation. This produced a heat map of values corresponding to intervention's effect for each layer range. Here, we plot the intervention's effect across all 3-layer layer ranges. Note that since there are 24 layers, there are a total of 22 ranges of 3 consecutive layers. Fig. 7 visualizes the effect of intervening in each such range.

As discussed in §5.3, we observe a steep drop in effect in the first 10 layers, followed by a more leveled slope of decrease in the upper layers.

C.2 Analyzing Changes in Rank and Probability of the Target Token

In addition to measuring how often an intervention changes memorized predictions (§5.3), we further measure the average change in the rank and probability of the target token. Note that the original target rank for memorized predictions is always zero, as the target token is the top candidate in the original output distribution.

Change in target rank Fig. 8 shows the change in the target token's rank for all intervention experiments. Overall, we observe similar trends as in §5.3. First, zeroing out either dominant or non-dominant FFN sub-updates in upper layers (layers 11-24) does not affect memory recall, as the target token is still ranked as the top candidate in the output distribution. Moreover, zeroing out in early layers (1-10) damages memory recall as the target rank increases by > 20 positions. Specifically, zeroing-out non-dominant FFN sub-updates in layers 2-4 increases the target rank by 60, and disabling either dominant or non-dominant sub-updates in the first layer completely eliminates memory recall as the rank increases to > 6000.

Change in target probability Fig. 9 shows the change in the target token's probability for all intervention experiments. Unlike the prediction rank, which is mostly influenced by the lower layers during memory recall, the prediction probability is highly influenced by the intermediate and upper layers, where confidence boosting happens. Disabling FFN sub-updates in only three of these layers reduces the prediction probability by up to 33%. Considering the lower layers (1-9), zero-outs lead to a large probability decrease (up to 50%). This is expected since these interventions often change the prediction, i.e. they eliminate the target from the top of the output distribution.

D Experimental Setting Details

Tab. 6 shows the evaluated models' hyperparameters.

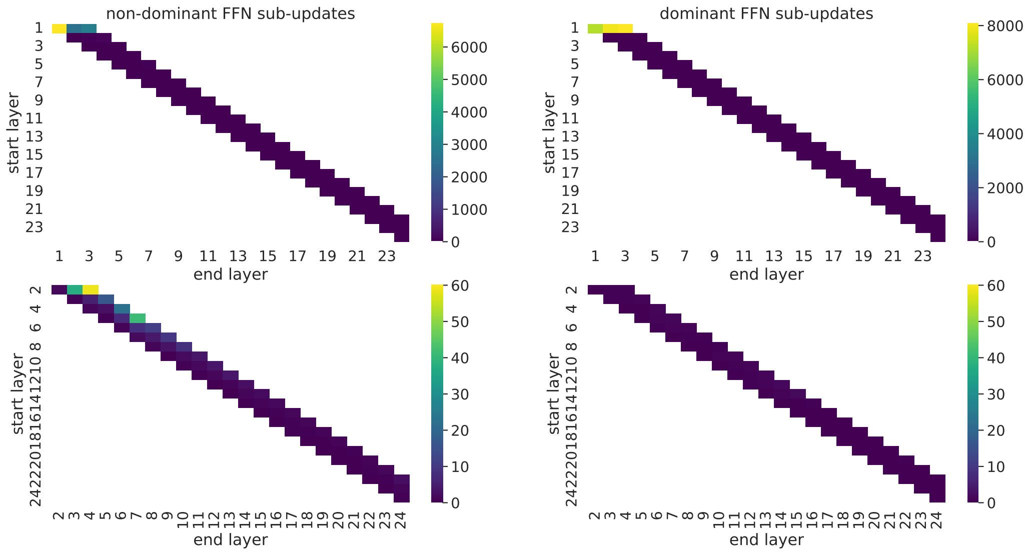

Figure 8: Change in the rank of the target token following intervention zeroing out non-dominant (left) and dominant (right) FFN sub-updates in GPT2$_\text{M}$. Each cell shows the average change in rank of the target token after zeroing out the sub-updates in the layers between the start and end layers. For readability, we provide plots with the first layer (top) and without (bottom).

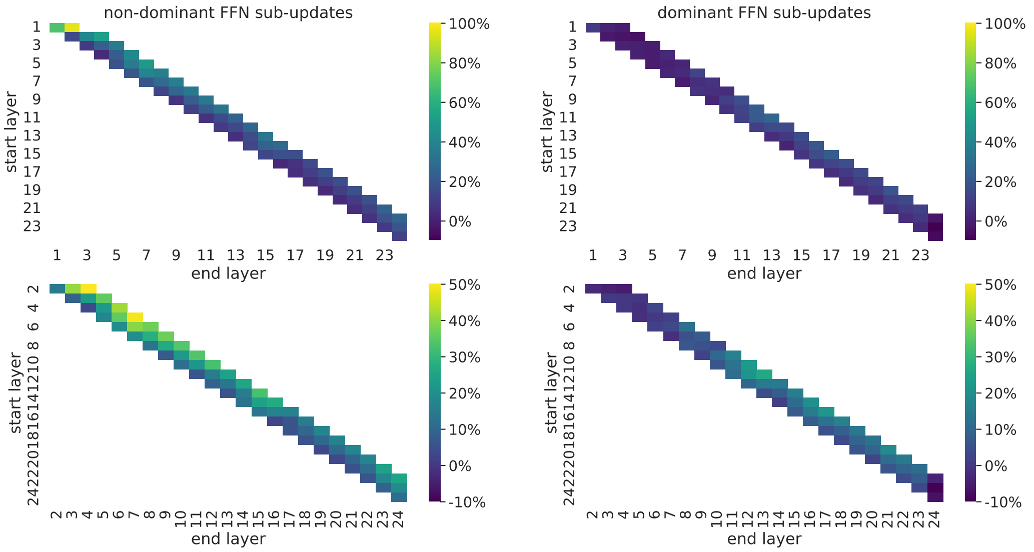

Figure 9: Change in the probability of the target token following intervention zeroing out non-dominant (left) and dominant (right) FFN sub-updates in GPT2$_\text{M}$. Each cell shows the average change in probability of the target token after zeroing-out the sub-updates in the layers between the start and end layers. For readability, we provide plots with the first layer (top) and without (bottom).

A Discerning Several Thousand Judgments:
GPT-3 Rates the Article + Adjective + Numeral + Noun Construction

Kyle Mahowald
mahowald@utexas.edu
Department of Linguistics
The University of Texas at Austin

Abstract

Knowledge of syntax includes knowledge of rare, idiosyncratic constructions. LLMs must overcome frequency biases in order to master such constructions. In this study, I prompt GPT-3 to give acceptability judgments on the English-language Article + Adjective + Numeral + Noun construction (e.g., "a lovely five days"). I validate the prompt using the CoLA corpus of acceptability judgments and then zero in on the AANN construction. I compare GPT-3's judgments to crowdsourced human judgments on a subset of sentences. GPT-3's judgments are broadly similar to human judgments and generally align with proposed constraints in the literature but, in some cases, GPT-3's judgments and human judgments diverge from the literature and from each other.

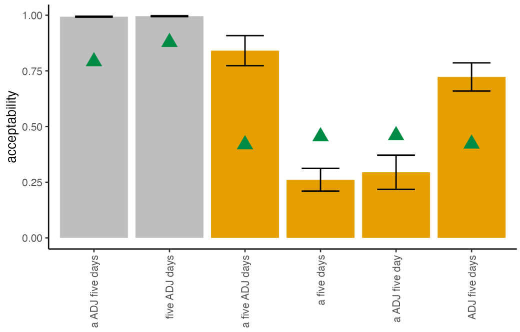

Figure 1: GPT-3 acceptability judgments (bars), compared to human ratings (green triangles) on a matched set of sentences. The comparison is between the AANN construction and the standard alternative, as well as 4 degenerate versions. Both humans and GPT-3 rank the AANN construction as being as acceptable as the standard, and all degenerate constructions are rated significantly lower.

1 Introduction

Consider the English Article + Adjective + Numeral + Noun (AANN) construction: " **a beautiful 228 pages** [iWeb]" or "The president has had **a terrible five weeks** [COCA]". Usually cardinal numbers precede the adjective ("five terrible weeks"), but here the adjective precedes the numeral. More strangely, the normally singular article "a" in this case is followed by a plural noun phrase.[1]

An eclectic dozen or so papers have been written on the construction, many focused on elucidating relevant semantic and syntactic constraints (Goldberg and Michaelis, 2017; Jackendoff, 1977; Dalrymple and King, 2019; Bylinina and Nouwen, 2018; Ionin and Matushansky, 2018, 2004; Solt, 2007; Keenan, 2013). The presence of the modifier is crucial: "a 228 pages" is unacceptable. The type of modifier is also crucial: "a pink 228 pages" is odd because color words are "stubbornly distributive" (Schwarzschild, 2011) and thus cannot refer to a set of items as a whole: the nominal phrase needs to function as a unit (Solt, 2007). These idiosyncratic constraints are typical of *constructions* (Goldberg, 2019).

Prior work on the AANN construction has focused on characterizing the semantic and syntactic constraints on the construction and proposing analyses in various frameworks. For instance, Solt (2007) focuses on how the construction coerces the phrase into a singular noun phrase; Keenan (2013) proposes treating it as akin to a partitive, and Dalrymple and King (2019) give an LFG analysis.

The same properties that make AANN interesting from the perspective of human language use—its low frequency but high sensitivity to constraints—also make it interesting from the perspective of LLMs and what they learn about linguistic structure. Indeed, much work on LLM syntactic competence has centered on ubiquitous abstract features of grammar like subject-verb number agreement (e.g., Linzen et al., 2016; Gulordava et al., 2018), part of speech (Tenney et al., 2019), and syntactic dependencies (e.g., Hewitt and Manning,

---

[1] Data and code: `https://github.com/mahowak/aann-public/`

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 265–273
May 2-6, 2023

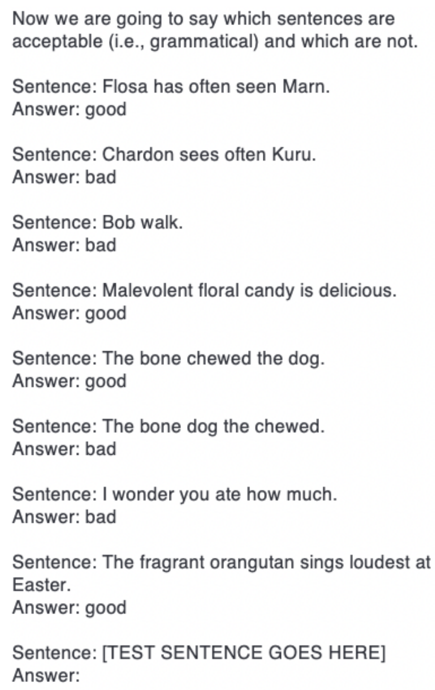
2019). That said, there has also been a recent spate of research on construction-grammar-inspired approaches in NLP, including studies showing that LLMs have access to construction information (Tayyar Madabushi et al., 2020; Tseng et al., 2022; Weissweiler et al., 2022) and capture verb argument construction biases (Hawkins et al., 2020) as well as fine-grained lexical semantic information (Petersen and Potts, 2022). Moreover, sentences with similar constructions cluster in embedding space (Li et al., 2022).

These works are valuable because better understanding how LLMs handle constructions could help us better understand what LLMs learn about linguistic structure (Baroni, 2021; Linzen and Baroni, 2021) and could also inform us as to what can be learned about language from primary data (Warstadt and Bowman, 2022, 2020). In our case, for an LLM to get the AANN construction right, a number of statistical regularities must be eschewed: "a" cannot be treated as a singular marker since the noun is plural, the normal ordering of the number and adjective must be reversed, and normal verb number agreement rules must in some cases be suspended. Understanding whether these heuristics (which work well for the vast majority of text) can be overcome can guide us towards future work understanding *how* they are overcome.

Here, I ask what GPT-3 `text-davinci-002` (now often classed as an instance of GPT-3.5) learns about the AANN construction by testing its sensitivity to several constraints proposed in the literature. In doing so, I treat the LLM as a linguistic test subject (Linzen et al., 2016; Futrell et al., 2019; Wilcox et al., 2021; Warstadt et al., 2019; Ettinger, 2020). I use a custom prompt to elicit quantitative grammaticality judgments (Schütze, 2016; Gibson and Fedorenko, 2013) from GPT-3, and show that the prompt performs well on CoLA, a data set of binary acceptability judgments on a carefully constructed 10,657 English sentences (Warstadt et al., 2019). I then unleash it on the AANN construction and compare GPT-3 to human ratings.

2 Methods

Attaining acceptability judgments from language models is not straightforward. Simply comparing sentence probabilities is difficult because they are dependent on the individual lexical items, as well as sentence length (Warstadt et al., 2020). I rely on the prompting paradigm to elicit acceptability judgments—validating the measure first using a known data set of judgments from CoLA. The prompt was created by drawing on a combination of CoLA training sentences and handcrafted sentences and iteratively experimenting. Ultimately, a diverse 8 sentences were chosen, some of which intentionally have low lexical probability to ensure that the model does not call all low-probability strings ungrammatical. Each prompt example sentence appears along with a binary judgment: "good" or "bad". Then, GPT-3 is passed the prompt, along with the critical test sentence, and asked to generate one more token (always either "good" or "bad"). The probability of the generated word (whether "good" or "bad") is our numerical rating.



Now we are going to say which sentences are acceptable (i.e., grammatical) and which are not.

Sentence: Flosa has often seen Marn.
Answer: good

Sentence: Chardon sees often Kuru.
Answer: bad

Sentence: Bob walk.
Answer: bad

Sentence: Malevolent floral candy is delicious.
Answer: good

Sentence: The bone chewed the dog.
Answer: good

Sentence: The bone dog the chewed.
Answer: bad

Sentence: I wonder you ate how much.
Answer: bad

Sentence: The fragrant orangutan sings loudest at Easter.
Answer: good

Sentence: [TEST SENTENCE GOES HERE]
Answer:

Figure 2: The prompt used for attaining grammaticality judgments. The target sentence is inserted, and then GPT-3 is asked to generate one token (overwhelmingly likely to be "good" or "bad"). That token's probability is taken as a rating.

To validate the measure, I tested the final prompt on the CoLA dev set. It attained accuracy of 84%, with a Matthew's correlation coefficient of 0.63. This is worse than, but in the ballpark of, human inter-annotator agreement on CoLA which is 86% and .697, respectively (Warstadt et al., 2019). It is also comparable to top performers on the GLUE leaderboard for the CoLA sub-task.

I used this technique to test the AANN con-

template	**temporal**: The family spent X in London; The diplomat worked X in Nairobi; The tourist stayed X in Papua New Guinea; **objects**: She bought X; They discovered X; Someone saw X; **human**: We served dinner to X; X greeted us at the door; We congratulated X; **art**: The newspaper reviewed X; I experienced X; Please enjoy X; **distance**: He drove X; Someone walked X; Someone traveled X; **unitlike**: Luis took in X; They consumed X; It lasted X
template for agreement task	**temporal**: X is/are just what you need; X is/are ideal **objects**: X is/are available; X make(s) a lovely gift; **human**: X regularly show(s) up at the door; X is/are here **art**: X was/were reviewed in the newspaper; X was/were enjoyed **distance**: X is/are a long way; X is/are not far; **unitlike** X was/were uncovered; X was/were make(s) an impression

Table 1: A superset of the items used, which were combined in various ways across experiments. In the templates, X is replaced by the AANN construction.

struction by templatically constructing sentences in which I parametrically vary the main sentence template, adjective, numeral, and nominal, from the superset shown in Table 1. Templates were designed to work with the key manipulations. Certain nouns work with some templates and not others, to ensure template/ noun pairs are always plausible.

Adjectives in the AANN construction behave differently depending on whether they are quantitative (i.e. modify the numeral as in "a mere 5 days"), qualitative (e.g., modify the noun as in "a beautiful five days), or are ambiguous between the two (e.g., "an astonishing five days" which leaves it unclear whether the number of days is astonishing, or the days themselves). It has been claimed (e.g., Dalrymple and King, 2019; Solt, 2007; Keenan, 2013) that quantitative and ambiguous adjectives are typically more acceptable than qualitative ones in AANN—although there are specific instances where qualitative adjectives are acceptable. I also consider "stubbornly distributive" (Schwarzschild, 2011) adjectives (e.g., "large" or "blue"), which "stubbornly" refer to individuals even when applied to a group. For instance, "The chairs are large." can refer only to the individual chairs being large, not to the collective group of chairs being large. It's claimed (Bylinina and Nouwen, 2018; Ionin and Matushansky, 2018; Keenan, 2013) that this same property makes a phrase like "a large five trees" less acceptable, compared to something like "a beautiful five trees" (in which it is possible for "beautiful" to refer to not just the individual trees but to the collection of trees).

Solt (2007) and others observe measure nouns work best in the AANN construction, but that other nouns can be okay as long as they can be treated as a single unit. I sampled nouns from 6 categories, as shown in Table 1. Also as shown in that table, I sampled numerals of various kinds but focused on "three" and "five" for the human experiments and most analyses. See Appendix B for a discussion of sensitivity to the numeral.

From these templates and candidate words, I generate semantically plausible sentences (meaning that, throughout the experiments, I only use human-appropriate sentence templates with human nouns and object-appropriate ones with object nouns). Depending on the specific question in each experiment, I run controlled subsets of these sentences (or their degenerate variants as in Experiment 1) through GPT-3 to obtain acceptability judgments, getting the probability of "good" or "bad" as the next word in the continuation.

I also use Amazon's Mechanical Turk to obtain human judgments on a subset of the test sentences. I asked raters to rate sentences on a rating bar scale from 1-10. For Experiments 1 and 3, each rater rated 3 critical sentences. They rated 18 critical sentences in Experiment 2 since there were many more conditions to test in that experiment.

To guard against raters becoming inured to the construction, half or more items were fillers not involving AANN. To maintain similar calibration between humans and GPT-3, these fillers always included all example judgments used in the GPT-3 prompt. I excluded participants who did the survey more than once, who did not rate the good filler items at least 1 point higher than the bad, or who did not have a US IP address. I obtained annotations for only a sample of sentences rated by GPT-3. When applicable, analyses focus on the union of sentences rated by both humans and GPT-3.

3 Exp. 1: AANN Fundamentals

First, I tested the basics of the AANN construction as laid out in the literature by having GPT-3 and human raters rate the AANN construction (e.g., "a beautiful five days") vs. the default ("five beautiful days") vs. a select four degenerate conditions: one with the order of the numeral and adjective switched, one with no modifier, one with a singular noun, and one with no article "a". To generate examples in each condition, I crossed 3 temporal nouns (days, weeks, months), with a low numeral (three), one of 14 appropriate adjectives, and one of 3 templates. For the resulting sentences, I attained human ratings from MTurk (after exclusions, 126 raters rating 3 sentences each, for 378 total ratings) and GPT-3 and focus on that subset for analysis.

Figure 1 shows results for this experiment. Although GPT-3 uses a wider range of the scale, both rate the AANN construction as just as good as the default and give lower ratings to the 4 degenerate versions. Humans rate the 4 degenerate constructions as about equally bad (all between .46 and .53), whereas GPT-3 rates the versions with swapped adjective/numeral order and a missing article as significantly better than the versions with a missing plural and a missing modifier. Running a mixed effect regression (Bates et al., 2015; Barr et al., 2013) comparing the AANN construction to the "default" construction and the degenerate alternatives (treating the default construction as the baseline, with random intercepts for adjective class, adjective, and template; and, for humans, for rater), both GPT-3 and humans show no significant difference in rating between AANN and default (both $p > .05$), but do show a significant difference between AANN and all 4 degenerate conditions (all $ps < .0001$). See Appendix C for regression details. Overall, I conclude that humans and GPT-3 "get" the AANN construction, even though they differ in the relative ratings of the bad variants.

4 Exp. 2: Adjectives and nouns

In this experiment, I focus on only the AANN construction and parametrically vary the kinds of adjectives (quantitative, ambiguously quantitative/qualitative, qualitative, human-referring, color adjective, stubbornly distributive; see Table 1 for examples) and kinds of nouns in the sentences (art, distance, human nouns, object nouns, temporal nouns, unit-like nouns; again see Table 1). This process produced a carefully controlled 12,960 unique sentences, from which we sampled a random subset for human ratings. After exclusions, there were 190 raters left who each rated 18 sentences, giving us ratings for 3,420 sentences.

I test whether GPT-3 and human raters agree with the attested claims that (a) more measure-like nouns (e.g., temporal nouns, distance nouns, and unit-like nouns) are more acceptable in AANN, (b) qualitative adjectives are acceptable in only some AANN cases, and (c) stubbornly distributive adjectives (including color words) are not acceptable in the AANN construction. To assess significance, I predicted acceptability separately for humans and GPT-3 in a mixed effect regression, using adjective class, noun class, and their interaction as predictors and with random effects for adjective, noun, numeral, and template. I treated qualitative adjectives with temporal nouns as the baseline.

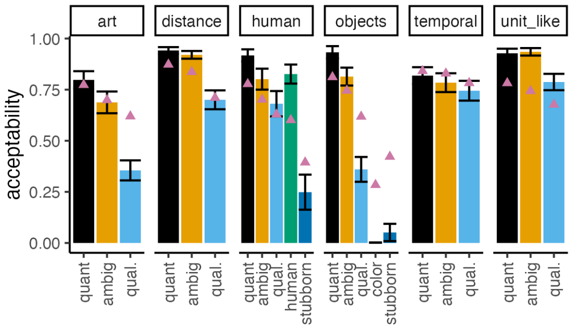

Figure 3: GPT-3 acceptability scores broken down by adjective type (x-axis), and noun type (on facets). Human ratings are pink triangles.

For both humans and GPT-3, there are significant differences in how nouns interact with adjectives (Figure 3). For temporal, distance, and unit-like nouns, all adjective types show high acceptability (although the qualitative adjectives are rated lowest). For art and object nouns, qualitative nouns score significantly worse ($p < .01$ for both humans and GPT-3) than ambiguous or quantitative nouns (an observation consistent with the literature). As predicted, colors and other stubbornly distributive adjectives (which can be tested only for humans and objects) show the lowest acceptability (significantly lower, $p < .01$, compared to qualitative adjectives, for both human and GPT-3 ratings). See Appendix D for regression details.

5 Exp. 3: Adjective Order

It is claimed that, in AANN, qualitative adjectives must appear before quantitative ones in order to be acceptable (Solt, 2007): "The family spent a beautiful mere five days in London." is preferred over "The family spent a mere beautiful five days in London.". To compare whether there is an effect of adjective ordering (putting the qualitative adjective

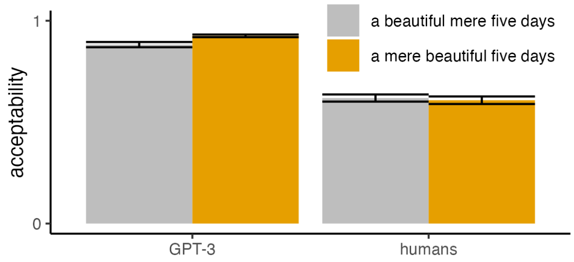

Figure 4: GPT-3 and human preference for adjective order (quantitative before qualitative; qualitative before quantitative).

before the quantitative one or vice versa), I ran an experiment crossing 3 templates; 5 adjectives (astonishing, impressive, beautiful, hideous, ugly); the noun "days"; and the numeral "three" or "five". I ran each sentence in two conditions (quantitative adjective first or qualitative adjective first). For instance, I compared: "The family spent a beautiful mere five days in London." to "The family spent a mere beautiful five days in London." This left 60 sentences total, rated by 99 raters (each sentence rated between 18 and 36 times; 1,782 ratings total).

GPT-3 significantly prefers the order *dispreferred* in the literature (quantitative first, as in "a mere beautiful five days"; $\beta = .04, p < .01$). Humans (n=99) showed no clear preference according to the model, under the same analysis (but with a random intercept for rater): $\beta = -.513, p > .05$. Thus, the attested claim does not replicate. But the ratings for these sentences are relatively low overall, so we should remain open to the possibility that there are better examples of the double-adjective constructions than the ones tested. See Appendix E for regression details.

6 Exp. 4: Verb Agreement

The AANN construction also challenges number agreement. AANN subjects sometimes take singular verbs (when the noun phrase would be singular anyway, as in "A mere fifty cents for a cup of coffee sounds/*sound reasonable to me!"); sometimes plural ("A delicious four courses *was/were served in the main dining room."), and sometimes either ("A healthy two runs weekly was/were prescribed by the doctor." See Keenan (2013).

I tested agreement by comparing phrases which differed only in the verb number (e.g., comparing "A beautiful five days is..." vs. "A beautiful five days are...."). Sampling a subset of noun classes (art, distance, human nouns, objects, unit-like nouns, and temporal nouns), I generated a total of 280 sentences (each appearing with a singular or plural verb for a total of 560 sentences) and attained judgments from GPT-3. As shown in Figure 5, these results replicated in detail several attested judgments in the literature: art nouns, human nouns, unit-like nouns, and object nouns all prefer the plural for the AANN construction (art and humans almost categorically so). Distance nouns and temporal nouns prefer the singular (although temporal nouns can also take the plural). See Appendix F for details.

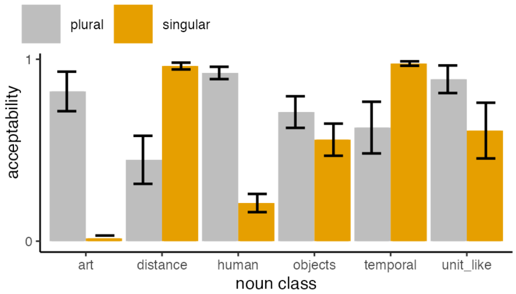

Figure 5: Mean GPT-3 acceptability ratings in the AANN construction for plural and singular verb agreement, as a function of noun class.

7 Conclusion

This work shows that GPT-3 can recognize and use the *form* of the AANN construction in a relatively (but not perfectly) human-like way, matching judgments across a variety of conditions, which is not the same thing as showing that it understands the meaning or *function* of the construction (Mahowald et al., 2023). In future work, we should study not just the form of the construction but its *construal* (Trott et al., 2020). This may be particularly relevant since Weissweiler et al. (2022), which studies the "Xer the Yer" construction (e.g., "the better the criticism, the better the science" [COCA]), show that LLMs can recognize the construction but fail at tests of understanding its meaning.

That said, GPT-3's performance on the AANN construction demands a significant amount of constructional knowledge and involves overriding major widespread "rules" of grammar (e.g., that the article *a* signals a singular noun). Future work exploring how LLMs override those heuristics, perhaps using causal intervention techniques (Ravfogel et al., 2021; Geiger et al., 2021) could illuminate their syntactic processing mechanisms.

8 Limitations

Many researchers have pointed out that the AANN construction is sensitive to context. For instance, Solt (2007) points out that "a hungry thirty hikers" may be acceptable in some sentences (namely ones where "hikers" is more easily construed as a single unit) than others. Because of the cost of running sentences through GPT-3 and on MTurk and the combinatoric nature of the construction, I could only run a constrained number of templates and did not consider larger context. Broader context may matter and so these results should be taken to apply to the particular contexts shown, which is why I show the exact templates used in the main text.

Another limitation is that the task of how to prompt GPT-3 for grammaticality judgments is not a settled question. Our focus in this paper was not on settling it, so I used one particular method for prompting GPT-3. While I explored the prompt space some, it is likely there are better prompts out there that would make GPT-3's performance on the task better. It's also possible that prompting GPT-3 for grammaticality judgments is not the best way to ascertain its knowledge of language and that a more naturalistic task would produce different results.

As has often been pointed out in the linguistics literature, naive human judges of out-of-context sentences may sometimes tap into different processes than they would when encountering language in the wild. Moreover, English is not a monolith and this construction's acceptability may vary across dialects of English. In a more detailed human study, it would be possible to tease apart effects of different dialects on ratings.

GPT-3 `text-davinci-002` is often categorized as GPT-3.5 because it is trained on more than just a word prediction task, and so we should not interpret its output as being purely reflective of what is learned by word prediction alone.

Finally, I note that I use templatically constructed sentences, which differ in important ways from naturalistic ones.

A Frequency of AANN

I sampled the AANN construction on SketchEngine for the English Web 2020 corpus with the following prompts: `[lemma="a[n]*"] [tag="JJ.*"] [tag="CD.*"] [tag="NNS"]` for AANN and `[tag="CD.*"] [tag="JJ.*"] [tag="NNS"]` for the vanilla construction. The AANN showed up 23.62 per million tokens, compared to 457.22 for the vanilla construction. Of the AANN construction examples, the vast majority contain quantitative adjectives (e.g., *mere*, *staggering*, etc.) and measurement nouns. Of a sample of 200 AANN constructions that I manually inspected on SketchEngine, none contained a qualitative adjective.

B Numerals

I sampled numerals from round low numbers (“three”, “five”, “six”, “eight”, “ten”), medium numbers (“twenty”, “fifty”), high numbers (500, 1000, 10,000), non-rounded medium numbers (21 and 51), and non-rounded high numbers (1,429 and 21,234). I focused on round low numbers (“three” and “five”) for most analyses.

For the overall analysis (across all adjectives and nouns in the main experiment), I get the below AANN ratings from GPT-3.

numclass	**example**	**avg. AANN score**
num-high	500	0.68
num-high_odd	1,429	0.93
num-low	three	0.80
num-med	twenty	0.70
num-med_odd	21	0.73

Low numbers like “three” and “five” are rated higher somewhat than other numbers, with the exception of high, non-round numbers (e.g., 1,429). These are rated unusually highly. Because of this anomalous behavior, I focus mostly on the low numerals for the analysis and did not attain human ratings for these other numerals. It remains an open question how humans would rate a sentence like “We spent a beautiful 1,429 days in London.”

C AANN vs. default vs. degenerate regression

I run the following regression using the R `lme4` (Bates et al., 2015) package.

```
lmer(value ~ construction +
             (1|adjclass) +
             (1|adj) +
             (1 | temp))
```

where I treat the construction as a predictor (with the AANN constructor as a default) and adjclass, adjective, template as random effects. (Other random effects were removed to help the model converge, by iteratively removing ones with the smallest variance.)

For humans, there is also a random intercept for worker.

coef.	β_{gpt3}	Sig	β_{human}	Sig
(Intercept)	0.99	*	.81	*
five ADJ days	0.00		.06	
a five ADJ days	-0.22	*	-.39	*
a five days	-0.87	*	-.35	*
a ADJ five day	-0.72	*	-.35	*
ADJ five days	-0.20	*	-.38	*

Table 2: Fixed effect coefficients for GPT-3 comparing across constructions on the subset of sentences also run with human annotators

D Regression for adjective x noun sub-experiment with GPT-3 and humans

To assess significance, I predicted acceptability separately for humans and GPT-3 in a mixed effect regression, using adjective class, noun class, and their interaction as predictors and with random effects for adjective, noun, numeral, and template. I treated qualitative adjectives with temporal nouns as the baseline. For the human regression, it was identical except I included a random intercept for each worker, with a random slope for adjective class and noun class (but not their interaction, due to convergence issues).

```
lmer(rating ~ adjclass *
        nounclass +
        (1|adj) +
        (1|noun) +
        (1|num) +
        (1 |template))
```

	beta	t-value	p<.05
(Intercept)	0.80	12.09	*

noun-art	0.20	2.52	*
singular:noun-unit_like	-0.63	-6.40	*
singular:noun-objects	-0.50	-6.12	*
singular:noun-human	-1.07	-12.96	*
singular:noun-distance	0.16	1.65	
singular:noun-art	-1.16	-11.71	*

Table 5: Fixed effect coefficients and significance values for an experiment comparing whether nouns in the AANN construction prefer singular or plural verbs.

F Agreement

I ran a regression predicting the rating based on the nounclass, and its interaction with whether there was singular plural. I included random intercepts for noun, adjective, and template, with a random slope for whether the verb was singular or plural on the noun factor.

```
lmer(rating ~ singplur *
        nounclass +
        (1 + singplur|noun) +
        (1|adj) +
        (1|template))
```

Results appear in Table 5, where the baseline values are temporal nouns in the plural (e.g., “days”). Singular verbs are preferred overall, relative to plurals for the temproal nouns (main effect of “singular”). There are various main effects of nouns, but the critical effects here are interactions. There are significant effects such that, *relative to temporal nouns* (e.g., “days”), unit-like nouns are less likely to prefer singular agreement, object nouns are less likely to prefer singular agreement, human nouns are less likely to prefer singular agreement, and art nouns are less likely to prefer singular agreement. Distance nouns are more likely than temporal nouns to prefer singular agreement (but not significantly so).

Triple-Hybrid Energy-based Model Makes Better Calibrated Natural Language Understanding Models

Abstract

Though pre-trained language models achieve notable success in many applications, it's usually controversial for over-confident predictions. Specifically, the in-distribution (ID) miscalibration and out-of-distribution (OOD) detection are main concerns. Recently, some works based on energy-based models (EBM) have shown great improvements on both ID calibration and OOD detection for images. However, it's rarely explored in natural language understanding tasks due to the non-differentiability of text data which makes it more difficult for EBM training. In this paper, we first propose a triple-hybrid EBM which combines the benefits of classifier, conditional generative model and marginal generative model altogether. Furthermore, we leverage contrastive learning to approximately train the proposed model, which circumvents the non-differentiability issue of text data. Extensive experiments have been done on GLUE and six other multiclass datasets in various domains. Our model outperforms previous methods in terms of ID calibration and OOD detection by a large margin while maintaining competitive accuracy.

1 Introduction

Since many industrial applications involve safety -critical domains such as healthcare (Li et al., 2019; Blinov et al., 2020; Li et al., 2020; Rasmy et al., 2021; Sarabadani, 2019), anticipating credit card defaults (Sun and Vasarhalyi, 2021) and self-driving (Khaitan et al., 2021), it's essential for machine learning systems to provide not only accurate but also well-calibrated predictions (Li et al., 2019), which can help to decide whether it can be trusted.

However, models achieving high accuracy usually lead to overconfidence and miscalibration (Guo et al., 2017; Thulasidasan et al., 2019; Ovadia et al., 2019). This motivates an interesting and important area that attempts to achieve a better trade-off between accuracy and calibration. In addition to ID calibration, it's more important for machine learning models to produce high uncertainty when OOD data is observed, rather than to produce wrong yet wildly confident predictions.

Related works. To overcome the problem of miscalibration, numerous methods have been proposed. The natural way is post-hoc calibration that transforms the output of the original network into calibrated confidence scores while maintaining the network's accuracy (Guo et al., 2017; Rahimi et al., 2020; Jung et al., 2020). The second method to mitigate miscalibration is to add regularizations during training such as label smoothing (Wang et al., 2020), Mixup (Zhang et al., 2018). Desai and Durrett (2020) and Kong et al. (2020) further conveys that the aforementioned methods can be applied to improve the calibration of pre-trained language models on NLU tasks. The third way is to design a specific loss function to minimize the discrepancy between accuracy and confidence. For example, Kong et al. (2020) lately propose the ID and OOD regularizer to leverage the relationship between accuracy and uncertainty, and it obtains a significant improvement over previous methods in ID calibration and OOD detection.

Energy-based Models. In another line of work, Joint EBM (JEM; Grathwohl et al., 2019) has been shown great improvements on ID calibration and OOD detection for images without explicit calibration correction mechanism. The core idea is to reinterpret a joint distribution $p_\theta(x, y)$ from a neural classifier $p_\theta(y|x)$ in the perspective of EBMs and jointly optimize the marginal distribution $p_\theta(x)$ and a neural classifier $p_\theta(y|x)$. Elflein et al. (2021) further investigate the OOD detection performance with different training approaches for $p_\theta(x)$ such as Stochastic Gradient Langevin Dynamics (SGLD; Welling and Teh, 2011), Sliced-Score-Matching (SSM; Song et al., 2020) and Variational Entropy Regularized Approximate maximum likelihood (VERA; Duvenaud et al., 2021).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 274–285
May 2-6, 2023 ©2023 Association for Computational Linguistics

Besides, Du and Mordatch (2019) propose an implicit generative models based on EBMs (IGEBM) and apply SGLD to optimize $p_\theta(x|y)$. It performs significantly better OOD detection than other generative models. However, as shown by Grathwohl et al. (2019), the accuracy of IGEBM has dropped dramatically to 49.1% on CIFAR10 while standard finetuning can achieve 95.8% accuracy. This result indicates that different loglikelihood factorization leads to great gaps in accuracy, ID calibration and OOD detection. Moreover, these training methods such as SGLD, SSM, VERA need to calculate the gradients about inputs, the none differentiability of text data limits the application of these methods on both calibration and OOD detection for NLU tasks.

Recently, He et al. (2021) proposes a joint training of classifier $p_\theta(y|x)$ and marginal distribution $p_\theta(x)$ based on Residual EBM (Deng et al., 2019) for NLU tasks. Different from JEM, their model is more flexible by designing various energy functions for marginal distribution without any restriction on joint distribution $p_\theta(x, y)$. To estimate the parameters of marginal distribution $p_\theta(x)$, they propose to apply noise contrastive estimation (NCE; Gutmann and Hyvärinen, 2010) to train the energy model by discriminating the real data and the fake data generated by a noise distribution. To make the noise distribution as close as possible to the data distribution, they finetune a task-specific GPT-2 (Radford et al.). Though it achieves improvements on ID calibration, it's often resource-intensive compared to previous methods to finetune GPT-2 (Li et al., 2022). Moreover, the quality and quantity of fake samples generated by noise distribution has great impacts for NCE training (He et al., 2021; Gutmann and Hyvärinen, 2010).

Contribution. Methodologically, we propose a novel model namely Triple-Hybrid Energy-based Model (THEM) based on the JEM (Grathwohl et al., 2019) through different decompositions of log$p(x, y)$ into a unified framework. Compared to Grathwohl et al. (2019) and Du and Mordatch (2019), our model combines the classifiers $p(y|x)$, class-conditional density $p(x|y)$ and unconditional data density $p(x)$ into a hybrid model. Due to the none differentiability of text data, we further propose to adopt InfoNCE (Oord et al., 2018) with memory bank (He et al., 2020) to approximate the normalized constant of EBM efficiently. This method makes it possible for EBM training on NLU tasks which is not well explored in previous works regardless of input differentiability. We conduct comprehensive experiments with BERT (Kenton and Toutanova, 2019) and RoBERTa (Liu et al., 2019) as the backbone and demonstrate the effectiveness of our framework on various datasets including GLUE (Wang et al., 2018) and six multiclass classification datasets (Kong et al., 2020) on various domains. Not only the experimental results show that our method achieves significant improvements in ID calibration and OOD detection with competitive accuracy over previous methods, but also it is more robust with respect to the temperature and size of memory bank compared to contrastive learning trained EBM including JEM(CL), IGEBM(CL) and HDGE.

Overall, the contributions can be summarized as follows:

- We propose a Triple-Hybrid Energy-based model (THEM) and apply InfoNCE with memory bank to optimize it efficiently and effectively for **discrete data**. It achieves significantly better performance compared to strong baselines including He et al. (2021) and Kong et al. (2020) in terms of ID calibration and OOD detection.
- We apply this training technique to JEM and IGEBM to obtain JEM(CL) and IGEBM(CL) respectively. THEM and JEM(CL) achieves better ID calibration and OOD detection compared to HDGE and IGEBM(CL) in average.
- We further study the effect of the temperature and size of memory bank for contrastive learning on ID calibration and OOD detection. THEM is more robust to these hyperparameters than JEM(CL) and HDGE(CL).

2 Preliminaries: Joint Energy Model and Contrastive Learning

Joint Energy Model (JEM). Energy-based models (EBMs; LeCun et al., 2006) measure the compatibility of the input variables $x \in \mathcal{X}$ and target variables $y \in \mathcal{Y}$ with an energy function $E_\theta(x, y) : \mathcal{X} \times \mathcal{Y} \to \mathbb{R}$, which is the main building block. Low energy corresponds to high compatability. With E_θ, the probability for data in an EBM can be written as

$$p_\theta(x, y) = \frac{\exp\left(-E_\theta(x, y)\right)}{Z_\theta}, \tag{1}$$

where Z_θ is the normalizing constant. EBMs are flexible to parameterize since they do not make restrictions on the tractability of Z_θ.

Joint Energy Model (JEM; Grathwohl et al., 2019) reinterpret a classifier $p_\theta(y|x)$ in supervised learning as an EBM for the joint distribution $p_\theta(x, y)$. Specifically, $p_\theta(y|x)$ is a categorical distribution:

$$p_\theta(y|x) = \frac{\exp(f_\theta(x)[y])}{\sum_y \exp(f_\theta(x)[y])}, \tag{2}$$

where $f_\theta(x) : \mathbb{R}^D \to \mathbb{R}^K$ maps each data point $x \in \mathbb{R}^D$ to K real-valued numbers known as logits, and $f_\theta(x)[y]$ indicates the logit of label y. JEM defines an EBM of the joint distribution with the same logits f_θ:

$$p_\theta(x, y) = \frac{\exp(f_\theta(x)[y])}{Z_\theta}, \tag{3}$$

where energy function $E_\theta(x, y) = -f_\theta(x)[y]$. To retain discriminative performance of $p_\theta(y|x)$, JEM factorizes the loglikelihood as

$$\log p_\theta(x, y) = \log p_\theta(x) + \log p_\theta(y|x), \tag{4}$$

and apply EBM training to benefit from generative models $p_\theta(x)$. Grathwohl et al. (2019) and Elflein et al. (2021) have shown that EBM training of the joint distribution improves calibration and out-of-distribution detection with various training methods.

Constrastive Learning. Our work is also related to contrastive learning, in that we approximate $\log p_\theta(x)$ and $\log p_\theta(x|y)$ by constrastive loss. Contrastive learning achieves remarkable success on downstream tasks, includes image classification, video understanding, knowledge distillation, etc (Khosla et al., 2020; Chen et al., 2020). In constrastive learning, a widely-used objective has the following form (Oord et al., 2018):

$$-\mathbb{E}_{p_{\text{data}}(x)}\left[\log \frac{\exp\{t_\theta(x)^\top t'_\theta(x)\}}{\sum_{i=1}^{N} \exp\{t_\theta(x)^\top t'_\theta(x_i)\}}\right], \tag{5}$$

where $t_\theta(x)$ and $t'_\theta(x)$ map each data point x to two different representation spaces. This is usually called InfoNCE loss. Different from existing methods for EBM training, we propose to leverage constrastive learning approximation for effective learning, without considering the generation ability such as SGLD, SSM and so on.

3 Triple-Hybrid Energy-based Model

Motivation. Many works (Grathwohl et al., 2019; Elflein et al., 2021; Du and Mordatch, 2019) have shown that EBMs could significantly reduce the expected calibration error and improve out-of-distribution detection for image classification. Specifically, the JEM proposed in Grathwohl et al. (2019) factorizes the joint distribution $\log p_\theta(x, y)$ into $\log p_\theta(x) + \log p_\theta(y|x)$, where $\log p_\theta(y|x)$ is to maintain the classification performance and $\log p_\theta(x)$ is the generative term which contributes to better calibration and out-of-distribution detection. On the contrary, the IGEBM proposed in Du and Mordatch (2019) factorizes the joint distribution $\log p_\theta(x, y)$ into $\log p_\theta(y) + \log p_\theta(x|y)$ for implicit generation and surprisingly find that it achieves better OOD performance. However, lack of $p_\theta(y|x)$ leads to terrible classification performance. It's shown in Grathwohl et al. (2019) that the classification accuracy dropped dramatically to 49.1% on the CIFAR10 dataset, while the accuracy is 92.9% by JEM.

On the other hand, Liu and Abbeel (2020) proposed a hybrid discriminative-generative energy-based model (HDGE) for both classification and generation. The loss function consists of a discriminative conditional log-likelihood $\log p_\theta(y|x)$ and a generative conditional log-likelihood $\log p_\theta(x|y)$. Compared to IGEBM, it includes $\log p_\theta(y|x)$ and thus achieves better classification performance. Compared to JEM, it includes the conditional generative model, rather than the marginal generative model. In other words, JEM targets to reduce the energy for data from the population $p_\theta(x)$, while HDGE aims at reducing the energy for compatible pair (x, y). This motivates us to combine the benefits of both conditional and marginal generative model for better calibration and OOD detection.

Triple-Hybrid Energy-based Model (THEM). We propose to make a hybrid model of the triple $\log p_\theta(y|x)$, $\log p_\theta(x|y)$ and $\log p_\theta(x)$, called Triple Hybrid Energy-based Model (THEM) and the objective function is

$$\mathbb{E}_{p_{\text{data}}(x,y)}\left[\log p_\theta(y|x) + \log p_\theta(x|y) + \log p_\theta(x)\right], \tag{6}$$

where $p_\theta(y|x)$ is the standard softmax neural classifer and the generative models $p_\theta(x), p_\theta(x|y)$ serve as regularization, always accompanied with better calibration and OOD detection.

From another perspective, we combine the two factorizations of the joint distribution $\log p_\theta(x, y)$ from JEM and IGEBM. We remark that the joint distribution can also be factorized as $(\log p_\theta(x) +$

$\log p_\theta(x|y) + \log p_\theta(y) + \log p_\theta(x|y))/2$. Our proposed THEM utilizes this factorization and treats $p_\theta(y)$ known as the label frequencies in data, which does not need to be optimized. Now we are ready to resolve the computational issues for THEM in the following.

Neural Classifier. The neural classifier term is easy to cope with. Specifically,

$$p_\theta(y|x) = \frac{\exp(f_\theta(x)[y])}{\sum_y \exp(f_\theta(x)[y])}, \tag{7}$$

where $f_\theta(x)[y]$ is the logit of label y. Thus we can derive the first term in (6) as the traditional cross-entropy loss:

$$\mathbb{E}_{p_{\text{data}}(x,y)} [\log p_\theta(y|x)] . \tag{8}$$

Conditional Generative Likelihood. The conditional generative likelihood can be derived from the joint distribution:

$$\begin{aligned}\log p_\theta(x|y) &= \log \frac{p_\theta(x,y)}{p_\theta(y)} = \log \frac{p_\theta(x,y)}{\sum_x p_\theta(x,y)}\\ &= \log \frac{\exp(f_\theta(x)[y])}{Z_\theta(y)},\end{aligned} \tag{9}$$

where $Z_\theta(y) = \sum_x \exp(f_\theta(x)[y])$. By definition, this is also an EBM with energy function $E_\theta(x, y) = -f_\theta(x)[y]$. Energy-based models are well-known to be difficult to train. The Fenchel duality method used in Chen et al. (2021b) can estimate $Z_\theta(y)$. The stochastic gradient langevin dynamics (SGLD) adopted in Grathwohl et al. (2019) can approximate the gradient of $\log p_\theta(x|y)$. However, these methods require to calculate the derivative with respect to the input x and thus can't be applied to discrete data such as text tasks.

Approximation with Contrastive Learning. The above training methods are successful for generation purpose. Differently, we focus on classification with better calibration and OOD detection. As such, we propose to coarsely approximate the normalization constant as

$$Z_\theta(y) \approx \sum_{i=1}^{N} \exp(f_\theta(x_i)[y]), \tag{10}$$

where x_i is sampled from the data no matter whether y_i is equal to y or not. The second term in (6) is approximately

$$\mathbb{E}_{p_{\text{data}}(x,y)} [\log p_\theta(x|y)] \approx \log \frac{\exp(f_\theta(x)[y])}{\sum\limits_{i=1}^{N} \exp(f_\theta(x_i)[y])}. \tag{11}$$

Since the samples for approximation are incorporated in the denominator using the same label y, the logits $f_\theta(x)[y]$ can be treated as the score function of input-label contrast (Rethmeier and Augenstein, 2021). As a result, this objective can be seen as the InfoNCE (5) in contrastive learning. Liu and Abbeel (2020) also proposed this approximation for image classification, while it's more suitable to text classification due to the discreteness of data.

To be more distinguishable between positive and negative samples but not concentrated on the nearest few samples (Zhang et al., 2021), we employ the temperature parameter τ in InfoNCE and the objective loss becomes

$$\log \frac{\exp(f_\theta(x)[y]/\tau)}{\sum\limits_{i=1}^{N} \exp(f_\theta(x_i)[y]/\tau)}. \tag{12}$$

For the effectiveness of contrastive learning, it often requires a large number of negative samples (Chen et al., 2021a). Since directly increasing N is limited to hardware memory, we instead propose to use a memory bank (He et al., 2020) to store logits with negligible computational resources. In detail, we store the logits $f_\theta(x)[y]$ of the past samples into the memory bank.

Marginal Generative Likelihood. The marginal generative likelihood can be handled in the similar way as conditional generative likelihood. Specifically,

$$\begin{aligned}\text{log} p_\theta(x) &= \log \left\{ \sum_y p_\theta(x,y) \right\}\\ &= \log \frac{\sum_y \exp(f_\theta(x)[y])}{Z_\theta},\end{aligned} \tag{13}$$

where $Z_\theta = \sum_x \sum_y \exp(f_\theta(x)[y])$. We propose to approximate the third term in (6) as

$$\mathbb{E}_{p_{\text{data}}(x,y)} [\log p_\theta(x)] \approx \log \frac{\sum_y \exp(f_\theta(x)[y])}{\sum\limits_{i=1}^{N} \sum_y \exp(f_\theta(x_i)[y])}, \tag{14}$$

where x_i is sampled from the data distribution. As the conditional generative likelihood, techniques of temperature parameter and memory bank are also employed.

4 Experiments

In this section, we conduct thorough experiments to investigate the empirical peformance of our proposed methods. We first introduce the criteria for ID calibration and OOD detection.

ID Calibration. For a well-calibrated model, the confidence estimate $\hat{p}$ of the model is expected to be comparable to true probability (accuracy): $\mathbb{P}(\hat{y} = y|\hat{p}) = \hat{p}$ (Desai and Durrett, 2020; Kong et al., 2020). The calibration error for a given confidence $p \in (0, 1)$ is defined as the followings:

$$\mathbb{E}_p = |\mathbb{P}(\hat{y}(x) = y(x)|\hat{P}(x) = p) - p|, \qquad (15)$$

where $\hat{y}(x)$ is the label predicted by the model, $y(x)$ is the true label for input x and $\hat{P}(x)$ is the output probability associated with the predicted label $\hat{y}(x)$. To evaluate the overall calibration error, we partition $(0, 1)$ into M bins of equal size and let b_m denote the set of prediction confidences which lie in the m-th bin. The expected calibration error (ECE) is calculated by weighting the difference between accuracy and confidence of each bin:

$$\begin{aligned} \text{acc}(b_m) &= \frac{1}{|b_m|} \sum_{i \in b_m} \mathbb{I}(\hat{y}_i = y). \\ \text{conf}(b_m) &= \frac{1}{|b_m|} \sum_{i \in b_m} \hat{p}_i. \qquad (16) \\ \text{ECE} &= \sum_{m=1}^{M} \frac{|b_m|}{N} |\text{acc}(b_m) - \text{conf}(b_m)|. \end{aligned}$$

OOD Detection. In general, OOD detection is a binary classification problem, where the model is required to produce a score $s_\theta(x) \in \mathbb{R}$. Usually we can set a threshold δ to detect OOD samples whose score functions are below the threshold. A well-calibrated model is expected to output higher scores for in-distribution examples than out-of-distribution examples. A widely used score function is maximum prediction probability (Hendrycks and Gimpel, 2016):

$$s_\theta(x) = \max_y p_\theta(y|x). \qquad (17)$$

Following Kong et al. (2020), we employ the empirical Normalized Bounded Area Under the Calibration Curve (NBAUCC) as the evaluation metric rather than the Area Under the Receiver-Operating curve (AUROC; Hendrycks and Gimpel, 2016) and the Area Under the Precision-Recall curve (AUPR; Elflein et al., 2021). The main reason is that we would like to use a threshold as low as possible to detect ODD samples and more details are referred to Kong et al. (2020).

Target. In our experiments, we are interested in answering the following questions:

1. Does THEM achieve better calibration compared to baselines?
2. Does THEM improve OOD detection?
3. The effect of temperature and the size of memory bank on THEM, JEM(CL) and HDGE(CL).

Datasets. We consider the eight datasets of GLUE used in He et al. (2021) to evaluate the ID calibration, since there are no out-of-distribution samples in GLUE. We use the official code[1] to acquire the development and test dataset of GLUE. Furthermore, we consider six more datasets used in Kong et al. (2020) to evaluate both ID calibration and OOD detection. Details of the datasets are in Table 4 and 5 in Appendix.

Baselines. For GLUE datasets, we compare our method against that of He et al. (2021), which is state-of-the-art EBMs on natural language understanding models. Their method is based on Residual-EBM which can work with more flexible energy functions, but the computational cost is also huge compared to our method. We also compare with other three strong baselines for calibration: finetune, Scal-bin and T-scale used in He et al. (2021). For fair comparisons, we follow the experiment settings in their work. We use Roberta as the backbone and the bins of ECE is set to 20.

For the additional six datasets, we compare our methods with nine strong baselines in Kong et al. (2020) including (1) BERT finetuning, (2) Post-calibration method: Temperature Scaling (TS; Guo et al., 2017), (3) Model ensemble: Monte Carlo Dropout (MCDP; Gal and Ghahramani, 2016), (4) Over-confident correction: Label Smoothing (LS; Müller et al., 2019), Entropy Regularized Loss (ERL; Pereyra et al., 2017), Virtual Adversarial Training (VAT; Miyato et al., 2018), and (5) Data-augmentation: Mixup (Zhang et al., 2018), Manifold-Mixup (M-Mixup; Verma et al., 2019), and Manifold-regularization (M-regularization; Kong et al., 2020). We use BERT as the backbone and the bins of ECE is set 15 just as Kong et al. (2020). Besides, we also use NBAUCC as the misclassification evaluation to make fair and

---

[1] We use the official code: `https://github.com/salesforce/ebm_calibration_nlu`

comprehensive comparisons. For these datasets, we don't compare our method with that of He et al. (2021) since it is time-consuming and needs more computational resources to finetune a noise distribution and generate negative samples for NCE training. At last, we use $\text{NBAUCC}_{0.5}$ as the evaluation metric for OOD detection. The OOD datasets often need an ID dataset for training and an OOD dataset for OOD detection evaluation. More details of datasets can be found in Appendix A.

Implementation Details. We employ ADAM (Kingma and Ba, 2014) as the optimizer for all experiments with the following parameters: $\beta_1 = 0.9$, $\beta_2 = 0.999$, gradient clip of 1.0, and L_2 weight decay of 0.1. We search learning rate in $[1\text{e}^{-5}, 2\text{e}^{-5}, 3\text{e}^{-5}, 5\text{e}^{-5}]$ with the training epochs in $[2, 3, 5, 10]$. Our model is built with a classifier on the top of the pretrained language models including BERT (Devlin et al., 2019) and Roberta (Liu et al., 2019) using the implementation of Huggingface (Wolf et al., 2020). For contrastive learning, we set the size of memory bank N to 65536 and the temperature τ to 0.1. All experiments run 5-times and we report the average performance on test dataset. The test result is selected based on loss and accuracy on the development dataset[2]. All experiments are conducted on a single NVIDIA RTX 2080TI 12G GPU. Our implementation is based on the official codes of MoCo[3] and Manifold-regularization[4].

Results on ID Calibration. Table 1 and 2 show the accuracy (acc) and ECE results for GLUE tasks and the six additional datasets respectively, with different baseline methods. Except our proposed THEM, we also include (1) HDGE: $\log p(x|y) + \log p(y|x)$, (2) JEM: $\log p(y|x) + \log p(x)$, (3) IGEMB: $\log p(x|y)$ but trained with contrastive learning (CL) proposed in this paper. These three EBMs are trained by MCMC for images in previous literatures, while we are the first to train them by contrastive learning for NLU tasks.

From Table 1, EBMs with contrastive learning achieves significant improvements on ECE with competitive accuracy, compared to He et al. (2021). He et al. (2021) redefines energy function based on Residual-EBM and estimates parameters using NCE with a finetuned GPT (Radford et al.) on dataset as noise distribution. Not only does it need more computing resources to finetune a GPT model for each dataset, but also the quantity and quality of negative samples generated by noise distribution have big impacts for accurate parameters estimation using NCE (He et al., 2021; Gutmann and Hyvärinen, 2010). In contrast, our model achieves better results with negligible computational resource compared to standard finetuning.

From Table 2, our method achieves the best ECE on six multiclass datasets on various domains. Compared to M-regularization (Kong et al., 2020) which is specifically designed to prevent overconfident predictions for both in-distribution and out-of-distribution, our framework without an explicit calibration mechanism achieves the best ECE, demonstrating the effectiveness of EBMs trained with contrastive learning paradigm. On average, the result of the proposed THEM is very close to the best one in terms of ECE.

Results on OOD Detection. In general, OOD detection is a binary classification problem, where the model is required to produce a score for a data point to detect whether it is an ID or OOD sample. Here we use equation (17) as score function and $\text{NBAUCC}_{0.5}$ as evaluation metric. Table 3 summarizes the $\text{NBAUCC}_{0.5}$ for misclassification detection and OOD detection. It can be seen that compared with all baselines, especially the strong baseline M-regularization (Kong et al., 2020), our method achieves the best misclassification on all data sets with significant improvements. In terms of OOD detection, our results averaged on six datasets are comparable to the performance of M-regularization and are superior to other baselines on all datasets except M-regularization on Yahoo. These results shows that THEM provides a simple yet effective way to improve OOD detection.

Analysis of Generative Density. From Table 1 and Table 2, the generative density including marginal data density $p_\theta(x)$ and class conditional data density $p_\theta(x|y)$ are mainly contributed to the improvements of ID calibration and OOD detection compared to standard finetuning and previous calibration methods. However, different generative terms may have different impacts on final performance. In most NLU tasks, JEM(CL) achieves better ID and OOD calibration performance compared to HDGE(CL) which is different from the experimental results observed in Liu and Abbeel (2020) on

---

[2] Following He et al. (2021), we don't use ECE as the metric to select the best model for evaluation

computer vision tasks. The main reason may lie on the estimation methods that it is more stable and effective to approximate the log-likelihood with contrastive loss compared to MCMC or score-matching for calibration, when the generation ability is not under consideration. While our model achieves comparable ID calibration performance across various datasets on average and better OOD detection.

The hyper-parameters study of InfoNCE on ID calibration and OOD detection. To study the effect of the hyper-parameters including the sample size, and temperature of InfoNCE for training THEM, JEM(CL) and HDGE(CL), we conduct numerous experiments on **20NG**, **Yahoo** and **WOS** dataset. Due to the limited computational resources, we set temperature to 0.1 and vary the size of memory bank from 128 to 65536 to study the effect of the memory bank size on ECE and OOD. Similarly, we set the memory bank size to 65536 and vary the temperature from 0.01 to 0.2 to study the effect of the temperature on ECE and OOD.

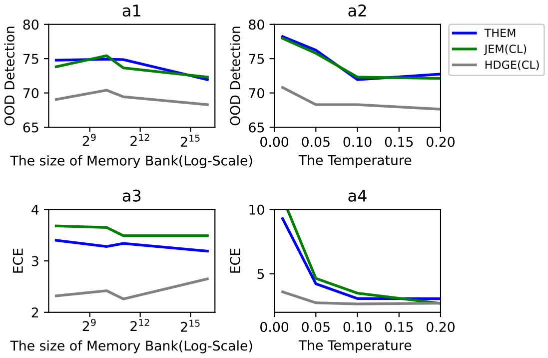

Figure 1: The effect of the memory bank size and temperature for ECE and OOD on **WOS** dataset.

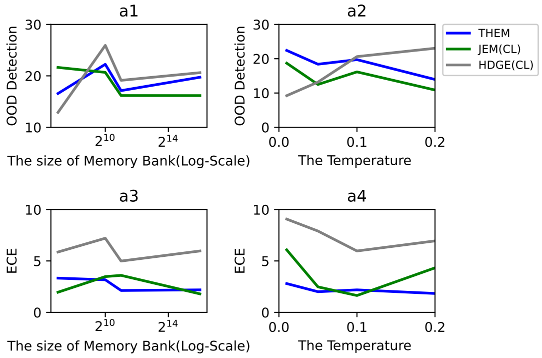

Figure 2: The effect of the memory bank size and temperature for ECE and OOD on **Yahoo** dataset.

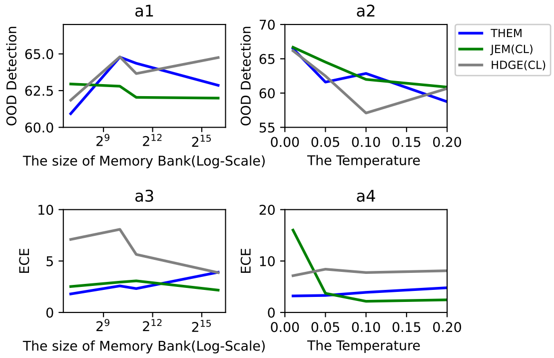

Figure 3: The effect of the memory bank size and temperature for ECE and OOD on **20NG** dataset.

From the trends of memory bank size and temperature on WOS(134-class) in Fig 1, HDGE performs better than THEM and JEM(CL) in terms of ECE. However, it performs significantly worse than THEM and JEM(CL) in terms of OOD. On the other hand, they are all stable in terms of ECE and OOD from the trend of memory bank size.

However, for Yahoo(10-class) in Fig 2 and 20NG(20-class) in Fig 3, from the trend of memory bank size, THEM and HDGE are superior to JEM(CL) in terms of OOD. THEM and JEM(CL) perform better than HDGE in terms of ECE. From the trend of temperature, THEM performs better than JEM(CL) and HDGE in all evaluation metrics. In general, THEM is more stable in terms of ECE from the trend of temperature and memory bank size.

5 Conclusion

In our work, we propose a triple-hybrid EBM with combination of classifier, conditional generative model and marginal generative model into a unified framework called THEM. To train EBMs effectively and efficiently, we leaverage contrastive learning to approximate the log-likelihood of EBMs with negligible computational resources. Extensive experiments demonstrates that our model outperforms the state-of-art methods in terms of ID calibration and OOD detection with competitive accuracy. We further apply contrastive learning to JEM and IGEBM without considering the generation ability to obtain JEM(CL) and IGEBM(CL) respectively. Compared to JEM(CL) and HDGE(CL), our model is more robust to the hyper-parameters of contrastive learning including the temperature and size of memory bank in terms of ID calibration and OOD detection.

6 Limitations

In our work, our model is derived from the perspective of EBMs. However, it lacks of generation ability due to the approximation of log-likelihoods with contrastrive learning which may limit the power of generative modeling such as data augmentation (Grathwohl et al., 2019). We will explore MCMC-based methods such as (Eikema et al., 2021; Qin et al., 2022) to train THEM to take advantage of generative modeling. As for OOD detection, we only use Maximum Prediction Probability. But many other OOD scoring functions are proposed from the perpective of EBMs (Ouyang et al., 2021; Zhou et al., 2021; Liu et al., 2020; Elflein et al., 2021; Grathwohl et al., 2019). And it may be explored in future works to study the OOD performance with different scoring functions.

1. 20NG[5]. The 20 Newsgroups dataset (20NG) contains news articles with 20 categories. We use Stanford Sentiment Treebank (SST-2) (Socher et al., 2012) as the OOD data.
2. 20NG_{15}. We take the first 15 categories of 20NG as the in-distribution data and the other 5 categories (20NG_5) as the OOD data.

---

[5] We use the 20 Newsgroups dataset from: `http://qwone.com/~jason/20Newsgroups/`

3. WOS (Kowsari et al., 2017). Web of Science (WOS) dataset contains 134 categories of scientific articles. We use AGnews (Zhang et al., 2015) as the OOD data.
4. WOS_{100}. We use the first 100 classes of WOS as the in-distribution data and the other 34 classes (WOS_{34}) as the OOD data.
5. Yahoo (Chang et al., 2008). This dataset contains 10 categories posted to 'Yahoo!Answers' of questions. We randomly draw 2000 from 140,000 samples for each category as the training set. We use Yelp (Zhang et al., 2015) as the OOD data.
6. Yahoo_8. We use the first 8 classes of Yahoo as the in-distribution data and the other 2 classes (Yahoo_2) as the OOD data.

A weakly supervised textual entailment approach to zero-shot text classification

Abstract

Zero-shot text classification is a widely studied task that deals with a lack of annotated data. The most common approach is to reformulate it as a textual entailment problem, enabling classification into unseen classes. This work explores an effective approach that trains on a weakly supervised dataset generated from traditional classification data. We empirically study the relation between the performance of the entailment task, which is used as a proxy, and the target zero-shot text classification task. Our findings reveal that there is no linear correlation between both tasks, to the extent that it can be detrimental to lengthen the fine-tuning process even when the model is still learning, and propose a straightforward method to stop training on time. As a proof of concept, we introduce a domain-specific zero-shot text classifier that was trained on Microsoft Academic Graph data. The model, called SCIroShot, achieves state-of-the-art performance in the scientific domain and competitive results in other areas. Both the model and evaluation benchmark are publicly available on HuggingFace[1] and GitHub[2].

1 Introduction

Ever since the first BERT (Devlin et al., 2019) and GPT (Radford et al., 2018) models were introduced to the world, the Transformer (Vaswani et al., 2017) has become the dominant architecture in the Natural Language Processing (NLP) field. As a consequence, in the years that followed, the pretrain-then-finetune paradigm (Howard and Ruder, 2018) has been widely adopted to progressively push the state-of-the-art in a wide variety of downstream tasks and languages (Nozza et al., 2020).

Even though the current training regime is far from being environmentally friendly due to the computational cost of pre-training (Patterson et al., 2021; Strubell et al., 2019), transfer learning removes the need of having to train a new model from scratch for each application. However, the fine-tuning of models for every single task is expensive both in terms of time and money as it is always preceded by a labor-intensive data labelling process (Wang et al., 2021a). In order to overcome this issue, as well as the fact that real world data can be scarce in many scenarios, the field has started to shift towards techniques that require smaller amounts of labelled examples or even none at all (Wang et al., 2021b; Schick and Schütze, 2021; Radford et al., 2019; Brown et al., 2020).

In particular, in the scientific domain, the growing amount of publications in an ever-increasing number of fields makes the classification task very challenging for neural language models (Larsen and Von Ins, 2010; Bornmann et al., 2021). The impossibility to predict the emergence of new fields of study and the high cost associated with the creation of new datasets (which often requires domain experts) generate a need for systems that are capable of adapting to new situations. Furthermore, the complexity and technicality of scientific language makes general-domain models perform poorly in comparison to domain-specific ones (Lee et al., 2020; Cohan et al., 2020).

This work addresses these problems by training an entailment-based zero-shot classifier for scientific text. Instead of using a general domain dataset such as the popular XNLI (Conneau et al., 2018) or MNLI (Williams et al., 2018), a textual entailment dataset of scientific documents was built from scratch in a weakly supervised manner. By training a vanilla model on the entailment task, it is then able to classify documents into unseen classes with a high degree of success. As a by-product of this, the study of the relation between the training and target tasks led to intriguing questions about the strengths and limitations of the entailment approach to Zero-Shot Text Classification (ZSTC).

2 Related Work

Zero-Shot Learning is a widely studied problem in Machine Learning that consists in completing a task for which no training examples were provided. Although the term became initially popular in computer vision (Lampert et al., 2009; Xian et al., 2018), it soon made the leap into NLP with an early paper (Chang et al., 2008) that presented a classifier capable of interpreting the Explicit Semantic Analysis (ESA) representations of documents and labels from a semantic point of view, using Wikipedia as a source of world knowledge.

This highlighted the importance of capturing the labels' semantics in their representations, unlike in conventional text classification where labels are mapped to meaningless indices. This became easier to capture with the arrival of word embeddings, and can be enhanced by simply replacing their name with a short description (Song and Roth, 2014).

In subsequent research, zero-shot tasks were occasionally tackled from another problem's perspective (Levy et al., 2017; Obamuyide and Vlachos, 2018), which implies training a model on a task for which annotated data is available and performing inference on a different one. Recognizing Textual Entailment (RTE) (Dagan et al., 2005) is arguably the most versatile task because of its generality, which is why it is commonly used to model other downstream tasks (Wang et al., 2021b).

The most popular approach at the time of writing is to reformulate ZSTC as a textual entailment problem as proposed by Yin et al. (2019), aiming to imitate the way humans would address this Natural Language Understanding task. The underlying idea is that a model trained on the entailment task should be able to perform classification of unseen classes by computing the entailment score between the input text, which acts as a premise, and candidate labels conveniently converted into hypotheses.

Later research showed that the Next Sentence Prediction (NSP) objective for sentence pair classification can also be used as a strong baseline for ZSTC, since competitive results where obtained using raw BERT models that were not fine-tuned on any Natural Language Inference (NLI) data (Ma et al., 2021). Even though entailment-based zero-shot text classifiers have shown to have certain limitations like a high instability or an excessive reliance on spurious lexical patterns, the current literature offers no better alternatives for a problem that is still far from being mastered by machines.

3 Creation of weakly supervised data

This section describes the methodology followed to transform a text classification dataset into entailment data that could potentially be used to fine-tune a domain-specific (or not) zero-shot text classifier. This approach takes advantage of the fact that there are plenty of publicly accessible labelled examples for classification while there is not so much available for entailment tasks, most likely due to the difficulty of producing this type of data.

In this work, a weakly supervised NLI dataset was constructed using Microsoft Academic Graph[3] (MAG) data as a starting point. To do so, all labels were converted to natural language sentences that would serve as hypotheses. Therefore, the generated training examples consist of pairs of sequences (premise and hypothesis) that are delimited by EOS tokens, where the first part of the text contains the abstract section from a scientific publication (premise) and the second part is an artificially generated sentence that somehow embeds the class label of the scientific text (hypothesis). Table 1 shows this idea in a simplified form.

Input Sequence	Label
<s>Text1</s></s>This example is X</s>	1
<s>Text1</s></s>This example is Y</s>	0
<s>Text2</s></s>This example is Z</s>	1

Table 1: Format of the training examples. The label is 1 if the premise entails the hypothesis and 0 otherwise.

Once the classification data has been turned into the entailment format, any model can be fine-tuned by predicting whether the premise of each input sequence entails the corresponding hypothesis or not. Note however that this is rather an adaptation of the RTE task, since the second sentence does not really "entail" the first in positive examples. It is basically like performing a text classification task where labels are not converted into numeric indices, ensuring that their semantic content is preserved.

Figure 1 illustrates how a ZSTC model would operate both during fine-tuning (left) and at inference time (right), providing a full picture of the methodology followed in this work. We basically adopt the approach introduced by Yin et al. (2019) but going one step further by fine-tuning on a weakly supervised domain-specific dataset instead of using already existing general-domain NLI data.

---

[3] `https://academic.microsoft.com/`

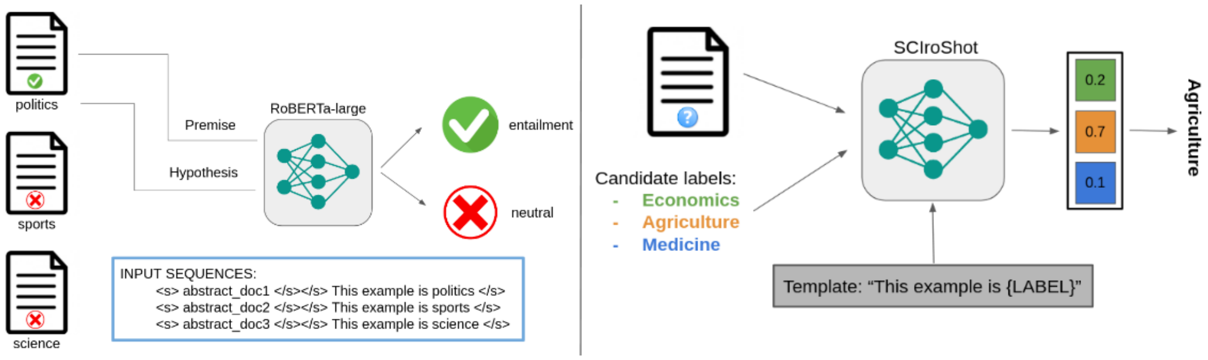

Figure 1: Overview of the entailment approach to ZSTC. On the left hand side it can be seen how the model is fine-tuned on a two-class textual entailment task, by providing the input text as a premise and the label name embedded in a natural language sentence that represents the hypothesis. On the right, the trained model classifies documents into unseen classes by computing the entailment score between the input text and each candidate label.

4 Data

4.1 Training Dataset

As mentioned in Section 3, our training dataset builds on top of scientific-domain annotated data from Microsoft Academic Graph (Sinha et al., 2015). This database consists of a heterogeneous graph with billions of records from both scientific publications and patents, in addition to metadata information such as the authors, institutions, journals, conferences and their citation relationships. The documents are organized in a hierarchical structure composed of hundreds of thousands of scientific concepts, creating a six-level hierarchy with a subsumption-based model (Shen et al., 2018), although the two top-most levels are manually curated to guarantee accuracy. As an example, the 0-level field of study (FoS) in the MAG taxonomy covers the following 19 scientific concepts: {*Art, Biology, Business, Chemistry, Computer Science, Economics, Engineering, Environmental Science, Geography, Geology, History, Materials Science, Mathematics, Medicine, Philosophy, Physics, Political Science, Psychology, Sociology*}.

Dataset	Labels	Examples
train	240	2,104,493
dev$_{\text{seen}}$	240	233,833
dev$_{\text{unseen}}$	52	5,200
Total	292	2,343,526

Table 2: Number of labels and examples in the train and development sets of our dataset. Note that the 240 labels from the train and dev$_{\text{seen}}$ set are the same, while the 52 labels from the dev$_{\text{unseen}}$ set were purposely kept aside for *label-fully-unseen* setups.

Due to the descriptive broadness of the 0-level MAG taxonomy, we have created our training corpus focusing exclusively the 1-level MAG taxonomy, which is composed of 292 FoS classes. The higher granularity of this level provides more descriptive information in the form of narrower scientific concepts, such as "*Computational biology*", "*Transport engineering*" or "*Civil engineering*".

Using the relationship between scientific texts and their matching concepts in the 1-level MAG taxonomy we are able to generate the premise-hypothesis pairs corresponding to the entailment label. Conversely, we generate the pairs for the neutral label by removing the actual relationship between the texts and their scientific concepts and creating a virtual relationship with those to which they are not matched (see Table 3).

Input Sequence	Label
One plus one is two.	Maths
Cancer is a disease.	Health
One plus one is two. This text is Maths.	entails
One plus one is two. This text is Health.	neutral
Cancer is a disease. This text is Maths.	neutral
Cancer is a disease. This text is Health.	entails

Table 3: Toy example of the initial classification dataset (top) and the adapted entailment dataset (bottom).

For each of the 292 classes, a random sample of scientific articles with a publication year between 2000 and 2021 was extracted with their respective titles and abstracts in English. We have collected a maximum of 5k and 10k positive and neutral textual entailment samples, respectively, for each of the possible 1-level FoS classes. In total, SCIroshot has been fine-tuned using 919k documents with a total of 465M words. In order to perform experiments in *label-fully-unseen* setups, the examples associated to 52 labels were kept aside. For computational reasons, the size of the development set was reduced considerably to the point that it became a fully balanced set of 100 examples per class. The number of labels and examples of each set are summarized in Table 2.

4.2 Evaluation Datasets

We evaluate the performance of our models on a collection of disciplinary-labeled textual datasets. For the in-domain evaluation, we gathered cross-disciplinary and domain-specific datasets of scientific publications. For the out-of-domain case, we use the three datasets from the benchmark provided by Yin et al. (2019), which study 3 aspects of ZSTC: topic categorization (Yahoo! Answers), emotion detection (UnifyEmotion) and situation frame detection (Situation Typing). Table 4 provides an overview of the number of examples and labels for each dataset.

Dataset	Labels	Examples
arXiv	11	3,838
SciDocs-MeSH	11	16,433
SciDocs-MAG	19	17,501
Konstanz	24	10,000
Elsevier	26	14,738
PubMed	109	5,000
Yahoo! Answers	10	60,000
UnifyEmotion	10	15,689
Situation Typing	12	3,311

Table 4: Statistics of each dataset from the scientific-domain (top) and general-domain (bottom) benchmarks.

4.2.1 Scientific-domain datasets

arXiv (**He et al., 2019**). 11-label dataset of papers from the arXiv repository. The labels are a set of sub-categories within the branches of Computer Science and Mathematics. While the original dataset contains the full publication texts, we only gathered titles and abstracts from the 3,838 publications for which a DOI was available in the API[4].

SciDocs-MeSH (**Cohan et al., 2020**). Over 16k papers from the medical domain. Each paper is assigned one of 11 high-level disease classes derived from the MeSH vocabulary (Lipscomb, 2000).

SciDocs-MAG (**Cohan et al., 2020**). More than 17k cross-disciplinary publications labelled using the 0-level MAG taxonomy (Wang et al., 2020). None of the labels are included in our training data.

Konstanz[5]. 10k journal articles produced by researchers at the University of Konstanz, extracted from the Konstanz Online Publication System (KOPS). Publications from this open-access repository are manually labelled by the research staff with a category taken from the DDC taxonomy (Dewey, 1876), which unfolds into more than 30 classes describing different scientific domains. We only consider English journal articles labelled within a reduced set of 24 categories.

Elsevier (**Kershaw and Koeling, 2020**). Cross-disciplinary corpus of 14.7k open access articles from Elsevier's journals. The document labels are given by their ASJC Subject Classification scheme, which links publication venues (and, transitively, each single publication) to 27 scientific subject domains. We removed all publications labelled with more than 1 subject area. Publications annotated with the non-informative "*Multidisciplinary*" label were removed as well.

PubMed[6]. We collected 5k publications labelled with a manually-selected subset of 109 MeSH terms within the *Disciplines and Occupations* and *Technology, Industry, and Agriculture* branches of the MeSH taxonomy. The chosen categories are general-domain and well-known concepts out of specific medical terminology, as most MeSH terms.

4.2.2 Out-of-domain datasets

Yahoo! Answers (**Zhang et al., 2015**). Topic categorisation dataset with questions and their corresponding best answer in *Yahoo! Answers*. We only use the test set, which consists of 60k examples that belong to exactly one of the 10 largest main categories in the website.

UnifyEmotion (**Oberländer and Klinger, 2018**). Emotion detection dataset with texts from a variety of sources (tweets, emotional events, tales, and artificial sentences) classified into 9 emotions and "none" when no emotion fits the case. We use the modified version from Yin et al. (2019), which removes all multi-label instances.

Situation Typing (**Mayhew et al., 2019**). Multi-label event-type classification dataset of 11 classes, designed for low-resource situation detection.

5 Experiments

5.1 Design choice

The newly-created scientific dataset from Section 4.1 was used to fine-tune a 355M parameters RoBERTa (Liu et al., 2020) and a 400M parameters BART (Lewis et al., 2020) models, in an attempt to determine which architecture (i.e. encoder or encoder-decoder) is best suited for the task at hand. As already noted in section 4.1, 52 labels from the training data were kept apart so that they could be used as a development set of fully-unseen classes. For a given input text, the entailment score with each candidate label has to be computed by the model. The final prediction will be the highest scoring class in a single-label classification setup, or the *N* classes above a certain threshold in a multi-label scenario. Table 5 shows the accuracy score of the last checkpoints evaluated in RTE's dev_{seen} set as well as the ZSTC $\text{dev}_{\text{unseen}}$ set.

Model	**RTE**	**ZSTC**
RoBERTa-large	98.00	48.78
BART-large	98.30	45.69

Table 5: Accuracy scores of our two models in the Recognizing Textual Entailment (RTE) and Zero-Shot Text Classification (ZSTC) tasks.

Even though both models achieved a similar accuracy in the entailment task, we could not help noticing that the best performing model on RTE (even if only by a small margin) was doing worse on ZSTC by three full points. This raised a concern as to whether our fine-tuning task, which at the end is no more than an adaptation of the real RTE, was positively correlated with the target task of ZSTC or not.

5.2 Correlation between the RTE-ZSTC tasks

In order to verify the correlation between both tasks, we conducted an exhaustive evaluation of all checkpoints using the 52-labels $\text{dev}_{\text{unseen}}$ set.

As it can be observed in Figure 2, after a certain point the performance in the ZSTC task begins to gradually worsen while on RTE it is still getting better at a slow but steady pace. This means that somehow, as the training progresses, the model forgets the meaning of the unseen labels, with the exception of the initial checkpoints where an exponential growth is experienced simultaneously in both tasks. We can observe a peak ZSTC performance when the model has an evaluation RTE score of roughly 0.96. Despite the high variability, it is clear that from that point onwards the zero-shot capacities of the model decrease. To mitigate this effect we propose an early stopping technique.

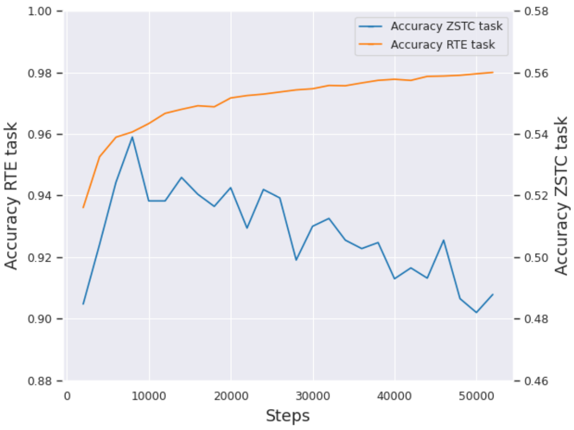

Figure 2: Accuracy scores obtained by the RoBERTa-large checkpoints. Each y-axis represents a different range of accuracies for better visualization.

5.3 Early stopping

We concluded that, at training time, the validation of the model should be done on the target task rather than the training task. This way the training process can be interrupted as soon as the model stops improving on ZSTC, something that we expect to happen at an earlier stage. We propose to evaluate each checkpoint on the subset of 52 unseen classes described in Section 4.1 and use early stopping with a patience of 10.

Model	**RTE**	**ZSTC**
$\text{RoBERTa-large}_{\text{last}}$	**98.00**	48.78
$\text{RoBERTa-large}_{\text{selected}}$	96.07	**53.90**
$\text{BART-large}_{\text{last}}$	**98.30**	45.69
$\text{BART-large}_{\text{selected}}$	96.59	**52.76**

Table 6: Accuracies in the RTE and ZSTC tasks. The *last* subscript indicates that it was the last checkpoint stored during fine-tuning, while the *selected* subscipt refers to the checkpoint selected with early stopping.

In Table 6 it is clear that the early stopping technique improves the results in the ZSTC evaluation task, since both architectures obtain a substantial boost when early stopping is applied. Overall, the RoBERTa-large model performs better than BART-large, what we hypothesize that might be caused by a loss of generality from models that achieve higher scores in the RTE task.

Model	**arXiv**	**SciDocs-MesH**	**SciDocs-MAG**	**Konstanz**	**Elsevier**	**PubMed**
fb/bart-large-mnli	33.28	**66.18**	51.77	54.62	28.41	**31.59**
bart-large-rte$_{\text{selected}}$	36.71	56.57	63.98	63.57	48.48	27.46
bart-large-rte$_{\text{last}}$	28.58	44.21	57.75	62.25	42.51	21.72
SCIroShot$_{\text{selected}}$	**42.22**	59.34	**69.86**	**66.07**	**54.42**	27.93
SCIroShot$_{\text{last}}$	35.44	52.27	65.27	60.74	50.92	22.85

Table 7: Label wise weighted F1 score of different models in our scientific benchmark. For simplicity, the hypothesis template was set to *"This example is {}."* in all cases.

6 Results

This section assesses the performance of our zero-shot classifiers, which were trained on a weakly supervised entailment dataset of scientific text. In an effort to obtain a more complete picture, we perform both an in-domain and out-of-domain study.

6.1 Scientific domain

For an in-domain evaluation, the in-house generated scientific benchmark from Section 4.2.1 was used. We compare our SCIroShot with the strong baseline set by Facebook's *bart-large-mnli* model[7]. This NLI-based model is the most downloaded zero-shot classifier in the HuggingFace Hub (over 1M monthly downloads) and the one used by default in the *zero-shot-classification* pipeline from their transformers library (Wolf et al., 2020). For an apples-to-apples comparison, we also consider a BART-large model that was trained following the same methodology employed for SciroShot, as it has the same architecture as the Facebook model.

The results presented in Table 7 prove the importance of domain-specific training, something that has been repeatedly seen in traditional text classification. The models trained on MAG data obtain the best results in four out of six datasets, by large margins in all cases, and interestingly enough the Facebook model only wins in the two medical datasets: PubMed and SciDocs-MeSH. The numbers also support our theory that too much training can be detrimental, as the models selected with early stopping score higher than their "last" counterpart in all cases.

6.2 General domain

For the out-of-domain study, we include ourselves in the benchmark proposed by Yin et al. (2019). This amounts to a total of three datasets that cover a variety of topics, with classes ranging from news article topics to human emotions.

(Yin et al., 2019)	Topic	this text is about {}
	Emotion	this text expresses {}
	Situation	The people there need {}
(Ma et al., 2021)	Topic	It is related with {} .
	Emotion	This person feels {} .
	Situation	The people there need {} .
SCIroShot (ours)	Topic	This example is {}
	Emotion	
	Situation	

Table 8: Hypothesis templates used for each dataset. The {braces} indicate the label name location.

The results reported in Table 9 show that our SCIroShot model is competitive in other domains as well. Actually, it is quite impressive that it was able to outperform the rest in two tasks and obtain the second highest score in the third one.

It is important to note that the Situation dataset has the added difficulty of being multi-label, meaning that a piece of text can be linked to an arbitrary number of labels. In a single-label setting, softmax is applied over all the labels logits (so that they sum up to one) and the highest scoring class is chosen as the final prediction. On the other hand, when performing multi-label classification, the softmax function is applied to each label separately (so they are independent variables that do not add up to one) and all labels with a probability above a certain threshold are selected. We did not tune such threshold, so the model's predictions included all labels with a score higher than 0.5.

7 Analysis

7.1 RTE vs ZSTC in the scientific benchmark

This section analyses the relation between the training task and the ZSTC task to assess the effectiveness of the early stopping technique presented in Section 5.3. We evaluate every checkpoint in our ZSTC Scientific Benchmark in the same way that several models were evaluated in Section 5.2.

---

[7] `https://huggingface.co/facebook/bart-large-mnli`

Model	Topic	Emotion	Situation
RTE (Yin et al., 2019)	43.8	12.6	**37.2**
FEVER (Yin et al., 2019)	40.1	24.7	21.0
MNLI (Yin et al., 2019)	37.9	22.3	15.4
NSP (Ma et al., 2021)	50.6	16.5	25.8
NSP (Reverse) (Ma et al., 2021)	53.1	16.1	19.9
$\text{SCIroShot}_{\text{last}}$	51.51	22.63	23.70
$\text{SCIroShot}_{\text{selected}}$	**59.08**	**24.94**	27.42

Table 9: Results obtained in the general benchmark. Accuracy is used for Topic classification and label-wise weighted F1 for the rest. For simplicity, the hypothesis template was set to "This example is ." in all cases.

Figures 3 and 4 corroborate our hypothesis that the performance in the ZSTC task does not necessarily improve hand-by-hand with the performance on RTE. Taking a closer look to the plots we can appreciate how the ZSTC accuracy drops after the model reaches an accuracy of 96% on RTE. The checkpoints selected using the early stopping technique based on the ZSTC task achieve 96.07% RTE accuracy in the case of RoBERTa-large and 96.60% for BART-large. We argue that, although the selected checkpoints are not the best possible option for all the datasets in the benchmark, our technique has stopped training before the overall ZSTC performance diminishes, and it has done so using a subset of unseen labels from the training dataset. This implies obvious savings in time and computation that would otherwise have been wasted for no good reason.

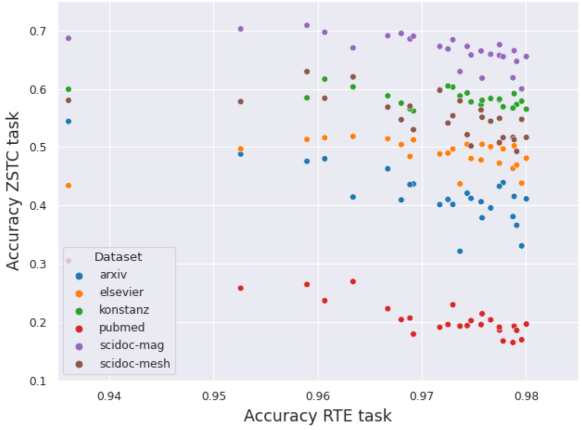

Figure 3: Evaluation of all RoBERTa-large checkpoints in the training (RTE) and testing (ZSTC) tasks.

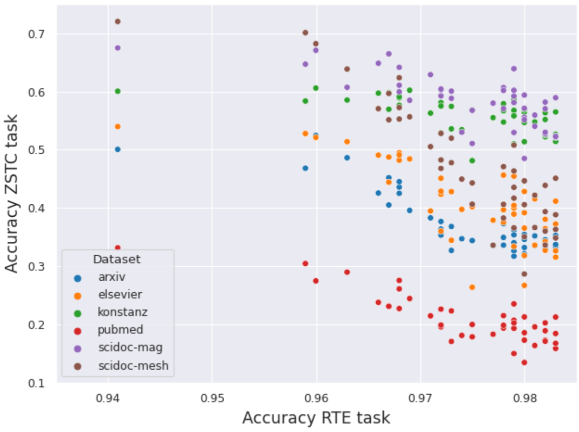

Figure 4: Evaluation of all BART-large checkpoints in the training (RTE) and testing (ZSTC) tasks.

7.2 Robustness to hypothesis templates

This section is an attempt to measure the importance of the hypothesis template and its impact on the final performance of a zero-shot model. With this goal in mind, we evaluate our SCIroShot and Facebook's *bart-large-mnli* with two hypothesis templates that are virtually the same: "*This example is {LABEL}*" and "*This example is {LABEL}.*". Note that their semantic content is exactly the same, being the only difference that the first template does not contain a punctuation mark at the end.

Figure 5 shows that SCIroShot is quite robust against changes in the hypothesis template. On the other hand, as it can be seen in Figure 6, *bart-large-mnli* can experience severe performance drops caused by an apparently insignificant change in the template. We hypothesize that this might happen because the model was trained with high-quality NLI data where dots were always present at the end of the hypothesis, and thus it is not used to the absence of these type of anchor tokens. It can also be inferred that our training task is quite robust to different hypothesis templates.

We would like to point out that the high sensitivity of the Facebook model was accidentally detected during our experiments. We noticed that using our default template the model obtained sur-

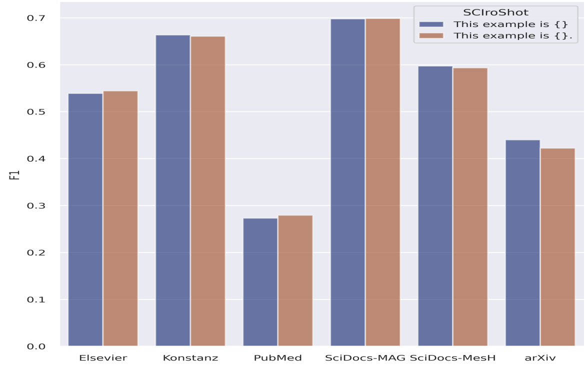

Figure 5: SCIroShot performances when using slightly different hypothesis templates.

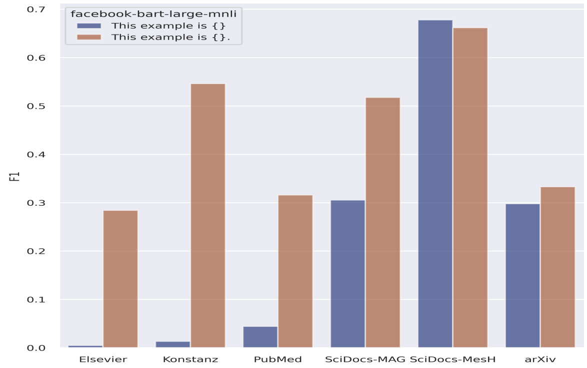

Figure 6: Facebook's bart-large-mnli performances when using slightly different hypothesis templates.

prisingly low results in several tests, something highly unexpected considering its great capabilities. In pursue of intelectual honesty, we decided to report the results obtained with the template that best suited the model's interests. The exact same template was given to our models so that there was one less thing to take into account when comparing performances, even though it might not be the one providing the best results.

Conclusion

The benefits offered by a zero-shot text classifier are four-pronged: (i) it removes the need for time-consuming annotation processes carried out by domain experts, (ii) reduces the computational cost of having to fine-tune a model for each application, (iii) allows the classification of documents in real-world scenarios where there is a scarcity of data, and (iv) is able to handle new classes that might not even have existed at the time of training.

This work proposes the usage of readily available classification datasets for effortless generation of entailment data, which can be used to train ZSTC models. By not using conventional RTE datasets of generic nature, the resulting model exhibits superior performance in the domain for which it has been trained. We show that this is the case for the scientific domain, but the idea could certainly be extrapolated to other fields (e.g. a model trained on news articles should excel at topic classification of this kind of documents). As a proof of concept, we present a scientific-domain zero-shot text classifier that achieves state-of-the-art performance in the scientific domain and competitive results in other areas.

Furthermore, our experiments and analysis suggest that entailment-based classifiers are no panacea: they are very sensitive to the input sequences and do not exhibit the linear correlation that one would expect between the performance on the training (RTE) and testing (ZSTC) tasks. We have empirically proven that the model can become worse at ZSTC as it improves in RTE, which is counter-intuitive and goes against the idea of entailment being a unified method to model other downstream tasks. Our analysis also show that our technique does not suffer from the instability observed in models trained with conventional RTE datasets, which can occasionally experience severe performance drops with minor changes such as removing a punctuation mark from the hypothesis template.

Future Work

In future work, we will further investigate the correlation between different tasks as this could only be the tip of the iceberg. It might also be interesting to increase the difficulty of the fine-tuning task by working with thousands of fine-grained labels from deeper levels of the MAG taxonomy, aiming to delay the point at which the model performance starts worsening in the ZSTC task.

Our findings also motivate an interesting research direction that we would like to explore: employing novel prompt tuning techniques to find the ideal hypothesis template. Having seen that zero-shot text classifiers experience dramatic performance drops caused by apparently insignificant modifications in the hypothesis text, it is clear to us that there is a need to find a suitable text in an automatic manner. We consider this to be a major pitfall of zero-shot models, and thus we are willing to study the feasibility of applying prompt tuning to this particular case as future work.

Limitations

Our main limitations had to do with time and computational constraints. Given the low efficiency of entailment-based classifiers, which need to execute a forward pass per class, the time required to traverse certain datasets was simply too high. Specially when the number of candidate labels is large, because every sequence-label pair has to be fed through the model to compute the logits of all possible combinations. This low ability to scale is certainly a drawback with respect to traditional classifiers, and the reason that forced us to discard datasets with over 500 labels as well as a few experiments that we intend to leave for future work.

Ethics Statement

We believe that this work meets the ACL Code of Ethics as it provides an already trained zero-shot text classifier that can be used in an endless number of situations that would otherwise require a task-specific fine-tuning. Moreover, one of the main findings of this work is that entailment-based text classifiers should not be over-trained as it negatively affects their final performance. This should encourage fellow NLP practitioners to shorten the training time of their ZSTCs thus minimizing their carbon footprint, which is in line with the idea of moving towards more sustainable language models.

Acknowledgements

This work has received funding from two projects within the European Union's Horizon 2020 research and innovation programme.

The work carried out by Barcelona Supercomputing Center was funded by the IntelComp project, under grant agreement number 101004870.

The work carried out by SIRIS Academic was partially funded by the INODE project, under grant agreement number 863410.

Fair Enough: Standardizing Evaluation and Model Selection for Fairness Research in NLP

Xudong Han[1,2] **Timothy Baldwin**[1,2] **Trevor Cohn**[1]

Abstract

Modern NLP systems exhibit a range of biases, which a growing literature on model debiasing attempts to correct. However current progress is hampered by a plurality of definitions of bias, means of quantification, and oftentimes vague relation between debiasing algorithms and theoretical measures of bias. This paper seeks to clarify the current situation and plot a course for meaningful progress in fair learning, with two key contributions: (1) making clear inter-relations among the current gamut of methods, and their relation to fairness theory; and (2) addressing the practical problem of model selection, which involves a trade-off between fairness and accuracy and has led to systemic issues in fairness research. Putting them together, we make several recommendations to help shape future work.[1]

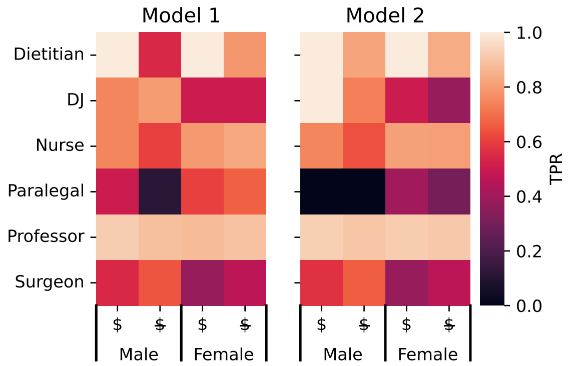

Figure 1: True positive rate (TPR) evaluation results over a biography classification dataset broken down by author demographic and selected profession classes. $ and ~~$~~ denote the economic status (wealthy vs. not, respectively). The pattern of results exhibits various biases, however it is difficult to distil this into a single figure of merit, and thus determine which is the better or fairer of the two models.

1 Introduction

In NLP and machine learning, there has been a surge of interest in fairness due to the fact that models often learn and amplify biases in the training dataset, leading to a range of harms (Badjatiya et al., 2019; Díaz et al., 2018). A central notion is group-wise fairness (Dwork et al., 2012; Chouldechova, 2017; Berk et al., 2021), which is typically measured as the model performance disparities across groups of data that are created by the combinations of protected attributes, such as race and gender. A broad range of bias evaluation metrics have been introduced in previous studies to capture different types of biases – such as *demographic parity* (Feldman et al., 2015) and *equal opportunity* (EO) (Hardt et al., 2016) – and different approaches have been adopted to both measure group disparities within each class, and aggregate over those disparities. Each of these choices implicitly encodes assumptions about the nature of fairness, but little work has been done to spell out what those assumptions are, or guide the selection of evaluation metric from first principles of what constitutes fairness.

As an illustration of this issue, Figure 1 depicts the true positive rate (TPR) values for two models.[2] Given that the EO fairness is satisfied if different groups achieve identical TPR, which model is fairer or "better" out of the two? The answer is far from clear, and in terms of evaluation practice, dictated by a series of choices which implicitly encode different assumptions about what fairness is.

In terms of research practice, these choices have led to a lack of consistency and direct empirical comparability between methods. Equally concerningly, given that fairness research involves an inherent trade-off between raw model performance and fairness, it has more subtly led to a lack of rigour in terms of how model selection has been carried out, meaning that methods are often deployed in

suboptimal ways relative to a particular evaluation methodology.

In this paper, we seek to address these problems. We start by surveying current practices for fairness evaluation aggregation within an integrated framework, and discuss considerations and motivations for using different aggregation approaches. To ensure fairness metrics are fully comparable, we present a checklist for reporting fairness evaluation metrics, and also recommendations for aggregation method selections. We next survey model comparison methods, and demonstrate the issues stemming from using inconsistent model selection criteria. To ensure fair comparisons, we further introduce a metric for comparison without model selection, which measures the area under the trade-off curve of each method.

Overall this paper makes two key contributions: (1) we characterise current practices for fairness evaluation and their grounding in theory, proposing a best-practice checklist; and (2) we propose a new method which resolves several issues relating to model selection and comparison.

2 Related Work

In terms of bias metrics, there are mainly two lines of work in the literature on NLP fairness: bias in the geometry of text representations (intrinsic bias), and performance disparities across groups in downstream tasks (extrinsic bias), respectively. Based on the hypothesis that measuring and mitigating intrinsic bias will also reduce extrinsic bias, previous work has mainly focused on measuring and mitigating intrinsic bias, such as the Word Embedding Association Test (WEAT) (Caliskan et al., 2017), Sentence Encoder Association Test (SEAT) (May et al., 2019), and Embedding Coherence Test (ECT) (Dev and Phillips, 2019). However, Goldfarb-Tarrant et al. (2021) recently showed that there is no reliable correlation between intrinsic and extrinsic biases, and suggest future work focusing on extrinsic bias measurement (which is the focus of this work).

As for bias mitigation, debiasing methods for intrinsic and extrinsic bias generally suffer from performance–fairness trade-offs controlled by particular hyperparameters such as the number of principal components used to define the intrinsic bias subspace (Bolukbasi et al., 2016), and the strength of addition objectives for performance parity across groups (Shen et al., 2022b). In measuring performance (perplexity and LM score for sentence embeddings, for example) and fairness simultaneously, the model comparison framework presented in this paper is generalizable for both intrinsic and extrinsic fairness.

3 Fairness Metrics

In this section, we discuss the considerations involved in fairness evaluation. We start with a survey of different methods for aggregating scores, and propose a two-step aggregation framework for fairness evaluation.

3.1 Formal Notation Preliminaries

We consider fairness evaluation in a classification scenario. Evaluation is based on a test dataset consisting of n instances $\mathcal{D} = \{(\boldsymbol{x}_i, \mathrm{y}_i, \mathrm{z}_i)\}_{i=1}^{n}$, where $\boldsymbol{x}_i$ is an input vector, $\mathrm{y}_i \in \{\mathrm{c}\}_{\mathrm{c}=1}^{\mathrm{C}}$ represents target class label, and $\mathrm{z}_i \in \{\mathrm{g}\}_{\mathrm{g}=1}^{\mathrm{G}}$ is the group label, such as gender.[3]

Given a model that has been trained to make predictions w.r.t. the target label $\hat{\mathrm{y}} = f(\boldsymbol{x})$, fairness evaluation metrics generally measure group-wise performance disparities for a particular metric $m(\mathrm{y}, \hat{\mathrm{y}})$. For example, positive predictive rate and true positive rate have been employed as the metric for demographic parity (Feldman et al., 2015) and equal opportunity (Hardt et al., 2016), respectively.

For each group, the results of a metric m are C-dimensional vectors, one dimension for each class. Given G protected groups, the full results are organized as a C × G matrix, denoted as $\boldsymbol{M}$. For the subset of instances $\mathcal{D}_{\mathrm{c,g}} = \{(\boldsymbol{x}_i, \mathrm{y}_i, \mathrm{z}_i) | \mathrm{y}_i = \mathrm{c}, \mathrm{z}_i = \mathrm{g}\}_{i=1}^{n}$, we denote the corresponding evaluation results as $M_{\mathrm{c,g}}$. Taking Figure 1 as an example, $\boldsymbol{M}$ refers to the heatmap plot, and $M_{\mathrm{c,g}}$ is the cell in the c-th row and g-th column.

Given $\boldsymbol{M}$, the question is how exactly to aggregate the result matrix as a single number that measures the degree of fairness. We split the aggregation into two steps: (1) group-wise aggregation, which aggregates evaluation results of all groups within a class ($[M_{\mathrm{c},1}, \ldots, M_{\mathrm{c,G}}]$) into a single number ($\beta_{\mathrm{c}}$); and (2) class-wise aggregation, which aggregates $[\beta_1, \ldots, \beta_{\mathrm{C}}]$ scores of all classes into a single number δ.[4]

---

[3] When considering multiple protected attributes, z can be intersectional identities as shown in Figure 1.

[4] Mathematically, it would be possible to do the class-wise aggregation first, and then the group-wise aggregation. However, aggregating class-wise performances within a particular group essentially measures the long-tail learning problem

Aggregation	Method	Description	Unit	Reference
Group-wise	mean gap	$\beta_{\mathrm{c}} = \frac{1}{\mathrm{G}} \sum_{\mathrm{g}} \lvert M_{\mathrm{c,g}} - \overline{M}_{\mathrm{c}} \rvert$	G	(Shen et al., 2022b)
	variance	$\beta_{\mathrm{c}} = \frac{1}{G-1} \sum_{\mathrm{g}} \lvert M_{\mathrm{c,g}} - \overline{M}_{\mathrm{c}} \rvert^2$	G	(Lum et al., 2022)
	max gap	$\beta_{\mathrm{c}} = \max_{\mathrm{g}} \lvert M_{\mathrm{c,g}} - \overline{M}_{\mathrm{c}} \rvert$	G	(Yang et al., 2020)
	min score	$\beta_{\mathrm{c}} = \min_{\mathrm{g}} M_{\mathrm{c,g}}$	S	(Lahoti et al., 2020)

	mean	$\delta = \frac{1}{\mathrm{C}} \sum_{\mathrm{c}} \beta_{\mathrm{c}}$	β	(Li et al., 2018)

Table 1: Summary of different aggregation approaches. Based on the basic unit, group-wise aggregations are additionally categorized into three types: **S**core ($M_{\mathrm{c,g}}$), **G**ap ($|M_{\mathrm{c,g}} - \overline{M}_{\mathrm{c}}|$), and **R**atio ($\frac{M_{\mathrm{c,g}}}{\overline{M}_{\mathrm{c}}}$).

3.2 Existing Aggregation Approaches

Table 1 summarizes several aggregation approaches from previous work, which are categorized based on the level of aggregation.

3.2.1 Basic Unit

The **basic unit** refers to the inputs to an aggregation function.

Group-wise Broadly, there are three types of basic units for group-wise aggregation:

1. the original **score** ($M_{\mathrm{c,g}}$), which maintains the actual performance level under aggregation and larger is better;
2. the **gap**, i.e., absolute difference, between the evaluation results of a group and the average performance ($|M_{\mathrm{c,g}} - \overline{M}_{\mathrm{c}}|$), where smaller is better and the minimum is 0; and
3. **ratio** of the evaluation results of a group to the average ($\frac{M_{\mathrm{c,g}}}{\overline{M}_{\mathrm{c}}}$), where closer to 1 is better.

Score describes the actual performance of each group, and is generally used to measure extrema of actual performances. For example, the *Rawlsian Max Min* criterion (Rawls, 2001) is satisfied if the utility of the worst-performing group is maximized. Related fairness notions are also known as per-group fairness (Hashimoto et al., 2018; Lahoti et al., 2020).

The other two units, **gap** and **ratio**, support the notion of group fairness, and evaluate whether or not ŷ is fair w.r.t. z. Taking EO (Hardt et al., 2016) as an example, it requires the true positive rate to be independent of z. Formally, for a particular class c, the EO criterion is satisfied iff

$$\mathrm{TPR}_{\mathrm{c,g}} = \overline{\mathrm{TPR}}_{\mathrm{c}}, \forall \mathrm{g} \in \{\mathrm{g}\}_{\mathrm{g}=1}^{\mathrm{G}}.$$

As such, it is straightforward to directly measure the absolute difference between $\mathrm{TPR}_{\mathrm{c,g}}$ and $\overline{\mathrm{TPR}}_{\mathrm{c}}$,

$$\mathrm{TPR}_{\mathrm{c,g}} = \overline{\mathrm{TPR}}_{\mathrm{c}} \Leftrightarrow |\mathrm{TPR}_{\mathrm{c,g}} - \overline{\mathrm{TPR}}_{\mathrm{c}}| = 0,$$

which is essentially the **gap** unit.

Alternatively, the **ratio** unit can be used to measure inequality as a percentage:

$$\mathrm{TPR}_{\mathrm{c,g}} = \overline{\mathrm{TPR}}_{\mathrm{c}} \Leftrightarrow \frac{\mathrm{TPR}_{\mathrm{c,g}}}{\overline{\mathrm{TPR}}_{\mathrm{c}}} = 1.$$

Ratio-based scores can also be interpreted via a "$q\%$-rule" (Zafar et al., 2017; Barocas et al., 2019), for example, the 80%-rule for *disparate impact* (Feldman et al., 2015), which requires that the ratio is no less than 0.8.

The $q\%$-rule can be captured more explicitly by a threshold (Kearns et al., 2018; Barocas et al., 2019), which is a relaxation of the equality based on a slack threshold $\epsilon \in \mathbb{R}^{+}$, $|1 - \frac{\mathrm{TPR}_{\mathrm{c,g}}}{\overline{\mathrm{TPR}}_{\mathrm{c}}}| \leq \epsilon$. Similarly, the threshold can be applied to **gap**, resulting in $|\mathrm{TPRc, g} - \overline{\mathrm{TPR}}_{\mathrm{c}}| \leq \epsilon$.

Class-wise The next step is class-wise aggregation, taking the group-wise aggregation for each class from above as inputs, $[\beta_1, \ldots, \beta_{\mathrm{C}}]$.

3.3 Generalized Mean Aggregation

Before discussing each of these aggregation methods, we first introduce the basic concept of the

---

rather than fairness.

Power (p)	**Formulation**
$-\infty$	Minimum: $\min\{v_1, \ldots, v_n\}$
-1	Harmonic Mean: $\frac{n}{\sum_{i=1}^{n} v_i^{-1}}$
1	Arithmetic Mean: $\frac{1}{n}\sum_{i=1}^{n} v_i$
2	Quadratic Mean: $\sqrt{\frac{1}{n}\sum_{i=1}^{n} v_i^2}$
$+\infty$	Maximum: $\max\{v_1, \ldots, v_n\}$

Table 2: Commonly-used cases of generalized mean aggregation.

generalized mean as a framework for describing aggregation functions, and then make the link between the generalized mean and existing aggregation methods.

Formally, the generalized mean is defined as:

$$\mathcal{M}_p(v_1, \ldots, v_n) = \left(\frac{1}{n} \sum_{i=1}^{n} v_i^p \right)^{\frac{1}{p}},$$

where $v_i \in \mathbb{R}^+$ are positive real numbers to be aggregated, and p is the exponent parameter. A desired property of the generalized mean is its inequality, which states that,

$$\mathcal{M}_p(v_1, \ldots, v_n) > \mathcal{M}_{p'}(v_1, \ldots, v_n), \forall p > p'.$$

Essentially, a larger value of p encourage the aggregation to focus more on the larger-valued elements, which can be illustrated with the specific cases shown in Table 2.

By setting $p = \pm\infty$, generalized mean returns extremum values, including (in Table 1): (1) the maximum value of gap (Yang et al., 2020), difference (Bird et al., 2020), and ratio (Feldman et al., 2015); and (2) the minimum value of score (Lahoti et al., 2020) and ratio (Zafar et al., 2017).

For other p values, the generalized mean reflects the relative dispersion of its inputs. For example, group-wise mean gap aggregation (Shen et al., 2022b) and class-wise mean aggregation (Li et al., 2018) are both equivalent to $p = 1$. Class-wise quadratic mean aggregation (Romanov et al., 2019) is essentially $p = 2$, which focuses more on those classes with higher bias. Similarly, group-wise variance aggregation (Lum et al., 2022) is proportional to the $p = 2$ setting, implying that groups with larger gaps will influence results more.

The additional advantage of using generalized mean aggregation is that comparison across arbitrary p values can be easily stated. For example, group-wise aggregation is the $p = -5$ generalized mean with respect to the **score** units in a toxicity classification competition,[5] meaning that evaluation focuses more on groups with lower performance.

Other Aggregation Methods: Although generalized mean aggregation is a powerful tool for describing and interpreting the aggregation process, there are other ways that need further discussion. Previous work has also considered assigning different weights under aggregation, for instance, Kearns et al. (2018) assign larger weights to groups with larger populations. Such aggregations can be implemented as the weighted generalized mean: $\mathcal{M}_{p,w}(v) = \left(\frac{1}{n}\sum_{i=1}^{n} w_i v_i^p\right)^{\frac{1}{p}}$, where w is the weight vector, and $\sum_{i=1}^{n} w_i = 1$.

An example of the weighted generalized mean for class-wise aggregation is binary aggregation that only considers the positive class in a binary classification setting (Hardt et al., 2016; Zafar et al., 2017; Kearns et al., 2018; Zhao et al., 2019; Lahoti et al., 2020; Han et al., 2021; Lum et al., 2022). The positive class is often treated as the “advantaged” outcome, so the analysis focuses solely on the positive class. Moreover, the one-versus-all trick is not necessary for the binary setting, and natural derivations of the confusion matrix can be used to refer to a particular class, e.g., TPR for the positive class and TNR for the negative class.

3.4 Recommendations

We are now in a position to be able to provide recommendations for fairness evaluation.

Following the work of Dodge et al. (2019), we provide a checklist for fairness evaluation metric aggregation:

- ☐ Statistics of the dataset $\mathcal{D}$, e.g., the probability table of the joint distribution of y and z, and the size of each partition.
- ☐ The evaluation metric m (e.g., TPR for *EO* fairness).
- ☐ The basic unit of group-wise aggregation, including **score**, **gap**, and **ratio**, or other possible measures.
- ☐ The aggregation function for **group-wise** aggregation, and the corresponding motivation.

---

[5] Jigsaw Unintended Bias in Toxicity Classification: `https://www.kaggle.com/competitions/jigsaw-unintended-bias-in-toxicity-classification/`

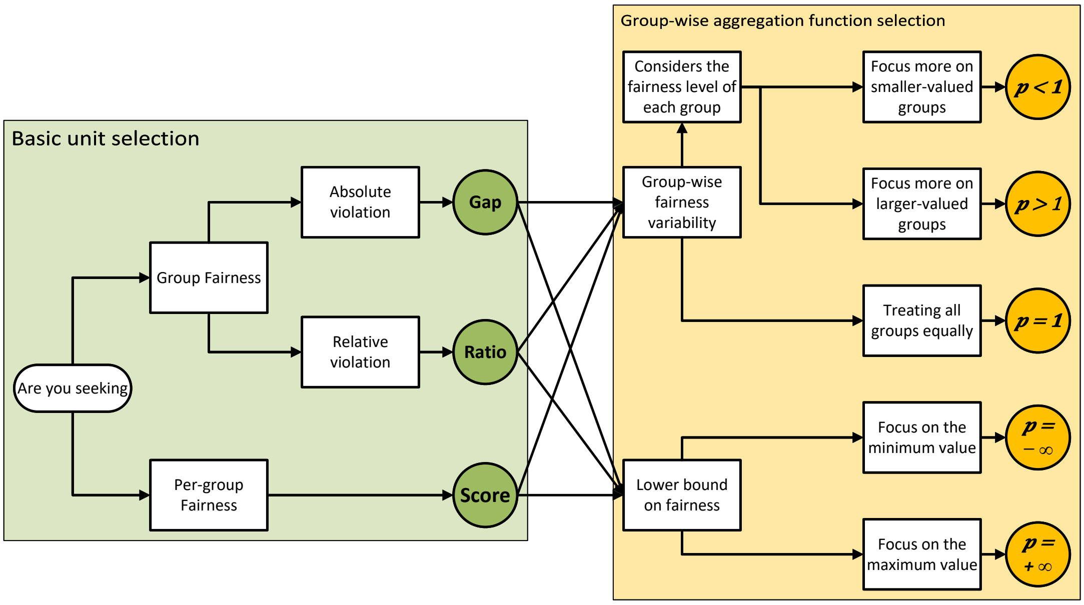

Figure 2: Decision path for exponent parameter selection for generalized mean aggregation.

☐ The aggregation function for **class-wise** aggregation, and the corresponding motivation.

Although the particular choice of evaluation dataset $\mathcal{D}$ and evaluation metric m are critical to the overall evaluation, they are not the main focus of this paper. Rather, we provide guidance based on the selection of basic unit, and methods for group- and class-wise aggregation, as detailed in Figure 2.

Basic Unit Selection: The circles in Figure 2 annotated as **Score**, **Ratio**, and **Gap** are the decision points for basic unit selection.

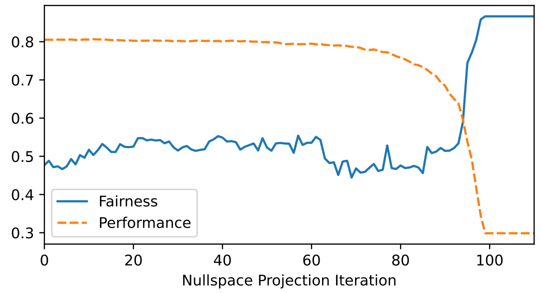
If per-group fairness is the primary criterion (e.g., Rawlsian Max-Min fairness (Rawls, 2001)), using **score** is the best practice, which maintains the original values under aggregation. On the other hand, if inter-group fairness is critical, **gap** and **ratio** are more appropriate choices. **Gap** reflects disparities in the same scale as the per-group scores, and is easy to visualize (e.g. as differences in height between clustered bars). However, if one wished to measure disparities in relative terms, e.g., the $q\%$-rule (Feldman et al., 2015), **ratio** is a better choice than **gap**.

Group-wise Aggregation Function Selection: The selection of group-wise aggregation functions is shown as the exponent parameters of the *generalized mean* aggregation.

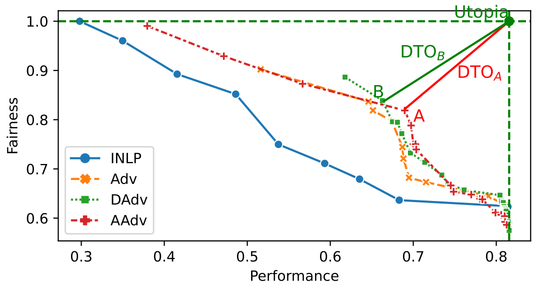
Measuring extrema is similar to the notion of per-group fairness, and encourages improvements in the worst-performing groups. For basic units where smaller is fairer, e.g., **gap**, aggregation generally focuses on the maximum (Yang et al., 2020), i.e., $p = +\infty$. For units like **score** ($p = -\infty$), on the other hand, the minimum value should be measured, as a lower bound.

Besides extrema, it is also reasonable to measure fairness variability across groups. A typical choice is taking the arithmetic mean (i.e., $p = 1$) across all groups, which implicitly assigns equal importance to each individual group. Similar to the signs in extremum aggregations, the value of p in variability aggregations should be selected based on the type of basic unit, to focus more on worse-performing groups. Taking the **gap** unit as an example, the quadratic mean ($p = 2$) is influenced more by larger gaps than the arithmetic mean. Moreover, quadratic mean aggregation based on **gap** is essentially the standard deviation of **scores**, and can be used to reconstruct variance aggregation (Lum et al., 2022).

Class-wise Aggregation Function Selection: Although our focus is on the fairness evaluation metric, class-wise aggregation is almost identical to aggregation methods for general utility metrics. Binary aggregation for fairness is the same as utility metrics, while mean aggregation (Li et al., 2018; Wang et al., 2019) for fairness evaluation is equivalent to "macro"-averaging in general evaluation.



(a) Tuning INLP trade-off hyperparameter



(b) Performance–fairness trade-offs

Figure 3: Figure 3a shows an example of performance and fairness with respect to different iterations of the nullspace projection in INLP. Figure 3b presents the Pareto frontiers in the performance–fairness trade-offs of four debiasing methods in recent work. Figure 3b also provides an illustration of DTO. The green dashed vertical and horizontal lines denote the best performance and fairness, respectively, and their intersection point is the *Utopia* point. The length of a line, e.g., the red line from A to the Utopia point, is the DTO for the corresponding candidate model.

4 Model Comparison

This section focuses on comparison of debiasing methods when considering utility and fairness simultaneously. We first introduce the performance–fairness trade-off curve (PFC) for debiasing methods, and then discuss the limitations of existing comparison frameworks. Finally, we propose a new metric, namely the area under the curve (AUC) w.r.t. PFC, which integrates existing approaches and reflects the overall goodness of a method.

4.1 Performance and Fairness Metrics

As discussed in Section 3, there are many options to measure performance and fairness. This paper is generalizable to all different metrics, but for illustration purposes, we follow Ravfogel et al. (2020); Subramanian et al. (2021) and Han et al. (2022c) in measuring the overall accuracy and equal opportunity fairness.

Specifically, equal opportunity fairness measures TPR disparities across groups, such as the situation depicted in Figure 1. We use the TPR **gap** across subgroups to capture absolute disparities. For group-wise aggregation, we treat all groups equally in computing the unweighted sum of *gap* scores ($\propto p = 1$). In the last step, class-wise aggregation, we focus more on less fair classes by using root mean square aggregation ($p = 2$).

4.2 Performance–Fairness Trade-off

It has been observed in previous work that a performance–fairness trade-off exists in bias mitigation (Li et al., 2018; Wang et al., 2019; Ravfogel et al., 2020; Han et al., 2022b; Shen et al., 2022b).

Typically, debiasing methods involve a trade-off hyperparameter to control the extent to which the model sacrifices performance for fairness. Examples of such trade-off hyperparameters include: (1) interpolation between the target and vanilla data distribution for pre-processing approaches (Wang et al., 2019; Han et al., 2022a); (2) the strength of additional loss terms for loss manipulation methods (Zhao et al., 2019; Lahoti et al., 2020; Han et al., 2021; Shen et al., 2022a); (3) the target level of fairness in constrained optimization (Kearns et al., 2018; Subramanian et al., 2021); and (4) the number of debiasing iterations for post-hoc bias mitigation methods (Ravfogel et al., 2020).

Taking INLP (Ravfogel et al., 2020) as an example, which debiases by iteratively projecting the text embeddings to the nullspace of the protected attributes, Figure 3a shows performance and fairness with respect to the number of nullspace projection iterations.[6] It is clear that more iterations lead to better fairness at the cost of performance.

Instead of looking at performance/fairness for different trade-off hyperparameter values, it is more meaningful to focus on the Pareto frontiers in trade-off plots (Figure 3b), where each point corresponds to a particular value of the trade-off hyperparameter in Figure 3a. The frontiers represent the best fairness that can be achieved at different performance levels, and vice versa.

One limitation of a trade-off plot is that it is hard to make quantitative conclusions based on the plot itself, and we cannot conclude that one method is better than another if there exists any intersection of their trade-off curves. As shown in Figure 3b, in addition to INLP, we also include the trade-

---

[6] Without loss of generality, we assume that for both fairness and performance, larger is better.

off curves for three recent adversarial debiasing variants: ADV (Li et al., 2018), DADV (Han et al., 2021), and A-ADV (Han et al., 2022b). Although A-ADV is better than the other methods under most conditions, there exist intersections between their trade-off curves. As such, we can only state that A-ADV is better than other methods within particular ranges, which is insufficient for making a precise comparison, especially when comparing multiple debiasing methods (as demonstrated in Figure 3b).

4.3 Model Selection

In order to conduct quantitative comparisons across different debiasing methods, current practice is to select a particular point on the frontier for each method, and then compare both the performance and fairness of the selected points.

One problem associated with model selection is that typically, no single method simultaneously achieves the best performance and fairness. For example, as shown in Figure 3b, if points **A** and **B** were the selected models for A-ADV and DADV, respectively, **A** would represent better performance and **B** better fairness. As such, although we have actual numbers for quantitative comparison, it is still hard to conclude which method is best.

Distance to the Optimal: To address this problem, we propose to measure the **D**istance **T**o the **O**ptimal point ("DTO") to quantify the performance–fairness trade-off (Salukvadze, 1971; Marler and Arora, 2004; Han et al., 2022a). A model is said to outperform others if it achieves a smaller DTO, i.e. the distance to the optimal (Utopia) point (the point at which performance and fairness are the maximum possible values) is minimized. Figure 3b illustrates the calculation of DTO for **A** and **B**, where the optimal point is the top-right corner[7] and DTO is measured by the normalized Euclidean distance (the length of the green and red lines) to the optimal point.

A notable advantage of DTO is that a Pareto improvement implies a smaller value of DTO. Therefore, DTO can be seen as relaxation of Pareto improvements, and the smallest DTO must be achieved by a point on the Pareto frontier. A key limitation of DTO is that it quantifies the trade-off of a single model rather than the full frontier, presupposing some means of model selection. This has been somewhat arbitrary in prior work, which is the problem we now seek to address.

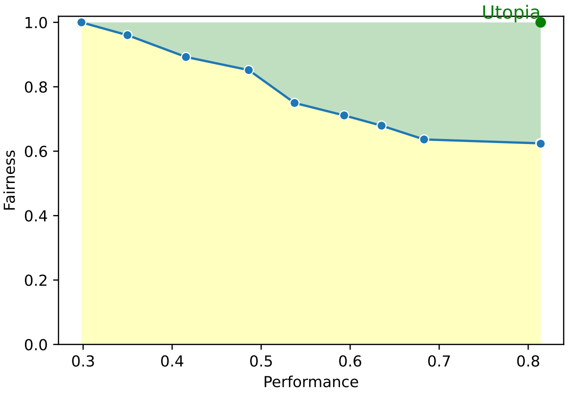


Figure 4: AUC of the performance–fairness trade-off curve. Taking the trade-off curve of INLP as an example, the yellow shaded area refers to the AUC-PFC, and the green shaded area refers to the integration of DTO in polar coordinates.

Selection Criteria: Similar to the aggregation of fairness metrics, model selection should be done in a domain-specific manner. Previous work has used different criteria for model selection, including: (1) minimum loss (Hashimoto et al., 2018; Li et al., 2018); (2) maximum utility (Lahoti et al., 2020), e.g., based on accuracy or F-measure; (3) manual selection based on visual inspection of the trade-off curve (Elazar and Goldberg, 2018; Ravfogel et al., 2020); (4) constrained selection (Han et al., 2021; Subramanian et al., 2021), by selecting the best fairness constrained to a particular level of performance, and vice versa; and (5) minimising DTO (Han et al., 2022b; Shen et al., 2022b).

Selection based on minimum loss and maximum utility is identical to classic model selection, and does not consider fairness explicitly. The other three types of criteria are based on trade-offs, differentiated by the method for aggregating fairness and performance.

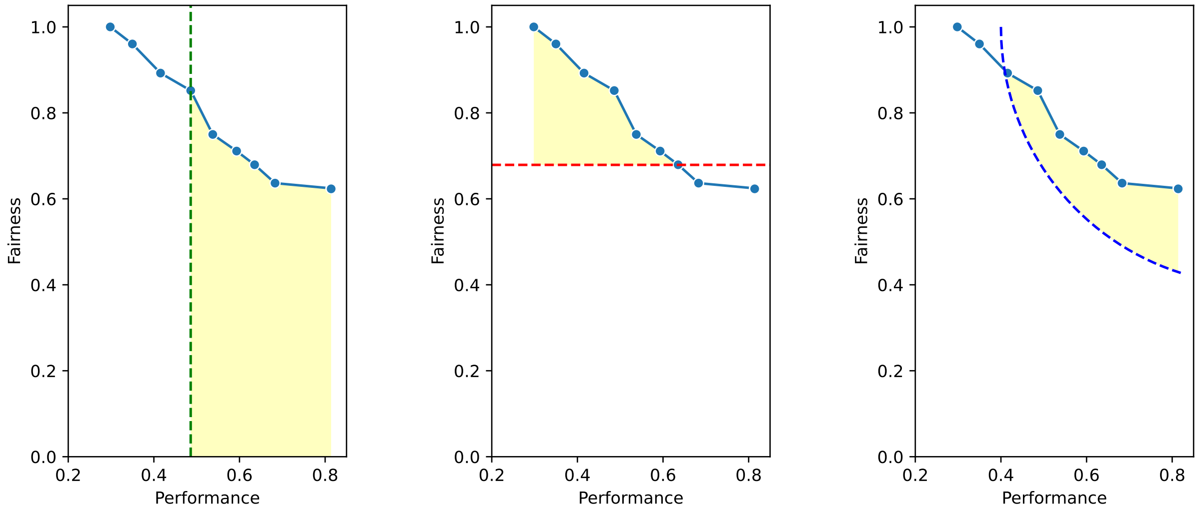
Such inconsistency in model selection makes it very hard to rigorously compare methods. The question we want to address is: *how can we quantitatively compare methods without model selection?*

4.4 AUC-PFC

Recall that DTO is a metric for measuring the goodness of the trade-off of a particular model, and model selection is a process for selecting a particular frontier model from the Pareto curve. To address the problem associated with model selec-

---

[7] The location of the utopia point and the scale of metrics are discussed in Appendix C.



(a) Accuracy is better than 0.49.

(b) Fairness is better than 0.68.

(c) DTO is better than 0.60.

Figure 5: Yellow shaded area denote the partial AUC-PFC score computed in the region where a particular condition applied.

tion, we propose to integrate DTO over the whole performance–fairness curve (PFC). Specifically, we integrate DTO in a polar coordinate system, where the reference point (pole) is the optimal point. Given that the DTO of a point on the trade-off curve is also the distance from the pole in the polar coordinate system, the trade-off curve can be treated as a function that maps angular coordinates to DTO. For example, as shown in Figure 4, the green area denotes the region enclosed by the performance–fairness trade-off curve of INLP and the utopia point with fairness = 1.00 and performance = 0.82.[8]

Alternatively, we can interpret the proposed metric from the performance–fairness perspective, in calculating the area under the Pareto curve, and subtracting this from the area under the optimal Pareto curve defined by the optimal point.

The magnitude of AUC-PFC differs from a single metric; for example, a 0.0001 improvement in the AUC-PFC score is equivalent to a 1 percentage point (pp) boost in both performance and fairness (0.01×0.01).

Partial AUC-PFC In practice, worse performance or fairness can be unacceptable, for example, one may want to prioritize fairness in particular applications. To address this problem, we present the Partial AUC-PFC score to focus on a specific region of the PFC Curve, where the AUC-PFC score is computed w.r.t. specific acceptable levels of performance and fairness.

Figure 5a shows an example of partial AUC-PFC, where the region can be considered if corresponding accuracy is better than 0.49. Similarly, Figures 5b and 5c show partial AUC-PFC scores with respect to particular fairness and DTO constraints.

With the partial AUC-PFC metric, one can explicitly compare different methods with a single number, and w.r.t. particular values of performance and fairness.

4.5 Case Studies

Experimental Details: We conduct experiments over the BIOS dataset (De-Arteaga et al., 2019) which was augmented with economic status by Subramanian et al. (2021), resulting in 28 professions as the target label and 4 intersectional demographic groups.[9] We use public implementations for all models in our experiments, primarily in *fairlib* (Han et al., 2022c).

Results: In Table 3, we investigate 7 different selection criteria and report the DTO score over the test set. Specifically, we conduct model selection over the development set based on: (1) minimum DTO; (2) maximum performance (**P**); (3) maximum performance within a fairness threshold of 5% improvement (**P@F+5%**); (4) maximum

---

[8] In the interests of consistent comparison, the Utopia point is typically $(1, 1)$, as in Table 3. In practice, this does not affect the calculation of AUC-PFC, as we discuss in Appendix C.

[9] Performance and fairness metrics have been introduced in Section 4.1.

Method	Selection Criteria DTO	P	P@F+5%	P@F+10%	F	F@P−5%	F@P−10%	AUC↑
INLP (Ravfogel et al., 2020)	41.9	**41.9**	52.6	52.6	70.2	41.9	41.9	39.8
ADV (Li et al., 2018)	39.0	44.6	43.3	41.8	49.4	41.2	**41.2**	43.6
DADV (Han et al., 2021)	37.9	44.7	41.0	40.5	**39.9**	**40.4**	41.9	**44.5**
A-ADV (Han et al., 2022b)	**36.9**	45.4	**39.5**	**39.0**	62.1	43.8	42.8	44.0

Table 3: DTO scores of selected models over the BIOS dataset (smaller is better), based on the distances from mean performance and fairness to (1,1) over the test set. Models are selected based on the criterion listed for each column over the development set. The final column is the AUC, which does not involve model selection. **Bold** = the best score per column. See Appendix B for the full results.

performance within a fairness threshold of 10% improvement (**P@F+10%**); (5) maximum fairness (**F**); (6) maximum fairness within a performance trade-off threshold of 5% (**F@P−5%**); and (7) maximum fairness within a performance trade-off threshold of 10% (**F@P−10%**). Criteria (3), (4), (6), and (7) are constrained selections as discussed in Section 4.3, where we select the model with the highest fairness/performance within 5/10% of performance trade-off/fairness improvement relative to the STANDARD model. Taking F@P−10% as an example, the model with the highest fairness is selected within 10% performance trade-off over the vanilla model performance (i.e., with performance greater than 72% (82% − 10%)). Similarly, P@F+5% selects the model with highest performance subject to at least 5% fairness improvement over the vanilla model ($63\% = 58\% + 5\%$).

It can be seen that each of the four methods is the best for at least one selection criteria, as a stark illustration of our claim about model selection criteria biasing any possible conclusions about which method is best. For example, INLP and ADV are the best methods with respect to selection criteria **P** and **F@P−10%**, respectively.

On the contrary, our proposed AUC-PFC score (in the final column of Table 3) is unaffected by model selection, and reflects the overall trade-off of a method. Consistent with the trend in Figure 3b, AUC scores in Table 3 are smaller for worse-performing methods, e.g., INLP, and larger for better-performing methods such as A-ADV and DADV. Moreover, as the trade-off curves for A-ADV and DADV overlap one another (see Figure 3b), it is hard to pick a winner visually, let alone make quantitative comparisons. By using the AUC-PFC metric, we can conclude that overall, DADV is slightly better than A-ADV over this dataset.

Discussion The current DTO calculation assumes that users have no preference for performance over fairness or vice versa, where in practice it is possible that the choice of the fairness metric could be influenced by task-specific goals or the relative importance of fairness. Such problems have been widely studied in the literature on multi-objective learning, and a typical line of work is weighted generalized mean, which incorporates additional weight parameters in the generalized mean framework to reflect the importance or preference of each objective.

5 Conclusion

We have discussed the current practice in evaluation, model selection, and method comparison in the fairness literature, and shown how current practice in experimental fairness lacks rigour and consistency. We made recommendations for selecting a fairness evaluation metric, and introduced a new metric for measuring the overall performance–fairness trade-off of a method.

Acknowledgements

We thank Lea Frermann, Aili Shen, and Shivashankar Subramanian for their discussions and inputs. We thank the anonymous reviewers for their helpful feedback and suggestions. This work was funded by the Australian Research Council, Discovery grant DP200102519.

Limitations

This paper focuses on the notion of group fairness, under the assumption that each individual belongs to a particular demographic group. One limitation of methods in this space is that the demographic attributes must be observed (for the development and test data, at least) in order to evaluate fairness.

We only investigate the proposed evaluation aggregation framework in a classification setting. However, our framework is naturally generalizable to other tasks with discrete outcomes, such as generation and sequential tagging. Moreover, in terms of continuous labels, such as regression, one can skip the class-wise aggregation.

Ethical Considerations

This work focuses on current practice in fairness evaluation and method comparison. Our proposed "checklist" recommendations are specific to the fairness literature and complement existing frameworks, to encourage future research to think carefully about harms and what type of fairness is appropriate.

Demographics are assumed to be available only for evaluation purposes and are not used for model training or inference. We only use attributes that the user has self-identified in our experiments. All data and models in this study are publicly available and used under strict ethical guidelines.

A Full Disaggregated Results

Figure 6 depicts the full TPR scores for two real-world models over a profession classification dataset, stratified across 4 protected attributes (male vs. female and high vs. low economic status) from Figure 1. Specifically, the two models are both trained naively without debiasing. They share the same hyperparameter settings and random seed, except that Model 1 and Model 2 are the 9th and 5th epochs, respectively. For professions such as Professor, there is little discernible difference either between the two models or across different combinations of protected attributes. For DJ, on the other hand, Model 1 appears to be reasonably fair w.r.t. economic status but biased for binary gender, whereas Model 2 is biased across both protected attributes but appears to have the higher overall TPR. Finally, with Paralegal, Model 2 appears to be fairer w.r.t. both economic status and binary gender but perform substantially worse than the more biased Model 1 in terms of the individual TPR scores for every combination of protected attributes. So it is hard to tell which model is fairer or "better" out of the two, without aggregation.

A.1 Dataset: Bios

All experiments are based on a biography classification dataset (De-Arteaga et al., 2019; Ravfogel et al., 2020), where biographies were scraped from the web, and annotated for the protected attribute of binary gender and target label of 28 profession classes.

Besides the binary gender attribute, we additionally consider economic status as a second protected attribute. Subramanian et al. (2021) semi-automatically labeled economic status based on the individual's home country (wealthy vs. rest of world), as geotagged from the first sentence of the biography. For bias evaluation and mitigation, we consider the intersectional groups, i.e., the Cartesian product of the two protected attributes, leading to 4 intersectional classes: female–wealthy, female–rest, male–wealthy, and male–rest.

Since the data is not directly available, in order to construct the dataset, we use the scraping scripts of Ravfogel et al. (2020), leading to a dataset with 396k biographies.[10] Following Ravfogel et al. (2020), we randomly split the dataset into train (65%), dev (10%), and test (25%).

The augmentation for economic attributes follows previous work (Subramanian et al., 2021), which results in approximately 30% of instances that are labelled with both protected attributes.

Table 4 shows the target label distribution and protected attribute distribution.

A.2 Experimental Details

This work focuses on evaluation and model comparison in the fairness literature. Instead of training models from scratch, we use existing checkpoints from previous work (Han et al., 2022c), which are publicly available online.[11] Please refer to the original work (Han et al., 2022c) for experimental details.

A.3 Subset Confusion Matrices

Figure 7 presents the confusion matrices of all 4 subgroups. For each confusion matrix, the i-th row and j-th column entry indicates the number of samples which have the true label of the i-th class and predicted label of the j-th class. Since the distributions of classes within each group can be highly imbalanced, without further normalization and aggregation, it is difficult to draw any conclusion by just observing the number of samples in each cell.

A.4 Fairness Reproducibility

So far, we have listed critical factors underlying the choice of fairness metric, and provided recommendations for metric selection. However, we acknowledge that, in actual applications, the selection should be made in a domain-specific manner in close consultation with stakeholders or policymakers. In practice, countless types of fairness evaluation metrics could be derived from different combinations of aggregation methods.

Instead of reporting all possible fairness metrics, we suggest providing a set of confusion matrices for classification tasks, as it can form the basis of calculating a large number of metrics, including PPR, TPR, TNR, accuracy, and F-measure. The other key advantage of reporting confusion matrices is that the number of reported values is generally much smaller than the model or dataset size. Given a C-class classification dataset with G distinct protected groups, the combined size of the confusion matrices is G $\times$ C^2 (one confusion matrix per group). Taking the BIOS dataset as an example, the sizes of the confusion matrices, test dataset, and model parameters (for a BERT-base classifier (Devlin et al., 2019)) are approximately 3×10^3, 4×10^4, and 1×10^8, respectively.

B Full Results of Case Studies

Table 5 shows the experimental results for both the test and development sets.

C AUC-PFC Extension

C.1 Weighted DTO

On the one hand, as suggested by Marler and Arora (2004), if fairness and performance have different scales, the Euclidean distance is not a suitable mathematical representation of closeness, resulting in worse approximation of Pareto optimality and efficiency. Therefore, the scales of performance and fairness should be normalized.

C.2 Selection of Utopia Point

Typically, most debiasing methods will share the same maximum performance, which is the performance of the vanilla model (corresponding to a hyperparameter setting where the debiasing method does nothing.) Accordingly this is a sensible choice for the performance of the Utopia point, as we have proposed for model selection. In terms of the calculation of areas of integration, moving the Utopia point to $(1, 1)$ has little effect, simply adding a constant triangular region which is identical for all methods, and thus irrelevant for model comparison. As such, it makes no difference whether we use 1 or the maximum-achieved model performance when comparing models based on AUC-PFC.

Distance to Arbitrary Ideal Point: Compared to the default value of DTO, moving the utopia point to the right (e.g., the $(1, 1)$ point) prioritizes methods with higher performance.

---

[10] There are slight discrepancies in the dataset composition due to data attrition: the original dataset (De-Arteaga et al., 2019) had 399k instances, while 393k were collected by Ravfogel et al. (2020).

Table 5: Evaluation results ± standard deviation (%) of selected models over the Bios dataset. DTO scores are the distance from mean performance and fairness to (1,1) over the test set.

where $b > 0$, e.g., $b = (1 - 0.82)$ for the running example.

Before discussing the influence of the optimum point selection, recall that the magnitude of vector sum, $|\vec{v}| = |\vec{v}_1 + \vec{v}_2|$ is:

$$|\vec{v}| = \sqrt{|\vec{v}_1|^2 + |\vec{v}_2|^2 + 2|\vec{v}_1||\vec{v}_2|\cos\alpha},$$

where α is the angle between $\vec{v}_1$ and $\vec{v}_2$.

Let QU denote the vector from candidate model Q to the Utopia point U, the DTO based on the Utopia point is the $r = \sqrt{a^2 + c^2}$.

When calculating DTO based on the arbitrary optimum point O, $r' = |QU + UO|$, which can be shown as:

$$r' = \sqrt{r^2 + b^2 + 2rb\cos\alpha'},$$

where α' is the angle between QU and UO, and is equivalent to $\angle PUQ$. Furthermore, as discussed in Section 4.4, given a trade-off curve, the DTO is a function of $\angle PUQ$, i.e., the green shaded area is $\int_0^{\pi/2} \text{DTO}(\angle PUQ) d\angle PUQ$.

Lemma C.1. *Let Q_1 and Q_2 be two models with the same DTO score ($r_1 = r_2$), r'_1 and r'_2 be the DTO to the new Utopia point O. If the performance of Q_1 is worse than Q_2, then $r'_1 > r'_2$.*

Proof. Assuming that $r'_1 > r'_2$,

$$\begin{gathered} |Q_1U + UO| > |Q_2U + UO| \\ |Q_1U + UO|^2 > |Q_2U + UO|^2 \\ 2r_1 b\cos\angle PUQ_1 > 2r_2 b\cos\angle PUQ_2 \end{gathered} \tag{1}$$

Since $\angle PUQ \leq \pi/2, \forall Q$, and $r_1 = r_2$,

$$a_1 = r_1 \cos\angle PUQ_1 > a_2 = r_2 \cos\angle PUQ_2,$$

where a_1 and a_2 are the performance distances from Q_1 and Q_2 to the maximum performance, respectively.

Abstract

We motivate and introduce **CHARD**: Clinical Health-Aware Reasoning across Dimensions, to investigate the capability of text generation models to act as implicit clinical knowledge bases and generate free-flow textual explanations about various health-related conditions across several dimensions. We collect and present an associated dataset, CHARDAT, consisting of explanations about 52 health conditions across three clinical dimensions. We conduct extensive experiments using BART and T5 along with data augmentation, and perform automatic, human, and qualitative analyses. We show that while our models can perform decently, **CHARD** is very challenging with strong potential for further exploration.

1 Introduction

Pretrained language models (PLM) have seen increasing popularity for NLP tasks and applications, including text generation. Researchers have become interested in the extent to which PLMs can: 1) act as knowledge bases, 2) reason like humans.

Rather than using external databases, exposure to large amounts of data during training combined with their large number of parameters, has given PLMs the ability to store knowledge that can be extracted through effective probing strategies such as text infilling (Donahue et al., 2020), prompting (Liu et al., 2021), and QA (Jiang et al., 2021). PLMs imitate a more high-level information store, allowing for greater abstractness, flexibility, and generalizability. They are also able to better exploit contextual information than simple retrieval.

Studies have also shown that as PLMs scale up, they have have emergent abilities (Wei et al., 2022a), including reasoning. There has been increasing attention on their commonsense reasoning through works like COMET (Bosselut et al., 2019). However, studies show that even large PLMs struggle with commonsense tasks that humans can reason through very easily (Talmor et al., 2020). There are works that investigate more complicated reasoning tasks, e.g. arithmetic and symbolic reasoning (Wei et al., 2022b). PLMs inherently have some extent of reasoning capability, and many more complex reasoning tasks are easier to carry out over abstract PLM embedding space.

A person with *rheumatoid* has a/an *therapy treatment* because/since/as *{explanation}*	A person with rheumatoid has a therapy treatment because *physiotherapy helps rheumatoid patients with pain control, reducing inflammation and joint stiffness and to return to the normal activities of daily living or sports.*

Table 1: Examples of **CHARD** templates with explanations (from CHARDAT). The human was asked to write the entire output text (not just the explanation) by infilling the template.

In this paper, we are interested in the intersection of these areas. Can PLMs act as knowledge bases and also reliably reason using their own knowledge? We investigate whether PLMs can learn and reason through health-related knowledge. Work on generation-based reasoning for health has been limited, with most prior work exploring retrieval-based methods. Generation-based reasoning is more difficult, as such a specialized domain contains esoteric information not prevalent in the PLM's training data, and involves a higher degree of specialized reasoning to handle domain-specific problems.

Healthcare is an important domain that deals with human lives. It is a large application area for machine learning and NLP. The need for automation in healthcare rises, as countless studies show that healthcare workers are overworked and burned out, especially recently due to the COVID-19 pandemic (Portoghese et al., 2014; Brophy et al.,

2021; Couarraze et al., 2021). Further, healthcare resources will continue to be strained as the baby boomer generation ages (Canizares et al., 2016).

To this end, we propose **CHARD**: Clinical Health-Aware Reasoning across Dimensions (§2.1). This task is designed to explore the capability of text generation models to act as implicit clinical knowledge bases and generate textual explanations about health-related conditions across several dimensions. The ultimate goal of **CHARD** is to eventually have a model that is knowledgeable and insightful across numerous clinical dimensions and reasoning pathways. For now, we focus on three relevant clinical dimensions using a template infilling approach, and collect an associated dataset, CHARDAT, which includes information for 52 health conditions across these dimensions (§2.2).

We perform extensive experiments on CHARDAT using two SOTA seq2seq models: BART (Lewis et al., 2020) and T5 (Raffel et al., 2020) (§3.1), with data augmentation using backtranslation (Sennrich et al., 2016) (§3.2,4.2). We benchmark our models through automatic, human, and qualitative analyses (§5). We show that our models show strong potential, but have room to improve, and that **CHARD** is highly challenging with room for additional exploration. Lastly, we discuss several potential directions for improvement (§6).

2 Task and Dataset

2.1 The CHARD Task

Our task, **CHARD**: Clinical Health-Aware Reasoning across Dimensions, investigates the capability of text generation models to produce clinical explanations about various health conditions across several clinical dimensions (DIM). Essentially, we assess how a PLM can be used as and reason through an implicit clinical knowledge base.

We focus on three DIM: **risk factors** (RF), **treatment** (TREAT), and **prevention** (PREV), as they are important and relevant in the context of health. A risk factor refers to something that increases the chance of developing a condition. For cancer, some examples are age, family history, and smoking. Treatment refers to something that helps treat or cure a condition. For migraines, some examples are medication, stress management, and meditation. Prevention refers to strategies to stop or lower the chance of getting a condition. For diabetes, some examples are a healthy diet and regular exercise.

As an initial approach to **CHARD**, we use a template infilling formulation, where given an input template that lays out the structure of the desired explanation, the model's goal is to generate a complete explanation of how the particular DIM attribute relates to the given condition. In particular, the templates end with an {explanation} span that the models fill in by explaining the appropriate relationship. Some examples are in Table 1.

2.2 CHARDAT Dataset

Collection Process: We collect a dataset for our task called CHARDAT (where DAT is short for data). We collect data across the three DIM for 52 health conditions, listed in Appendix A. This is a manually curated list of health conditions which range from common conditions such as migraine and acne to rare conditions such as Lyme disease and Paget–Schroetter. The conditions were also selected by volume of online activity (e.g. number of active subreddit users), treatable vs. chronic conditions, and whether a condition can be self-diagnosed or not. This allows us to assess **CHARD** across a variety of conditions.

For each DIM, we manually collect an exhaustive list of DIM-related attributes (e.g. risk factors) for each condition. By *attribute*, we refer to a particular example of that DIM (e.g. "obesity"). This was accomplished by searching through reliable and reputable medically-reviewed sources such as MayoClinic, CDC, WebMD, and Healthline.

We collect the final text (with explanations) using Amazon Mechanical Turk (AMT). We ask approved AMT workers (with strong qualifications and approval ratings on healthcare-related tasks) to write factually accurate, informative, and relatively concise passages given a particular condition and DIM attribute template (per HIT), while encouraging them to consult the aforementioned health resources. Three separate annotation studies (one per DIM) with strict quality control were conducted to collect an annotation per example.[1] Annotations were regularly verified by authors, and a large subset of CHARDAT was manually examined for medical accuracy. More details are in Appendix B. Some examples from CHARDAT are in Table 1.

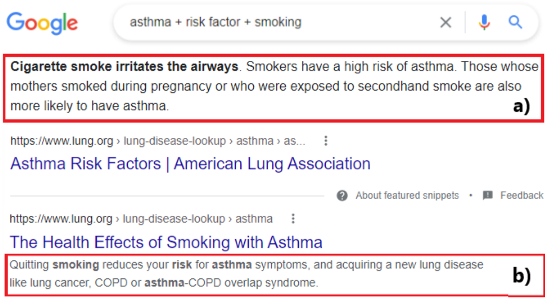
Splits and Statistics: We split CHARDAT by DIM into train, val, and test splits of $\approx$ 70%/15%/15%, and combine the individual splits per DIM to form the final splits called CHAR-

---

[1] Explanations for **CHARD** are typically quite standardized, and additional annotations were repetitive. Differences are mainly in language, so we instead opt for paraphrasing data augmentation techniques such as backtranslation (§3.2).

Dataset Stats	Train	Val	Test (seen/unseen)
# conditions = 52	44	39	41 (37/4)
RF = 52	44	26	26 (22/4)
TREAT = 52	43	21	20 (16/4)
PREV = 44	35	11	21 (17/4)
# sentences = 937	655	141	141 (70/71)
RF = 457	319	69	69 (32/37)
TREAT = 297	207	45	45 (20/25)
PREV = 183	129	27	27 (18/9)
Avg length = 36.2	37.7	36.1	35 (35.9/34.2)

Table 2: CHARDAT statistics. Differing #s by DIM are because there are more risk factors for most conditions, and some do not have prevention strategies. Length is in words.



asthma + risk factor + smoking

Cigarette smoke irritates the airways. Smokers have a high risk of asthma. Those whose mothers smoked during pregnancy or who were exposed to secondhand smoke are also more likely to have asthma.

Asthma Risk Factors | American Lung Association

https://www.lung.org › lung-disease-lookup › asthma

The Health Effects of Smoking with Asthma

Quitting **smoking** reduces your **risk** for **asthma** symptoms, and acquiring a new lung disease like lung cancer, COPD or **asthma**-COPD overlap syndrome.

Figure 1: An example of the Google search results for the query {*asthma* + *risk factor* + *smoking*} highlighting: a) the *featured snippet*, b) the text below the first link.

DAT$_{tr}$, CHARDAT$_{val}$, and CHARDAT$_{test}$, respectively. The individual DIM splits are called DIM$_{tr}$, DIM$_{val}$, and DIM$_{test}$, where DIM is a short-form of the particular dimension: RF, TREAT, or PREV. The individual dimension subsets of CHARDAT are called CHARDAT$_{DIM}$.

For each DIM's test split, we ensure that approximately half consist of examples from conditions entirely unseen during training for that DIM, called DIM$_{test-unseen}$. This is to assess whether the model can generalize to unseen conditions. The other half contains examples from conditions seen during training called DIM$_{test-seen}$, but the specific condition and DIM attribute combination was unseen. The combined halves (across DIM) are called CHARDAT$_{test-unseen}$ and CHARDAT$_{test-seen}$. We do the same for the val split to ensure consistency for model selection purposes. CHARDAT statistics are in Table 2.

3 Methodology

3.1 Models

BART and T5: We experiment using two pretrained seq2seq models: BART and T5 (both base and large versions). These are suitable for our task formulation (template infilling). T5 (Raffel et al., 2020) has strong multitask pretraining. BART (Lewis et al., 2020) is trained to reconstruct original text from noised text (as a denoising autoencoder). We use their HuggingFace codebases.

Retrieval Baseline (Retr): We use a retrieval-based approach as a baseline. We manually query Google using {*condition* + DIM + DIM *attribute*}, e.g. {*asthma* + *risk factor* + *smoking*}, and extract either the *featured snippet* at the top of the results page, or the text below the first link if there is no featured snippet. If the featured snippet is a list or table, we manually concatenate the items into a single piece of text. An example is in Figure 1.

The extracted text approximates an explanation, which we then concatenate to the first part of the associated template to form the final text, e.g. *A person with asthma has a/an smoking risk factor because/since/as* ***{retrieved explanation}***. Retr leverages Google's strong search and summarization capabilities, serving as a useful baseline. Further, Google Search is an evolving baseline that continually challenges our **CHARD** models.[2]

3.2 Data Augmentation (DA)

Since CHARDAT is relatively small, which is mainly a function of our task and domain, i.e. there are a limited number of non-obscure medical conditions and associated DIM attributes, we hypothesize that data augmentation (DA) techniques (Feng et al., 2021a, 2020) may be useful.

As noted by Feng et al. (2021a), text generation and specialized domains (such as healthcare) both present several challenges for DA. In our case, many explanations contain clinical or health jargon which makes techniques that leverage lexical databases such as WordNet, e.g. synonym replacement (Feng et al., 2020), challenging or impossible.

We decide to use backtranslation (BT) (Sennrich et al., 2016) to augment examples in CHARDAT$_{tr}$, a popular and easy DA technique which translates a sentence into another language and back to the original language.[3] This usually results in a slightly altered version (paraphrase) of the original text. BT is effective here as healthcare-related terms are preserved relatively well, and the resulting paraphrased explanation remains relatively intact.

We use UDA (Xie et al., 2020) for BT, which translates sentences from English to French, then back to English. UDA is a DA method that uses unsupervised data through consistency training on $(x, DA(x))$ pairs. An advantage of UDA's BT is that we can control for the degree of variation using

---

[2] We will release our current baseline data.

[3] This is sometimes referred to as *round-trip translation*.

Tmp	Text
0	A person with acne has an avoid irritants prevention because *using oily or irritating personal care products clog your pores causing acne.*
0.5	*if you use oily or irritant personal care products, you block pores and cause acne.*
0.7	*using oily or irritating personal care products, you block acne pores.*
0.9	*use oily and irritating disinfectant products freezing your pores to cause the Acne restructurs.*
0	A person with MultipleSclerosis has a stress management prevention because *stress is more likely to exacerbate the symptoms of MS and bring about a flare or relapse.*
0.5	*stress is more likely to exacerbate MS symptoms and lead to an outbreak or relapse*
0.7	*stress is more likely to exacerbate symptoms of MS and trigger a flare or relapse.*
0.9	*severe mourning problems occurred at Vancouver Hospital (Prince Edward Island), British Columbia. (...)*

Table 3: Examples of original (tmp=0) and BT text. The explanation portion (which is backtranslated) is italicized.

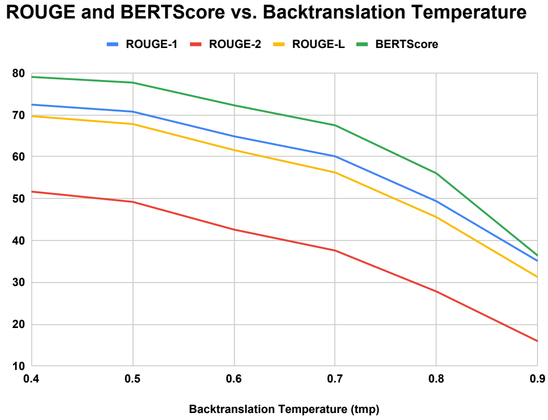

Figure 2: Graph showing how avg. ROUGE and BERTScore of BT vs. original text vary by BT tmp on CHARDAT$_{tr}$.

a *temperature (tmp)* parameter, where higher values (e.g. 0.9) result in more varied paraphrases. We only backtranslate the explanation portion of examples (concatenating them back to the preceding part) as we wish to keep the preceding part intact.

From the examples in Table 3, we can see that higher tmp typically results in more varied text, albeit with issues with content preservation and fluency. For the second example, the tmp=0.9 BT is completely unrelated to the original text. This is not entirely undesirable, as some noise may make our trained models more robust. From Figure 2, we see that the average ROUGE and BERTScore of backtranslated CHARDAT$_{tr}$ text compared to the original text decrease as tmp increases, as expected.

3.3 Evaluation Metrics

We use several standard text generation evaluation metrics including reference-based token and semantic comparison metrics used in works like Lin et al. (2020) such as ROUGE (Lin and Hovy, 2003), CIDEr (Vedantam et al., 2015), and SPICE (Anderson et al., 2016). SPICE translates text to semantic scene graphs and calculates an F-score over graph tuples. CIDEr captures sentence similarity, grammaticality, saliency, importance, and accuracy.[4]

We also use average word length (Len), BERTScore (Zhang et al., 2019), and Perplexity (PPL). BERTScore serves as a more semantic similarity measure by assessing BERT (Devlin et al., 2019) embeddings similarity between individual tokens. We multiply by 100 when reporting BERTScore. PPL approximately measures fluency, where lower values represent higher fluency. We use GPT-2 (Radford et al., 2019) for PPL. Higher is better for all metrics other than PPL and Len.

4 Experimental Setup

4.1 Model Finetuning and Generation

For the standard (non-augmented) **CHARD** models, we train and evaluate four versions of each on CHARDAT, CHARDAT$_{RF}$, CHARDAT$_{TREAT}$, and CHARDAT$_{PREV}$, respectively. The first of these is a combined model that learns to handle all three DIM at once depending on the DIM given at inference, while the latter three are models trained on each individual DIM. We predict that while the latter three may perform better on their particular DIM, the first model is more effective overall as it accomplishes our goal of having a single PLM that can store knowledge and reason through several DIM. It is thus more adaptable and generalizable.

For training the **CHARD** models, we keep most hyperparameters static, other than learning rate (LR) which is tuned per individual model. For each model, we select the epoch that corresponds to highest ROUGE-2 on CHARDAT$_{val}$, and decode using beam search. See Appendix C for more.

4.2 Data Augmentation Experiments

We try several backtranslation DA experiments.

2x DA with Different Tmp: Our first set of experiments involves 2x DA (backtranslating each CHARDAT$_{tr}$ explanation once, to 2x the original training data) using different BT tmp which we call BT-set: {0.4, 0.5, 0.6, 0.7, 0.8, 0.9}. We predict that the optimal tmp lies in the 0.6-0.7 range, as the text is modified to a reasonable degree.

Different DA Amounts (2x-10x): We also try further DA amounts: 3x, 4x, 5x, 7x, and 10x the original amount of training data. We explore whether the amount of augmentation affects performance, and hypothesize that performance will

---

[4] Matching metrics are sufficient as **CHARD** explanations are standardized (space for explanations is low) since our inputs present a particular condition and DIM attribute combo.

increase to a certain point and decline afterward. This is because the advantages of DA may taper off since the augmented data are variations of the original, and models may overfit past a point.

DA Amount Strategies (best-tmp vs. diff-tmp): We also investigate two strategies for selecting each successive iteration of augmented examples. The first is best-tmp, where all the augmented data comes from BT of the tmp that performed best for 2x DA (e.g. all from 0.7).[5]

The second is diff-tmp, where each successive iteration is the tmp that performed next best (e.g. 2x is the best tmp, 3x is additionally the second-best tmp, etc.). For the highest DA amounts (e.g. 10x), when the six tmp values in BT-set have been exhausted, we go back to the best tmp and repeat.

Base vs. Large Models: For the base models (BART-base and T5-base), we try all aforementioned tmp, DA amounts, and amount strategies. For the large models, we try the top three temperatures (for 2x DA) and amount strategy that performed best on the corresponding base model, and only 3x, 5x, 7x, and 10x DA amounts.

Note that BT tmp and DA amounts are both hyperparameters, so while we train models corresponding to different values of them, the final chosen models correspond to the ones that performed best on CHARDAT$_{val}$. We then use these final models to generate on CHARDAT$_{test}$. We report the results of the overall best models in §5.

4.3 Human Evaluation

We conduct human evaluation using AMT.[6] We ask two approved annotators (with strong qualifications and approval ratings on healthcare-related tasks) to each evaluate all 141 CHARDAT$_{test}$ examples. Our evaluation uses pairwise comparison of the outputs from two methods, split into three studies per DIM: RETR vs. best **CHARD** model, RETR vs. human, and human vs. best **CHARD** model.

We ask annotators to choose which amongst the two outputs (presented in a random order per example) has better 1) medical accuracy (MedAcc), 2) informativeness (Inform), and 3) readability (Read). Medical accuracy refers to which explanation is more clinically correct for the given DIM attribute and condition. Informativeness refers to which is more complete and explains in sufficient detail (including *why?*). Readability refers to which is more readable, which includes fluency (natural-sounding English) and conciseness/brevity (not overly long).

Metric	RETR	BART-base	BART-large	T5-base	T5-large
ROUGE-1	43.30	51.37	**51.54**	50.00	50.66

Table 5: Avg. auto eval results of T5-large on CHARDAT$_{test}$ and the test-seen and test-unseen halves.

There are 3 choices for each evaluation aspect - O1: first is better, O2: second is better, O3: both are indistinguishable. To aggregate multiple annotations per example, we find the overall fraction of responses towards each outcome value.

5 Results and Analysis

We report automatic results on CHARDAT$_{test}$ of the best models (for BART-base, BART-large, T5-base, T5-large) trained on CHARDAT compared to RETR in Table 4. The best models are tmp=0.9 2x DA for BART (base and large), 5x DA with diff-tmp for T5-base, and tmp=0.6 2x DA for T5-large.

Our best overall **CHARD** model is T5-large based on automatic results and qualitative analysis. We break down results of T5-large on CHARDAT$_{test-seen}$ and CHARDAT$_{test-unseen}$ in Table 5. We show results of T5-large compared to T5-large$_{DIM}$ (models trained on the individual DIM) in Table 6. We conduct human evaluation with T5-large, and the results are in Table 7.

Graphs displaying models' ROUGE-2 on CHARDAT$_{val}$ for 2x DA across various BT tmp and different DA amounts can be found in Figures 3 and 4, respectively. Tables 8 and 9 contain qualitative examples, with more in Appendix E.

---

[5] This is possible because UDA uses sampling, so even for the same tmp, the backtranslations differ each time.

[6] See Appendix D for further human evaluation details.

Method	**Text**
Input (1)	A person with Hyperhidrosis has a medication treatment because {explanation}
Human	A person with Hyperhidrosis has a medication treatment because anticholinergics medicines such as glycopyrrolate, oxybutynin, benztropine, propantheline etc are helping to prevent the stimulation of sweat glands and, thus, decreasing sweating.
RETR	A person with Hyperhidrosis has a medication treatment because the most common medications used to manage excessive sweating are anticholinergics, including but not limited to: Glycopyrrolate (Robinul). Oxybutynin (Ditropan). Benztropine. Propantheline bromide.
T5-L	A person with Hyperhidrosis has a medication treatment because medications such as ibuprofen, phenytoin, and phenobarbital can help reduce the amount of sweating in the body.
T5-B	A person with Hyperhidrosis has a medication treatment because it helps to reduce the amount of blood in the body and reduces the risk of a blood clot.
Input (2)	A person with Alzheimers has an engage in activity prevention because {explanation}
Human	A person with Alzheimers has an engage in activity prevention because engaging in activity will increase nerve connections in the brain or release hormones that increase nerve cell creation and this helps preserve nerve cells in the brain and mental function
T5-L	A person with Alzheimers has an engage in activity prevention because activities such as walking, jogging, swimming, and playing games can help prevent Alzheimer's
BART-B	A person with Alzheimers has an engage in activity prevention because a person with Alzheimer's disease is more likely to develop dementia
Input (3)	A person with Prostatitis has an infection risk factor because {explanation}
Human	A person with Prostatitis has an infection risk factor because the condition is caused by common strains of bacteria which spread from other parts of the urinary or reproductive systems to infect and inflame the prostate resulting in prostatitis.
T5-L	A person with Prostatitis has an infection risk factor because infections of the prostate, urethra, and genital tract can lead to prostatitis.

Table 8: Qual examples for CHARDAT$_{test-seen}$: human, RETR, T5-large (L), T5-base (B), BART-base (B).

5.1 Automatic Evaluation Results

From Table 4, we see that all **CHARD** models perform better than RETR across most metrics. RETR's average outputs are much longer than those of our models and humans. Among our models, T5-large and BART-large perform best, demonstrating that larger models are more adept. T5-large performs best overall (combined with the qual analysis in §5.3), with the longest average outputs among our models. Some of our models achieve better average fluency (PPL) compared to humans, but the outputs are generally noticeably shorter.

From Table 5, we see that T5-large surprisingly performs better on the test-unseen half. It appears that the model can generalize decently to unseen conditions when trained on CHARDAT. This may partially be due to similar explanations for particular DIM attributes across conditions, e.g. why *sleep* helps treat some conditions may be similar.

From Table 6, we see that for most DIM (namely RF and PREV), the model trained on that specific DIM performs better on that DIM. However, our

Method	Text
Input (4)	A person with Costochondritis has a fix improper posture prevention because {explanation}
Human	A person with Costochondritis has an fix improper posture prevention because bad posture puts stress on joints and tissues, causing joint stiffness, weakened muscles, and inflammation that is so common in Costochondritis.
RETR	A person with Costochondritis has a fix improper posture prevention because what can I do to relieve costochondritis? Lifestyle and home remedies. Nonprescription pain relievers. Acetaminophen (Tylenol, others) ibuprofen (Advil, Motrin IB, others) or naproxen sodium (Aleve, others) (...)
T5-L	A person with Costochondritis has a fix improper posture prevention because poor posture can lead to pain and stiffness.
Input (5)	A person with rheumatoid has a diet risk factor because {explanation}
Human	A person with rheumatoid has a diet risk factor because unhealthy food choices can increase inflammation from rheumatoid
RETR	A person with rheumatoid has a diet risk factor because the results of this study revealed that high intakes of carbohydrates (e.g., potatoes) might be associated with increased RA risks.
T5-L	A person with rheumatoid has a diet risk factor because people who eat a high-fat diet are at a higher risk of developing the disease.
BART-L	A person with rheumatoid has a diet risk factor because a diet rich in red meat, dairy products, and dairy products can cause inflammation
Input (6)	A person with depression has a life-changing event risk factor because {explanation}
Human	A person with depression has a life-changing event risk factor because approximately 70% of first depression episodes and 40% of recurrent episodes of depression are preceded by a severe life event
RETR	A person with depression has a life-changing event risk factor because psychological and Psychosocial Risk Factors for Recurrence · by SL Burcusa · 2007 · Cited by 1085 — These factors include age at onset of the first episode, lifetime number of
T5-L	A person with depression has a life-changing event risk factor because a major life event, such as the death of a loved one, can increase the risk of depression.

Table 9: Qual examples for CHARDAT$_{test-unseen}$: human, RETR, T5-large (L), BART-large (L).

general T5-large model performs better on TREAT. It may be that training on CHARDAT has allowed the model to learn from data of other DIM, improving its overall knowledge and generation capabilities (an advantage of a single combined model).

From Figure 3, we see that the BART models generally increase in performance with higher BT tmp (upward trend), whereas T5 fluctuates. This may be due several reasons, e.g. differences in the architecture and pretraining strategies of the models, allowing BART to leverage noisy data more effectively. From Figure 4, we see that performance generally increases for each model up to a certain point (e.g. 2x or 3x DA), and then decreases afterward, aligning with our hypothesis from §4.2.

5.2 Human Evaluation Results

From Table 7, we see that both RETR and T5-large are outperformed by humans, although RETR is relatively close in informativeness and medical accuracy, and T5-large slightly outperforms on readability. RETR outperforms T5-large on medical accuracy and informativeness, which is somewhat expected as it uses Google Search. It is worse than T5-large on readability, as our models generate more fluent, concise, and readable text (see §5.3).

5.3 Qualitative Analysis

We examine the qualitative examples in Tables 8 and 9. Firstly, we see that RETR is able to generally perform well by extracting relevant information (ex.1 - a list of medications for Hyperhidrosis, ex.5 - that carbohydrates increase RA risk), which is expected using Google Search. However, it sometimes extracts a lengthy amount of irrelevant information. For ex.4, RETR extracts a difficult-to-read list of different TREAT strategies, which is for the wrong DIM, and does not narrow down on an explanation for the specific DIM attribute in the input. For ex.6, it extracts the info and beginning of a passage from a scientific article, ending abruptly and not explaining the given DIM attribute.

Our models, specifically T5-large, are generally able to output more concise, readable, and sometimes relevant explanations compared to RETR. For ex.1, T5-large outputs a list of medications, albeit not for Hyperhidrosis - showing weaknesses in medical accuracy. Other than ibuprofen, the other medications are not in CHARDAT$_{tr}$, showing that these were likely already known to T5-large through pretraining. For ex.2, it generates a reasonable list of activities to help prevent Alzheimer's, and for ex.3, it lists correct body parts where an infection can occur to cause Prostatitis. It can generalize well to unseen conditions, as shown through ex.4-6. It reasons that poor posture can lead to pain and stiffness, high-fat diets can increase the chance of rheumatoid, and that a major life event (*"death of a loved one"*) can cause depression. These generalization capabilities are likely from a combination of pretraining and CHARDAT$_{tr}$.

Compared to humans, T5-large's outputs are lacking. Human explanations are typically longer and more informative, explaining the exact reason (*why?*) a specific DIM attribute relates to the given condition. For ex.2, it explains how activities can help *"preserve nerve cells in the brain and mental function"*, whereas T5-large simply lists activities. This similarly occurs for ex.3-5. Human explanations are also typically more medically accurate, e.g. for ex.1, the listed medications are correct. However, we do see that some of T5-large's outputs (for ex.1,2,4) are more readable. Further, T5-large sometimes presents more information, e.g. an exact list of activities for ex.2, a specific type of diet (*"high-fat"*) for ex.5 (human just says *"unhealthy"*), and an example of a life-changing event for ex.6.

BART-large also performs decently. In ex.5, it lists several specific and correct types of foods (*"red meat, dairy products"*). The base models perform much worse. For ex.1, T5-base talks about medication reducing *"blood clots"*, unrelated to Hyperhydrosis. For ex.2, BART-base writes an explanation completely irrelevant to the input DIM.

6 Directions for Improvement

We see that our models are decent and generate readable text, but can improve on medical accuracy and informativeness. While they are not nearly ready for real-world use, they show potential.

As stated, the purpose of **CHARD** is to assess the capabilities of PLMs to act as implicit clinical knowledge bases that can reason through several dimensions. How can we improve our models, and possibly our dataset and task formulation?

Dataset and task formulation: We introduce **CHARD** and initially frame the task using a template infilling approach which is more constrained. More flexible formulations may better leverage the knowledge and generation capabilities of PLMs.

Our current approach involves generating explanations about a single condition and DIM attribute at a time. We can possibly improve CHARDAT by annotating for more complicated input queries. This is because a PLM may be more effective at answering more complicated queries, e.g. comparing and contrasting conditions and DIM and multi-hop reasoning. It is likely easier to make complicated inferences and connections over the abstract PLM embedding space than over retrieved text passages.

Further, we can expand CHARDAT to include more dimensions and topics in the health domain. These improvements may allow for the training of a single system that is able to make complicated clinical inferences across various topics and DIM.

Model improvements: We can explore models such as GPT-3 (Brown et al., 2020) and PALM (Chowdhery et al., 2022) for **CHARD** that are larger with stronger pretraining. We can also investigate enhancing PLMs with information retrieval, e.g. using a retrieval approach to obtain relevant scientific literature as evidence, combined with a text summarization system to digest the content. Our model can then conduct its clinical reasoning on this digested content. Users can potentially take advantage of such a system to automatically verify the medical accuracy of generated explanations, and then improve the generation model itself using this feedback loop (i.e. a self-improving system).

7 Related Work

Constrained Text Generation: There have been several works on constrained text generation. For creative text generation, Gangal et al. (2022) introduce narrative reordering (NAREOR) to edit the temporality of narratives. Keh et al. (2022) and Keh et al. (2023) explore the generation of personifications and tongue twisters, respectively. Donahue et al. (2020) introduce and investigate the task of infilling. Feng et al. (2019) propose Semantic Text Exchange to adjust topic-level text semantics using infilling. Rajagopal et al. (2021) investigate cross-domain reasoning using a prompt-tuning setup. Our work distinctly investigates template infilling for clinical reasoning along dimensions.

Commonsense Reasoning for Models: One large commonsense KG is COMET, which trains on KG edges to learn connections between words and phrases. COSMIC (Ghosal et al., 2020) uses COMET to inject commonsense into models. CommonGen (Lin et al., 2020) assesses the commonsense reasoning of text generation models. Several works investigate CommonGen, including SAPPHIRE (Feng et al., 2021b) and VisCTG (Feng et al., 2022), the latter of which uses visual grounding. Unlike these works, **CHARD** distinctly investigates reasoning for the clinical/health domain.

Reasoning for Clinical/Health Domain: Most existing work here involves retrieval or extraction. MIMICause (Khetan et al., 2022) extracts causal medical information from electronic health records to help understand narratives in clinical texts. Ahne et al. (2022) extract a causal graph and reason about diabetes distress for better understanding the opinions, feelings, and observations of the diabetes online community from a causality perspective.

For generation, Moramarco et al. (2021) investigate the use of LMs to simplify medical text. Abaho et al. (2022) probe factual knowledge from LMs to elicit answers related to treatment outcomes. **CHARD** has a different goal: rather than simply probe for factual knowledge, we assess how LMs can act as and reason through an implicit knowledge base. Meng et al. (2022) investigate probing biomedical knowledge by introducing a benchmark, MedLAMA, that focuses on 19 relations. **CHARD** instead focuses on clinical knowledge reasoning along different dimensions.

8 Conclusion and Future Work

In conclusion, we proposed and investigated the task of **CHARD**: Clinical Health-Aware Reasoning across Dimensions, to explore the capability of text generation models to act as implicit clinical knowledge bases and generate explanations across several health dimensions. We presented a dataset, CHARDAT, and conducted experiments with BART and T5. Extensive evaluation and qualitative analysis demonstrated that our models are decent, especially for generating concise and readable text, but can be improved on medical accuracy and informativeness, and that **CHARD** is challenging with much potential for further exploration. We highly encourage the research community to further investigate and improve upon **CHARD**.

Future directions are discussed in §6. Some additional ideas include trying more data augmentation strategies and decoding strategies for text infilling.

Limitations

We discuss some limitations of our work and potential directions for improvement in §6. Specifically, our template-infilling approach is less flexible, and we can expand to more complicated input queries to better leverage the power of PLMs in future work. Further, CHARDAT focuses on three main clinical dimensions, which can be expanded upon to include more dimensions and topics in the future. Our seq2seq models are also relatively weaker compared to GPT-3, PALM, and recent larger PLMs, which may perform more effectively on **CHARD**. We are also investigating a completely generative approach, and combining generation with retrieval in interesting ways may be more effective. Overall, our current **CHARD** models have room to improve on medical accuracy and informativeness, and are not nearly ready for real-world use.

However, we note again that we are the first to propose **CHARD**, and our work is the first step towards longer-term goals regarding clinical reasoning using PLMs. We are after more of the *commonsense* medical reasoning for now, rather than very deep medical knowledge. In this paper, we see how far one can get with a standard task formulation, NLP methods, seq2seq models, and AMT annotations. As they say, *"walk before you run"*!

Ethics

We collected CHARDAT and conducted our human evaluation studies using AMT, in a manner consistent with terms of use of any sources and intellectual property and privacy rights of AMT crowd workers.

Our collected dataset, CHARDAT, consists of general clinical information, where explanations are impersonal. We also manually examined a large subset of the data, and ensured there were no issues with respect to privacy and other ethical concerns, e.g. offensive words, profanities, racism, gender bias, and other malicious language.

We acknowledge the weaknesses of **CHARD** models and the potential risks if they are used for real-world purposes. We will never use our models or encourage their use for real-world purposes, at least in their current state, and also emphasize this in the paper. As we noted, we propose **CHARD** and conduct our initial experiments purely for investigation purposes and to test our hypotheses. Our paper presents an important contribution to the ML, NLP, and healthcare communities, and we encourage researchers to further improve upon it.

Our task, models, dataset, and accompanying publication are intended only for research purposes and to assess the capabilities of text generators.

A Full List of Health Conditions

See Table 10 for a list of all health conditions in CHARDAT.

B CHARDAT Annotation Details

Human annotation for CHARDAT was done via paid crowdworkers on AMT, who were from Anglophone countries. They were selected through a series of qualification tests on a small subset of the samples, and have a history of high approval rates ($> 95\%$) and good performance on related tasks. Based on initial annotations and performance on the qualification tests, workers were only re-hired if their performance was sufficient over time and they reliably followed the given instructions. The annotators were paid variable amounts (with periodic bonuses over time) depending on their performance and consistency, and the pay for all workers exceeds the minimum wage for the USA.

The workers were asked to write passages (that include explanations) that are as specific and factually accurate as possible, describing how a specific dimension attribute relates to the given condition. Each HIT (annotation page) contains a single condition + dimension attribute combination, and they write a single passage that fills in the given template with an explanation. In the instructions, we describe each dimension in detail, and include several examples of correct and incorrect passages (regarding medical/factual accuracy, brevity/readability, and informativeness). We also encourage them to consult useful and trusted clinical resources such as MayoClinic, CDC, WebMD, and Healthline, if necessary, while writing the explanation.

Annotations were manually examined by the authors as they came in, and annotators were asked to improve their explanations if necessary. Annotators with consistently poor annotations were asked to stop annotating, and their completed annotations were re-annotated by others. At the end of the data collection process, the authors manually examined a large subset of CHARDAT, ensuring sufficiently high quality of annotations in terms of medical accuracy, informativeness, and readability.

C Further Model Finetuning and Generation Details

T5-large consists of 770M params, T5-base 220M params, BART-large 406M params, and BART-base 139M params. For all models, we use beam search with a beam size of 5, decoder early stopping, a decoder length penalty of 0.6, and a decoder minimum length of 1. We set the maximum encoder and decoder lengths depending on values that can fit all examples in CHARDAT_{tr}, which ended up being 32 and 128 (for encoder and decoder, respectively) for the BART models, and 35 and 128 for the T5 models. Models are trained using fp16, and Adam optimizer with epsilon=1e-08. We use a training seed of 42 for all models, and a random seed of 42 for all other scripts that involved randomization. Decoding is done using beam search with a beam width of 5.

For model training, we use a batch size of either 64 or 32 for T5-base and BART-base, and either 8 or 16 for BART and T5-large (depending on GPU memory). For T5-base and BART-base, we use 400 warmup steps, 500 for BART-large, and 1200 for T5-large. We train all models up to a reasonable number of epochs (e.g. 20 to 30 for base models and 10 to 15 for large models). The learning rates for **CHARD** models were determined by trying a range of values (e.g. from 1e-8 to 5e-1), and finding ones which led to good convergence behavior. For the best-performing models, learning rates are as follows: BART-base = 5e-06, BART-large = 1e-05, T5-base = 1e-03, T5-large = 1e-05.

Training was done using single GTX 1080 Ti, TITAN RTX, RTX 2080 Ti, and GTX TITAN X GPUs. Model training time varied depending on the model type+size and amount of data augmentation, and varied between 5 minutes to 3 hours.

D Further Human Evaluation Details

Human evaluation was done via paid crowdworkers on AMT, who were from Anglophone countries. They were selected through qualification tests and have a history of high approval rates ($> 95\%$) and good performance on related tasks. Each example was evaluated by 2 annotators. The time given for each AMT task instance or HIT was 1 hour maximum for an approximately 1-minute task. Sufficient time to read instructions, as calibrated by authors, was also considered. Annotators were paid 20 cents per HIT. This rate ($12/hr) exceeds the minimum wage for the USA ($7.25/hr) and constitutes fair pay. Workers who performed well were also paid periodic bonuses based on the timeliness and quality of their annotations.

The human evaluation was split into 9 studies: 3 pairwise method comparisons (RETR vs. T5-large,

Dysthymia	cfs	ibs	Narcolepsy	bulimia
Hypothyroidism	Costochondritis	psychosis	CysticFibrosis	POTS
MultipleSclerosis	Gastroparesis	gout	adhd	diabetes
CrohnsDisease	lupus	rheumatoid	Sinusitis	thyroidcancer
Hyperhidrosis	gerd	AnkylosingSpondylitis	endometriosis	schizophrenia
asthma	bipolar	depression	pcos	covid19
acne	anxiety	dementia	ptsd	dystonia
Epilepsy	ErectileDysfunction	Herpes	insomnia	Anemia
LymeDisease	migraine	ocd	parkinsons	Alzheimers
hpv	Prostatitis	backpain	Sciatica	Fibromyalgia
bpd	PagetSchroetter			

Table 10: A list of all 52 health conditions used in CHARDAT.

RETR vs. human, and human vs. T5-large) by 3 dimensions (risk factors, treatment, and prevention). Each HIT or task page presented a given condition, the associated dimension attribute, and two explanations (from the two methods of the study) in a random order. They are asked to select among the three choices (first explanation is better, second explanation is better, *hard to prefer one over the other*) for the three evaluation aspects of medical accuracy, informativeness, and readability. In the instructions, we describe the clinical dimension and each evaluation aspect in detail with positive and negative examples of each, and encouraged them to consult useful and trusted clinical resources such as MayoClinic, CDC, WebMD, and Healthline, if necessary, while evaluating the explanations.

E Further Qualitative Examples

See Tables 11 and 12 for more qualitative examples on CHARDAT_{test}.

Method	**Text**
Input	A person with Hyperhidrosis has a/an infection risk factor because/since/as {explanation}
Human	A person with Hyperhidrosis has an infection risk factor because some kinds of infections like tuberculosis, HIV, bone infection cause hyperhidrosis
RETR	A person with Hyperhidrosis has a/an infection risk factor because/since/as this increases the risk of skin conditions such as athlete's foot and more severe conditions such as bacterial infections or pitted keratolysis. Study results report a nearly 30% greater risk of skin infections in patients with hyperhidrosis compared with healthy controls.
T5-L	A person with Hyperhidrosis has an infection risk factor because infections such as staph, typhoid, hepatitis and polio can cause excessive sweating.
T5-B	A person with Hyperhidrosis has an infection risk factor because a person who has a viral infection is more likely to have a virus infection.
BART-L	A person with Hyperhidrosis has an infection risk factor because infection can cause hyperhidrosis
BART-B	A person with Hyperhidrosis has an infection risk factor because a person with hyperhidrosis is more likely to have an infection.
Input	A person with AnkylosingSpondylitis has a/an age risk factor because/since/as {explanation}
Human	A person with AnkylosingSpondylitis has an age risk factor because about 80 percent of people first develop ankylosing spondylitis symptoms under age 30
RETR	A person with AnkylosingSpondylitis has a/an age risk factor because/since/as about 80 percent of people first develop ankylosing spondylitis symptoms under age 30
T5-L	A person with AnkylosingSpondylitis has an age risk factor because people over 50 years of age are at a higher risk of developing the disease
T5-B	A person with AnkylosingSpondylitis has an age risk factor because older adults are more likely to develop ankylosis.
BART-L	A person with AnkylosingSpondylitis has an age risk factor because the risk of developing ankylosis increases with age
BART-B	A person with AnkylosingSpondylitis has an age risk factor because older people are more likely to develop the disease
Input	A person with rheumatoid has a/an regular exercise treatment because/since/as {explanation}
Human	A person with rheumatoid has a/an regular exercise treatment because it helps reduce the disability often associated with rheumatoid arthritis and boosts strength and flexibility
RETR	A person with rheumatoid has a/an regular exercise treatment because/since/as but exercise is one of the key treatments to help reduce the disability often associated with rheumatoid arthritis. Regular exercise can boost strength and flexibility in people who have rheumatoid arthritis. Stronger muscles can better support your joints, while improved flexibility can aid joint function.
T5-L	A person with rheumatoid has a regular exercise treatment because exercise can help reduce inflammation and improve blood flow to the joints.
T5-B	A person with rheumatoid has a regular exercise treatment because regular exercise can help reduce the symptoms of the disease.
BART-L	A person with rheumatoid has a regular exercise treatment because exercise can help reduce inflammation and pain
BART-B	A person with rheumatoid has a regular exercise treatment because regular exercise can help reduce inflammation and inflammation in the body.

Table 11: More qual examples for CHARDAT$_{test}$: human, RETR, T5-large (L), T5-base (B), BART-large (L), BART-base (B)

Method	**Text**
Input	A person with thyroidcancer has a/an chemotherapy treatment because/since/as {explanation}
Human	A person with thyroidcancer has a chemotherapy treatment because Chemotherapy (chemo) uses anti-cancer drugs that are injected into a vein or are taken by mouth. Chemotherapy is systemic therapy, which means that the drug enters the bloodstream and travels throughout the body to reach and destroy cancer cells and stops cancer growth.
RETR	A person with thyroidcancer has a/an chemotherapy treatment because/since/as chemotherapy is seldom helpful for most types of thyroid cancer, but fortunately it is not needed in most cases. It is often combined with external beam radiation therapy for anaplastic thyroid cancer and is sometimes used for other advanced cancers that no longer respond to other treatments.
T5-L	A person with thyroidcancer has a chemotherapy treatment because chemotherapy destroys the cells that cause the cancer.
T5-B	A person with thyroidcancer has a chemotherapy treatment because chemotherapy reduces the risk of thyroid cancer.
BART-L	A person with thyroidcancer has a chemotherapy treatment because chemotherapy can slow down the growth of thyroid cancer
BART-B	A person with thyroidcancer has a chemotherapy treatment because chemotherapy can help reduce the risk of thyroid cancer
Input	A person with depression has a/an medical conditions risk factor because/since/as {explanation}
Human	A person with depression has a medical conditions risk factor because the pain and stress that come with certain conditions, including cancer, stroke, or heart disease, can take a toll on a person's mental state resulting in depression.
RETR	A person with depression has a/an medical conditions risk factor because/since/as more commonly studied were the connections between depression and cardiovascular disease, metabolic syndrome, biochemical alterations, diabetes, dementia, cognitive impairment, Alzheimer's disease, somatization and chronic pain, asthma, arthritis, and hyperlipidemia.
T5-L	A person with depression has a medical conditions risk factor because depression can be caused by a number of medical conditions, such as diabetes, heart disease, high blood pressure, high cholesterol and high blood sugar.
T5-B	A person with depression has a medical conditions risk factor because medical conditions such as diabetes, heart disease, diabetes, AIDS, and other conditions that cause depression, such as cancer, are linked to depression.
BART-L	A person with depression has a medical conditions risk factor because depression can be caused by a variety of medical conditions.
BART-B	A person with depression has a medical conditions risk factor because depression can be a cause of depression.
Input	A person with depression has a/an grief risk factor because/since/as {explanation}
Human	A person with depression has a grief risk factor because grief associated with loss of dear one greatly increases the risk of psychiatric complications such as depression
RETR	A person with depression has a/an grief risk factor because/since/as risk Factors · Genetics: A history of depression in your family may make it more likely for you to get it. · Death or loss: Sadness and grief are ...
T5-L	A person with depression has a grief risk factor because people who have experienced a loss of a loved one are more likely to develop depression.
T5-B	A person with depression has a grief risk factor because grief is the most common cause of depression.
BART-L	A person with depression has a grief risk factor because grief can cause depression
BART-B	A person with depression has a grief risk factor because grief is associated with depression.

Prompt Tuning with Contradictory Intentions for Sarcasm Recognition

Yiyi Liu, Ruqing Zhang, Yixing Fan, Jiafeng Guo, Xueqi Cheng
CAS Key Lab of Network Data Science and Technology, Institute of Computing Technology,
Chinese Academy of Sciences, Beijing, China
University of Chinese Academy of Sciences, Beijing, China
{liuyiyi17s,zhangruqing,fanyixing,guojiafeng,cxq}@ict.ac.cn

Abstract

Recently, prompt tuning has achieved promising results in a variety of natural language processing (NLP) tasks. The typical approach is to insert text pieces (i.e., templates) into the input and transform downstream tasks into the same form as pre-training. In essence, a high-quality template is the foundation of prompt tuning to support the performance of the converted cloze-style task. However, for sarcasm recognition, it is time-consuming and requires increasingly sophisticated domain knowledge to determine the appropriate templates and label words due to its highly figurative nature. In this work, we propose SarcPrompt, to incorporate the prior knowledge about contradictory intentions into prompt tuning for sarcasm recognition. SarcPrompt is inspired by that the speaker usually says the opposite of what they actually mean in the sarcastic text. Based on this idea, we explicitly mimic the actual intention by prompt construction and indicate whether the actual intention is contradictory to the literal content by verbalizer engineering. Experiments on three public datasets with standard and low-resource settings demonstrate the effectiveness of our SarcPrompt for sarcasm recognition.

1 Introduction

Sarcasm is a sophisticated language phenomenon in which one conveys implicit intention with the opposite meaning of what is said or written literally (Campbell and Katz, 2012; Joshi et al., 2015). Due to its high ambivalence and figurative nature, sarcasm recognition which targets to predict a text as sarcastic or non-sarcastic, becomes a particularly challenging classification task. With the usage of sarcasm becoming prevalent on social media platforms like microblogs and online forums, sarcasm recognition has received growing research attention to facilitate sentiment analysis applications. Recent advances have shown that Pre-trained Language Models (PLMs), such as RoBERTa (Liu et al., 2019b), BERT (Devlin et al., 2019), can achieve promising performance in many downstream Natural Language Processing (NLP) tasks (Xu et al., 2019; Liu et al., 2019a; Zhou et al., 2021). The success of PLMs has also attracted much attention for sarcasm recognition. Researchers mainly add extra classifiers on top of PLMs (Lou et al., 2021) to further train the models under classification objectives, or re-train popular PLMs by incorporating sentiment knowledge and external sarcastic corpus (Babanejad et al., 2020).

Despite fine-tuning has achieved satisfying results, some recent studies (Schick and Schütze, 2021a,b) have found that one of its critical challenges is the significant gap in objective forms between pre-training and fine-tuning. This largely limits the transfer and adaptation of knowledge in PLMs to downstream tasks. Recently, a series of studies propose to use prompt tuning (Han et al., 2021; Schick and Schütze, 2021a; Chen et al., 2022b) to bridge the gap between pre-training and fine-tuning. Specifically, the downstream task is formulated as a (masked) language modeling problem similar to the pre-training. By fusing the original input with the specially constructed prompt template to predict `[MASK]` and then mapping predicted words to corresponding labels, we can stimulate the task-related knowledge in PLMs to boost the model's performance.

Nevertheless, there are still several non-trivial challenges for sarcasm recognition with prompt tuning as follows. On the one hand, texts of a specific task can differ from that of PLMs used in prompt tuning (Chen et al., 2022b). For sarcasm recognition, the sarcastic data is usually composed of abundant deliberately ambiguous texts. In contrast, the corpora for PLMs in prompt tuning mainly include objective and deterministic texts (Liu et al., 2022). This greatly restricts PLMs from taking full advantage of their knowledge. On the other hand, though prompt tuning works well in text classifica-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 328–339
May 2-6, 2023

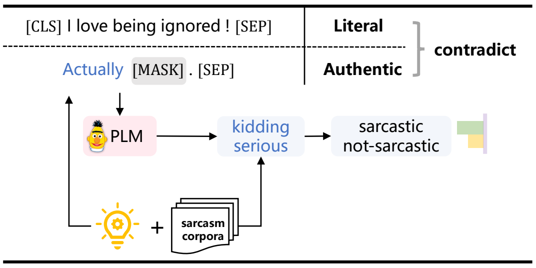

Figure 1: The example of prompt tuning to stimulate the contradictory for sarcasm recognition.

tion tasks, prompt templates and verbalizer are not easily transferable to sarcasm recognition. Both handcrafting an appropriate prompt template and choosing effective label words require domain expertise in sarcasm language. Furthermore, there exists deliberate ambiguity in sarcasm and the special written content cannot be ignored. In this sense, we argue that the power of prompt tuning has not been fully exploited for sarcasm recognition.

Shed light by the above challenges and insights, in this paper, we propose SarcPrompt, a novel prompt tuning method to leverage the contradiction knowledge-enhanced prompts to tune the PLMs. SarcPrompt is inspired by that sarcasm is known as "the activity of saying or writing the opposite of what you mean" (Tungthamthiti et al., 2014). According to this definition, we can recognize sarcasm by evaluating the inconsistency between the actual intention and the literal content in sarcastic texts. Based on intention contradiction, we carefully devise the prompt templates that can mimic the speakers' actual intention and then select label words to judge whether the prompt is contradictory to the literal content. Take the sentence in Figure 1 as an example, the original input is "I love being ignored". A good prompt template may denote "***Actually*** *[MASK]*". "Actually" is an indicator to trigger the authentic intention. If PLMs predict the masked position with a good label word "kidding", the new completed sentence denotes "I love being ignored. ***Actually*** *kidding*.". The intention of the prompt template completed with the predicted word is contradictory to the original input's content. Then we can intuitively recognize a sarcastic text.

To be specific, SarcPrompt mainly contains two steps: prompt construction and verbalizer engineering. Firstly, in the stage of prompt construction, we devise two kinds of sarcasm-specific prompts with different patterns to mimic the actual intention straightforwardly. Secondly, during the verbalizer engineering, we determine the label words that trigger contradictory or suggest sarcasm based on the statistical information of sarcastic corpora. Furthermore, we investigate a contrastive loss to comprehend various sarcastic contrast patterns, jointly with the cross-entropy loss for optimization. The contrastive loss strives to pull the representation of a sarcastic text towards that of other sarcastic texts in the same mini-batch, while pushing it away from representations of other non-sarcastic texts.

We conduct extensive experiments on three benchmark datasets for sarcasm recognition. Empirical experimental results demonstrate that our SarcPrompt[1] has achieved state-of-the-art performance under both standard supervised settings and low-resource settings.

2 Related Work

In this section, we briefly review two lines of related work, including sarcasm recognition and prompt tuning.

Sarcasm Recognition. Identifying sarcasm in texts has evolved from traditional methods to deep neural methods. Traditional approaches mostly utilize machine learning methods with manually engineered features (Riloff et al., 2013; González-Ibáñez et al., 2011; Patra et al., 2016; Hee et al., 2018b; González-Ibánez et al., 2011; Joshi et al., 2015). Deep neural models for sarcasm recognition aim to capture the contrast of sarcasm through the design of the model structure. They are mainly divided into two categories: contrast between words or phrases intra-sentence(Ghosh and Veale, 2016; Wu et al., 2018; Ghosh and Veale, 2018; Tay et al., 2018; Xiong et al., 2019; Lou et al., 2021) and contrast based on the essence of sarcasm phenomenon (Liu et al., 2022).

With the advent of pre-trained language models, a lot of sarcasm recognition methods based on PLMs have been proposed. There are two lines of utilizing PLMs: fine-tuning and pre-training. Fine-tuning mode uses PLMs as an encoder to obtain text representation (Lou et al., 2021; Liu et al., 2022; Li et al., 2021). Pre-training mode usually combines sentiment knowledge and external sarcastic corpora to advance the performance of sarcasm recognition (Babanejad et al., 2020). However, the existing methods using PLMs have many drawbacks which make PLMs ineffective in sarcasm recognition. Pre-training a new language model for a specific task is seriously affected by the external

---

[1] https://github.com/yiyi-ict/sarcprompt.

knowledge used, and also increases the complexity. And the acquisition and selection of external knowledge suitable for different sarcasm patterns are not easy.

Prompt Tuning. With the emergence of GPT-3 (Brown et al., 2020), prompt tuning, as a new paradigm for utilizing PLMs, has attracted more and more attention of researchers. Prompt tuning methods have achieved promising performance in many NLP tasks (Schick and Schütze, 2021a; Hu et al., 2022; Chen et al., 2022a; Zhong et al., 2021; Chen et al., 2022b). Especially, a lot of work has been proposed to solve text classification, which can be divided into two categories: manual prompts (Schick and Schütze, 2021a) and automatic prompts (Gao et al., 2021; Schick et al., 2020). Hu et al. (2022) propose to incorporate external knowledge into verbalizer for text classification. Chen et al. (2022b) propose to use input with prompt as a query to retrieve relevant task-specific data from large raw texts, which makes prompt tuning better fit classification tasks. Shin et al. (2020) propose gradient-guided search method to automatically generate prompt templates. However, these work cannot be adapted to sarcasm recognition directly. So far there is no prompt tuning method specially designed for sarcasm recognition.

3 Background

Before introducing SarcPrompt, we first briefly review the regular prompt tuning method for sentiment classification. Formally, let M be a masked language model with vocabulary V and mask token `[MASK]` $\in V$, and let $\mathcal{Y}$ be the set of labels for sentiment classification.

Traditional classification methods including fine-tuning PLMs train a model to take in an input $\mathbf{x} = (x_0, x_1, \ldots, x_n)$, generate a probability distribution over class $\mathcal{Y}$ and predict an output y as $P(y|\mathbf{x})$. As for prompt tuning, the input $\mathbf{x}$ is wrapped with a *prompt template*. For example, assuming we need to classify the input sentence $\mathbf{x} =$ "Best pizza ever!" into label POSITIVE or NEGATIVE, the prompt template is defined as "It is `[MASK]`.". This is a general template widely accepted and used in text classification tasks (Schick and Schütze, 2021a; Hu et al., 2022), which is also applicable to sarcasm recognition task. Then the wrapped input is

$$\mathbf{x}_{\mathrm{p}} = \mathbf{x} \text{ It is } \texttt{[MASK]}.$$

Then M generates a probability over vocabulary V on position `[MASK]`, which gives the probability of each token $v \in V$ being filled in `[MASK]` token $P_M(\texttt{[MASK]} = v|\mathbf{x}_{\mathrm{p}})$. Furthermore, a *verbalizer* is to map from *label word* set $V_y \in V$ to the label space $\mathcal{Y}$. Corresponding to the above prompt, we may define $V_{pos} = \{\text{"positive"}\}$ as the label word of "positive" class, $V_{neg} = \{\text{"negative"}\}$ denotes the label word of "negative" class. Then the probability of label y is calculated as

$$P(y|\mathbf{x}_{\mathrm{p}}) = g(P_M(\texttt{[MASK]} = v|\mathbf{x}_{\mathrm{p}})|v \in V_y),$$

where g is a function that transforms the probability of label words into the probability of the class. If $P(y_{pos}) > P(y_{neg})$, we classify the instance into POSITIVE.

4 SarcPrompt

In this section, we introduce our prompt tuning model for sarcasm recognition (SarcPrompt) in detail. The overview of SarcPrompt is shown in Figure 2. We first introduce prompt construction and then verbalizer engineering. Finally we elucidate the training objective.

4.1 Prompt Construction

Recall that the representative characteristic of sarcastic texts is the contradiction between the literal content and the actual intention. The actual intention usually hides behind the literal content obscurely. The goal of prompt construction is to mimic the actual intention. Specifically, we define two kinds of prompts, including clash prompt and question prompt.

Clash Prompt. The goal of clash prompt for sarcasm recognition is to mimic the actual intention. For sarcastic texts, a good prompt template should reflect disapproval of the original text; for non-sarcastic texts, the prompt should agree with the meaning of the original text. Therefore, we utilize fact-related phrases which can either express the inconsistency with facts or consistency with facts.

We design five clash prompts $T_{c_1}(\mathbf{x})$~$T_{c_5}(\mathbf{x})$. Key phrases such as "in fact", "actually" are used to elicit whether the prompt clause has contradictory intentions with original input $\mathbf{x}$.

$T_{c_1}(\mathbf{x}) = \mathbf{x}$ Actually `[MASK]`.

$T_{c_2}(\mathbf{x}) = \mathbf{x}$ In reality, it was `[MASK]`.

$T_{c_3}(\mathbf{x}) = \mathbf{x}$ As a matter of fact, it was `[MASK]`.

$T_{c_4}(\mathbf{x}) = \mathbf{x}$ To tell you the truth, it was `[MASK]`.

$T_{c_5}(\mathbf{x}) = \mathbf{x}$ In fact, it was `[MASK]`.

Question Prompt. Question prompt is equiva-

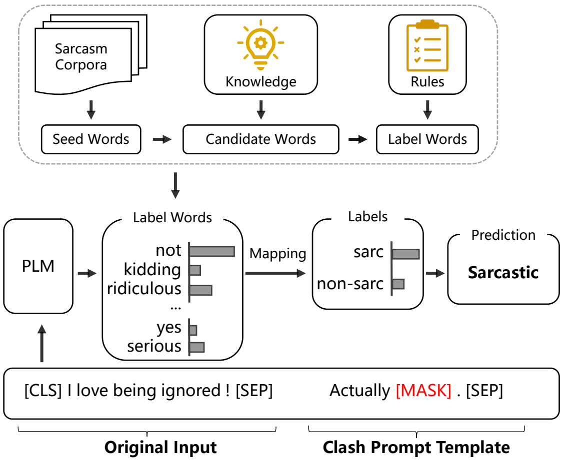

Figure 2: SarcPrompt specified with clash prompt.

lent to directly telling the model that the task is to identify sarcasm by asking a question. Inspired by the summary of prompt design for different tasks in (Liu et al., 2021), we propose three question prompt templates $T_{q_1}(\mathbf{x})$~$T_{q_3}(\mathbf{x})$ for sarcasm recognition. Compared with clash prompt, question prompt is a more direct way to judge whether the input text $\mathbf{x}$ is sarcastic.

$T_{q_1}(\mathbf{x}) = \mathbf{x}$ Are you kidding? `[MASK]`.

$T_{q_2}(\mathbf{x}) = \mathbf{x}$ Are you sarcastic? `[MASK]`.

$T_{q_3}(\mathbf{x}) = \mathbf{x}$ Are you ironic? `[MASK]`.

4.2 Verbalizer Engineering

By fusing the original input with the prompt template, we can obtain a new input $\mathbf{x}_\mathrm{p}$. Then PLMs can output a probability distribution over the vocabulary set V. The goal of verbalizer engineering is to determine label words that should be filled in the masked position, and then how to map label words to the corresponding labels. Verbalizer engineering is crucial because label words directly determine the corresponding relationship with sarcasm or not. Specifically, verbalizer engineering consists of two steps: label word searching and verbalizer mapping.

4.2.1 Label Word Searching

The goal of label word searching is to find words that are appropriate in the masked position. The key idea is to find words that suggest the contradictory intention between the original input and the prompt template. For question prompt, “Yes” or “No” is enough to answer the questions. There is no need to search for label words.

For clash prompt, the label word searching mainly includes three steps: (1) to determine seed words based on the statistical information of sarcastic corpora; (2) to retrieve candidate words by knowledge based on the seed words, and (3) to denoise and obtain the final label words based on rules. In the next, we will introduce the process of label word searching for the clash prompt.

Table 1: Top 5 frequently appearing hashtags in a sarcastic tweet dataset.

Hashtag	Frequency
#not	42.12%
#sarcasm	37.62%
#irony	21.14%
#joke	0.84%
#kidding	0.37%

Seed Words. The regular prompt tuning method usually uses the class name as the only label word for each class directly. For the sarcastic class, the label word can be "sarcasm", however, for the non-sarcastic class, the label word is not trivial to find. The intuitive idea of designing verbalizer is to reflect the contradiction of the literal content and the actual intention in one sarcastic text. We observe that people tend to add sarcasm-related hashtags to suggest the content they post expresses sarcastic meaning especially on the Twitter platform, which is shown below.

I love waking up with migraines ***#not***
I just love when you test my patience!! ***#sarcasm***

We count the frequency of the hashtags used in a sarcastic dataset consisting of tweets[2]. And the top five frequently appearing hashtags in sarcastic texts are shown in Table 1. Expressions in real scenes provide us with prior knowledge for determining label words of sarcasm recognition, which is exactly what we want in SarcPrompt. We use “not”, “irony”, “sarcasm”, “kidding”, “joke”, which appear frequently in the sarcasm-related hashtags as seed words for sarcastic class. On the contrary, their antonyms serve as seeds for the non-sarcastic class. These words are well-suit to indicate that the prompt template has contradictory intentions with the original input’s content.

Candidate Words. Based on the seed words, we can retrieve more candidate words from the knowledge base. The process of predicting masked words based on the context is not a single-choice procedure. There is no standard correct answer. Maybe abundant words fit this context. So it is necessary to expand the candidate word set.

---

[2] https://github.com/Cyvhee/SemEval2018-Task3

Table 2: Examples of the final label words for different prompts.

Prompt Type	Label	Label Words
Clash Prompt	Sarcastic	not, sarcasm, irony, joke, kidding, no, ridiculous...
	Non-sarcastic	yes, do, so, serious, true, real, indeed...
Question Prompt	Sarcastic	yes
	Non-sarcastic	no

Inspired by (Hu et al., 2022), we choose Related Words[3] as our external KB to widen the coverage of candidate words. Related Words is a knowledge graph $\mathcal{G}$ aggregated from multiple resources, including ConceptNet (Speer et al., 2017), WordNet (Pedersen et al., 2004), et al..

Label Words. After the expansion of seed words, we obtain comprehensive candidate words. However, the collected candidate words can be noisy since the vocabulary of the KB is not tailored for sarcasm. Thus we refine the candidate word set by frequency and part of speech. There are several criteria for denoising candidate words: (1) For words out of PLMs' vocabulary and sarcastic corpus, discard them; (2) Only keep words whose parts of speech are adjective, noun, verb, and adverb to ensure consistency with prompt templates syntactically and semantically. Finally, label words are defined in Table 2.

4.2.2 Verbalizer Mapping.

The goal of verbalizer mapping is to map the predicted probability of label words to the final label y. For question prompt, since there is only one label word in each class, the probability of the label word is the probability of the corresponding class.

For clash prompt, there is more than one label word for each class. We use the average of label words based on label word searching process as the probability of each class, which is

$$P(\hat{y}) = \frac{\sum_{v \in V_y} P_M(\texttt{[MASK]} = v|\mathbf{x}_p)}{|V_y|}. \quad (1)$$

4.3 Training Objective

The process of SarcPrompt is a prompt-oriented fine-tuning approach (Gu et al., 2022). We need to compute the loss based on the supervised label of datasets and train the model. The training objective of SarcPrompt considers two aspects including cross-entropy loss and contrastive loss.

Cross-entropy Loss. The first training objective is to minimize the cross-entropy loss of the sarcasm label probability distribution. The cross-entropy loss is to ensure the basic ability of sarcasm recognition. The objective L_{sarc} is formulated as:

$$L_{sarc}(\theta) = \sum \text{cross-entropy}(y, P(\hat{y})), \quad (2)$$

where y is the groundtruth of the sarcasm label, and $P(\hat{y})$ is the predicted score.

Contrastive Loss. Inspired by (Khosla et al., 2020), we introduce contrastive learning objective to our SarcPrompt model. Sarcasm takes many patterns of expression such as sarcasm by clash, situational sarcasm, and other sarcasm (Hee et al., 2018a). Supervised contrastive learning is an automatic way of capturing the entailed similarity of various sarcasm patterns.

Specifically, for $(\mathbf{x}_i, y_i)$ within a batch, we first extract sentence representation s_i. Recall that in Equation 1, we obtain the probability distribution of the label by computing the score of predicted words in the masked position. This can not only be viewed as word representation in the masked position, but also be viewed as a kind of sentence representation. So we use this probability distribution as sentence representation s_i to calculate the contrastive loss. Then the supervised contrastive loss in a batch L_{con} is defined as:

$$P_{con}(i,c) = \frac{\exp\left(sim(s_i, s_c)/\tau\right)}{\sum_{b \in B, b \neq i} \exp\left(sim(s_i, s_b)/\tau\right)} \quad (3)$$

$$L_{con}(\theta) = \sum_{i \in B} -\log \frac{1}{C_i} \sum_{y_i = y_c, c \neq i} P_{con}(i,c). \quad (4)$$

Here $P_{con}(i,c)$ indicates the likelihood that s_c is most similar to s_i. τ is the temperature of softmax. We use $sim(s_i, s_c) = s_i \cdot s_c$ for similarity calculation. Supervised contrastive loss L_{con} is calculated for each input sentence representation s_i in a batch. And $C_i = |\{c|y_c = y_i, c \neq i\}|$ is the number of samples in the same category y_i in a batch.

Considering the two objectives, we obtain the final objective function L by adding them together:

$$L(\theta) = \lambda_1 L_{sarc}(\theta) + \lambda_2 L_{con}(\theta),$$

---

Table 3: Statistics of datasets. Avg ℓ denotes the average length of texts in the number of tokens.

Dataset	Train	Valid	Test	Avg ℓ
IAC-V1[5]	1,595	80	320	68
IAC-V2[6]	5,216	262	1,042	43
Tweets[7]	3,634	200	784	14

where θ is the parameter set of the model. λ_1, λ_2 are used to leverage the contributions.

5 Experimental Settings

5.1 Datasets

We carry out experiments on three benchmark datasets: IAC-V1, IAC-V2, and Tweets.

- **IAC-V1** (Lukin and Walker, 2017) and **IAC-V2** (Oraby et al., 2016) are collected from online political debates forum[4]. IAC-V2 contains more data than IAC-V1.
- **Tweets** dataset is proposed in SemEval 2018 Task 3 Subtask A (Hee et al., 2018a).

Table 3 reports the statistics. For all datasets, we follow the train/valid/test split in (Liu et al., 2022). All datasets are class-balanced.

5.2 Baselines

We adopt three types of baseline methods for comparison, including deep models without pre-training, pre-trained models with fine-tuning, and pre-trained models with prompt tuning.

Deep Models without Pre-training. We choose recent and widely compared deep models including LSTM-based Bi-LSTM (Hochreiter and Schmidhuber, 1997), CNN-LSTM-DNN (Ghosh and Veale, 2016), attention-based MIARN (Tay et al., 2018), graph neural network-based ADGCN (Lou et al., 2021) and state-of-the-art DC-Net (Liu et al., 2022). In this work, we study context-free sarcasm recognition. The input is a sentence without contexts like history posts and user profiles (Hazarika et al., 2018). So the baselines we choose are restricted with this area.

Pre-trained Models with Fine-tuning. For fine-tuning pre-trained models, we utilize RoBERTa$_{\text{base}}$ as the basic encoder to make a fair comparison. Both ADGCN and DC-Net report versions of fine-tuning pre-trained models in their paper. So we use the RoBERTa as backbone and implement ADGCN-RoBERTa and DC-Net-RoBERTa based on their released code.

Pre-trained Models with Prompt Tuning. Recall that in Section 3, we introduce a regular prompt tuning method for sentiment classification. We utilize this approach as the prompt tuning baseline. Specifically, the vebalizer of regular prompt tuning method is the same as clash prompt.

5.3 Implementation Details

Under the **standard supervised settings**, we utilize the whole datasets to fine-tune. For hyperparameters, we employ $\lambda_1 = 1$, and λ_2 among $\{0, 0.001, 0.005, 0.01, 0.05, 0.1, 0.5, 1\}$ on the validation set respectively. 0.005, 0.5 and 0.05 are the best λ_2 for IAC-V1, IAC-V2 and Tweets respectively. As for the **low-resource settings**, we randomly sample $\mathbf{r}\%$ instances of each class from the initial training and validation sets to form the few-shot training and validation sets. $\mathbf{r}$ ranges from $\{1, 5, 10, 20\}$. Our model is implemented based on the open source PET[8]. PET (Schick and Schütze, 2021a) is a regular prompt tuning method that uses the class name as the only label word for each class. But we do not use any tricks in the original PET paper since we want to study the effect of sarcasm-specific templates and label words alone. For each method, we train them with three seeds and report the results of the best seed.

6 Experimental results

In this section, we report and analyze the experimental results to demonstrate the effectiveness of the proposed SarcPrompt method. Specifically, we target the following research questions:

- **RQ1:** How does SarcPrompt perform under the standard supervised settings?
- **RQ2:** How does SarcPrompt perform under the low-resource settings?
- **RQ3:** Which prompt performs best and why?
- **RQ4:** How does the contrastive loss affect the performance of SarcPrompt?
- **RQ5:** Can we better understand how SarcPrompt performs via some case studies?

6.1 Results under Standard Settings

To answer **RQ1**, we compare SarcPrompt with three kinds of strong baselines on three benchmark

datasets under standard supervised settings. Table 4 shows the results. We observe that: (1) Fine-tuning models perform better than traditional deep models on IAC-V1 and IAC-V2, which demonstrates the effectiveness of fine-tuning models. However, on Tweets, the results for fine-tuning models are similar to or even worse than traditional deep models. The reason may be that tweets are non-standard and chatty compared with the corpora of pre-trained models. (2) The performance of applying prompt tuning method for text classification directly to sarcasm recognition is similar to or even worse than fine-tuning methods. This indicates that neither fine-tuning models nor regular prompt tuning method can make enough use of the knowledge in PLMs for sarcasm recognition.

When we look at the two types of SarcPrompt, we find that: (1) SarcPrompt with clash prompt outperform all the baseline methods. SarcPrompt with clash prompt improves a lot over regular prompt tuning, which demonstrates that it is improper to simply transplant the regular prompt tuning method to sarcasm recognition. By stimulating sarcastic characteristics, SarcPrompt is able to well exploit the capability of pre-trained language models in sarcasm recognition. (2) SarcPrompt with clash prompt performs better than with question prompt, showing clash prompt is more valid to reflect the contradictory intentions of sarcastic texts. (3) The improvements of SarcPrompt over baselines on Tweets are higher than that on both IAC-V1 and IAC-V2. The reason may be that the label words selection process relies on the seed words extracted from Tweets. It is necessary to explore other ways to obtain the prior information in the future.

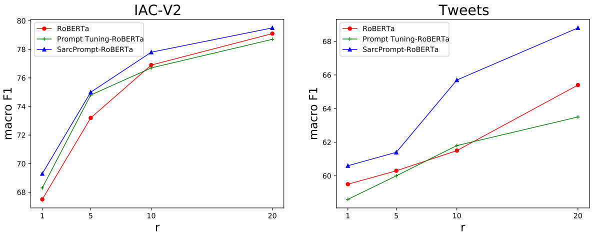

Figure 3: Macro $F1$ scores under low-resource settings, using 1%, 5%, 10%, and 20% instances for IAC-V2 and Tweets datasets.

6.2 Results under Low-resource Settings

In real-word scenes, it is often time-consuming and labor-intensive to collect annotated data to fine-tune classification models especially for difficult tasks like sarcasm recognition. To answer **RQ2**, we choose RoBERTa and Prompt Tuning-RoBERTa as baselines. For SarcPrompt, we use clash prompt type, which achieves the best performance under standard settings. IAC-V1 and IAC-V2 have the same source, and experimental results show the same trend under low-resource settings. So we report the results of IAC-V2 and Tweets datasets.

The experimental results are shown in Figure 3. We observe that: (1) Our SarcPrompt consistently outperforms the baseline methods with less training data on both datasets, which demonstrates the

Table 5: Cases of right and wrongly classified by SarcPrompt. The check mark indicates classification is correct, while the cross mark indicates wrong.

ID	Input	Prompt with predicted word	Result
1	Pretty excited about how you gave up on me.	Actually *not*.	✓
2	I just love being ignored	Actually *kidding*.	✓
3	thanks I thought it was tomorrow	Actually *indeed*.	✗
4	make sure you don't say Christmas!! The decorate for the holiday.	Actually *yes*.	✗

effectiveness of SarcPrompt model under low resource settings. (2) As **r** increases from 1 to 20, the improvement in our SacrPrompt over IAC-V2 decreases gradually. But for Tweets, with the increase of data, the improvement of SarcPrompt is also greater. The reason may be Tweets are short and non-standard, and may lack information. Also, SarcPrompt is based on the statistical information of Tweets. Therefore as the training data of Tweets increases, SarcPrompt can obtain more information and achieve better results, which is consistent with performance under standard settings.

6.3 Results of Different Prompts

To answer **RQ3**, we report the performance of different prompts of SarcPrompt model in Table 6. We observe that: (1) Among question prompts, T_{q_1} performs best on IAC datasets and T_{q_2} on Tweets. As for clash prompt, T_{c_2} performs best on IAC datasets while T_{c_1} on Tweets. It is worth noting that the best clash template on Tweets T_{c_1} is short and colloquial, which is similar to the usage of Tweets. On the contrary, T_{c_2} is a complete sentence. It matches IAC datasets, which are longer and more formal. (2) The effect of the template fluctuates more on IAC-V1 and Tweets datasets because they are relatively small and do not contain enough sarcastic patterns. An appropriate template can be well adapted to most of the data while an inappropriate template may perform poorly. This also shows that it is more difficult to find suitable templates for small datasets.

6.4 Ablation Study

To answer **RQ4**, we conduct an ablation study to analyze the impact of contrastive loss, which is shown in Table 7. Note that the removal of contrastive loss degrades the performance a lot, which indicates that the similarity information between the same class and the contrast information between different classes are significant in sarcastic expressions' learning.

Table 6: Performance (Macro $F1$) comparison of different prompt templates of SarcPrompt model. "AVG±VAR" means average results and the variances of question and clash prompts.

Prompt Type	IAC-V1	IAC-V2	Tweets
Question-T_{q_1}	**72.9**	**84.2**	73.1
Question-T_{q_2}	71.1	83.7	**73.7**
Question-T_{q_3}	69.4	84.1	69.3
AVG±VAR	71.1±3.1	84.0±0.1	72.0±5.7
Clash-T_{c_1}	73.4	83.3	**76.6**
Clash-T_{c_2}	**75.2**	**84.9**	75.3
Clash-T_{c_3}	70.8	83.5	73.8
Clash-T_{c_4}	71.7	83.4	72.9
Clash-T_{c_5}	73.0	84.6	73.7

SarcPrompt-Clash-RoBERTa	**75.2**	**84.9**	**76.6**
w/o contrative loss	74.3	82.4	75.2

6.5 Case Study

To answer **RQ5**, we analyze sarcasm recognition results on Tweets by several cases in Table 5. We observe that: (1) Our SarcPrompt is good at dealing with input samples that contain subjective sentiment expressions, such as "excited" and "love" in the first and second samples. When combined with the prompt clause, the contradictory intention is obvious to recognize. (2) However, in the third and fourth samples, the contradictory intentions are not strong enough and hidden in deeper semantics. They require external contexts to assist sarcasm recognition. Specifically, the speaker remembers the wrong time in the third sample. In the fourth sample, the speaker complains the decoration is not good-looking for Christmas. This indicates that current templates and label words are not suitable for recognizing sarcasm in factual texts.

7 Conclusion

In this paper, we have proposed SarcPrompt, a simple and effective prompt tuning method to recognize sarcasm in texts. Specifically, we design several prompt templates to mimic the actual intention behind the sarcastic literal content. We define verbalizers based on the statistics of sarcastic corpus. Then it is able to determine whether the prompt is contradictory to the literal content by the predicted label words. Empirical experimental results show that SarcPrompt achieves state-of-the-art performance under both standard supervised settings and low-resource settings.

Limitations

Although our SarcPrompt has achieved the SOTA performance on several benchmark datasets for sarcasm recognition, there are still limitations, mainly in the following aspects.

Firstly, we combine sarcastic characteristics into prompt tuning in a hard-coded form by manually designing prompt templates and label words based on the statistical information in sarcastic corpora. This hard-coded approach may not be able to adapt to all sarcasm patterns and may miss some good prompt templates or label words. Moreover, in the current verbalizer mapping process, we decay the weight of each label word according to the relationship in the knowledge base. The mapping approach is trivial and not learnable. Lastly, as we analyzed in the case study, current SarcPrompt is not good at dealing with situational sarcasm. In situational sarcasm pattern, there is no contradictory intention by looking at the literal content alone, which is hard to recognize even for humans.

In future work, we will explore continuous prompt templates and learnable mapping functions for prompt tuning in sarcasm recognition. Combining external knowledge is also a direction to make prompt tuning suitable for situational sarcasm in our future work.

Abstract

Open knowledge graph (KG) consists of *(subject, relation, object)* triples extracted from millions of raw text. The *subject* and *object* noun phrases and the *relation* in open KG have severe redundancy and ambiguity and need to be canonicalized. Existing datasets for open KG canonicalization only provide gold entity-level canonicalization for noun phrases. In this paper, we present **COMBO**, a **Com**plete **B**enchmark for **O**pen KG canonicalization. Compared with existing datasets, we additionally provide gold canonicalization for relation phrases, gold ontology-level canonicalization for noun phrases, as well as source sentences from which triples are extracted. We also propose metrics for evaluating each type of canonicalization. On the **COMBO** dataset, we empirically compare previously proposed canonicalization methods as well as a few simple baseline methods based on pretrained language models. We find that properly encoding the phrases in a triple using pretrained language models results in better relation canonicalization and ontology-level canonicalization of the noun phrase. We release our dataset, baselines, and evaluation scripts at `https://github.com/jeffchy/COMBO/tree/main`.

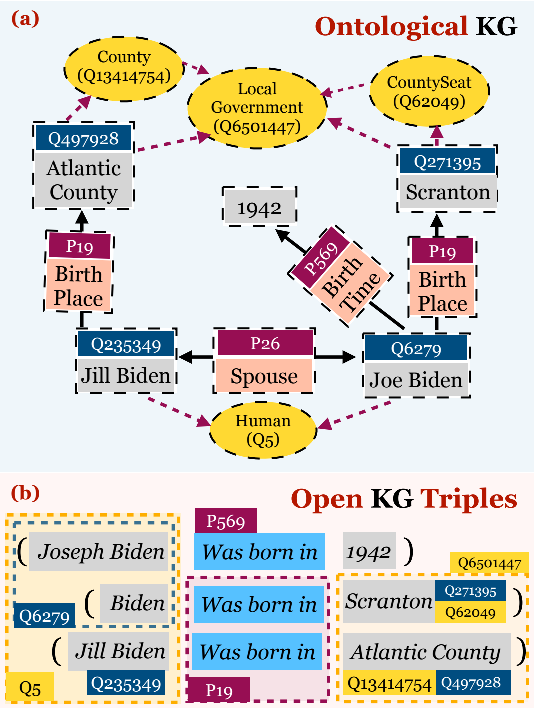

Figure 1: Example of ontological KG (a) and Open KG triples (b). The differently colored bounding boxes and the tags on the open KG triples illustrate three types of gold canonicalization. Yellow (e.g., *Q5* Human) shows the gold ontology-level NP cluster, the salvia blue (e.g., *Q6279*) indicates the gold entity-level NP cluster, and the purple (e.g., P19) indicates gold RP cluster.

1 Introduction

Large ontological knowledge graphs (KG) such as Wikidata (Vrandečić and Krötzsch, 2014), DBpedia (Bizer et al., 2009), Freebase (Bollacker et al., 2008) use a complex ontology to formalize and organize all the entities and relations. Figure 1(a) shows an example ontological knowledge graph (Wikidata): "*Joe Biden (Q6279)*" is categorized as "*Human (Q5)*" in Wikidata and linked to "*Scranton (Q271395)*" with relation "*birth place (P19)*", where prefix *Q* and *P* denote unique identities for entity and relation respectively in Wikidata[1]. As ontological KGs are well organized and canonicalized, one can efficiently query information and extract knowledge from them to assist NLP models in various tasks (Rao et al., 2013; Luo et al., 2015; Cui et al., 2019; Murty et al., 2018; Wang et al., 2021; Liu et al., 2023; Gao et al., 2022; Liu et al., 2022). However, building and maintaining an accurate ontological KG requires large human effort (Färber et al., 2015).

In contrast, open knowledge graphs such as Re-

[†] This work was done during Chengyue Jiang's internship at DAMO Academy, Alibaba Group.

Verb (Fader et al., 2011) and OLLIE (Mausam et al., 2012) are built using *(subject, relation, object)* triples automatically extracted from millions of raw text by OpenIE systems (Angeli et al., 2015; Fader et al., 2011; Mausam et al., 2012). They are frequently used to assist in building ontological KGs (Martinez-Rodriguez et al., 2018; Dessì et al., 2021) and slot filling (Broscheit et al., 2017). As OpenIE systems do not rely on pre-defined ontologies or human supervision, the extracted triples contain noun phrases (NPs) and relation phrases (RPs) that are not canonicalized. Take the open KG triples shown in Figure 1(b) as an example. The NP *"Joseph Biden"* and *"Biden"* both refer to the US president Joe Biden, but the open KG regards them as two different nodes because of their different surface forms. On the other hand, *"was born in"* in the first and second triple means *"birth place of"* and *"birth time of"* respectively, but the open KG cannot disambiguate them. These examples reveal the redundancy and ambiguity of uncanonicalized open KG (Vashishth et al., 2018), which makes querying open KG inaccurate and inefficient. To this end, open KG canonicalization aims to improve the quality of open KGs to the level of ontological KGs. It is therefore different from tasks such as entity linking (Rao et al., 2013) and KB aligning (Elsahar et al., 2018) that align entity mentions or sentences to an existing ontological KG.

Existing open KG canonicalization datasets such as ReVerb-base, ReVerb-ambiguous (Galárraga et al., 2014), ReVerb45K (Vashishth et al., 2018) and CanonicNELL (Dash et al., 2021) mainly focus on entity-level canonicalization of NPs, providing the gold **E**ntity-level **NP C**anonicalization (**NPC-E**). The blue tags and dashed boxes in Figure 1(b) show examples of **NPC-E**, e.g., *"Biden"* and *"Joseph Biden"* should be canonicalized as the same entity *Q6279*. However, these datasets do not provide the gold **RP C**anonicalization (**RPC**), and do not consider the **O**ntology-level **C**anonicalization of **NP** (**NPC-O**). **RPC** is to canonicalize RPs that mean same relation together, for example, the second and the third *"was born in"* in Figure 1(b) should be canonicalized into the same cluster of *birth place (P19)*, different from the first one which means *"birth time (P569)"*. Similarly, **NPC-O** is to canonicalize NPs that have same type together, for example, the *"Scranton"* should be canonicalized into class *"CountySeat"* and into class *"Local Government"* together with *"Atlantic County"*, it can be viewed as canonicalizing special ontological relations such as "*instance of*", "*subclass of*" represented by dotted arrows in Fig. 1(a). We formally define these tasks in Sec. 3.

RPC and **NPC-E** are important as parts of a canonicalization benchmark (1) Relations and ontology are necessary for an expressive KG (Klyne and Carroll, 2004) (2) Most KG queries involve relations and ontology (e.g., the query *"actress that was born in California"*, involve the relational constraint "*X, birth place, California*" and the ontological constraint "*X, instance of, Actress*").

In this paper, we present **COMBO**, a complete benchmark for open KG canonicalization consisting of three subtasks: besides **NPC-E** which has been adequately studied in previous work, we additionally provide gold **RPC** and **NPC-O** along with their evaluation metrics. Gold **NPC-O** is obtained by querying the Wikidata using SPARQL, and **RPC** is obtained by performing Stanford OpenIE on sentences from Wiki20 (a distantly labeled relation extraction dataset), and a per-instance human revision process to ensure the quality of extracted RPs. We introduce the data construction process detailedly in Sec. 4.

Our new benchmark makes it possible for the first time to quantitatively evaluate the full range of open KG canonicalization. We conduct comprehensive experiments to compare existing canonicalization methods as well as a few simple baseline methods proposed by us. Somewhat surprisingly, none of the existing methods utilizes pretrained contextualized word embedding, probably because previous work only focuses on NPC-E and NPs are often not very ambiguous, making contextualization not so helpful. For example, the "*Joe Biden*" and "*Joseph Biden*". However, contexts are more helpful in RPC and NPC-O. For RPC, relations are more ambiguous and diverse in surface forms (e.g., "*was born in*" in Figure 1) and contexts are needed for disambiguation. For NPC-O, the RP and the other NP in the triple will help understand the type of an NP. Therefore, our proposed baseline methods are based on pretrained language models (PLM) (Devlin et al., 2019; Liu et al., 2019b; Sun et al., 2019) which produce contextualized embedding and have been shown to contain a certain amount of factual knowledge (Petroni et al., 2019; Lauscher et al., 2020). We found that, after properly encoding triples and contexts, our baseline methods outperform well on all three subtasks compared with previous state-of-the-art methods, especially on RPC and NPC-O. We also propose a triple-based pretraining method and find that it further boosts the performance on all subtasks. Therefore, our work provides strong baselines for future research on open KG canonicalization.

In summary, our contributions are threefold. First, we propose a complete definition of the open KG canonicalization problem along with the metrics. Second, we construct the complete benchmark for open KG canonicalization consisting of entity-level and ontology-level NP canonicalization and RP canonicalization. Third, we propose a stronger baseline based on autoencoding PLMs and conduct a comprehensive empirical comparison of canonicalization methods on our benchmark.

2 Open KG Canonicalization Datasets

We introduce existing open KG canonicalization datasets and **COMBO**. The statistics of datasets are shown in Table 1.

ReVerb-Base (Galárraga et al., 2014) Constructed using the ReVerb open KB. As half of the NPs in ReVerb triples are linked to an entity in the ontological database FreeBase (Bollacker et al., 2008), the authors sample 150 FreeBase entities that have at least two surface forms, collect all triples containing these 150 entities, and use the entity labels as the gold NP clusters.

ReVerb-Ambiguous (Galárraga et al., 2014) ReVerb-Ambiguous is constructed similarly as ReVerb-Base, it has 37K triples, but with only 445 gold NP clusters (entities). One problem with the ReVerb-Base and ReVerb-Ambiguous datasets is they contain too few NP clusters and too many NP aliases, which is inconsistent with real open KGs.

ReVerb45K(Vashishth et al., 2018) ReVerb45K increases the entity number to 7.5K and has 45K triples in total. ReVerb45K, Reverb-Base, and ReVerb-Ambiguous extract a source sentence for each triple from ClueWeb09 Callan et al. (2009). However, some of the source sentences are simply the concatenation of triples.

CanonicNELL (Dash et al., 2021) Constructed using the open KB NELL (Mitchell and Fredkin, 2014) and the entity linking information for NPs (Pujara et al., 2013). They remove triples containing NPs without aliases. CanonicNELL does not provide source sentences.

COMBO (Ours) As shown in the Table 1, the main differences of our dataset between others are that we additional provide gold RP canonicalization and ontology-level NP canonicalization. Constructed based on the large Ontological KG Wikidata[2], the OpenIE system, a relation extraction dataset Wiki20m and human revisions, as detailed in next section. Our dataset contains 18K triples with their source sentences and we provide gold NPC-E, RPC and NPC-O annotations. We compare **COMBO** with existing datasets in Table 1. Although our dataset is middle-sized, it has the longest average triple length and the largest number of unique NPs, indicating the diversity of the surface forms of NPs and RPs. Providing source sentences of extracted OpenIE triples is natural but important since additional contextual information can be helpful in understanding and disambiguating NPs and RPs. We ensure all triples contain rich context, and the average length of source sentences is 21. We show some data samples in Appendix A, and analyze our data in Sec. 4.

3 Task Definition and Evaluation Metrics

Task Definition The goal of open KG canonicalization is to assign NPs and RPs in triples into clusters, such that NPs that refer to the same entity (NPC-E) or have the same type (NPC-O) are clustered together, and similarly, RPs that refer to the same relation are clustered together. Note that the task is unsupervised, meaning that the canonicalizer does not have access to gold annotations. We have N samples containing triples and their corresponding source sentences: $\mathcal{T} = \{c_i, t_i = (s_i, r_i, o_i)|\, i = 1 \ldots N\}$, where c_i is the i-th sentence, t_i is the i-th triple containing subject NP s_i, RP r_i, and object NP o_i. $\mathcal{S} = \{(s_i, i)|\, i = 1 \ldots N\}$ is the indexed subject NP set. The indexed RP set $\mathcal{R}$ and object NP set $\mathcal{O}$ are defined similarly as $\mathcal{R} = \{(r_i, i)|\, i = 1 \ldots N\}$ and $\mathcal{O} = \{(o_i, i)|\, i = 1 \ldots N\}$. We have $|\mathcal{S}| = |\mathcal{O}| = |\mathcal{R}| = N$. The gold NPC-E, RPC, and NPC-O annotations are defined as sets of clusters. As subject NPs and object NPs are asymmetric (Juffs and Harrington, 1995; McGinnis, 2002), we follow Vashishth et al. (2018) and evaluate the clusters of subject NPs and object NPs separately. The gold NPC-E and NPC-O for subject NPs are defined as *NPC-E (Subj)* $= \{C_1 \ldots C_{K_s^E}\}$, *NPC-O (Subj)* $= \{C_1 \ldots C_{K_s^O}\}$, where C_i denotes the i-th cluster of NP. The NPC-E and NPC-O

Table 2: Evaluation of the three subtasks. Ma, Mi, Pair are abbreviations of macro, micro and pairwise metrics.

of object NPs are defined similarly, the gold RPC is defined as *RPC* as $\{C_1 \ldots C_{K_r}\}$. *NPC-E (Subj)* is a *non-overlapping* cluster assignment and satisfies two conditions: (1) $\bigcup_{i=1}^{K_s^E} C^i = \mathcal{S}$; (2) $C_i \cap C_j = \emptyset, i \neq j$. *NPC-E (Obj)* and *RPC* satisfy similar conditions. *NPC-O (Subj)* and *NPC-O (Obj)* are *overlapping* cluster assignments, i.e., we allow an NP to belong to multiple clusters, so they only need to satisfy the first condition. The task is to predict the cluster assignments of NPs and RPs given their source triples and sentences. Following previous works, we assume the cluster number is unknown beforehand and split our data into the dev (20%) and test (80%) sets.

Task Evaluation Most clustering algorithms such as K-means (Lloyd, 1982) and Hierarchical Agglomerative Clustering (HAC) (Maimon and Rokach, 2005) produce non-overlapping cluster assignments, and several algorithms (e.g., HAC) can also produce hierarchical and overlapping cluster assignment. For the *NPC-E* subtask, we adopt the classic macro, micro and pairwise metrics to compare the gold and predicted *NPC-E* cluster assignments (please refer to App. C for details). For *RPC*, the macro metrics that calculate the fractions of pure clusters are too strict because gold RP clusters are large and hence are unlikely to be pure. Therefore we only use the micro and pairwise metrics to evaluate *RPC*.

For *NPC-O*, the gold cluster assignments are overlapping. If the predicted clusters are non-overlapping, we can apply the macro and pairwise metrics and a modified micro metric (Appendix D). If the predicted clusters are overlapping, say $\mathcal{P} = \{C_1^p \ldots C_M^p\}$, we propose evaluation metrics $J_{g\to p}$ and $J_{p\to g}$ based on the Jaccard index (Jaccard, 1908; Tanimoto, 1958). $J_{g\to p}$ (Eq.1) calculates the average Jaccard index of a gold cluster and its best matched predicted cluster. $J_{p\to g}$ is similarly defined but with the roles of *NPC-O* and $\mathcal{P}$ switched. Table 2 summarizes the evaluation metrics of each subtask.

$$\begin{aligned} \text{Jaccard}(g,p) &= \frac{|g \cap p|}{|g \cup p|} \\ J_{g\to p} &= \frac{1}{|\mathit{NPC\text{-}O}|} \sum_{g \in \mathit{NPC\text{-}O}} \max_{p \in \mathcal{P}} \left(\text{Jaccard}(g,p)\right) \end{aligned} \tag{1}$$

4 Construction of Our Dataset

We illustrate the construction process of **CoMBO** in Figure 2. We rely on the Wiki20 dataset (Han et al., 2020) to obtain the source sentence and the gold NPC-E. Wiki20 is a large multi-domain relation extraction dataset constructed by aligning the Wikipedia corpus with Wikidata using distant supervision. As shown in the bottom of Figure 2, each sample of Wiki20 contains a sentence with the object and subject NP spans labeled and linked to entities in Wikidata and the relation between them is also labeled. To ensure data quality, we use the recently revised version of Wiki20 (Gao et al., 2021), which aligns the Wiki20 relation labels with the supervisedly constructed Wiki80 dataset (Han et al., 2019) and provides 56K human-annotated data samples. The object and subject NP spans and its entity linking information (e.g., *Q6275*) are from Wikipedia and have high precision, so we directly use it for task NPC-E.

Extracting Relational Phrases Wiki20 only provides the relation label of two NPs for each instance. We further extract RP for Wiki20 instances to obtain full open KG triples. We first discard samples with the relation label “NA” and then run the Stanford OpenIE system on Wiki20 sentences to extract triples. We choose Stanford OpenIE[3] because compared with older OpenIE systems such as ReVerb and NELL that are used in constructing previous datasets, Stanford OpenIE can leverage the linguistic structure of a sentence and generalizes better to out-of-domain and longer utterances (Angeli et al., 2015). We empirically find that Stanford OpenIE yields a better recall and can extract more triples per sentence compared to ReVerb. We use the default model configuration of Stanford OpenIE. After obtaining the OpenIE triples of each non-NA Wiki20 instance, we select the triples whose subject NP and object NP are consistent with the NP spans provided by Wiki20. This triple selection step ensures the NPs in the extracted triples have gold NPC-E annotations, and remove wrong relation spans caused by wrongly extracted head and tail entities. We filter out 88% of the original triples through this step. Although this step reduces noises caused by OpenIE, the extracted relation spans could still be wrong in two ways:

1. **Invalid RP between correct NPs**. For example, for sentence *“. . . the Althing, the ruling legislative body of Iceland . . . ”*, OpenIE wrongly extracts *(the Althing, body of, Iceland)*, while the true triple should be *(the Althing, ruling legislative body of, Iceland)*.

2. **Correct NPs and valid RP but RP does not imply the relation given by Wiki20**. For the given relation *mother of* and sentence *“. . . bart and lisa got sent out of the house by marge simpson . . . ”*, the extracted triple *(lisa, got sent out of the house by, marge simpson)* is valid but cannot imply the *mother of* relation.

Therefore, we manually check all the extracted triples for these two types of errors, correcting invalid relational phrase spans and removing triples whose RP cannot imply the given relation. We also standardize the form of RP (e.g., OpenIE sometimes includes “a” and “the” and sometimes does not). The detailed guidelines for the check and revision process are shown in the Appendix B. The error analysis is shown in Table 3.

After all these steps, we obtain an open KG consisting of 18K triples. Similar to NPC-E, we use the relation labels given by the Wiki20 annotations (e.g., *P19*) as the gold RPC. As shown in Figure 3, the constructed open KG contains 79 relations in various domains, such as relations between geopolitical entities (*mouth of the watercourse* (7.3%), *mountain range* (3.8%), etc), relations between people (*spouse of* (1.7%), *child of* (1.6%), etc), and various relations between people and other objects (*citizenship* (2.4%), *work location* (3.7%), etc). The extracted RPs are diverse in surface forms. The number of distinct RPs is 3.2K. We show RP examples in Table 4. There exist some RPs that represent multiple relations and one representative example is *“in”*.

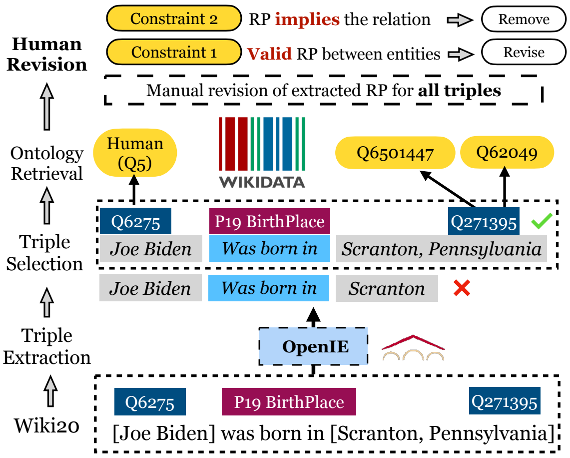

Figure 2: Steps of dataset construction.

Error Type	Rate
Invalid RP	23.5%
RP doesn’t imply relation	5.5%

Table 3: OpenIE error analysis.

Extracting Ontology To obtain ontology-level NP clusters for the NPC-O subtask, we query Wiki-

spouse of	*was married twice to , was married to, lover, consort of, second husband, widow of ’s wife, ’s second wife, arranged a wedding with*
mountain range	*peak, large nunatak, summits of, the only crossing of the most prominent feature of, small glacier, summits in valley in, only crossing of, northernmost subrange of,* ***in***
location	*is headquartered in, moved to, is carved on took place at, ironworks in, was again held at,* ***in***

Table 4: RP examples.

---

[3] https://stanfordnlp.github.io/CoreNLP/

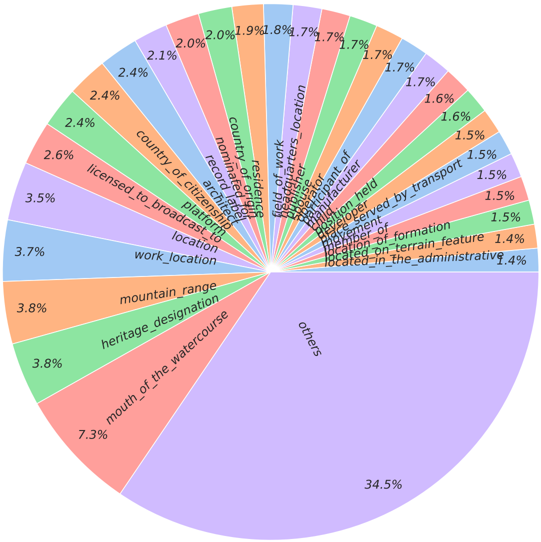

Figure 3: Pie charts of 79 RP clusters.

data for the classes of each entity. For example, to obtain the classes of *"Joe Biden (Q6275)"*, we run the SPARQL (RDF query language) query " `Q6275 P31 ?`", where P31 represents the "instance of" relation in Wikidata. This query obtains all the classes of an NP. If an NP does not have a class, its NPC-O annotation is the same as its NPC-E annotation. If an NP has more than one class, we include all of them in the NPC-O annotation (e.g., *city* and *big city* for "New York"). We query Wikidata using a third-party client Wikidata Integrator[4].As the ontology information in Wikidata is crowdsourced and contains errors, we apply pattern-based corrections to the extracted ontological NP clusters, for example, if an NP belongs to the cluster *million cities*, it should also belong to the cluster *city*. The resulting 2.9K ontological NP clusters form a 6-level overlapping hierarchy which allows a node to have more than one parent. We illustrate part of the hierarchy in Figure 5 and show the statistics of the top 12 ontological NP clusters in Figure 4.

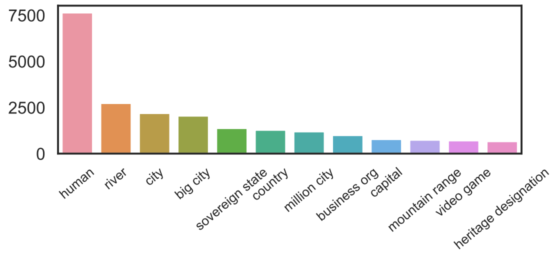

Figure 4: Size of top 12 ontological NP clusters.

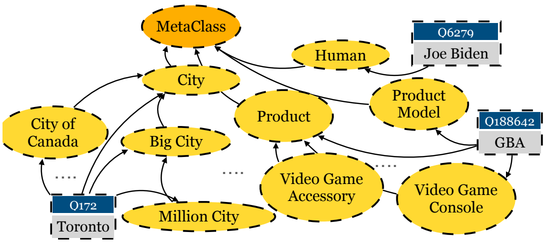

Figure 5: Part of the class hierarchy in our dataset.

5 Comprehensive Evaluation of Methods

Our benchmark makes it possible to conduct a comprehensive empirical comparison of different methods on the full range of open KG canonicalization. Below we first give an overview of existing methods and propose a few new baseline methods. Then we present our experimental settings and results.

5.1 Previous Methods

Non-neural Methods Galárraga et al. (2014) utilizes token features such as TF-IDF scores and Jaccard token similarity to canonicalize NPs. They merge similar NPs based on a threshold (tuned on the validation set) to form clusters. For RPs, they use AMIE (Galárraga et al., 2013), an unsupervised algorithm based on statistical rule mining, to obtain relation clusters. Vashishth et al. (2018) use additional side information obtained from various sources (such as PPDB (Ganitkevitch et al., 2013), WordNet (Miller, 1992)) to produce clusters.

SE-HAC Trivial baseline that performs HAC clustering over phrase embeddings produced by averaging static word embeddings such as GloVe (Pennington et al., 2014) or random embeddings.

CESI Vashishth et al. (2018) encode phrases using the same method as in SE-HAC; then apply the HolE graph embedding algorithm (Nickel et al., 2016) on triples and incorporate side information to finetune the embedding, and finally run HAC clustering on the learned embeddings.

CUVA Dash et al. (2021) adopt VAEGMM (Jiang et al., 2017) to jointly learn and cluster the embeddings. They initialize VAEGMM by performing HAC clustering on GloVe NP and RP embeddings, and then simultaneously optimize the knowledge embedding loss, side information loss, and VAE loss for the final clustering.

Previous methods encode NPs and RPs using either token frequency features or static word embedding. Although CESI and CUVA learn graph embedding on open KG triples, they assign the

---

[4] `https://github.com/SuLab/WikidataIntegrator`

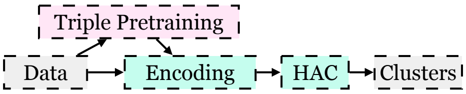

Figure 6: Pipeline of the proposed PLM-based method.

same representation to phrases with the same surface form and therefore cannot deal with ambiguity. No method utilizes original sentences to provide additional contexts. HAC is a popular choice of the clustering algorithm because it does not require knowing the number of clusters, but instead requires a distance threshold indicating when to stop merging. Unlike the number of clusters, the threshold can be tuned on a validation set and directly applied to the test set.

5.2 PLM-Based Baseline Methods

We propose a set of new baseline methods based on PLMs that produce contextualized embedding. We use a pipeline similar to CESI as shown in Figure 6. We encode NPs and RPs using different PLMs, PLM layers, and span representation methods and apply HAC clustering over their representations. We use the cosine similarity as the distance function and apply the complete linkage variant of HAC clustering because we prefer compact clusters and the single linkage variant suffers from the chaining phenomenon. Before encoding, an optional triple-level continuous pretraining step can be applied for better canonicalization. Token similarity and other side information are not used in our PLM-based method, but we generate them for our data using the code provided by Vashishth et al. (2018) to facilitate running of other methods.

5.2.1 Encoding

PLMs We use autoencoding PLMs[5] including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019b), ERNIE2.0 (Sun et al., 2019) which integrates entity information, and SpanBERT (Joshi et al., 2020) which is pretrained with span masks.

Input Given a triple $t_i = (s_i, r_i, o_i)$ and its corresponding source sentence c_i, we formulate the input of PLM in the following four ways to obtain the contextualized embedding of words in the NPs and RP. Note that the fourth method *sep* independently encodes each phrase in the triple.

$$\begin{aligned} \textit{sentence:}\;& [CLS]\ \ldots s_i \ldots r_i \ldots o_i \ldots\ [SEP] \\ \textit{triple:}\;& [CLS]\ s_i\ r_i\ o_i\ [SEP] \\ \textit{triple-sep:}\;& [CLS]\ s_i\ [SEP]\ r_i\ [SEP]\ o_i\ [SEP] \\ \textit{sep:}\;& [CLS]\ s_i/r_i/o_i\ [SEP] \end{aligned} \tag{2}$$

Phrase Representation After obtaining the contextualized embedding of words in an NP or RP span, denoted as $h_i \ldots h_j$, we follow Toshniwal et al. (2020) and use three methods to produce a single span embedding. Following Timkey and van Schijndel (2021), we also standardize the embeddings to remove rogue dimensions (Appendix E). Previous work (Vulić et al., 2020; Liu et al., 2019a) shows that different layers of a PLM contain different information, so we investigate contextualized embedding from different layers .

$$\begin{aligned} \textit{mean:}\;& average\_pooling(h_i \ldots h_j) \\ \textit{max:}\;& max\_pooling(h_i \ldots h_j) \\ \textit{diff-sum:}\;& [h_i - h_j; h_i + h_j] \end{aligned} \tag{3}$$

5.2.2 Triple-level Pretraining

Inspired by the HolE algorithm used in previous works (Vashishth et al., 2018; Dash et al., 2021), we may perform an optional triple-level continuous pretraining step before encoding to mimic the link prediction objectives in knowledge graph embedding learning. For each sentence in our dataset, we randomly mask a phrase in the triple and then train the PLM to predict the whole masked span. We perform pretraining for 10 epochs using the AdamW optimizer (Loshchilov and Hutter, 2019) with a linear scheduler and a start learning rate of 5e-5. We then use the continuously pretrained version of PLM as the phrase encoder. We also use the causal subword-level MLM strategy in BERT (Devlin et al., 2019) for comparison.

5.3 Experimental Setup

For each subtask, we use grid search to tune the HAC distance threshold on the dev set to obtain non-overlapping clusters for all the methods. We select the best threshold based on the average of the metrics shown in Table 2. We obtain overlapping clusters for NPC-O from the full HAC hierarchy. As HAC is deterministic, we run experiments once for methods without randomness and four times for methods involving random initialization (CUVA, Random+HAC). As Token Sim+SI and VAEGMM based methods cannot provide overlapping cluster assignments, we do not evaluate them by metrics based on the Jaccard index. For our PLM-based

Table 5: Averaged metrics (of Table 2) on all the subtasks. For example, ***NPC-O, Subj*** is the average of Ma,Mi and Pair metrics on the ontology-level canonicalization of subject NPs, and ***NPC-O, Obj-Jaccard*** is the average of $J_{p\rightarrow g}$ and $J_{g\rightarrow p}$ for the overlapping clustering assignment of object NPs. Full results including the results of *large-triple* models are shown in Appendix F

methods, we select the best input form and span representation strategy based on the dev set performance. We also compare different **encoding strategies** in Appendix G, and **layer-wise performances** in Appendix H.

5.4 Overall Results

We report averaged metrics for each subtask in Table 5 because of limited space. The full results are shown in Appendix F. The results show that our PLM-based baseline methods outperform previous methods in most cases, especially on RPC and NPC-O, indicating the importance of contextual information. Trivial baselines such as Token Sim+SI, Random+HAC and GloVe+HAC already perform well (around 80%) on NPC-E, because NPs referring to the same entity usually have similar surface forms and do not have to rely on contexts for correct prediction. However, they perform badly on RPC and NPC-O, because surface forms alone are no longer adequate for these two subtasks because of higher ambiguity. CESI has bad RPC performance but is very competitive on NPC-E (Obj), and better than SpanBERT and RoBERTa without triple-level pretraining, but is still worse than the other PLM-based methods. CUVA performs generally badly, probably because it is sensitive to VAEGMM initialization and relies heavily on side information. As our dataset has the longest average triple length and consists of texts from various domains, it could be more challenging for methods that do not use contextualized embedding.

For PLM-based methods, BERT leads to the best overall performance on NPC-E (Obj), RPC and NPC-O (Subj); ERNIE2.0 performs best on NPC-E (Subj) and NPC-O (Obj) and is comparable to Bert on NPC-E (Obj) and RPC; RoBERTa and SpanBERT fall behind, but are still better than most other non-PLM methods on NPC-O and RPC. Large PLMs are better than base PLMs on NPC-E, comparable on NPC-O, but worse on RPC. We also found the triple-level pretraining effective, having a positive influence in most cases, especially on RPC (e.g., +9.73 for RoBERTa). In contrast, using the causal subword-level pretraining for Bert improves the object NPC but harms the subject NPC and RPC (-1.07 points). A detailed comparison between triple-level and subword-level pretraining is shown in Appendix I.

6 Conclusion

We present **COMBO**, a complete benchmark for open KG canonicalization. **COMBO** consists of three subtasks, entity-level and ontology-level NP canonicalization, and RP canonicalization. We construct the data and propose the evaluation metrics for the RPC and NPC-O that are not been adequately studied before. We also propose a stronger canonicalization method based on autoencoding PLMs and conduct a comprehensive comparison of different canonicalization methods on our dataset.

For future study, NPC-O and RPC still have a lot of room for improvement and the efficiency of canonicalization methods is also worth studying. We also note that **COMBO** can be additionally used as a probing benchmark for PLMs and as a phrase-level relation classification dataset.

Limitations

One limitation of our work is that, the size of our dataset (18K) is relatively small compared to previous datasets (Table 1). Another limitation is that, similar to previous work, we perform clustering for three subtasks and evaluate the canonicalization results independently, but canonicalization of the head NP, tail NP and RP is in fact closely correlated. For example, the NPC-O clusters of the head NP and tail NP reveal the domain and range of the relation given by RPC. We leave jointly canonicalization and evaluation as future work. Our proposed baseline is straightforward. We encourage future studies to investigate better canonicalization methods based on pretrained language models.

Ethics Statement

Our dataset is constructed based on Wiki20 and Wikidata. The two sources are both publicly available. Wiki20 is under the MIT Licence and the Wikidata is under the Creative Commons CC0 License. Both of them allow modification and distribution. Regarding human revision during dataset construction, the annotators were properly paid. The annotating procedure lasted 12 days and the daily workload was relatively light: around 2.5 hours per day. During human inspection, we did not identify any unethical instances in our dataset. Regarding baseline models, we use PLMs as our text encoder and our task is inherently unsupervised. As PLMs are learned on large corpora, our method can potentially create biased clustering results. How to de-bias PLM embedding is worth further investigation.

A Dataset Examples

We show examples of our dataset in Figure 7.

B Guidelines for Revising Relational Phrases

B.1 RP Annotating Procedure

1. We first split all triples by relations and form 79 json files for two major paid annotators, each annotator is responsible for around 40 relations.
2. Annotators should check one relation file at a time for annotating consistency, and start the next one after the former one is finished.
3. For each relation, annotators are given: (a) The original sentences of the relation with markers indicating the head NP, tail NP and RP extracted by OpenIE. (b) The name (e.g., *composer*), and the Wikidata ID (e.g., *P86*) of the gold relation.
4. Annotators should first understand the relation by querying the Wikidata, take the relation *"composer (P86)"* as an example, annotators should first query Wikidata through the link `https://www.wikidata.org/wiki/Property:P86` to obtain the definition of the relation and skim through example relational phrases of RPs. The Figure 8 shows the Wikidata page containing the definition and examples of *"composer"*.
5. After fully comprehend the relation, annotators can start to check and revise triples in each file, the details and examples of RP revision and justification of if RP implies the relation are shown in the next two subsection (Appendix B.2, Appendix B.3).
6. After two annotators finished their part, we randomly sample 100 samples from each part and ask the annotator responsible for the other part to check. The annotators reached a consensus for approving 97% of these samples.

B.2 Guideline for checking the validity of RPs and revision

Definition of relational phrases Relational phrases are textual representations of relations between named entities (Grycner et al., 2015), we follow ReVerb (Fader et al., 2011) and require the relational phrases be continuous span in the sentence. We summarize most cases of relational phrases occurring in our dataset, and the guideline for annotating each case. The annotated RPs are shown in pink.

- **Case 1: Verb** example: *[A] married [B]*, include different tenses of verbs.
- **Case 2: Verb+preposition** example: *[A] located at [B]*.
- **Case 3: Passive voice** example: *[A] is designed by [B]*, *[A] is headquartered in [B]* the linking verb is sometimes omitted: *[A], designed by [B]*.
- **Case 4: When the tail entity is the appositive of the head entity** example: *[A] 's son is [B]*, *[A] 's son , [B]*, *[A] 's masterpiece , [B]*, the content between the appositives is usually informative and regarded as RPs.
- **Case 5: Compound predicate** A common case is that the tail NP is a part of the compound predicate of the head NP, e.g., *[A] is the civil branch of [B]*, *[A] is an agency of [B]*, *[A] is a novel by [B]*. When encountering these cases, we do not include the linking verb and article because they are not informative (e.g., *"is the"*).
- **Case 6: Cases omit verb** Some cases omit verb, we only annotate the preposition. For example, *[yokosuka arts theatre], part of the bay square complex by [kenzou tange]*, this sentence omits the verb *"built"*.

```
{'h': {'id': 'Q533336', 'instance': ['Q18812508'], 'name': ['node', '1'], 'pos': [16, 18]}, 'r':
{'label': 'manufacturer', 'name': ['built', 'by'], 'pos': [19, 21]}, 't': {'id': 'Q66', 'instance':

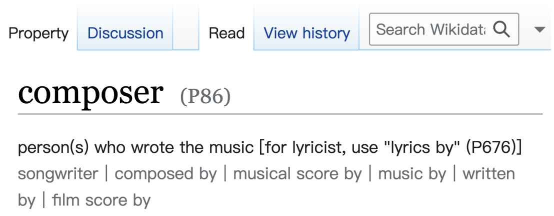
'suitable', 'for', 'children', 'and', 'adults', '.']}
```

Figure 7: Examples of our dataset, "h" means head or subject NP, "r" means relation, "t" means tail or object NP. "instance" stands for the gold ontology-level clusters.



composer (P86)

person(s) who wrote the music [for lyricist, use "lyrics by" (P676)]

songwriter | composed by | musical score by | music by | written by | film score by

Figure 8: Wikidata query example.

We also provide several revision examples of wrong OpenIE triples, part of them are shown in the Table 6 below.

B.3 Guideline for justifying if RP implies the given relation

As we stated in the fourth step of the overall annotating process in the Appendix B.1, we require annotators to fully understand the meaning of the given relation. For each triple, annotators should ask themselves if the relational phrase could express the relation of the head and tail NP in the given context sentence. Note that we don't require the relation could be solely implied by the RP, for example, given the triple and its context: *"[mount elbert]* ***in*** *the [sawatch range] is the highest summit of the rocky mountains"*, it is impossible to infer the relation by the RP *"in"*, but RP is a reasonable text representation of the relation *mountain range* in this context. We found that the extracted RPs can imply the relation in most cases, we show some concrete bad cases to the annotators to help them identify the bad RPs, part of the examples are shown in the Table 7.

C Classic Metrics

Gold cluster assignment: $\mathcal{G} = \{C_1^g \dots C_K^g\}$, predicted cluster assignment: $\mathcal{P} = \{C_1^p \dots C_M^p\}$, where C_i^g and C_j^p are gold and predicted cluster respectively.

Macro Metrics

$$P_{macro}(\mathcal{G}, \mathcal{P}) = \frac{|\{p \in \mathcal{P} | \exists g \in \mathcal{G}, p \subseteq g\}|}{|\mathcal{P}|}$$
$$R_{macro}(\mathcal{G}, \mathcal{P}) = P_{micro}(\mathcal{P}, \mathcal{G}) \tag{4}$$

Micro Metrics

$$P_{micro}(\mathcal{G}, \mathcal{P}) = \frac{\sum_{g \in \mathcal{G}} \max_{p \in \mathcal{P}} |g \cap p|}{N}$$
$$R_{micro}(\mathcal{G}, \mathcal{P}) = P_{micro}(\mathcal{P}, \mathcal{G}) \tag{5}$$

Where N is the total number of different phrases that appear in $\mathcal{G}$ (or $\mathcal{P}$).

Pairwise Metrics

$$P_{pair}(\mathcal{G}, \mathcal{P}) = \frac{\sum_{p \in \mathcal{P}} |\{(u, u') \in p, \exists g \in \mathcal{G}, \forall (u, u') \in p\}|}{\sum_{p \in \mathcal{P}} C_2^{|p|}}$$
$$R_{pair}(\mathcal{G}, \mathcal{P}) = \frac{\sum_{p \in \mathcal{P}} |\{(u, u') \in p, \exists g \in \mathcal{G}, \forall (u, u') \in p\}|}{\sum_{g \in \mathcal{G}} C_2^{|g|}} \tag{6}$$

For more details about classic metrics, please refer to the Sec. 7.2 of the CESI paper (Vashishth et al., 2018).

Table 7: Examples of bad RPs that cannot imply the given relations.

D Extension of Micro Metrics

Gold overlapping clusters: $\mathit{NPC\text{-}O} = \{C_1^O \dots C_{K_3}^O\}$, predicted clusters $\mathcal{P} = \{C_1^p \dots C_M^p\}$.

$$
\begin{aligned}
P_{micro}(\mathit{NPC\text{-}O}, \mathcal{P}) &= \frac{\sum_{g \in \mathit{NPC\text{-}O}} \max_{p \in \mathcal{P}} |g \cap p|}{\sum_{g \in \mathit{NPC\text{-}O}} |g|} \\
R_{micro}(\mathit{NPC\text{-}O}, \mathcal{P}) &= P_{micro}(\mathcal{P}, \mathit{NPC\text{-}O})
\end{aligned}
\tag{7}
$$

We modify the denominator compared to the micro metric in (Vashishth et al., 2018).

E Standardization

Following Timkey and van Schijndel (2021), we perform standardization for phrase embeddings to remove the rogue dimensions. Denote $\boldsymbol{E}_{\mathcal{R}} \in \mathbb{R}^{N \times D}$ as the embedding matrix of all RP phrases, where N is the number of triples, and D is the dimension of contextual embedding. The standardized RP embedding matrix $\boldsymbol{E}'_{\mathcal{R}}$ is:

$$
\begin{aligned}
\boldsymbol{\mu} &= \frac{1}{N} \sum_{i}^{N} \boldsymbol{E}_{\mathcal{R}}[i] \\
\boldsymbol{\sigma} &= \sqrt{\frac{1}{N} \sum_{i}^{N} (\boldsymbol{E}_{\mathcal{R}}[i] - \boldsymbol{\mu})^2} \\
\boldsymbol{E}'_{\mathcal{R}}[i] &= \frac{\boldsymbol{E}_{\mathcal{R}}[i] - \boldsymbol{\mu}}{\boldsymbol{\sigma}}
\end{aligned}
\tag{8}
$$

We empirically find that the standardized phrase embedding is better than the original one in most cases.

F Full Result

We show the full results in Table 8 and Table 9.

Table 8: Full results of NPC-E and RPC.

G Encoding Strategy Comparison

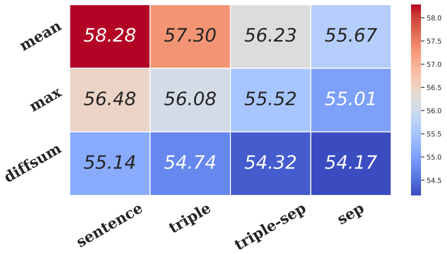

Figure 9: Overall average performance of different encoding strategies.

We compare the performance of encoding strategies averaged on all subtask metrics and PLM models in Figure 9, and the task-specific and model-specific comparison of encoding strategies are shown in Figure 10. *sentence* is the best input form in general, probably because it is easier for a PLM to encode a valid sentence and the source sentence contains more context. *sep* is the worst on the RPC because it separately encodes the RPs and NPs. However, it is comparable to *triple-sep* and *triple* on NPC-E because NPC-E requires less context. *mean* is the best strategy for phrase representation, which is consistent with the results obtained by (Toshniwal et al., 2020)[6], and *diffsum* is a bad choice for phrase canonicalization.

H Layerwise PLM Performance

We show the layerwise performance for all PLMs (base) on all subtasks in Figure 11, and find different layers perform differently on three subtasks. We empirically find that lower layers [1,2,3] perform well for NPC-E, upper layers [10,11,12] perform best for RPC and NPC-O (subj), while middle layers [3,4,5,6,7] perform relatively better on NPC-O (obj). As context-specificity increases in upper layers (Ethayarajh, 2019), these results make sense as NPC-E requires less context while RPC and NPC-O need more context.

I Triple Pretraining

We show the average performance difference after triple-level or causal subword-level pretraining in Figure 12 for different PLMs and subtasks.

---

[6] Toshniwal et al. (2020) shows that mean pooling is best for named entity labeling, which is a semantic task for NPs.

nl2g.github.io

Abstract

The vast majority of evaluation metrics for machine translation are supervised, i.e., (i) are trained on human scores, (ii) assume the existence of reference translations, or (iii) leverage parallel data. This hinders their applicability to cases where such supervision signals are not available. In this work, we develop *fully unsupervised* evaluation metrics. To do so, we leverage similarities and synergies between evaluation metric induction, parallel corpus mining, and MT systems. In particular, we use an unsupervised evaluation metric to mine pseudo-parallel data, which we use to remap deficient underlying vector spaces (iteratively) and to induce an unsupervised MT system, which then provides pseudo-references as an additional component in the metric. Finally, we also induce unsupervised multilingual sentence embeddings from pseudo-parallel data. We show that our fully unsupervised metrics are effective, i.e., they beat supervised competitors on four out of five evaluation datasets. We make our code publicly available.[1]

1 Introduction

Evaluation metrics are essential for judging progress in natural language generation (NLG) tasks such as machine translation (MT) and summarization, as they identify the state-of-the-art in a key NLP technology. Despite their wide dissemination, classical lexical overlap evaluation metrics like BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) have difficulties judging the quality of modern NLG systems (Mathur et al., 2020a; Marie et al., 2021), necessitating novel metrics that correlate better with humans. Lately, this has been a very active research area (Zhang et al., 2020; Zhao et al., 2019, 2022; Colombo et al., 2021; Yuan et al., 2021).[2]

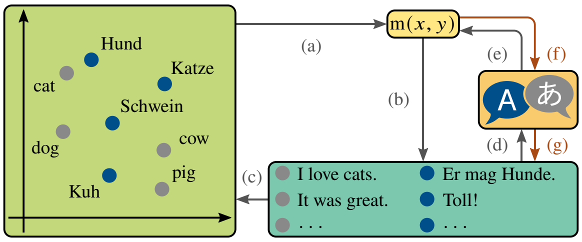

Figure 1: Relationship between metrics m, vector spaces, parallel data, and MT systems: Metrics build on (potentially deficient) multilingual vector spaces (a), and can be used to mine (pseudo-)parallel sentences (b), which in turn can be used to improve deficient vector spaces (c). (Pseudo-)parallel data can also be used to train MT systems (d), which can generate pseudo-references (e). Conversely, metrics can also be optimization criteria for MT systems, which in turn can generate additional pseudo-parallel data through translation (f & g; not explored in this work).

Recently, more and more *supervised* metrics are being proposed. E.g., BLEURT (Sellam et al., 2020) trains on human annotated datasets ranging from 5k-150k pairs, the COMET (Rei et al., 2020) models regress on 12k-370k data points and UniTE (Wan et al., 2022), before fine-tuning on the same data as COMET, pre-trains on 5m-10m parallel sentences. Of course, training on larger amounts of data leads to better metrics (measured on in-domain data), but also increases the risk of learning biases from the data (Poliak et al., 2018)—and limits the applicability to domains and language pairs where supervision is available. Here, we go the opposite route and try to minimize the amount of supervision as much as possible.

We classify existing metrics making use of different types of supervision as follows (cf. Table 1). **TYPE-1** metrics are *trained* on human assessments such as Direct-Assessment (DA) or Post-Editing (PE) scores, and compare system outputs to either human references (reference-based; Sellam et al., 2020; Rei et al., 2020) or directly to source texts (reference-free; Ranasinghe et al., 2021). **TYPE-2** metrics, by comparison, do not use human assessments for training but still require

---

[2] Of course, the search for high quality metrics dates back at least to the invention of BLEU and its predecessors.

	Training	**References**	**Parallel Data**
TYPE-1	✓	(✓)	(✓)
TYPE-2	✗	✓	(✓)
TYPE-3	✗	✗	✓
Unsupervised	✗	✗	✗

Table 1: Different types of supervision used by TYPE-1/2/3 metrics compared to unsupervised metrics. Checkmarks surrounded by parentheses denote optional supervision signals.

human references, i.e., are untrained and reference-based (Yuan et al., 2021; Zhao et al., 2019; Zhang et al., 2020). Finally, **TYPE-3** metrics are untrained (unlike TYPE-1) and reference-free (unlike TYPE-2), i.e., do not use supervision as in TYPE-1 or 2. However, to work well, they still rely on parallel data (Zhao et al., 2020; Song et al., 2021), which is considered a form of supervision, e.g., in the MT community (Artetxe et al., 2018; Lample et al., 2018).

In contrast, we aim for *fully unsupervised evaluation metrics* (for MT) that do not use any form of supervision (cf. Table 1). In addition, subject to the constraint that no supervision is allowed, our metrics should be of *maximally high quality*, i.e., correlation with human assessments. We have two use cases in mind: (a) Such *sample efficiency*[3] is a prerequisite for the wide applicability of the metrics. This is especially important when we want to overcome the current English-centricity (Anastasopoulos and Neubig, 2020) of MT systems and evaluation metrics and also cover low-resource *languages* like Nepali or Sinhala (Fomicheva et al., 2021) and low-resource *pairs* like Yoruba-German.[4] (b) Our fully unsupervised evaluation metrics should be considered *strong lower bounds* for any future work that uses (mild) forms of supervision for metric induction, i.e., we want to push the lower bounds for newly developed TYPE-κ metrics.

To achieve our goals, we employ *self-learning* (He et al., 2020; Wei et al., 2021) and in particular, we leverage the following dualities to make our metrics maximally effective, cf. Figure 1: (1) Evaluation metrics and NLG systems are closely related; e.g., a metric can be an optimization criterion for an NLG system (Böhm et al., 2019), and a system can conversely generate *pseudo references* (a.o.) from which to improve a metric. (2) Evaluation metrics and parallel corpus mining (Artetxe and Schwenk, 2019) are closely related; e.g., a metric can be used to mine parallel data, which in turn can be used to improve the metric (Zhao et al., 2020), e.g., by remapping deficient embedding spaces.

Our contributions are: **(i)** We show that effective unsupervised evaluation metrics can be obtained by exploiting relationships with parallel corpus mining approaches and MT system induction; **(ii)** to do so, we explore ways to (a) make parallel corpus mining *efficient* (e.g., overcome cubic runtime complexity) and (b) induce unsupervised multilingual sentence embeddings from pseudo-parallel data; **(iii)** we show that pseudo-parallel data can rectify deficient vector spaces such as mBERT; **(iv)** we show that our metrics beat three state-of-the-art supervised metrics on four of five datasets we evaluate on.

2 Background

We take inspiration from three recent supervised (reference-free; TYPE-3) metrics: XMoverScore (Zhao et al., 2020), DistilScore (Reimers and Gurevych, 2020), and SentSim (Song et al., 2021). Below, we review key aspects of them, and show where supervision plays a role.

2.1 XMoverScore

Central to XMoverScore is the use of Word Mover's Distance (WMD) as a similarity between two sentences (Zhao et al., 2020). WMD and further enhancements are discussed below.

WMD WMD is a distance function that compares sentences at the token level (Kusner et al., 2015), by leveraging word embeddings which in XMoverScore's case come from mBERT (Devlin et al., 2019). From a source sentence x and an MT hypothesis y, WMD constructs a *distance matrix* $\mathbf{C} \in \mathbb{R}^{|x|,|y|}$, where $\mathbf{C}_{ij}$ is the distance between two word embeddings, $\mathbf{C}_{ij} = \| \mathrm{E}(x_i) - \mathrm{E}(y_j) \|$; x_i, y_j index respective words in x, y. WMD uses this distance matrix to compute the similarity of the two sentences. This can be defined as the linear programming problem

$$\mathrm{WMD}(x,y) = \min_{\mathbf{F}} \sum_{i=1}^{|x|} \sum_{j=1}^{|y|} \mathbf{F}_{ij}\mathbf{C}_{ij}, \qquad (1)$$

---

[3] We use the term sample efficiency in a generalized sense to denote the amount of supervision required.

[4] Neither Yoruba (a language spoken in Nigeria) nor German are classical low-resource languages. For German, this is clear and Yoruba is even included in mBERT, i.e., belongs to the languages with 100+ largest Wikipedias. Nonetheless, from own experience, we find it inherently difficult to obtain high-quality annotations for the language pair, as a result of few competent parallel speakers as well as technical difficulties (e.g., lack of adequate compute infrastructure in Nigeria).

where $\mathbf{F} \in \mathbb{R}^{|x|,|y|}$ is an *alignment matrix* with $\mathbf{F}_{ij}$ denoting how much of word x_i travels to word y_j. Additional constraints prevent it from becoming a zero matrix.

Vector space remapping Zhao et al. (2020), akin to similar earlier and subsequent work (Cao et al., 2020; Schuster et al., 2019), argue that the monolingual subspaces of mBERT are not well aligned. As a remedy, they investigate linear projection methods which post-hoc improve cross-lingual alignments. We refer to this approach as vector space *remapping*. XMoverScore explores two different remapping approaches, CLP and UMD. They both leverage parallel data on sentence-level from which they extract word-level alignments using fast-align, which are then used for remapping. We give more details in the Appendix A.

Language Model XMoverScore linearly combines WMD with the perplexity of a GPT-2 language model (Radford et al., 2019). Allegedly this penalizes ungrammatical translations. This updates XMoverScores scoring function to

$$\mathfrak{m}(x, y) = w_{\text{xlng}}\,\text{WMD}(x, y) + w_{\text{lm}}\,\text{LM}(y). \quad (2)$$

Here, w_{xlng}, w_{lm} are weights for the cross-lingual WMD and LM components of XMoverScore.

2.2 DistilScore

Reimers and Gurevych (2020) show that the cosine between multilingual sentence embeddings captures semantic similarity and can be used to assess cross-lingual semantic textual similarity. Their approach to inducing embedding models is based on multilingual knowledge distillation. We refer to this metric as DistilScore. Their approach requires supervision at multiple levels. First, parallel sentences are needed to induce multilingual models, and second, NLI and STS corpora are required to induce teacher embeddings in the source language.

2.3 SentSim

A key difference between XMoverScore and DistilScore is that one approach is based on word- and the other on sentence embeddings. Song et al. (2021) and Kaster et al. (2021) show that combining approaches based on word-level and sentence-level representations can substantially improve metrics. The metric of Song et al. (2021), which is called SentSim, combines supervised DistilScore with one of two word embedding-based metrics. The first one is quite similar to XMoverScore, as it is also based on WMD. The other one is a multilingual variant of BERTScore (Zhang et al., 2020).

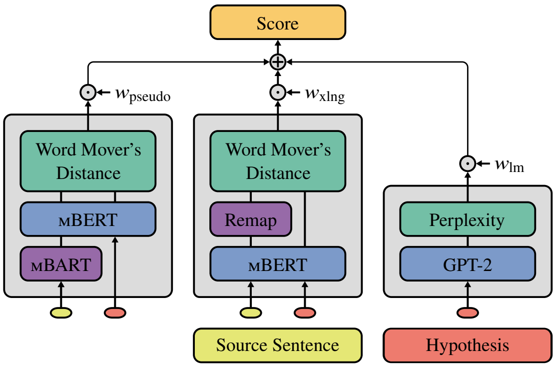

Figure 2: UScore$_{\text{WRD}}$ with pseudo references (left), unsupervised remapping (middle) and a LM (right).

3 Methods

In this section, we introduce our fully unsupervised metric UScore. UScore builds upon the existing metrics XMoverScore, DistilScore, and SentSim, but eliminates all supervision signals and instead leverages the dualities shown in Figure 1. In particular, we mine pseudo-parallel data from unsupervised metrics, which we use (iteratively) to (a) rectify deficient vector spaces (for XMoverScore) and to (b) train unsupervised MT systems which can generate pseudo-references (as pseudo-references are in the same language as the hypothesis, this eliminates problems of cross-lingual deficiency). Furthermore, we use pseudo-parallel data to (c) induce an unsupervised sentence embedding model analogous to DistilScore, which we can then (d) integrate with the unsupervised word based model analogous to SentSim. We now give details.

3.1 UScore$_{\text{WRD}}$

XMoverScore uses sentence-parallel data to extract word pairs for vector space remapping. (i) We replace this parallel data with pseudo-parallel data.[5] (ii) In addition, we use pseudo-references to address the issue of deficient vector spaces. We now give details on (i) and (ii) below.

Efficient WMD Pseudo-Parallel Data Mining Metrics such as XMoverScore could in principle be used for pseudo-parallel corpus mining since

---

[5] To extract the word pairs from the sentence-parallel data, XMoverScore uses fast-align (Dyer et al., 2013), but since this depends directly on how well sentences are aligned, we first replace it with unsupervised awesome-align (Dou and Neubig, 2021) which only relies on pre-trained language models.

they can compare arbitrary sentences. However, when WMD-based metrics are scaled to corpus mining, algorithmic efficiency problems arise: (a) the computational complexity of WMD scales cubically with sentence length (Kusner et al., 2015); (b) to compare m source to m target sentences, m^2 WMD invocations are necessary, which quickly becomes intractable. Thus, we explore ways to improve the performance of WMD to mine efficiently. In particular, Kusner et al. (2015) define a linear approximation of WMD called *word centroid distance* (WCD) and a mining algorithm that first sorts all target samples according to their WCD to a given query and computes exact WMD for the k nearest neighbors. We use this algorithm for efficient WMD-based pseudo-parallel data mining.

In our work, we apply this approach *iteratively* (cf. Figure 1): we start out with an initial WMD metric (based on mBERT), obtain *sentence-level* pseudo-parallel data with it via the efficient approximation algorithm described, and obtain a dictionary of word pairs from unsupervised AWESOME-ALIGN from the sentence pseudo-parallel data. We use the pseudo-parallel word pairs with UMD and CLP to remap mBERT. From this, we obtain a better WMD metric; then we iterate.

Pseudo References Apart from remapping, pseudo-parallel data could be used to overcome problems of deficient vector spaces in other ways. Specifically, we want to mine enough pseudo-parallel data to train an unsupervised MT system to translate source sentences into the target language to create *pseudo references* (Albrecht and Hwa, 2007; Gao et al., 2020; Fomicheva et al., 2020b). This would allow for a comparison with the hypothesis in the target language, similar to reference-based metrics, circumventing alignment problems in multilingual embeddings. This approach updates UScore$_{\text{WRD}}$ to

$$\mathfrak{m}(x, y, y') = w_{\text{xlng}}\, \text{WMD}^{(n)}(x, y) + w_{\text{lm}}\, \text{LM}(y) + w_{\text{pseudo}}\, \text{WMD}(y, y'), \tag{3}$$

where n denotes the iterations of remapping, and w_{pseudo} is a new weight to control the influence of the pseudo reference y'. All components of UScore$_{\text{WRD}}$ are illustrated in Figure 2.

3.2 UScore$_{\text{SNT}}$

Besides a word-based metric, we use pseudo-parallel data to induce an unsupervised *sentence level* metric, UScore$_{\text{SNT}}$ = $\cos(x, y)$, based on the cosine similarity between sentence embeddings. One could, similarly to DistilScore, perform knowledge distillation but since our initial experiments showed that this doesn't work well with pseudo-parallel data, we chose another approach.

Contrastive Learning We explore contrastive learning for unsupervised *multilingual* sentence embedding induction, which has recently been successfully used to train unsupervised *monolingual* sentence embeddings (Gao et al., 2021). In our context, the basic idea is to pull semantically close sentences together and to push distant sentences apart in the embedding space. Let x_i and y_i be the embeddings of two sentences that are semantically related and N an arbitrary batch size. The training objective for this pair can be formulated as

$$L_i = -\log \frac{\exp\left(\frac{\cos(x_i, y_i)}{\tau}\right)}{\sum_{j=1, j\neq i}^{N} \exp\left(\frac{\cos(x_i, y_j)}{\tau}\right)}, \tag{4}$$

where τ is a temperature hyperparameter that can be used to either amplify or dampen the assessed distances. For each sentence x_i, all remaining sentences $y_{j\neq i}$ in the current batch should be pushed apart in the embedding space. For positive sentences that should be pulled together, we again use pseudo-parallel sentence pairs. Since noisy data is beneficial for contrastive learning (Gao et al., 2021), we expect this paradigm to work well with pseudo-parallel data. We use pooled XLM-R embeddings as sentence representations, and, as with unsupervised remapping, we experiment with multiple iterations of successive mining and sentence embedding induction operations.

Ratio Margin Pseudo-Parallel Data Mining As UScore$_{\text{SNT}}$ is based on sentence embeddings, we cannot use the WMD-based mining algorithm to obtain pseudo-parallel sentences since it requires access to word-level representations. An alternative would be to just use cosine similarity for mining, but that approach is susceptible to noise in the data (Artetxe and Schwenk, 2019). Instead, we follow Artetxe and Schwenk (2019) and use a ratio margin function defined as

$$\text{margin}(x, y) = \frac{\cos(x, y)}{\sum\limits_{z \in N_x} \frac{\cos(x, z)}{2k} + \sum\limits_{z \in N_y} \frac{\cos(y, z)}{2k}}, \tag{5}$$

where N_x and N_y are the k nearest neighbors of sentence embeddings x and y in the respective language. Informally, this ratio margin function divides the cosine similarities of the nearest neighbor by the average similarities of the neighborhood.

3.3 UScore$_{\text{WRD} \oplus \text{SNT}}$

Inspired by SentSim, which combines word and sentence embeddings, we similarly ensemble UScore$_{\text{WRD}}$ and UScore$_{\text{SNT}}$. We refer to this final metric as UScore $=$ UScore$_{\text{WRD} \oplus \text{SNT}}$ with two new weights w_{wrd} and $w_{\text{snt}} = 1 - w_{\text{wrd}}$:

$$\begin{aligned} \text{UScore}(x, y) = w_{\text{wrd}}\, &\text{UScore}_{\text{WRD}}(x, y) \\ &+ w_{\text{snt}}\, \text{UScore}_{\text{SNT}}(x, y). \end{aligned} \tag{6}$$

4 Experiments

In this section, we evaluate all UScore variants at the segment level[6] and compare them to TYPE-1/2/3 upper bounds. We detail additional hyperparameters in Appendix D.

4.1 Datasets

We use various datasets to assess the performance of our metrics on **MT evaluation**, i.e., computing the correlation with human assessments using Pearson's r correlation, and **parallel sentence matching**, a standard evaluation measure in the corpus mining field where a set of shuffled parallel sentences is searched to recover correct translation pairs (Guo et al., 2018; Kvapilíková et al., 2020). For this we report Precision at N (P@N).

MT evaluation In **WMT-16** and **WMT-17,** each language pair consists of tuples of source sentences, hypotheses and references. Each tuple was annotated with a direct assessment (DA) score, which quantifies the adequacy of the hypothesis given the reference translation. Following Zhao et al. (2020) and Song et al. (2021), we use these DA scores to assess the adequacy of the hypothesis given the source. **MLQE-PE** has been used in the WMT 2020 Shared Task on Quality Estimation (Specia et al., 2020), and only provides source sentences and hypotheses for its language pairs, with no references. Each source sentence and hypothesis pair was annotated with cross-lingual direct assessment (CLDA) scores. In terms of annotation, **Eval4NLP** is very similar to MLQE-PE but focuses on non-English-centric language directions, especially de-zh and ru-de. **WMT-MQM** uses fine-grained error annotations from the Multidimensional Quality Metrics (MQM) framework (Freitag et al., 2021a) for adequacy assessments. Like MLQE-PE and Eval4NLP, WMT-MQM also assigns scores based on source sentences and hypotheses. Additional statistics can be found in the appendix in Table 8. Using ISO 639-1 codes, our datasets cover the language pairs de-zh, ru-de, en-ru, en-zh, cs-en, de-en, en-de, et-en, fi-en, lv-en, ne-en, ro-en, ru-en, si-en, tr-en, zh-en.

Parallel sentence matching To evaluate on parallel sentence matching, we use the **News Commentary**[7] dataset. It consists of parallel sentences crawled from economic and political data.

4.2 Fine-grained analysis on de-en

To gain an understanding of the properties of the iterative techniques and the influence of individual parameters / components, we conduct a fine-grained analysis on the de-en language direction of WMT-16 (for MT evaluation) and News Commentary v15 (for parallel sentence matching). We list examples of pseudo-parallel data used during training in the appendix in Table 3. The mined sentences are often semantically similar, but contain factuality errors (e.g., have wrong places or numbers in hypotheses).

Vector space remapping We explore if remapping works with pseudo-parallel data. We use News Crawl for mining. We randomly extract 40k monolingual sentences per language, and select the top 5% sentence pairs with the highest metric scores for remapping. This gives us the same number of sentences (2k pairs) as were used for remapping XMoverScore.

The results for UMD and CLP-based remapping on de-en can be seen in Figure 3 (top). The figure contains two graphs, one for correlation with human judgments and one for precision on parallel sentence matching. Each graph illustrates model performance before remapping (Iteration 0) and after remapping one to five times. After remapping once, both UMD and CLP improve substantially in Pearson's r correlation. The improvement of CLP, however, is noticeably larger. For subsequent iterations, UMD seems to continue to improve slightly, but the correlations of CLP seem to drop. This can be explained by the results for precision where the P@1 of CLP drops each iteration, meaning the remapping capabilities of the metrics decrease. UMD does not exhibit this problem. Thus, UMD

---

[6] We do not evaluate at the system level since metrics there often perform very similarly, making it difficult to determine the best metric (Mathur et al., 2020b; Freitag et al., 2021b).

[7] `data.statmt.org/news-commentary`

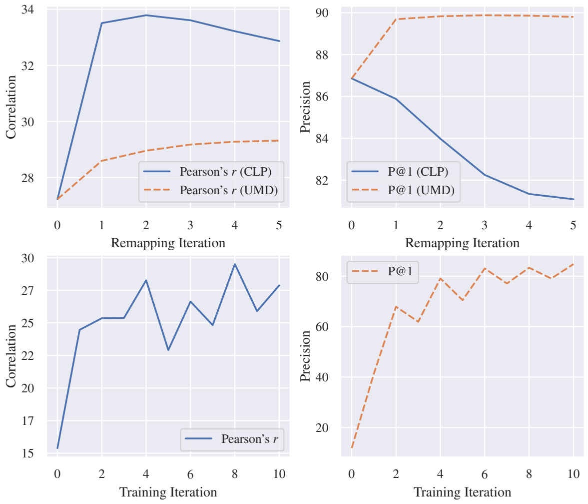

Figure 3: Results for unsupervised vector space remapping (top) and contrastive learning with USCORE$_{\text{SNT}}$ (bottom) for de-en. Pearson's r is computed on WMT-16 (MT evaluation) and P@1 on News Commentary v15 (parallel sentence matching).

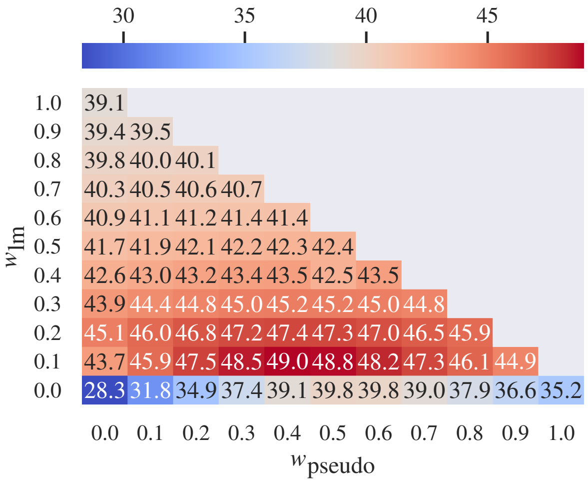

Figure 4: Influence of a language model and an MT system on USCORE$_{\text{WRD}}$, segment-level Pearson's r for different values of w_{pseudo} (weight for pseudo references) and w_{lm} (weight for the language model) on WMT-16 de-en data. Note that the point $w_{\text{pseudo}} = w_{\text{lm}} = 0$ uses only WMD(x, y); see Equation 3. Here, $n = 1$.

could be a more robust choice for metrics that should perform reasonably well on both tasks.

Pseudo References & Language Model Next, we add a language model to the metric and investigate pseudo-parallel corpus mining to train an MT system for pseudo references. Tran et al. (2020) show that fine-tuning MBART using pseudo-parallel data leads to very promising results, so we use MBART for our own experiments as well. Since fine-tuning for MT is a very resource-intensive undertaking requiring many parallel sentence pairs (Barrault et al., 2020), especially compared to our vector space remapping experiments, we need considerably more training data. On average, Tran et al. (2020) use around 200k pseudo-parallel sentence pairs for training. To obtain the same amount with our extraction rate of 5%, we now use a pool of 4m sentences per language for mining. Our results on the de-en data of WMT-16 are reported in Figure 4, which is similar to an ablation study. On the x-axis, we vary the weight $w_{\text{pseudo}} \in \{0.0, 0.1, \ldots, 0.9, 1.0\}$ for USCORE$_{\text{WRD}}$ with pseudo references, and on the y-axis, we explore different weights $w_{\text{lm}} \in \{0.0, 0.1, \ldots, 0.9, 1.0\}$ for the language model. We set $w_{\text{xlng}} = 1 - w_{\text{pseudo}} - w_{\text{lm}}$. The best correlation uses $w_{\text{pseudo}} = 0.4$, $w_{\text{lm}} = 0.1$, and $w_{\text{xlng}} = 0.5$. The improvement when pseudo references and a language model are included is substantial (over only using WMD)—e.g., we improve from 28% correlation with humans ($w_{\text{pseudo}} = w_{\text{lm}} = 0$) to 49% with the best weight combination, an improvement of 75%.

Contrastive Learning For USCORE$_{\text{SNT}}$, we also use 4m monolingual sentences per language for mining but only retain the top 100k sentence pairs, as for the contrastive training objective we additionally have to filter out duplicate sentences. The results of USCORE$_{\text{SNT}}$ are shown in Figure 3 (bottom). The P@1 scores seem to steadily improve every two training iterations. Beginning with the sixth iteration, the precision seems to converge.

4.3 Other Languages: Results & Analysis

We now test our metrics on other languages and datasets. For USCORE$_{\text{SNT}}$, we train its sentence embedding model for six iterations. For USCORE$_{\text{WRD}}$, we remap MBERT once with UMD and make use of a language model and pseudo references obtained from an MT system. Based on Section 4.2, we set $w_{\text{pseudo}} = 0.4$, $w_{\text{lm}} = 0.1$, and $w_{\text{xlng}} = 0.5$. Additionally, based on analogous, unreported experiments, we set $w_{\text{wrd}} = 0.6$ and $w_{\text{snt}} = 0.4$ for ensembling. Since determining the weights for USCORE$_{\text{WRD}}$ and USCORE$_{\text{WRD} \oplus \text{SNT}}$ this way constitutes a form of supervision, we also evaluate weights chosen independently from our conducted experiments. Namely, we also evaluate USCORE^{+} with $w_{\text{wrd}} = w_{\text{snt}} = 0.5$. For w_{lm}, we follow XMOVERSCORE and set it to 0.1 (setting w_{lm} lower makes sense because the LM only addresses the hypothesis without considering the source); accordingly, we set $w_{\text{xlng}} = w_{\text{pseudo}} = 0.45$. Since $w_{\text{lm}} = 0.1$ coincides with our findings in Section 4.2, we also evaluate UScore^{++} where each component uses entirely uniform weights, i.e., $w_{\text{wrd}} = w_{\text{snt}} = \frac{1}{2}$ and $w_{\text{lm}} = w_{\text{xlng}} = w_{\text{pseudo}} = \frac{1}{3}$.

Correlations with human judgments averaged over language pairs are shown in Table 2 (individual results are in the appendix). We also present the results of the popular TYPE-2 metric BLEU, where possible, and the recent TYPE-1 metrics MonoTransQuest (Ranasinghe et al., 2020b,a) and COMET-QE (Rei et al., 2021). Finally, as more direct competitors, we compare to the TYPE-3 metrics XMoverScore, SentSim, and DistilScore. We compute all reported scores ourselves.

Overall, the tuned weights of UScore perform marginally better than UScore^{+} on most datasets, but UScore^{+} is usually a very close second. UScore^{++} performs worse, however, and only competitively on two of the five datasets. This indicates that the language model should be set to a lower value, a choice that makes intuitively sense.

Expectedly, DistilScore, which uses parallel data, is always better than UScore$_{\text{SNT}}$, which uses pseudo-parallel data. In contrast, UScore$_{\text{WRD}}$ is generally on par with XMoverScore, even though XMoverScore uses real parallel data—the difference is that UScore$_{\text{WRD}}$ also leverages pseudo-references which XMoverScore does not. Indeed, from Figure 4, we observe that the pseudo-references can make an improvement of up to 1–11 points in correlation (comparing 'column' labeled $w_{\text{pseudo}} = 0$ to the columns $w_{\text{pseudo}} > 0$).

Our metrics beat reference-based TYPE-2 BLEU across the board. TYPE-1 metrics, which are fine-tuned on human scores, are generally the best. Intriguingly, the only two language pairs where our metrics are on par with them are the non-English de-zh and ru-de from Eval4NLP. These languages are outside the training scope of the current TYPE-1 metrics and thus test their generalization abilities. For example, on ru-de our best metric outperforms MonoTransQuest by 5 points correlation and COMET-QE by 9 points (Table 7 in the appendix).

UScore and UScore^{+} also outperform the TYPE-3 upper bounds on four of five datasets. On WMT-16, WMT-17 and Eval4NLP, they have the best overall results. On WMT-MQM, UScore$_{\text{WRD}}$ alone is best. The drop in performance for the combined metric is caused by UScore$_{\text{SNT}}$, which on its own performs very badly. As supervised DistilScore exhibits the same issues, this could be a general problem for sentence embeddings based metrics on this dataset. We identify further reasons in Appendix E.

For MLQE-PE, the SentSim metrics perform best on average among TYPE-3 and our metrics—although our reproduced scores for this dataset differ noticeably from the authors' results, due to issues in their original code (Chen et al., 2022). Among our self-learned metrics, the combined variant performs best on average again, but still is 3–5 points below SentSim and DistilScore, even though it outperforms both XMoverScore variants by over 6 points. Interestingly, UScore$_{\text{SNT}}$ works better than UScore$_{\text{WRD}}$, unlike for the other datasets. Similarly, DistilScore clearly outperforms XMoverScore. This could be because MLQE-PE contains Sinhala, a language mBERT was not trained on. Another explanation is the data collection scheme for ru-en, which uses different sources of parallel sentences, mainly colloquial data and Russian proverbs, which use rather unconventional grammar (Fomicheva et al., 2022). This apparently confuses the language model and MT system which have been trained on data from other domains. When we exclude si-en and ru-en from MLQE-PE, UScore$_{\text{WRD} \oplus \text{SNT}}$ performs best, with an average Pearson's r of 44.22 for tuned weights and 44.45 for default weights vs. 43.82 for SentSim (BERTScore). In Appendix C, we show that incorporating real parallel data (in addition to pseudo-parallel data) at an order of magnitude lower than SentSim allows us to outperform SentSim on MLQE-PE also.

5 Discussion

Throughout, we have presented a mix of results and analysis, which we now summarize and discuss. In Figure 4, we conducted an ablation study on the individual components of UScore$_{\text{WRD}}$ (on de-en). This showed that all three components (pseudo-references, language model, WMD) matter; by itself, the LM is more important than the pseudo-references which are more important than WMD. However, in combination, the LM is least important. We also showed that pseudo-parallel data can successfully rectify deficient multilingual vector spaces, similar to real parallel data, see Figure 3. We note, however, that pseudo-parallel data may introduce an important bias in our data sampling: namely, it may mine factually incorrect parallel

	Metric	**WMT-16**	**WMT-17**	**MLQE-PE**	**Eval4NLP**	**WMT-MQM**

Table 2: Segment-level Pearson's *r* correlations with human judgments, averaged over language directions. The best results are highlighted in bold, while results that are not significantly worse (as determined by a two-sample t-test with 10% significance level) are underlined.

sentences, see Table 3 in the appendix, which may amplify issues of adversarial robustness; see our discussion in Section 8.

We remark that, depending on the annotation scheme, better correlations with human judgments do not necessarily entail better metrics (Freitag et al., 2021a). The datasets in this work were annotated using either DA, CLDA, or MQM scores, with MQM explicitly addressing this problem. Since our metrics are consistent regardless of the annotation scheme, they are unlikely to overfit a particular one.

We finally note that combining word and sentence-level models is meaningful, because they offer complementary views (Song et al., 2021). Kaster et al. (2021) also show that they capture orthogonal linguistic factors to varying degrees. Such complementarity may also stem from different underlying vector spaces, i.e., MBERT vs. XLM-R that we use in sentence- and word-level metrics.

6 Related Work

All metrics in this work presented so far treated the MT model generating the hypotheses as a black-box. There also exists a recent line of work of so-called glass-box metrics, which actively incorporate the MT model under test into the scoring process (Fomicheva et al., 2020a,b). In particular, Fomicheva et al. (2020b) explore whether the MT model under test can be used to generate additional hypotheses (Dreyer and Marcu, 2012). A crucial difference to our metrics is the required availability of the original MT model, which we are agnostic about. The MT models used in Fomicheva et al. (2020b) are all trained on parallel data, which makes their approach a supervised metric in our sense.

Other recent metrics that leverage the relationship between metrics and (MT) systems are PRISM (Thompson and Post, 2020) and BARTSCORE (Yuan et al., 2021). We do not classify them as unsupervised, however, as PRISM is trained from scratch on parallel data and BARTSCORE uses a BART model fine-tuned on labeled summarization or paraphrasing datasets.

There are also multilingual sentence embedding models which are highly relevant in our context. Kvapilíková et al. (2020), for example, fine-tune XLM-R on synthetic data translated with an unsupervised MT system. Similar to our contrastive learning approach, the resulting embedding model is completely unsupervised. Important differences are that our sentence embedding model can be improved iteratively and does not rely on an MT system. We leave a comparison to future work.

Finally, the idea of fully unsupervised text generation systems has originated in the MT community (Artetxe et al., 2018; Lample et al., 2018; Artetxe et al., 2019). Given the similarity of MT systems and evaluation metrics, designing fully unsupervised evaluation metrics is an apparent next step, which we take in this work.

7 Conclusion

In this work, we aimed for sample efficient evaluation metrics that do not use any form of supervision.

In addition, our novel metrics should be maximally effective, i.e., of high quality. To achieve this, we leveraged pseudo-parallel data obtained from fully unsupervised evaluation metrics in three ways: we (i) remapped deficient vector spaces using the pseudo-parallel data, (ii) trained an unsupervised MT system from it (yielding pseudo references), and (iii) induced unsupervised multilingual sentence embeddings. To enable our approach, we also explored *efficient* pseudo-parallel corpus mining algorithms based on our metrics as an orthogonal contribution. Finally, we showed that our approach is effective and can outperform three supervised upper bounds (making use of parallel data) on 4 out of 5 datasets we included in our comparison.

In future work, we want to aim for algorithmic efficiency, include *pseudo source texts* as additional components (using the MT system in backward translation), and address the missing dualities discussed in Figure 1 (i.e., use of metrics as optimization criteria and MT systems to generate additional pseudo-parallel data). Further, our approach has substantial room for improvement given that we selected hyperparameters completely unsupervised or based on one high-resource language pair (de-en). Thus, it will be particularly intriguing to explore *weakly-supervised approaches* which leverage minimal forms of supervision.

8 Limitations

Limitations of our metrics include (1) *algorithmic inefficiency*, (2) *resource inefficiency*, (3) the brittleness of unsupervised MT systems in certain situations, and (4) issues of adversarial robustness.

(1) Some of the components of USCORE$_{\text{WRD}}$ (mainly the MT system) have high computational costs. For example, XMOVERSCORE and SENTSIM (BERTSCORE) take less than 30 seconds to score 1000 hypotheses on an Nvidia V100 GPU. USCORE$_{\text{WRD}}$, on the other hand, takes over 2.5 minutes. This algorithmic inefficiency trades off with our sample efficiency, by which we did not use any supervision signals. In future work, we aim to experiment with efficient MT architectures to reduce computational costs (Kamal Eddine et al., 2022; Grünwald et al., 2022).

(2) Similarly to XMOVERSCORE, MONOTRANSQUEST or SENTSIM, our metrics use high-quality encoders such as MBERT, which are not only memory and inference inefficient but also leverage large monolingual resources. Future work should thus not only investigate using smaller MBERT models but also models that leverage smaller amounts of monolingual resources. Wang et al. (2020), for example, propose a competitive LSTM-based approach that completely forgoes monolingual resources and instead uses small parallel corpora (i.e., a few hundred parallel sentences as a weak supervision signal). Similarly, we give a recipe for improving MBERT for unseen languages using limited amounts of parallel data in Appendix C.

(3) Using unsupervised MT approaches, as we do via pseudo references, may be less effective for truly low-resource languages (Marchisio et al., 2020). However, this remains a very active research field with a constant influx of more powerful solutions (Ranathunga et al., 2022; Sun et al., 2021).

(4) As indicated in Sections 4.2 and 5, our mined pseudo-parallel data tends to contain factual inconsistencies such as “Uruguay was seventh” vs. (a translation of) “Russia was second”. As a consequence, our induced metrics may be less robust than existing metrics (Chen and Eger, 2022; Rony et al., 2022). An approach to address this inconsistency would be to retain only high probability aligned words in parallel sentences (recall that we infer word-level parallel data from sentence-level parallel data).

A Vector Space Remapping

Zhao et al. (2020) explore two different remapping approaches for XMoverScore, which are defined as follows:

Procrustes alignment Mikolov et al. (2013) propose to compute a linear transformation matrix $\mathbf{W}$ which can be used to map a vector x of a source word into the target language subspace by computing $\mathbf{W}x$. The transformation can be computed by solving the problem

$$\min_{\mathbf{W}} ||\mathbf{WX} - \mathbf{Y}||_2. \tag{7}$$

Here $\mathbf{X}, \mathbf{Y}$ are matrices with embeddings of source and target words, respectively, where the tuples $(x_i, y_i) \in \mathbf{X} \times \mathbf{Y}$ come from parallel word pairs. XMoverScore constrains $\mathbf{W}$ to be an orthogonal matrix such that $\mathbf{W}^\top\mathbf{W} = \mathbf{I}$, since this can lead to further improvements (Xing et al., 2015). Zhao et al. (2020) call this remapping Linear Cross-Lingual Projection remapping (CLP).

De-biasing The second remapping method of XMoverScore is rooted in the removal of biases from word embeddings. Dev and Phillips (2019) explore a bias attenuation technique called Universal Language Mismatch-Direction (UMD). It involves a bias vector v_B, which is supposed to capture the bias direction. For each word embedding e, an updated word embedding e' is computing by subtracting their projections onto v_B, as in

$$e' = e - (e \cdot v_B)v_B, \tag{8}$$

where $\cdot$ is the dot product. To obtain the bias vector v_B, Dev and Phillips (2019) use a set $\mathcal{E}$ of word pairs that should be de-biased (e.,g. *man* and *woman*). The subtractions of the embeddings of the words in each pair are then stacked to form a matrix $\mathbf{Q}$, and the bias vector v_B is its top-left singular vector. Zhao et al. (2020) use the same approach for XMoverScore, but $\mathcal{E}$ instead consists of parallel word pairs.

Zhao et al. (2020) show that these remapping methods lead to substantial improvements of their XMoverScore metric (on average, up to 10 points in correlation). The required parallel word pairs were extracted from sentences of the EuroParl corpus (Koehn, 2005) using the fast-align (Dyer et al., 2013) word alignment tool. The best results were obtained when remapping on 2k parallel sentences.

	—	10k	20k	30k	200k
Avg	40.60	42.95	44.42	45.17	**46.57**

Figure 5: Pearson's r correlations on MLQE-PE for UScore$_{\text{WRD}\oplus\text{SNT}}$ when fine-tuning on limited amounts of parallel data. We explore sample sizes of 10k, 20k, 30k, and 200k.

B Filtering

Since large corpora tend to include low-quality data points, we follow Artetxe and Schwenk (2019) and Keung et al. (2021) and apply three simple filtering techniques. We first remove all sentences from each monolingual corpus for which the fastText language identification tool (Joulin et al., 2017) predicts a different language. We then filter all sentences which are shorter than 3 tokens or longer than 30 tokens. As the last step, we discard sentence pairs sharing substantial lexical overlap, which prevents degenerate alignments of, e.g., proper names. We remove all sentence pairs for which the Levenshtein distance detects an overlap of over 50%.

C Fine-Tuning on Parallel Data

To examine whether and by how much we can further improve our metrics using forms of supervision, we experiment with a fine-tuning step on *parallel sentences* and treat self-learning on pseudo-parallel data as pre-training (He et al., 2020). We use the parallel data to fine-tune the contrastive sentence embeddings of UScore$_{\text{SNT}}$ and the MT system of UScore$_{\text{WRD}}$, which is responsible for generating pseudo references. Further, we also compute new remapping matrices for UScore$_{\text{WRD}}$. Since CLP is superior to UMD when parallel data is used (see Section 4.2), we compute these remapping matrices using CLP instead of UMD. To assess how different amounts of parallel sentences affect performance, we fine-tune our metrics on 10k, 20k, 30k, and 200k parallel sentences. We use WikiMatrix (Schwenk et al., 2021) and the Nepali Translation Parallel Corpus (Duwal et al., 2019) to obtain parallel sentences.

Pearson's r correlations with human judgments for individual and averaged language pairs are shown in Figure 5; we focus on MLPQE-PE, where our metrics performed worst. Overall, introducing parallel data into the training process consistently improves performance for the majority of language directions; more parallel data leads to better results. The relatively biggest improvements are achieved for the si-en language direction, which is in accordance with our discussion above. When fine-tuning with 30k parallel sentences, the performance of our metrics is roughly on par with the SentSim variants (see Table 2). With 200k parallel sentences, our metrics clearly outperform SentSim, which uses millions of parallel sentences and NLI data as supervision signals.

D Hyperparameters

For efficient WMD pseudo-parallel mining, we set $k = 20$ for remapping, and $k = 1$ for training mBART. For ratio-margin-based pseudo-parallel mining, we use $k = 5$. With regard to training UScore$_{\text{SNT}}$, we follow Gao et al. (2021), and iteratively train XLM-R for one training epoch with a learning rate of 5e-5, a batch size of 256, and a temperature coefficient of $\tau = 0.05$ utilizing the AdamW optimizer (Loshchilov and Hutter, 2019). Fine-tuning of mBART was performed for three epochs with a batch size of four and using the same learning rate of 5e-5 as well as AdamW optimizer.

We decided to continue using mBERT in UScore$_{\text{WRD}}$ for two reasons. Firstly, we want UScore$_{\text{WRD}}$ to remain directly comparable to XMoverScore which is based on mBERT. Secondly, in our own experience, vanilla mBERT is very robust in terms of layer choice, especially compared to vanilla XLM-R. Intuitive choices like the first or last layer work very well for a lot of problems. This is an important property for unsupervised metrics, since we can't easily justify a (supervised) hyperparameter search in an unsupervised setting to determine the best layer or even a linear combination of those.

E Supplementary Data and Results

Table 3 shows examples of pseudo-parallel data obtained with UScore$_{\text{WRD}}$ and UScore$_{\text{SNT}}$. Tables 4, 5, 6, and 7 show segment-level Pearson's r correlations with human judgments on WMT-16, WMT-17, MLQE-PE, as well as WMT-MQM and Eval4NLP, respectively. Table 8 provides additional statistics for each dataset.

A surprising finding is the poor performance of UScore$_{\text{SNT}}$ and DistilScore on the German-English language pair in Table 7. It is well known that high-resource language directions, such as English-German, can be affected by a lack of low-quality translations (Fomicheva et al., 2022), and with only high-quality translations available, there is little variation in the scores, which makes a meaningful assessment of correlation difficult (Specia et al., 2020). Further, since both UScore$_{\text{SNT}}$ and DistilScore are based on sentence embeddings of XLM-R, and sentence embedding-based metrics are known to be a bit worse on average than their word embedding-based counterparts, we believe that both aspects combined could be the root cause for this.

Case	**Source**	**Target**
Top-WRD	Uruguay belegt mit vier Punkten nur Platz Sieben.	Russia was second with four gold and 13 medals.
Top-WRD	Soweit lautet zumindest die Theorie.	That, at least, is the theory.
Rnd-WRD	Die USA stellen etwa 17.000 der insgesamt 47.000 ausländischen Soldaten in Afghanistan.	Currently, there are about 170,000 U.S. troops in Iraq and 26,000 in Afghanistan.
Rnd-WRD	“Das ist eine schwierige Situation”, sagte Kaczynski.	“It seemed like a ridiculous situation,” Vanderjagt said.

Abstract

Home cooks often have specific requirements regarding individual ingredients in a recipe (e.g., allergies). Substituting ingredients in a recipe can necessitate complex changes to instructions (e.g., replacing chicken with tofu in a stir fry requires pressing the tofu, marinating it for less time, and par-cooking)—which has thus far hampered efforts to automatically create satisfactory versions of recipes. We address these challenges with the *RecipeCrit* model that allows users to *edit* existing recipes by proposing individual ingredients to add or remove. Crucially, we develop an unsupervised critiquing module that allows our model to iteratively re-write recipe instructions to accommodate the complex changes needed for ingredient substitutions. Experiments on the Recipe1M dataset show that our model can more effectively edit recipes compared to strong language-modeling baselines, creating recipes that satisfy user constraints and humans deem more correct, serendipitous, coherent, and relevant.

1 Introduction

Individual preferences and dietary needs shape the types of recipes that home cooks choose to follow. Cooks must often accommodate the desire for versions of recipes that do not contain a specific ingredient (substitution—e.g., for food allergies) or *do* make use of particular ingredients (addition—e.g., to use up near-expiry items). We thus aim to build a system for *recipe editing* that accommodates fine-grained ingredient preferences.

Prior research in recipe editing has focused on substituting individual ingredients in the ingredients list (Yamanishi et al., 2015) or recommending new recipes based on similar ingredients (Teng et al., 2012). Individual ingredient substitution rules (e.g., tapioca flour and xanthan gum for wheat flour) often necessitate additional changes to the cooking procedure to function properly (Li et al., 2022). Other studies employed recommendation-based approaches. However, they suffer from data sparsity: there is an extremely large set of possible recipes that differ by a single ingredient, and many specific substitutions may not appear in recipe aggregators (Petrescu et al., 2021).

Recipe editing can be seen as a combination of recipe generation and controllable natural language generation (Shin et al., 2020), and has been explored to adapt recipes for broad dietary constraints (Li et al., 2022) and cuisines (Pan et al., 2020). Pre-trained language models have been used to create recipe directions given a known title and set of ingredients (Kiddon et al., 2016; Bosselut et al., 2018), but generated recipes suffer from inconsistencies. Li et al. (2022) instead build a paired recipe dataset, but face challenges scaling due to the large set of possible recipes and dietary restrictions; people often express even more specific ingredient-level preferences (e.g., dislikes of certain ingredients or allergies).

In this work, we address the above challenges and propose **RecipeCrit**, a denoising-based model trained to complete recipes and learn semantic relationships between ingredients and instructions. The novelty of this work relies on an *unsupervised* critiquing method that allows users to provide ingredient-focused feedback iteratively; the model substitutes ingredients and also re-writes the recipe text using a generative language model. While existing methods for controllable generation require paired data with specially constructed prompts (Keskar et al., 2019) or hyperparameter-sensitive training of individual models for each possible piece of feedback (Dathathri et al., 2020), our unsupervised critiquing framework enables recipe editing models to be trained with arbitrary un-paired data. This generalizes recipe editing, unlike existing methods for controllable generation that rely on paired data with specially constructed

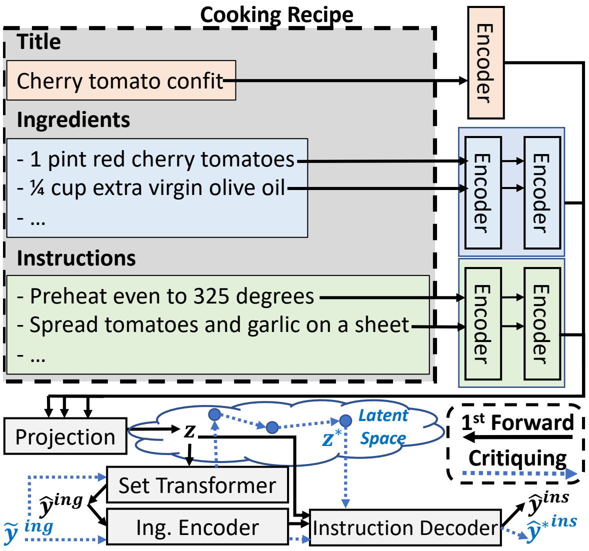

Figure 1: RecipeCrit includes a recipe encoder and an ingredient and instruction decoders using the base recipe and target ingredients to edit cooking instructions.

prompts (Keskar et al., 2019) or hyperparameter-sensitive training of individual models for each possible feedback (Dathathri et al., 2020).

Experiments on the Recipe1M (Salvador et al., 2017) dataset show that RecipeCrit edits recipes in a way that better satisfies user constraints, preserves the original recipe, and produces coherent recipes (i.e., recipe instructions are better conditioned on the ingredients list) compared to state-of-the-art pre-trained recipe generators and language models. Human evaluators judge RecipeCrit's recipes to be more serendipitous, correct, coherent, and relevant to the ingredient-specific positive and negative feedback (i.e., critiques).

2 RecipeCrit: a Hierarchical Denoising Recipe Auto-encoder

Previous methods to edit recipes focused on broad classes like dietary categories (Li et al., 2022) and cuisines (Pan et al., 2020) and require paired corpora (which do not exist for fine-grained edits). We propose **RecipeCrit**: a hierarchical denoising recipe auto-encoder that does not require paired corpora to train and accommodates positive and negative user feedback about ingredients (Figure 1).

RecipeCrit is divided into three submodels: an Encoder $E(\cdot)$, which produces the latent representation $\mathbf{z}$ from the (potentially noisy) recipe; an ingredient predictor $C(\cdot)$, which predicts the ingredients $\hat{\mathbf{y}}^{ing}$, and a decoder $D(\cdot)$, which reconstructs the cooking instructions $\hat{\mathbf{y}}^{ins}$ from $\mathbf{z}$ conditioned on the $\hat{\mathbf{y}}^{ing}$.

Recipe Encoder $E(\cdot)$ We build a powerful latent representation that captures the different elements of a recipe via the mean-pooled output of the representation of each sentence using a Transformer encoder (Vaswani et al., 2017). We provide the title $\mathbf{x}^{ttl}$, ingredients $\mathbf{X}^{ing}$, and instructions $\mathbf{X}^{inst}$ as *raw* text input. While the title $\mathbf{x}^{ttl}$ comprises a single sentence, the ingredients $\mathbf{X}^{ing}$ and instructions $\mathbf{X}^{inst}$ are provided as lists of sentences; we use raw recipe texts directly as input, removing the need of a pre-processing step. We encode the ingredients and instructions in a hierarchical manner using another Transformer to create fixed-length representations. We compute the latent representation $\mathbf{z}$ by concatenating the representations of each component and applying a projection followed by a tanh function: $\mathbf{z} = \tanh(\mathbf{W}[\mathrm{TRF}(\mathbf{x}^{ttl}) \parallel \mathrm{HTRF}(\mathbf{X}^{ing}) \parallel \mathrm{HTRF}(\mathbf{X}^{ins})])$, where $\parallel$ is the concatenation, and $\mathbf{W}$, $\mathbf{b}$ the projection parameters.

Ingredient Predictor $C(\cdot)$ We treat ingredient prediction as multi-label binary classification over an ingredient vocabulary I, with a boolean target vector $\mathbf{y}^{ing}$ representing ingredients in a ground truth recipe. We use a Set Transformer (Salvador et al., 2019) to decode ingredients, pooling ingredient logits over time-steps to compute binary cross-entropy loss against the target; we also employ an *EOS* token to predict the ingredient set cardinality:

$$\mathcal{L}_{ing}(\cdot) = -\sum_i^{|I|} \mathbf{y}_i^{ing} \log \hat{\mathbf{y}}_i^{ing} - \lambda \mathbf{y}_{eos}^{ing} \log \hat{\mathbf{y}}_{eos}^{ing},$$

where λ controls the impact of the *EOS* loss. At inference, we return the top-k ingredients, where k is the first position with a positive *EOS* prediction.

Instruction Decoder $D(\cdot)$ The last component generates cooking instructions using a Transformer decoder. We condition the decoder on $\mathbf{z}$, previously generated outputs $\hat{\mathbf{y}}^{ins}_{1:t-1}$, and ingredients $\hat{\mathbf{y}}^{ing}$. Specifically, we encode the ingredients using an embedding layer $A(\cdot)$ and concatenate their representations with the recipe representation $\mathbf{z}$. We train using teacher-forcing and cross-entropy:

$$\mathcal{L}_{ins}(\mathbf{z}, A(\hat{\mathbf{y}}^{ing})) = -\sum_t \mathbf{y}_t^{ins} \log \hat{\mathbf{y}}_t^{ins}.$$

Taking inspiration from masked language and span modeling (Devlin et al., 2019; Joshi et al., 2020), we train RecipeCrit as a de-noising recipe auto-encoder via the task of *recipe completion*: We mask random ingredients and instruction sentences in model input, and task our model to generate the full recipe. We train our model in two stages: first minimizing ingredient prediction loss $\mathcal{L}_{ing}$; then freezing the encoder and optimizing for instruction decoding loss $\mathcal{L}_{ins}$ using ground truth ingredients.

Unsupervised Critiquing We aim to refine a recipe based on the user's feedback and the predicted ingredients $\hat{\mathbf{y}}^{ing}$. We denote $\tilde{\mathbf{y}}^{ing}$ the vector of desired ingredients. Simply incorporating user feedback by explicitly including/removing ingredients before generating instructions often cannot satisfy user preferences due to weak conditioning between predicted ingredients and generated instructions. In RecipeCrit we turn to a critiquing method that modifies the recipe representation $\mathbf{z}$ before using the updated representation to jointly generate the edited ingredients and instructions. Specifically, users add a new ingredient c by setting $\hat{\mathbf{y}}_c^{ing} = 1$ or remove some using $\hat{\mathbf{y}}_c^{ing} = 0$.

Inspired by success in editing the latent space in text style transfer and recommendation (Antognini et al., 2021a; Wang et al., 2019), we first compute the gradient with respect to $\mathbf{z}$:

$$\mathbf{g}_{t-1} = \nabla_{\mathbf{z}_{t-1}} \mathcal{L}_{ing}(C(\mathbf{z}_{t-1}), \tilde{\mathbf{y}}^{ing}).$$

Then ,we use the gradient to modulate $\mathbf{z}$ such that the new predicted ingredients $\hat{\mathbf{y}}^{ing}$ are close to the desired ingredients $\tilde{\mathbf{y}}^{ing}$:

$$\mathbf{z}_t = \mathbf{z}_{t-1} - \alpha_{t-1}\mathbf{g}_{t-1}/||\mathbf{g}_{t-1}||_2.$$

Prior work stopped updating $\mathbf{z}$ when $\|\ \tilde{\mathbf{y}}^{ing} - \hat{\mathbf{y}}^{ing}\ \|_1 < \epsilon$ for some threshold ϵ. We instead propose to compute the absolute difference $|\tilde{\mathbf{y}}_c^{ing}$ - $\hat{\mathbf{y}}_c^{ing}|$. Since the optimization is nonconvex, we improve convergence by using an early stopping mechanism. Our approach is unsupervised and can update the full recipe latent representation, reflecting how adding or removing an ingredient can necessitate adjustments to other ingredients and cooking steps. Pseudo-code is available in the App.

Another advantage of our approach is the possibility to update multiple ingredients simultaneously: adding or removing an ingredient might affect other ones as well and thus, a local-based stopping criteria allows such a change.

3 Experiments

Dataset We assess our model on the Recipe1M (Salvador et al., 2017) dataset of 1M recipe texts. Each recipe contains a title, a list of ingredients, and a list of cooking instructions. We filter out recipes with more than 20 ingredients or steps, creating train, val, and test splits with 635K, 136K, and 136K recipes, respectively. The average recipe comprises 9 ingredients and 166 words. We follow Salvador et al. (2019) and build a set of $1,488$ ingredients. For critiquing, we select 20 ingredients to be critiqued among the most and the least popular ingredients across the train set. For each critique, we randomly sample 50 recipes that contain the critiqued ingredient and 50 that do not.

Baselines We compare our proposed RecipeCrit architecture against large language models trained using our denoising objective. We fine-tune BART (Lewis et al., 2020), an encoder-decoder language model trained to denoise documents, as well as RecipeGPT (Lee et al., 2020), a decoder-only language model pre-trained on Recipe1M to predict ingredients and cooking steps. To demonstrate the necessity of our denoising approach, we also compare against PPLM (Dathathri et al., 2020), a recent method for controllable generation from language models that leverages sets of desired and undesired sequences (for ingredient addition and substitution, respectively). All models use greedy decoding.

Metrics We evaluate edited recipes via metrics that reflect user preferences. First, a user wants a recipe similar to the base recipe—we measure *ingredient fidelity* via IoU (Jaccard distance) and F1 scores between the edited and base recipe ingredients list. Next, the recipe must satisfy the user's specific ingredient feedback—we report the percentage of edited recipes that properly include/exclude the target ingredient (*Success Rate*). Finally, the recipe must be *coherent*: able to be followed and internally consistent. As an ingredient constraint can be satisfied in many ways, we follow Kiddon et al. (2016) and measure coherence via precision, recall, and F1-score of ingredients mentioned in the generated steps compared to the predicted ingredients. This verifies that the recipe itself relies on the listed ingredients.

Training Details For fair comparison, we compare similar-sized models. RecipeCrit uses an encoder and decoder with 4 Transformer layers, 4 attention heads, and hidden size of 512. We randomly mask 50% of the ingredients and instructions during training, and tune them on the validation set using random search. We give more details in App. B.

			Ingr. Fidelity		*Predicted Instr.*		
	Model	**% Succ.**	**IoU**	**F1**	**Prec.**	**Rec.**	**F1**

	RecipeCrit	**95.8**	**68.8**	**80.7**	**74.0**	**74.5**	**74.2**

Table 1: Critiquing performance: success rate of adding/removing an ingredient, IoU and F1 ingredient scores, and the Precision, Recall, and F1 of ingredients in cooking instructions.

RQ1: Recipe Editing via Critiquing We evaluate whether our models can edit recipes by creating new ingredient sets and corresponding recipe instructions when faced with positive and negative feedback: an ingredient that must be added or removed (substituted) from the recipe to create a new version. For ingredient substitution, we mask the critiqued ingredient and all steps that reference it as denoising inputs; for addition, we use the full base recipe. For RecipeGPT and BART, we filter the predicted ingredients lists to exclude/include the target ingredient. For PPLM, we provide the target ingredient as a bag of words to steer generation, using RecipeGPT as the base generative model. RecipeCrit uses our iterative critiquing framework (Section 2) to accommodate user feedback.

We show results for constraint satisfaction (success rate), ingredient fidelity, and recipe coherence (predicted instructions) in Table 1. RecipeCrit outperforms baselines across all metrics for ingredient addition and removal. While our baselines take advantage of pre-trained language models, they cannot successfully incorporate user feedback during editing. PPLM-guided constrained decoding is not only two orders of magnitude slower than our denoising models (3min vs. 1s per recipe), but we observe poor fidelity and frequent incoherent instructions (e.g., repetition). Meanwhile, forcing ingredient lists to omit or contain specific ingredients has little impact on the generated recipe instructions—even when the desired ingredient is manually inserted into the ingredients list, RecipeGPT and BART mention using the ingredient only in 33% and 41% of generated instructions.

Our model and gradient-based critiquing method leads to a stronger influence of the edited ingredients on recipe instructions. By directly modifying the recipe latent representation that is then attended over during step generation, RecipeCrit achieves 30-50% relative improvement in success rate for adding ingredients and 20-65% relative improvements in coherence (F1 score between predicted ingredients and those mentioned in the instructions) for both addition and removal. Meanwhile, baselines tend to ignore many ingredients in the ingredient list when generating new recipe directions.

Model	**Ser.**	**Cor.**	**Coh.**	**Rel.**
RecipeGPT	-0.04^*	-0.03^*	-0.01^*	-0.07^*
PPLM	-0.03^*	-0.05^*	0.01	0.00^*
BART	-0.05^*	-0.07^*	-0.09^*	-0.07^*
RecipeCrit	$\mathbf{0.12}$	$\mathbf{0.14}$	$\mathbf{0.10}$	$\mathbf{0.14}$

Table 2: Human evaluation of edited recipes in terms of best-worst scaling for serendipity, correctness, coherence, and relevance. $*$ denotes a significant difference compared to RecipeCrit (posthoc Tukey test, $p < 0.01$).

Human Evaluation We have established that RecipeCrit creates edits that better satisfy user constraints (as expressed via critiques), more closely resemble the user's original preferences (base recipe), and make better use of the predicted ingredients (ingredient coherence). We next perform a qualitative human evaluation of our edited recipes via Mechanical Turk, asking the user: how pleasantly surprised they were (Serendipity); whether the recipe respected their feedback (Correctness); how easy the recipe was to follow (Coherence); and whether the recipe resembled the original recipe (Relevance). We uniformly sampled 800 edited recipes (400 for adding and 400 for removing) across the ingredients to critique and showed them in random order. The annotators judged the edited recipes using best-worst scaling (Louviere et al., 2015) with scores normalized to $[-1, +1]$. Table 2 shows that our edited recipes are largely preferred on all criteria. Our results highlight that critiquing improves the coherence of generated recipes and their resemblance to the original ones.

Case Study Table 3 shows a sample of our best-performing baseline (BART) and RecipeCrit editing the "cherry tomato confit" recipe to include "kale". While both edited recipes include kale, RecipeCrit stays faithful to the user's preference for "tomato confit" while incorporating the new feedback: it makes a slightly different tomato confit but uses kale as the "fresh" or salad part of the dish. However, BART generates a *cocktail* recipe instead that ignores the base recipe: it's a drink rather than food, sweet rather than savory, and ig-

Cherry tomato confit (base recipe)	**BART**	**RecipeCrit (Ours)**
clove, oil, pepper, rosemary, salt, tomato	**kale**, cachaca, cream, ice, juice, liqueur, pineapple, rum, strawberries, sugar, water ~~clove~~, ~~oil~~, ~~pepper~~, ~~rosemary~~, ~~salt~~, ~~tomato~~	clove, **kale**, oil, pepper, rosemary, salt, tomato
1) preheat oven to 325 degrees 2) spread tomatoes and garlic on a sheet. 3) drizzle with oil, and sprinkle with rosemary, crushed red pepper, a large pinch of salt and several grinds of pepper. 4) bake until tomatoes are wrinkled and fragrant, about 45 minutes, shaking pan. 5) transfer tomato pan to a rack to cool. 6) discard garlic.	1) place ice cubes in a cocktail shaker. 2) add pineapple juice, coconut liqueurs, cachacca, cream and rum ; shake well add crushed ice to a collins glass. 3) add **kale** and strawberries to shaker. 4) strain drink into glass over crushed ice. 5) garnish with strawberry and pineapple.	1) heat oven to 350 degrees. 2) place tomatoes in a large bowl. 3) drizzle with olive oil and sprinkle with rosemary, salt and pepper; coat. 4) spread in a single layer on a sheet. 5) roast for 40 minutes. 6) remove and let cool for 10 minutes. 7) toss **kale** with tomatoes and garlic.

Table 3: Comparison of a cherry tomato confit recipe with its edited versions to include "**kale**" as an additional ingredient. RecipeCrit proposes tomato confit with **kale**, but BART disregards the base recipe to make a cocktail.

nores tomatoes altogether. This aligns with the results of the human evaluation. Complementary results are shown in Table 5 and 6.

RQ2: Variants of Critiquing Algorithms Now we show the significance of the early stopping mechanism in our particular critiquing module compared to previous thresholding methods (Antognini et al., 2021a; Wang et al., 2019). To demonstrate why, we re-run experiments from RQ1 and compare our early stopping against two baseline thresholding criteria using 1) the absolute difference (i.e., $|C(\mathbf{z}_t^*)_c - \tilde{\mathbf{y}}_c^{ing}| < \tau$) and 2) the L1 norm (i.e., $||C(\mathbf{z}_t^*) - \tilde{\mathbf{y}}^{ing}||_1 < \tau$). We find that an L1-based stopping criterion is suboptimal due to the high dimensionality of the ingredients. Using the absolute difference considerably improves the success rate ($+25\%$ for add and $+12\%$ for remove). Finally, our early stopping further increases the success rate ($+10\%$) for both adding and removing an ingredient (see App. for exact numbers).

4 Conclusion

We present RecipeCrit, a denoising-based model to edit cooking recipes. We first trained the model for recipe completion to learn semantic relationships between the ingredients and the instructions. The novelty of this work relies on the user's ability to provide ingredient-focused feedback. We designed an unsupervised method that substitutes the ingredients and re-writes the recipe text accordingly. Experiments show that RecipeCrit can more effectively edit recipes compared to strong baselines, creating recipes that satisfy user constraints and are more serendipitous, correct, coherent, and relevant as measured by human judges. For future work, we plan to extend our method to large pre-trained language models for other generative tasks and to explainable models in the context of rationalization (Bastings et al., 2019; Antognini et al., 2021b; Lei et al., 2016; Yu et al., 2021; Antognini and Faltings, 2021).

5 Limitations

We demonstrated the effectiveness of our method for the English language since, to the best of our knowledge, there is no multi-lingual dataset similar to Recipe1M. We would expect similar behavior for languages having similar morphology to English.

Regarding computational resources, the training on a single GPU takes a couple of hours, while the inference and the critiquing can run on a single-core CPU (in the range of 10 to 100 ms).

Cooking recipes are long and complex documents. While current language models and similar ones have achieved impressive results, they still suffer from a lack of coherence for long documents. We have shown in our experiments that RecipeCrit produced recipes whose coherence is preferred over the baselines by human annotators. However, there is still room for improvement as language modeling approaches for recipe generation do not have an explicit guarantee of coherence (i.e. only listed ingredients used, instructions only make use of ingredients or products mentioned before).

Similarly, as recipe instructions can consist of free-text, there is no guarantee that recipe texts will, for example, completely remove an ingredient. In real-world usage, our system can be adapted by post-processing the recipe, including performing beam-search sampling and eliminating non-satisfactory recipes. As a result, we continue to urge caution for users with e.g. severe ingredient allergies who may still need to carefully review edited recipes to ensure compliance.

RecipeGPT	73.5	84.7	61.2	72.6	66.4
BART	76.7	86.4	61.5	64.7	63.1
RecipeCrit	**78.6**	**88.2**	**68.2**	**73.0**	**70.5**

A Ingredient & Recipe Reconstruction

As baseline recipe generation models are unable to perform editing, we train all models using our denoising recipe completion task. To evaluate their generalization performance, we ask the models to reconstruct recipes from the unseen test set, with results shown in Table 4. We measure how well each model can infer the missing ingredients given the partial recipe context (IoU and F1 ingredient scores), as well as how coherent the reconstructed recipes are—the precision, recall, and F1 score of ingredients mentioned in the generated instructions compared to the predicted ingredients list.

RecipeCrit outperforms baselines in both measures. In particular, we find a significant improvement in ingredient mention precision, indicating that RecipeCrit better constrains its generated recipe directions based on the predicted ingredients list. Meanwhile, RecipeGPT and BART both tend to mention new ingredients in the recipe text even if they are not included in the ingredients list. As we see in Section 3, this is problematic because such models can include ingredients in the recipe steps even if users have specified dislikes or allergies.

Such text-to-text models capture the distribution of *language* well, producing fluent-sounding text. However, their lower scores for ingredient completion and recipe text coherence suggest that RecipeGPT and BART cannot distinguish how recipes are procedural texts with internal consistency, compared to generic text documents.

B Additional Training Details

We use a batch size of 32, dropout of 0.2, and Adam with learning rate 0.0001. For the baselines RecipeGPT and PPLM, we reuse the official code from the authors. For BART, we employ the HuggingFace library.

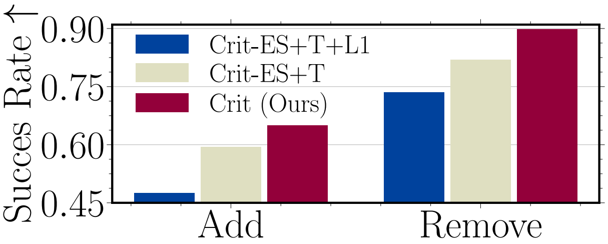

Figure 2: Critiquing algorithm comparison between global or local stopping criteria with threshold or early stopping.

Table 5: Comparison of a cherry tomato confit recipe with its edited versions to include "**kale**" as an additional ingredient. None of those baselines add the critique ingredient. RecipeGPT disregards the base recipe. PPLM generates a recipe in the same style than the base one, but three times longer and with a lack of coherence.

Cherry tomato confit (base recipe)

clove, oil, pepper, rosemary, salt, tomato

1) preheat oven to 325 degrees
2) spread tomatoes and garlic on a sheet.
3) drizzle with oil, and sprinkle with rosemary, crushed red pepper, a large pinch of salt and several grinds of pepper.
4) bake until tomatoes are wrinkled and fragrant, about 45 minutes, shaking pan.
5) transfer tomato pan to a rack to cool.
6) discard garlic.

RecipeGPT

cream, cheese, margarine, milk, onion, pepper, salmon, salt, tea
~~clove~~, ~~oil~~, ~~rosemary~~, ~~tomato~~

1) saute green peppers and onions in margarine.
2) add cream cheese and stir until melted.
3) add velveeta, milk and corn.
4) heat until melted, stirring occasionally.
5) add salt.
6) garnish with thin strips of red pepper and cilantro.
7) serve with crackers.

PPLM

oil, pepper, tomato, ~~clove~~, ~~rosemary~~, ~~tomato~~

1) preheat the oven to 400 degrees f.
2) place a large roasting pan in the center of the oven.
3) heat the olive oil in a large skillet over medium heat until hot.
4) add the tomatoes and cook for about 3 minutes or until the skins begin to split.
5) place in the oven for about 30 to 40 minutes until the skins begin to blister and shrivel.
6) place the tomatoes in cold water to cool, then remove the skins.
7) in a bowl, combine the tomatoes and their juices, salt, and pepper, tossing well to coat evenly.
8) remove the tomatoes, place them on a sheet tray, and bake for about 45 minutes, until the skins begin to blister and shrivel.
9) the tomatoes should still be juicy, and the skins should be very wrinkly. remove the tomatoes from the oven and let cool.
10) remove the skins from the tomatoes and discard the skins. transfer the tomatoes to a clean food processor.
11) blend the tomatoes with the roasted garlic, and add the peppercorns in the last 3 minutes of the cooking time, just until you can no longer process the tomatoes into a paste. place a sheet of parchment paper 12) on a clean work surface.
13) place a sheet of the phyllo on the work surface.
14) (keep the rest of the oil covered with damp paper towel.
15) brush the sheet of phyllo with oil. repeat with two more sheets of phyllo to form the second sheet.
16) you should have four layers.
17) if you have extra sheets left, place on a baking sheet and toast in oven with the oven door propped open until the sheets become golden brown.
18) remove the phyllo sheets from the oven and place on a clean work surface. cut each layered sheet along the scored lines into quarters.
19) place 1 heaping tablespoon of the tomato-peppercorn mixture in the center of each of four phyllo sheets.
20) fold the phyllo over into a triangle and place on a parchment-lined baking sheet. bake at 400 degrees f for 7 to 8 minutes, until lightly browned.
21) cool slightly before removing from the baking sheet, and serve warm.

Table 6: Comparison of a baked parmesan fish recipe with its edited versions to include “**cream**” as an additional ingredient. RecipeCrit incorporates the cream into a single-batter style fry, while BART only uses cream as a “serve with sour cream” addition to the original recipe. RecipteGPT disregards the base recipe to make a pizza. PPLM generates a completely different and incoherent recipe, and it suffers from text degeneration.

Baked parmesan fish (base recipe)	**BART**	**RecipeCrit (Ours)**
catfish, cheese, egg, flour, milk, paprika, pepper, salt	**cream**, egg, fillets, flour, garlic, milk, paprika, parsley, pepper, salt, thyme ~~**catfish**~~, ~~**cheese**~~	catfish, cheese, **cream**, egg, flour, paprika, pepper, salt ~~**milk**~~
1) preheat oven to 350 degrees. 2) rinse fillets and pat dry with paper towel. 3) in a pie plate , combine parmesan cheese , flour , paprika , salt and pepper. 4) in another pie plate , combine milk and beaten egg. 5) dip fillet in egg mixture and then coat with parmesan cheese mixture. 6) place in a well greased 9 x 13 pan. 7) bake uncovered for 25-30 minutes or until fish easily flakes with a fork.	1) preheat oven to 350 degrees. 2) rinse fillets and pat dry with paper towel. 3) in a pie plate, combine parmesan cheese, flour, paprika, salt and in another pie plate or bowl, combine milk and beaten egg. 4) dip fillet in egg mixture and then coat with parmesa cheese mixture. 5) place in a well greased 9 x 13 pan. 6) bake uncovered for 25-30 minutes or until fish easily flakes with a fork. 7) remove from oven and let stand for 5 minutes. 8) serve with sour **cream** and lemon wedges. 9) enjoy!	1) preheat oven to 350 degrees f (175 degrees c). 2) grease a baking dish. 3) rinse fillets and pat dry with paper towel. 4) in a medium bowl , mix together the **cream** cheese , sour **cream** , flour , salt , paprika , and pepper. 5) beat in the eggs. 6) dip filles 7) pour the mixture into the baking dish. 8) bake in the preheated oven until the fish flakes easily with a fork , about 30 minutes.

`{shankum,asoujanya,sadandap,susitara,monojitc}@microsoft.com`

Abstract

Zero-shot cross-lingual transfer is promising, however has been shown to be sub-optimal, with inferior transfer performance across low-resource languages. In this work, we envision languages as domains for improving zero-shot transfer by jointly reducing the feature incongruity between the source and the target language and increasing the generalization capabilities of pre-trained multilingual transformers. We show that our approach, *DiTTO* , significantly outperforms the standard zero-shot fine-tuning method on multiple datasets across all languages using solely unlabeled instances in the target language. Empirical results show that jointly reducing feature incongruity for multiple target languages is vital for successful cross-lingual transfer. Moreover, our model enables better cross-lingual transfer than standard fine-tuning methods, even in the few-shot setting.

1 Introduction

Due to the emergence of pre-trained Massively Multilingual Transformers (MMTs) such as mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020) and mT5 (Xue et al., 2020), zero-shot cross-lingual transfer (Hu et al., 2020; Ruder et al., 2021; Lauscher et al., 2020; Ansell et al., 2021; Pfeiffer et al., 2022) has received significant attention in the NLP community. This approach originated due to the skew in resource distribution in languages (Joshi et al., 2020), with most languages of the world having a scarcity of labeled data. Zero-shot transfer involves fine-tuning the MMT with task-specific data in one or more source languages, followed by evaluation on target languages whose labeled instances are not used during fine-tuning. Accurate zero-shot transfer is crucially important for MMTs to be useful for low-resource languages.

The performance of MMTs drops in the following two cases - when the source and target languages exhibit dissimilar typological features, or when the size of pre-training data in the target language is limited (Lauscher et al., 2020; Ebrahimi et al., 2022). Two common techniques to improve zero-shot performance include few-shot cross-lingual transfer (Lauscher et al., 2020; Kumar et al., 2022) and the translate-train approach (Ruder et al., 2021; Ahuja et al., 2022). Several studies have been conducted comparing these approaches, of which (Ahuja et al., 2022) concludes that if the cost of machine translation is greater than zero, the optimal and lowest-cost performance is achieved with at least some manually labeled data (i.e. the few-shot method). Since annotating data is expensive for many languages (Dandapat et al., 2009; Sabou et al., 2012; Fort, 2016), we investigate improving cross-lingual zero-shot transfer using only unlabelled data in this paper.

Zero-shot Cross-lingual Transfer has been identified as an under-specified optimization problem (Wu et al., 2022). A majority of the solutions reports a high performance on the source language but fluctuating performance on target languages. Wu et al. (2022) use linear interpolation to prove that it is possible to obtain a subset of solutions which have optimal performance on both source and target languages. Furthermore, they also conclude that current optimization techniques cannot converge to this smaller subset of optimal solutions without the availability of labeled target language data. Aghajanyan et al. (2020) and Liu et al. (2021) have observed similar behavior in the zero-shot setup and hypothesize that sub-optimal zero-shot performance may be due to the degradation of generalizable representations of MMTs during the fine-tuning stage. This leads to the model trained on the source language not being able to generalize well to the target languages. MMTs have also been shown to be over-parameterized (Smith and Le, 2018; Kolesnikov et al., 2020; Zhang et al., 2021), which leads to memorizing the training data (source language) and achieving poor generalization during

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 385–406
May 2-6, 2023

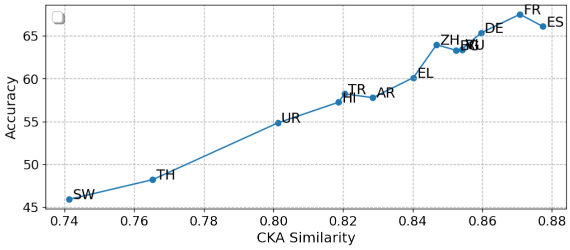

Figure 1: Relation between the zero-shot performance using mBERT, and CKA similarity between the source (EN) and various target languages in XNLI dataset.

cross-lingual transfer.

Similar to Deshpande et al. (2022), in our experiments, we also observe that once MMTs are fine-tuned on source languages, there is an incongruity between the features of the source and target languages, as shown in Figure 2. We speculate that the mismatch in the feature representation space causes problems in generalization. We also find that this mismatch strongly correlates with zero-shot performance as shown in Figure 1.

Furthermore, we hypothesize that this instability can be reduced either by finding solutions that can generalize well or learning to match the feature representations. Solutions (Zhang et al., 2018; Jiang et al., 2020) that have been used for improving generalization in other tasks can be considered, so that the model reaches to a better local minima. Sharpness-aware Optimization (SAM) (Foret et al., 2021) is one such technique that has been used to improve the generalization of language models (Bahri et al., 2022) and vision transformers (Chen et al., 2021) by smoothing the loss landscape for various adversarial tasks. SAM is used to generalize across domains, however, by treating languages as separate domains, we can apply SAM for generalizing across languages. While SAM looks promising, our experiments (cf. 7.3) showed that it does not guarantee optimal generalization at all times. We need to further reduce the incongruency between language features by aligning target language features to mimic the features of the source language. We propose ***DiTTO*** for improving cross-lingual transfer by source language **Di**rected adversarial **T**ransition of **T**arget language using sharpness aware **O**ptimization.

The key contributions of this work are: 1) Exhibiting the limitations of standard fine-tuning by unveiling the feature incongruity between source and target languages. 2) *DiTTO* enhances cross-lingual transfer by joint feature transformation of the multiple target languages to mimic the source. 3) *DiTTO* makes cross-lingual transfer cost-effective and efficient for distant (typologically different languages), resource-lean and unseen (not present in the pre-training data) languages. 4)*DiTTO* exhibits superior performance compared to augmenting the training data for either the source or the target language.

2 Related Work

Cross-Lingual Transfer: Since the inception of pre-trained MMTs, zero-shot learning has become popular for cross-lingual tasks. Recent works (Lauscher et al., 2020; Ebrahimi et al., 2022; Wu et al., 2022) have shown it to be sub-optimal for target languages which are either distant to the source language or have limited data during pre-training of the MMT. Some works (Wu and Dredze, 2020; Yu and Joty, 2021) have tried to improve the transfer using feature alignment from parallel data or bitexts (Zhang et al., 2020; Tiedemann, 2012) which is often expensive to obtain for many languages. To address this issue, *DiTTO* relies only on unlabeled data in the target languages. As pre-training size of the language affect transfer performance, adapter-based frameworks (Pfeiffer et al., 2020; Ansell et al., 2021) have been proposed for learning language and task representations for low-resource languages and languages that are unseen during pre-training. Though this framework is helpful for unseen languages, it provides limited gains for typologically dissimilar and high resource languages, and our method can easily be integrated with adaptors to further improve the transfer performance.

Improving Generalization: Deep neural networks such as MMTs are generally over-parameterized and fine-tuning leads to easy memorization of the labeled training data, does not always generalize well to other domains (Smith and Le, 2018; Kolesnikov et al., 2020; Zhang et al., 2021). Various methods have been proposed to improve the generalization like dropout (Srivastava et al., 2014), label smoothing (Müller et al., 2019), batch normalization (Ioffe and Szegedy, 2015), mixup (Zhang et al., 2018).

A few papers (Dziugaite and Roy, 2017; He et al., 2019; Jiang et al., 2020) have explored the connection between the flatness of minima and generalization gaps, showing flatter minima leads to better generalization. Recently, SAM has been proposed to find a smoother minima by minimizing the loss value and its sharpness. SAM has been shown to improve the generalization capabilities of vision transformers (Chen et al., 2021). Recently, Bahri et al. (2022) employed SAM in language models such as GPT-3 (Brown et al., 2020) and T5 (Raffel et al., 2020), showing significant improvements in generalization in English. In this work, we use SAM to improve the generalization across other languages. Another line of work (Aghajanyan et al., 2020; Liu et al., 2021) hypothesizes that inferior transfer is due to forgetting and degradation of feature representation from pre-trained MMTs when they are fine-tuned on the source language data. They propose to preserve the pre-trained features to improve the generalization using regularization and continual learning.

Unsupervised Domain Adaptation (UDA): Various studies have been proposed to reduce the domain shift to perform UDA by minimizing discrepancy distances such as Maximum Mean Discrepancy (MMD) (Long et al., 2015) and correlation alignment distance (Sun and Saenko, 2016). Adversarial-based feature alignment methods (Ganin and Lempitsky, 2015; Ganin et al., 2016; Long et al., 2018; Kurmi et al., 2019) have been one of the popular UDA methods where the domain discrepancy between the domains is reduced using an adversarial objective. In this work, we use Domain-Adversarial Neural Networks (DANN) (Ganin et al., 2016) for performing adversarial adaptation of languages.

3 Background

Training a Zero-Shot Model: In zero-shot cross-lingual transfer, we fine-tune an MMT on a source language and evaluate its performance on the target language, whose instances are not used during fine-tuning. To do this, we need a source language s and task-specific labeled dataset $\mathbb{L}_s = \{(x_i^s, y_i^s)\}_{i=1}^n$ with n examples. We use the provided MMT $\mathcal{M}$ as the encoder and fine-tune it along with the task-specific classifier C by minimizing the cross-entropy loss:

$$\mathcal{L}_{\text{train}}(\mathcal{M}, C) = \mathbb{E}_{(\mathbf{x}_i^s,\mathbf{y}_i^s)\sim\mathbb{L}_s} \mathcal{L}(C(\mathcal{M}(\mathbf{x}_i^s)), \mathbf{y}_i^s) \tag{1}$$

Sharpness-Aware Minimization (SAM): SAM seeks to find the parameter w such that even its neighborhood has seemingly similar low training loss $\mathcal{L}_{\text{train}}$ with minimal variation by optimizing the following objective:

$$\min_{w} \max_{||\epsilon||_2\le\rho} \mathcal{L}_{\text{train}}(w+\epsilon) \tag{2}$$

where ρ is the size of the neighborhood. Since, the exact solution of the inner maximization is hard to obtain, the authors of SAM propose a simple first order approximation:

$$\begin{aligned} &\epsilon(\hat{w}) \approx \\ &\arg\max_{||\epsilon||_2\le\rho} \mathcal{L}_{train}(w) + \epsilon^T \nabla_w \mathcal{L}_{\text{train}}(w) \\ &\qquad = \rho \nabla_w \mathcal{L}_{\text{train}}(w) / ||\nabla_w \mathcal{L}_{\text{train}}(w)||_2 \end{aligned} \tag{3}$$

After computing $\hat{\epsilon}$, the parameter w is updated based on the the sharpness-aware gradient $\nabla_w \mathcal{L}_{\text{train}}(w)|_{w+\epsilon(\hat{w})}$.

Domain-Adversarial Neural Networks (DANN): DANN (Ganin et al., 2016) has been successful applied for many unsupervised domain adaptation tasks for minimizing the domain shift (Du et al., 2020; Long et al., 2018). DANN needs a labeled source domain dataset $\mathbb{L}_s = \{(x_i^s, y_i^s)\}_{i=1}^n$ with n examples and an unlabeled target domain dataset $\mathbb{U}_t = \{x_i^t\}_{i=1}^m$ with m examples. It consists of three modules: Encoder $\mathcal{E}$, Task-Specific Classifier $\mathcal{C}$, and Domain Discriminator $\mathcal{D}$. In a nutshell, DANN requires solving a two-player game where the first player is the Domain Discriminator $\mathcal{D}$, is trained to distinguish the target domain from the source domain, and the second player is the encoder $\mathcal{E}$, which is trained simultaneously to confuse the Discriminator $\mathcal{D}$ such that the encoder learns to generate domain invariant features. We minimize the task-specific classification loss $\mathcal{L}_{\mathcal{C}}$ using the source domain labeled dataset for optimizing the classifier $\mathcal{C}$ and encoder $\mathcal{E}$.

$$\mathcal{L}_{\mathcal{C}}(\mathcal{E}, \mathcal{C}) = \mathbb{E}_{(\mathbf{x}_i^s,\mathbf{y}_i^s)\sim\mathbb{L}_s} \mathcal{L}(\mathcal{C}(\mathcal{E}(\mathbf{x}_i^s)), \mathbf{y}_i^s) \tag{4}$$

$\mathcal{D}$ is trained to predict the domains by minimizing domain classification loss:

$$\begin{aligned} \mathcal{L}_{\mathcal{D}}(\mathcal{E}, \mathcal{D}) = &-\mathbb{E}_{\mathbf{x}_i^s\sim\mathbb{L}_s} \log[\mathcal{D}(\mathcal{E}(\mathbf{x}_i^s))] \\ &-\mathbb{E}_{\mathbf{x}_j^t\sim\mathbb{U}_t} \log[1-\mathcal{D}(\mathcal{E}(\mathbf{x}_j^t))] \end{aligned} \tag{5}$$

$\mathcal{L}_D$ is maximized for $\mathcal{E}$ so that $\mathcal{D}$ is not able to distinguish between the domains. The minimax optimization of DANN is defined as:

$$\begin{aligned} &\min_{\mathcal{E},C} \quad \mathcal{L}_C(\mathcal{E}, C) - \lambda \mathcal{L}_{\mathcal{D}}(\mathcal{E}, \mathcal{D}) \\ &\min_{\mathcal{D}} \quad \mathcal{L}_{\mathcal{D}}(\mathcal{E}, \mathcal{D}) \end{aligned} \tag{6}$$

where λ is a hyper-parameter to control trade-off between classification and domain adversarial loss.

4 Limitations of Zero-shot Learning

Inconsistent Cross-Lingual Transfer: We have reported the average difference (δ) in the zero-shot performance between the target and the source language in Table 1. We experiment with mBERT and XLM-R on XNLI (Conneau et al., 2018), AmNLI (Ebrahimi et al., 2022) and MARC (Keung et al., 2020) datasets to measure the average δ between zero-shot performance of the target and source language. Table 1 shows that XNLI and AmNLI having relatively higher δ due to diverse number of languages. We also notice that mBERT has a higher δ than XLM-R across all tasks except AmNLI, showing the importance of amount of pre-training size.

Feature Incongruity between Languages: We hypothesize that the inconsistent zero-shot performance is due to the mismatch in the feature representation space of the fine-tuned MMT on the source language. To verify that we visualize the target and source language feature representations learned using standard zero-shot training method using 3D t-SNE (Van der Maaten and Hinton, 2008) in Figure 2. In Figure a, there is clear distinction between the source (En) and target language (Ru) features. While in Figure 2b and 2c, the feature space for the entailment class is overlapping with the source language, but fairly distinct for the other two classes, this could be potential cause for inferior cross-lingual transfer.

We measure centered kernel alignment (CKA) (Kornblith et al., 2019) between the source and the target language feature representations to quantify the incongruity. In Figure 1. We have plotted the CKA similarity with the zero-shot performance across all the languages. The plot suggests that there is a strong correlation between CKA and zero-shot performance, with Pearson and Spearman correlation coefficients as 0.98 and 0.96, respectively establishing our hypothesis.

5 Unveiling *DiTTO*

Typological similarity and incongruency between feature representations lead us to envision different languages as domains. As discussed in the previous section, DANN is useful in minimizing the domain shift across domains using only unlabeled data in the target domain. We propose to perform adversarial adaptation of the target language features for transforming the same towards the source language feature distribution.

We have a set of target languages $\mathbb{T}$ with each target language t having dataset $\mathbb{U}_t = \{x_i^t\}_{i=1}^{\mathcal{T}}$ with $\mathcal{T}$ unlabeled examples and an unlabeled set $\mathbb{U}_s = \{x_i^s\}_{i=1}^{\mathcal{S}}$ with $\mathcal{S}$ examples in the source language. In DANN, there is one target domain, whereas in our case we have a set of target languages $\mathbb{T}$ and we hypothesize and empirically show that performing adaptation for each language separately may cause degradation in other target languages, as seen in Table 5. Hence, we propose *DiTTO* where we jointly perform adaptation across all target languages.

DiTTO consists of an MMT $\mathcal{M}$ for encoding the features, a task-specific classifier $\mathcal{C}$ and Language Discriminators $\mathcal{D}^L = \{\mathcal{D}_t^L\}_{i=1}^{|\mathbb{T}|}$. We train these modules using two losses: task-specific classification loss $\mathcal{L}_{\mathcal{C}}$, defined in the Equation (1) and language discrimination loss $\mathcal{L}_{\mathrm{L}}$ for distinguishing the target and source language.

As we have $|\mathbb{T}|$ discriminators, we randomly sample a target language t from a prior distribution $p(\mathbb{T})$ at each training step and train the discriminator $\{\mathcal{D}_t^L\}$ to accurately distinguish target t and source language using the following loss:

$$\begin{aligned} \mathcal{L}_L(\mathcal{M}, \mathbf{D}_t^L) = -\mathbb{E}_{\mathbf{x}_i^s \sim \mathbb{U}_s} \log[b_t^L(\mathcal{M}(\mathbf{x}_i^s))] \\ -\mathbb{E}_{\mathbf{x}_j^t \sim \mathbb{U}_t} \log[1 - \mathcal{D}_t^L(\mathcal{M}(\mathbf{x}_j^t))] \end{aligned} \tag{7}$$

We maximize the above loss $\mathcal{L}_L(\mathcal{M}, \mathcal{D}_t^L)$ for confusing the language discriminator $\mathcal{D}_t^L$ to transform the target features towards the source language.

In our initial experiments (reported in Table 4), we observed some instability due to adversarial adaptation (Mao et al., 2017; Xing et al., 2021). We propose optimizing the task-specific loss $\mathcal{L}_C$ using SAM so that it may generalize to the target languages, improving the stability during adversarial adaptation. We directly fine-tune the MMT $\mathcal{M}$ on the source language labeled dataset $\mathcal{D}_s^l$ by minimizing Equation (1) using SAM. Following DANN and SAM, the final optimization objective of *DiTTO* can be defined as:

$$\min_{\mathcal{M}, C} \max_{||\epsilon||_2 \leq \rho} \mathcal{L}_C(\hat{\mathcal{M}}, \hat{C}) - \lambda \mathbb{E}_{t \sim p(\mathbb{T})} \mathcal{L}_L(\mathcal{M}, \mathcal{D}_t^L) \tag{8}$$

$$\min_{\mathcal{D}_L} \quad \mathbb{E}_{t \sim p(\mathbb{T})} \mathcal{L}_L(\mathcal{M}, \mathcal{D}_t^L) \tag{9}$$

where $\hat{\mathcal{M}}$, $\hat{C}$ are the updated parameters using ϵ.

6 Experimental Setup

6.1 Datasets

We evaluate our method on three benchmark datasets consisting of languages from various language families, to ensure better cross-lingual transfer evaluation. **XNLI** dataset (Conneau et al., 2018) consists of translated dataset in 14 languages from English. The task requires any model to predict whether the premise entails, contradicts, or neutral to the given hypothesis. AmericasNLI (**AmNLI**) dataset (Ebrahimi et al., 2022) is an extension of XNLI to 10 indigenous languages of the Americas, which are even unseen during pre-training of XLM-R and mBERT. Multilingual Amazon Review Corpus (**MARC**) dataset (Keung et al., 2020) is a large-scale dataset consisting of Amazon reviews for text classification in 6 languages. We use the review text and title to predict its star rating.

6.2 Baselines and *DiTTO* Variants

In the **Baseline** experiments, we fine-tune MMTs on labeled data of the source language using Equation (1). In the vanilla ***DiTTO*** setup, we use all the target languages available in the dataset. In the vanilla setup, we want to assign a higher probability to those target languages with a lower zero-shot performance from the Baseline method. We defined the prior distribution $p(\mathbb{T})$ of target languages as follows:

$$\Delta_t = \max(\mathcal{Z}(s) - \mathcal{Z}(t), 0) \tag{10}$$

$$p(t) = \delta_t + \sigma_{\Delta_t} \tag{11}$$

where, $\mathcal{Z}$ is the zero-shot performance from the Baseline method, Δ_t is the non-negative delta between the source and target language, and σ_δ is the standard deviation of the Δ_t across all the target languages.

DiTTO (UNF) is a variant of vanilla *DiTTO* in which we set the prior distribution $p(\mathbb{T})$ to be uniform across all the target languages. ***DiTTO* (t)** is a single target language variant of *DiTTO* where only one target language t is used during training. ***DiTTO*-LA** does not perform adaptation of the target languages, however optimization is done using SAM on the source language labeled data. ***DiTTO*-SAM** performs language adaptation without SAM.

6.3 Training Details

We conduct all of our experiments using mBERT (*bert-base-multilingual-cased*) and XLM-R (*xlm-roberta-base*). We use a batch size of 32 and a maximum sequence length of 128 across all the datasets. We fine-tune for $\{15, 20, 25\}$, $\{3, 5, 7\}$, $\{2, 3, 5\}$ epochs while using 1%, 10% and 100% of the source language data respectively. We use the AdamW (Loshchilov and Hutter, 2018) optimizer with linear scheduler and learning rate as 1e-5 for the encoder and classifier and 5e-5 for the discriminator. We set the λ hyper-parameter as 1 for all the experiments. We run experiments for each hyper-parameter and report the best average accuracy on three random seeds.

7 Results

In this section, we describe the results of several experiments to analyze the *DiTTO* method and compare its performance with the Baseline in the zero-shot setting. In order to justify the robustness of our method, we conduct experiments with the varying amount of source language data. In our experiments, EN is the default source language and we categorize target languages as follows: 1. *Distant*: languages that are typologically dissimilar to the source language 2. *Low-resource*: languages that have scarcity of data for pre-training 3. *Unseen*: languages that were not included in the pre-training data of MMT. Furthermore, we compare the techniques in the few-shot setting with few labeled examples in target languages. Then, we perform a thorough ablation study and analyze various variants of *DiTTO* . Finally, we show evidence in the form of congruity between the source and target language feature representations and t-SNE visualization in support of our hypothesis.

7.1 Zero-shot Transfer Results

Performance across datasets: In Table 2, we have reported the relative gains from *DiTTO* for zero-shot setting averaged across all the languages over the baseline method using 1%, 10% and 100% of the source language data. We observe the gains are positive (upto 23.05%) across all the training configurations. The gains are much higher for mBERT than XLM-R due to lower cross-lingual transfer in mBERT except the AmNLI dataset. The relative gains start to decrease with the increased amount of the source language data S on all the datasets except AmNLI, where the gains remains consistent for higher values of S (10% and 100%).

Performance across Seen Target Languages: We have reported the absolute gains of *DiTTO* in Figure 3 on XNLI using XLM-R We observe positive gains from *DiTTO* for all the target languages, with much larger gains especially on the low-resource and distant languages compared to the Baseline model. Similar to the earlier observation in Table 2, the gains starts to decrease across target languages as we increase the amount of the source language data.

	mBERT			XLM-R		
Dataset	1%	10%	100%	1%	10%	100%
XNLI	**23.05**	6.58	2.10	13.57	4.10	2.71
AmNLI	11.61	**19.72**	15.10	17.95	**19.87**	**19.09**
MARC	12.28	15.40	**19.03**	5.61	3.04	2.41

Table 2: Relative gains (in %) of *DiTTO* over Baseline. grey

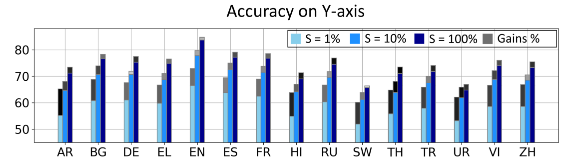

Figure 3: Absolute gains (darker shades of grey denotes higher gains) from *DiTTO* for XLM-R on XNLI dataset. Magnified view available in Figure 7 in Appendix.

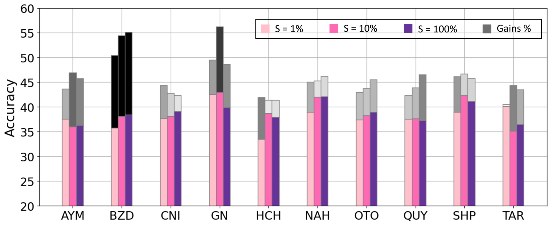

Figure 4: Absolute gains (darker shades of grey denotes higher gains) from *DiTTO* for XLM-R on AmNLI.

Performance across Unseen Target Languages: To measure the impact of *DiTTO* on unseen languages, we report the absolute gains from *DiTTO* on XLM-R on the AmNLI dataset in Figure 4. We have provided a similar analysis for mBERT in Figure 8 of the Appendix. The gains from *DiTTO* are consistent across all unseen languages. We observe that the gains are higher for languages with better Baseline performances, which is in contrast to trends on seen languages. For unseen languages, we do not observe the trend of diminishing gains with an increase in the source language data. If we compare the gains on AmNLI with the XNLI dataset, we notice *DiTTO* providing on average 1.7 times higher gains across all the configurations.

7.2 Few-shot Transfer Results

It can be argued that the gains from *DiTTO* in zero-shot setting can be achieved using few-shot cross-lingual transfer. Therefore, we conduct experiments in the few-shot setting by adding k labeled instances in each of the target languages to measure capabilities of *DiTTO* when some labeled data is available along with unlabeled data. In Figure 5, we have reported the accuracy and relative gains[1] using Baseline and *DiTTO* on MARC dataset. We have provided a similar analysis for AmNLI dataset in Figure 11 in the Appendix.

	S	Baseline k=0	Baseline k=10	Baseline k=100	Baseline k=500	DiTTO k=0	DiTTO k=10	DiTTO k=100	DiTTO k=500
mBERT	1%	39.5	39.8	41.0	44.9	43.5	44.5	46.1	49.3
mBERT	10%	42.7	43.6	46.2	49.1	49.1	49.2	50.3	51.8
mBERT	100%	45.2	45.1	48.7	52.0	53.5	53.4	53.3	54.7
XLM-R	1%	51.9	52.1	51.7	52.8	54.7	54.5	54.9	55.7
XLM-R	10%	55.4	55.3	55.7	56.5	57.0	56.8	57.1	57.6
XLM-R	100%	56.9	57.1	57.1	58.5	58.3	58.5	58.4	58.9

	S	Baseline k=0	Baseline k=10	Baseline k=100	Baseline k=500	DiTTO k=0	DiTTO k=10	DiTTO k=100	DiTTO k=500
mBERT	1%	0.0	0.8	3.9	13.8	10.2	12.7	16.7	24.7
mBERT	10%	8.2	10.4	16.9	24.3	24.2	24.5	27.4	31.1
mBERT	100%	14.4	14.2	23.2	31.6	35.4	35.1	35.0	38.6
XLM-R	1%	0.0	0.5	-0.2	1.8	5.6	5.1	5.9	7.3
XLM-R	10%	6.8	6.7	7.5	8.9	9.9	9.4	10.1	11.1
XLM-R	100%	9.8	10.1	10.2	12.8	12.3	12.7	12.5	13.5

Figure 5: Accuracy/relative gains on MARC dataset.

The heat maps in Figure 5 show that while XLM-R has better accuracy than mBERT for both Baseline and *DiTTO* setup, but the gains (both absolute and relative) on mBERT for both methods are higher compared to XLM-R. We also notice that by increasing either the source or the target language data, performance for both Baseline and DiTTO increased and hence, we will compare the gains of *DiTTO* with Baseline in these two dimensions.

Impact of Target Language Labeled Data: We observe that when we fix the amount of source language data and increase the value of k, the gains from *DiTTO* are higher than Baseline. Also, the gains from *DiTTO* on k=0 is comparable with the gains of baseline on k=500. In AmNLI, the gains from *DiTTO* for lower values of k are quite high compared to baseline, while for higher values of k Baseline performance for XLM-R is comparable to DiTTO.

Impact of Source Language Labeled Data: We also noticed that by fixing the value of k and increasing the size of source language data S, there is an increase in gains for both methods on MARC. However, the increase in gains from *DiTTO* is much higher than Baseline. At the same time, on the AmNLI dataset consisting of unseen target languages, the gains is much smaller with the increase in S (cf. Appendix).

Chinese as Source Language: To measure the effectiveness of *DiTTO* across different source languages, we conduct zero-shot experiments considering Chinese (ZH) as the source language on the MARC dataset. We have reported the average accuracy across all the languages in Table 3. *DiTTO* provides consistent gains over the Baseline method across all the training configurations, comparatively higher gains than EN as the source language.

	mBERT			XLM-R		
Dataset	1%	10%	100%	1%	10%	100%
Baseline	32.88	39.48	42.68	45.83	50.86	51.38
DiTTO	**39.09**	**46.90**	**50.82**	**51.84**	**53.34**	**55.27**
RG(%)	**19.45**	**20.80**	**20.67**	**13.31**	5.34	8.12

Table 3: We have reported the zero-shot accuracy averaged across all languages with **ZH** as the source language data on MARC dataset. RG denotes the relative gains averaged across all the languages from using *DiTTO* over Baseline.

Performance and Cost Trade-off: *DiTTO* is seven times more cost-effective in terms of both source and target language data. We validate this by plotting the accuracy from both methods against the cost incurred while collecting the labeled data for fine-tuning. For detailed analysis refer to the section B in the Appendix.

7.3 Ablations and Variants Analysis

Ablation Study: Here we scrutinize the contributions from adaptation of target languages and optimization with SAM. We report the zero-shot relative gains in Table 4 by ablating each of these components. We observe that removing any component reduces the performance for most of the training configurations, indicating that both target language adaptation and optimization have a contribution in achieving better results. We also observe that removing SAM (*DiTTO* - SAM) leads to unstable performances on XNLI and AmNLI datasets with negative relative gains on AmNLI (S=1%) for both MMTs, and on XNLI (S=10%) for mBERT, showing instability caused in adversarial training (Mao et al., 2017; Xing et al., 2021). Removing target language adaptation (*DiTTO*-LA) reduces the relative gains by a significant margin, showing the importance of adaptation of target language

---

[1] The relative gain is calculated with respect to the accuracy obtained by the Baseline method on $S = 1\%$ and $k = 0$.

features. It performs similar to *DiTTO* on XNLI (S=1%) dataset using mBERT, demonstrating just optimization using SAM can also improve cross-lingual transfer. The performance of *DiTTO* - SAM, it is often higher compared to *DiTTO* - LA, which indicates that Language Adaptation is a much more crucial for improving cross-lingual transfer.

		mBERT			XLM-R		
	Method	1%	10%	100%	1%	10%	100%
XNLI	*DiTTO*	**23.05**	**6.58**	**2.10**	**13.57**	**4.10**	**2.71**
	DiTTO - SAM	8.84	-0.36	1.80	6.04	1.81	2.02
	DiTTO - LA	22.25	3.89	2.02	7.43	2.81	1.74
MARC	*DiTTO*	**12.28**	**15.40**	**19.03**	**5.61**	**3.05**	**2.41**
	DiTTO - SAM	8.64	9.90	14.98	2.89	-0.13	2.27
	DiTTO - LA	5.5	1.54	2.20	4.02	0.35	-0.54
AmNLI	*DiTTO*	**11.61**	**19.72**	**15.10**	**17.95**	**19.87**	**19.09**
	DiTTO - SAM	-3.85	14.35	14.52	-11.88	14.81	15.89
	DiTTO - LA	7.21	5.17	-1.00	7.57	7.58	9.33

Table 4: Ablation Study: Zero-shot relative gains (in %) averaged across all the languages over Baseline.

Single vs Multiple Target Language Adaptation: In the base setup of *DiTTO* , we propose to perform an adaptation of all the target languages available in the dataset. We conduct zero-shot experiments with a single target language variant *DiTTO* (t) to validate our assumption. In Table 5, we observe that the single language variant provides similar gains as the vanilla *DiTTO* in the selected language t. However, often there is very little/no improvement observed in languages other than t. *DiTTO* (JA) and *DiTTO* (ZH) under-perform than Baseline for most of the languages.

Method	EN	DE	ES	FR	JA	ZH	AVG
Baseline	54.3	42.3	42.3	43.8	36.8	32.3	42.0
DiTTO (DE)	55.7	**48.2**	42.4	44.0	**36.5**	34.9	43.8
DiTTO (ES)	55.5	42.5	**45.9**	45.7	**36.4**	34.8	43.5
DiTTO (FR)	55.2	44.9	43.7	**46.4**	**36.5**	35.6	43.7
DiTTO (JA)	55.2	**40.9**	**41.3**	**42.5**	**38.1**	33.9	42.0
DiTTO (ZH)	**55.8**	**41.8**	**41.9**	**42.9**	**35.1**	**40.2**	43.0

Table 5: Accuracy for single and multiple target language variants of *DiTTO* on MARC (S=1%, mBERT).

Target Language Prior Distribution: In *DiTTO* with multiple target language variant, the prior language distribution $p(\mathbb{T})$ is used to sample a target language for adaptation. To measure the importance of prior distribution, we experiment with two variants: (i) sampling based on the zero-shot performance of the Baseline method, which is used in the base setup of *DiTTO* and (ii) *DiTTO* (UNF) - with uniform sampling. Both the variants outperform Baseline with similar gains as shown in Table 5. In the vanilla *DiTTO* , where languages with lower zero-shot performance have a higher likelihood during sampling, provides better gains on these selected languages compared to the *DiTTO* (UNF).

Task-Adaptive Pre-training (TAPT): The Baseline method does not utilize the available unlabeled data in the target languages, whereas *DiTTO* uses the unlabeled data to improve the performance across all the target languages. Recently task-adaptive pre-training (TAPT) (Gururangan et al., 2020; Hossain et al., 2020; Caselli et al., 2021) using unlabeled task-specific data has been shown to improve the performance for pre-trained language models across multiple tasks. However, TAPT has yet to be evaluated in a multilingual setting.

To make a fair comparison, we have compared our proposed method with another baseline using unlabelled data, we shall refer this as *Baseline (TAPT)*. *TAPT* uses continued pre-training on the unlabeled target language data and fine-tuning is performed using the source language labelled dataset. We have reported the comparison between the new baseline method in Table 6. The *Baseline (TAPT)* method outperforms the Baseline method where unlabeled data is not used in the source language (EN); however, it regresses for all the target languages. We hypothesize that the TAPT method generally improves the performance of the language used during fine-tuning. Still, it suffers from similar issues which the Baseline method suffers, such as low feature congruity in the fine-tuned features between the languages. *DiTTO* , which does not suffer the feature incongruity issue, outperforms *Baseline (TAPT)* for all the languages.

Method	EN	DE	ES	FR	JA	ZH
Baseline	56.40	56.02	53.29	52.15	49.77	48.05
Baseline (TAPT)	**57.80**	55.58	52.14	51.70	49.60	45.71
DiTTO	**61.28**	**59.06**	**54.87**	**55.50**	**53.29**	**51.01**

Table 6: Comparison of Baseline and *DiTTO* methods with the new Baseline method using Task-Adaptive Pre-training (TAPT) on MARC (S=1%, XLM-R).

7.4 Congruity in Feature Representation

As shown in Figure 1 earlier that the zero-shot performance and feature congruity between the source and target languages are highly correlated. To validate our hypothesis that increasing the congruity between the features (via language adaptation) will improve the performance, we have plotted the increment in CKA similarity from *DiTTO* over the Baseline method in Figure 6. We observe increment in CKA similarity across all the languages using *DiTTO* , which is comparatively higher for distant or low-resource target languages. We also visualize the t-SNE projection of the feature representations of the source and the target languages in Figure 2. It is difficult to distinguish between both languages in this figure, showcasing the quality of language adaptation.

8 Discussion and Conclusion

In this work, we propose a novel method to improve the cross-lingual transfer capability of pre-trained MMTs. We find that zero-shot performance is correlated with incongruency between the features of source and target languages. Experiments show that our proposed method *DiTTO* outperforms the standard fine-tuning approach across multiple setups. In general, the gains from our method are higher on the models (as in mBERT) with less cross-lingual transfer. AmNLI consists only of languages that were not present in the pre-trained MMTs leading to similar transfer performance to the Baseline method. *DiTTO* improves cross-lingual transfer using the pre-training features, hence the gains from *DiTTO* are similar on both mBERT and XLM-R. Due to a similar reason, the relative gains for unseen languages do not follow the trend observed on seen languages, where the gains are higher for languages with the lower cross-lingual transfer. We find higher relative gains on unseen and low-resource languages, followed by distant languages. We also notice that the cross-lingual transfer improves with the amount of source language data S for seen languages. In contrast, for unseen languages, improvements are limited. Due to this, the gains from *DiTTO* start to decrease for high values of S for seen languages but remain significant for unseen languages.

Our method provides similar gains using only unlabeled data compared to the fine-tuned Baseline model (using 500 instances for each target language). Our ablation study shows that both LA and SAM are essential components of *DiTTO*, with LA being the primary contributor to the gains. Experiments show that single language adaptation improves on that corresponding target language but may regress on other languages as the feature may remain incongruent to the source. However, *DiTTO* that adapts to multiple target languages performs best. *DiTTO* tries to exploit the pre-training knowledge for improving the cross-lingual transfer, however few promising works such as adaptors (Pfeiffer et al., 2020; Ansell et al., 2021) have been proposed to improve the pre-training features for low-resource and unseen languages. However, task specific adaptors trained on the source language will also face the issue of incongruity in the feature representations. Hence, adaptors will not improve the cross-lingual transfer, but only improves the pre-trained features. We plan to extend our method towards integrating with adaptors to take advantage of pre-training features and improve performance.

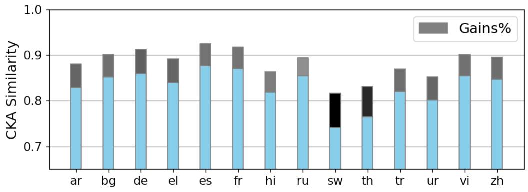

Figure 6: Gains in CKA similarity (between features of source and target language) from *DiTTO* over the Baseline method using mBERT on XNLI (S=10%).

9 Limitations

Unlabeled data in the target language is essential for the proposed method *DiTTO* for improving cross-lingual transfer. Obtaining unlabeled data can be challenging for specific tasks where the proposed approach may not be applicable. However, we recommend using the *DiTTO*-LA variant for these scenarios. Another limitation of *DiTTO* is that it requires all the target languages to be present during the fine-tuning stage to obtain the performances mentioned in our work, which might not be viable for all the tasks. Nevertheless, the gains from *DiTTO* may transfer to the new target languages if these languages are typologically similar to the target languages used during the fine-tuning of *DiTTO* . In the vanilla setup of *DiTTO* , the prior language probability depends upon the zero-shot accuracy using the Baseline method, which requires a validation or test dataset in each target language. This dependency may limit its application. However, *DiTTO* (UNF) can be used for obtaining similar gains if the validation sets are not available.

A Data Statistics

We have provided the statistics of training and test data after removing any duplicates in each of the target languages for all the datasets in Tables 7, 8, and 9.

B Performance and Cost Trade-off

From the above results, it seems that *DiTTO* is more cost-effective in terms of both source and target language data We validate this by plotting the accuracy from both methods against the cost incurred while collecting the labeled data for fine-tuning. Assuming there is no cost associated with collecting unlabeled data, we define the cost $\mathbb{C}$ for building a fine-tuning dataset as follows:

$$\mathbb{C} = c_s * n_s^l + c_s * c_{t/s} * k * |\mathbb{T}| \tag{12}$$

where c_s is the cost of obtaining one instance labeled in the source language and we assume it to be 3 cents considering EN as the source language. $c_{t/s}$ is the relative cost of obtaining labeled data in target language compared to the source language. We use Gaussian Process Regression with a dot product kernel for modeling performance with cost. In Figure 12 and 13, we plot the accuracy for various values of $c_{t/s}$ against the total cost incurred using mBERT on the MARC dataset, we observe a convex curve with increasing curvature as the value of $c_{t/s}$ increases. From the plot, we can see that higher accuracy can be achieved using *DiTTO* than Baseline at the same cost for all the values of $c_{t/s}$, showing the cost-saving nature of *DiTTO* with average savings of 7 times.

Evaluating NLP Models' Understanding of Feasibility

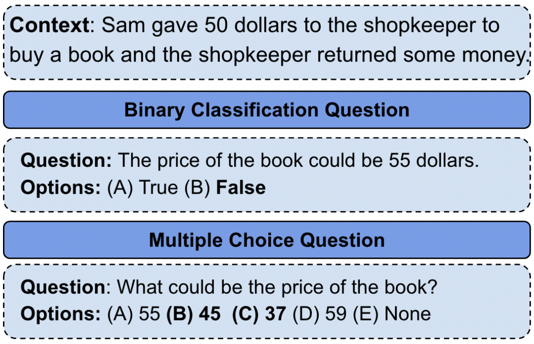
Arizona State University

Abstract

In current NLP research, large-scale language models and their abilities are widely being discussed. Some recent works have also found notable failures of these models. Often these failure examples involve complex reasoning abilities. This work focuses on a simple commonsense ability, reasoning about when an action (or its effect) is feasible. To this end, we introduce FeasibilityQA, a question-answering dataset involving binary classification (BCQ) and multi-choice multi-correct questions (MCQ) that test understanding of feasibility. We show that even state-of-the-art models such as GPT-3, GPT-2, and T5 struggle to answer the feasibility questions correctly. Specifically, on MCQ and BCQ questions, GPT-3 achieves an accuracy of just (19%, 62%) and (25%, 64%) in zero-shot and few-shot settings, respectively. We also evaluate models by providing relevant knowledge statements required to answer the question. We find that the additional knowledge leads to a 7% gain in performance, but the overall performance still remains low. These results make one wonder how much commonsense knowledge about action feasibility is encoded in state-of-the-art models and how well they can reason about it. [1]

1 Introduction

Commonsense reasoning has been a key aspect of AI since its advent in the 1950s. It is closely associated with reasoning about actions and their effects, which is considered a big challenge, especially for deep learning-based AI approaches and language models (LeCun, 2022; Dalvi et al., 2018; Banerjee et al., 2020). While several datasets have been developed to evaluate large-scale language models, in this paper, we propose a dataset focused on reasoning about actions and their effects; specifically, the ability to reason if an action or its effect is feasible.



Context: Sam gave 50 dollars to the shopkeeper to buy a book and the shopkeeper returned some money.

Binary Classification Question

Question: The price of the book could be 55 dollars.
Options: (A) True (B) **False**

Multiple Choice Question

Question: What could be the price of the book?
Options: (A) 55 **(B) 45** **(C) 37** (D) 59 (E) None

Figure 1: Illustrating a binary classification (BCQ) and a multiple choice question (MCQ) from FeasibilityQA. The correct answer options (**False** in BCQ and **(45, 37)** in MCQ) are highlighted in **bold**.

Figure 1 illustrates an example of our dataset; given the information "*Sam gave 50 dollars to the shopkeeper to buy a book and the shopkeeper returned some money*", it is not possible to compute the exact price of the book; however, it can be established that the feasible price of the book is *less than* 50 since the shopkeeper returned some money. We often come across such questions in our daily life and find it trivial to reason about them. Therefore, in order to develop NLP systems that can reliably reason about real-world situations, it is important to evaluate their understanding of feasibility.

Recently, many datasets have been created that test different reasoning skills such as pronoun resolution (Sakaguchi et al., 2021; Levesque et al., 2012), commonsense reasoning (Singh et al., 2021; Mihaylov et al., 2018; Banerjee et al., 2021), numerical reasoning (Mishra et al., 2022b; Ravichander et al., 2019; Lin et al., 2020; Zhang et al., 2020; Amini et al., 2019; Mishra et al., 2022e; Creswell et al., 2022; Pal and Baral, 2021), qualitative reasoning (Tafjord et al., 2019b,a), discrete reasoning (Dua et al., 2019), and temporal reasoning (Zhou et al., 2019). However, they do not have an ample number of examples that test understanding of feasibility.

Category	Knowledge	Context	Questions
Attribute Comparison	Larger volume holds more amount of water.	Barrett's has two cylindrical shaped bottles. A bottle with a higher volume holds 32 units of water.	Amount of water in other bottle could be 28 units. Amount of water in other bottle could be 33 units. What could be the amount of water in other bottle?
Change with Time	Age increases with time	Today, while filling the application form Edward filled the age field with 16.	Edward could have been 8 years old on his last birthday. Edward could have been 19 years old on his last birthday. What could have been Edward's age last year?
Change with Action	Selling something reduces its quantity	Joshua organized a garage sale yesterday. Joshua sold a total of 273 items at a minimum price of 1 USD each.	Joshua could have made 300 dollars in the garage sale. Joshua could have made 260 dollars in the garage sale. How much money Joshua could have made from the garage sale?
Implicit Numerical Knowledge	4 quarters make 1 dollar	Christopher is accepting quarters for a donation and fails to collect 12 dollars.	He could have collected 35 quarters. He could have collected 52 quarters. How many quarters could Christopher have collected?
Non Numerical	New movies can be watched after the release date.	The latest superhero movie was releasing on 28th February 2022. Ashton wanted to see the movie.	He could have watched the movie on 2nd March 2022. He could have watched the movie on 3rd February 2022. When could Ashton have watched the movie ?

Table 1: Illustrative examples of two binary choice questions and one multiple choice question corresponding to a context statement. We also provide the corresponding category and relevant knowledge for the questions.

In this work, we address the above limitation and introduce FeasibilityQA, a dataset consisting of questions that require an understanding of feasibility. This dataset comprises of two types of questions: binary classification (BCQ) and multi-choice multi-correct questions (MCQ). In BCQ, the task is to determine whether the question is feasible or not given a context; in MCQ, the task is to select all feasible answers to the given question. The dataset consists of ∼5K instances covering diverse aspects of feasibility. Table 1 illustrates examples of various categories of feasibility questions.

We conduct comprehensive experiments with GPT-3, GPT-2, and T5 models (Brown et al., 2020; Radford et al., 2019; Raffel et al., 2020) in zero-shot and few-shot settings and show that all of these models struggle to correctly answer feasibility questions. Specifically, on (MCQ, BCQ) questions, GPT-3 achieves an accuracy of just (19%, 62%) and (25%, 64%) in zero-shot and few-shot settings, respectively.

Prior work has found that explicitly providing relevant knowledge helps the model reason better and improves its performance (Chen et al., 2018; Xiong et al., 2019; Banerjee et al., 2019; Varshney et al., 2022a). We explore this aspect of reasoning by explicitly providing relevant knowledge statements and find that it leads to ∼7% improvement in performance. However, the overall performance still remains low. We further investigate GPT-3's ability to reason about feasibility questions by prompting it to generate the reasoning chain. In many cases, we find that GPT-3 successfully generates the correct reasoning chain but still fails to output the correct answer. This analysis further leads to several interesting findings (Section 3).

2 FeasibilityQA

2.1 Dataset Creation

For creating data instances of FeasibilityQA, we first create a context statement that describes a real-life situation. Then, we write two binary classification questions and one multiple choice question conditioned on the context that tests the understanding of feasibility.

Dataset creation and verification process Seven computer science graduate students were involved in creating the dataset. Dataset creation consists of 3 phases. First, in the data creation stage, each student created 700 samples over the period of 3 months. In the next phase, each dataset creator's questions were verified by a different student to ensure fairness during data validation. The 3rd stage of the validation was done when all the questions were compiled and cross-verified. In each verification stage, the dataset creators rejected some samples where the inter-annotator agreement was low. [2]

2.1.1 Context Creation

We create context statements from real-life situations spanning diverse topics such as elementary physics, profit-loss scenarios, temporal comparisons, and quantity comparisons. We divide the contexts into the following five categories:

Attribute comparison: This category consists of questions that test feasibility aspects involving the comparison of attributes of two quantities. **Implicit numerical:** Questions in this category involve fundamental mathematical facts that test the ability to use those facts in real-world situations. **Change with action:** This category tests the abil-

---

[2] All the dataset creators are authors of the paper.

ity to perceive a change in an item or state as an outcome of an action. **Change with time:** Here, questions test the understanding of feasibility related to temporal-based events. **Non Numerical:** This category includes questions where numbers are not explicitly involved in reasoning about feasibility. Table 1 provides examples of these categories. More details about them are in Appendix A.

Motivation behind category selection The motivation behind developing a large language model such as GPT-3 is to mimic human intelligence and come closer to Artificial General Intelligence. We attempt to gauge the performance of models' intelligence by developing simple commonsense reasoning questions. GPT-3 models are few-shot learners but find it hard to do proper numerical reasoning. Earlier datasets like this attempted to analyze numerical reasoning in this aspect. We are also trying to study it in the aspect of feasibility. Previous datasets, such as Numersense (Lin et al., 2020) and MC Taco (Zhou et al., 2019), do not have such a category, and we tried to bridge those gaps.

We think that these five categories are also a good representation of numerical feasibility. We found that questions from those categories had an adequate amount of complexity that the average human could easily figure out. So we expected that large language models should also be able to understand and answer accordingly. We created these categories to compare the models' numerical reasoning ability with and without knowledge. This gives us insights into whether knowledge helps in each aspect. We hope that these comparative studies across these five preliminary categories will inspire more future categories.

Target of our dataset: Our selection of categories in feasibility is inspired by the limitations in existing datasets since it is not possible to cover all the aspects of feasibility exhaustively.

2.1.2 Question Creation

From each context, we create two binary classification and one multiple-choice question. Recall that in our questions, the context may not provide sufficient information to find the exact answer. However, the information is sufficient to test the validity of question/answer options (notice the use of the word '**could**'). In question creation, we ensure that all our contexts and questions describe realistic situations, e.g., we keep a range of numerical entities and units appropriate for their context. Table 1 illustrates examples of our dataset.

Category	**Binary Instances**	**MCQ Instances**
Attribute comparison	1696	848
Non numerical	700	350
Implicit numerical	444	222
Change with action	196	98
Change with time	36	18
Total	3072	1536

Table 2: Categorization of FeasibilityQA across different categories .

Correct Answers	#Instances
1	555
2	622
3	285
4	31
None	43

Table 3: Frequency of correct answers for MCQ section.

BCQ: For each context, we create two binary classification questions where the correct answer is *True* for one and *False* for the other. Evaluating models' consistency in answering two contrasting hypotheses conditioned on the same context provides an additional benefit.

MCQ: For each context, we create a multi-correct multiple-choice question. Here, a context-question pair and the corresponding answer options are given, and the task is to select all feasible options for the question. We ensure that there is also a *None* option, which needs to be selected when all the other options are not feasible. For a question, *one or more options* (including 'None') could be correct.

2.2 Dataset Statistics

Our dataset consists of 1536 contexts and 4608 context-question pairs (3072 BCQ and 1536 MCQ). The category-wise distribution of the dataset is present in Table 2. BCQ dataset is label balanced, i.e., 1536 instances for each of *True* and *False* labels. MCQ dataset has a varying number of correct options. Table 3 shows the number of correct answers in the MCQ category.

	GPT-3				**GPT-2**				**T5**			
	BCQ (%)		MCQ (%)		BCQ (%)		MCQ (%)		BCQ (%)		MCQ (%)	
	w/o K	w/ K	w/o K	w/ K	w/o K	w/ K	w/o K	w/ K	w/o K	w/ K	w/o K	w/ K
Zero Shot	62.96	69.11	19.43	25.89	50.00	50.00	0.19	0.45	50.55	50.64	0.13	0.39
One Shot	57.94	64.66	20.94	24.15	50.00	50.00	0.58	1.69	50.61	50.33	0.45	0.58
Few Shot	64.72	68.55	25.94	37.23	50.00	50.00	0.97	0.39	49.81	49.87	0.84	1.10

Table 4: *Exact match accuracy* of three models in BCQ (Binary Classification) and MCQ (multi-choice multi-correct) tasks across three settings. w/o K and w/ K represents without knowledge and with knowledge respectively.

3 Experiments

3.1 Performance Evaluation & Metrics

For **BCQ**, we calculate *exact match accuracy* against the gold label (True or False) for each question. We also use a stricter evaluation metric, *pairwise accuracy*, to better estimate the model's capability of understanding feasibility. Here we only consider a sample to be correct if both BCQ (True and False questions) are correctly answered by the model for one context statement. For **MCQ**, we evaluate *exact match accuracy*, i.e., the model's prediction is considered to be correct if all the correct answer options are predicted. We also compute *recall*, which we define as the number of correct answers predicted by the model out of all the correct answer options. Other results (false positive, false negative, category-wise) are in Appendix B.

Models: We evaluate the performance of **GPT-3** (Text-DaVinci-002, with 256 max tokens, top p of 1, and frequency & presence penalty of 0), **T5-11B**, and **GPT-2 large** models on our dataset.

3.2 Results

Low Performance of All Models: Table 4 shows the accuracy of all three models in zero-shot, one-shot, and few-shot settings. On BCQ, GPT-3 achieves *exact match accuracy* of just 62.9%. GPT-2 and T5 perform even worse and achieve close to the majority baseline (50%). GPT-2 gets an exact 50, indicating that the model does not understand such feasibility reasoning [3]. On MCQ, which is a more difficult task than BCQ, all models, including GPT-3, achieve a very low *strict accuracy* score. This highlights that feasibility questions are challenging for even state-of-the-art models.

Decrease in performance in one-shot setting: In the one-shot setting, the model's prediction is heavily influenced by the label of the example (one) presented to the model. This phenomenon is also observed in several prior zero-shot, and one-shot studies (Zhao et al., 2021). A similar trend is observed in the chain of thought experiments (results described in Table 8).

	w/o Knowledge	w/ Knowledge
Zero	46.2	49.9
One	63.5	64.5
Few	66.7	70.3

Table 5: *Recall* scores of GPT-3 on MCQ task.

	w/o Knowledge	w/ Knowledge
Zero Shot	42.9	56.8
One Shot	17.9	34.3
Few Shot	39.8	55.8

Table 6: *Pairwise Accuracy* of GPT-3 in BCQ Task.

Providing Knowledge Improves GPT-3's performance by $\sim$ 7% across all settings. The accuracy particularly increases ($\sim$ 12%) in the MCQ task in the few-shot setting. Although GPT-3 performs better than T5 and GPT-2, it achieves just 68.5% and 37.2% on BCQ and MCQs, respectively.

GPT-3 achieves High Recall Scores on MCQs: In Table 5, we show recall scores of GPT-3 on MCQs. GPT-3 achieves a high score (up to 70%), highlighting that it gives correct responses but fails to give all the correct responses.

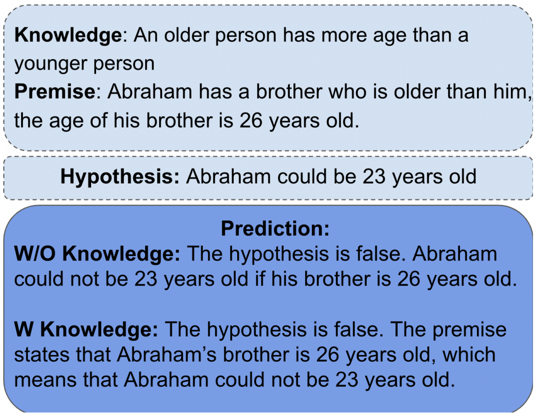
Pairwise Evaluation: Recently, instance-level analysis of the evaluation data has received considerable research attention (Zhong et al., 2021; Varshney et al., 2022b; Rodriguez et al., 2021; Mishra et al., 2022a). Motivated by this, we analyze GPT-3's performance on BCQ questions using the stricter *pairwise accuracy* metric. Even though the model performs $\sim$ 63% using *exact match accuracy*, Table 6 shows that the models' performance is at most $\sim$ 43% via *pairwise accuracy*, highlighting a performance gap. The accuracy increases ($\sim$ 13%) when knowledge is introduced, and the gap between different settings also narrows down, indicating that the addition of knowledge helps.

---

[3] Please refer Appendix B.2 for details

	BCQ		MCQ	
	w/o K	w/ K	w/o K	w/ K
Attribute Comparison	58.2	62.5	17.7	23.2
Non Numerical	77.2	89.4	23.6	30.9
Implicit Numerical	54.7	50.9	16.7	21.9
Change with Action	66.3	78.2	20.3	26.6
Change with Time	58.3	66.6	17.8	23.4

Table 7: Category wise *Exact Match Accuracy* of GPT-3 on BCQ and MCQ in one-shot setting.



Knowledge: An older person has more age than a younger person

Premise: Abraham has a brother who is older than him, the age of his brother is 26 years old.

Hypothesis: Abraham could be 23 years old

Prediction:

W/O Knowledge: The hypothesis is false. Abraham could not be 23 years old if his brother is 26 years old.

W Knowledge: The hypothesis is false. The premise states that Abraham's brother is 26 years old, which means that Abraham could not be 23 years old.

Figure 2: Answers with explanations given by GPT-3 on FeasibilityQA dataset.

	BCQ		MCQ	
	w/o K	w/ K	w/o K	w/ K
Zero Shot	61.3	70.2	20.1	25.1
One Shot	59.7	67.2	19.5	22.8
Few Shot	65.4	69.1	23.4	35.7

Table 8: *Exact Match Accuracy* of GPT-3 on BCQ and MCQ tasks with chain of thought setting.

Category wise results: Table 7 shows the category-wise results in one-shot setting for BCQ and MCQ tasks on GPT-3. Non Numerical category performed the best out of all categories (15% more than other categories). Addition of knowledge improves the performance of all categories by around 5% to 10%. Similar trends are observed across MCQ task as well. We believe that Non Numerical performed the best because these samples were conditioned around factual knowledge and that it could be present in the pretraining corpus of GPT-3. We further analyze this in Appendix B.

Investigating Chain of Thoughts Prompting: Recent work has demonstrated the success of learning from instructions (Wei et al., 2021; Wang et al., 2022; Mishra et al., 2022d,c; Lu et al., 2022; Parmar et al., 2022; Mishra and Nouri, 2022; Luo et al., 2022) and chain of thought (Wei et al., 2022) and scratchpad prompting (Nye et al., 2021). To test this on FeasibilityQA, we add explanations to one-shot and few-shot examples provided in the context. Table 8 shows marginal improvement. More details are in Appendix C.

A Case Study on Prompting GPT-3 to Provide Explanation: We further investigate the reason behind GPT-3's poor performance on FeasibilityQA by prompting it to provide the reason behind its answer. Specifically, we add *"Explain the reason behind your answer"* in the prompt. Figure 2 illustrates a response from GPT-3. The answer demonstrates that it did not understand the numerical value of Abraham's age. We also provide additional knowledge to assist the model, as shown in Figure 2. Even with knowledge, the model could not understand the feasible age.

4 Conclusion

In this work, we proposed FeasibilityQA, a question-answering dataset that evaluates the understanding of feasibility. We conducted extensive experiments with several state-of-the-art models in zero-shot, one-shot, and few-shot settings and show that these models struggle to answer the feasibility questions correctly. We also experimented by providing additional knowledge (relevant to the question) and showed that it leads to a small gain in performance, but the overall performance still remains low. We further analyzed the performance of models that reveals several interesting findings. Finally, we release our dataset and hope that our work will encourage further research in feasibility reasoning, an important yet underexplored aspect of commonsense reasoning.

Limitations

Like any other commonsense reasoning ability, the concept of feasibility, in general, can be applied in numerous real-world situations. In our dataset, we try to cover a diverse set of such situations that test the understanding of feasibility, but it is in not an exhaustive list. In the future, we will expand the category space by either converting existing numerical datasets into feasibility questions or manually creating new category spaces. Along with the dataset, we release the list of contexts and situations on which the question is based. In the future, this would help expand the dataset to cover other domains and situations. The human evaluation of the dataset could also be an interesting study, but it can be an expensive. The selection of humans in terms of their educational background and age is also required for unbiased evaluation. A completely random selection of humans is also required for a comprehensive study. Finally, our dataset includes questions in only one language, i.e., English.

Ethical Considerations

The names used in this dataset are selected from the most common English names. In question creation, we ensure that all our contexts and questions describe realistic situations, e.g., we keep a range of numerical entities and units appropriate for their context. No personal information from data creators has been collected during the creation of the dataset.

Appendix

A Dataset characteristics

In this section, we describe FeasibilityQA in more detail. Table 1 shows illustrative examples of each category discussed in section 4. Each row of the 4th Column of the table shows three questions that were prepared in response to a context. Table 2 gives the distribution of each category of the dataset. We will explain the motivation behind each category. Please note that the explanations are with respect to examples presented in Table 1.

Attribute Comparison shows the comparative properties between two similar objects. The context from attribute comparison is designed to show that quantities can be measured using words like higher and lower, and the model has to understand the relation between them to answer different questions. In this example, it is not possible that the smaller bottle can have a volume of 33 units since the larger one is 32 units.

Change with Time gives the events that have time as the changing factor. The context is designed to test the model's ability to deduce time-based changes and how certain actions/ events/ quantities can or cannot be done before/ after a certain time. In this case, it is impossible that Edward's age could be 19 on his last birthday as his current age is 16.

Change with Action describes the actions which alter certain quantities/events and test the model's ability to understand that. In this case, it is demonstrated that selling/giving away a certain quantity reduces it. In the example, it is demonstrated that selling all 273 items at least 1 dollar will leave Joshua with at least 273 dollars. Hence the question that he could have 260 dollars is false.

Implicit Numerical Knowledge tests the model's ability to understand numerical entities as facts and how to manipulate them in different situations. In this case, using the knowledge (or without using it) that four quarters make 1 dollar, the model needs to understand how many quarters will be used in 12 dollars, which is 48 quarters. Hence the question tells us that Christopher can have 52 quarters.

Non Numerical category tests the model's understanding of very broad domains. They do not have to be numerical based in all the cases.

The dataset contains diverse topics ranging from physics, mathematics, biology, and numerical reasoning. A total of 422 subcategories are present in the dataset. Table 2 shows the distribution of BCQ and MCQ questions across different categories in the dataset.

B Other performance results

B.1 Performance Metrics

For the MCQ setting of the dataset, we study true positive, false positive, and false negative rates as the evaluation metrics. Each metric definition is listed below:

False Negative rate is defined as the number of

	w/o Knowledge	w/ Knowledge
Zero	0.17	0.13
One	0.36	0.32
Few	0.33	0.24

Table 9: False Positive rate of GPT-3 on MCQ section

	w/o Knowledge	w/ Knowledge
Zero	0.42	0.42
One	0.21	0.24
Few	0.18	0.20

Table 10: False negative rate of GPT-3 on MCQ section

Zero shot BCQ		
	w/o Knowledge	w/ Knowledge
Attribute Comparison	51.2	55.8
Non Numerical	72.7	85.7
Implicit Numerical	52.9	52.0
Change with Action	60.7	65.3
Change with Time	55.5	55.5
Zero shot MCQ		
	w/o Knowledge	w/ Knowledge
Attribute Comparison	17.9	20.4
Non Numerical	25.5	29.0
Implicit Numerical	18.5	21.1
Change with Action	21.3	24.2
Change with Time	19.4	22.2

Table 11: Category wise Accuracy of GPT-3 on BCQ and MCQ task in zero-shot setting.

incorrect predictions the model gave as correct. For example, if the model gave output as A, B, C, and the predicted result is A, C, then B is missed. The number of false negatives would be 1 (B).

False Positive rate is defined as the number of correct predictions the model gave as incorrect. For example, if the given output is A, B and the predicted result is A, B, C, then the number of false negatives would be 1 (C).

B.2 Results

False positive results shown in Table 9 follow trends similar to accuracy where the performance of one-shot experiments is worse than zero-shot and few-shot. But with the addition of knowledge, the false positive rate decreases.

As shown in Table 10, the False negative rate decreases from zero-shot to few-shot experiments, but contrary to other experiments, it increases with the addition of knowledge in almost all the cases.

Table 11 shows the category-wise results in zero-shot settings for BCQ and MCQ tasks. For the BCQ task, accuracy was lowest in the Attribute comparison category and highest in Non-Numerical Category. Performance of the Non Numerical category improved significantly in with knowledge setting.

In the MCQ portion of the dataset, the performance gap between Non-Numerical and other categories reduces significantly. It is still the best-performing category for the model, but the Change with Action Category also produced similar results. There was no significant improvement in both Non-Numerical and change with action as observed in the Non-Numerical with the addition of knowledge.

Few shot BCQ		
	w/o Knowledge	w/ Knowledge
Attribute Comparison	64.5	69.5
Non Numerical	85.9	99.4
Implicit Numerical	60.8	56.6
Change with Action	73.7	86.8
Change with Time	64.8	74.1
Few shot MCQ		
	w/o Knowledge	w/ Knowledge
Attribute Comparison	25.2	35.8
Non Numerical	33.5	47.6
Implicit Numerical	23.7	33.7
Change with Action	28.8	40.9
Change with Time	25.3	35.9

Table 12: Category wise Accuracy of GPT-3 on BC and MCQ task in few-shot setting.

Table 12 shows the category-wise results for BCQ and MCQ tasks in few shot setting. For the BCQ task, accuracy was lowest in the Attribute comparison category and highest in Non-Numerical Category. Performance of the Non Numerical category improved significantly in the knowledge setting with accuracy reaching above 90% for the first time in any of the categories.

In the MCQ portion of the dataset, the performance gap between Non-Numerical and other categories reduces significantly. It is still the best-performing category for the model. There was a significant improvement in Non Numerical and change with action and change with time categories with the addition of knowledge.

Exact 50% accuracy of GPT-2: The input format for all models was as follows: Zero-Shot, Question (Different questions), and Options (True or False). Example(s) preceded the question in the one-shot and few-shot settings. Based on this format, GPT-2 gave the probability of "False" higher in all cases. Since the dataset is label balanced, all the True hypothesis questions were incorrectly predicted, hence giving a 50% accuracy.

Example or Evaluation sample		Text / Context
Example fed in GPT-3 as 1 shot learning example	**Prompt**	Select the best option for the questions based on the Context and explain the reasoning. An Example to show how it works:
	Context	Eric boiled a glass of water to drink the hot water. The level of the water in the glass is 63 units. After boiling was done, she took the water into the glass.
	Question	What could be the level of the water after boiling?
	Options	A: 65, **B: 59**, C: 64, **D: 61**, E: None
	Answer:	Since boiling leads to evaporation, there is a possibility that the volume of water would have decreased. Due to this, the current water level should be less than 63 units. Hence the answer is B:59 and D: 61
Example given to GPT-3 for evaluation	**Context**	A negative number was added to 70.
	Question	What could be the result?
	Options	A: 70, B: 89, C: 87, **D: 68**, E: None
	GPT-3 Answer	The result could be A: 70, since **adding a negative number would not change the value of 70**. The result could also be C: 87, since adding a negative number would increase the value of 70
Example given to GPT-3 for evaluation	**Context**	Last year 758 people joined the company and this vear the number of people who joined was more than double the last time
	Question	How many people could have joined this year?
	Options	A: 1440, **B: 1600**, C: 1460, D: 1370, E: None
	GPT-3 Answer:	Since the number of people who joined this year was **more than double the last time**, the number of people who joined this year could be up to 1460. Therefore, the answer is C: 1460.

Table 13: Illustrating chain of thought approach on some examples of feasibilityQA dataset in 1 shot setting without providing knowledge. 1st set of rows demonstrate the example fed into GPT-3 for 1 shot learning. 2nd and 3rd set of rows show GPT-3's response to Context, Question and Options asked.

Example or Evaluation sample		Text / Context
Example fed in GPT-3 as 1 shot learning example	**Prompt**	Select the best option for the questions based on the context, knowledge and explain the reasoning. An Example to show how it works:
	Context	Eric boiled a glass of water to drink the hot water. The level of the water in the glass is 63 units. After boiling was done, she took the water into the glass.
	Knowledge	Water will convert into water vapour on boiling.
	Question	What could be the level of the water after boiling?
	Options	A: 65, B: 59, C: 64, D: 61
	Answer	Since boiling leads to evaporation, there is a possibility that the volume of water would have decreased. Due to this, the current water level should be less than 63 units. Hence the answer is B:59 and D: 61
Example given to GPT-3 for evaluation	**Context**	Two boys competed in a race. The loser finished the race in 24 minutes.
	Knowledge	Loser will take more time to finish the race.
	Question	How many minutes the other boy could have taken to finish the race?
	Options	A: 32, B: 25, C: 15, D: 22, E: None
	GPT-3 Answer	The other boy **could have taken less time to finish the race**. Hence, the answer is B: 25.

Table 14: Illustrating chain of thought approach on some examples of feasibilityQA dataset in 1 shot setting with providing knowledge. 1st set of rows demonstrate the example fed into GPT-3 for 1 shot learning. 2nd row shows GPT-3's response to Context, Question and Options asked.

C Case study: Chain of Thought Reasoning Approach

Table 13 and 14 show the unsuccessful attempts in the chain of thought reasoning approach. Table 13 shows the setting where the 1st example is fed into the model as an example of how to reason out the answer. The reason and answer were clearly mentioned that told that evaporation leads to a decrease in water level and hence water level should decrease. This led to a decrease in water level; hence, the correct answers were quantities less than 63; **59 and 61**.

The 2nd and 3rd sets of rows show the Context, question, and options supplied to GPT-3, and we get responses in GPT-3 Answer row. The logic given for the addition of a number is wrong.

Adding a negative number should decrease the value, and hence rest of the answer will be wrong. In the 3rd row GPT-3's response, the logic used to calculate the answer is correct, but it was unable to calculate that 1600 was double 758. Both parts are highlighted in the table.

The situation did not improve much when knowledge was supplied with other rows, as shown in Table 14. The model was able to interpret the logic correctly but could not associate that logic with numerical quantities.

Efficient Encoders for Streaming Sequence Tagging

Abstract

A naive application of state-of-the-art bidirectional encoders for streaming sequence tagging would require re-encoding all tokens from scratch whenever a new token appears in an incremental streaming input (like transcribed speech). The lack of re-usability of previous computation leads to a higher number of Floating Point Operations (or FLOPs) and higher number of unnecessary label flips. Increased FLOPs consequently lead to higher wall-clock time and increased label flipping leads to poorer streaming performance. In this work, we present **H**ybrid **E**ncoder with **A**daptive **R**estart (HEAR) that addresses these issues while maintaining the performance of bidirectional encoders over offline (or complete) inputs and improving performance on streaming (or incomplete) inputs. HEAR uses a HYBRID unidirectional-bidirectional encoder architecture to perform sequence tagging, along with an Adaptive Restart Module (ARM) to selectively guide the restart of bidirectional portion of the encoder. Across four sequence tagging tasks, HEAR offers FLOPs savings in streaming settings upto 71.1% and also outperforms bidirectional encoders for streaming predictions by upto +10% streaming exact match.

1 Introduction

State-of-the-art text encoding methods assume the *offline setting*, where the entire input text is available when encoding it. This differs from the *streaming setting* where the input text grows over time (such as transcribed speech or a typed query) (Cho and Esipova, 2016; Gu et al., 2017; Chang et al., 2022). Processing streaming input incrementally can enable suggestions on partial inputs (Iranzo Sanchez et al., 2022), reduced final latency (Zhou et al., 2022) and lead to more interactive NLU agents (Cai and de Rijke, 2016).

Existing state-of-the-art bidirectional encoders (such as Devlin et al. (2019)) are computationally expensive for streaming processing. When a new token is received, these models require a *restart*, i.e., re-computation of representation of each token by re-running the bidirectional layer (Kahardipraja et al., 2021). This adds to the computational cost (i.e., Higher FLOPs) during streaming and leads to higher wall clock time. Another limitation of these encoders is poorer generalization to partial inputs (Madureira and Schlangen, 2020), stemming from these models being trained only on complete (and offline) inputs. Despite these disadvantages, such bidirectional models offer better *offline* performance than unidirectional models across several NLP tasks like sequence tagging (Kahardipraja et al., 2021).

Model	GFLOPs	Offline F1	Streaming EM
BiDi encoder	74.7	**93.1**	75.1
HYBRID encoder	43.4	93.0	72.5
HEAR (HYBRID + ARM)	**21.6**	93.0	**85.1**

Table 1: Computation cost (**G**iga **FLOPs**), **Offline F1** and **Streaming E**xact **M**atch accuracy of standard bidirectional (BiDi) encoder, HYBRID encoder model and HEAR (HYBRID encoder with ARM for guiding Adaptive Restarts) on SNIPS test set.

We address these issues by proposing HEAR – **H**ybrid **E**ncoder with **A**daptive **R**estarts, where a separate Adaptive Restart Module (ARM) predicts when to restart the encoder. The encoder in HEAR is a HYBRID encoder that reduces the computational cost of running the models in streaming settings. In a HYBRID encoder, the earlier layers are unidirectional and the deeper layers are bidirectional. This design allows early contextualization, and limits the need for restart to the later layers. While HYBRID encoder reduce streaming computational overhead, restarting them at every new token may not be required. Thus, we propose a lightweight Adaptive Restart Module (ARM) to guide restarts, by predicting whether restarting the

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 418–429
May 2-6, 2023

bidirectional layers of the HYBRID encoder will benefit the model performance. This module is also compatible with fully bidirectional encoders.

Table 1 showcases the strength of HEAR on one of the sequence tagging dataset we consider. In terms of streaming computation, measured in terms of FLOPs (lower is better), HYBRID encoder offers significant saving from purely bidirectional (BiDi) encoders and FLOPs savings improve upon incorporating ARM in HEAR. In terms of offline performance, HYBRID encoder and HEAR achieves parity with BiDi encoders and in terms of streaming performance, HEAR significantly outperforms BiDi encoders.

Following are our key contributions:

- We introduce HYBRID encoder for computationally cheaper streaming processing (§3.1), that maintains the offline F1 score of bidirectional encoders, while reducing FLOPs by an average of 40.2% across four tasks.
- We propose the ARM module (§3.2) to decide when to restart. The ARM reduces FLOP of HYBRID encoder by 32.3% and improves streaming predictions by +4.23 Exact Match.
- Our best model HEAR combines HYBRID encoder with ARM (§5) to achieve strong streaming performance while saving FLOPs and offering competitive offline performance across four sequence tagging tasks.

2 Streaming Sequence Tagging

In the streaming sequence tagging task, we assume that at time $1 \leq t \leq n$, we have received the first t tokens $\mathbf{x}_t = (x_1, \cdots x_t)$ as input from a stream of transcribed speech or user-typed input.[1] The model then predicts the tags for all t tokens $\hat{\mathbf{y}}_t = (\hat{y}_{1,t}, \hat{y}_{2,t} \cdots \hat{y}_{t,t})$. The models predictions $\hat{\mathbf{y}}_n$ over the offline input $\mathbf{x} = \mathbf{x}_n$ is the offline tag sequence prediction which is evaluated against the ground truth $\mathbf{y}^*_n = (y^*_1, y^*_2 \cdots y^*_n)$. However, in the streaming settings, we are concerned with predicted label sequences over all of the prefixes $\hat{\mathbf{Y}} = (\hat{\mathbf{y}}_1, \hat{\mathbf{y}}_2 \cdots \hat{\mathbf{y}}_n)$.

During training we only have access to the offline ground-truth label sequence over the offline input sequence $\mathbf{y}^*_n$, even though ground truth labels for tokens may change as additional context is received in the future timesteps.

3 Streaming Sequence Tagging with HEAR

In order to motivate HEAR, consider how existing BiDi encoders would be used in streaming sequence tagging. At time t and the input sequence $\mathbf{x}_t$, the model restarts to predicts the label sequence $\hat{\mathbf{y}}_t$ i.e. it re-computes all its layers for all tokens, without leveraging any of its previous computation or any previously predicted labels. Consequently, running a typical $O(n^2)$ encoder would have $O(n^3)$ computations in streaming settings, over n input tokens. Therefore, naively using existing BiDi encoders for streaming settings is highly inefficient. Previous works tackle inefficiency by modifying the streaming model to infer only once for each word, after k future tokens have been received (Oda et al., 2015; Grissom II et al., 2014). This leads to a k-delayed output with possibility for revisions after additional future words have been received. However, this may lead to poor performance for tasks involving long-range dependency (e.g., SRL) and a higher output lag.

HEAR is a system consisting of a trained HYBRID encoder model and an ARM that is trained over the HYBRID encoder. The early unidirectional layers in HYBRID encoder, reduces the computational cost of restart of the encoder. The ARM guides when to restart the HYBRID encoder. It saves computational cost by keeping the model from restarting at each timestep and also improves streaming performance by avoiding unnecessary label flips stemming from avoidable restarts. Figure 2 shows running of HEAR in streaming settings over an example. For each new token in the streaming input, all the unidirectional layers and a part of first bidirectional layer is ran for the token, to obtain its unidirectional encodings and updated cache. These are then used by ARM to predict whether to restart the bidirectional layer or not. If the bidirectional layer is to be restarted, then we obtain updated labels for all the tokens received in the stream. Otherwise, the auxiliary predictor is ran over the unidirectional encoder for the current token to obtain its label and the labels from previous timestep is copied for all other tokens.

We now formally introduce HYBRID encoder (§3.1), followed by ARM (§3.2).

---

[1] We assume that new tokens get added without changing previous tokens (contrary to some ASR systems), even though, our method can be used in such settings.

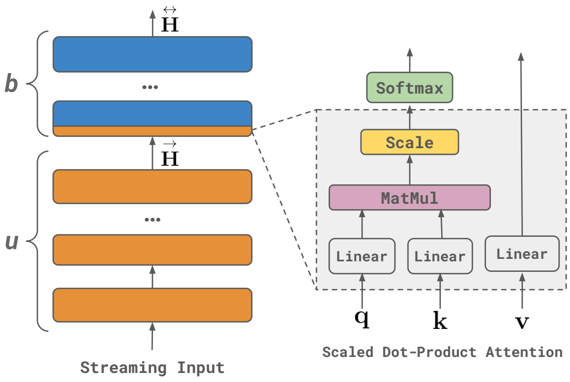

Figure 1: In HYBRID encoder architecture, the earlier u layers are unidirectional, and later b layers are bidirectional. The blue layers require restart, i.e. at each timestep when the model receives a new token of the streaming input, these layers will recompute all intermediate representations for all the input tokens. The orange layers (like unidirectional layers) can avoid restart by caching the intermediate state. A portion of the first bidirectional layer before application of softmax also does not require restart and can be cached.

3.1 HYBRID Encoder

The HYBRID encoder is a combination of unidirectional and bidirectional encoding layers, where the early layers are unidirectional and the later layers are bidirectional as shown in Figure 2. The earlier unidirectional layers do not require a restart as the previous tokens' embeddings do not need to be updated for the newly received tokens. Thus, the HYBRID encoder only require a restart for its later bidirectional layers. Formally, the HYBRID encoder has u unidirectional and b bidirectional layers where total layers in the model are $u + b = l$. Let $\overrightarrow{L}$ and $\overleftrightarrow{L}$ denote unidirectional and bidirectional layers in the model respectively. Each of the $\overrightarrow{L}$ layers are one of the existing unidirectional layers - RNN, GRU, transformer with causal masking etc. with the first of these being the static embedding layer. Each of the $\overleftrightarrow{L}$ layers are bidirectional layers, being one of bi-GRU, bi-LSTM, transformer etc.

3.1.1 HYBRID Encoder in Offline Setting:

First, the input tokens $\mathbf{x}$ are fed to u unidirectional layers to get the unidirectional encodings $\overrightarrow{\mathbf{H}}$,

$$\overrightarrow{\mathbf{H}} = [\overrightarrow{\mathbf{h}}_1, \cdots \overrightarrow{\mathbf{h}}_n] = \overbrace{\overrightarrow{L} \circ \overrightarrow{L} \circ \cdots \overrightarrow{L}}^{u \text{ layers}}(\mathbf{x}) \tag{1}$$

where $\circ$ denotes the functional composition and $\overrightarrow{\mathbf{h}}_i$ is the unidirectional encoding for the token x_i.

Notation	Meaning
$\overrightarrow{L}$, $\overleftrightarrow{L}$	Unidirectional and bidirectional layers, respectively.
$\overrightarrow{\mathbf{h}}_i$, $\overleftrightarrow{\mathbf{h}}_{i,t}$	Encoding of x_i token when t tokens have been received, using $\overrightarrow{L}$ and $\overrightarrow{L} + \overleftrightarrow{L}$, respectively.
$\overrightarrow{\mathbf{H}}_t$, $\overleftrightarrow{\mathbf{H}}_t$	$\overrightarrow{\mathbf{h}}_i$, $\overleftrightarrow{\mathbf{h}}_{i,t}$ of first t tokens, respectively.
$\overrightarrow{y}_i$, $\overleftrightarrow{y}_{i,t}$	Predicted label of x_i token using $\overrightarrow{\mathbf{h}}_i$ and $\overleftrightarrow{\mathbf{h}}_{i,t}$, respectively.

Table 2: Notations used in HYBRID encoder for layers, token representations, and predicted labels.

Then the bidirectional encodings $\overleftrightarrow{\mathbf{H}}$ are computed and used to predict the label sequence:

$$\overleftrightarrow{\mathbf{H}} = [\overleftrightarrow{\mathbf{h}}_1, \cdots \overleftrightarrow{\mathbf{h}}_n] = \overbrace{\overleftrightarrow{L} \circ \overleftrightarrow{L} \circ \cdots \overleftrightarrow{L}}^{b \text{ layers}}(\overrightarrow{\mathbf{H}}) \tag{2}$$

The final offline labels are obtained by passing $\overleftrightarrow{\mathbf{H}}$ through a feed-forward neural network layer.

3.1.2 HYBRID Encoder in Streaming Setting

In the streaming setting, the unidirectional layers' computation can be cached.[2] These cached intermediate representations for the previously received tokens $\mathbf{x}_{t-1}$ are used in computing the unidirectional encoding $\overrightarrow{\mathbf{h}}_t$ of the new token x_t. This along with the cached unidirectional encoding of $\mathbf{x}_{t-1}$ gives us $\overrightarrow{\mathbf{H}}_t = [\overrightarrow{\mathbf{H}}_{t-1}; \overrightarrow{\mathbf{h}}_t]$. The bidirectional encoding, however, for each token in $\mathbf{x}_t$ is restarted at time t as $\overleftrightarrow{\mathbf{H}}_t = [\overleftrightarrow{\mathbf{h}}_{1,t}, \cdots \overleftrightarrow{\mathbf{h}}_{t,t}]$ using the obtained final unidirectional encoding $\overrightarrow{\mathbf{H}}_t$ as input.

3.1.3 Training and Inference of HYBRID Encoder

We predict labels over both $\overrightarrow{\mathbf{H}}_t$ and $\overleftrightarrow{\mathbf{H}}_t$ of the HYBRID encoder using a linear layer with softmax at each timestep. Let $\overleftrightarrow{\mathbf{y}}_t = [\overleftrightarrow{y}_{1,t}, \cdots \overleftrightarrow{y}_{t,t}]$ denote the predictions over bidirectional embeddings at time t for all the tokens received so far. Let $\overrightarrow{\mathbf{y}}_t = [\overrightarrow{y}_1, \cdots \overrightarrow{y}_t]$ be predictions over unidirectional embeddings at time t. While the unidirectional predictions do not perform as well as bidirectional predictions, these auxiliary predictions enables waited restarts (§3.2).

---

[2] Cache for RNNs and causally masked transformer consists of hidden states and keys-values respectively. This is similar to implementations of auto-regressive models (Wolf et al., 2020; Heek et al., 2020).

HYBRID encoder is trained over the offline input-output sequence pairs and optimize both the bidirectional predictions and unidirectional predictions. for the standard softmax cross entropy loss against the offline ground truth label sequence $\mathbf{y}^*$. In order to preserve the strong performance of the BiDi encoders, we inhibit backward flow of gradient from the parameters θ_{uni} of unidirectional prediction head (consisting only of a linear layer with softmax) to the remaining parameters - θ_{bi}.Following are the losses of these two portions of the model, optimized together with equal weight.[3]

$$\mathcal{L}(\theta_{bi}, \overleftrightarrow{\mathbf{y}}_n, \mathbf{y}^*) = CE(\overleftrightarrow{\mathbf{y}}_t, \mathbf{y}^*) \tag{3}$$

$$\mathcal{L}(\theta_{uni}, \overrightarrow{\mathbf{y}}_n, \mathbf{y}^*) = CE(\overrightarrow{\mathbf{y}}_t, \mathbf{y}^*) \tag{4}$$

$$\mathcal{L}(\theta) = \mathcal{L}(\theta_{bi}, \overleftrightarrow{\mathbf{y}}_n, \mathbf{y}^*) + \mathcal{L}(\theta_{uni}, \overrightarrow{\mathbf{y}}_n, \mathbf{y}^*) \tag{5}$$

3.2 Waited Restarts

The HYBRID encoder reduces the computational overhead of each *restart* by limiting the recomputation over previous tokens only to the later bidirectional layers. However, restarting at each step is not required and the auxiliary predictions from the unidirectional layers can suffice.

We define a variable $\text{RESTART}(t)$ to decide whether to restart the bidirectional layers at time t. When $\text{RESTART}(t) = 1$, we restart the model to get the bidirectional predictions $\overleftrightarrow{\mathbf{y}}_t$ as the final predicted label sequence $\hat{\mathbf{y}}_t = \overleftrightarrow{\mathbf{y}}_t$. If $\text{RESTART}(t) = 0$, the model does not run the bidirectional encoder, but uses the unidirectional encoding to predict the current token's label $\overrightarrow{y}_t$ and copy the label sequence from the previous step $\hat{\mathbf{y}}_{t-1}$ to obtain $\hat{\mathbf{y}}_t$. Formally, the predicted sequence $\hat{\mathbf{y}}_t = (\hat{y}_{1,t}, \cdots \hat{y}_{t,t})$ at time t is

$$\hat{\mathbf{y}}_t = \begin{cases} \overleftrightarrow{\mathbf{y}}_t & \text{if } \text{RESTART}(t) = 1 \text{ or } t = n \\ [\hat{\mathbf{y}}_{t-1}; \overrightarrow{y}_t] & \text{otherwise} \end{cases} \tag{6}$$

where ';' denotes the concatenation. We always restart in the final timestep (i.e., $\text{RESTART}(n) = 1$) to preserve the offline performance.

3.2.1 Adaptive Restart Module (ARM)

A baseline restart strategy for waited restarts would be to restart the bidirectional layers every fixed k steps, i.e., $\text{RESTART}(t) = 1$ whenever t is a multiple of k. Note that $k = 1$ reduces to a HYBRID encoder model without waited restarts. We refer to this as **RESTART-k**.

Rather than having a heuristic function for $\text{RESTART}(t)$, we can let a lightweight parametric module determine when to do the restart by determining $\text{RESTART}_\theta(t)$ for each t. We refer to this as **A**daptive **R**estart **M**odule (**ARM**). We first discuss the set of features for ARM (§3.2.2), followed by its architecture (§3.2.3) and training (§3.2.4).

3.2.2 Input Features for ARM

We use HYBRID encoder's intermediate representations that do not require restart as the features for ARM. This includes the unidirectional layers as well as from the pre-softmax features from the first $\overleftrightarrow{L}$ layer. The main motivation to use these features is to incorporate more information without incurring any restarts.

The following features are stored in unidirectional cache and used without any restart for ARM:

(i) *unidirectional encodings* $\overrightarrow{\mathbf{h}}_t$ from the last unidirectional layer computed once and cached for capturing the backward flow,

(ii) *query* $\mathbf{q}_t$ and *key* $\mathbf{k}_t$ from the first bidirectional layer computed only from $\overrightarrow{\mathbf{h}}_t$,

(iii) *unnormalized forward attention scores* $\mathbf{a}_t = [\mathbf{q}_1 \cdot \mathbf{k}_t, \cdots, \mathbf{q}_{t-1} \cdot \mathbf{k}_t]$ from the first bidirectional layer, where '$\cdot$' is the dot product. These scores are concatenated across the prefix tokens (restricted and padded to latest m tokens) across all heads.

These features are then concatenated and provided as input to the ARM as $\mathbf{f}_t = [\overrightarrow{\mathbf{h}}_t, \mathbf{q}_t, \mathbf{k}_t, \mathbf{a}_t]$.

3.2.3 ARM Architecture

We use a single-layered GRU (Cho et al., 2014) to predict restart. The probability of restart $p_\theta(\text{RESTART}(t) = 1)$ is modeled as,

$$(\mathbf{o}_t, \mathbf{s}_t) = \text{GRU}(\mathbf{f}_t, \mathbf{s}_{t-1}) \tag{7}$$

$$p_\theta(\text{RESTART}(t) = 1) = \sigma(\text{LINEAR}(\mathbf{o}_t)) \tag{8}$$

Here $\mathbf{s}_t$ and $\mathbf{o}_t$ are the GRU hidden state and output at time t, respectively. These outputs can be post-processed to handle too frequent or too infrequent waiting and obtain the final selector predictions.Details can be found in Appendix (§A.2).

---

[3] CE is the Cross Entropy Loss

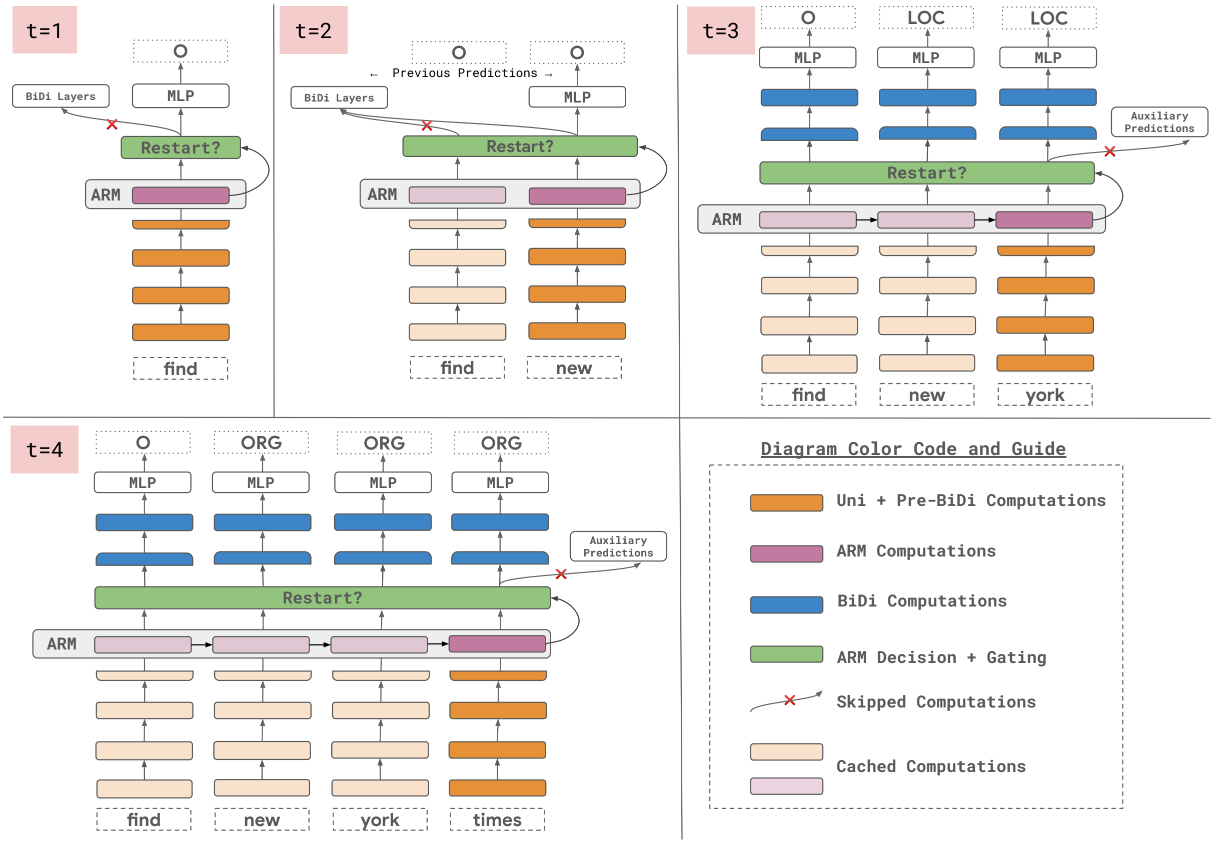

Figure 2: The HEAR model in streaming setting. At $t = 1$, ARM decides not to run the bidirectional layers and exit early through the auxiliary predictor over unidirectional encoding. Similarly at $t = 2$, ARM decides not to restart and considers the auxiliary predictions of the latest token and the predictions from the previous steps. At $t = 3$ and $t = 4$, ARM decides to restart and runs the bidirectional layers to get prediction for all the tokens from scratch. Note that in all the steps, for unidirectional layers and ARM, the computation is performed only for the latest token received.

3.2.4 Training the ARM

Ideally, HYBRID encoder should restart only when it would lead to improved predictions over the prefixes i.e., more number of prefix inputs should have the same output as the the offline ground truth for those prefixes. We use this to define our ground truth RESTART sequence for training the ARM.

Given the ground truth offline tag sequence $\mathbf{y}^*$, unidirectional predictions $\vec{\mathbf{y}} = [\vec{y}_1, \cdots \vec{y}_n]$ and final bidirectional prediction sequence over each of the n prefixes $\overleftrightarrow{\mathbf{Y}} = [\overleftrightarrow{\mathbf{y}}_1, \cdots \overleftrightarrow{\mathbf{y}}_n]$, we define the ground truth policy RESTART$^*(t) = \pi_t^*$ for ARM, at time t, as follows.

$$\pi_t^* = \begin{cases} 1 & \text{if } |y^*_{\leq t} = \vec{y}_{\leq t}| < |y^*_{\leq t} = \overleftrightarrow{y}_{\leq t}| \\ 0 & \text{otherwise} \end{cases} \tag{9}$$

The policy decides to restart at time t if more tokens in bidirectional predictions match with the ground truth ($|y^*_{\leq t} = \overleftrightarrow{y}_{\leq t}|$) than those from unidirectional predictions ($|y^*_{\leq t} = \vec{y}_{\leq t}|$).[4] ARM is trained against this policy with features from a frozen and trained HYBRID encoder model with a standard binary cross entropy loss.

4 Experimental Setup

Datasets and Tasks. We consider four common sequence tagging tasks – Slot Filling over SNIPS (Coucke et al., 2018), Semantic Role Labelling (SRL) over Ontonotes (Pradhan et al., 2013), and Named Entity Recognition (NER) and Chunking (CHUNK) over CoNLL-2003 (Sang and Meulder, 2003). The standard train, dev and test splits are used for all datasets.

Models and Baselines. For our models, we consider a layer budget of 4 for the encoder. Naturally, our baselines are the UniDi encoder and BiDi encoder with all unidirectional and bidirec-

---

[4] This policy is greedy. The optimal policy obtained via dynamic programming relies on the future tokens.

Current Token	Prefix Predictions	Total Edits	Unnecessary Edits	Exact Match w/ ground truth	Exact Match w/ final prediction
find	`O`	1	0	1	1
new	`O O`	2	1	1	1
york	`O LOC LOC`	4	3	2	1
times	`O ORG ORG ORG`	7	3	2	2
square	`O ORG ORG ORG LOC`	8	3	2	3
Ground Truth	`O LOC LOC LOC LOC`	**EO**= $\frac{\text{Unnecessary Edits}}{\text{Total Edits}} = \frac{3}{8}$		**Streaming EM** = $\frac{\text{EM w/ ground truth}}{\text{\# steps}} = \frac{2}{5}$	**RC** = $\frac{\text{EM w/ final labels}}{\text{\# steps}} = \frac{3}{5}$

Table 3: Example computation for the metrics described in §4.1 . **EO** is calculated as fraction of edits that were *unnecessary*. **RC** measures the fraction of prefix predictions that matches the model's final predictions. **Streaming EM** measures the fraction of prefix predictions that are correct with respect to the ground truth labels.

tional layers, respectively. For HEAR, we tune for the optimal fractions of unidirectional layers in encoder by selecting the one that maximizes the offline F1 performance over the development set. We consider RESTART-k baseline for ARM. For each dataset, we picked the best value of k from $\{2, 3, 5, 8\}$, maximizing the Streaming EM over development set.

4.1 Metrics

The model evaluation is done over three criteria: offline performance over complete input text, streaming performance over prefixes and efficiency of running the model in streaming settings.

Offline Metrics. The offline performance of the model is measured using the widely used chunk-level F1 score for sequence labelling tasks (Sang and Meulder, 2003).

GFLOPs. We measure total number of Floating Point Operations (FLOPs) required for running the model in a streaming setting in GigaFLOPs (**GFLOP**), estimated via XLA compiler's High Level Operations (HLO) (Sabne, 2020). GFLOP positively correlates with how computation-heavy a model is and its wall-clock execution time.

Streaming Metrics. An ideal streaming model should predict the correct labels for all prefixes early (Trinh et al., 2018) and avoid unnecessary label flips. Following previous works (Madureira and Schlangen, 2020; Kahardipraja et al., 2021), we use Edit Overhead (EO) and Relative Correctness (RC) metrics from Baumann et al. (2011).

EO (Edit Overhead) is a measure of the fraction of the label edits that were unnecessary with respect to the final prediction on complete output. Consider the example in Table 3. At the first timestep, the token "*find*" is assigned a label "`O`" from "`N/A`"; taking the total edits to 1. Similarly, in the second timestep, the newly received token "*new*" gets a label edit; taking the total edit to 2. In the third timestep, however, not only the newly received token "*york*" receives a label edit but the second token "*new*" is also edited from "`O`" to "`LOC`"; resulting in 4 total edits. Of these edits, the label edit for token "*new*" in timestep 2 from "`N/A`" to "`O`" was unnecessary as it differs from its final label "`ORG`". Similarly, the label flips for "*new*" and "*york*" in the timestep 3 from "`O`" and "`N/A`" to "`LOC`" and "`LOC`", respectively, were also unnecessary. Cumulatively, towards the end of fifth timestep, we have 3 out of 8 total edits which were *overhead*. Thus, the EO turns out to be $\frac{3}{8}$, where lower is better.

RC measures the relative correctness of prefixes, i.e. correctness of prefix prediction sequence with respect to the final label set over the complete input. For the example in Table 3, only the label sequence in the first timestep ("`O`"), fourth timestep ("`O ORG ORG ORG`") and final (fifth) timestep are prefixes of the label sequence in the final timestep ("`O ORG ORG ORG LOC`"). Thus 3 prefixes of a total 5 prefixes were correct. So, the Relative Correctness is $\frac{3}{5}$, where higher is better.

While EO and RC capture consistency and stability in streaming predictions, neither of these measures performance with respect to the ground truth label over offline input. Relying on these metrics alone is not sufficient to measure streaming performance. For example, a UniDi encoder achieves perfect EO and RC scores, despite have poor predictions with respect to the offline ground truth. Thus, we consider **Streaming** Exact Match (**Streaming EM**), which is the streaming setting analogue of the Exact Match metric. Streaming EM calculates the percentages of prefix label sequence which are correct with respect to the offline ground truth labels. For example in Table 3, only the first label sequence ("`O`") for input "*find*" and third label se-

Model	SNIPS	CHUNK	NER	SRL
UniDi encoder	86.8	88.1	73.8	56.4
HYBRID encoder	93.0	**89.4**	**86.8**	80.0
BiDi encoder	**93.1**	**89.4**	86.0	**80.1**

Table 4: Offline F1 over test set of datasets described in §4. On all datasets, HYBRID encoder achieves performance parity with the BiDi models.

quence (“`O LOC LOC`”) for input “*find new york*” is a prefix of the ground truth label sequence (“`O LOC LOC LOC LOC`”), leading to only 2 out of 5 prefix label sequence being correct. Thus, the Streaming EM is $\frac{2}{5}$. Similar to RC, higher score is better as more prefixes have exact matches.

5 Experimental Results

In this section, we provide empirical results to answer the following questions:

(a) In offline setting, does HYBRID encoder achieve parity with BiDi encoders?

(b) In streaming setting, by how much does HYBRID encoder reduce GFLOPs count?

(c) Does HEAR improve streaming performance and save on GFLOP count?

HYBRID Encoder’s Offline Performance is Competitive to BiDi Encoders. Table 4 shows the offline F1 scores of the HYBRID encoder, UniDi and BiDi encoders across the four tasks. The HYBRID encoder has similar offline F1 as BiDi encoders. In fact, on NER, it even outperforms it by a margin of 0.8 F1 score. As expected, the UniDi model performs poorly compared to the BiDi encoder across all the tasks. From here on, we omit UniDi encoder.

HYBRID Encoder Improves Streaming Efficiency. Table 5 shows the GFLOP (per input instance) in streaming settings across the four datasets for the HYBRID encoder and BiDi encoders, with a trivial restart at every new token to get predictions over streaming text. We observe that HYBRID encoder consistently offers lower GFLOP count than BiDi encoder across the datasets, and in three of the four datasets, offering more than 40% FLOP reduction. However, HYBRID encoder does not improve on streaming performance (Streaming EM, EO, and RC) over BiDi, and its FLOP can be further reduced. We next see how incorporating HEAR addresses this.

HEAR Improves Streaming Efficiency and Performance. Across all datasets, we observe HEAR further reduces GFLOP count from the already computationally lighter HYBRID encoder, giving us upto 71% total FLOP reduction from BiDi. HEAR has better streaming predictions, as its Streaming EM is much higher (upto +10.0) than BiDi, improving on the shortcoming of Hybrid. This highlights that naively restarting at each timestep can worsen the streaming performance, as evident through the lower performance of Hybrid and BiDi. HEAR also offers reduced number of avoidable label flips, as signified by a lower EO. Its high RC score signifies that its streaming predictions are more consistent with its final prediction.

All these results demonstrate that HEAR preserves the offline performance of BiDi encoders, while being computationally lighter by 58.9% on average across tasks. HEAR has more consistent streaming predictions which are accurate with respect to offline ground truth.

6 Analysis and Ablations

In this section, we perform various analysis pertaining to the HYBRID encoder and ARM.

6.1 HYBRID Encoder’s Unidirectional Layers Performance

Table 6 compares the performance of the prediction over the intermediate (unidirectional) and final (bidirectional) encodings for the best HEAR model. While the intermediate ones lag in comparison to the final, we get decent performance from intermediate ones across all except for SRL dataset. This shows that, when used selectively, UniDi intermediate predictions can serve as a good source of auxiliary predictions.

6.2 ARM vs RESTART-k.

Table 6 shows the performance of baseline - the best RESTART-k from {2, 3, 5, 8} over dev set Streaming EM and the ARM. We observe that across all the datasets, on both Streaming EM and EO metric, ARM performs significantly better than the heuristic RESTART-k mechanism. This shows that using a fixed length wait is not sufficient.

6.3 Intrinsic Performance of ARM

Table 6 shows the performance of the ARM on its binary classification task. Given the lightweight ARM architecture and the task complexity, the

Dataset	GFLOP ↓			Streaming EM ↑			EO ↓			RC ↑		
	BiDi	Hybrid	HEAR	BiDi	Hybrid	HEAR	BiDi	Hybrid	HEAR	BiDi	Hybrid	HEAR
SNIPS	74.7	43.4	**21.6**	75.1	72.5	**85.1**	15.9	16.7	**6.3**	78.2	76.3	**88.5**
CHUNK	238.8	126.3	**91.3**	77.7	77.7	**77.9**	5.0	4.8	**4.5**	91.6	**91.9**	91.6
NER	238.8	126.2	**83.8**	79.3	78.2	**81.9**	8.7	8.3	**5.4**	87.2	88.2	**90.9**
SRL	741.2	557.7	**460.4**	43.6	49.1	**50.6**	33.0	29.9	**21.0**	56.0	61.5	**62.5**

Table 5: Streaming performance over test set of datasets. HEAR significantly outperforms BiDi on all metrics improving upon efficiency and performance. Direction of arrow indicates whether higher or lower is better.

Dataset	Offline F1↑		Streaming EM ↑		EO ↓		ARM Classification
	BiDi	UniDi	restart-k	ARM	restart-k	ARM	Micro-F1
SNIPS	**93.6**	79.1	82.1	**85.3**	7.9	**6.0**	79.5
CHUNK	**90.4**	86.8	75.6	**76.5**	4.5	**4.5**	67.1
NER	**91.3**	77.9	85.6	**87.8**	4.1	**4.0**	75.7
SRL	**79.7**	42.8	41.8	**48.9**	31.5	**21.6**	80.2

Table 6: Development set ablation and analyses. From left to right - comparing performance of Hybrid encoder over sequence tagging using its bidirectional (final) vs unidirectional (intermediate) encoding, comparison of Streaming EM and EO of restart-k vs ARM, and the performance of ARM w.r.t. its ground truth policy labels.

performance is satisfactory with 80.2 F_1. However, there is a considerable margin for its improvement both in terms of model architecture and features.

6.4 ARM's Architecture Ablation

Dataset	Streaming EM ↑	EO ↓
No ARM	73.8	16.3
Linear ARM	81.3	6.8
MLP ARM	81.4	6.9
GRU ARM	**85.3**	**6.0**

Table 7: Performance of HEAR with different ARM model architectures over SNIPS development set.

Table 7 shows the Streaming EM and EO scores of HEAR with different ARM model architectures for the SNIPS development set. We observe that HEAR having either a Linear layer or MLP as ARM does much better than having no ARM and restarting at each timestep. However, modeling ARM as a GRU recurrent model gives the best scores in both metrics.

7 Related Work

Streaming (or incremental) setting has been widely studied in machine translation and parsing, dating as far back as two decades (Larchevêque, 1995; Lane and Henderson, 2001). Specifically, for incremental parsing, there are two broad approaches that have been studied: transition-based and graph-based. Transition-based incremental parsers allow for limited backtracking and correcting parsing over prefixes by keeping track of multiple parse segments (Buckman et al., 2016) or via beams search (Bhargava and Penn, 2020). Such methods can fail on garden-path sentences and long-range dependencies and only work proficiently with a large beam. Graph-based parsers incrementally assign scores to edges of the graph, discarding those edges that cause conflicts to tree-structure of the graph. (Yang and Deng, 2020) proposed an attach-juxtapose system to grow the tree, requiring restart at each new token over streaming input. (Kitaev et al., 2022) improved on its efficiency by proposing a information bottleneck. However, these methods rely on the structured nature of parsing output can not be adapted to incremental sequence tagging tasks without restarting at each token.

Recently, Madureira and Schlangen (2020) benchmarked the modern encoders on streaming sequence labelling and observed poor streaming performance of pretrained transformer models. They explored improvement strategies by adopting techniques from other streaming streaming like chunked training (Dalvi et al., 2018), truncated training (Köhn, 2018) (training model on heuristically-aligned partial input-output pairs), and prophecy (Alinejad et al., 2018) (autocompleting input using a separate language model). They observed performance degradation from truncated training unless used with prophecies. However, running a language model at each timestep for prophecy is computationally infeasible. Therefore, unlike our approach, neither methods can improve performance feasibly.

Previous works have attempted to improve computation efficiency in BiDi encoders. Monotonic attention moves away from $O(n^2)$ soft attention overhead by restricting attention to monotonically increase across timesteps (Raffel et al., 2017; Chiu and Raffel, 2018; Ma et al., 2020). However, unlike HEAR, such attempts can't maintain offline performance. Recently, Kahardipraja et al. (2021) used linear transformer (Katharopoulos et al., 2020) as unidirectional model using masking for streaming sequence tagging and classification. This approach performs well under the assumption of delayed output (Grissom II et al., 2014; Oda et al., 2015), a relaxation, where the model waits for additional tokens before predicting. Furthermore, the unidirectional model could not revise its output, rendering the model incapable of handling long-range dependency or tasks that go backward like SRL — an ability common to any model with some bidirectionality, such as HEAR. Similar drawbacks were in the partial bidirectional encoder, a bidirectional attention with restricted window, proposed by Iranzo Sanchez et al. (2022).

Improving efficiency through adaptive computing has been independently studied for reasoning-based tasks (Eyzaguirre and Soto, 2020), text generation models (Arumae and Bhatia, 2020; Eyzaguirre et al., 2022) and diffusion models (Ye et al., 2022). These works are restricted to offline settings and can be readily incorporated within the proposed overall approach of HEAR.

8 Conclusion

We propose HEAR for sequence tagging in streaming setting where the input is received one token at a time to the model. The encoder in our model is HYBRID encoder where early layers are unidirectional and later are bidirectional. It reduces the computational cost in streaming settings, by reducing the need of restart only to the later bidirectional layers while preserving the offline performance of the model. HEAR additionally consists of an ARM to predict when to restart the model. Using ARM leads to reduced number of restart of the encoder, leading to better streaming performance and further savings in computation. Compared to BiDi encoders, our model, HEAR (HYBRID encoder + ARM) reduces the computation by upto 71% in streaming settings while maintaining the performance of the BiDi encoders across various sequence tagging tasks. HEAR improved streaming EM by upto +10.0% and reduced unnecessary edits by upto -12.0%.

Limitations

An additional but small training cycle is required to train the lightweight ARM module of HEAR in order to reap the benefits of extra savings in efficiency and streaming performance. Also, even though we do not assume any language specific-design choices, we benchmarked on the standard streaming sequence labelling benchmark datasets, all of which were in English.

A Experiment Details

A.1 Implementation Details

All the experiments were done using the Flax (Heek et al., 2020) and Jax (Bradbury et al., 2018) with Adam optimizer (Kingma and Ba, 2014) on TPUs. We measure flops in terms of XLA's HLO (Sabne, 2020). The optimizer's learning rate is set to 1e-3, betas are set to default at (0.9, 0.999), batch size is 256 and feedforward hiden is 2048 with 512 transformer dimension and 8 heads.

For all the datasets we use the standard splits, the links to which can be found in their respective papers along with statistics. Following (Ratinov and Roth, 2009), we use the BIOES tagging scheme for the NER task and BIO scheme for the rest. In SRL, following (He et al., 2017) the indicator for predicate verb is also used as input the along with the sentence.

All the values over test sets are averaged across four seeds. For experiments involving ARM we average across four different HYBRID encoder trained from different seeded initialization. We initialize static embeddings with 300 dimensional glove embedding (Pennington et al., 2014).

A.2 Postprocessing ARM Predictions

We post process the ARM predictions to prevent too frequent or too infrequent restarts. Specifically, for hyperparameters α and β where $0 \leq \alpha < \beta$, at any time t, if the ARM hasn't restarted once since $max(0, t - \beta)$ timesteps, then ARM's prediction is set to 1, else, if the ARM has restarted atleast once since $max(0, t - \alpha)$ timesteps, then it is set to 0. We tune for the values of α and β in the range {0, 1, 2, 3, 5, 10} over the development set.

We also observe that even if bidirectional layers improve predictions over previous tokens, for the latest token only, the unidirectional label $\overrightarrow{y}_t$ is often better than $\overleftrightarrow{y}_t$. If this is observed, then, we exclude the most recent token from getting updated during restart. We tune for this binary postprocessor over the development set as well.

B Analysis and Ablation

B.1 Benefits of Optimizing Unidirectional Predictor Separately

In HYBRID encoder the performance we inhibit backward gradient flow from the auxiliary predictor over the unidirectional layers unidirectional. This is because we observed offline F1 performance drop of bidirectional predictor when trained with unidirectional predictor, dropping from 81.20 to 71.62 on CoNLL development set. Even after tuning for loss scaling for the to predictors in ratio {1:1, 3.3:1, 10:1, 33:1, 100:1}, the performance was only increased upto 75.06 F1.

B.2 Oracle Policy for ARM

We also experimented with alternate policy for ARM where it's label is conditioned on the last bidirectional restart. However, it led to a performance drop in terms of Streaming EM from 86.7 to 83.0, as observed across SNIPS development set. We attribute this poor performance on alternate policy, due to the lightweight nature of ARM. Thus, we did not proceed with this policy.

Retrieve-and-Fill for Scenario-based Task-Oriented Semantic Parsing

Abstract

Task-oriented semantic parsing models have achieved strong results in recent years, but unfortunately do not strike an appealing balance between model size, runtime latency, and cross-domain generalizability. We tackle this problem by introducing scenario-based semantic parsing: a variant of the original task which separates disambiguating an utterance's "scenario" (an intent-slot template with variable leaf spans) and generating its frame, complete with ontology and utterance tokens. This formulation closely ties to the data collection process where the scenarios are first designed followed by crowd sourced utterance annotation. Concretely, we create a Retrieve-and-Fill (RAF) architecture comprised of (1) a retrieval module which ranks the best scenario given an utterance and (2) a filling module which imputes spans into the scenario to create the frame. Our model is modular, differentiable, interpretable, and allows us to garner extra supervision from scenarios. RAF achieves strong results in high-resource, low-resource, and multilingual settings, outperforming recent approaches despite, using base pre-trained encoders and efficient decoding.

1 Introduction

Task-oriented conversational assistants typically first use semantic parsers to map textual utterances into structured frames for language understanding (Hemphill et al., 1990; Coucke et al., 2018; Gupta et al., 2018; Rongali et al., 2020; Aghajanyan et al., 2020). While these parsers achieve strong performance with rich supervision, they often face obstacles adapting to novel settings, especially ones with distinct semantics and scarce data. Recent approaches address this by improving parsers' data efficiency, such as by using pre-trained representations (Aghajanyan et al., 2020; Rongali et al., 2020), optimizing loss functions (Chen et al., 2020b), and supplying natural language prompts (Desai et al., 2021). However, these approaches typically rely on larger models and longer contexts, impeding their applicability in real-world conversational assistants. Even though non-autoregressive models can alleviate some concerns (Babu et al., 2021; Shrivastava et al., 2021; Zhu et al., 2020), to the best of our knowledge, there exists no approach which strikes an appealing balance between model size, runtime latency, and cross-domain generalizability.

We begin tackling this problem by introducing **scenario-based task-oriented semantic parsing** which is more closely tied to how new task domains are developed. A slight variation on original semantic parsing, we are given access to all supported scenarios apriori and have to parse the utterance given this scenario bank. Here, a scenario is akin to a *incomplete* frame; it is, precisely, an intent-slot template with variables as leaf spans (e.g., `IN:GET_WEATHER [SL:LOCATION` x_1 `] ]`), indicating it maps to a family of linguistically similar utterances. As domain development and data-collection usually starts out with designing the set of supported scenarios, our intuition is that by giving the model access to this bank we can train it to more explicitly reason about scenarios and improve performance especially in the low data regime.

Concretely, we propose RAF (Retrieve-and-Fill), a modular yet differentiable architecture for scenario-based task-oriented semantic parsing. Guided by the definition of our task, RAF also proceeds in two steps: (1) given an utterance, a **retrieval** module finds the highest ranking scenario and (2) given the utterance and retrieved scenario, a **filling** module imputes spans into the scenario, creating the final frame. This approach requires no extra supervision despite performing auxiliary inference: utterances and frames are typically provided, and scenarios are obtained by stripping leaf text in frames. We design RAF to capitalize on the advantages of prior work but avoid their disadvantages; using base pre-trained encoders across-the-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 430–447
May 2-6, 2023 ©2023 Association for Computational Linguistics

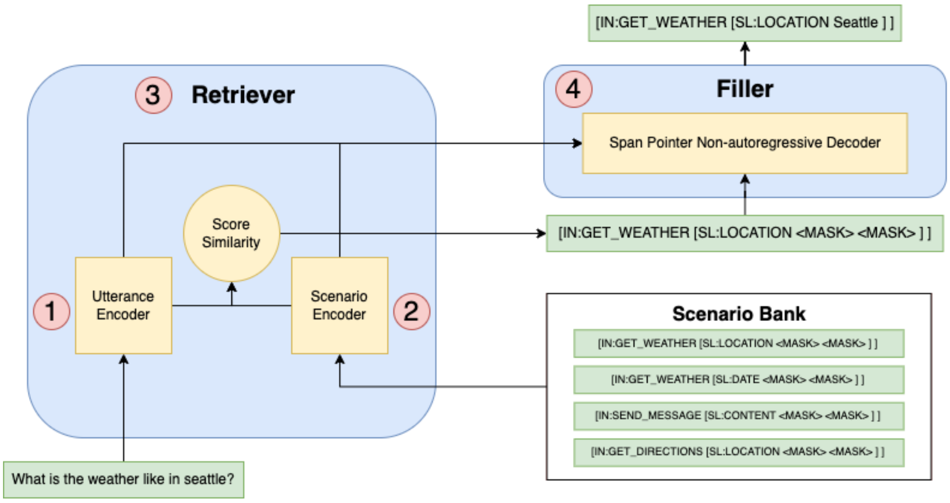

Figure 1: **High-Level Overview.** Retrieve-and-Fill (RAF) consists of 4 steps: (1) Encode the utterance via an utterance encoder (e.g., RoBERTa); (2) Encode all scenarios (Desai et al., 2021) in the scenario bank into a cached index via a scenario encoder (e.g., RoBERTa); (3) Compute the dot product similarity amongst the incoming utterance and the index of all scenarios, obtaining the top-n candidates; (4) For each retrieved scenario, leverage the non-autoregressive span pointer decoder (Shrivastava et al., 2021) to impute each scenario's spans.

board, our retrieval module caches intrinsic representations during inference and our filling module non-autoregressively decodes leaf spans in a generalizable fashion.

We evaluate our approach in high-resource, low-resource, and multilingual settings using standard task-oriented semantic parsing datasets. RAF achieves 87.52% EM on TOPv2 (Chen et al., 2020b) and 86.14% EM on TOP (Gupta et al., 2018), outperforming recent autoregressive and non-autoregressive models. RAF also excels in weakly supervised settings: on TOPv2-DA, we outperform Inventory (Desai et al., 2021) on 4 domains (alarm, music, timer, weather) despite using <128 token sequence lengths and 2-4x less parameters, on TOPv2 low resource, we outperform BART (Lewis et al., 2020), RINE (Mansimov and Zhang, 2021), and RoBERTa + Span Pointer (Shrivastava et al., 2021), and on MTOP (Li et al., 2021), we outperform XLM-R + Span Pointer, achieving 42% EM averaged across en→{es, fr, de, hi, th} transfer tasks.

To summarize, our contributions are: (1) Introducing scenario-based task-oriented semantic parsing, a novel task which requires disambiguating scenarios during typical utterance→frame predictions; (2) Creating RAF (Retrieve-and-Fill), a modular yet differentiable architecture composed of a retrieval and filling module for solving scenario-based task-oriented semantic parsing; and (3) Achieving strong results in high-resource, low-resource, and multilingual settings, outperforming recent models such as Span Pointer, Inventory, and RINE by large margins, while also optimizing for model size, runtime latency, and cross-domain generalizability.

2 Scenario-based Semantic Parsing

We formally introduce the task of scenario-based semantic parsing. Task-oriented conversational assistants support a wide range of domains (e.g., calling, reminders, weather) to maximize coverage over users' needs. Over time, in response to requests and feedback, developers often iterate on assistants' skill-sets by adding new domains. Though the crowdsourcing process of collecting and annotating samples—utterances and frames—for new domains can be accomplished in many ways, we propose a two-step methodology where developers (a) develop scenarios which roughly describe a family of samples and (b) collect linguistically-varied samples consistent with each scenario. We elaborate more on our scenario-based methodology below.

Scenario Definition. We define a **scenario** as an intent-slot rule which abstracts away linguistic variation in utterances. More specifically, it is a decoupled semantic frame (Aghajanyan et al., 2020) with variables in leaf spans, indicating it can subclass utterances with similar syntactic and semantic structure, an example is showing in table 1. Our no-

Utterance	Frame
Scenario: `[IN:GET_WEATHER [SL:LOCATION` x_1 `] ]`	
what's the weather in seattle	`[IN:GET_WEATHER [SL:LOCATION` seattle `] ]`
how's the forecast in sf	`[IN:GET_WEATHER [SL:LOCATION` sf `] ]`
Scenario: `[IN:GET_WEATHER [SL:LOCATION` x_1 `] [SL:DATE_TIME` x_2 `] ]`	
what's the weather in seattle tomorrow	`[IN:GET_WEATHER [SL:LOCATION` seattle `] [SL:DATE_TIME` tomorrow `] ]`
how's the forecast in sf at 8pm	`[IN:GET_WEATHER [SL:LOCATION` sf `] [SL:DATE_TIME` 8pm `] ]`

Table 1: **Scenario Description.** Scenarios are intent-slot templates with missing slot text, suggesting they subclass linguistically similar utterances. We show examples of utterances, scenarios, and frames in the weather domain; each scenario consists of multiple (utterance, frame) pairs.

tion of a scenario is inspired by production rules in constituency parsing (Chomsky, 1959), but the parallel is not exact given our scenarios have semantic not syntactic types.

Using scenarios, we can effectively quantize the space of possible utterances by identifying and defining slices of user requests. Our solution also offers fine-grained control over precision and recall, which is important in real-world systems; we can collect more paraphrases to improve precision and we can create more scenarios to improve recall.

We collect scenarios by taking train, eval, and test frames from our datasets, and stripping out the utterance text, to yield a decoupled semantic frame. As discussed later in this manuscript, our approach requires knowing, beforehand, the space of possible scenarios, in order to perform global inference.

Case Study: Weather. Table 1 shows an example setting where we crowdsource weather domain samples using the scenario-based methodology outlined above. To begin, we may envision building a weather system which supports requests with location and/or date-time information. Therefore, we can define two scenarios: (1) a family of samples with one location span; and (2) a family of samples with one location span and one date-time span. Each scenario explicitly outlines the intents and slots that must be present, as scenarios are not "one-size-fits-all" rules with optional slotting. So, as an example, the utterance "how's the forecast in sf" would not be compatible with the scenario `[IN:GET_WEATHER [SL:LOCATION` x_1 `] [SL:DATE_TIME` x_2 `] ]` since it does not have a date-time span as specified by the x_2 variable.

Task Definition. Finally, we precisely define our task of scenario-based semantic parsing. For the typical task of semantic parsing, we define U as a random variable over utterances, F as a random variable over frames, and model $P(F|U)$: find the most likely frame given the utterance. However, because we introduce scenarios as a coarse, intermediate representation of frames, we additionally define S as the set of all supported scenarios given a priori, and model $P(F|U, S)$.

3 RAF: Retrieve and Fill

We propose a model called RAF (Retrieve and Fill) for scenario-based semantic parsing that naturally decomposes the task into a coarse-to-fine objective where we (a) find the most likely scenario given the utterance and (b) find the most likely frame given the utterance and scenario. More concretely given an utterance u and scenarios $s_1, \cdots, s_n$, as well as a gold scenario s^* and gold frame f^*, we learn our model as follows:

1. Retrieve (Coarse Step; §3.1): A **retrieval module** maximizes $P(S = s^*|U = u)$ by learning to retrieve scenario s_i given utterance u, e.g., "what's the weather in seattle" → `[IN:GET_WEATHER [SL:LOCATION` x_1 `] ]`.

2. Fill (Fine Step; §3.2): A **filling module** maximizes $P(F = f^*|U = u, S = s^*)$ by decoding the most likely frame f given the structure of scenario s_i^* and spans of utterance u, e.g., `[IN:GET_WEATHER [SL:LOCATION` x_1 `] ]` → `[IN:GET_WEATHER [SL:LOCATION` seattle `] ]`.

RAF is a composable yet differentiable model which implements coarse-to-fine processing: we first develop a coarse-grained sketch of an utterance's frame, then impute fine-grained details to achieve the final frame. In these types of approaches, there often exists a trade-off when creating the intermediate representation; if it is "too coarse", the filling module suffers, but if it is "too fine", the retrieval module suffers. We find scenarios, as defined in §2, offer the most appealing solution, as the retrieval module unearths rough syntactic-semantic structure, while the filling module focuses in on imputing exact leaf spans.

In the following sub-sections, we discuss the technical details behind the retrieval and filling modules, as well as describe the training and inference procedures.

3.1 Retrieval Module

First, we discuss the **coarse-grained step** of RAF, which aims to find the best-fitting scenario for an utterance. We formulate this task as a metric learning problem. Here, we can maximize the similarity $\text{sim}(u, s^*)$ between an utterance u and scenario s^* as judged by a scalar metric. This offers numerous advantages: we can explore ad-hoc encodings of utterances and scenarios, adjust the output space dynamically during inference, and compute exact conditional probabilities by leveraging a (tractable) partition function.

3.1.1 Bi-Encoder Retrieval

Following retrieval modeling in open-domain QA (Karpukhin et al., 2020), we specifically leverage pre-trained encoders (E_U for utterances and E_S for scenarios) to compute dense vector representations, then maximize the dot product similarity $\text{sim}(u, s^*) = E_U(u)^\top E_S(R(s^*))$ between utterance-scenario pairs (u, s^*); the precise nature of R is discussed in §3.1.3. To learn such a metric space and avoid degenerate solutions we need to train the encoders to *pull* positive pairs together and *push* negative pairs apart. Hence, we need access to both positive (gold; (u, s^+)) and negative (non-gold; (u, s^-)) pairs.

3.1.2 Negatives Sampling

The choice of negatives has a large impact on retrieval performance, which is consistent with findings in information retrieval (Zhan et al., 2021; Karpukhin et al., 2020). We explore two types of negative sampling to improve retrieval performance: in-batch negatives and model-based negatives.

In-Batch Negatives. We mine positive and negative pairs from each training batch using in-batch negatives (Karpukhin et al., 2020). Let $\mathbf{U}$ and $\mathbf{S}$ be the utterance and scenario matrices, each being a $(B \times d)$ matrix consisting of d-dimensional embeddings up to batch size B. We obtain B^2 similarity scores upon computing the similarity matrix $\mathbf{M} = \mathbf{US}^\top$, where $\mathbf{M}_{i=j}$ consists of positive scores and $\mathbf{M}_{i\neq j}$ consists of negative scores. For each positive utterance-scenario pair (u_i, s_i^+), we now have $(B-1)$ negative pairs $\{(u_i, s_{ij}^-)\}_{i\neq j}$. Having collected multiple negative pairs per positive pair, we leverage the contrastive loss for utterance i is defined in Karpukhin et al. (2020); Chen et al. (2020a):

$$\mathcal{L}^i_{\text{retrieval}}(u_i, s_1, \cdots, s_b) = \log \frac{e^{\text{sim}(u_i, s_i)}}{\sum_{j=0}^{b} e^{\text{sim}(u_i, s_{ij})}} \quad (1)$$

Since our set of scenarios isn't huge this can result in conflicts so we additionally implement **identity masking** while training which ensures that for every utterance each scenario is present at-most once in it's positive/negative set.

Model-Based Negatives. Following prior work in IR (Xiong et al., 2020; Oğuz et al., 2021) we train an initial retrieval model that uses only In-Batch negatives. This model is used to rank all scenarios for each utterance and the top K ranked scenarios which are not the gold scenario are selected as additional negative examples. Those negatives examples are expected to be harder examples since they were ranked higher by the initial model. We train a new model using those added k scenarios as explicit negative examples for each positive example.

3.1.3 Frame Representation

While we have covered scenario-based retrieval above, we have not yet precisely described how dense vectors for scenarios are computed. Recall our definition of utterance-scenario similarity in §3.1.1: our objective is to maximize $\text{sim}(u, s) = E_U(u)^\top E_S(R(s))$, where R is a string transformation applied to scenarios.

Following Desai et al. (2021), we leverage **intrinsic modeling** to rewrite intents and slots as a composition of their intrinsic parts in a single string. Desai et al. (2021) define two, in particular: the categorical type (e.g., "intent" or "slot") and language span (e.g., "get weather" or "location"). Using this methodology, we can transform the scenario `IN:GET_WEATHER [SL:LOCATION` x_1 `] ]` → `[ intent | get weather [ slot | location` x_1 `] ]`, which is inherently more natural and descriptive.

Guided by the general concept of intrinsic modeling, our goal here is to define R such that

$E_U(u)^\top E_S(s) \leq E_U(u)^\top E_S(R(s))$, all else being equal. We discuss our approach in detail in the following sub-sections.

3.1.4 Language Spans

Desai et al. (2021) chiefly use an **automatic** method to extract language spans from ontology labels. For example, using standard string processing functions, we can extract "get weather" from `IN:GET_WEATHER`. While this method is a surprisingly strong baseline, it heavily relies on a third-party developers' notion of ontology nomenclature, which may not always be pragmatically useful. In TOPv2 (Chen et al., 2020b), our principal evaluation dataset, there exists ambiguous labels like `SL:AGE`—is this referring to the age of a person, place, or thing?

Therefore, to improve consistency and descriptiveness, we propose a **handmade** method where we manually design language spans for each ontology label.[1] The most frequent techniques we use are (1) using the label as-is (e.g., `IN:GET_WEATHER` → "get weather"); (2) inserting or rearranging prepositions (e.g., `IN:ADD_TO_PLAYLIST_MUSIC` → "add music to playlist"; and (3) elaborating using domain knowledge (e.g., `IN:UNSUPPORTED_ALARM` → "unsupported alarm request").

3.1.5 Example Priming

Despite using curation to improve ontology label descriptions, there are still many labels which remain ambiguous. One such example is `SL:SOURCE`; this could refer to a travel source or messaging source, but without seeing its exact manifestations, it is challenging to fully grasp its meaning. This motivates us to explore **example priming**: augmenting scenario representations with randomly sampled, dataset-specific slot values. This can help our model further narrow down the set of spans each slot maps to during parsing. Furthermore, our examples are just spans, so they are straightforward to incorporate into our representation. For example, for the slot `SL:WEATHER_TEMPERATURE_UNIT`, we can augment and contextualize its representation "slot | unit of weather temperature" with "slot | unit of weather temperature | F / C" where "F" and "C" are examples which appear in our dataset.

3.1.6 Representation Sampling

Our scenario-based retrieval task performs reasoning over a compact set of scenarios, unlike large-scale, open-domain tasks such as information retrieval and question answering which inculcate millions of documents. As such, **the chance our system overfits to a particular representation is much greater**, no matter what it is set to. So, we instead make R stochastic by uniformly sampling unique frame representations for encoding scenarios, and only using the handmade representations during inference; Table 12 enumerates the complete set of outcomes.

3.2 Filling Module

We use Span pointer model (Shrivastava et al., 2021; Nicosia et al., 2021) as the basis of our infilling model. Figure 2.A shows the how the model works. In our case, we use scenario tokens from the retrieved scenario as input tokens to decoder as shown in figure 2.B. We also tried to pass the scenario encoder output as input to the decoder to replace the discrete input to the decoder and called this **scenario fusion** as shown in figure 2.C.

Our final objective is $\mathcal{L}_{\text{filling}} = \text{NLL}(f^*, f) + \alpha\text{LS}(f)$ where LS refers to label smoothing (Pereyra et al., 2017).

4 Experiments and Results

We evaluate RAF in three settings: a high-resource setting (100,000+ training samples), low-resource setting (1-1,000 training samples), and multilingual setting (0 training samples). Hyper parameter details are described in Appendix §E. Our goal here is to show that our system both achieves competitive performance on established benchmarks and offers substantial benefits in resource-constrained environments where training samples are limited.

4.1 Datasets for Evaluation

Following prior work in task-oriented semantic parsing, we use 5 datasets for evaluation: TOP (Gupta et al., 2018), TOPv2 (Chen et al., 2020b), TOPv2-LR (Low Resource; Chen et al. (2020b)), TOPv2-DA (Domain Adaptation; Desai et al. (2021)), and MTOP (Li et al., 2021). TOP and TOPv2 are used for high-resource experiments, TOPv2-LR and TOPv2-DA are used for low-resource experiments, and MTOP is used in multilingual experiments.

---

[1] See Appendix §D for our curated intent and slot descriptions, respectively.

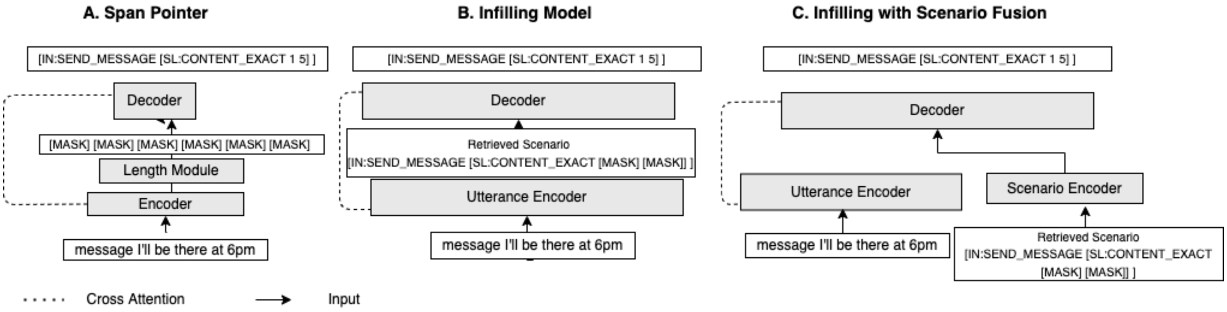

Figure 2: **Infilling Model.** A. the Span Pointer model in (Shrivastava et al., 2021). B. the Infilling model using tokens from retrieved scenario and C. the infilling model with scenario fusion where scenario encoder output is connected to the decoder directly. Note in all cases the decoder apply cross attention on the utterance encoder output.

4.2 Systems for Comparison

We compare against multiple task-oriented semantic parsing models, which cover autoregressive (AR), and non-autoregressive (NAR) training. See Aghajanyan et al. (2020); Mansimov and Zhang (2021); Babu et al. (2021); Shrivastava et al. (2021) for detailed descriptions of these models.

The autoregressive models consist of BART (Lewis et al., 2020) and RoBERTa (Liu et al., 2019), and RINE (Mansimov and Zhang, 2021), and the non-autoregressive models are RoBERTa NAR (Babu et al., 2021) and RoBERTa NAR + Span Pointer (Shrivastava et al., 2021). These models are applicable to both high-resource and low-resource settings; though, for the latter, we also add baselines from Desai et al. (2021): CopyGen (BART + copy-gen decoder) and Inventory (BART + intrinsic modeling). The multilingual setting only requires swapping RoBERTa with XLM-R (Conneau et al., 2020).

We denote our system as RAF in our experiments. Unless noted otherwise, we use RoBERTa$_{\text{BASE}}$ for the utterance encoder θ_U and secnario θ_S and a random-init, copy-gen, transformer decoder for the frame decoder θ_F. As alluded to before, we swap RoBERTa$_{\text{BASE}}$ with XLM-R$_{\text{BASE}}$ for multilingual experiments.

4.3 High-Resource Setting

First, we evaluate RAF in a high-resource setting where hundreds of thousands are samples are available for supervised training; Table 2 shows the results. RAF achieves strong results across-the-board, using both base and large pre-trained encoders: **RAF$_{\text{BASE}}$ consistently outperforms other base variants by 0.25-0.5 EM and RAF$_{\text{LARGE}}$ comparatively achieves the best results on TOPv2.**

Model	TOPv2	TOP
Type: Autoregressive Modeling (Prior)		
RoBERTa$_{\text{BASE}}$	86.62	83.17
RoBERTa$_{\text{LARGE}}$	86.25	82.24
BART$_{\text{BASE}}$	86.73	84.33
BART$_{\text{LARGE}}$	87.48	85.71
RINE$_{\text{BASE}}$	—	87.14
RINE$_{\text{LARGE}}$	—	**87.57**
Type: Non-Autoregressive Modeling (Prior)		
RoBERTa$_{\text{BASE}}$	85.78	82.37
+ Span Pointer	86.93	84.45
RoBERTa$_{\text{LARGE}}$	86.25	83.40
+ Span Pointer	87.37	85.07
Type: Scenario Modeling (Ours)		
RAF$_{\text{BASE}}$	87.11	86.00
RAF$_{\text{LARGE}}$	**87.52**	86.14

Table 2: **High-Resource Results.** Exact Match (EM) on TOPv2 (Chen et al., 2020b) and TOP (Gupta et al., 2018). We compare various semantic parsing paradigms: autoregressive, non-autoregressive, and scenario. RAF achieves strong performance on TOPv2 and TOP, illustrating its competitiveness with state-of-the-art models.

4.4 Low-Resource Setting

Having established our system is competitive in high-resource settings, we now turn towards evaluating it in low-resource settings, where training samples are not as readily available. Here, we chiefly consider two setting types: a **high difficulty** setting (TOPv2-DA) with 1-10 samples and a **medium difficulty** setting (TOPv2-LR) with 100-1,000 samples. The exact number of samples in a few-shot training subset depend on both the subset's cardinality and sampling algorithm.

Tables 3 and 4 show results on the high and medium difficulty settings, respectively. **RAF achieves competitive results in the high-difficulty setting, outperforming both CopyGen$_{\text{BASE}}$ and Inventory$_{\text{BASE}}$ by large**

	alarm	music	timer	weather
CopyGen$_{\text{BASE}}$	47.24	25.58	16.62	47.24
CopyGen$_{\text{LARGE}}$	36.91	23.84	32.64	53.08
Inventory$_{\text{BASE}}$	62.13	23.00	28.92	54.53
Inventory$_{\text{LARGE}}$	**67.25**	**38.68**	48.45	**61.77**
RAF$_{\text{BASE}}$ (ours)	62.71	35.47	**55.06**	61.05

Table 3: **High-Difficulty Low-Resource Results.** EM on the 1 SPIS split of TOPv2-DA (Desai et al., 2021). Compared to Inventory and CopyGen baselines, RAF achieves competitive performance with a fraction of parameter usage.

	Weather Domain (SPIS)					
	10	25	50	100	500	1000
Type: Autoregressive Modeling (Prior)						
RoBERTa$_{\text{BASE}}$ AR	69.71	74.90	77.02	78.69	—	86.36
BART$_{\text{BASE}}$ AR	73.34	73.35	76.58	79.16	—	86.25
RINE$_{\text{BASE}}$	—	74.53	—	—	87.80	—
RINE$_{\text{LARGE}}$	—	77.03	—	—	87.50	—
Type: Non-Autoregressive Modeling (Prior)						
RoBERTa$_{\text{BASE}}$ NAR	59.01	72.12	73.41	78.48	—	87.42
+ Span Pointer	72.03	74.74	74.85	78.14	—	**88.47**
Type: Scenario Modeling (Ours)						
RAF$_{\text{BASE}}$	**75.10**	**78.74**	**77.53**	**79.67**	**87.91**	88.17

Table 4: **Medium-Difficulty Low-Resource Results.** EM on various SPIS splits of the TOPv2 (Chen et al., 2020b) weather domain. RAF largely outperforms autoregressive and non-autoregressive models, trailing RoBERTa-Base + Span Pointer only in a high-resource split.

margins; notably, on timer, we nearly double Inventory$_{\text{BASE}}$'s exact match score. RAF also performs well in the medium-difficulty setting; our system consistently outperforms prior autoregressive, and non-autoregressive models.

4.5 Multilingual Setting

Finally, we consider a multilingual setting, where a model trained on English samples undergoes zero-shot transfer to non-English samples. In Table 5, we see that, **compared to XLM-R$_{\text{BASE}}$ NAR + Span Pointer, RAF achieves +2.3 EM averaged across all 5 non-English languages.** Upon inspecting this result more closely, RAF's performance is strong across both typologically *similar* languages (+4.8 EM on Spanish, +3.5 EM on French) and *distinct* languages (+2.7 EM on Hindi and Thai).

5 Ablations and Analysis

We perform model ablations on RAF, removing core retrieval- and filling-related components we originally introduced in §3 to better understand the design decisions. From Tables 6 and Table 7, we draw the following conclusions:

Negatives are important for accurate scenario retrieval. The metric learning objective for retrieval, as introduced in §3.1.2, precisely delineates between positive and negative samples. Our ablations show model-based negatives and identity masking are critical to achieve best performance; when removing model-based negatives, for example, retrieval accuracy drops by 3%+. We also investigate training RAF with heuristic-based negatives: a simple algorithm which finds top-k similar scenarios with string-based edit distance (Appendix C). However, heuristic-based negatives regress both retrieval-only and end-to-end approach, suggesting model-based negatives are more informative.

Sharing parameters between retrieval encoders improves quality. Our retrieval module has two encoders: an utterance encoder E_U and a scenario encoder E_S. An important design decision we make is tying both encoders' parameters together with RoBERTa (Liu et al., 2019); this improves end-to-end performance by roughly +0.6 EM. We believe that parameter sharing among retrieval encoders improves generalizability: because there are more vastly more unique utterances than scenarios, the scenario encoder may overfit to a select set of scenarios, so weight tying enables the joint optimization of both encoders.

Scenario fusion enables better end-to-end modeling. Because RAF is composed of two neural modules—the retrieval and filling modules—chaining them together arbitrarily may result in information loss. The filling module chiefly uses scenario token embeddings to reason over the retrieval module's outputs. Our results show that scenario fusion, initializing these embeddings using the scenario encoder's final state, improves upon random init by +0.77 EM and +0.65 EM-S.

Intrinsic representations improve low-resource performance. When comparing the high-level scenario representation, we see that canonical (e.g., "[IN:GET_WEATHER [SL:LOCATION]") underperforms intrinsic (e.g., "[intent | get weather [slot | location]]") by a wide margin (-4.49%) in the target domain. This implies RAF *better* understands scenarios' natural language descriptions even if they contain unseen, domain-specific terms. **Furthermore, we see leveraging all concepts (handmade, automatic, examples) achieves both competitive source and target performance.** Even though excluding handmade improves target perfor-

		Zero-Shot Evaluation					
	`en`	`en`→`es`	`en`→`fr`	`en`→`de`	`en`→`hi`	`en`→`th`	Avg
XLM-R$_{\text{BASE}}$ NAR	78.3	35.2	32.2	23.6	18.1	16.7	25.2
+ Span Pointer	**83.0**	51.2	51.4	**42.0**	29.6	27.3	40.3
RAF$_{\text{BASE}}$ (ours)	81.1	**56.0**	**54.9**	40.1	**32.1**	**30.0**	**42.6**

Table 5: **Multilingual Results.** We perform zero-shot experiments where we fine-tune a parser on English (`en`), then evaluate it a non-English language—Spanish (`es`), French (`fr`), German (`de`), Hindi (`hi`), and Thai (`th`)—without fine-tuning. Average EM (Avg) is taken over the five non-English languages. RAF outperforms XLM-R-Base + Span Pointer by +2.3% on average.

Model	EM	EM-S
Classify and Fill	84.80	87.16
RAF$_{\text{BASE}}$	**87.03**	**89.34**
- Hard Negatives	83.69	86.00
- Identity Masking	85.87	88.23
- Scenario Fusion	86.26	88.69
- Parameter sharing	86.76	89.10
- Repr. Sampling	86.70	89.05
+ Heuristic negatives	85.66	89.10

Table 6: **Model Ablations.** We assess several components of our model, individually removing them and evaluating EM (Exact Match) and EM-S (Exact Match of Scenarios, i.e., intent-slot templates without slot text) on TOPv2 (Chen et al., 2020b) validation set.

	Source Fine-Tuning		Target Fine-Tuning	
Model	EM	EM-S	EM	EM-S
Canonical Repr.	86.67	88.74	74.25	76.80
Intrinsic Repr.	**87.10**	**89.15**	78.74	81.70
- Automatic	87.02	89.06	78.92	81.80
- Handmade	86.85	88.87	**79.27**	**82.29**
- Examples	86.91	88.90	78.25	80.89

Table 7: Scenario representation ablation, where the target domain is a 25 SPIS split of the TOPv2 (Chen et al., 2020b) weather. Following the typical few-shot fine-tuning methodology, we perform source fine-tuning on all domains except weather and reminder, then perform target fine-tuning on a specific split.

mance (+0.53%), it regresses source performance (-0.28%), suggesting sampling all representations is more generalizable.

Runtime Latency Empirically we find that RAF retains the runtime latency of Span Pointer, due to it's non-autoregressive decoding nature despite leveraging the retrieval module. We find that the difference is within 3ms P99 and significantly faster than the autoregressive counter part (189ms). We report the full experiment details in A.2.

Interpretablity RAF offers a more interpretable modeling paradigm Due to (1) RAF encoding utterances and scenarios into a joint embedding space which we can directly visualize. We present two case studies leveraging these visualizations: domain development (B.1) and error analysis (B.2). (2) RAF retains modularity of components to isolate retrieval vs filling issues. In A.1 we show the comparisons of retrieval vs filling to highlight potential of each module, in particular on the TOPv2 eval dataset, oracle retrieval improves performance +9.5% where oracle filling improves performance +2.3% indicating the importance of retrieval.

5.1 Extra-Scenario Generalization

A core difference between scenario-based and non-scenario-based (seq2seq; autoregressive or non-autoregressive) models is that scenario-based models "know" of all scenarios beforehand, while seq2seq models do not, and therefore have to purely rely on generalization. We further quantify the impact that this has by dividing overall EM using two groups: (1) Known vs. Unknown - i.e scenarios in the training dataset vs. scenarios only in the test dataset and (2) In-Domain vs. Out-of-Domain - scenarios with a supported intent vs. unsupported intent (e.g., `IN:UNSUPPORTED_*`).

From the results in Table 8, we draw a couple of conclusions. First on Unknown EM, even though Span pointer, BART models are capable of generating novel scenarios not part of the train set they do so poorly. RAF does much better on this given the caveat that it adds the novel scenarios to its frame index beforehand but it hasn't seen any paired utterance to them. Second, RAF outperforms on In-Domain EM but underperforms on Out-of-Domain EM. Because RAF leverages intrinsic descriptions of scenarios, the word "unsupported" may not precisely capture what it means for an utterance to be in- vs. out-of-domain.

6 Related Work

Scaling Semantic Parsing A critical theme in semantic parsing is reducing data requirements to stand up new domains and scenarios. Existing works rely on leveraging large language models such as BART (Lewis et al., 2020) with augmenta-

Model	EM	Known EM	Unknown EM	ID EM	OOD EM
RAF_{BASE}	**87.14**	88.30	**59.96**	**88.67**	44.11
$\text{SpanPointer}_{\text{BASE}}$	86.76	**88.50**	46.20	88.07	**49.70**
$\text{BART}_{\text{BASE}}$	86.72	88.33	49.15	88.03	49.69

Table 8: Comparing EM on Known vs. Unknown and In-Domain (ID) vs. Out-of-Domain (OD) frames. RAF performs better on unknown frames, but struggles with out-of-domain frames.

tions for scaling. In particular Chen et al. (2020b) introduce a meta-learning approach to improve domain scaling in the low-resource setting. Other works such as (Liu et al., 2021; Zhu et al., 2020; Mansimov and Zhang, 2021) aim to improve scaling through new decoding formulations. Desai et al. (2021) introduce the concept of **intrinsic modeling** where we provide a human-readable version of the semantic parsing ontology as context to encoding to improve few-shot generalization.

Our work leverages the intrinsic modeling paradigm by building a function R to convert each intent-slot scenario into a readable representation via intent slot descriptions and example priming. Furthermore, our bi-encoder based retrieval setup allows us to inject additional context into each scenario and cache it to an index in order to retain inference efficiency.

Retrieval Based Semantic Parsing Finally, there has been a recent trend towards dense retrieval in various NLP domains such as machine translation (Cai et al., 2021), question answering (Karpukhin et al., 2020), text generation (Cai et al., 2019) and language modeling (Borgeaud et al., 2018). Recent works also introduce retrieval-based semantic parsing: RetroNLU (Gupta et al., 2021) and CASPER (Pasupat et al., 2021) both leverage a retrieval step to provide examples as context to seq2seq models.

Our approach differs in two ways: (1) We phrase our problem as utterance-to-scenario retrieval rather than utterance-to-utterance retrieval. This allows us to look into supporting new scenarios with minimal-to-no-data required for retrieval. (2) Prior work leverage a separate module (Pasupat et al., 2021) or separate iteration (Gupta et al., 2021) for retrieval. We conduct our retrieval after encoding but prior to decoding as an intermediate step for non-autoregressive parsing. This allows our model to retain similar inference speed to one shot non-autoregressive decoding despite leveraging retrieval.

7 Conclusion

In this paper, we tackle scenario-based semantic parsing with retrieve-and-fill (RAF), a coarse-to-fine model which (a) retrieves a scenario with the best alignment to an utterance and (b) fills the scenario with utterance spans in leaf positions. Experiments show our model achieves strong results in high-resource, low-resource, and multilingual settings. The modular nature of our architecture also lends itself well to interpretability and debuggability; we perform several case studies uncovering the inner-workings of our approach.

8 Limitations

Although RAF has shown promising results on task oriented parsing, we identify the following limitations.

Use of Scenario Index Critically we introduce the scenario based parsing task, a problem where we assume knowledge of all possible scenarios across train/test/eval. This new task is inspired by how domain development usually happens 1)Define scenarios 2) collect and annotate utterances. While powerful and applicable when grammars and downstream applications can provide a scenario index, it prohibits generating novel scenarios or intent/slot combination that have not been indexed, where as prior seq2seq approaches are capable of this. We argue that such generalization is not a priority in pipelined task oriented assistant systems as the downstream application usually handles a set of pre-defined scenarios. Refer to §5.1 for more analysis/commentary on this.

Training Cost RAF has a high training cost due to the use of dense retrieval models and model based negative sampling. While inference is cheap due to a cached index and non-autoregressive decoding. During training, we must compute forward/backward over 2 large encoders (utterance encoder/scenario encoder) which uses significant memory and prohibits larger batch sizes. Additionally, model based negative samples requires two training iterations: first with in-batch negatives, second using the first stage model to identify hard negative samples from the model.

A Analysis

A.1 Retrieval vs. Filling

We now turn towards better understanding the aspects our model struggles with. Because RAF jointly optimizes both the retrieval and filling modules, one question we pose is whether the retrieval or filling task is more difficult. We create three versions of RAF: (1) standard retrieval + standard filling, (2) oracle retrieval + standard filling, and (3) standard retrieval + oracle filling. By comparing models (1), (2), and (3), we can judge the relative difficulty of each task.

We begin by evaluating these models in a high-resource setting; on the TOPv2 eval dataset, the standard model gets 87.03%, retrieval oracle gets 96.56%, and filling oracle gets 89.34%. **Here, the gap between models (1)-(2) is +9.53%, while the gap between models (1)-(3) is +2.31%, indicating the retrieval module is the main performance bottleneck.** We also perform experiments in low-resource and multilingual settings, displaying results in Tables 9 and 10, respectively. These results also confirm the same trend: in both settings, the retrieval oracle achieves the best performance, notably achieving +18.3% averaged across 5 multilingual transfer experiments.

Despite retrieval having the most room for improvement, we also see some evidence filling struggles in certain multilingual transfer cases; for example, providing gold spans can improve en→th transfer by +16.7%. As such, there is ample opportunity for optimizing the retrieval and filling modules in future work.

A.2 Runtime Latency

We compare the latency of the non-autoregressive Span Pointer Networks against RAF to show that there is minimal degradation, despite the improved generalization from RAF. In order to measure latency, we measure wall clock time (ms) of the SpanPointer$_{\text{BASE}}$, RAF$_{\text{BASE}}$, and Autoregressive$_{\text{BASE}}$, all models use a 12-layer RoBERTa$_{\text{BASE}}$ encoder with a 1 layer transformer decoder. We run the benchmark on the TOPv2 source domain evaluation set (17k utterances across 6 domains) on a Tesla V100 GPU, using batch size of 1. In table 11 we report P50, P90, and P99. Our results find that there is less than a 3ms in latency increase in P99 for RAF compared to SpanPointer due to the non-autoregressive nature, despite leveraging our retrieval based model in RAF, and both models are significantly faster than the autoregressive counter part.

B Visualizations

Because RAF encodes utterances and scenarios into a joint embedding space, we can directly visualize this space to further understand our models' inner-workings. We present two case studies: domain development (§B.1) and error analysis (§B.2).

B.1 Domain Development

Figure 3 presents an example of performing domain development on the weather domain. Here, we train RAF with 4 dataset sizes (0 SPIS, 10 SPIS, 25 SPIS, and 1,000 SPIS) to simulate zero-shot, few-shot, low-resource, and high-resource settings, respectively. Each utterance (from the high-resource split) is projected using an utterance encoder and colored according to its gold scenario. Interestingly, the zero-shot setting has multiple, apparent clusters, but the overall performance is poor given many scenarios overlap with each other. The clusters spread further apart as the dataset size increases, suggesting the scenarios become more well-defined.

B.2 Error Analysis

While we have demonstrated how RAF refines the utterance-scenario space as we increase dataset size, we now dive deeper into how each space can be used to further analyze domain semantics. In figure 4, using our high-resource-trained RAF model, we create multiple scenario spaces: each utterance is projected using an utterance encoder and colored according to its predicted frame. We use these scenario spaces in several debugging exercises:

- **Slot Ambiguity:** In Figure 4 (a), we investigate the scenario `[IN:CREATE_ALARM [SL:ALARM_NAME ] [SL:DATE_TIME ]`. Here, we notice a cluster of predictions with the frame `[IN:CREATE_ALARM [SL:DATE_TIME ]` missing the `[SL:ALARM_NAME ]`. These map to utterances such as "I want to wake up at 7 am" where the annotation has "wake up" is `SL:ALARM_NAME`; however, our model does not identify this. There are other examples, such as "wake me up at 7 am", which are annotated without `SL:ALARM_NAME`, leading to ambiguity of whether or not "wake up" is an alarm name.

- **Incorrect Annotations:** In Figure 4 (b), we investigate the scenario `[IN:PLAY_MUSIC`

	Weather Domain (SPIS)							
	0	10	25	50	100	500	1000	Avg
RAF$_{\text{BASE}}$								
Standard Retrieval + Standard Filling	26.19	75.10	78.74	77.53	79.67	87.91	88.17	73.33
Oracle Retrieval + Standard Filling	**81.68**	**90.43**	**92.13**	**91.97**	**93.35**	**95.74**	**96.27**	**91.65**
Standard Retrieval + Oracle Filling	27.67	77.84	81.70	79.92	81.78	89.88	90.44	75.60

Table 9: Evaluating whether retrieval or filling is the most challenging components of RAF in low-resource settings. We fine-tune several variants of RAF, using either a standard / oracle retriever and a standard / oracle filler, on various SPIS splits of the TOPv2 (Chen et al., 2020b) weather domain. RAF with oracle retrieval achieves the best performance, suggesting utterance→scenario retrieval is the most difficult piece to model.

		Zero-Shot Evaluation					
	en	en→es	en→fr	en→de	en→hi	en→th	Avg
RAF$_{\text{BASE}}$							
Standard Retrieval + Standard Filling	81.1	56.0	54.9	40.1	32.1	30.0	42.6
Oracle Retrieval + Standard Filling	**91.0**	**68.9**	**71.6**	**67.5**	**47.5**	**48.9**	**60.9**
Standard Retrieval + Oracle Filling	83.8	66.5	62.8	45.5	40.2	46.7	52.3

Table 10: Evaluating whether retrieval or filling is the most challenging components of RAF in low-resource settings. See Table 9 for a description of our methodology; we use MTOP (Li et al., 2021) for evaluation instead.

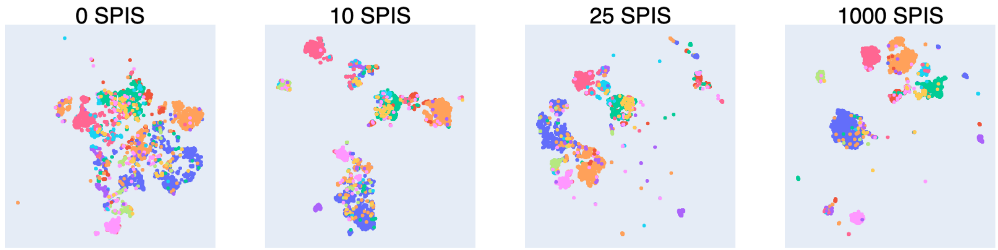

Figure 3: Visualizing the semantic space for the weather domain as the model is trained on more and more data. We visualize the index prior to any training (0 SPIS) to low-resource (10, 25 SPIS) and high resource (1000 SPIS). The graphs are TSNE projections of the utterance vectors used for retrieval color coded by the scenario each utterance belongs to.

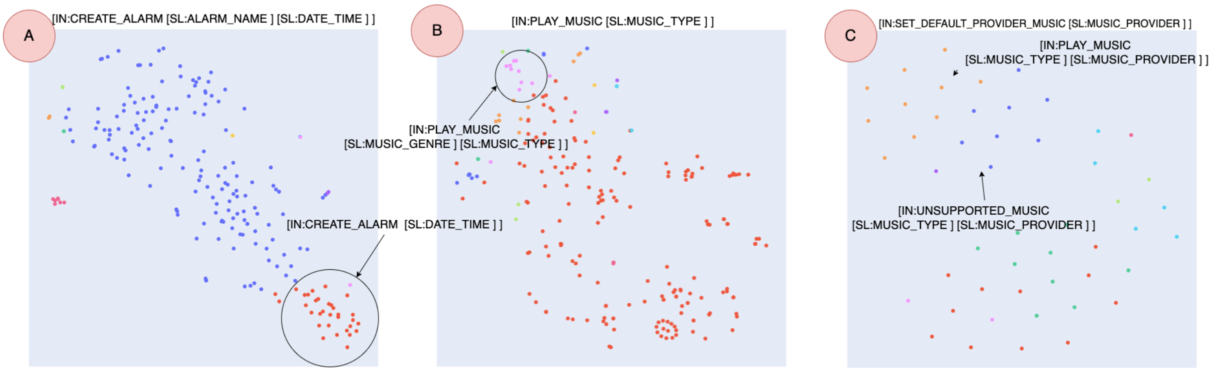

Figure 4: Depicting scenario visualizations, where each is a TSNE projection of utterances belonging to the specified scenario color coded by the predicted scenario. (A) covers the scenario `[IN:CREATE_ALARM [SL:ALARM_NAME ] [SL:DATE_TIME ]` showing a case of ambiguity of alarm names. (B) covers the scenario `[IN:PLAY_MUSIC [SL:MUSIC_TYPE ]` where annotations are missing the slot "music type". (C) covers the scenario `[IN:SET_DEFAULT_PROVIDER_MUSIC [SL:MUSIC_PROVIDER ]` showing how our model requires more support here as the predictions for this scenario span OOD and music domain.

Model	P50	P90	P99
SpanPointer$_{\text{BASE}}$	28.30	29.62	37.78
RAF$_{\text{BASE}}$	28.92	31.40	39.94
Autoregressive$_{\text{BASE}}$	90.29	155.11	228.92

Table 11: Runtime latency (ms) comparison of SpanPointer$_{\text{BASE}}$, RAF$_{\text{BASE}}$, and Autoregressive$_{\text{BASE}}$ using batch size 1 on the TOPv2 source evaluation set.

  `[SL:MUSIC_TYPE ]`. Here, we notice a cluster of predictions with the frame `[IN:PLAY_MUSIC [SL:MUSIC_GENRE ] [SL:MUSIC_TYPE ]` adding the `[SL:MUSIC_GENRE ]`. These map to utterances such as "Play 1960s music" where here the annotation only has "music" as `SL:MUSIC_TYPE`, but our model predicts "1960s" as `SL:MUSIC_GENRE`. We believe this is an incorrect annotation in this cluster.

- **Underfitting:** In Figure 4 (c), we investigate the scenario `[IN:SET_DEFAULT_PROVIDER_MUSIC [SL:MUSIC_PROVIDER ]`. This cluster is highly diverse, consisting of predictions from other music intents (e.g., `IN:PLAY_MUSIC`) and out-of-domain intents (e.g., `IN:UNSUPPORTED_MUSIC`). This scenario may need more data in order to be more properly defined.

C Heuristic negatives

In order to understand the importance of model based hard negatives, we develop a simple heuristic to curate a set of hard negative scenarios for each gold scenario. Our heuristic involves selecting the top-N scenarios that share the top level intent but have the lowest Levenshtein edit distance (Levenshtein, 1966) compared to the gold scenario. The full algorithm is described in Algorithm 1.

In §5 and Table 6 we present the full results depicting the importance of model based negative sampling. We show that while our heuristic improves on top of no hard negatives (in-batch negatives only), it still lags behind model based hard negatives (-1.37%).

D Intrinsic Descriptions

In table 12 we provide brief examples of the various representation functions used in RAF training.

Algorithm 1 Heuristic-based negative sampling via edit distance.

```
procedure EDIT DISTANCE NEGATIVES
    S ← all scenarios
    s* ← current scenario
    S_same intent ← Scenarios with the same top level intent as Si
    heap ← min heap of score and structure
    for $S_i$ ∈ S_same intent do
        score ← LevenshteinDistance(s*, $S_i$)
        heappush(heap, score, $S_i$)
    return heap
```

In tables 13, 14, 15, and 16 we present the intrinsic hand made descriptions used for each intent/slot on TOPv2 (Chen et al., 2020b) and MTOP (Li et al., 2021) respectively. §3.1.3 describes the various scenario representations used in full detail.

E Hyperparameters

In this section we describe the hyper parameters for training our various RAF models.

Architecture Parameters. For our RAF architectures we leverage a shared RoBERTa (Liu et al., 2019) or XLM-R (Conneau et al., 2020) encoder for both the utterance and scenario encoders. We augment each of these encoders with an additional projection layer with a hidden dimension of 768 (base models) or 1024 (large models). For our span pointer decoder we leverage a 1 layer transformer decoder with the same hidden dimension as the respective encoder (1L, 768/1024H, 16/24A).

Optimization Parameters. We train our models with the Adam (Kingma and Ba, 2015) optimizer along with a warmup and linear decay. We train our models across 8 GPUs with 32GB memory each. Additionally we optionally augment our models with the R3F loss (Aghajanyan et al., 2021) based on validation set tuning in each setting. To determine hyperparameters, we conduct hyperparameter sweeps with 56 iterations each. The hyperparameters for the high resource runs on TOPv2 (Chen et al., 2020b) are described in Table 17.

R Type	R Example
`type-only`	`[ intent [ slot ] ]`
`automatic-span`	`[ add time timer [ measurement unit ] ]`
`automatic-type-span`	`[ intent | add time timer [ slot | measurement unit ] ]`
`automatic-type-span-exs`	`[ intent | add time timer [ slot | measurement unit | sec / min / hr ] ]`
`curated-span`	`[ add time to timer [ unit of measurement ] ]`
`curated-type-span`	`[ intent | add time to timer [ slot | unit of measurement ] ]`
`curated-type-span-exs`	`[ intent | add time to timer [ slot | unit of measurement | sec / min / hr ] ]`

Table 12: List of intrinsic representations used for encoding scenarios in RAF.

Intent Token	Description
IN:ADD_TIME_TIMER	add time to timer
IN:ADD_TO_PLAYLIST_MUSIC	add music to playlist
IN:CANCEL_MESSAGE	cancel message
IN:CREATE_ALARM	create alarm
IN:CREATE_PLAYLIST_MUSIC	create playlist music
IN:CREATE_REMINDER	create reminder
IN:CREATE_TIMER	create timer
IN:DELETE_ALARM	delete alarm
IN:DELETE_REMINDER	delete reminder
IN:DELETE_TIMER	delete timer
IN:DISLIKE_MUSIC	dislike music
IN:GET_ALARM	get alarm
IN:GET_BIRTHDAY	get birthday
IN:GET_CONTACT	get contact
IN:GET_DIRECTIONS	get directions
IN:GET_DISTANCE	get distance between locations
IN:GET_ESTIMATED_ARRIVAL	get estimated arrival time
IN:GET_ESTIMATED_DEPARTURE	get estimated departure time
IN:GET_ESTIMATED_DURATION	get estimated duration of travel
IN:GET_EVENT	get event
IN:GET_EVENT_ATTENDEE	get event attendee
IN:GET_EVENT_ATTENDEE_AMOUNT	get amount of event attendees

Document Flattening: Beyond Concatenating Context for Document-Level Neural Machine Translation

Minghao Wu♡ **George Foster**♠ **Lizhen Qu**♡ **Gholamreza Haffari**♡

Abstract

Existing work in document-level neural machine translation commonly concatenates several consecutive sentences as a *pseudo-document*, and then learns inter-sentential dependencies. This strategy limits the model's ability to leverage information from distant context. We overcome this limitation with a novel Document Flattening (DocFlat) technique that integrates Flat-Batch Attention (FBA) and Neural Context Gate (NCG) into Transformer model to utilize information beyond the pseudo-document boundaries. FBA allows the model to attend to all the positions in the batch and learns the relationships between positions explicitly and NCG identifies the useful information from the distant context. We conduct comprehensive experiments and analyses on three benchmark datasets for English-German translation, and validate the effectiveness of two variants of DocFlat. Empirical results show that our approach outperforms strong baselines with statistical significance on BLEU, COMET and accuracy on the contrastive test set. The analyses highlight that DocFlat is highly effective in capturing the long-range information.

1 Introduction

Remarkable progress has been made in neural machine translation (NMT) (Sutskever et al., 2014; Vaswani et al., 2017; Chen et al., 2018), yet human translation still clearly outperforms NMT at the document level (Läubli et al., 2018; Freitag et al., 2021), because current sentence-level NMT systems ignore the inter-sentential relationships. To narrow this gap, numerous document-level NMT (DocNMT) approaches have been proposed in recent years to improve the context awareness by incorporating the contextual information during the translation (Tiedemann and Scherrer, 2017; Maruf and Haffari, 2018; Wong et al., 2020).

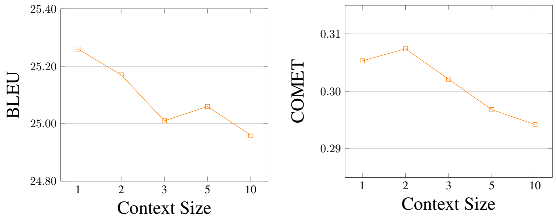

Figure 1: The change of BLEU (left) and COMET (right) given by Doc2Doc on `TED` with regard to the context size of *pseudo-document* (in sentences) based on the experimental setup described in Section 4.1.

Existing DocNMT systems commonly concatenate several consecutive sentences to form a *pseudo-document*, instead of processing the *entire document* (Zhang et al., 2018b; Voita et al., 2019; Junczys-Dowmunt, 2019; Fernandes et al., 2021). One typical pseudo-document contains the *current sentence* to be translated and the *surrronding context*. Intuitively, larger context should result in better performance. In our preliminary study, the model performance does not always grow as the context size increases as shown in Figure 1. Liu et al. (2020) and Bao et al. (2021) also observe that Transformer's performance declines with longer inputs. We refer to this phenomenon as the *quality saturation problem* (Glaser and Strauss, 1967). Therefore, such formation of pseudo-document limits the DocNMT systems to leverage the information from a relatively small context. Consequently, once the entire original document is segmented into several pseudo-documents for reducing the sequence length, the information out of the pseudo-document's scope is no longer accessible to the current sentence. Therefore, a natural research question to ask is that, *is there a more effective way to model the parallel documents in DocNMT?*

In this work, we seek DocNMT approaches that could better expand the context scope and improve the corresponding translation performance. Instead of directly training DocNMT system on the entire document, we propose to store the document as multiple pseudo-documents in a single batch and

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 448–462
May 2-6, 2023 ©2023 Association for Computational Linguistics

optimize the DocNMT models by leveraging the inter-pseudo-document relationships at the batch level. Inspired by Kossen et al. (2021), we propose a Document Flattening (DocFlat) technique that integrates Flat-Batch Attention (FBA) and Neural Context Gate (NCG) into the Transformer model (Vaswani et al., 2017). FBA flattens all the current sentences in the batch with the original order into a sequence along the temporal dimension. It then applies the attention mechanism to the flattened sequence. The goal of this design is to preserve the linguistic structure of documents and expand the scope of context by explicitly learning the pseudo-document relationships. As there is both supportive and noisy information in the longer context, we introduce NCG, a simple feed-forward network, to identify the usefulness of contextual information and filter out the noise. With the combination of FBA and NCG, DocFlat effectively captures the information in the distant context. To the best of our knowledge, Morishita et al. (2021) propose mini-batch embedding (MBE), which is the only close work to ours. They compute the average representation for all the source tokens in the batch and prepend it to the source and target pseudo-documents. The compressed representation ignores the linguistic structure of documents, providing limited contextual information.

Our contributions are summarized as follows. Firstly, we propose a novel approach DocFlat that allows the model to attend the content beyond the pseudo-document boundaries using FBA and NCG. Secondly, we demonstrate that DocFlat outperforms strong baselines with statistical significance, in terms of BLEU, COMET and accuracy on the contrastive test set, on three DocNMT benchmark datasets, including `TED`, `News Commentary` and `Europarl`. Thirdly, we conduct comprehensive analyses to understand the effectiveness of DocFlat. The analyses highlight that DocFlat is highly effective in capturing the distant context.

2 Preliminaries

Sentence-level NMT (SentNMT) The sentence-level NMT model neglects the inter-sentential dependencies between the current sentence and its context. Its probability of translation is defined as:

$$P(\boldsymbol{y}_i|\boldsymbol{x}_i) = \prod_{t=1}^{d} P(y_{i,t}|\boldsymbol{y}_{i,<t}, \boldsymbol{x}_i), \quad (1)$$

where $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ are the i-th source and target training sentence, $y_{i,t}$ denotes the t-th token in $\boldsymbol{y}_i$ and d is the sentence length of $\boldsymbol{y}_i$.

Document-level NMT (DocNMT) Given a document pair $\{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^{M}$ where we denote the aligned sentence pair as $\boldsymbol{x}_i$ and $\boldsymbol{y}_i$ and M is the length of document in sentences, the i-th pseudo-document pair $\boldsymbol{X}_i$ and $\boldsymbol{Y}_i$ can be defined as:

$$\begin{aligned} \boldsymbol{X}_i &= \text{Concat}([\boldsymbol{x}_{i-c^-}, \ldots, \boldsymbol{x}_i, \ldots, \boldsymbol{x}_{i+c^+}]), \\ \boldsymbol{Y}_i &= \text{Concat}([\boldsymbol{y}_{i-c^-}, \ldots, \boldsymbol{y}_i, \ldots, \boldsymbol{y}_{i+c^+}]), \end{aligned} \quad (2)$$

where c^- is the context size before the current sentence and c^+ is the context size after the current sentence. The translation probability of target *current* sentence $\boldsymbol{y}_i$ in the target pseudo-document $\boldsymbol{Y}_i$ given the source pseudo-document $\boldsymbol{X}_i$ in DocNMT can be written as:

$$P(\boldsymbol{y}_i|\boldsymbol{x}_i, \boldsymbol{C}_{-i}) = \prod_{t=1}^{d} P(y_{i,t}|\boldsymbol{y}_{i,<t}, \boldsymbol{x}_i, \boldsymbol{C}_{-i}), \quad (3)$$

where $\boldsymbol{C}_{-i}$ is the collection of all the sentences in the pseudo-document pair except $(\boldsymbol{x}_i, \boldsymbol{y}_i)$, and $\boldsymbol{x}_i$ is the source *current* sentence. We do not consider the context after the current sentence in this work, so c^+ is 0.

3 Document Flattening

In this section, we firstly describe the overview of DocFlat (Section 3.1). We then introduce DocFlat's core components, Flat-Batch Attention (FBA; Section 3.2) and Neural Context Gate (NCG; Section 3.3). Finally, we discuss the practical considerations (Section 3.4 and Section 3.5) of DocFlat along with a concrete example.

3.1 Overview of DocFlat

We present the overall architecture of DocFlat in Figure 2. Given a sequence-to-sequence Transformer with L encoder layers and L decoder layers, we apply the FBA and NCG to the input word embeddings with the residual connection and Layer Normalization, instead of directly feeding the embeddings into either encoder or decoder. DocFlat's translation probability of the i-th target current sentence $\boldsymbol{y}_i$ of the original document in the i-th target pseudo-document $\boldsymbol{Y}_i$ given the i-th source pseudo-document $\boldsymbol{X}_i$ in the batch

$\boldsymbol{B} = \{(\boldsymbol{X}_j, \boldsymbol{Y}_j)\}_{j=1}^{n}$, where n is the batch size, is defined as:

$$P(\boldsymbol{y}_i|\boldsymbol{x}_i, \boldsymbol{C}_{-i}, \boldsymbol{B}_{-i}) = \prod_{t=1}^{d} P(y_{i,t}|\boldsymbol{y}_{i,<t}, \boldsymbol{x}_i, \boldsymbol{C}_{-i}, \boldsymbol{B}_{-i}), \tag{4}$$

where $\boldsymbol{C}_{-i}$ is defined as in Equation 3 and $\boldsymbol{B}_{-i}$ is the collection of all the current sentences in the batch except $(\boldsymbol{x}_i, \boldsymbol{y}_i)$. We categorize the context for the current sentence into two groups, the global context (GC) from other pseudo-documents $\boldsymbol{B}_{-i}$ and the local context (LC) from its own pseudo-document $\boldsymbol{C}_{-i}$ (See Figure 3).

3.2 FLAT-BATCH ATTENTION

Multi-Head Self-Attention (MHSA) Scaled dot-product attention is the core mechanism of Transformer model with the inputs of query $\boldsymbol{Q}$, key $\boldsymbol{K}$ and $\boldsymbol{V}$ (Vaswani et al., 2017). The attention mechanism computes the attention weights by comparing queries $\boldsymbol{Q}$ with keys $\boldsymbol{K}$ and then updates the representations of queries by computing the weighted sum of values $\boldsymbol{V}$ with the attention weights, which is described as follows:

$$\text{Attn}(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \text{softmax}(\frac{\boldsymbol{Q}\boldsymbol{K}^\top}{\sqrt{e}})\boldsymbol{V}, \tag{5}$$

where e is the hidden state dimension. Multi-head self-attention (MHSA) then allows the model to jointly attend to information from different hidden subspaces by concatenating a sequence of independent attention heads as follows:

$$\text{MHSA}(\boldsymbol{Q}, \boldsymbol{K}, \boldsymbol{V}) = \text{Concat}(\text{head}_1, \ldots, \text{head}_k), \tag{6}$$

where head_j is the scaled dot-product attention in Equation 5 with independent parameters and $j \in \{1, \ldots, k\}$ for each head j.

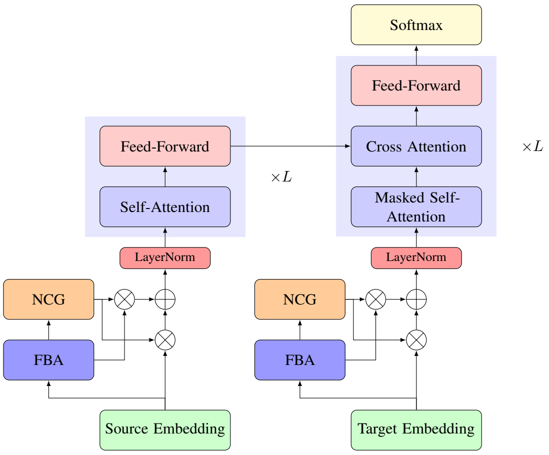

Figure 2: The model architecture of DOCFLAT. $\otimes$ denotes the element-wise multiplication. $\oplus$ denotes the element-wise addition. More details are in Section 3.

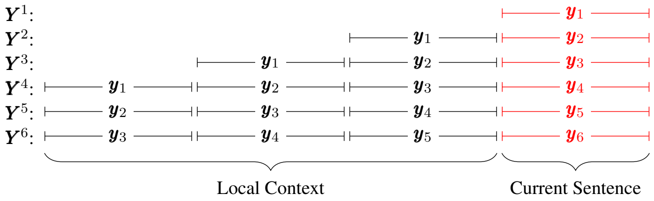
FLAT-BATCH ATTENTION (FBA) To leverage the contextual information beyond the pseudo-document boundaries, we propose FLAT-BATCH ATTENTION (FBA). It explicitly transforms the stacked instances in the batch to a single flattened sequence of tokens as shown in Figure 3. Given a batch of hidden representations $\boldsymbol{H} \in \mathbb{R}^{n \times d \times e}$ consisting of n instances padded to the length of d with the hidden dimension of e, FBA operates as follows:

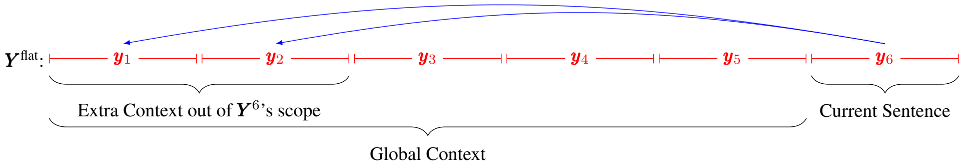
$$\begin{aligned}
\hat{\boldsymbol{H}}_{\text{flat}} &= \text{Flatten}(\boldsymbol{H}) \in \mathbb{R}^{(n \times d) \times e}, \\
\hat{\boldsymbol{H}}_{\text{mhsa}} &= \text{MHSA}(\hat{\boldsymbol{H}}_{\text{flat}}, \hat{\boldsymbol{H}}_{\text{flat}}, \hat{\boldsymbol{H}}_{\text{flat}}), \\
\hat{\boldsymbol{H}}_{\text{rsh}} &= \text{Reshape}(\hat{\boldsymbol{H}}_{\text{mhsa}}) \in \mathbb{R}^{n \times d \times e}, \\
\hat{\boldsymbol{H}} &= \text{LN}((1 - \boldsymbol{g}) \otimes \boldsymbol{H} + \boldsymbol{g} \otimes \hat{\boldsymbol{H}}_{\text{rsh}}).
\end{aligned} \tag{7}$$

As shown in Equation 7, we first flatten $\boldsymbol{H} \in \mathbb{R}^{n \times d \times e}$ to $\hat{\boldsymbol{H}}_{\text{flat}} \in \mathbb{R}^{(n \times d) \times e}$, where $(n \times d)$ indicates the flattened sequence length. The $\hat{\boldsymbol{H}}_{\text{flat}}$ is then fed into a MHSA layer and reshaped back to $\hat{\boldsymbol{H}}_{\text{rsh}} \in \mathbb{R}^{n \times d \times e}$. We then add a residual connection with $\boldsymbol{g}$ given by NCG $\boldsymbol{\psi}$ followed by a sigmoid function σ and apply the Layer Normalization (LN; Ba et al., 2016) following the reshape operation. $\otimes$ denotes the element-wise multiplication. We discuss the details of NCG in Section 3.3. Note that FBA at the decoder side is associated with a causal mask to preserve the auto-regressive property. By attending to all the other current sentences in the batch, FBA effectively allows the current sentences to access a much larger context than the self-attention on the pseudo-documents. In addition, this does not increase the input length of each instance, preventing the quality saturation problem as shown in Figure 1.

Complexity Given a Transformer model with L encoder layers and L decoder layers, suppose the average sentence length is n, the pseudo-document contains c consecutive sentences, and the batch size is b. The complexity of self-attention layer in the concatenation-based DOC2DOC is $\mathcal{O}(L(cn)^2)$. The extra complexity introduced by FBA is $\mathcal{O}((bn)^2)$. Lc^2 and b^2 have the same order



(a) An example batch of pseudo-documents $\boldsymbol{B}_{\text{tgt}} = \{\boldsymbol{Y}^1, \boldsymbol{Y}^2, \boldsymbol{Y}^3, \boldsymbol{Y}^4, \boldsymbol{Y}^5, \boldsymbol{Y}^6\}$ at the target side. Each $\boldsymbol{Y}^j$ contains four consecutive sentences and $\boldsymbol{y}_i$ indicates the i-th sentence of the same original document. The segments in red indicate the current sentence of each pseudo-document.



(b) An example of the flattened sequence $\boldsymbol{Y}^{\text{flat}}$ transformed from $\boldsymbol{B}_{\text{tgt}}$ in Figure 3a with FLAT-BATCH ATTENTION. For the current sentence $\boldsymbol{y}_6$, The blue arrows indicate the extra inter-sentential attention for $\boldsymbol{y}_6$ that our approach can model. $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$ are the extra context introduced by our approach.

Figure 3: An example batch of pseudo-documents at the target side and its flattened sequence. Another example at the source side can be found at Appendix A.

of magnitude. The batch size b is set to be constant in practice and the self-attention operation in FBA is highly parallelizable, so integrating FBA into Transformer does not significantly increase the computational cost. Empirically, DOCFLAT is only 3% slower in training and 15% slower in inference, compared with DOC2DOC (See Section 4.2).

3.3 NEURAL CONTEXT GATE

The distant context can contain both supportive and noisy information. Supportive information can assist the translation of the current sentence, while the noise may damage the model predictions. To address this issue, we introduce a novel NEURAL CONTEXT GATE (NCG) to automatically identify the context usefulness and control the information flow from the distant context.

In this work, NCG $\boldsymbol{\psi}$ is a single-layer element-wise feed-forward neural network followed by a sigmoid function σ. Given a batch of hidden representations $\boldsymbol{H}$, the operations are defined as follows:

$$\begin{aligned} \boldsymbol{g} &= \sigma(\boldsymbol{\psi}(\text{FBA}(\boldsymbol{H}))), \\ \boldsymbol{H}^o &= (1-\boldsymbol{g}) \otimes \boldsymbol{H} + \boldsymbol{g} \otimes \text{FBA}(\boldsymbol{H}), \end{aligned} \tag{8}$$

where $\boldsymbol{g}$ is the information gate given by NCG $\boldsymbol{\psi}$ and the sigmoid function σ, $\boldsymbol{H}^o$ is output of the residual connection and $\otimes$ denotes the element-wise multiplication. The values of $\boldsymbol{g}$ are continuous, so we denote DOCFLAT with NCG described in Equation 8 as DOCFLAT$_\text{C}$.

However, the continuous gate may result in the noise leakage. In a long document, the noise at different positions may accumulate, even if they are only associated with very small gating values. The accumulated noise can make a substantial negative impact on the model predictions. Hence, we propose the discrete NCG as follows:

$$\begin{aligned} \boldsymbol{g}_\text{D} &= \mathbb{1}_\gamma(\sigma(\boldsymbol{\psi}(\text{FBA}(\boldsymbol{H})))), \\ \boldsymbol{H}^o &= (1-\boldsymbol{g}_\text{D}) \otimes \boldsymbol{H} + \boldsymbol{g}_\text{D} \otimes \text{FBA}(\boldsymbol{H}), \end{aligned} \tag{9}$$

where $\mathbb{1}_\gamma(\cdot)$ is indicator function defined as:

$$\mathbb{1}_\gamma(g) = \begin{cases} 1 & \text{if } g \geq \gamma, \\ 0 & \text{otherwise}, \end{cases} \tag{10}$$

where γ is the threshold for binarizing the gating values. We denote DOCFLAT with the discrete NCG in Equation 9 as DOCFLAT$_\text{D}$ and set $\gamma = 0.5$ in this work. We expect DOCFLAT$_\text{D}$ is more robust against the noise in the context.

3.4 Data Shuffling

DOCFLAT aims to leverage the distant context with FBA by flattening a batch of sequences into a single sequence. As the ordering information among sentences is critical in DocNMT, we do not shuffle the pseudo-documents during the training and inference to preserve the linguistic structure of the original document. For each sentence, we replace the `<BOS>` symbol with its global index i in the document to preserve the ordering information. Figure 3a is an example at the target side to demonstrate how the pseudo-documents in the batch is

	Train	Valid	Test
`TED`	$204.4K/1.7K$	$8.9K/93$	$2.2K/23$
`News`	$242.4K/6.1K$	$2.3K/81$	$3.2K/155$
`Europarl`	$1.8M/117.9K$	$3.8K/240$	$5.5K/360$

Table 1: The number of sentences/documents of each split of the parallel corpora.

organized in this work. Figure 3b demonstrates how FBA flattens a batch of pseudo-documents. Since the pseudo-documents are not shuffled, $\boldsymbol{y}_6$ can attend to $\boldsymbol{y}_1$ and $\boldsymbol{y}_2$ which are not in the pseudo-document $\boldsymbol{Y}^6$. We apply the causal mask to FBA at the decoder side for preserving the auto-regressive property. Note that the pseudo-documents in a batch are mostly from the same original document. The batches crossing the document boundaries are relatively rare and have little effect on performance in our preliminary study.

3.5 Inference

We discuss the batch inference of DOCFLAT in this section. At the encoder side, each source current sentence can attend to its own local context (LC) and all other source current sentence as the global context (GC) in the batch during the inference, as it is at the training stage. At the decoder side, all the target current sentences are translated simultaneously, so each target current sentence can attend to its own LC and partially translated target GC. For example, all the target current sentences in Figure 3a are translated simultaneously during the inference. $\boldsymbol{y}_6$ is conditioned on its own LC, $\boldsymbol{y}_3$, $\boldsymbol{y}_4$ and $\boldsymbol{y}_5$, and partially translated target GC. Additionally, we use the batched inference as usual and there is no overlap between batches. For example, the first batch of sentences to be translated is $\{\boldsymbol{y}_1, \cdots, \boldsymbol{y}_b\}$, and the second batch of sentences to be translated is $\{\boldsymbol{y}_{b+1}, \cdots, \boldsymbol{y}_{2b}\}$, where b is the inference batch size. For decoding, we used the iterative decoding method for decoding (Maruf and Haffari, 2018; Maruf et al., 2019). The initial translations of each sentence were generated by a SentNMT model, and then, we translate each sentence using the DOCNMT model with the translations in the first pass as the context.

4 Experiments

4.1 Setup

Datasets We conduct experiments on three benchmark datasets for English-German translation, including the small-scale datasets `TED` (Cettolo et al., 2012) and `News Commentary` (Tiedemann, 2012), and the large-scale dataset `Europarl` (Koehn, 2005). We tokenize the datasets with the Moses (Koehn et al., 2007) and apply BPE (Sennrich et al., 2016b) with $32K$ merges. Data statistics can be found in Table 1. We choose up to 3 previous sentences as the local context for each source and target sentence to form the pseudo-document unless otherwise specified.

Evaluation We report the detokenized BLEU (Papineni et al., 2002) using SacreBLEU (Post, 2018) and the neural-based COMET (Rei et al., 2020) to measure the translation quality.[1] We report the results with inference batch size of 16 and beam size of 5 for all the approaches, unless otherwise specified.

Contrastive Evaluation This evaluation paradigm is proposed to evaluate the contextual awareness of DOCNMT models with an independent test set, where each test example includes one correct translation and several incorrect translations. The model is required to identify the correct translation and its overall performance is measured by micro-average *Accuracy*. In this work, we use the large-scale English-German anaphoric pronoun test set from Müller et al. (2018), containing $12K$ contrastive examples. Given the provided context, the model of interest is required to identify the translation with the correct use of pronoun from *er*, *es* and *sie* in German.

Models All the models in this work are based on the standard Transformer base (Vaswani et al., 2017). Besides the direct comparisons with prior works, we also compare DOCFLAT with several re-implemented baselines, including SENT2SENT (Vaswani et al., 2017), DOC2DOC (Tiedemann and Scherrer, 2017), FLATTRANS (Ma et al., 2020), MBE (Morishita et al., 2021) and ABD (Kossen et al., 2021). We only apply ABD at the encoder side in this work unless otherwise specified, which is its best-performing setup as shown in Appendix C. We re-produce the results of GTRANS (Bao et al., 2021) with its official code and recommended hyperparameters. The optimization details are in Appendix B.

---

4.2 Main Results

We present the main results in Table 2.

Comparisons with Baselines Compared with all the baselines regardless whether they utilize the batch information or not, both DocFlat$_\text{C}$ and DocFlat$_\text{D}$ substantially outperform these strong baseline approaches, especially in terms of the context awareness (accuracy) which is the main emphasis of this work. For the approaches that utilize the batch information, we observe that MBE and ABD only marginally improves the performance compared with Doc2Doc, suggesting the importance of preserving the linguistic structure in utilizing the batch-level information for DocNMT. We also observe the larger performance gain from DocFlat on small `TED` and `News`, implying DocFlat performs better in the low-resource settings.

DocFlat$_\text{C}$ vs. DocFlat$_\text{D}$ As shown in Table 2, DocFlat$_\text{C}$ and DocFlat$_\text{D}$ demonstrate different strengths: DocFlat$_\text{C}$ mainly improves the translation quality (BLEU and COMET), while DocFlat$_\text{D}$ improves the context awareness (accuracy). In the contrastive evaluation, we have no access to the entire document, so the model predictions are always conditioned on the golden local context (LC) and irrelevant global context (GC). DocFlat$_\text{D}$ outperforms DocFlat$_\text{C}$ in terms of accuracy, suggesting the discrete NCG is more robust against the noise in the context as we expected in Section 3.3. However, DocFlat$_\text{D}$ also aggressively filters out the supportive information in the context as demonstrated on its lower results in BLEU and COMET on `News` and `Europarl`. We believe tuning γ in Equation 9 can fix this issue.

Computational Efficiency As described in Section 3.2, FBA introduces additional computational overhead. We thus evaluate computational efficiency of DocFlat along with the baselines in terms of update per second (UPS) and report the results in Table 2. When the context size of the pseudo-document is the same, our approach DocFlat is almost as fast as the standard Doc2Doc on the identical computational infrastructure (one Tesla A40 GPU) with significant performance gain. Note that GTrans (Bao et al., 2021) does not support FP16 mode, so its UPS is not reported. During the inference, DocFlat is only 15% slower than Doc2Doc.

4.3 Ablation Study

Ablation Study for FBA We conduct the ablation study for FBA and present the results in Table 3. Compared with Doc2Doc, FBA at either side can effectively improve the model performance of DocFlat in terms of BLEU, COMET and accuracy, although both FBAs does not demonstrate orthogonal effectiveness. We also observe that, when the FBA at the decoder side is removed, the contextual awareness (accuracy) is slightly im-

Table 6: Accuracy (in %) on the contrastive test set for `TED` with regard to the anaphoric pronoun types. The best results are highlighted in **bold**.

proved. All these results demonstrate that FBA can effectively leverage the distant context beyond the pseudo-document boundaries.

Ablation Study for NCG We present the ablation study for NCG in Table 4. To probe the utility of NCG, we replace NCG in Equation 7 with identity mapping (He et al., 2016) and denote this variant of DocFlat as DocFlat$_{\text{I}}$. The results from DocFlat$_{\text{I}}$ support our argument that not all the information in the context is useful. Both DocFlat$_{\text{C}}$ and DocFlat$_{\text{D}}$ outperform DocFlat$_{\text{I}}$ on BLEU, COMET and accuracy, which confirms NCG can effectively filter out the noise in the context.

Ablation Study for Data Shuffling To preserve the linguistic structure of the original document, we do not shuffle examples during training. If the examples are shuffled, the predictions of the current sentence are conditioned on the gold local context (LC) and the irrelevant global context (GC). In this section, we investigate how the data shuffling affects DocFlat. We present the results in Table 5. We observe the performance reduction for DocFlat$_{\text{C}}$ and DocFlat$_{\text{D}}$ when the current sentence is conditioned on the gold LC but irrelevant GC. When conditioned on the irrelevant GC, DocFlat even performs worse than Doc2Doc which is free from the irrelevant GC. We also train DocFlat and Doc2Doc with the completely irrelevant context and find out that both models fail to converge. Hence, we confirm that the relatedness between the context and current sentence is of vital importance in DocNMT and DocFlat can effectively leverage the information from the context beyond the scope of the pseudo-documents.

5 Analysis

In this section, we investigate the effectiveness of DocFlat on the contextual awareness and the quality saturation problem. We also demonstrate how the inference batch size affects the model predictions. A visualization of FBA attention map is presented in Appendix D.

Contextual Awareness In English-German translation, the choice of anaphoric pronoun types, including feminine *sie*, neutral *er* and masculine *es*, commonly depends on its context. We present the accuracy with regard to the anaphoric pronoun types given by the selected models trained on `TED` in Table 6. DocFlat$_{\text{D}}$ is the only approach that demonstrates substantial improvements on the neutral *er*. For the feminine *sie*, DocFlat$_{\text{C}}$ and DocFlat$_{\text{D}}$ both outperform Doc2Doc by approximately 12% accuracy. MBE and ABD only improves the accuracy on the feminine *sie* by 7%

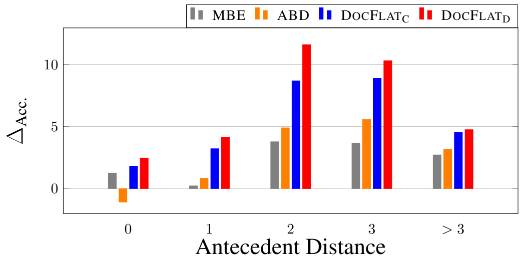

Figure 4: The change of accuracy (in %; Δ_{acc}) given by the selected models against Doc2Doc with regard to the antecedent distance (in sentences) on `TED`.

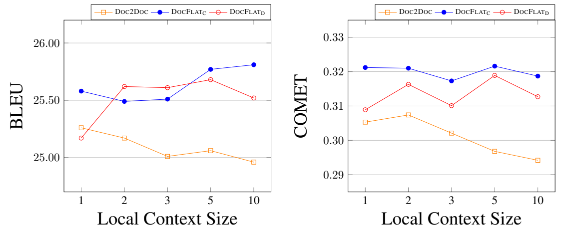

Figure 5: BLEU (left) and COMET (right) against the LC size of pseudo-document (in sentences) by Doc2Doc, DocFlat$_{\mathrm{C}}$ and DocFlat$_{\mathrm{D}}$ on `TED`.

and 4% respectively. We also present the change of accuracy given by the selected models against Doc2Doc with regard to the antecedent distance on `TED` in Figure 4. Compared with Doc2Doc, the approaches that leverage the batch-level information all effectively improves the accuracy on the distant context (antecedent distance ≥ 2). DocFlat$_{\mathrm{C}}$ significantly outperforms Doc2Doc with regard to the accuracy on the distant context by more than 8%, while DocFlat$_{\mathrm{D}}$ outperforms Doc2Doc by more than 10% on the distant context. All these results demonstrate that DocFlat can effectively improve the contextual awareness on the discourse phenomena.

Effect of DocFlat on Quality Saturation Doc2Doc suffers from the *quality saturation problem* as shown in Figure 1. We investigate if DocFlat also suffers from the same problem. We display the results in Figure 5 and observe that DocFlat$_{\mathrm{C}}$ and DocFlat$_{\mathrm{D}}$ perform consistently with regard to the LC size. We conjecture the reasons for this observation from two perspectives. When the LC size is small, the information from GC introduced by FBA complements the missing information in LC. When the LC size is large enough, most information from GC is already covered by LC and FBA functions as a regularizer.

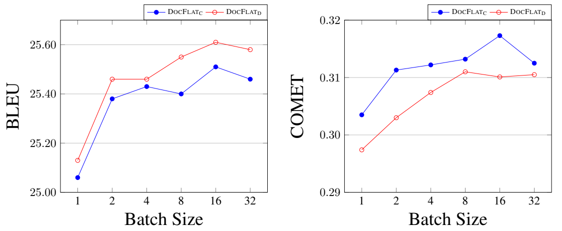

Figure 6: BLEU (left) and COMET (right) against the inference batch size (in sentences) given by DocFlat$_{\mathrm{C}}$ and DocFlat$_{\mathrm{D}}$ on `TED`.

Inference Batch Size At the inference stage, DocFlat is also able to leverage the batch-level information. We visualize how the inference batch size impacts the model performance in Figure 6. Overall, the model performance of DocFlat is positively correlated to the inference batch size. When the batch size is 1, DocFlat$_{\mathrm{C}}$ and DocFlat$_{\mathrm{D}}$ still outperform Doc2Doc, suggesting the FBA can help the model utilize the distant context during training. The performance gain on BLEU and COMET for both DocFlat$_{\mathrm{C}}$ and DocFlat$_{\mathrm{D}}$ diminishes as the inference batch size increases, and we do not observe further improvement when the inference batch size is larger than 16, suggesting the over-distant context is less influential to the predictions of the current sentence.

6 Related Work

Document-Level NMT Numerous document-level NMT approaches have been proposed in recent years. Tiedemann and Scherrer (2017) firstly proposed the simple concatenation-based DocNMT model. Existing works in the document-level NMT widely spread on a variety of research topics, including the model architecture (Miculicich et al., 2018; Maruf et al., 2019; Zhang et al., 2021), training methods (Sun et al., 2022; Lei et al., 2022), evaluation (Bawden et al., 2018; Jiang et al., 2022), etc. Zhang et al. (2018b) incorporate the contextual information using an independent context encoder. Bao et al. (2021) propose group attention that introduce a locality bias to force the model to focus on the recent context. Morishita et al. (2021) compute the average representation of all the source tokens, which is the only close work to ours. Maruf et al. (2021) present a detailed review on DocNMT.

Batch-Level Information Modeling instance relationships in the batch is relatively less explored. Prior works leveraging the instance relationships are mostly from the computer vision area. Ioffe and Szegedy (2015) keep the running mean and variance in the batch to normalize the training and testing instances. Zhang et al. (2018a) linearly combine a random pair of instances to improve the model generalization. Mondal et al. (2021) use graph neural networks to aggregate information from similar images. Hou et al. (2022) propose BATCHFORMER to improve the long-tail recognition by combining different instances. Our work is directly inspired by Kossen et al. (2021) that computes the pairwise similarity among all the batched instances, with distinct motivation. We aim to utilize distant context beyond the pseudo-document boundaries, instead of finding the similar patterns.

7 Conclusion

In this work, we address the limitation of the pseudo-document formation in the DocNMT by utilizing the batch-level information. We propose a novel Document Flattening (DOCFLAT) technique that integrates FLAT-BATCH ATTENTION (FBA) and NEURAL CONTEXT GATE (NCG) into the Transformer model. FBA enables the current sentence to access the information beyond the pseudo-document boundaries and NCG identifies the usefulness of context and controls the information flow. We conduct comprehensive experiments and analyses on three benchmark datasets for English-German translation. We demonstrate that DOCFLAT outperforms several strong baselines with statistical significance. The analyses highlight that DOCFLAT can effectively alleviate the quality saturation problem in DocNMT and capture the long-range information.

8 Limitations

As suggested in Figure 6, the performance of DOCFLAT is positively correlated to the inference batch size. This is because large inference batch size could help DOCFLAT to better utilize distant context within the same inference batch. However, this property of DOCFLAT could become an issue when there are only limited inference computational resources available.

A A Concrete Example at the Source Side

We present a concrete example at the source side in Figure 7.

B Optimization and Hyperparameters

We use a two-stage training routine following the previous works (Zhang et al., 2018b; Voita et al., 2019; Lopes et al., 2020; Bao et al., 2021).

Stage I We first train a SENT2SENT NMT model. The model is randomly initialized and optimized with Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9$, $\beta_2 = 0.98$ and the learning rate $\alpha = 5 \times 10^{-4}$. The model is trained with the batch size of $32K$ tokens for both datasets and the dropout rate $p = 0.3$. The batch size of $32K$ tokens is achieved by using the batch size of 4096 tokens and updating the model for every 8 batches. The learning rate schedule is the same as described in Vaswani et al. (2017) with $4K$ warmup steps. We use early stopping on validation loss.

Stage II The document-level models are all fine-tuned from the best SENT2SENT model in the Stage I. With the same learning rate schedule as the Stage I, we set the learning rate $\alpha = 2 \times 10^{-4}$. All the other hyperparameters are identical. Training is early stopped on validation loss, and we average the last 5 checkpoints to report the model performance, following Vaswani et al. (2017). Following Bao et al. (2021), we apply word dropout (Gal and Ghahramani, 2016; Sennrich et al., 2016a) to the inputs with $p = 0.1$.

C ATTENTION BETWEEN DATAPOINTS

We adapt ATTENTION BETWEEN DATAPOINTS (ABD) proposed by Kossen et al. (2021) to the DocNMT. The model architecture is identical to DOCFLAT as shown in Figure 2 with FBA replaced with ABD. Given a batch of hidden representations $\boldsymbol{H} \in \mathbb{R}^{n \times d \times e}$, ABD is defined as follows:

$$\begin{aligned}
\tilde{\boldsymbol{H}}_{\text{avg}} &= \text{AvgPool}(\boldsymbol{H}) \in \mathbb{R}^{n \times 1 \times e}, \\
\tilde{\boldsymbol{H}}_{\text{flat}} &= \text{Flatten}(\tilde{\boldsymbol{H}}_{\text{avg}}) \in \mathbb{R}^{1 \times n \times e}, \\
\tilde{\boldsymbol{H}}_{\text{mhsa}} &= \text{MHSA}(\tilde{\boldsymbol{H}}_{\text{flat}}, \tilde{\boldsymbol{H}}_{\text{flat}}, \tilde{\boldsymbol{H}}_{\text{flat}}) \in \mathbb{R}^{1 \times n \times e}, \\
\tilde{\boldsymbol{H}}_{\text{rsh}} &= \text{Reshape}(\text{Repeat}(\tilde{\boldsymbol{H}}_{\text{mhsa}})) \in \mathbb{R}^{n \times d \times e}, \\
\tilde{\boldsymbol{H}} &= \text{LN}(\boldsymbol{H} + \tilde{\boldsymbol{H}}_{\text{rsh}}) \in \mathbb{R}^{n \times d \times e}.
\end{aligned} \tag{11}$$

There is a noticeable difference in Equation 11 from Equation 7 that we apply the average pooling to the sequence to obtain the instance representation, instead of directly flattening the token representations into a single vector. ABD is originally designed for fixed-length data, and it is non-trivial to apply ABD to the variable-length inputs, and hence, we use the average pooling for simplicity.

	Enc.	Dec.	BLEU	COMET	Acc.
DOC2DOC	✗	✗	25.01	0.3021	66.99
ABD			18.57	-0.1202	66.55
	✗		18.46	-0.1123	66.47
		✗	24.97	0.3046	68.25

Table 7: Preliminary study on the usage of ABD on `TED`. ✗ indicates ABD is removed.

We present the preliminary study of ABD on `TED` in Table 7. When ABD is applied at the decoder side, the model performance is significantly reduced. This observation suggests that the linguistic structure at the target side is of vital importance to DocNMT.

D Visualization of FBA

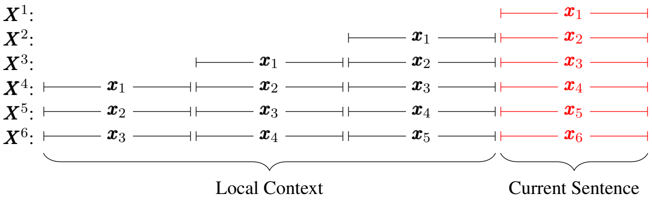
To better understand the behavior of FBA, we visualize the sentence-wise attention map learned by the FBA of $\text{DOCFLAT}_{\text{C}}$ and $\text{DOCFLAT}_{\text{D}}$ at the encoder side in Figure 8. The sample document for producing Figure 8 can be found in Table 8.

It is infeasible to visualize the token-wise attention map for a very long sequence, so we aggregate the token-wise attention scores into the sentence-level. We denote the token-wise attention map for the flattened sequence as $\mathcal{A}$. For each pair of sentences $\boldsymbol{s}_i$ attending to $\boldsymbol{s}_j$, their token-wise attention map is a patch of $\mathcal{A}$, denoted as $\mathcal{A}^p_{ij}$. We aggregate the token-level attention scores in the attention patch $\mathcal{A}^p_{ij}$ into a sentence-level score, as follows:

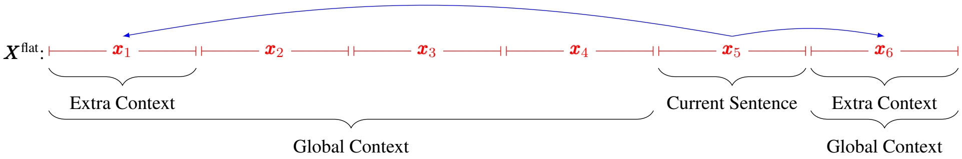
$$\mathcal{A}_{\mathcal{S}}(i,j) = \frac{1}{\left|\mathcal{A}^p_{ij}\right|} \sum \mathcal{A}^p_{ij} \tag{12}$$

where $\left|\mathcal{A}^p_{ij}\right|$ is the size of $\mathcal{A}^p_{ij}$ and $\mathcal{A}_{\mathcal{S}}(i,j)$ is the sentence-level attention score for $\boldsymbol{s}_i$ attending to $\boldsymbol{s}_j$.

The FBA of $\text{DOCFLAT}_{\text{C}}$ at the encoder side considers all the sentences in the document to be equally important, while the one of $\text{DOCFLAT}_{\text{D}}$ approximately splits the whole documents into two parts. As shown by $\text{DOCFLAT}_{\text{D}}$ in Figure 8, sentences in the first half focus more on its neighbors in the same split but those in the second half



(a) An example batch of pseudo-documents $\boldsymbol{B}_\text{src} = \{\boldsymbol{X}^1, \boldsymbol{X}^2, \boldsymbol{X}^3, \boldsymbol{X}^4, \boldsymbol{X}^5, \boldsymbol{X}^6\}$ at the source side. Each $\boldsymbol{X}^j$ contains four consecutive sentences and $\boldsymbol{x}_i$ indicates the i-th sentence of the same original document. The segments in red indicate the current sentence of each pseudo-document.



(b) An example of the flattened sequence $\boldsymbol{X}^\text{flat}$ transformed from $\boldsymbol{B}_\text{tgt}$ with Flat-Batch Attention. For the current sentence $\boldsymbol{x}_5$, The blue arrows indicate the extra inter-sentential attention for $\boldsymbol{x}_5$ that our approach can model. $\boldsymbol{x}_1$ and $\boldsymbol{x}_6$ are the extra context introduced by our approach.

Figure 7: An example batch of pseudo-documents at the source side and its flattened sequence.

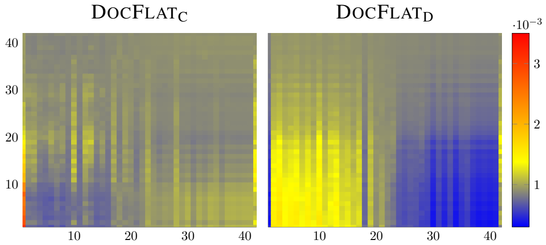


Figure 8: Sentence-wise attention map produced by the FBA of DocFlat$_\text{C}$ and DocFlat$_\text{D}$ at the encoder side. x-axis indicates sentences as the keys of FBA. y-axis indicates sentences as the queries of FBA.

roughly attend to all the sentences in the documents. This observation implies that the latter context is more dependent on the former context.

idx	Context
1	<d>
2	We're at a tipping point in human history, a species poised between gaining the stars and losing the planet we call home.
3	Even in just the past few years, we've greatly expanded our knowledge of how Earth fits within the context of our universe.
4	NASA's Kepler mission has discovered thousands of potential planets around other stars, indicating that Earth is but one of billions of planets in our galaxy.
5	Kepler is a space telescope that measures the subtle dimming of stars as planets pass in front of them, blocking just a little bit of that light from reaching us.
6	Kepler's data reveals planets' sizes as well as their distance from their parent star.
7	Together, this helps us understand whether these planets are small and rocky, like the terrestrial planets in our own Solar System, and also how much light they receive from their parent sun.
8	In turn, this provides clues as to whether these planets that we discover might be habitable or not.
9	Unfortunately, at the same time as we're discovering this treasure trove of potentially habitable worlds, our own planet is sagging under the weight of humanity.
10	2014 was the hottest year on record.
11	Glaciers and sea ice that have been with us for millennia are now disappearing in a matter of decades.
12	These planetary-scale environmental changes that we have set in motion are rapidly outpacing our ability to alter their course.
13	But I'm not a climate scientist, I'm an astronomer.
14	I study planetary habitability as influenced by stars with the hopes of finding the places in the universe where we might discover life beyond our own planet.
15	You could say that I look for choice alien real estate.
16	Now, as somebody who is deeply embedded in the search for life in the universe, I can tell you that the more you look for planets like Earth, the more you appreciate our own planet itself.
17	Each one of these new worlds invites a comparison between the newly discovered planet and the planets we know best: those of our own Solar System.
18	Consider our neighbor, Mars.
19	Mars is small and rocky, and though it's a bit far from the Sun, it might be considered a potentially habitable world if found by a mission like Kepler.
20	Indeed, it's possible that Mars was habitable in the past, and in part, this is why we study Mars so much.
21	Our rovers, like Curiosity, crawl across its surface, scratching for clues as to the origins of life as we know it.
22	Orbiters like the MAVEN mission sample the Martian atmosphere, trying to understand how Mars might have lost its past habitability.
23	Private spaceflight companies now offer not just a short trip to near space but the tantalizing possibility of living our lives on Mars.
24	But though these Martian vistas resemble the deserts of our own home world, places that are tied in our imagination to ideas about pioneering and frontiers, compared to Earth Mars is a pretty terrible place to live.
25	Consider the extent to which we have not colonized the deserts of our own planet, places that are lush by comparison with Mars.
26	Even in the driest, highest places on Earth, the air is sweet and thick with oxygen exhaled from thousands of miles away by our rainforests.
27	I worry – I worry that this excitement about colonizing Mars and other planets carries with it a long, dark shadow: the implication and belief by some that Mars will be there to save us from the self-inflicted destruction of the only truly habitable planet we know of, the Earth.
28	As much as I love interplanetary exploration, I deeply disagree with this idea.
29	There are many excellent reasons to go to Mars, but for anyone to tell you that Mars will be there to back up humanity is like the captain of the Titanic telling you that the real party is happening later on the lifeboats.
30	Thank you.
31	But the goals of interplanetary exploration and planetary preservation are not opposed to one another.
32	No, they're in fact two sides of the same goal: to understand, preserve and improve life into the future.
33	The extreme environments of our own world are alien vistas.
34	They're just closer to home.
35	If we can understand how to create and maintain habitable spaces out of hostile, inhospitable spaces here on Earth, perhaps we can meet the needs of both preserving our own environment and moving beyond it.
36	I leave you with a final thought experiment: Fermi's paradox.
37	Many years ago, the physicist Enrico Fermi asked that, given the fact that our universe has been around for a very long time and we expect that there are many planets within it, we should have found evidence for alien life by now.
38	So where are they?
39	Well, one possible solution to Fermi's paradox is that, as civilizations become technologically advanced enough to consider living amongst the stars, they lose sight of how important it is to safeguard the home worlds that fostered that advancement to begin with.
40	It is hubris to believe that interplanetary colonization alone will save us from ourselves, but planetary preservation and interplanetary exploration can work together.
41	If we truly believe in our ability to bend the hostile environments of Mars for human habitation, then we should be able to surmount the far easier task of preserving the habitability of the Earth.
42	Thank you.

Table 8: The sample document used for producing Figure 8.

Abstract

Sign language gloss translation aims to translate the sign glosses into spoken language texts, which is challenging due to the scarcity of labeled gloss-text parallel data. Back-translation (BT), which generates pseudo parallel data by translating in-domain spoken language texts into sign glosses, has been applied to alleviate the data scarcity problem. However, the lack of large-scale high-quality in-domain spoken language text data limits the effect of BT. In this paper, to overcome the limitation, we propose a **P**rompt based domain text **Gen**eration (PGEN) approach to produce the large-scale in-domain spoken language text data. Specifically, PGEN randomly concatenates sentences from the original in-domain spoken language text data as prompts to induce a pre-trained language model (i.e., GPT-2) to generate spoken language texts in similar style. Experimental results on three benchmarks of sign language gloss translation in varied languages demonstrate that BT with spoken language texts generated by PGEN significantly outperforms the compared methods. In addition, as the scale of spoken language texts generated by PGEN increases, the BT technique can achieve further improvements, demonstrating the effectiveness of our approach. We release the code and data for facilitating future research in this field[1].

1 Introduction

Sign language is the dominant form of communication for the deaf and hearing impaired community. Sign language processing has received substantial attention in the last few years and achieved significant progress (Bragg et al., 2019; Yin et al., 2021; Shterionov, 2021; De Coster et al., 2022). Among them, sign language translation (SLT) aims to transform continuous sign language videos into natural spoken language texts (Bungeroth and Ney, 2004; Camgoz et al., 2018). SLT consists of two subtasks: (1) sign language understanding task that recognizes the continued videos to the sign glosses; and (2) spoken language gloss translation (SLGT) task that generates the spoken language text of the given sign glosses. In this work we focus on the second sub-task, i.e., SLGT.

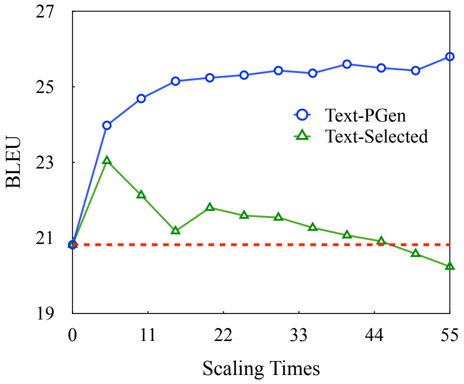

Figure 1: The translation performance of back-translation when scaling the generated spoken language data from 1) our PGEN which uses the large pretrained language model, and 2) selected in-domain data from large-scale spoken language corpus. The red dashed line denotes the baseline model without back-translation. Best viewed in color.

Data scarcity has been considered the major limitation of sign language gloss translation (Moryossef et al., 2021; Zhang and Duh, 2021). To alleviate the data scarcity problem, back-translation (Sennrich et al., 2016), which translates in-domain spoken language texts into sign glosses to construct synthetic parallel data, has been adopted and achieved certain success in SLGT. However, the lack of large-scale high-quality in-domain spoken language text data limits the capability of back-translation for the SLGT task (Zhang and Duh, 2021). The common practice is adopt-

ing data selection (Axelrod et al., 2011), or data mining (Jiang et al., 2009) approaches to obtain in-domain data. But theses approaches assume the availability of enough in-domain data or expert knowledge (e.g., language background to mine the in-domain data in a specific language), which prevents them from applying to gloss translation task that has broader scenarios (e.g., more languages and domains).

In this work, we propose a **P**rompt-based domain text **Gen**eration (PGen) to generate large-scale high-quality in-domain spoken language text data, motivated by the advances in data augmentation with pretrained language models (PLMs). The main idea is to induce the large PLMs to mimic the style of original spoken language texts with prompt-based learning techniques (Radford et al., 2019; Liu et al., 2021). Our PGen approach is able to generate large-scale in-domain spoken language texts based on the small-scale original monolingual texts and maintains diversity (§2.1). Besides, our approach can be performed without requiring large-scale in-domain data or expert knowledge of the sign language domain and maintain the high quality of generated in-domain spoken language texts. Finally, we employ a sequence-sequence pretrained model (e.g, mT5) to translate spoken language texts generated by PGen into sign glosses and synthesize gloss-text pseudo-parallel data (§2.2).

We conduct extensive analyses of the spoken language texts generated by PGen. We find that the generated and original spoken language texts share a similar word distribution (§3.2). To further verify the effectiveness of PGen, we also conduct back-translation experiments for the SLGT task with large-scale in-domain spoken language texts generated by PGen (§3.3). Experimental results on three widely used benchmark datasets across languages and domains show that back-translation with spoken language texts generated by PGen significantly outperforms the compared methods. Most importantly, as shown in Figure 1, when scaling the spoken language texts generated by PGen in BT approach, the performance of the gloss-to-text translation task can achieve constant improvement while conventional data selection approach failed. The contributions of our work are summarized as follows:

- We propose a novel text generation approach, i.e., PGen, to produce large-scale in-domain spoken language texts which share similar linguistic properties as the original spoken language texts.
- We scale back-translation with the proposed PGen approach and achieve significant and consistent improvements on three benchmark SLGT datasets.
- We release the code and the large-scale synthetic gloss-text datasets produced by the proposed approach to promote the research in sign language gloss translation field.

2 Methodology

The whole framework of this work includes two components, i.e., the PGen method for in-domain text generation and the BT model (i.e., text-to-gloss translation) for constructing synthetic data. We will introduce more details for these two components in this section. For clarity, we provide the definition of SLGT (i.e., gloss-to-text translation task) and notations used throughout the paper as below.

Task Definition. Let X and Y denote the gloss annotations and spoken language texts, and $\mathcal{X}$ and $\mathcal{Y}$ represent the sentence sets of corresponding languages. The dataset of gloss-text pairs can be expressed as $\mathcal{D}_{\text{g2t}} = \{(\mathbf{x}^i, \mathbf{y}^i)\}_{i=1}^{N}$, where $\mathbf{x}^i \in \mathcal{X}$ is the annotations, $\mathbf{y}^i \in \mathcal{Y}$ is the spoken language sentence and N is the number of pairs. Given a sequence of gloss annotations, the task is to output the corresponding fluent and semantically equivalent sentence.

2.1 Prompt-Based Domain Text Generation

We exploit the large PLMs for domain text generation. Large PLMs have been successfully applied for text generation in NLP, such as text classification (Kumar et al., 2020) and medical dialogue summarization (Chintagunta et al., 2021), for two advantages: (1) PLMs are demonstrated to memorize the knowledge of their training data (Carlini et al., 2021), which usually covers different domains. With proper guidance (e.g., prompts), we can export the memorized sentences that belong to the same domain as the sign language text data. (2) Large PLMs are also able to generate abundant new sentences rather than only the memorized sentence in training data (Qiu et al., 2020). Therefore, we propose the **P**rompt-based domain text **Gen**eration (PGen) approach to produce large-scale in-domain spoken language text

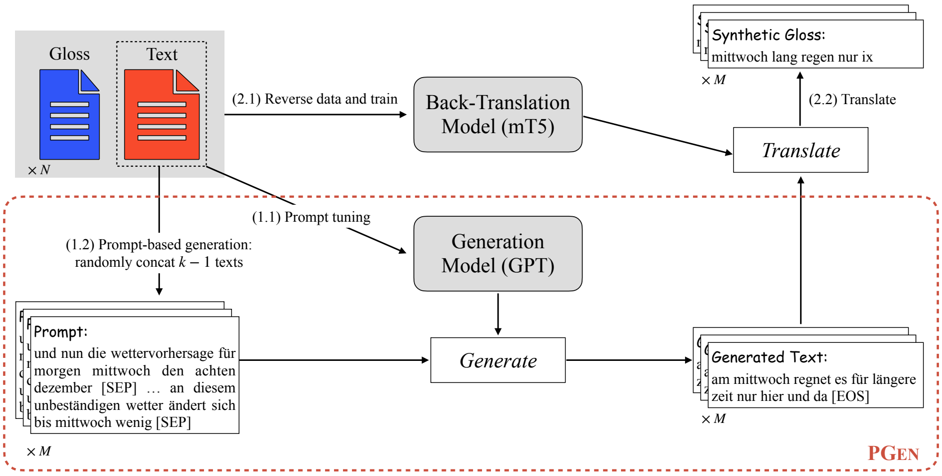

Figure 2: The overall framework of back-translation for gloss-to-text translation in this work. Procedures framed in the red dashed box corresponds to our prompt-based domain text generation (PGEN) approach.

corpora based on the text part of the original small-scale dataset $\mathcal{D}_{\mathrm{g2t}}$.

For the original text $\mathcal{D}_{\mathrm{t}} = \{\mathbf{y}^i\}_{i=1}^N$ from $\mathcal{D}_{\mathrm{g2t}}$, and a PLM $\mathcal{M}_G$, we attempt to generate an in-domain spoken language text dataset $\hat{\mathcal{D}}_{\mathrm{t}} = \{\hat{\mathbf{y}}^i\}_{i=1}^M$ with a much larger data size than $\mathcal{D}_{\mathrm{t}}$ (i.e., $M \gg N$). As shown in Figure 2, our PGEN approach includes two phases:

- **Prompt Tuning:** Following (Kumar et al., 2020), we finetune the PLM on the original small-scale spoken text dataset $\mathcal{D}_{\mathrm{t}}$ with artificial prompts. Specifically, we randomly concatenate k sentences from $\mathcal{D}_{\mathrm{t}}$ as a training sample, i.e., $[\mathbf{y}^{i_1}; \texttt{[SEP]}; \mathbf{y}^{i_2}; \texttt{[SEP]}; \dots; \mathbf{y}^{i_k}; \texttt{[EOS]}]$, where `[SEP]` and `[EOS]` represent the delimiter and the end-of-sentence tokens, respectively. We denote the finetuned PLM as $\mathcal{M}_{G_{\mathrm{FT}}}$.

- **Prompt-Based Generation:** In the generation phase, we randomly select $k-1$ sentences from $\mathcal{D}_{\mathrm{t}}$ to form a prompt, i.e., $\texttt{prompt} = [\mathbf{y}^{j_1}; \texttt{[SEP]}; \mathbf{y}^{j_2}; \texttt{[SEP]}; \dots; \mathbf{y}^{j_{k-1}}; \texttt{[SEP]}]$. Then, we input the prompt into $\mathcal{M}_{G_{\mathrm{FT}}}$ to generate the k-th sentence $\hat{\mathbf{y}}^{j_k} = \mathcal{M}_{G_{\mathrm{FT}}}(\texttt{prompt})$. We complete the text generation process when the model produces an `[EOS]` token.

According to the design of prompts, the number of permutations for any $k-1$ sentences from the full set with N sentences is $A_N^{k-1} = \frac{N!}{(N-k-1)!} \gg N$, which allows us to generate a large number of in-domain sentences and maintain the diversity of $\hat{\mathcal{D}}_{\mathrm{t}}$.

2.2 Back-Translation

Generally, the BT model is trained on the same dataset for the gloss-to-text task but in the opposite direction, i.e., $\mathcal{D}_{\mathrm{t2g}} = \{(\mathbf{y}^i, \mathbf{x}^i)\}_{i=1}^N$. However, the data scale of $\mathcal{D}_{\mathrm{t2g}}$ is too small to develop a well-performing text-to-gloss translation model. Previous study (Hoang et al., 2018) on machine translation also suggests that the quality of BT models heavily affects the performance of the final models. Therefore, we take advantage of pretrained sequence-to-sequence models by finetuning them on $\mathcal{D}_{\mathrm{t2g}}$ to improve the performance of the BT model. Specifically, we utilize a multilingual pretrained model, i.e., mT5 (Xue et al., 2020), to support the different languages (i.e., German, Chinese and English) of the SLT benchmarks.

2.3 Overall Framework

The workflow of our approach is illustrated in Figure 2, which is divided into four steps: (1.1) finetune the pretrained GPT-2 model on the original small-scale spoken language text dataset; (1.2) apply the finetuned GPT-2 model for in-domain spoken language texts generation with artificial prompts; (2.1) finetune the pretrained sequence-to-sequence model (i.e., mT5) on the original text-gloss dataset $\mathcal{D}_{\mathrm{t2g}}$ to obtain the BT model; (2.2) adopt the BT model to translate the generated in-domain spoken language texts into glosses to synthesize a large-scale pseudo-parallel data, which are combined with the original small-scale dataset $\mathcal{D}_{\mathrm{g2t}}$ to train the final gloss-to-text translation model.

Dataset	Language Pair	Gloss-Text Pairs
Phoenix2014T	DSL-German	7,086 / 519 / 642
CSL-Daily	CSL-Chinese	18,401 / 1,077 / 1,176
ASLG-PC12	ASL-English	82,709 / 4,000 / 1,000

Table 1: Statistics of the three benchmark datasets for gloss-to-text translation used in this work. The third column presents the number of gloss-text pairs in the training, validation and test sets, respectively.

3 Experiments

In this section, we conduct both intrinsic and extrinsic evaluations (Kumar et al., 2020) for the proposed PGEN approach. For intrinsic evaluation (§3.2), we perform analyses on the domain properties of spoken language texts generated by PGEN. As for extrinsic evaluation (§3.3), we conduct sign gloss translation experiments using back-translation approach with the generated texts. The performance of the downstream task can indirectly reflect the effectiveness of PGEN.

3.1 Experimental Setup

Dataset. We employ three widely used benchmark datasets for sign language translation, namely, Phoenix2014T (Camgoz et al., 2018), CSL-Daily[2] (Zhou et al., 2021a), and ASLG-PC12[3] (Othman and Jemni, 2012), which are in German, Chinese and English, respectively. Statistics of the datasets are presented in Table 1.

Model. As shown in Figure 2, there are three kinds of models involved in this work for 1) in-domain text generation, 2) gloss-to-text translation and 3) back-translation, respectively. Details of the model and training settings can be found in §3.2 , §3.3 and Appendix A.1.

3.2 Domain Text Generation

We perform intrinsic evaluation by analyzing the domain properties of spoken language texts generated by PGEN. Unless otherwise stated, we primarily conduct the analyses on the German Phoenix2014T dataset. More results on ASLG-PC12 and CSL-Daily datasets can be found in Appendix A.3.

We first adopt the pre-trained GPT-2 model (e.g., German GPT-2[4] for Phoenix2014T) and finetune the model on the artificial prompts created from the text part of SLT dataset. Specifically, the PLM is finetuned to predict the next token in the exact way that GPT-2 was pretrained, with the same training procedure and hyper-parameters. Then, we use the finetuned PLM to generate in-domain spoken language texts for each SLT task (§2.1). By default, we set the hyper-parameter k to 20.

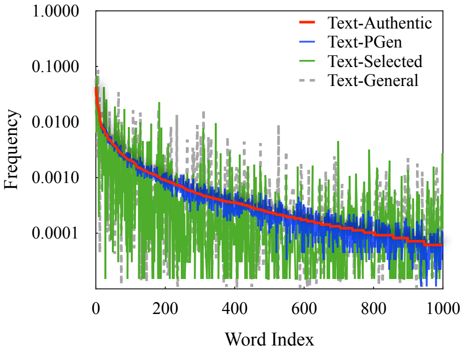

Figure 3: The word frequency distribution on different types of spoken language texts. The X-axis represents different words, while the Y-axis represents the normalized word frequency. Best viewed in color. Analyses is conducted on the German Phoenix2014T

For comparison, we consider four types of spoken language texts:

- TEXT-AUTHENTIC: The text side of the SLT dataset.
- TEXT-PGEN: The spoken language texts generated by our PGEN approach with $k = 20$.
- TEXT-SELECTED: We use the cross-entropy difference selection method (Moore and Lewis, 2010) to collect in-domain texts data from IWSLT17 Multilingual Task[5] based on the AUTHENTIC texts.
- TEXT-GENERAL: We randomly sample sentences from the target text part of IWSLT17 Multilingual Task. TEXT-GENERAL can be considered as the general domain spoken language texts.

We measure the similarity of the other three spoken language texts to the TEXT-AUTHENTIC at both word level and sentence level.

Word Distribution. Recent study by Wang et al. (2022) suggests that the word frequency distributions can reflect the domain difference of datasets.

Data		JS↓
TEXT-PGEN	vs. TEXT-AUTHENTIC	0.01
TEXT-SELECTED	vs. TEXT-AUTHENTIC	0.18
TEXT-GENERAL	vs. TEXT-AUTHENTIC	0.26

Table 2: The JS divergence between different types of spoken language texts for Phoenix2014T dataset.

Test Data	In-domain	General
TEXT-AUTHENTIC	99.38%	0.62%
TEXT-PGEN	98.60%	1.40%
TEXT-SELECTED	56.23%	43.77%
TEXT-GENERAL	0.31%	99.69%

Table 3: The domain classification results of different spoken language texts on Phoenix2014T dataset.

Thus, we count the word frequencies for the above four spoken language texts and present the results by both visualization and the Jensen-Shannon (JS) divergence (Lin, 1991). For a fair comparison, we sample the same number of texts from the other three spoken language texts as TEXT-AUTHENTIC (i.e., 7086 for Phoenix2014T).

Figure 3 visualizes the word frequency distributions of top 10000, in which the words are ranked according to their frequencies in the TEXT-AUTHENTIC corpus. We can observe that TEXT-PGEN (blue line) shows a similar distribution as TEXT-AUTHENTIC (red line) while TEXT-SELECTED and TEXT-GENERAL differ from TEXT-AUTHENTIC significantly. This result qualitatively shows that the spoken language texts generated by our PGEN approach are more close to the domain of TEXT-AUTHENTIC (e.g. the domain of sign language).

To quantitatively measure the distance between these distributions, we compute the JS divergence expressed as:

$$\mathrm{JS}\,(P||Q) = \frac{1}{2}\left(\mathrm{KL}(P||\frac{P+Q}{2}) + \mathrm{KL}(Q||\frac{P+Q}{2})\right),$$

where $\mathrm{KL}(\cdot||\cdot)$ denotes the Kullback–Leibler divergence (Kullback and Leibler, 1951) of two distributions (i.e., P and Q). Table 2 lists the JS divergence from the other three corpora to TEXT-AUTHENTIC. We find that the JS divergence from TEXT-PGEN to TEXT-AUTHENTIC is much smaller than the others, further demonstrating that the spoken language texts generated by PGEN are closer to the domain of TEXT-AUTHENTIC. These demonstrate the effectiveness and generalizability of the proposed PGEN approach.

Domain Classifier. The word frequency distribution only characterizes one aspect of the domain. More features, for example, the styles of texts, can not be explicitly modeled. Thus, we follow Du et al. (2020) to train a domain classifier to distinguish the in-domain and the general domain data with the consideration of all potential features implicitly. We perform a binary classification task with equal examples (i.e., train/valid as 7086/519) from TEXT-GENERAL and TEXT-AUTHENTIC, respectively. To train the domain classifier, we finetune the German BERT[6] on the above dataset (Sun et al., 2019). Specifically, we use the German BERT to encode the input sentence and feed the `[CLS]` token vector as a reasonable sentence embedding to the domain discriminator. For testing, we also sample the same number of examples from the other three spoken language text corpora as the test set of TEXT-AUTHENTIC (i.e., 642) and predict their domains (i.e., general or in-domai).

The results are listed in Table 3. We observe that the domain classifier successfully predicts the true labels of TEXT-AUTHENTIC and TEXT-GENERAL, indicating the significant domain differences between sign language spoken texts and general spoken language texts. As for TEXT-PGEN, the examples are categorized into authentic texts with very high accuracy (i.e., 98.60%), while the value is much lower for TEXT-SELECTED (i.e., 56.23%). These results again demonstrate that our PGEN approach can produce better in-domain spoken language texts than the compared methods.

3.3 Sign Language Gloss Translation

We perform extrinsic evaluation for the proposed PGEN by applying back-translation with the generated spoken language texts to the sign language gloss translation task. For the different SLT tasks in 1, we adopt the corresponding German[7], Chinese[8] and English[9] GPT-2 models to generate in-domain spoken language texts with PGEN.

For the gloss-to-text translation task, we follow

Table 4: Gloss-to-text translation performance on Phoenix2014T, ASLG-PC12 and CSL-daily. "+ Scaling BT(PGen)" represents that training data is increased by 40 times with BT, in which the monolingual is generated by our PGen approach.

Yin and Read (2020) to train a Transformer model with 2 encoder layers and 2 decoder layers. For back-translation, we first finetune the mT5 pretrained model on the authentic text-gloss parallel data and then use it to translate the collected spoken language texts (sampled from Text-PGen, Text-Selected or Text-General) into glosses. Following Wu et al. (2019), we train the Transformer model on the combination of the authentic and synthetic parallel data, and then finetune it on the authentic gloss-to-text parallel data.

For evaluation, we follow previous studies (Camgoz et al., 2018, 2020b; Zhou et al., 2021a) to evaluate the performance of gloss-to-text translation with BLEU score (Papineni et al., 2002), ROUGE-L (Lin, 2004), and METEOR (Banerjee and Lavie, 2005) scores. Specifically, we report the BLEU-1,2,3,4 scores to reflect the translation quality at different phrase levels.

Table 4 lists the main results of the gloss-to-text translation performance on the Phoenix2014T, ASLG-PC12 and CSL-daily datasets. By scaling the BT synthetic data to 40 times of the authentic parallel data with the different types of spoken text data, Text-PGen (i.e., “+ Scaling BT(PGen)”) improves the performance over the baseline Transformer model significantly and consistently (e.g., up to 11.03 BLEU-4 points on CSL-daily), while Text-General and Text-Selected only improve slightly or even hurt the performances (e.g., down to 1.33 BLEU-4 points on Phoenix2014). We also report the translation performance in terms of ROUGE-L and METEOR in Appendix A.4. These demonstrate the effectiveness and generalizability of the proposed PGen approach.

4 Analysis

To gain a deeper understanding on our PGen approach, we conduct extensive analyses in terms of ablation study and translation outputs.

4.1 Ablation Study

We conduct three ablation studies regarding the prompt length, the back-translation model and the scale of synthetic data on the Phoenix2014T dataset. We introduce more details as below:

Prompt Length. We first investigate the impact of the prompt length k on the gloss-to-text translation task, which decides how many sentences are concatenated as prompts for generation via PGen. Specifically, we increase k from 0 to 35 to induce the PLM to generate in-domain spoken language texts with a data size 5 times of the authentic par-

	Text-to-Gloss Dev Set				Gloss-to-Text Dev Set			
	BLEU-1	BLEU-2	BLEU-3	BLEU-4	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Transformer	–	–	–	–	43.05	32.57	25.50	20.81
+ BT Model SC	57.72	39.41	27.86	19.66	44.80	34.33	27.47	22.86
+ BT Model mT5	**59.78**	**43.70**	**32.58**	**25.01**	**46.87**	**35.95**	**28.59**	**23.54**

Table 5: Translation performance with different back-translation models on text-to-gloss and gloss-to-text tasks.

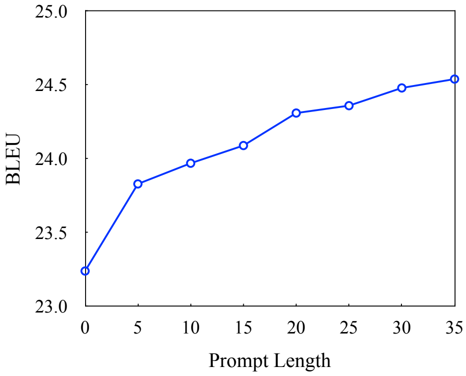

Figure 4: Gloss-to-text translation performance with respect to different prompt sizes. The X-axis represents the number of sentences in one prefix, while the Y-axis represents the BLEU-4 score.

allel data. Then, we perform back-translation with the generated spoken language texts on the gloss-to-text translation task, individually. The results are shown in Figure 4, in which we observe that the performance of gloss-to-text translation constantly improves with the increase of prompt length. This is because a larger prompt length can provide more domain signals so as to encourage the generation of higher-quality spoken language texts with closer domain and higher diversity (see Appendix A.2). However, the larger prompt length requires more computation memory, slowing down the generation process. Therefore, we set the prompt length to 20 throughout the work for a good tradeoff between the generation quality and the computation costs.

Back-Translation Model. In §2.2, we state that the quality of BT models heavily affects the performance of final models. To validate this claim, we compare two back-translation models: a Transformer model trained from scratch (i.e., "+ BT Model SC") and the finetuned mT5 (Xue et al., 2020) model (i.e., "+ BT Model mT5"). As shown in the left of Table 5, the finetuned mT5 model produces higher-quality pseudo parallel data according to BLEU scores on the validation set of the text-to-gloss translation (i.e., back-translation) task. Consequently, the performance of gloss-to-text translation is considerably improved when synthesizing data by "+ BT Model mT5", which reconfirms our claim. Therefore, throughout this work, we adopt the finetuned mT5 model for back-translation.

Scale of Synthetic Data. In §2.1, we show the potential of PGEN in generating large-scale in-domain spoken language texts. Let us recap Figure 1, where we increase the scale of spoken language texts used for back-translation. We observe that scaling the spoken language texts generated by PGEN can improve the performance of the gloss-to-text translation task consistently while that by retrieval degrades the performance. It suggests that our approach can scale the BT technique to play its maximum effect for gloss-to-text translation, which has not been achieved in previous studies.

4.2 Translation Output

We conduct further analyses to understand how the proposed approach improves the gloss-to-text translation quality. Specifically, we analyze the translation outputs of Phoenix2014 in Table 4 by the `compare-mt`[10] toolkit in terms of word frequency and sentence length.

Words Frequency. Previous study (Fadaee and Monz, 2018) shows that the back-translation improves the translation performance by improving the low-frequency word predictions. Meanwhile, our analyses in §3.2 suggest that the spoken language texts generated by our PGEN shows a similar word frequency distribution as TEXT-AUTHENTIC. We wonder how such consistency benefits the prediction of low-frequency words in gloss-to-text translation. Specifically, we first categorize the vocabulary into three groups based on the word frequency in the training data, including High: frequency $\in [2000, +\infty)$; Medium: frequency $\in [100, 2000)$; Low: frequency $\in (0, 100]$. Then,

we utilize `compare-mt` to calculate the prediction accuracy of target words in the test set with respect to the three groups.

Table 6 lists the results for different models with scaling back-translation (e.g. 40 times synthetic data). As seen, scaling back-translation with in-domain spoken language texts of Text-PGen improves the prediction of words in all three groups, especially for low-frequency words. However, the situation is much different for Text-Selected and Text-General such that they bring little improvement for high-frequency words and inversely harm the performance on low-frequency words. It indicates that back-translation becomes ineffective when the domains of spoken language texts and authentic parallel data are mismatched, which implies the importance of our PGen approach.

Sentence Length. We investigate the translation quality of examples with varied lengths, which can be biased during generating or retrieving spoken language texts. Similar to word frequency, we also categorize the examples of test set into three groups based on the sentence length, including Long: $(20, +\infty)$ tokens; Medium: $(10, 20]$ tokens; Short: $(0, 10]$ tokens.

Table 7 lists the corresponding results. Clearly, long sentences are more difficult to translate (Zheng et al., 2020) and our PGen can particularly improve the translation quality of medium and long sentences. In contrast, the other methods show little improvement on medium and long sentences and degrade the performance on short sentences significantly. This demonstrates the better stability of our approach regarding the distribution of sentence length over the compared methods.

5 Related Work

Sign Language Gloss Translation. SLGT translates sign gloss to spoken language texts, which has attracted more attention in recent years with the development of neural machine translation (NMT). For example, Camgoz et al. (2018) released the PHOENIX14T and for the first time proposed a neural SLT model to translate from spatial representations or sign glosses. Recent studies attempt to improve both SLR and gloss-to-text translation for the better performance of SLT. Yin and Read (2020) proposed the STMC-Transformer network (Zhou et al., 2020) to improve SLR and exploited Transformer for gloss-to-text translation. Camgoz et al. (2020b) formulated SLR and gloss-to-text translation in the multi-task form while Li et al. (2020) explored the hierarchical structure for learning sign video representations. More recently, multi-cue characteristics of sign language have also been utilized for improving SLT (Camgoz et al., 2020a; Zhou et al., 2021b; Kan et al., 2022). Different from these works, we improve SLT by focusing on the gloss-to-text translation task in the perspective of spoken language generation.

Data Augmentation. Data augmentation has been proposed and proven valuable and effective in machine translation research (Sennrich et al., 2016; Zhang and Zong, 2016; Wang et al., 2018; Jiao et al., 2020, 2021). To address the data scarcity issue in gloss-to-text translation, there have been studies on producing synthetic gloss-text pairs for data augmentation. One stream is to extract discrete phrases from natural texts based on linguistic rules (Moryossef et al., 2021). Another is to adopt BT technique (Sennrich et al., 2016) to generate glosses from natural texts by a pretrained text-to-gloss translation model. However, the limited in-domain spoken language texts prevent BT from playing its maximum effect for the gloss-to-text translation task. While we may collect in-domain texts from public websites as Zhou et al. (2021a), it is unreliable due to both the requirement for domain knowledge and the accessibility of websites. Our approach exploits the knowledge and generalization capability of large PLMs to produce in-domain texts with prompt learning. While large PLMs have been successfully applied for text generation in NLP (Kumar et al., 2020; Chintagunta et al., 2021), we craft the prompts to theoretically guarantee that we can produce large-scale in-domain texts based on the small-scale original spoken language texts data.

6 Conclusion

In this paper, we propose the PGEN approach to produce large-scale in-domain monolingual texts based on the original small-scale texts of the gloss-text parallel data. With PGEN, we scale back-translation and achieve significant and consistent improvements on three benchmark datasets for SLGT task. Extensive analyses suggest that our approach generates monolingual texts with similar linguistic properties as the original monolingual texts, thus outperforms the compared methods in terms of both low-frequency word prediction and long sentence translation. Future work includes exploring ChatGPT for sign language translation task by using proper prompts (Jiao et al., 2023).

7 Limitations

We identify two limitations of our PGEN approach:

- We rely on the seed in-domain spoken language texts and the pretrained models. Therefore, a bit of expert knowledge is still required for the selection of the seed dataset, and the pretrained models need to be carefully selected to ensure a large data coverage and a strong generalization ability.
- We only investigate the sign language translation without considering the sign language understanding part. Since the latter part may introduce errors into glosses, it requires the sign gloss translation models to be robust to noisy inputs. We leave this for the future work.

A Appendix

A.1 Model Training

We perform extrinsic evaluation for the proposed PGEN by applying back-translation with the generated spoken language texts to the sign language gloss translation task. For the Chinese and English SLT tasks, we adopt the corresponding English[11] and Chinese[12] GPT-2 models to generate in-domain spoken language texts with PGEN.

For the gloss-to-text translation task, we follow Yin and Read (2020) to train a Transformer model with 2 encoder layers and 2 decoder layers. We use Adam (Kingma and Ba, 2015) with $\beta = (0.9, 0.98)$ and $\epsilon = 10^{-6}$ for optimization. We adopt the warm-up learning rate scheduler, which linearly increases from 1.0×10^{-4} to a peak of 5.0×10^{-4} within 2000 steps, and then decays with the inverse square root schedule. The dropout rate is 0.3 and the label smoothing is 0.1.

For back-translation, we first finetune the mT5 pre-trained model on the authentic text-gloss parallel data and then use it to translate the collected spoken language texts (sampled from TEXT-PGEN or TEXT-SELECTED) into glosses. Following Wu et al. (2019), we train the Transformer model on the combination of the authentic and synthetic parallel data, and then finetune it on the authentic gloss-to-text parallel data.

Table 8 presents the hyper-parameters of different transformer models used in this work.

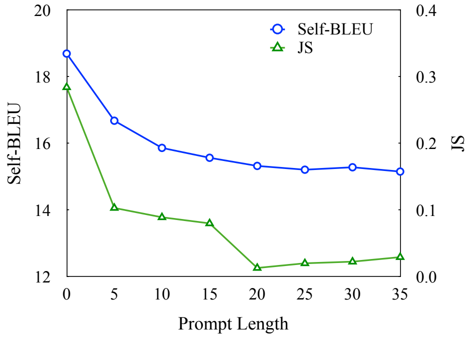

Figure 5: Diversity and domain closeness of sign language texts generated by PGEN measured by Self-BLEU and JS with respect to different prompt sizes.

A.2 Diversity and Quality

Figure 5 shows the diversity and domain closeness of sign language texts generated by PGEN measured by Self-BLEU and JS scores with respect to prompt length. Lower Self-BLEU (Zhu et al., 2018) and JS scores indicate higher diversity and closer domain, respectively.

A.3 Intrinsic Analsys Results for ASLG-PC12 and CSL-Daily Datasets

We extend the intrinsic analyses to both ASLG-PC12 and CSL-Daily datasets. Tabel 9 shows the JS divergence between different types of spoken language texts on the two SLT datasets. As seen, the JS divergence from TEXT-PGEN to TEXT-AUTHENTIC is much smaller than TEXT-GENERAL to TEXT-AUTHENTIC. Table 10 lists the domain classification results on the ASLG-PC12 and CSL-Daily datasets. The results indicate the significant domain differences between sign language spoken texts and general spoken language texts, and our PGEN approach can produce in-domain spoken language texts.

Clearly, the results on both ASLG-PC12 and CSL-Daily datasets are consistent with that in section 3.2, which demonstrates the effectiveness and generalizability of the proposed PGEN approach.

A.4 Other Metrics

Table 11 presents the ROUGE-L and METEOR scores of the gloss-to-text translation performance on the Phoenix2014T, ASLG-PC12 and CSL-daily datasets.

Abstract

Conversational Question Answering (ConvQA) models aim at answering a question with its relevant paragraph and previous question-answer pairs that occurred during conversation multiple times. To apply such models to a real-world scenario, some existing work uses predicted answers, instead of unavailable ground-truth answers, as the conversation history for inference. However, since these models usually predict wrong answers, using all the predictions without filtering significantly hampers the model performance. To address this problem, we propose to filter out inaccurate answers in the conversation history based on their estimated confidences and uncertainties from the ConvQA model, without making any architectural changes. Moreover, to make the confidence and uncertainty values more reliable, we propose to further calibrate them, thereby smoothing the model predictions. We validate our models, Answer Selection-based realistic Conversation Question Answering, on two standard ConvQA datasets, and the results show that our models significantly outperform relevant baselines. Code is available at: `https://github.com/starsuzi/AS-ConvQA`.

1 Introduction

Conversational Question Answering (ConvQA) is the task of answering a series of questions during conversation, taking into account a given relevant paragraph (Choi et al., 2018; Reddy et al., 2019). Contrary to traditional extractive question answering tasks (Rajpurkar et al., 2016; Trischler et al., 2017) that answer each question with the given paragraph just once, ConvQA aims at answering the current question using its previous question-answer pairs taking into account the given paragraph multiple times. For example, as illustrated in Figure 1, the goal of ConvQA is to correctly answer the question Q_3 based on the previous conversation history such as Q_2, A_2, Q_1, and A_1, as well as the current context C.

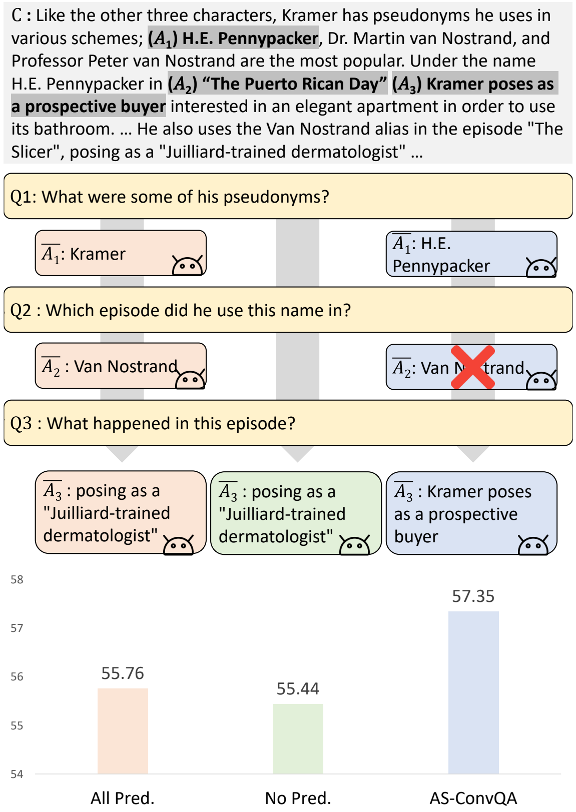

Figure 1: Illustration of realistic ConvQA evaluation with three models: 1) using all predicted answers (All Pred.); 2) not using predicted answers (No Pred.); 3) only using probably correct answers while filtering out others (AS-ConvQA, Ours). The scores in the bar chart underneath represent the F1 scores measured by all test samples (see Table 1 for full results).

ConvQA has recently gained much attention as it follows the human's information seeking process through multi-turn interactions with others. However, it is also known to be quite challenging since it requires capturing all the information over the current question, previous conversation, and the given paragraph. To tackle this problem, a considerable amount of work focuses mainly on developing a model architecture for ConvQA (Qu et al., 2019a,b; Huang et al., 2019; Chen et al., 2020; Kim et al., 2021; Qiu et al., 2021; Raposo et al., 2022).

Despite their successes, however, there remains

---

[*] Corresponding author

a critical limitation in that they use the ground-truth answers (i.e., A_2 and A_1) in the conversation history during both training and evaluation steps. Such an evaluation procedure is not applicable to the real-world scenario, since the ground-truth answers are not accessible when the user's query is posed. Therefore, the supporting dialogue history for the current question should consist of the model's predictions $\bar{A}_1$ and $\bar{A}_2$ in the real-world application, instead of the nonexistent gold answers A_1 and A_2.

There is some recent work (Mandya et al., 2020; Siblini et al., 2021) that considers such a realistic setting on evaluation. In particular, they propose to use the model's predicted answers (i.e., $\bar{A}_1$ and $\bar{A}_2$), instead of the ground-truth answers (i.e., A_1 and A_2), for its evaluation. However, in such a setting, the model faces inconsistency between training and evaluation since the model is evaluated with the predictions while trained with the ground-truth answers. To handle such a discrepancy, Mandya et al. (2020) and Siblini et al. (2021) suggest strategies that randomly decide whether to use predicted or gold answers for the input question during training.

However, as Figure 1 shows, using all predictions as the answer history is not effective: The performance difference is not so significant when compared to not using them at all. We see that this originates from a model's failure to answering previous questions. Specifically, if a model incorrectly predicts an answer $\bar{A}_1$ for the previous question Q_1, using the incorrectly predicted answer $\bar{A}_1$ for the question Q_2 not only affects the model's current prediction $\bar{A}_2$ negatively, but also engenders further errors in the future prediction for Q_3.
