Figure 3: We compare LPBS in its default form (attribute-LPBS) and target-LPBS for BERT-large. The plot shows a general positive correlation between the two metrics. In both cases, Sent-debias maintains the lowest bias score — lower scores are desirable in both cases. See Figure 9 for ALBERT-large.

The use of some metrics can be problematic for evaluating some mitigation techniques for intrinsic bias. We find that some metrics are not ideal to use with some mitigation techniques due to differences in how various mitigation techniques interact with a language model. Consider a metric like LPBS which measures the association between a stereotype term and a gender $\frac{P(A{=}a|X{=}x)}{P(A{=}a)}$. This association is captured at the inner layers of the model, but since post-hoc approaches like Sent-debias do not alter the internal representation of the model, LPBS in its original form becomes ineffective — Figure 7. We refer to this original form of LPBS as ***attribute-LPBS***. Sent-debias ends up debiasing the attribute terms rather than the stereotype terms, thus, constantly producing low probability difference scores. Even so, we find LPBS being used in this form with Sent-debias in works such as (Steed et al., 2022). Using stereotype terms instead of attribute terms $P(X = x|A = a)$, which we refer to as ***target-LPBS***, is an option to solve this discrepancy, but given that many stereotype terms are usually out of vocabulary, these models will resort to wordpiece tokenization (Sennrich et al., 2016) which will be more challenging to handle. Nonetheless, in Figure 3, when the two versions of LPBS are compared, Sent-debias continues to have the best intrinsic fairness scores in both cases [10].

5 Probing further to uncover bias

We use the methodology in Section 3 to probe for bias in pretrained language models and their bias-mitigated versions to see if the intrinsic bias mitigation techniques actually mitigate biases or superficially conceal them from commonplace metrics like SEAT and LPBS. Gonen and Goldberg (2019) discovered that, for non-contextualized word embeddings, the bias mitigation techniques proposed by (Bolukbasi et al., 2016) were hiding bias instead of resolving bias. We use our probe to see if this is equally the case for intrinsic bias mitigation in contextualized embeddings. The consequence of mitigation techniques superficially hiding bias is that downstream classifiers can learn to pick up residual traces of gender information.

We validate our results by carrying out a randomization test, as described in Section 3, to test for statistical significance of our results. We conduct the test under the null hypothesis H_0 that the prediction accuracy of our original gender-stereotype sets will not differ significantly from the random split. We show in Table 2 the very low p-values that indicate statistical significant results, thus refuting H_0.

5.1 RQ2: Can intrinsic bias techniques and metrics hide bias instead of resolving it?

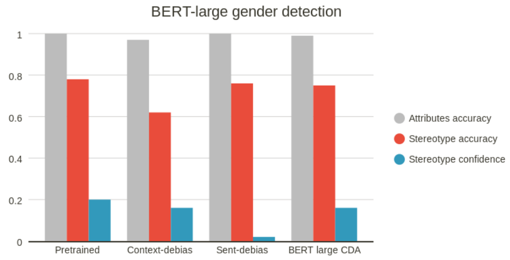

Figure 4: Gray bars indicate the accuracy of detecting gender information in attribute terms (high scores are desirable). Red bars indicate the accuracy of detecting gender information in stereotype terms (this should ideally be 0.5 in a fair classifier, showing the inability to correctly predict the gender association of stereotype terms). Blue bars indicate the average confidence of prediction: $\frac{1}{N}\sum_i^N |bias(e_i) - 0.5|$ (low scores are desirable).

In Figure 4, we show the results[11] of our probe for BERT-large. We highlight some key observations.

Bias accuracy and mean bias confidence do not correlate. We see from both plots in Figure 4

---

[10] For this comparison we only selected single-wordpiece attribute words to avoid challenges with multiple wordpieces.

[11] see Table 2 and Figure 10 for full results.

that, counter-intuitively, high bias accuracy does not concur with high mean bias confidence. Actually, Sent-debias, which consistently has the highest bias accuracy among the mitigation techniques, consistently has the lowest mean bias confidence. This indicates that these two notions of bias may not correspond. This, coupled with the finding in Figure 2 about the inconsistency between SEAT and LPBS, suggests that intrinsic bias could be perceived or measured from conflicting perspectives.

Some mitigation techniques can conceal gender information. For Sent-debias in ALBERT-large, we can, almost to the same degree of accuracy as for the unmitigated pretrained model, correctly predict the association of stereotypes to their respective genders using a simple linear classifier even with a low confidence. This will render a mitigation technique useless if a downstream classifier can correctly predict gender. This could only indicate that although models like Sent-debias significantly reduce the degree of association between stereotypes and their respective genders, hence the low confidence in prediction, this reduction does not inhibit the capability to correctly predict the associated gender of stereotypes; confirming that an intrinsic mitigation process can be rendered useless for downstream fairness even if the degree of association (confidence) is significantly reduced, so long as the information retained remains just enough to correctly associate the gender groups with their associated stereotypes.

5.2 RQ3: Do intrinsic bias mitigation techniques in language models improve fairness in downstream tasks?

To investigate the relationship between intrinsic and extrinsic gender bias, we train both BERT-large and ALBERT-large together with their intrinsic-bias-mitigated versions on the Bias-in-bios and Jigsaw datasets using a 10-fold train-test scheme to correctly predict the profession of each profile. We evaluate extrinsic bias based on gender TPRD and gender CF scores described in § 2.4. We conduct the test under three settings: 1) Using the original version of the training data. 2) Using our attribute scrubbed version (see Section 2.3). 3) Using the attribute-swap augmented version of the data (see Section 2.3). These three settings of the dataset are important to understand how intrinsic bias affects downstream fairness under different data settings.

In Figure 5, we show the extrinsic bias score [12] for BERT-large and its *debiased* versions, and the corresponding downstream data type for the Bias-in-Bios dataset — see Figure 11 and Figure 12 for all models and datasets.

Intrinsic mitigation techniques do not show a significant improvement on TPRD. We observe that all the intrinsic bias mitigation interventions we consider do not significantly improve bias in TPRD on their own. There is only a slight improvement or worsening bias in some cases. For Context-debias, we postulate this could be due to the limited list of words used to mitigate bias. If these limited words are not key terms in the downstream task or do not exist in the downstream text instances, the mitigation may not have a consequential effect on the downstream task.

Downstream data processing significantly improves downstream fairness. Secondly, we realize that the downstream data has a lot more material effect on downstream fairness. The data processing techniques: *attribute scrubbing and attribute swapping* showed improvements in TPRD producing the best results.

Combining intrinsic CDA and Downstream CDA produces best TPRD results. Thirdly, we realize that although the downstream data seems key to downstream fairness, a combination of intrinsic and downstream data intervention produces even better extrinsic fairness results.

Sent-debias significantly improves CF scores. Sent-debias is the only intrinsic technique that shows significant improvement in counterfactual fairness. Context-debias and CDA produce worse CF scores in some cases. We observe that the mode of application of Sent-debias in downstream classification tasks does not entirely align with the notion of intrinsic since gender information is removed from the sentence-level representation instead of word-level representation.

Combining Sent-Debias and fair downstream data produces the best CF scores. We also realize from BERT (Figure 5) and ALBERT that combining Sent-debias as a mitigation technique and a downstream data intervention produces the best CF scores.

---

[12] Full results with error margins are given in Table 3, Table 4, Table 5 and Table 6.

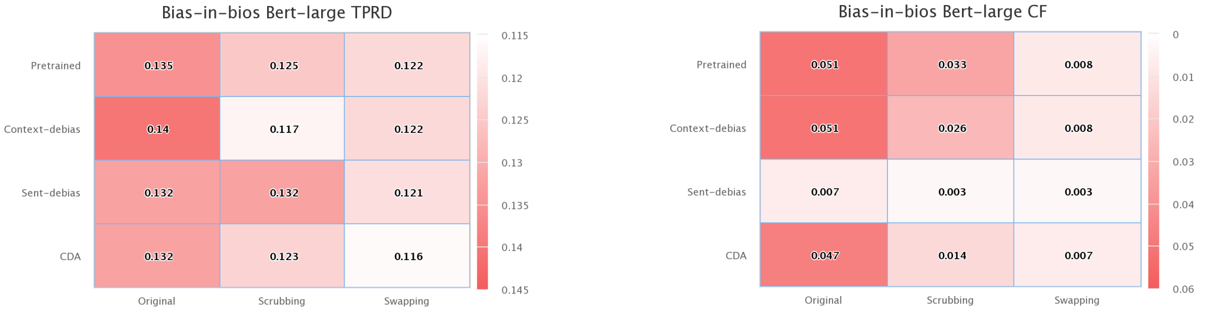

Figure 5: How intrinsic mitigation and downstream data intervention interact to influence fairness on the bias-in-bios data — BERT-large.

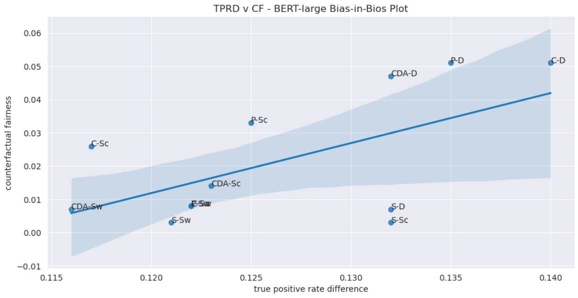

Figure 6: Relationship between TPRD and CF based on results from BERT model and Bias-in-Bios dataset. See Figure 13 for ALBERT-large.

TPRD vs Counterfactual-fairness. Here, we look at the relationship between TPRD and counterfactual fairness. As both measures are used as extrinsic fairness metrics, we aim to see how both results correlate. From Figure 6 we find a positive correlation in general between the two metrics. The downstream data interventions tend to improve both TPRD and CF the most.

6 Related work

Park et al. (2018) study the effects of three techniques to mitigate gender bias in abusive language detection; *debiased word embeddings* (based on the approach by Bolukbasi et al. (2016)), *gender swap* (counterfactual augmentation of classification data), *bias finetuning* using non-contextualized word embeddings: word2vec (Mikolov et al., 2013) and FastText (Bojanowski et al., 2017). They found that a combination of debiasing and gender swapping produced the best fairness results when implemented with a Gated Recurrent Unit (GRU).

Prost et al. (2019) examine three debiasing techniques for mitigating gender bias in downstream text classification using bias-in-bios (De-Arteaga et al., 2019b), with non-contextualized embeddings. Specifically, they examine *scrubbing* (deletion of identity terms) and approaches that focus on non-contextualized embeddings namely: *debiasing* (based on neutralization and equalization by Bolukbasi et al. (2016)), and *strong debiasing* Prost et al. (2019). Experimenting with Glove embeddings (Pennington et al., 2014), they show that strong debiased produces the best fairness results whilst maintaining a good accuracy score (second only to the unmitigated model). They again show that standard debiasing (Bolukbasi et al., 2016) can be counter-productive in terms of fairness; it can rather reduce fairness in downstream text classification.

Steed et al. (2022) meticulously investigate the effect of intrinsic bias in downstream text classification in RoBERTa. They also conclude that intrinsic/upstream bias does not significantly contribute to downstream bias. However, as we have previously discussed, using the default form of Log probability Bias score (attribute-LPBS) (Kurita et al., 2019) which they adopt to measure intrinsic bias may not be an effective technique to use with Sent-debias.

Orgad et al. (2022), the closest and concurrent with our work, investigate the relationship between intrinsic and extrinsic bias and also develop a probe based on a classification-based technique *minimum description length* (Voita and Titov, 2020) to detect bias in RoBERTa. They reach similar conclusions indicating how intrinsic metrics, like CEAT in their case, could conceal bias.

7 Conclusion

In this paper, we develop a probe to investigate intrinsic bias in two language models, BERT-large and ALBERT-large on two text classification tasks.

We use this probe to answer key research questions outlined for this research. We find that intrinsic bias metrics can be sensitive to certain intrinsic bias mitigation techniques. We also show that intrinsic bias mitigation techniques and metrics are capable of concealing bias instead of resolving it. We discover that intrinsic bias mitigation techniques we considered do not significantly improve fairness in text classification when used without other fairness interventions like data pre-processing. We recommend that intrinsic bias mitigation should ideally be combined with other fairness interventions.

Limitations

One obvious limitation of this work is the restriction to the use of English language as a basis. In future, we will explore how these conclusions vary in other language settings. Secondly, although we aimed to make the list of gender and attribute terms used in our experiments as extensive as possible, it is nearly impossible to cover all possible gender and target words in such contexts. Nonetheless, for the scope under consideration, we believe our compilation is extensive enough to give a general outlook and to draw the necessary conclusions. Finally, our work is heavily based on binary notions of gender which is a limitation considering the growing use of non-binary categorizations of gender and other biases which we outline in the ethical considerations section.

Ethical considerations

For practical reasons such as access to datasets and resources on gender bias, we limit our work to a binary representation of gender. We draw readers' attention to the fact that non-binary gender representations are nuanced and intricate (Dev et al., 2021), as such, this should be in cognizance when applying conclusions from this work in non-binary settings. Nonetheless, considering binary gender as a base form of gender categorization, the insights and conclusions from this work can form the baseline for exploring more complex gender categorizations.

Appendix

A Word lists for experiments

We generate the wordlist we use, given below, from the more extensive wordlist from (Kaneko and Bollegala, 2021). To mitigate the effect of multi-wordpiece tokens, we only select tokens with a single wordpiece. Hence we obtain the following wordlists:

A.1 attribute terms

- **female list:** ’witches’, ’mothers’, ’diva’, ’actress’, ’mama’, ’dowry’, ’princess’, ’abbess’, ’women’, ’widow’, ’ladies’, ’madam’, ’baroness’, ’niece’, ’lady’, ’sister’, ’nun’, ’her’, ’mare’, ’convent’, ’ladies’, ’queen’, ’maid’, ’chick’, ’empress’, ’mommy’, ’feminism’, ’gal’, ’estrogen’, ’goddess’, ’aunt’, ’hostess’, ’wife’, ’mom’, ’females’, ’ma’, ’belle’, ’maiden’, ’witch’, ’miss’, ’cow’, ’granddaughter’, ’her’, ’mistress’, ’nun’, ’actresses’, ’girlfriend’, ’lady’, ’maternal’, ’ladies’, ’sorority’, ’duchess’, ’ballerina’, ’fiancee’, ’wives’, ’maternity’, ’she’, ’heroine’, ’queens’, ’sisters’, ’stepmother’, ’daughter’, ’lady’, ’daughters’, ’mistress’, ’hostess’, ’nuns’, ’priestess’, ’filly’, ’herself’, ’girls’, ’lady’, ’vagina’, ’wife’, ’mother’, ’female’, ’womb’, ’heiress’, ’waitress’, ’woman’, ’bride’, ’grandma’, ’bride’, ’gal’, ’lesbian’, ’ladies’, ’girl’, ’grandmother’, ’mare’, ’maternity’, ’nuns’
- **male list:** ’wizards’, ’fathers’, ’actor’, ’bachelor’, ’papa’, ’dukes’, ’hosts’, ’airmen’, ’penis’, ’prince’, ’governors’, ’abbot’, ’men’, ’gentlemen’, ’sir’, ’baron’, ’gods’, ’nephew’, ’lord’, ’brother’, ’priest’, ’his’, ’marquis’, ’princes’, ’emperors’, ’stallion’, ’chairman’, ’monastery’, ’priests’, ’king’, ’spokesman’, ’tailor’, ’cowboys’, ’dude’, ’emperor’, ’daddy’, ’guys’, ’guy’, ’godfather’, ’god’, ’patriarch’, ’uncle’, ’sir’, ’brotherhood’, ’host’, ’testosterone’, ’husband’, ’dad’, ’steward’, ’males’, ’pa’, ’beau’, ’stud’, ’bachelor’, ’wizard’, ’sir’, ’bull’, ’grandson’, ’horsemen’, ’rooster’, ’bachelor’, ’him’, ’master’, ’lad’, ’policeman’, ’monk’, ’actors’, ’boyfriend’, ’statesman’, ’paternal’, ’landlord’, ’brethren’, ’lords’, ’fraternity’, ’duke’, ’fiance’, ’colts’, ’husbands’, ’he’, ’businessman’, ’hero’, ’deer’, ’kings’, ’brothers’, ’masters’, ’stepfather’, ’son’, ’cowboy’, ’sons’, ’baritone’, ’salesman’, ’monks’, ’lads’, ’congressman’, ’priest’, ’barons’, ’beard’, ’colt’, ’himself’, ’boys’, ’lions’, ’gentleman’, ’penis’, ’his’, ’bulls’, ’uncles’, ’lion’, ’sorcerer’, ’father’, ’male’, ’sperm’, ’prostate’, ’businessmen’, ’heir’, ’waiter’, ’headmaster’, ’man’, ’governor’, ’god’, ’grandpa’, ’groom’, ’dude’, ’gay’, ’boy’, ’grandfather’, ’priests’

A.2 List of stereotypes(target words)

- **female list:** ’beauty’, ’blonde’, ’cheerleading’, ’cooking’, ’flirt’, ’flower’, ’gossip’, ’housekeeper’, ’jewelry’, ’nanny’, ’nurse’, ’nurses’, ’pink’, ’pretty’, ’receptionist’, ’sewing’, ’softball’, ’makeup’, ’therapist’, ’maid’, ’chairperson’
- **male list:** ’warrior’, ’strong’, ’terrorist’, ’soldier’, ’sniper’, ’baseball’, ’sergeant’, ’body-

guard', 'boss', 'boxer', 'captain', 'carpenter', 'chancellor', 'colonel', 'commander', 'conductor', 'diplomat', 'drummer', 'engineer', 'gangster', 'geek', 'guitarist', 'industrialist', 'marshal', 'mechanic', 'philosopher', 'physicist', 'scientist', 'rapper', 'mechanic', 'carpenter', 'clergy'

B Intrinsic metrics

B.1 Context-debias

$$L_i = \sum_{t \in \mathcal{V}_t} \sum_{x \in \Omega(t)} \sum_{a \in \mathcal{V}_a} (v_i(a)^T E_I(t, x; \theta_e))^2))$$

$$L_{reg} = \sum_{x \in A} \sum_{w \in x} \sum_{i=1} ||E_i(w, x; \theta_e) - E_i(w, x; \theta_pre)||^2$$

$$L = \alpha L_i + \beta L_{reg}$$

Where L_i is the orthogonality constraint such that $E_i(w, x; \theta_e)$ denotes the embedding of token w in the i-th layer of a contextualised word embedding model E with parameters θ_e. $v_i(a)$ is the non-contextualised embedding of an attribute word a. L_{reg} is a regularizer that constrains the Euclidean distance between the contextualized word embedding of a word w in the ith layer in the original pretrained model with parameters θ_{pre}.

B.2 Sent-debias

$$v = PCA_k(\cup_{j=1} \cup_{w \in \mathcal{R}_j} (w - \mu_j))$$

$$h_v = \sum_{j=1}^{k} \langle h, v_j \rangle v_j$$

$$\hat{h} = h - h_v$$

where v represents the top-k gender subspace, h the representation of a given embedding, h_v the projection of h onto v, and $\hat{h}$ the resulting debiased subspace.

C Experiment set-up

We train all models for 4 epochs, a learning rate of $2e^{-5}$ on Tesla V100-SXM3-32GB. We use a sequence length of 100 as the default for all extrinsic tasks. For all downstream tasks, we use a one-layer linear classifier.

D Datasets

Bias-in-bios (De-Arteaga et al., 2019a) consists of online English biographies of people. We use this dataset to predict the occupations of people. Since the gender labels are provided, we can compute disparities in predictive performance between male and female gender groups.

We select the top 7 female and top 7 male professions based on the gender percentages. We take these two sets to represent female and male dominated jobs respectively.

Jigsaw dataset [13] from the online platform *Civil comments* contains online comments. This dataset is scored from 0 to 10 with the perceived gender of the targets of these comments as well as the toxicity levels of these comments. We use this dataset to predict whether or not a comment is toxic against the target persons. We use gender labels to compute predictive disparities.

We select all comments with toxicity score above 0.5 as the toxic comments and those with a score of exactly 0 as the non-toxic ones in order to eliminate fine-margins. We use the same technique to annotate gender by labeling a gender positive if it scores above 0.5 whilst its complimentary gender has a score of exactly 0.

E Measuring intrinsic bias with LPBS when debiasing is done with Sent-debias

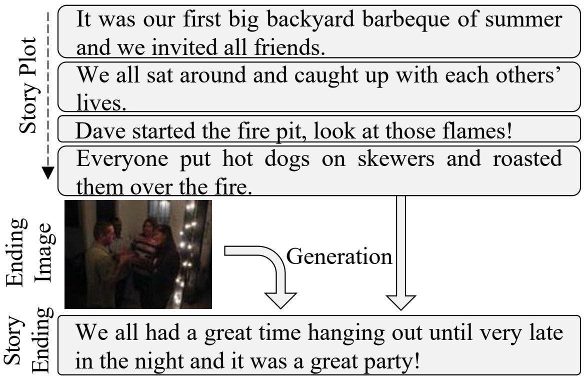
Abstract

Image-guided story ending generation (IgSEG) is to generate a story ending based on given story plots and ending image. Existing methods focus on cross-modal feature fusion but overlook reasoning and mining implicit information from story plots and ending image. To tackle this drawback, we propose a multimodal event transformer, an event-based reasoning framework for IgSEG. Specifically, we construct visual and semantic event graphs from story plots and ending image, and leverage event-based reasoning to reason and mine implicit information in a single modality. Next, we connect visual and semantic event graphs and utilize cross-modal fusion to integrate different-modality features. In addition, we propose a multimodal injector to adaptive pass essential information to decoder. Besides, we present an incoherence detection to enhance the understanding context of a story plot and the robustness of graph modeling for our model. Experimental results show that our method achieves state-of-the-art performance for the image-guided story ending generation.

1 Introduction

Story ending generation (Guan et al., 2019) aims to generate a reasonable ending for a given story plot. It requires deep models to integrate powerful language understanding capability, which is crucial for artificial intelligence. Many efforts (Wang and Wan, 2019; Guan et al., 2019; Yao et al., 2019; Guan et al., 2020) have been proposed and achieved promising results since neural models designed for comprehending natural language allow them to understand story plots and reason reasonable story endings. With the advance of automatic story generation, it has attracted outstanding attention in multimodality research (Jung et al., 2020; Yu et al., 2021; Chen et al., 2021).



It was our first big backyard barbeque of summer and we invited all friends.

We all sat around and caught up with each others' lives.

Dave started the fire pit, look at those flames!

Everyone put hot dogs on skewers and roasted them over the fire.

We all had a great time hanging out until very late in the night and it was a great party!

Figure 1: Given a multi-sentence story plot and an ending image, the image-guided story ending generation aims to generate a story ending related to the image.

However, since story plots and story ending usually correspond to different content, the context with information bottleneck is not enough to deduce an informative story ending, i.e., generated endings tend to be inane and generic. To address this issue, Huang et al. (2021) propose an image-guided story ending generation (IgSEG) task that combines story plots and ending image to generate a coherent, specific and informative story ending. IgSEG demands not only introducing information from the ending image to story plots for story ending generation but also reasoning and mining implicit information from story plots and ending image, respectively. As shown in Figure 1, for story plots, "party" can be inferred from "big backyard barbeque" and "invited all friends", and "all friends", "all sat around" and "caught up with" can deduce "had a great time". For the ending image, "dim indoor" and "bright lights" can infer "very late in the night".

Existing methods (Huang et al., 2021; Xue et al., 2022) focus on cross-modal feature fusion but overlook reasoning and mining implicit information from story plots and ending images. Nonetheless, to effectively conduct cross-modal feature fusion, it is necessary to reason and mine more implicit

information from single-modality data. An event is a fine-grained semantic unit, which refers to a text span composed of a predicate and its arguments (Zhang et al., 2020). Recently, event-centric reasoning displays excellent capability for context understanding and subsequent event prediction (Zhou et al., 2022b). In this work, we propose a multimodal event transformer (MET) to mine implicit information to improve cross-modal fusion. For story plots, we leverage semantic role labeling (SRL) parser (He et al., 2017) to extract events from story plots and then construct them into a semantic event graph. For an ending image, we utilize scene graph parser (Zellers et al., 2018) to capture visual concepts and their relation to construct visual event graphs. Since edges contain relationships between nodes in visual and semantic event graphs, we employ relational graph convolutional networks (RGCN) (Schlichtkrull et al., 2018) to encode event graphs to infer implicit information.

For cross-modal feature fusion, most recent works (Huang et al., 2021; Xue et al., 2022) adopt attention-based neural network models to implicitly integrate multi-modal features. However, due to the complexity of cross-modal features and the existence of dependency between single-modal features, it is often difficult for these models to complement cross-modal features. To tackle the issue, we propose cross-modal fusion to integrate different-modality features. Specifically, we merge visual and semantic event graphs and use RGCN to fuse cross-modal features for feature complement.

Moreover, since features from different modalities suffer from domain inconsistency, previous methods (Huang et al., 2021; Xue et al., 2022) directly concatenate them and pass them to the decoder, which is not a crafted manner. To appropriately combine features from different modalities, we design a multimodal injector to integrate relevant features into the decoder. In addition, we propose an incoherence detection to enhance the context understanding for a story plot and the robustness of graph modeling for our model.

In experiments, we conduct extensive evaluations on two datasets (i.e., VIST-E (Huang et al., 2021) and LSMDC-E (Xue et al., 2022)). Experimental results show that our method outperforms strong competitors and achieves state-of-the-art performance. In addition, we conduct further analysis and human evaluation to demonstrate the effectiveness of our method.

2 Related Work

2.1 Story Ending Generation

Story ending generation aims to generate a story ending for given story plots, and it is one of the important tasks in natural language generation. Many efforts have been invested in story ending generation (Wang and Wan, 2019; Guan et al., 2019; Yao et al., 2019; Guan et al., 2020). To make the generated story ending more reasonable, Guan et al. (2019) propose a model encapsulating a multi-source attention mechanism, which can utilize context clues and understand commonsense knowledge. To ensure the coherence in generated story endings, Wang and Wan (2019) propose a transformer-based conditional autoencoder, which can capture contextual clues in story splot. To improve long-range coherence in generated stories, Guan et al. (2020) pre-train model on external commonsense knowledge bases for the story ending generation. Zhou et al. (2022b) propose a correlation-aware context-to-event pre-trained transformer, which applies to a wide range of event-centric reasoning and generation scenarios, including story ending generation. Beyond the limit of single-modal information, Huang et al. (2021) introduce visual information to enrich the generation of story endings with more coherent, specific, and informative. To improve cross-modal feature fusion, Xue et al. (2022) propose a multimodal memory transformer, which fuses contextual and visual information to capture the multimodal dependency effectively.

2.2 Visual Storytelling

Visual storytelling task is proposed by Huang et al. (2016), which aims to generate a story based on a given image stream. Wang et al. (2018) present an adversarial reward learning framework to learn an implicit reward function from human demonstrations. To inject imaginary concepts that do not appear in the images, some works (Yang et al., 2019; Chen et al., 2021; Xu et al., 2021) propose building scene graphs and injecting external knowledge into model to reason the relationship between visual concepts. Qi et al. (2021) propose a latent memory-augmented graph transformer to exploit the semantic relationships among image regions and attentively aggregate critical visual features based on the parsed scene graphs.

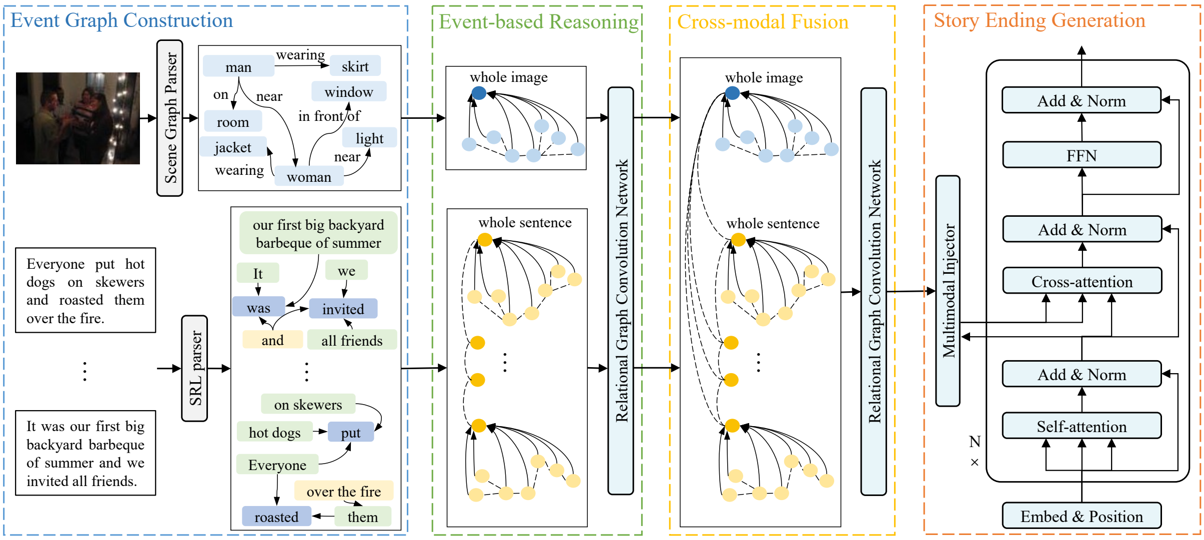

Figure 2: An overview of our model. Grey rounded rectangles denote fixed model. Blue rounded rectangles denote parameters that will be optimized.

2.3 Event-centric Reasoning

Events always play an essential role in a story because a story is composed of multiple events and implies the relationship between the events. An event is a text span composed of a predicate and its arguments (Zhang et al., 2020). Multiple events include relations between events that conform to human commonsense (Zhou et al., 2022a). Some works use plot events for story generation, which is generating a prompt and then transforming it into a text (Ammanabrolu et al., 2020; Fan et al., 2019). To generate a more coherent and specific ending, understanding events in story plots and their relationship can obtain informative context, which is a crucial step for story ending generation.

3 Method

This section will elaborate on our method for image-guided story ending generation, including event graph construction, event-based reasoning, cross-modal fusion, multimodal injector and story ending generation. The details of our method are shown in Figure 2. Lastly, details about objectives and training are elaborated.

3.1 Event Graph Construction

Semantic Event Graph. The story plot contains multiple events which are correlated with each other. The definition of an event is a text span composed of a predicate and its arguments (Zhang et al., 2020). The event-centric reasoning shows excellent capability for context understanding and subsequent event prediction (Zhou et al., 2022b). To effectively reason and mine more implicit information from story plots, we use semantic role labeling (SRL) to parse the story and extract events from parsing results, as shown in Figure 2. Specifically, Given story plots $\mathcal{S} = \{\boldsymbol{S}_1, \boldsymbol{S}_2, \boldsymbol{S}_3, \boldsymbol{S}_4\}$, we construct semantic event graphs $\mathcal{G}_i^s = (\mathcal{V}_i^s, \mathcal{E}_i^s)$ by SRL. $\mathcal{E}_i^s$ consists of two vectors, one for the positive direction and one for the opposite direction, and $\mathcal{V}_i^s = \{\boldsymbol{s}_0^i, \boldsymbol{s}_1^i, \boldsymbol{s}_2^i, \cdots, \boldsymbol{s}_n^i\}$. To obtain features of each node, we use a pre-trained transformer encoder to obtain token representations in sentence $\boldsymbol{S}_i$.

$$\boldsymbol{T}_i = \text{Trans-Enc}(\boldsymbol{S}_i), \boldsymbol{T}_i \in \{\boldsymbol{t}_i^1, \boldsymbol{t}_i^2, \cdots, \boldsymbol{t}_i^g\} \quad (1)$$

where $\boldsymbol{t}_i^g$ denotes token representation, and g is length of sentence $\boldsymbol{S}_i$. Next, we conduct a mean pooling operation for tokens presentations based on SRL parsing result $\hat{\boldsymbol{S}}_i$ to get presentation $\hat{\boldsymbol{s}}_j^i$ for each node. In addition, we take pooling for all token presentations of sentence $\boldsymbol{S}_i$ to obtain a presentation of sentence node $\hat{\boldsymbol{s}}_0^i$. Each node $\hat{\boldsymbol{s}}_j^i$ in sentence $\boldsymbol{S}_i$ is connected to the sentence node. To preserve the relationship between sequences, we connect sentence nodes in the order of the sequence.

Visual Event Graph. For ending images, previous works (Huang et al., 2021; Xue et al., 2022) use pre-trained convolutional neural networks (CNN) to extract feature maps directly. We construct visual event graphs to reason and mine more implicit information from ending images. Scene graphs have been used for many tasks to produce structured graph representations of visual scenes (Zellers et al., 2018). Inspired by the success of these tasks, we parse the ending image $\boldsymbol{I}$ to a scene graph via the scene graph parser. A scene graph can be denoted as a tuple $\mathcal{G}^I = \{\mathcal{V}^I, \mathcal{E}^I\}$, where $\mathcal{V}^I = \{\boldsymbol{v}_0, \boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_k\}$ is a set of k detected objects. $\boldsymbol{v}_0$ denotes a representation of the whole image, and other $\boldsymbol{v}_i$ is a region representation of detected object. $\mathcal{E}^I = \{e_1, e_2, \cdots, e_m\}$ is a set of directed edges and each edge e_i refers to a triplet $(\boldsymbol{v}_i, \boldsymbol{r}_{i,j}, \boldsymbol{v}_j)$, which includes two directional edges from $\boldsymbol{v}_i$ to $\boldsymbol{r}_{i,j}$ and from $\boldsymbol{r}_{i,j}$ to $\boldsymbol{v}_j$. Specifically, the construction of the scene graph can be divided into two parts: one is object detection, and the other is visual relation detection.

For object detection, we leverage a well-trained object detector, Faster-RCNN (Ren et al., 2017) with a ResNet-152 (He et al., 2016) backbone, to classify and encode objects in the ending image $\boldsymbol{I}$. The outputs of detector include a set of region representations $\mathcal{V}^I = \{\boldsymbol{v}_1, \boldsymbol{v}_2, \cdots, \boldsymbol{v}_k\}$ and object categories $\mathcal{O} = \{o_1, o_2, \cdots, o_k\}$. For visual relation detection, we leverage MOTIFS (Zellers et al., 2018) as our relation detector to classify the relationship between objects. We train the relation detector on Visual Genome dataset (Krishna et al., 2017). The output of relation detector is a set of relation $\mathcal{E}^I = \{e_1, e_2, \cdots, e_m\}$, where e_i refers to a triplet $(\boldsymbol{v}_i, \boldsymbol{r}_{i,j}, \boldsymbol{v}_j)$. Lastly, we obtain the scene graph $\mathcal{G}^I = \{\mathcal{V}^I, \mathcal{E}^I\}$ of ending image by combining the results of object detection and relationship detection.

3.2 Event-based Reasoning

We perform graph-structure reasoning over semantic and visual event graphs to effectively reason and mine more implicit information from story plots and ending images. Since event graphs have multiple relations between nodes (e.g., relations between visual objects, relations between predicates and arguments, etc.), we select relational graph convolutional networks (RGCN), which can pass different messages along different relations. Specifically, for each layer l in L-layer RGCN, the node representation $\boldsymbol{w}_i^l$ is updated as follows:

$$\boldsymbol{w}_i^{l+1} = \text{ReLU}\Big(\sum_{r \in \mathcal{R}} \sum_{j \in \mathcal{N}_r(i)} \frac{1}{|\mathcal{N}_r(i)|} \boldsymbol{W}_r \cdot \boldsymbol{w}_j^l\Big) \quad (2)$$

where $\mathcal{R}$ denote a set of all edges types, and $\mathcal{N}_r(i)$ is the neighborhood of node i under relation r. To reason and mine more implicit information in single-modality, we conduct event-based reasoning on semantic and visual event graphs, respectively.

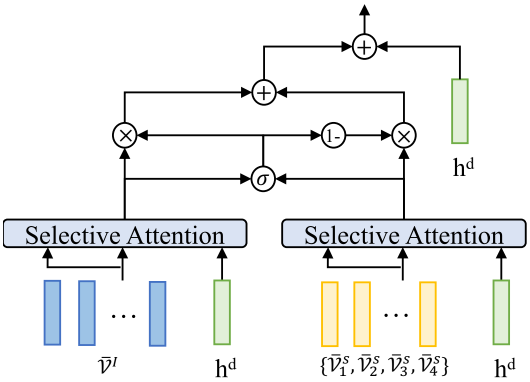

Figure 3: Details of the multimodal injector.

3.3 Cross-modal Fusion

We propose cross-modal fusion for visual and semantic event graphs to integrate information from story plots and ending images. We adopt a layer normalization for node features to reduce the cross-modal gap between visual and semantic graphs. For cross-modal feature fusion, previous works (Huang et al., 2021; Xue et al., 2022) adopt attention-based neural network models to implicitly integrate multimodal features. However, these models neglect the dependency between single-modal features. Therefore, we maintain graph structure for visual and semantic features and connect nodes that represent whole image and sentences, as shown in Figure 2. Moreover, we utilize RGCN as Eq.2 to integrate cross-modal features in event graph, and outputs denote as $\bar{\mathcal{V}}_i^s = \{\bar{\boldsymbol{s}}_0^i, \bar{\boldsymbol{s}}_1^i, \bar{\boldsymbol{s}}_2^i, \cdots, \bar{\boldsymbol{s}}_n^i\}$ and $\bar{\mathcal{V}}^I = \{\bar{\boldsymbol{v}}_0, \bar{\boldsymbol{v}}_1, \bar{\boldsymbol{v}}_2, \cdots, \bar{\boldsymbol{v}}_k\}$.

3.4 Multimodal Injector

To integrate different modal sources, we propose a multimodal injector, which adaptly extracts key information from different modal features and integrates them appropriately. As shown in Figure 3, inputs of multimodal injector include a hidden state $\boldsymbol{h}^d$ from the decoder, visual features $\bar{\mathcal{V}}^I$ and semantic features $\bar{\mathcal{V}}_i^s$. Specifically, we first use selective attention for key information extraction, i.e.,

$$\boldsymbol{h}_{attn}^u = \text{softmax}\left(\frac{QK^{\mathrm{T}}}{\sqrt{d_k}}\right) V, u \in \{I, S\} \quad (3)$$

where Q is $\boldsymbol{h}^d$ from decoder; K and V are visual features $\bar{\mathcal{V}}^I$ or semantic features $\bar{\mathcal{V}}_i^s$; and d_k is the same as the dimension of $\boldsymbol{h}^d$. Then, the gate $\lambda \in [0, 1]$ and the fused output are defined as:

$$\lambda = \sigma\left(\boldsymbol{U}\boldsymbol{h}^I_{attn} + \boldsymbol{V}\boldsymbol{h}^S_{attn}\right) \tag{4}$$

where $\boldsymbol{U}$ and $\boldsymbol{V}$ are trainable weights. λ controls how much visual information is attended.

$$\hat{\boldsymbol{h}}^d = \lambda \cdot \boldsymbol{h}^I_{attn} + (1-\lambda) \cdot \boldsymbol{h}^S_{attn} + \boldsymbol{h}^d \tag{5}$$

where the fusion vector $\hat{\boldsymbol{h}}^d$ is fed into the decoder.

3.5 Story Ending Generation

Recently, Transformer (Vaswani et al., 2017) shows its powerful ability to generate natural language (Radford et al., 2019). For story ending generation, we use a Transformer decoder as the decoder for our model. Specifically, the decoder input includes a segment of the generated story ending $\bar{\boldsymbol{C}}$ and fusion vector $\hat{\boldsymbol{h}}^d$ from the multimodal injector. The purpose of the decoder is to predict a probability distribution of the next word of the segment $\bar{\boldsymbol{C}}$, i.e.,

$$\begin{aligned} \boldsymbol{h}_i &= \text{Trans-Dec}(\hat{\boldsymbol{h}}^d, \bar{\boldsymbol{C}}) \in \mathbb{R}^d \\ &\quad \text{where } \bar{\boldsymbol{C}} = [c_1, \ldots, c_{i-1}] \qquad (6) \\ \boldsymbol{p}_i &= \text{LM-Head}(\boldsymbol{h}_i) \in \mathbb{R}^V \qquad (7) \end{aligned}$$

where $\boldsymbol{h}_i$ refers to the hidden representation in i-th step; V denotes token vocabulary and $\boldsymbol{p}_i$ refers to a probability distribution over $\mathcal{V}$; d in $\hat{\boldsymbol{h}}^d$ denotes the current number of layer. Lastly, the story ending generation objective is defined as a maximum likelihood estimation. The loss function is defined as:

$$\mathcal{L}^{(gen)} = -\frac{1}{|N|}\sum\nolimits_{i=1}^{N} \log \boldsymbol{p}_i(c_i), \tag{8}$$

where $\boldsymbol{p}_i(c_i)$ denotes fetching the probability of the i-th step gold token $c_i \in \boldsymbol{C}$ from $\boldsymbol{p}_i$. $\boldsymbol{C}$ refers to the gold caption, and N is its length.

3.6 Incoherence Detection

To enhance the understanding context of a story plot and robustness of graph modeling for our model, we introduce a training objective: incoherence detection. We set a 10% probability to replace a whole sentence node in semantic event graph randomly. In the objective, the final step output $\boldsymbol{h}_n$ of the decoder is passed into a MLP to classify whether each whole sentence node is changed, i.e.,

$$\boldsymbol{p}^{clf} = \sigma(\text{MLP}(\boldsymbol{h}_n)) \in \mathbb{R}^4 \tag{9}$$

where σ denotes a sigmoid function. The loss function is defined as:

$$\begin{aligned} \mathcal{L}^{(clf)} = -\frac{1}{4}\sum_{i=1}^{4} & y_i \cdot \log(\boldsymbol{p}_i^{clf}) \\ & + (1-y_i) \cdot \log(1-\boldsymbol{p}_i^{clf}) \qquad (10) \end{aligned}$$

3.7 Training

In model training, we set a trade-off parameter α for two losses $\mathcal{L}^{(gen)}$ and $\mathcal{L}^{(clf)}$. The total loss function of our model is definite as follows:

$$\mathcal{L} = \mathcal{L}^{(gen)} + \alpha \times \mathcal{L}^{(clf)} \tag{11}$$

4 Experiment

4.1 Dataset and Evaluation Metric

VIST-Ending. We compare our model and other state-of-the-art methods on the VIST-Ending (VIST-E) dataset (Huang et al., 2021). The dataset is built over VIST dataset (Huang et al., 2016). The VIST-E dataset comprises 39,920 samples for training, 4,963 samples for validation and 5,030 samples for testing. In experiments, we follow the data split in (Huang et al., 2021).

LSMDC-Ending. LSMDC-Ending (LSMDC-E) (Xue et al., 2022) contains 20,151 training samples, 1,477 validation samples and 2,005 test samples, which are collected from LSMDC 2021 (Rohrbach et al., 2017).

Visual Genome. We use the Visual Genome (VG) dataset to train a visual relationship detector. The dataset includes 108,077 images annotated with scene graphs, and we follow the setting in (Xu et al., 2017), which contains 150 object classes and 50 relation classes.

Evaluation Metric. As follow Xue et al. (2022), we utilize the same metrics to report evaluation results, and the evaluation code is open-source[1]. The evaluation metrics include: BLEU (Kingma and Ba, 2015), METEOR (Banerjee and Lavie, 2005), CIDEr (Vedantam et al., 2015), ROUGE-L (Lin, 2004) and Result Sum (rSUM) (Xue et al., 2022).

4.2 Implementation Details

For the scene graph, we limit the maximum number of objects to 10 and the maximum number of relationships to 20. The relational graph convolution network includes four relational graph convolution

layers, and the size of input and output sets of 768. For semantic event reasoning, we use a pre-trained BERT model (Devlin et al., 2019) as the language model. The layers and attention heads of the decoder are 12 and 8. The dimension of embedding vectors in the decoder is 768, and the dimension of hidden states is 768. The visual feature encoder is ResNet-152. For model training, we select the Adam optimizer (Kingma and Ba, 2015) to optimize the model with learning rate of 2e-4. The maximum training epoch of our model is 25. The trade-off parameter α in Eq.11 is 0.2. The batch size, weight decay and warm-up proportion are 128, 0.01 and 0.1. During inference, we use the beam search with a beam size of 3 to generate a story ending with maximum sentence length is 25. Our model is trained on one V100 GPU.

4.3 Baselines

We compare our model with following state-of-the-art baselines: (1) **Seq2Seq** is a stack RNN-based model (Luong et al., 2015) with attention mechanisms, and image features are directly concatenated. (2) **Transformer**, proposed by Vaswani et al. (2017), is an encoder-decoder model with self-attention mechanisms. (3) **IE+MSA** is a story ending generation model incorporating external knowledge (Guan et al., 2019). (4) **T-CVAE** (Wang and Wan, 2019) is a conditional variational autoencoder based on transformer for missing story plots generation. (5) **MG+Trans** consists of multi-layer graph convolutional networks and a transformer decoder (Huang et al., 2021). (6) **MG+CIA** consists of multi-layer graph convolutional networks, top-down LSTM and one context-image attention unit in the decoder (Huang et al., 2021). (7) **MGCL** is an image-guided story ending generation model with multi-layer graph convolution networks and cascade-LSTM (Huang et al., 2021). (8) **MMT** is a multimodal memory transformer for image-guided story ending generation (Xue et al., 2022).

4.4 Main Results

The experimental results on VIST-E and LSMDC-E are shown in Table 1 and Table 2. From the tables, we can make two observations. Firstly, our model achieves state-of-the-art performance on the VIST-E and LSMDC-E datasets compared to other strong competitors. In addition, MG+CIA, MGCL, MMT and our model significantly and consistently outperform other models that directly concatenate visual features. It indicates that mining visual information is essential and can provide rich information to predict the ending. Moreover, our model

Table 4: Result of the SEG task on the VIST-E dataset (plain text). The bold / underline denotes the best and the second performance, respectively.

achieves better results than MG+CIA, MGCL and MMT, demonstrating that reasoning and mining implicit information from story plots and ending image is significant for image-guided story ending generation.

4.5 Ablation Study

To verify the effectiveness of our method, we conduct an ablation study and show the results in Table 3. Firstly, the table shows that removing each component or objective decreases the model performance, which demonstrates our method's effectiveness. In addition, we observe that removing cross-modal fusion and multimodal injector brings a great performance drop, which shows that cross-modal information mining and adaptive integration play a crucial role in story ending prediction.

4.6 SEG Setting

To investigate the effectiveness of visual information mining in our method, we remove the image from the VIST-E dataset and evaluate it on only plain text. The results are shown in Table 4. From the table, we observe that our model keeps competitive with Plan&Write (Yao et al., 2019) and KE-GPT2 (Guan et al., 2020) models designed especially for textual story generation. Moreover, our model outperforms MG+trans, which verifies the effectiveness of our incoherence detection and semantic event-based reasoning. Our model performs better when adding the image, as shown in Table 1. It demonstrates that mining implied visual information can help story ending generation.

4.7 Analysis

4.7.1 Impact of Event-based Reasoning

To investigate the effectiveness of event reasoning, we analyze its impact, and the results are shown in Table 5. From the table, we can observe that replacing semantic role labeling with dependency parsing leads to decreased performance. Moreover, replacing the visual event graph with whole image features (i.e., features extracted by pre-trained CNN) shows a performance drop. In addition, removing cross-modal fusion also shows a performance drop. These demonstrate the effectiveness of event-based reasoning for the image-guided story ending generation.

4.7.2 Case Study

To extensively evaluate our method, we conduct a case study for our model and MGCL, and some random sampling examples are shown in Figure 4. For example, in the left case, we can observe that our model can reason that the man in the image is a soldier, while the result from MGCL is not significantly related to visual content. For example, in the right case, our model can generate the word "relax"

Method	Gram.	Logic.	Rele.
MET	**3.49**	**3.37**	**2.94**
MGCL	3.36	3.15	2.66
MG+Trans	3.22	2.78	2.71

Table 6: Human evaluation.

based on the objects "human" and "chair". It shows that our model can mine the implicit information based on visual and semantic information.

4.7.3 Interpretable Visualization Analysis

To investigate the effectiveness of the multimodal injector, we conduct an interpretable visualization analysis. The results are shown in Figure 5. The word with a blue underline denotes that the multimodal injector is assigned the greater probability in the node of visual event graph. Green corresponds to greater probability in the node of semantic event graph. The dotted boxes below represent the specific content of nodes. From the results, we can observe that nodes in visual and semantic event graphs are able to deduce implicit information.

4.7.4 Human Evaluation

To evaluate our method more comprehensively, we conducted a human evaluation to compare further the performance of our model and MGCL and MG+trans. As follow Huang et al. (2021), we considered three metrics for the story ending generated by models: Grammaticality (Gram.) (Wang and Wan, 2019) evaluates correctness, natural, and fluency of story endings; Logicality (Logic.) (Wang and Wan, 2019) evaluates reasonability and coherence of story endings; Relevance (Rele.) (Yang et al., 2019) measures how relevant between images and generated story endings. We randomly sampled 100 samples from the test set and display them to 3 recruited annotators. Thereby, each annotator worked on 300 items from 3 models. We show 3 annotators all outputs from all 3 models at once and shuffle the output-model correspondence to ensure that annotators do not know which model the output is predicted from. Following Yang et al.

(2019), we set a 5-grade marking system, where one is the worst grade, and five is the maximum. The results show that the performance of our model is significantly better than MGCL and MG+trans. That is, our model can generate higher-quality story endings.

5 Conclusion

In this work, we propose a multimodal event transformer, a framework for image-guided story ending generation. Our method includes event graph construction, event-based reasoning, cross-model fusion, multimodal injector and story ending generation. Different from previous work, our method not only focuses on cross-modal information fusion but also on reasoning and mining implicit information from single-modality data. In addition, we propose an incoherence detection to enhance the understanding context of a story plot and robustness of graph modeling for our model. In the experiments, results show that our method delivers state-of-the-art performance.

Limitations

Although our proposed method can effectively reason and mine implicit information from story plots and ending image, it suffers from weaknesses in integrating cross-modal information. Specifically, our method connects visual and semantic event graphs by connecting whole image nodes and whole sentence nodes. It lacks fine-grained information to pass between semantic events to visual objects. In further work, we will study how to pass fine-grained information between visual and semantic event graphs.

Abstract

Text-guided image inpainting (TGII) aims to restore missing regions based on a given text in a damaged image. Existing methods are based on a strong vision encoder and a cross-modal fusion model to integrate cross-modal features. However, these methods allocate most of the computation to visual encoding, while light computation on modeling modality interactions. Moreover, they take cross-modal fusion for depth features, which ignores a fine-grained alignment between text and image. Recently, vision-language pre-trained models (VLPM), encapsulating rich cross-modal alignment knowledge, have advanced in most multimodal tasks. In this work, we propose a novel model for TGII by improving cross-modal alignment (CMA). CMA model consists of a VLPM as a vision-language encoder, an image generator and global-local discriminators. To explore cross-modal alignment knowledge for image restoration, we introduce cross-modal alignment distillation and in-sample distribution distillation. In addition, we employ adversarial training to enhance the model to fill the missing region in complicated structures effectively. Experiments are conducted on two popular vision-language datasets. Results show that our model achieves state-of-the-art performance compared with other strong competitors.

1 Introduction

Text-guided image inpainting (TGII), involving computer vision (CV) and natural language processing (NLP), aims to restore visual content for a missing area in a damaged image based on a given text (Zhang et al., 2020a). With the development of CV and NLP, it plays an essential role in many real-world applications, such as image editing (Zhu et al., 2020), damaged image restoration (Liu et al., 2019), and image rendering (Kirillov et al., 2020). Therefore, it has become one of the most crucial areas in CV and NLP.

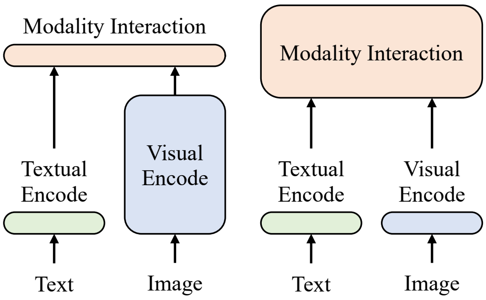

Figure 1: Different categories of vision-and-language models. *left*: most of the computation on visual encoding; *right*: most of the computation on modeling modality interactions.

Existing methods (Zhang et al., 2020b; Lin et al., 2020; Wu et al., 2021) adopt an encoder-decoder framework as their backbone with a vision-language fusion module to introduce textual information. These methods use separate encoders for images and texts, heavier on the former. Then, the vision-language fusion module is used to integrate the features from the two modalities through a simple similarity calculation of features, or shallow attention layers (Vaswani et al., 2017), as shown on the left of Figure 1. Most of the computation of these methods on visual encoding, while textual features only serve as a complement to deep visual features, which ignores the importance of deep interaction of multimodal information. Moreover, these methods share a common drawback: they do not perform well for natural image datasets with a wide variety of objects (e.g., MSCOCO (Lin et al., 2014)). The reason is that these methods lack fine-grained alignment knowledge of texts and images to guide the fusion of cross-modal information in multimodal interactions. Besides, their fusion modules lack powerful cross-modal reasoning capabilities.

Recently, providing the success of pre-trained language/vision Transformer (Devlin et al., 2019; Dosovitskiy et al., 2021; Zhou et al., 2022a),

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3445–3456
May 2-6, 2023

some works (e.g., ViLT (Kim et al., 2021) and SimVLM (Wang et al., 2021)) pre-train a vision-and-language Transformer on a large-scale image-text dataset. These Vision-and-Language Pre-trained Models (VLPM) achieve exciting performance on many multimodal downstream tasks. The reason is that VLPM encapsulates rich image and text alignment knowledge and has a strong cross-modal reasoning capability (Chen et al., 2020; Kim et al., 2021). To enhance the cross-modal interaction between images and texts, Kim et al. (2021) propose ViLT, which focuses most of the computation on modeling the multimodal interaction, as shown on the right side of Figure 1.

Motivated by Kim et al. (2021), we propose a novel model enhanced by cross-modal alignment (CMA) for text-guided image inpainting, comprising a vision-and-language encoder, an image generator and global-local discriminators. Different from previous works (Zhang et al., 2020b; Lin et al., 2020; Wu et al., 2021), we employ a vision-and-language encoder based on VLPM to encode images and texts instead of separate vision and language encoders. The vision-and-language encoder can encode images and texts in a cross-modal interaction manner to implement visual priors reconstruction. Then, the visual features integrating textual information (i.e., reconstructed visual priors) obtained by VLPM are passed to an image generator to generate a restored image. To improve cross-modal alignment for image inpainting, we introduce cross-modal alignment distillation to guide a fine-grained fusion of cross-modal knowledge. Moreover, to further strengthen the visual priors reconstruction, we utilize in-sample distillation to enhance the model's cross-modal reasoning capability for the content of missing regions. Besides, we employ adversarial learning to improve the quality of generated images through global-local discriminators.

Experiments are conducted on two popular image-text datasets with a wide variety of objects (i.e., MSCOCO (Lin et al., 2014) and Flicker30K (Plummer et al., 2017)). Experimental results demonstrate that our method achieves state-of-the-art performance compared to other strong competitors. In addition, we analyze the effectiveness of each module of our method and the impact of cross-modal alignment. Moreover, we also conduct extensive analysis to verify the effectiveness of our method.

2 Method

In this section, we will introduce our CMA model as shown in Figure 2. CMA model consists of a vision-and-language encoder, an image generator and global-local discriminators. In addition, details about training and inference are elaborated.

2.1 Vision-and-Language Encoding

In previous works (Zhang et al., 2020b; Lin et al., 2020; Wu et al., 2021), images and texts are encoded by separate encoders. Specifically, a CNN-based image encoder is used to extract visual features for images, while a RNN-based text encoder is used to encode text to obtain textual features. Next, the image and text features are integrated by a multimodal fusion module to obtain multimodal representations (i.e., reconstructed visual priors). In this work, we employ a novel Transformer-based cross-modal encoder for image and text encoding, a vision-and-language encoder instead of two separate encoders. For language encoding, we employ a word embedding matrix to embed text $\boldsymbol{T} \in \mathbb{R}^{L\times|V|}$ into $\bar{\boldsymbol{T}} \in \mathbb{R}^{L\times e}$, where L, $|V|$, and e denote the length of text, size of vocabulary and size of embedding, respectively. For visual encoding, an image $\boldsymbol{I} \in \mathbb{R}^{C\times H\times W}$ is sliced into patches and flattened to $\boldsymbol{V} \in \mathbb{R}^{N\times(P^2\times C)}$, where P is the size of patch and N equal to $(H \times W)/P^2$. Following Kim et al. (2021), $\boldsymbol{V}$ is embedded into $\bar{\boldsymbol{V}} \in \mathbb{R}^{N\times e}$:

$$\bar{\boldsymbol{V}} = \text{Linear-Projection}(\boldsymbol{V}) \tag{1}$$

where the details of linear projection can be found in (Kim et al., 2021). Next, images and texts are encoded in a cross-modal interaction manner:

$$[\hat{\boldsymbol{T}}; \hat{\boldsymbol{V}}] = \text{Trans-Enc}([\bar{\boldsymbol{T}}; \bar{\boldsymbol{V}}]) \tag{2}$$

where $[;]$ denote a concatenation operation, and outputs of the vision-and-language encoder can be represented as $\hat{\boldsymbol{T}} \in \mathbb{R}^{L\times e}$ for textual representations and $\hat{\boldsymbol{V}} \in \mathbb{R}^{N\times e}$ for reconstructed visual priors. Compared to CNN constrained by its inherent properties (e.g., spatial-invariant kernels), which are not conducive to understanding global features (Wan et al., 2021), Transformer-based encoders have a natural advantage in encoding global features across modalities.

2.2 Image Generation

The process of image generation includes two stages. The first stage is to downsample the visual priors to extract deep visual representations.

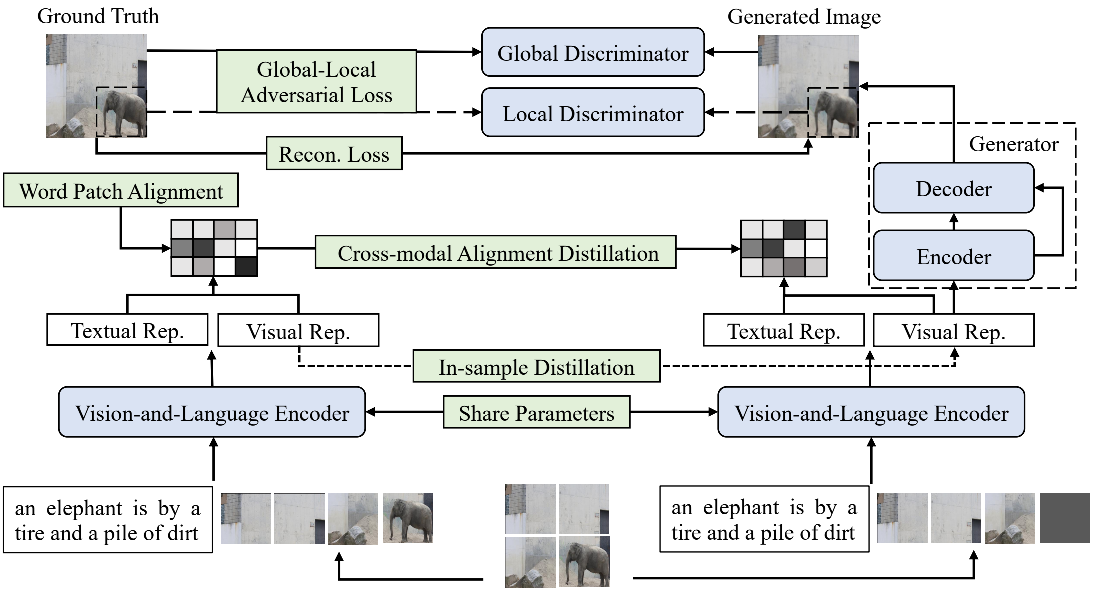

Figure 2: Overview of our model. Blue rounded rectangles denote trainable modules. Green right rectangles indicate training objectives or operations.

Next, performing upsampling for deep visual representations to generate a restored image. Different from the previous works (Zhang et al., 2020b; Lin et al., 2020; Wu et al., 2021), we do not integrate a fusion module to introduce textual features in the image generation process because the texts are introduced into the vision-and-language encoders. Although transformers demonstrate their effectiveness in long-term relations and the advantage of understanding global features, their computational complexity is quadratic with the input length, which hinders image generation (Wan et al., 2021). Therefore, our image generator consists of two CNN-based components, an encoder for downsampling and a decoder for upsampling. Similar to (Zhang et al., 2020a), we employ a 5-layer ResNet (He et al., 2016) as the downsampling encoder, and the visual priors are fed into it to obtain deep visual representations:

$$\boldsymbol{v} = \text{Down-Sampling}(\hat{\boldsymbol{V}}) \tag{3}$$

In addition, we pass $\boldsymbol{v}$ into the upsampling decoder to perform image reconstruction to generate a restored image, and the upsampling decoder consists of a 5-layer residual generator network.

$$\boldsymbol{I}_r = \text{Up-Sampling}(\boldsymbol{v}, \hat{\boldsymbol{V}}) \tag{4}$$

The visual priors obtained by the vision-and-language encoder are input to the upsampling decoder through a skip connection to provide detailed information that forgets in the downsampling stage.

2.3 Training

For model training, we construct five training objectives, including cross-modal alignment distillation, in-sample distillation, word patch alignment, reconstruction loss and global-local adversarial loss.

Cross-Modal Alignment Distillation. To guide image inpainting through cross-modal alignment knowledge, we pass the original image and text to the vision-and-language encoder to obtain a text representation $\hat{\boldsymbol{T}}_o$ and a visual priors $\hat{\boldsymbol{V}}_o$. Then, we obtain the correlation map $\boldsymbol{M}_o$ between each token of text and each image patch by calculating the similarity between them. The correlation map corresponding to the corrupted image and text is denoted as $\boldsymbol{M}_r$. Next, we compute the pair-wise similarity distillation loss between the two correlation maps:

$$\ell_{\text{CMAD}} = \frac{1}{N \times L}\sum_{i=1}^{L}\sum_{j=1}^{N}(a_{ij}^r - a_{ij}^o)^2 \tag{5}$$

$$a_{ij}^r = \frac{\boldsymbol{t}_i^{r\top}\boldsymbol{v}_j^r}{\|\boldsymbol{t}_i^r\|_2\|\boldsymbol{v}_j^r\|_2}, a_{ij}^r \in \boldsymbol{M}_r \tag{6}$$

$$a_{ij}^o = \frac{\boldsymbol{t}_i^{o\top}\boldsymbol{v}_j^o}{\|\boldsymbol{t}_i^o\|_2\|\boldsymbol{v}_j^o\|_2}, a_{ij}^o \in \boldsymbol{M}_o \tag{7}$$

where $\boldsymbol{t}_i^r \in \hat{\boldsymbol{T}}$, $\boldsymbol{v}_j^r \in \hat{\boldsymbol{V}}$, $\boldsymbol{t}_i^o \in \hat{\boldsymbol{T}}_o$ and $\boldsymbol{v}_j^o \in \hat{\boldsymbol{V}}_o$, respectively.

In-Sample Distillation. Besides using cross-modal alignment knowledge to guide image inpainting, we propose in-sample distillation. The purpose of this objective is to guide the damaged image to infer visual priors closer to that from the original image based on the text and known regions, i.e.,

$$\ell_{\text{ISD}} = \frac{1}{N} \sum_{i=1}^{N} \text{KL}\left(\boldsymbol{v}_i^o \| \boldsymbol{v}_i^r\right). \tag{8}$$

where KL denotes Kullback–Leibler divergence.

Word Patch Alignment. To maintain that the cross-modal alignment knowledge of the model is not degraded, we use the word patch alignment objective to preserve the cross-modal alignment knowledge integrated into the model.

$$\ell_{\text{WPA}} = \min_{\mathbf{T} \in \Pi(\mathbf{a},\mathbf{b})} \sum_{i=1}^{N} \sum_{j=1}^{L} \mathbf{T}_{ij} \cdot c\left(\boldsymbol{v}_i^o, \boldsymbol{t}_j^o\right) \tag{9}$$

$$c(\boldsymbol{v}_i^o, \boldsymbol{t}_j^o) = 1 - \frac{\boldsymbol{v}_i^{o\top} \boldsymbol{t}_j^o}{\|\boldsymbol{v}_i^o\|_2 \|\boldsymbol{t}_j^o\|_2} \tag{10}$$

$$\Pi(\mathbf{a},\mathbf{b}) = \{\mathbf{T} \in \mathbb{R}^{N \times L} \mid \mathbf{T}\mathbf{1}_m = \mathbf{a}, \mathbf{T}^\top \mathbf{1}_n = \mathbf{b}\} \tag{11}$$

where $\mathbf{1}_n$ denotes an n-dimensional all-one vector; $\mathbf{T}$ is a transport plan. The details can be found in (Kim et al., 2021).

Reconstruction Loss. We adopt the ℓ_1-norm error as the loss function between the restored image and its corresponding ground-truth image $\boldsymbol{I}_{gt}$:

$$\ell_1 = ||\boldsymbol{I}_r - \boldsymbol{I}_{gt}||_1, \tag{12}$$

Global Adversarial Loss. In image generation, the adversarial loss (Goodfellow et al., 2014) effectively improves the quality of the generated image. However, adversarial training is unstable since keeping the balance between the generator and discriminator is difficult. To tackle this problem, Arjovsky et al. (2017) propose the Wasserstein generative adversarial nets (WGAN) that can improve the stability of adversarial learning. We employ a WGAN hinge loss as the adversarial loss, and it can be formulated as follows:

$$\ell_{\text{G-adv,G}} = \mathbb{E}_{\hat{\boldsymbol{x}} \sim P_{data}(\boldsymbol{I}_r)}[-D(\hat{\boldsymbol{x}})] \tag{13}$$

$$\begin{aligned} \ell_{\text{G-adv,D}} =& \mathbb{E}_{\boldsymbol{x} \sim P_{data}(\boldsymbol{I}_{gt})}[\text{ReLU}(1 - D(\boldsymbol{x}))] \\ &+ \mathbb{E}_{\hat{\boldsymbol{x}} \sim P_{data}(\boldsymbol{I}_r)}[\text{ReLU}(1 + D(\hat{\boldsymbol{x}}))] \end{aligned} \tag{14}$$

where $D(\cdot)$ denotes a global discriminator; ReLU is the rectified linear unit function; $\mathcal{L}_{adv,G}$ and $\mathcal{L}_{adv,D}$ are loss function for inpainting model and discriminator, respectively.

The discriminator $D(\cdot)$ consists of 5-layer ResNet, followed by a fully connected layer. Each convolutional layer in ResNet applies spectral normalization to satisfy the Lipschitz constraints of Wasserstein GANs.

Local Adversarial Loss. For the local discriminator, we use the same settings as the global discriminator, and the loss is defined as:

$$\ell_{\text{L-adv,G}} = \mathbb{E}_{\hat{\boldsymbol{x}}_l \sim P_{data}(\boldsymbol{I}_r)}[-D_l(\hat{\boldsymbol{x}}_l)] \tag{15}$$

$$\begin{aligned} \ell_{\text{L-adv,D}} =& \mathbb{E}_{\boldsymbol{x}_l \sim P_{data}(\boldsymbol{I}_{gt})}[\text{ReLU}(1 - D_l(\boldsymbol{x}_l))] \\ &+ \mathbb{E}_{\hat{\boldsymbol{x}}_l \sim P_{data}(\boldsymbol{I}_r)}[\text{ReLU}(1 + D_l(\hat{\boldsymbol{x}}_l))] \end{aligned} \tag{16}$$

where x_l denotes the restored image or ground truth corresponding to the missing region; $D_l(\cdot)$ denotes a local discriminator.

Considering the loss functions above, the objective function of our model in the generation stage can be defined as:

$$\begin{aligned} \ell_G =& \lambda \ell_{\text{CMAD}} + \lambda \ell_{\text{ISD}} + \alpha \ell_{\text{WPA}} + \beta \ell_1 \\ &+ \gamma \ell_{\text{G-adv,G}} + \gamma \ell_{\text{L-adv,G}} \end{aligned} \tag{17}$$

where the λ, α, β and γ are the hyper-parameters used to balance the objective function.

In addition, the objective function of our model in the discriminative stage can be defined as:

$$\ell_D = \gamma \ell_{\text{G-adv,D}} + \gamma \ell_{\text{L-adv,D}} \tag{18}$$

2.4 Inference

During inference, we first pass image $\boldsymbol{I}$ and text $\boldsymbol{T}$ into the cross-modal encoder (i.e., Equ.1 and Equ.2) to obtain the visual representation $\hat{\boldsymbol{V}}$. Next, we deliver the visual representation $\hat{\boldsymbol{V}}$ into the generator (i.e., Equ.3 and Equ.4) to generate a restored image $\boldsymbol{I}_r$.

3 Experiments

3.1 Dataset and Evaluation Metrics

We conduct the experiment on two datasets: MSCOCO (Lin et al., 2014) and Flicker30K (Plummer et al., 2017). For the MSCOCO and Flicker30K datasets, we split them following their original training, validation and test set. Following Zhang et al. (2020a), we also set the mask for an image in two types: center mask and object mask. A center mask refers to a square mask taking 50%

area in the center of an image. An object mask indicates masking an image based on the object boxes provided by every image. To evaluate the performance of our model and other methods on these datasets, we utilize the ℓ_1 loss, Frechet Inception Distance (FID) (Heusel et al., 2017), Kernel Inception Distance (KID) (Heusel et al., 2017), total variation (TV) (Rudin et al., 1992), peak signal-to-noise ratio (PSNR) (Fardo et al., 2016) and structural similarity index (SSIM) (Wang et al., 2004) as metrics to report the results. ℓ_1 measure the ℓ_1 distance between restored and original images. FID and KID measure the quality of restored images based on human perception. PSNR and SSIM measure structural similarity between restored and original images and the ℓ_2 distance.

3.2 Experimental Settings

For training images in MSCOCO and Flicker30K, we resize them to make their minimal height/width 256 and crop them based on size 256 × 256 at the center. During training, we set the λ as 2, α as 1, β as 1 and γ as 0.1 in the objective function, and the model is trained by an Adam optimizer (Kingma and Ba, 2015) with the learning rate of 1×10^{-4}. In the vision-and-language encoder, the patch size, intermediate size and hidden size are 32, 3072 and 768. For a masked patch, we utilize a special token `[Vmask]` as input. We employ ViLT (Kim et al., 2021) to initialize our vision-and-language encoder. The weight decay and gradient clipping are set to 0.01 and 1.0. The maximum training epoch and batch size are 200 and 128. Warmup steps and maximum sequence length are set to 2000 and 40. Our experiments are conducted on 2 × V100 GPUs. We choose models with the best result on the validation set and report the results on the test set based on the models.

3.3 Main Results

Table 6: Results on CUB with the object mask.

in Table 1, Table 2, Table 3 and Table 4. From the tables, we can see that our model achieves state-of-the-art results compared with other strong competitors. In addition, we can make two observations: Firstly, using text to guide image inpainting can significantly improve the performance. For example, the text-guided image inpainting methods (i.e., MMFL, TGII, TDANet, ALMR and CMA) outperform standard image inpainting methods (i.e., CSA, PICNet and CTSDG). Next, for the gap between results on center masks and object masks, it shows that recovering completely removed objects is more difficult. Besides, we show results on the CUB (Wah et al., 2011) dataset without a wide variety of objects in Tabel 5 and Tabel 6. Results show our method outperforms other methods.

Method	**FID ↓**	**KID ↓**	**PSNR ↑**	**SSIM (%) ↑**
CMA	39.52	1.34	22.07	85.18
w/o G-Adv.	43.72	2.17	21.39	84.12
w/o L-Adv.	42.59	1.84	21.74	84.75
w/o Adv.	50.94	2.91	19.68	82.49
w/o Recon.	47.57	2.48	20.49	83.56
w/o CMAD	53.39	3.12	19.55	81.94
w/o ISD	52.84	3.06	19.67	82.23
w/o WPA	52.33	3.10	19.63	82.58

Table 7: Ablation study. ‘G-Adv.’, ‘L-Adv.’ and ‘Adv.’ denote global, local and both adversarial losses, respectively. ‘Recon.’, ‘CMAD’, ‘ISD’ and ‘WPA’ indicate reconstruction loss, cross-modal alignment distillation, in-sample distillation objectives and word patch alignment, respectively.

3.4 Ablation Study

We conduct an ablation study to investigate the effectiveness of each component of our approach and the results are reported in Table 7. We first investigate the impact of the adversarial learning by removing global adversarial loss, local adversarial loss and both adversarial losses and find that the performance drops. The reason is that adversarial objectives focus on high-level features, which can

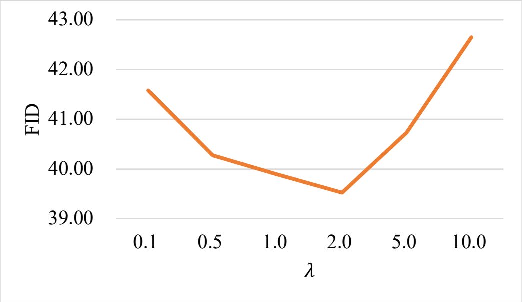

Figure 3: Performance of our model with different trade-off parameters λ.

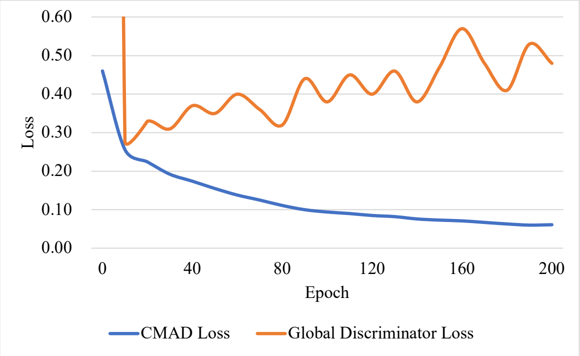

Figure 4: The adversarial loss and cross-modal alignment distillation loss on the training set w.r.t different epochs in the training phase.

effectively fill the missing region on complicated structures. Next, we test our method without reconstruction loss, which also decreases scores on all metrics. It demonstrates that image reconstruction plays an essential role in model training. Finally, we compare our method with the baseline without cross-modal alignment distillation and in-sample distillation, and the performance drops significantly. It indicates that the CMAD and ISD objectives can enhance the cross-modal alignment for text-guided image inpainting.

3.5 Analysis

3.5.1 Impact of Cross-Modal Alignment

To assess the impact of cross-modal alignment for our method, we set different trade-off parameters λ. Specifically, during model training, we set a different λ for the loss function in Eq.17. The performance of our method in different λ is reported in Figure 3. It is observed that with the λ increased, FID first drops and then rises, indicating that our method's performance first rises and then drops. The results demonstrate that the cross-modal alignment objective is crucial for our method, but overemphasizing the objective may hinder model learning.

Method	Naturalness	Semantic Consistency
CMA	1.44	1.46
TDANet	2.39	2.52
ALMR	2.77	2.64
CSA	3.40	3.38

Table 8: Numerical ranking score of user study. The lower the score, the better the performance.

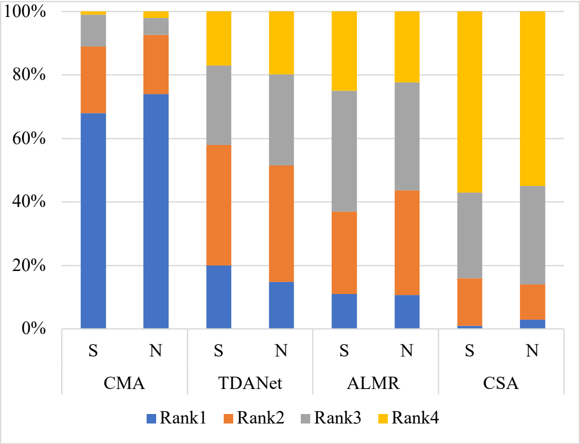

Figure 5: Ranking score distribution of the user study. "S" means semantic consistency score, "N" means naturalness.

3.5.2 Deep Dive into Cross-Modal Alignment

We take a deep dive into the impact of cross-modal alignment. In our method, adversarial learning involves a global discriminator to distinguish whether the generated image is original or generated, and the cross-modal alignment objective is to guide visual priors reconstruction. Their loss values, i.e., $\ell_{\mathrm{G-adv,D}}$ and ℓ_{CMAD}, are plotted in Figure 4. We can see that the loss of cross-modal alignment objective quickly drops and then slowly drops, indicating that the model gets good performance on visual priors reconstruction. Meanwhile, we can observe that the adversarial loss of the discriminator quickly drops and then slowly goes up, demonstrating that we can see that the classification loss of the discriminator gets good performance and then is fooled later by the image generated from the image generator. Therefore, it shows that the cross-modal alignment objective supports the adversarial learning very well.

3.5.3 User Study

Following Zhang et al. (2020a), we take a user study to quantify the qualitative comparison from

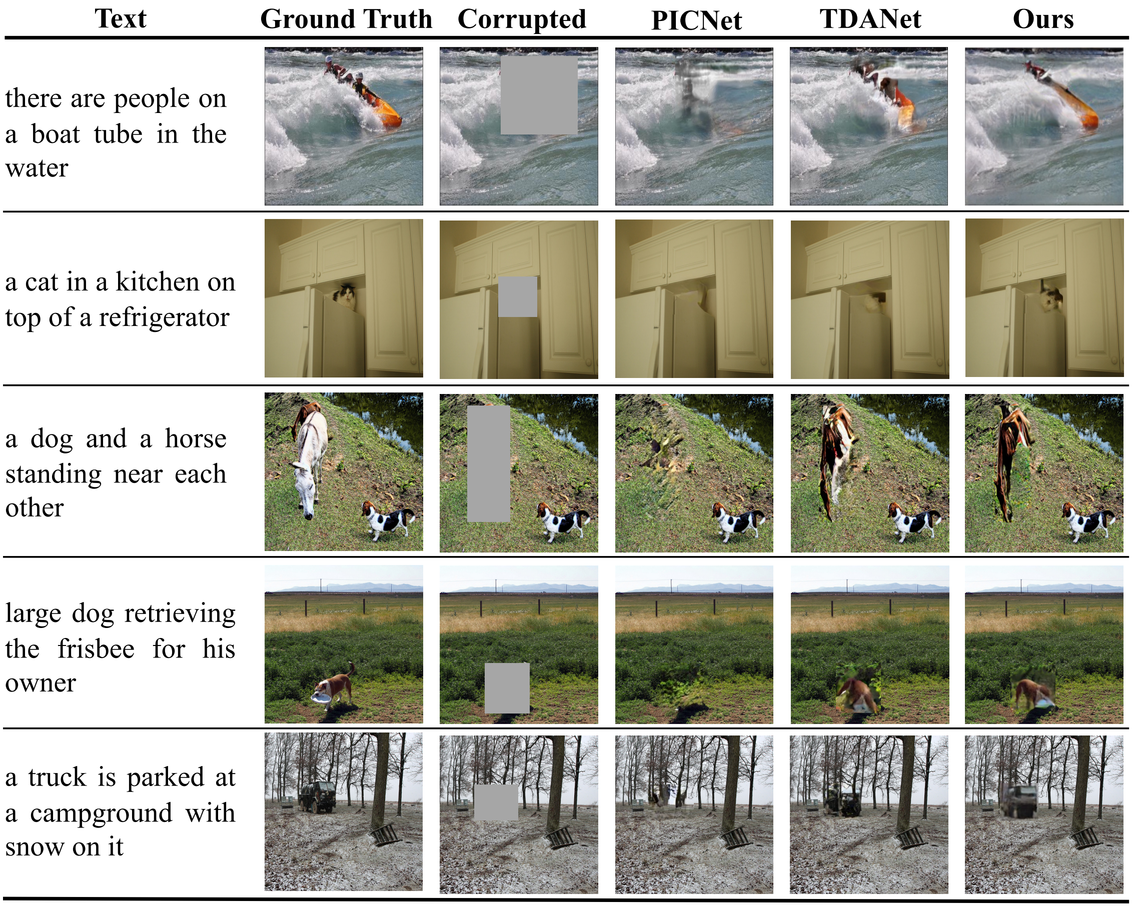

Figure 6: Qualitative results randomly sampled from MSCOCO test set.

the human perspective. We randomly collected 100 images in center masks from the MSCOCO test dataset. Each sample includes four generated images from CMA, PICNet, ALMR and CSA, respectively. These four images are randomly shuffled for five volunteers who rank images according to naturalness and the semantic consistency with the text description. Next, we computed the average ranking score as shown in Table 8 and show their distribution in Figure 5. From the results, we can observe that our model outperforms other competitors in naturalness and semantic consistency. It demonstrates the effectiveness of our method from a qualitative perspective.

3.6 Qualitative Results

As demonstrated in Figure 6, we give qualitative comparison examples of our method and other methods. We can find that our model can generate more semantically plausible objects in the missing region. Firstly, comparing PICNet with TDANet and our method, extracting the semantic information from the text can improve the repair effect of the model in the missing area of the image. Secondly, we can observe that TDANet can generate preliminary results, such as the outlines and part content of "cat", "truck" and "people" in examples, but many details of the object are very unnatural. In contrast, our method can further generate the details of the object based on generating the outline and content of the object. It demonstrates that cross-modal alignment can effectively supplement missing object information.

4 Related Work

4.1 Image Inpainting

Image inpainting (Bertalmío et al., 2000) aims to restore a damaged image, whose categories of approaches mainly are patch-based and deep learning-based. The patch-based methods (Barnes et al., 2009; Huang et al., 2014) fill the holes through searching and pasting patches based on image known regions. Huang et al. (2014) propose a method using the mid-level structural cues to automatically guide the image inpainting. However, these methods are not effective to fill in the missing region on complicated structures, due to the focus on low-level features. To address the limitation of existing patch-based methods, there has been growing interest in deep learning-based methods (Pathak et al., 2016; Iizuka et al., 2017; Ren et al., 2019). The Context Encoder (CE) is proposed by (Pathak et al., 2016), which uses the encoder-decoder architecture and the Generative Adversarial Networks (GAN) (Goodfellow et al., 2014) to learn image features. Although the CE improves the inpainting by the image features learning, it is not effective to tackle the visual artifacts and exhibits blurriness in the image recovered regions. For solving the aforementioned problems, Iizuka et al. (2017) introduce the local and global discriminator for the image inpainting of arbitrary missing regions, which improves the local and global consistency of generated image. The StructureFlow (Ren et al., 2019) consisted of a structure reconstructor and a texture generator, which can focus on recovering global structures and synthesizing high-frequency details. Although the existing image inpainting methods can fill in the holes in the image, generating specific content in the missing region remains challenging, without any known information.

4.2 Text-Guided Image Inpainting

To address this problem, many text-guided image inpainting works are proposed (Zhang et al., 2020b; Lin et al., 2020). In these works, the specific content in the missing area can be restored based on the given descriptive text. Existing text-guided image inpainting methods include two processes: semantic information extraction and multimodal fusion. The semantic information extraction aims to obtain semantic information which does not match the image, such as the dual multimodal attention mechanism (Zhang et al., 2020a). However, these methods are hard to work well in the image set with a variety of different objects. The reason is that these methods lack fine-grained alignment knowledge of texts and images to guide the fusion of cross-modal information in multimodal interactions. Besides, their fusion modules lack powerful cross-modal reasoning capabilities.

4.3 Vision-Language Pre-training (VLP)

Motivated by the success of the language/vision pre-trained model (Devlin et al., 2019; Dosovitskiy et al., 2021; Zhou et al., 2022b), there is a surging interest in developing a pre-trained model for multiple modalities (e.g., vision and language) (Chen et al., 2020; Radford et al., 2021; Kim et al., 2021; Zhou, 2022). For example, a pioneering work CLIP (Radford et al., 2021) employs contrastive learning to predict whether matching between image and text and shows its powerful capability in many downstream tasks. UNITER (Chen et al., 2020) and UNIMO (Chen et al., 2020) employ an object detector (e.g., Faster R-CNN (Ren et al., 2017)) to capture vision features, and a multi-layer transformer (Vaswani et al., 2017) is used to joint learn vision features and text features. Kim et al. (2021) discuss different taxonomy of vision-and-language models and propose ViLT, a pre-trained model more focused on modeling modality interactions. In addition, ViLT totally discards convolutional visual features and adopts vision transformers.

5 Conclusion

In this work, we explore a novel CMA model for text-guided image inpainting. In the CMA model, we integrate a vision encoder and a text encoder into a vision-and-language encoder, which is different from previous works. The vision-and-language encoder allocates more computation on modeling modality interactions instead of visual encoding. In addition, we introduce two objectives to improve cross-modal alignment, dubbed cross-modal alignment and in-sample distillation. The cross-modal alignment objective guides the model to fuse cross-modal features. Experimental results demonstrate that the proposed model delivers new state-of-the-art performance, followed by further analyses to provide comprehensive insights.

Limitations

Compared with previous text-guided image inpainting methods (Zhang et al., 2020b; Lin et al., 2020; Wu et al., 2021), our method performs well for natural image datasets with a wide variety of objects. However, the recovery of our method for completely missing objects in images is not perfect. The reason is that the size of our model limits its capabilities. The large image generation models (e.g., DALL·E (Ramesh et al., 2021)) show their powerful capability to generate a plausible image. Due to the limitation of computational resources, we could not train a large model of similar size to DALL·E, which hinders verifying the effectiveness of our method on a large model.

Semantic Specialization for Knowledge-based Word Sense Disambiguation

Sakae Mizuki and **Naoaki Okazaki**
Tokyo Institute of Technology
`{sakae.mizuki@nlp., okazaki@}c.titech.ac.jp`

Abstract

A promising approach for knowledge-based Word Sense Disambiguation (WSD) is to select the sense whose contextualized embeddings computed for its definition sentence are closest to those computed for a target word in a given sentence. This approach relies on the similarity of the *sense* and *context* embeddings computed by a pre-trained language model. We propose a semantic specialization for WSD where contextualized embeddings are adapted to the WSD task using solely lexical knowledge. The key idea is, for a given sense, to bring semantically related senses and contexts closer and send different/unrelated senses farther away. We realize this idea as the joint optimization of the Attract-Repel objective for sense pairs and the self-training objective for context-sense pairs while controlling deviations from the original embeddings. The proposed method outperformed previous studies that adapt contextualized embeddings. It achieved state-of-the-art performance on knowledge-based WSD when combined with the reranking heuristic that uses the sense inventory. We found that the similarity characteristics of specialized embeddings conform to the key idea. We also found that the (dis)similarity of embeddings between the related/different/unrelated senses correlates well with the performance of WSD.

1 Introduction

Word Sense Disambiguation (WSD) is the task of choosing the appropriate sense of a word from a given sense inventory using contextual information. WSD has proven its usefulness for Information Retrieval (Zhong and Ng, 2012) and Machine Translation (Campolungo et al., 2022). A series of extensive studies has led supervised WSD task performance to surpass the milestone of 80% accuracy (Bevilacqua and Navigli, 2020), which is the estimated human performance (Navigli, 2009).

In contrast, the goal of this study is *knowledge-based WSD*: a variant of WSD that does not rely on supervision data but only on lexical knowledge (e.g., word ontology). This task setting is practically appealing because it does not use a corpus with sense annotations (Bevilacqua et al., 2021), which is costly and labor-intensive to prepare.

A promising approach is based on similarity: to select the sense that is the nearest to a target word in the embedding space (Wang and Wang, 2020). Specifically, a pre-trained language model, typically BERT (Devlin et al., 2019), is used to compute *sense embeddings* for definition sentences. Similarly, a target word is encoded into a *context embedding* for a given sentence. Then, the model predicts the sense of the target word by finding the most similar sense embedding to the context.

The inherent challenge of the similarity-based approach is how we associate two different representations of word meanings, either by definition sentences or by words in context. Although the BERT embeddings capture the coarse-grained word meanings (Reif et al., 2019; Loureiro et al., 2021), there should be room for improvement. Notably, Wang and Wang (2020) proposed `SREF`, sense embedding adaptation by bringing semantically related senses closer. Extending their work, Wang et al. (2021b) proposed `COE`, context embedding enhancement heuristics during inference using the document-level global contexts of the given sentence, and reported the best performance. Despite being effective, `COE` cannot be applied to stand-alone texts, e.g., short messages on social media or search queries, limiting its applicability.

Our study aims to improve both accuracy and applicability to stand-alone texts. Specifically, we propose an adaptation method of the sense and context embeddings for the WSD task solely using lexical knowledge. Then, what are good embeddings for WSD? Our key idea is to 1) bring semantically related sense and context embeddings that convey the same meaning closer, and 2) send unrelated and/or different senses that share the same

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3457–3470
May 2-6, 2023 ©2023 Association for Computational Linguistics

surface form farther away (Fig. 1-d). We formulate the idea as the Attract-Repel objective and self-training objective. The main novelty is the joint optimization to utilize their complementary nature: the former should improve the distinguishability between senses whereas the latter offers pseudo signals of context-sense associations, which has not been explored in previous methods.

The Attract-Repel objective, inspired by Vulic and Mrksic (2018), injects semantic relation knowledge into the similarity of sense pairs. Specifically, we make semantically related senses more similar while making different and unrelated senses more dissimilar (Fig. 1-a). While `SREF` performs Attract only, our method utilizes both Attract and Repel.

The self-training objective, inspired by the idea of retraining on the classifier's own predictions instead of annotated senses (Navigli, 2009), updates the similarity of context-sense pairs in a pseudo labeling manner (§ 6.1). Specifically, for each training step and given context, we bring the nearest neighbor sense among candidates closer (Fig. 1-b). We also impose distance constraints during adaptation to control the deviation from BERT embeddings (Fig. 1-c) because excessive deviation may cause an inaccurate nearest neighbor sense selection, which would cause a performance drop.

We call the overall proposed method `SS-WSD`, Semantic Specialization for WSD, following Vulic and Mrksic (2018). We evaluated `SS-WSD` using the standard evaluation protocol (Raganato et al., 2017) and confirmed that it outperforms the previous embeddings adaptation method. Furthermore, it achieved state-of-the-art (SoTA) performance when combined with the reranking heuristic that uses a sense inventory (Wang and Wang, 2021), and thus is applicable to stand-alone texts.

The contributions of our study are as follows:

- We proposed `SS-WSD`, an embedding adaptation method that achieves new SoTA in knowledge-based WSD, regardless of the availability of document-level global contexts.
- We found that the performance gain originates from the joint optimization of Attract-Repel and self-training objectives and the prevention of deviation from the original embeddings.
- Empirically, we found that the similarity of related/different/unrelated senses *relative to* the similarity of ground-truth context-sense pairs correlates well with the WSD performance.

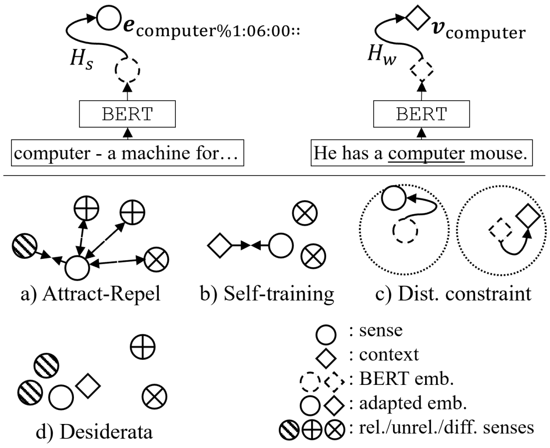

Figure 1: Schema of the proposed method. The BERT embeddings representing senses and contexts are adapted by transformation (top). Transformation functions are optimized using Attract-Repel and self-training objectives under distance constraints so that the adapted embeddings are effective for WSD (bottom).

2 Related Work

2.1 Knowledge-based WSD

Knowledge-based WSD is a variant of WSD that does not use a sense annotation corpora such as the SemCor (Miller et al., 1993) but uses lexical resources instead, typically WordNet. The majority vote based on sense frequencies, also known as the WordNet first sense heuristic (Jurafsky and Martin, 2009), is a simple but strong baseline method of this category. Sense definitions and usage examples are also used to measure the similarity of the target word in a sentence. The simplest method is based on word overlap (Lesk, 1986).

One recent direction is the use of BERT as a contextualized encoder. BERT embeddings showed empirical success on the supervised WSD task when used as features. Some analyses reported that BERT embeddings capture the coarse-grained word meanings (Reif et al., 2019; Loureiro et al., 2021). Wang and Wang (2020) proposed a similarity-based method in the embedding space. It chooses the sense which has the most similar embedding, formed from the concatenation of its lemma, definition, and usage examples, to the embedding of a target word. They also proposed the Semantic Relation Enhancement Framework ($\texttt{SREF}_{\texttt{emb}}$), which adapts sense embeddings by weighted averages over semantically related senses, e.g., hyponyms and derivations. $\texttt{SREF}_{\texttt{emb}}$ is the most high-performing adaptation method so far. We report that our proposed method achieves better performance.

2.2 Heuristics for Knowledge-based WSD

Another recent direction is the heuristics for choosing the most similar sense, which is further divided into those that use the sense inventory information and those that exploit the document-level global contexts of a given sentence. Wang and Wang (2020) proposed the former, the Try-again Mechanism (TaM). It reranks candidates by adding the similarity between the target word and the lexicographer class (supersense) that a candidate sense belongs to. Subsequent studies (Wang et al., 2021b; Wang and Wang, 2021) refined TaM using Coarse Sense Inventory (Lacerra et al., 2020). We examine the effectiveness of the proposed method combined with TaM because it can be applied to stand-alone texts.

Wang et al. (2021b) proposed contextual information enhancement (CIE), which enhances context embeddings by exploiting the document-level global contexts of a given sentence on evaluation. This idea originally stems from the one-sense-per-discourse hypothesis (Gale et al., 1992): that the sense of a word is highly consistent within a document.

2.3 Attract-Repel Framework

The Attract-Repel Framework is used to inject lexical knowledge into embeddings by encouraging similar instances to have closer embeddings while encouraging dissimilar instances to be farther away. Vulic and Mrksic (2018) and Mrkšić et al. (2017) reported that updating static word embeddings using lexical knowledge improves the performance of the word-level semantic relation classification task. Our study proposes its application to sense and context embeddings for the WSD task. We also reformulate the original loss function with the contrastive loss, inspired by its success in Computer Vision (Chen et al., 2020) and NLP (Gao et al., 2021; Wang et al., 2021a; Giorgi et al., 2021).

2.4 Supervised WSD

Supervised methods rely on corpora of sense-annotated contexts, such as SemCor, for training models. However, the coverage of words and senses is limited and biased towards more frequent senses (Pasini, 2020). Recent studies have addressed these limitations by incorporating lexical resources into the methods. Barba et al. (2021a) and its subsequent study (Barba et al., 2021b) reframed WSD as a span extraction task by appending definition sentences of candidate senses to the target context. They reached the SoTA performance among supervised methods.

Similarity-based approaches are also used with supervised methods. Supervised k-nearest neighbors (`Sup-kNN`) (Loureiro and Jorge, 2019) defines sense embeddings as the averaged context embeddings of annotated senses. The Bi-Encoder model (`BEM`) (Blevins and Zettlemoyer, 2020) jointly fine-tunes two BERT encoders for definition sentences and contexts, ensuring that context embeddings will be closer to the correct sense embeddings. The proposed method is similar in architectural design to `BEM`, but differs in that we do not fine-tune the BERT encoders. We will compare our results with `Sup-kNN` and `BEM` to assess the effect of using no sense annotation and of freezing BERT encoders on performance.

3 Semantic Specialization for WSD

3.1 Formalization of WSD

The proposed method adapts BERT embeddings by trainable transformation functions H_s and H_w:

$$\mathbf{v}_w = H_w(\hat{\mathbf{v}}_w), \tag{1}$$

$$\mathbf{e}_s = H_s(\hat{\mathbf{e}}_s), \tag{2}$$

where the inputs $\hat{\mathbf{v}}_w$ and $\hat{\mathbf{e}}_s$ are the context and sense embeddings computed by a BERT encoder and the outputs $\mathbf{v}_w$ and $\mathbf{e}_s$ are the specialized embeddings.

We train the transformation functions by minimizing the weighted sum of the Attract-Repel objective and the self-training objective on the specialized embeddings. Note that the BERT encoder is frozen (not fine-tuned). We integrate the constraints on the distance between the input and output into the architecture of transformation functions (§ 3.4).

To predict a sense for a given target word w, we look up the candidate senses $\mathcal{S}_w$ and compute their specialized sense embeddings using the learned function H_s. Similarly, we compute specialized context embeddings using H_w. Then, we select the nearest neighbor sense s^* using cosine similarity:

$$s^* = \underset{s' \in \mathcal{S}_w}{\arg\max}\, \rho_{w,s'}, \tag{3}$$

$$\rho_{w,s} = \cos(\mathbf{v}_w, \mathbf{e}_s) = \frac{\mathbf{v}_w \cdot \mathbf{e}_s}{\|\mathbf{v}_w\| \|\mathbf{e}_s\|}. \tag{4}$$

Element	Noun	Verb	Adj.	Adv.	All
# Lemmas	117,798	11,529	21,479	4,481	155,287
# Senses	146,320	25,047	30,002	5,580	206,949
Rel. senses	7.8	13.0	6.2	3.9	8.1
Diff. senses	0.8	4.1	1.2	0.7	1.3

Table 1: Summary statistics of lexical resources by part-of-speech tag. Values in the related and different senses rows indicate the average per sense.

3.2 Lexical Knowledge in WordNet

We use WordNet (Fellbaum, 1998) as a lexical resource and sense inventory. WordNet mainly consists of synsets, lemmas, and senses. A synset is a group of synonymous words that convey a specific meaning. A lemma presents a canonicalized form of a word and belongs to one or more synsets. A sense is the lemma disambiguated by a sense key, and belongs to a single synset. We use the sense key as the identifier of a sense.

The proposed method makes use of relational knowledge between senses for training the transformation functions. Specifically, for each sense s, we collect three sets of senses: *related* $\mathcal{S}_s^P$, *different* $\mathcal{S}_s^N$, and *unrelated* $\mathcal{S}_s^U$. The *related* set consists of sense keys of synonyms and semantically related senses (e.g., hyponyms) to the target sense. We followed the definition of related senses used in Wang and Wang (2020) (Appendix A). The *different* set consists of sense keys sharing the same lemma to the target sense excluding itself. In other words, the different senses correspond to the polysemy of the lemma of the target sense. The *unrelated* set presents sense keys that are randomly chosen from the sense inventory (see § 3.5.1 for details). Table 1 shows the statistics of lemmas and senses. See Table 6 (in Appendix A) for examples of the concepts explained in this subsection.

3.3 BERT Embeddings for Sense and Context

For obtaining BERT embeddings, we follow the standard practice of the previous studies (Wang et al., 2020; Bevilacqua and Navigli, 2020; Wang and Wang, 2020). Specifically, we use `bert-large-cased`[1] with special tokens `[CLS]` and `[SEP]`. For each subword, we compute a sum over outputs at the last four layers of Transformer blocks.

A context embedding is the average of BERT embeddings over constituent subwords. For the computation of sense embeddings, we follow the method that Wang and Wang (2020) used. See Appendix B for details.

3.4 Transformation Functions

The proposed method adapts embeddings by applying the trainable transformation, i.e., the specialization is learned by optimizing the transformation functions. This approach enables the adaptation of context embeddings on the fly during inference, which was not possible in the original approach that directly learns adapted embeddings (Vulic and Mrksic, 2018).

Let $\hat{\mathbf{v}}_w$ and $\hat{\mathbf{e}}_s$ be context and sense BERT embeddings. We transform them independently using residual mapping functions F_w and F_s, which are both two-layer feedforward networks, FFNN_w and FFNN_s. These networks are comprised of a linear layer with a ReLU activation, followed by a linear layer with a sigmoid activation.

$$\mathbf{v}_w = H_w(\hat{\mathbf{v}}_w) = \hat{\mathbf{v}}_w + \epsilon\|\hat{\mathbf{v}}_w\|F_w(\hat{\mathbf{v}}_w), \quad (5)$$

$$\mathbf{e}_s = H_s(\hat{\mathbf{e}}_s) = \hat{\mathbf{e}}_s + \epsilon\|\hat{\mathbf{e}}_s\|F_s(\hat{\mathbf{e}}_s), \quad (6)$$

$$F_w(\hat{\mathbf{v}}_w) = 2\sigma(\mathrm{FFNN}_w(\hat{\mathbf{v}}_w)) - 1, \quad (7)$$

$$F_s(\hat{\mathbf{e}}_s) = 2\sigma(\mathrm{FFNN}_s(\hat{\mathbf{e}}_s)) - 1, \quad (8)$$

where $\mathbf{v}_w$ and $\mathbf{e}_s$ are the specialized embeddings. ϵ is the hyperparameter that controls how far away the specialized embeddings can be. Specifically, the L2 distance relative to the original embedding $\|\mathbf{v}_w - \hat{\mathbf{v}}_w\|/\|\hat{\mathbf{v}}_w\|$ is bounded by $\epsilon\sqrt{N_d}$, where N_d is the dimension size of embeddings[2]. This is because the residual functions map the inputs to the space $[-1, +1]^{N_d}$.

3.5 Objectives

We jointly optimize the Attract-Repel objective for sense pairs and the self-training objective for context-sense pairs by minimizing the weighted sum of the loss functions,

$$L = L^{\mathrm{AR}} + \alpha L^{\mathrm{ST}}, \quad (9)$$

where α is the hyperparameter that determines the relative importance of the self-training objective.

The joint optimization is motivated by the complementary nature of these two objectives. The Attract-Repel objective should improve the separability of similar/different senses but does not contribute to determining which context and sense should be associated. In contrast, the self-training objective provides pseudo-supervision signals for

---

[1] We use `transformers` package (Wolf et al., 2020).

[2] $N_d = 1{,}024$ for `bert-large-cased`.

context-sense associations, although the informativeness is, when used alone, limited because it essentially reinforces the similarity to the initial nearest neighbor sense of the target context (§ 3.5.2).

3.5.1 Attract-Repel Objective

We formulate Attract-Repel objective loss L^{AR} using contrastive loss: we bring *related* senses closer while *different* and *unrelated* senses farther away[3] (§ 3.2). Specifically, for a given minibatch of senses $\mathcal{S}^B$ and a specific sense $s \in \mathcal{S}^B$, we define the subset excluding itself $\mathcal{S}^B \setminus \{s\}$ as the unrelated senses $\mathcal{S}_s^U$. Then, we randomly choose a sense s_p from the related senses $\mathcal{S}_s^P$. Similarly, we randomly choose up to five senses without replacement $\tilde{\mathcal{S}}_s^N$ from different senses $\mathcal{S}_s^N$. Finally, L^{AR} for the minibatch $\mathcal{S}^B$ is defined as follows:

$$L^{\mathrm{AR}} = -\sum_{s \in \mathcal{S}^B} \ln \frac{e^{\beta \rho_{s,s_p}}}{\sum\limits_{s' \in \left(\{s_p\} \cup \mathcal{S}_s^U \cup \tilde{\mathcal{S}}_s^N\right)} e^{\beta \rho_{s,s'}}}, \quad (10)$$

$$\rho_{s,s'} = \cos(\mathbf{e}_s, \mathbf{e}_{s'}). \quad (11)$$

We set the scaling parameter β to 64, following the suggestions in metric learning studies (Deng et al., 2019; Wang et al., 2018).

3.5.2 Self-training Objective

We formulate the self-training objective loss L^{ST} so that we bring the contexts and nearest neighbor senses closer. In the self-training process, we label a word in context with the sense whose embedding is the closest to that of the word. Specifically, let $\mathcal{W}^B$ denote a minibatch of words. For a word $w \in \mathcal{W}^B$, we obtain a set of candidate senses[4] $\mathcal{S}_w$. Then, L^{ST} for the minibatch $\mathcal{W}^B$ is defined as,

$$L^{\mathrm{ST}} = \sum_{w \in \mathcal{W}^B} (1 - \max_{s \in \mathcal{S}_w} \rho_{w,s}), \quad (12)$$

$$\rho_{w,s} = \cos(\mathbf{v}_w, \mathbf{e}_s). \quad (13)$$

Note that the nearest neighbor sense for the same context changes during training as we update parameters of the transformation functions for embeddings. Our intention is to bootstrap the performance, which was impossible in the "static counterpart", e.g., pseudo-labeling with the WordNet first sense heuristic. That is also a motivation of introducing the distance constraint in Eq. 5 and 6: we were concerned about the performance drop when a large deviation occurs in the semantic specialization. We report empirical evidence that the constraint improves the performance (§ 6.3).

In principle, the training data can be any corpus annotated with lemmas and part-of-speech tags. Nevertheless, we used the SemCor (Miller et al., 1993) corpus with the sense annotations removed. This is because using these de-facto standard corpora contributes to better reproducibility and fairer comparisons.

3.6 Try-again Mechanism (TaM) Heuristic

We examine the effectiveness of the proposed method when combined with TaM. Specifically, we employ the variant (Wang and Wang, 2021)[5] that utilizes Coarse Sense Inventory (CSI) (Lacerra et al., 2020) because of its simplicity. In essence, TaM reranks candidate senses by updating similarities under the assumption that the context should be also similar to the coarse semantic category that the candidate sense belongs to. Let s_1 and s_2 be the top two nearest neighbors for the target word w and $\mathcal{S}_s^{\mathrm{CSI}}$ be the set of senses[6] belonging to the same CSI class as s belongs to. Then, we refine the similarity $\rho_{w,s}^+$ for each $s \in \{s_1, s_2\}$,

$$\rho_{w,s}^+ = \rho_{w,s} + \max_{s' \in \mathcal{S}_s^{\mathrm{CSI}}} \rho_{w,s'}. \quad (14)$$

Finally, we choose the sense from s_1 and s_2 with highest similarity using $\rho_{w,s}^+$, i.e., we use the refined similarity $\rho_{w,s}^+$ instead of $\rho_{w,s}$ (Eq. 3).

4 Experiment Settings

4.1 Training

We used WordNet senses for optimizing the Attract-Repel objective and the sense-annotated words in the SemCor corpus for the self-training objective. Note that we solely use lemmas and part-of-speech tags and disregard the sense annotations. The number of senses in WordNet is 206,949, and the number of words in the corpus is 226,036. We independently sampled minibatches N_B for each objective. For the Attract-Repel objective, we iterate

---

[3] In the contrastive learning literature, related, unrelated, and different senses correspond to the positives, weak negatives, and hard negative examples, respectively.

[4] Querying WordNet for a tuple of lemma and part-of-speech tag returns the candidate senses.

[5] We followed author's implementation: `https://github.com/lwmlyy/SACE`

[6] $\mathcal{S}_s^{\mathrm{CSI}}$ will be the empty set if s doesn't exist in the CSI because it does not cover all synsets.

over all sense keys in the WordNet with 15 epochs[7]. For hyperparameter optimization, we disabled TaM heuristics and used the evaluation set of SemEval-2007 as the development set, following the standard practice (Pasini et al., 2021). See Appendix C for details of the hyperparameter search. We set $N_B = 256$, $\alpha = 0.2$, and $\epsilon = 0.015$. We used the Adam optimizer with learning rate 0.001.

4.2 Evaluation

For evaluation, we used the WSD unified evaluation framework (Raganato et al., 2017)[8]. We used the nearest neighbor sense as the prediction (Eq. 3). For the evaluation metric, we adopt the micro-averaged F1 score[9] that is commonly used in the literature. Unless otherwise specified, we run the training process five times with different random seeds, and report the mean and standard deviations.

4.3 Baselines

We compare the proposed method in two experimental configurations: *Intrinsic* and *With Heuristics*. For the *Intrinsic* configuration, we compare it with the methods that do not use any heuristic. Specifically, we choose `PlainBERT` and $\texttt{SREF}_{\texttt{emb}}$ (Wang and Wang, 2020) as baselines. `PlainBERT` uses BERT embeddings $\hat{\mathbf{v}}_w$ and $\hat{\mathbf{e}}_s$ as is. $\texttt{SREF}_{\texttt{emb}}$[10] adapts sense embeddings so that it brings semantically related senses closer. For the *With Heuristics* configuration, we compare the proposed method with the methods that combine heuristics. Specifically, we choose $\texttt{SREF}_{\texttt{kb}}$ (Wang and Wang, 2020) and `COE` (Wang et al., 2021b) as baselines. $\texttt{SREF}_{\texttt{kb}}$ combines $\texttt{SREF}_{\texttt{emb}}$ with TaM. `COE` also utilizes $\texttt{SREF}_{\texttt{emb}}$, but it employs refined TaM and CIE. `COE` is the current SoTA method on knowledge-based WSD.

We also compare with supervised methods which employ the similarity-based approach to assess the effect of not using sense annotations and of freezing BERT encoders. Specifically, we compare with `Sup-kNN` (Loureiro and Jorge, 2019) and `BEM` (Blevins and Zettlemoyer, 2020) (§ 2.4), which both use SemCor as the trainset. `Sup-kNN` computes sense embeddings as the context embeddings averaged over the annotated senses. `BEM` fine-tunes BERT encoders so that context embeddings and correct sense embeddings are brought closer. We consider `BEM` as the de-facto upper bound of similarity-based approach, given its usage of a supervision signal to fine-tune the BERT encoders.

5 Experimental Results

Table 2 shows the WSD task performance. In both configuration, the proposed method $\texttt{SS-WSD}_{\texttt{emb}}$ outperformed all knowledge-based baselines.

In the *Intrinsic* configuration, $\texttt{SS-WSD}_{\texttt{emb}}$ outperformed $\texttt{SREF}_{\texttt{emb}}$ by 3.9pt, which is as much as a 9.3pt improvement over `PlainBERT`. Looking at the results for each part-of-speech, we observed the largest improvement over $\texttt{SREF}_{\texttt{emb}}$ for verbs (9.0pt). This result reflects the fact that verbs have the richer supervision signal for the Attract-Repel objective because of the largest number of related and different senses (Table 1) for verbs. This suggests that the richer semantic relation knowledge is, the higher performance the proposed method may achieve.

In the *With Heuristics* configuration, $\texttt{SS-WSD}_{\texttt{kb}}$ outperformed `COE` by 0.8pt without using the CIE heuristic, which shows an advantage over the baselines regardless of whether the evaluation sentence is a stand-alone text or in a document. The improvement brought by TaM was 2.2pt. Although $\texttt{SS-WSD}_{\texttt{kb}}$ lagged behind `COE` on the SE07 (SemEval-2007) subset, we think this result is understandable because `COE` also used SE07 for hyperparameter optimization.

When compared to supervised methods, $\texttt{SS-WSD}_{\texttt{emb}}$ outperformed `Sup-kNN` by 1.4pt, while falling behind `BEM` by 4.1pt. The results indicate that the proposed method associates contexts with senses more precisely than the example-based sense embeddings computation using sense-annotated contexts. It also shows the effectiveness of the supervised fine-tuning of BERT encoders in `BEM`, as evidenced through their ablation study (Blevins and Zettlemoyer, 2020).

6 Analysis

6.1 Vanilla BERT Embeddings

The proposed method adapts the BERT embeddings (`PlainBERT`) by transformation. Therefore,

---

[7] In each epoch, we discarded the remaining examples in the self-training objective trainset once all sense keys have been traversed.

[8] Available at: `http://lcl.uniroma1.it/wsdeval/`

[9] Note that F1 score is equal to Precision and Recall (Pasini et al., 2021) because proposed method predicts a single sense.

[10] We applied their method to `PlainBERT`, consistent with the proposed method, to ensure a fair comparison of the effect of adaptation.

Method	TaM	CIE	By subset					By part-of-speech				All
			SE2	SE3	SE07	SE13	SE15	Noun	Verb	Adj.	Adv.

Table 2: WSD performance by subset and part-of-speech tag. `SS-WSD`$_{\texttt{emb,kb}}$ are the proposed methods. Numbers in parentheses represent the standard deviation. Asterisks (*) indicate that the difference to the best baseline is statistically significant at $p < 0.05$ by the Student's t-test (two-tailed test). Checkmarks (✓) in the TaM and CIE columns represent the usage of those heuristics. We bolded the best result among knowledge-based methods in each configuration and underlined the objective for hyperparameter tuning. The scores of `BEM`, `Sup-kNN`, `SREF`$_{\texttt{kb}}$, and `COE` are taken from the original papers.

Method	WSD (All)
`WN1`$^{\texttt{st}}$`Sense`	65.2
`PlainBERT`	65.6

Table 3: F1 score of BERT embeddings (`PlainBERT`) and WordNet the first sense heuristic (`WN1`$^{\texttt{st}}$`Sense`).

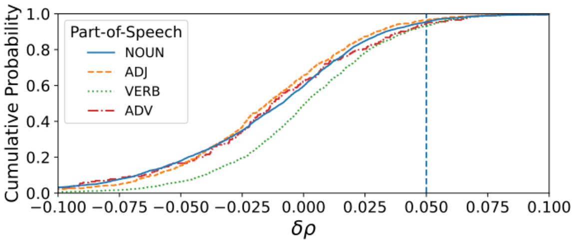

Figure 2: Cumulative distribution of the similarity margin between the incorrect sense and correct sense: $\delta\rho_w = \max_{s'\in\mathcal{S}_w\setminus\mathcal{S}_w^{\mathrm{gt}}} \rho_{w,s'} - \max_{s'\in\mathcal{S}_w^{\mathrm{gt}}} \rho_{w,s'}$, where $\mathcal{S}_w^{\mathrm{gt}}$ is the set of ground-truth senses of the word w.

its performance is influenced by the ability of `PlainBERT` to disambiguate senses.

Table 3 shows the WSD task performance using `PlainBERT`. We also reported the WordNet first sense heuristic (`WN1`$^{\texttt{st}}$`Sense`) for reference. We observe that `PlainBERT` is comparable to `WN1`$^{\texttt{st}}$`Sense`, indicating that self-training is a more effective strategy than `WN1`$^{\texttt{st}}$`Sense` for obtaining pseudo sense labels.

Fig. 2 shows the distribution of the similarity margin (difference) between the nearest neighbor incorrect sense and ground-truth sense computed by `PlainBERT`. We used the evaluation set for this analysis. We found that the similarity margin is below 0.05 for approximately 90% of all instances. This indicates that a large deviation from `PlainBERT` is not necessary for replacing nearest neighbor senses with the ground-truth ones.

6.2 Effect of Objectives

Table 4 shows the performance comparison when we eliminate a specific component from the semantic specialization objectives (§ 3.5). We keep all hyperparameters unchanged.

When we exclude either the Attract-Repel objective or the self-training objective, we see the performance drop by 3.3pt and 4.4pt, respectively. This finding supports the claim that joint optimization is crucial for its complementary nature.

When we remove either the unrelated senses or different senses from the Attract-Repel objective, we also see the performance drop by 5.0pt and 1.4pt, respectively. This result supports the idea that bringing semantically unrelated and different senses farther away contributes to performance. We also find that unrelated senses are more effective than different senses. A possible cause is the number of examples: while the number of unrelated

Ablation	WSD (All)	Δ[pt]
`SS-WSD`$_{\texttt{emb}}$	74.9	—
-Attract-Repel *objective*	71.6	-3.3
-Self-training *objective*	70.5	-4.4
-Unrelated senses $\mathcal{S}^U$ *repelling*	69.9	-5.0
-Different senses $\mathcal{S}^N$ *repelling*	73.5	-1.4
-Context *adaptation*	71.7	-3.2

Table 4: Ablation study of training objective. *Objective* rows represent the corresponding objective is excluded. *Repelling* rows represent the corresponding sense pairs are removed from the Attract-Repel objective (Eq. 10). *Adaptation* rows represent the usage of identity transformation. All differences are statistically significant at $p < 0.05$ by Welch's *t*-test (two-tailed test).

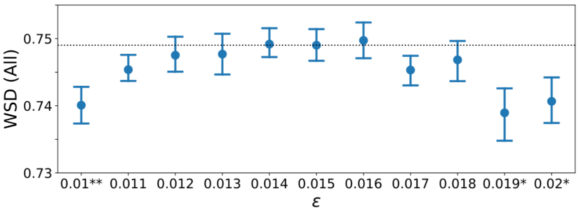

Figure 3: Ablation study of hyperparameter ϵ (§ 3.4). Dot and error bar represent the mean and standard deviation, respectively. Horizontal line represents the default setting ($\epsilon = 0.015$) performance. Asterisks indicate that the difference with respect to the default setting is statistically significant at $p < 0.05$ (*) and $p < 0.005$ (**) by Welch's *t*-test (two-tailed test).

senses is always[11] 255, the number of different senses is, on average, just 1.3 (see Table 1)[12].

Disabling the adaptation of context embeddings (by using identity transformation) caused a performance drop of 3.2pt, indicating that adapting both sense and context embeddings is necessary.

6.3 Effect of Distance Constraint

Fig. 3 shows the performance comparison when we change ϵ, the hyperparameter that bounds how farther away the specialized embeddings can be, in the interval [0.01,0.02] with a step size of 0.001. We found that performance follows an inverted U-shaped curve along ϵ, indicating that a sweet spot exists. Briefly, it shows that a severe constraint (small ϵ) results in an insufficient update for replacing nearest neighbors with ground-truth senses. In contrast, a looser constraint (large ϵ) results in a substantial deviation, eventually making the self-training less effective in the training process. The latter fact supports the claim that controlling the deviation from the original embeddings is necessary.

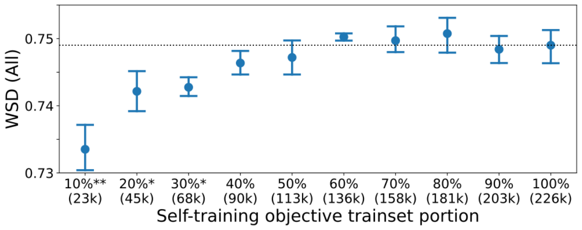

Figure 4: Impact of varying the self-training dataset size from 10% (23k examples) to 100% (224k). The dot and error bar indicates the mean and standard deviation, respectively. The horizontal line represents the performance when utilizing the 100% examples. Asterisks denote that the deviation from the 100% is statistically significant at $p < 0.05$ (*) and $p < 0.005$ (**) by Welch's *t*-test (two-tailed test).

7 Effect of Self-training Dataset Size

Fig. 4 illustrates the impact of varying the number of examples used for the self-training objective on the WSD task performance. It should be noted that 100% in the figure corresponds to using all examples in the SemCor corpus. We found that performance improves as the number of examples increases and reaches a saturation point at 60%, corresponding to 136k examples. While the coverage of words and senses appearing in the contexts also matters, it indicates that the benefits of self-training do not necessarily increase with the scaling to millions of examples.

7.1 Similarity Characteristics

We quantitatively investigate how well the proposed method achieved the key idea (Fig. 1-d): bringing related senses and contexts closer while unrelated and different senses farther away. Specifically, in Table 5, we reported averages of similarity values between related senses $\rho_{\mathcal{S}^P}$, unrelated senses $\rho_{\mathcal{S}^U}$, and different senses $\rho_{\mathcal{S}^N}$, along with averages of similarity values between ground-truth context-sense pairs[13] $\rho_{\mathcal{W}^{\text{gt}}}$. See Appendix D for formal definitions. We found that the proposed method `SS-WSD`$_{\texttt{emb}}$ brought context-sense pairs closer than `PlainBERT` ($\rho_{\mathcal{W}^{\text{gt}}}$: $0.64 \rightarrow 0.77$). In contrast, it pushed the unrelated and different senses away: $\rho_{\mathcal{S}^U}$:$0.77 \rightarrow 0.64$ and $\rho_{\mathcal{S}^N}$:$0.87 \rightarrow 0.78$. These results demonstrate that joint optimization of the Attract-Repel and self-training objectives realized the key idea successfully.

Can we expect better performance if we realize the key idea more precisely? We investigated the

---

[11] Minibatch size (=256) minus one yields 255.

[12] In fact, only 38% of all senses have different senses.

[13] We used sense-annotated words in the evaluation dataset.

Models	$\rho_{\mathcal{S}^P}$	$\rho_{\mathcal{S}^U}$	$\rho_{\mathcal{S}^N}$	$\rho_{\mathcal{W}^{\mathrm{gt}}}$	$\Delta\rho_{\mathcal{S}^P}\uparrow$	$\Delta\rho_{\mathcal{S}^U}\downarrow$	$\Delta\rho_{\mathcal{S}^N}\downarrow$	$\overline{\Delta\rho}\uparrow$	WSD (All)
`PlainBERT`	0.91	0.77	0.87	0.64	0.27	0.12	0.23	-0.030	65.6
`SS-WSD`$_{\texttt{emb}}$	0.88	0.64	0.78	0.77	0.11	-0.13	0.01	0.078	74.9
-Attract-Repel	0.92	0.79	0.90	0.81	0.11	-0.02	0.08	0.014	71.6
-Self-training	0.88	0.64	0.78	0.61	0.27	0.02	0.17	0.027	70.5

-Context adaptation	0.88	0.64	0.78	0.63	0.25	0.01	0.15	0.032	71.7

Table 5: Similarity characteristics of sense pairs and context-sense pairs. $\rho_{\mathcal{S}^P}$, $\rho_{\mathcal{S}^U}$, and $\rho_{\mathcal{S}^N}$ are the similarity to related, unrelated, and different senses (Eq. 15). $\rho_{\mathcal{W}^{\mathrm{gt}}}$ is the similarity of the context and its ground-truth senses (Eq. 16). $\Delta\rho_*$ is the difference to $\rho_{\mathcal{W}^{\mathrm{gt}}}$ (Eq. 17). $\overline{\Delta\rho} = \frac{1}{3}(\Delta\rho_{\mathcal{S}^P} - \Delta\rho_{\mathcal{S}^U} - \Delta\rho_{\mathcal{S}^N})$. Uparrow↑ (downarrow↓) represents the positive (negative) direction is favorable. WSD (All) are replicated from Tables 2 and 4 for reference.

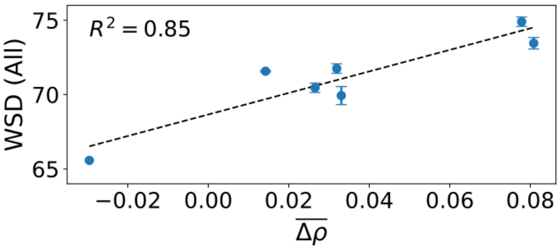

Figure 5: The relationship between the similarity characteristic metric $\overline{\Delta\rho}$ and WSD performance in Table 5.

relationship between these similarity metrics and WSD task performance. Specifically, we subtract $\rho_{\mathcal{W}^{\mathrm{gt}}}$ from each metric in order to capture the closeness of senses *relative to* the correct context-sense pairs, defining $\Delta\rho_*$ as $\rho_* - \rho_{\mathcal{W}^{\mathrm{gt}}}$. For example, $\Delta\rho_{\mathcal{S}^N} = \rho_{\mathcal{S}^N} - \rho_{\mathcal{W}^{\mathrm{gt}}}$ should be a negative value because the average similarity among different senses $\rho_{\mathcal{S}^N}$ should be smaller than that among correct context-sense pairs $\rho_{\mathcal{W}^{\mathrm{gt}}}$. Therefore, we compute the value $\overline{\Delta\rho} = \frac{1}{3}(\Delta\rho_{\mathcal{S}^P} - \Delta\rho_{\mathcal{S}^U} - \Delta\rho_{\mathcal{S}^N})$ to estimate the WSD performance.

Fig. 5 shows that $\overline{\Delta\rho}$ correlates well with WSD task performance ($R^2 = 0.85$). It suggests that if we achieve the key idea more precisely, we may improve the WSD performance. For instance, using a richer lexical relation knowledge, exploitation of the monosemous words, and self-training with confidence thresholding may be promising. We leave it for future work.

8 Conclusion

In this paper, we proposed `SS-WSD`: Semantic Specialization for WSD[14]. The proposed method learns how to adapt BERT embeddings by transformation and uses the semantic relation knowledge as a supervision signal. The key idea is the desired characteristics of similarities: bringing related senses and the contexts closer while unrelated senses and different senses farther away. We realized it as the joint optimization of the Attract-Repel and self-training objectives while preventing large deviations from original embeddings. Experiments showed that the proposed method outperformed the previous embedding adaptation method. When combined with the reranking heuristic that can be applied to stand-alone texts, it established a new SoTA performance on knowledge-based WSD. The proposed method performs well regardless of the availability of global contexts beyond the target sentence during inference, which the previous study did not achieve. Several analyses showed the effectiveness of the objectives and constraints introduced for specialization. We also found that the closeness of semantically related/different/unrelated senses relative to the closeness of correct context-sense pairs positively correlates with the WSD task performance.

9 Future Work

Given that the proposed method only necessitates lexical resources, it has the potential to effectively address the knowledge acquisition bottleneck problem (Pasini, 2020). Thus, we are interested in applying the proposed method to multilingual WSD using multilingual language models as contextualized encoders. One approach is the zero-shot cross-lingual transfer, which involves learning embeddings adaptation using only English lexical resources. Another option is the joint training of all target languages using multilingual lexical resources such as BabelNet (Navigli et al., 2021). We are also interested in integrating the proposed method into supervised WSD and applying the transfer learning of the specialized embeddings to other NLP tasks.

---

10 Limitations

One limitation of this work is that it is specific to BERT. Although this is in line with the standard practice in previous studies, experimenting with other pre-trained language models is preferred to assess the utility of the proposed method, or to improve the performance further. Another limitation is that it is evaluated on a single dataset and task. While we also followed the de-facto standard protocol, evaluating on rare senses (Maru et al., 2022) or Word-in-Context task (Pilehvar and Camacho-Collados, 2019; Martelli et al., 2021) will bring us more comprehensive insights on the effectiveness and applicability.

11 Ethics Statement

This work does not involve the presentation of a new dataset, nor the utilization of demographic or identity characteristics in formation. In this work, we propose a method for adapting contextualized embeddings for WSD using lexical resources. The proposed method is not limited to a specific resource, we used WordNet as the source of semantic relation knowledge and sense inventory. Therefore, adapted embeddings and sense disambiguation behavior may reflect the incomplete lexical diversity of WordNet in culture, language (Liu et al., 2021), and gender (Hicks et al., 2016).

A Lexical Resources

Table 6 shows an example of lexical resources for a sense key `computer%1:06:00::`. Note that unrelated senses are randomly chosen in practice.

For *related* senses lookup, we followed Wang and Wang (2020)'s paper and implementation[15]. Briefly, for a given sense key, we collect the synsets that encompass either itself or the sense keys connected by `derivationally_related_forms` relation. Then, for each collected synset, we extend the synsets via semantic relations shown in Table 7. Finally, we collect the sense keys that belong to either one of the synsets in the extended set of synsets, together with those connected to a given sense key by semantic relations shown in Table 7. We used the `nltk.corpus.wordnet` package for implementation.

B BERT Embeddings for Sense

For the computation of sense embeddings, we followed Wang and Wang (2020)'s method. Specifically, for a given sense key, we generate a sentence by filling in the following template using the lemma, synset lemmas, definition, and examples:

```
[lemma] - [syn. lemma 1], ...,
[syn. lemma n] - [definition]
[example 1] ... [example m],
```

where `n` and `m` represent the number of synonym lemmas and the number of examples. Then we take the average over all subwords in a sentence. For example, applying the template to the sense `computer%1:06:00::` will produce the following sentence.

> computer - computer, computing device, data processor, ... - a machine for performing calculations automatically

We solely use the examples available in WordNet Gloss Corpus and do not use the augmented examples that Wang and Wang (2020) collected.

C Hyperparameter Search

For the hyperparameter search, we first jointly optimized on the number of minibatches N_B, relative importance between objectives α (Eq. 9), and constraint on the distance from BERT embeddings ϵ (Eq. 3.5). We used `TPESampler` in the `optuna` package (Akiba et al., 2019) for optimization. We run hyperparameter search over $N_B \in \{64, 128, 256, 512, 1024\}$, $\alpha \in [0.1, 10]$, and $\epsilon \in [0.001, 0.1]$. The number of search trials is 210. Then, we ran a grid search on ϵ over the interval in [0.01,0.02] using a step size of 0.001. During hyperparameter search, we observed that 1) large minibatch size of 256 or above doesn't produce any statistically significant difference and 2) α is much less sensitive compared to ϵ.

D Analysis of Similarity Characteristics

We quantify the similarity characteristic as the macro average of similarity between senses and the similarity of ground-truth context-sense pairs. Specifically, for a given sense s, we calculate the average similarity to its related senses $\mathcal{S}_s^P$, unrelated senses $\mathcal{S}_s^U$, and different senses $\mathcal{S}_s^N$. Following Attract-Repel objective (§ 3.5.1), we define the minibatch excluding itself as the unrelated senses: $\mathcal{S}_s^U = \mathcal{S}^B \setminus \{s\}$. Then, we take the average over all senses $\mathcal{S}$, yielding the similarity among related senses $\rho_{\mathcal{S}^P}$, unrelated senses $\rho_{\mathcal{S}^U}$, and different senses $\rho_{\mathcal{S}^N}$ as follows:

$$\begin{aligned}
\rho_{\mathcal{S}^P} &= \frac{1}{|\mathcal{S}|}\sum_{s\in\mathcal{S}}\frac{1}{|\mathcal{S}_s^P|}\sum_{s'\in\mathcal{S}_s^P}\rho_{s,s'}, \\
\rho_{\mathcal{S}^U} &= \frac{1}{|\mathcal{S}|}\sum_{s\in\mathcal{S}}\frac{1}{|\mathcal{S}_s^U|}\sum_{s'\in\mathcal{S}_s^U}\rho_{s,s'}, \\
\rho_{\mathcal{S}^N} &= \frac{1}{|\mathcal{S}^N|}\sum_{s\in\mathcal{S}^N}\frac{1}{|\mathcal{S}_s^N|}\sum_{s'\in\mathcal{S}_s^N}\rho_{s,s'},
\end{aligned} \tag{15}$$

where $\mathcal{S}^N = \{s; |\mathcal{S}_s^N| > 0\}$.

For the similarity of ground-truth context-sense pairs $\rho_{\mathcal{W}^{\text{gt}}}$, we use the pairs of the word and annotated senses in the evaluation dataset (§ 4.2). For a given word w, we calculate the average similarity to its ground-truth senses $\mathcal{S}_w^{\text{gt}}$. Then, we take the average over all words $\mathcal{W}$ as follows:

$$\rho_{\mathcal{W}^{\text{gt}}} = \frac{1}{|\mathcal{W}|}\sum_{w\in\mathcal{W}}\frac{1}{|\mathcal{S}_w^{\text{gt}}|}\sum_{s\in\mathcal{S}_w^{\text{gt}}}\rho_{w,s}. \tag{16}$$

Finally, we define $\Delta\rho_*$ as the difference to $\rho_{\mathcal{W}^{\text{gt}}}$ for each relation types. We also define $\overline{\Delta\rho}$ as the arithmetic average over them while taking favorable positive/negative directions into account.

$$\begin{aligned}
\Delta\rho_{\mathcal{S}^P} &= \rho_{\mathcal{S}^P} - \rho_{\mathcal{W}^{\text{gt}}} \\
\Delta\rho_{\mathcal{S}^U} &= \rho_{\mathcal{S}^U} - \rho_{\mathcal{W}^{\text{gt}}} \\
\Delta\rho_{\mathcal{S}^N} &= \rho_{\mathcal{S}^N} - \rho_{\mathcal{W}^{\text{gt}}} \\
\overline{\Delta\rho} &= \frac{1}{3}(\Delta\rho_{\mathcal{S}^P} - \Delta\rho_{\mathcal{S}^U} - \Delta\rho_{\mathcal{S}^N})
\end{aligned} \tag{17}$$

Abstract

A persona-grounded dialogue model aims to improve the quality of responses to promote user engagement. However, because the given personas are mostly short and limited to only a few informative words, it is challenging to utilize them to generate diverse responses. To tackle this problem, we propose a novel persona expansion framework, **C**oncept-based **P**ersona e**X**pansion (**CPX**). CPX takes the original persona as input and generates expanded personas that contain conceptually rich content. We constitute CPX with two task modules: 1) Concept Extractor and 2) Sentence Generator. To train these modules, we exploit the duality of two tasks with a commonsense dataset consisting of a concept set and the corresponding sentences which contain the given concepts. Extensive experiments on persona expansion and response generation show that our work sufficiently contributes to improving the quality of responses in diversity and richness.

1 Introduction

A persona-grounded dialogue model aims to generate more human-like and engaging responses based on given traits called persona (Zhang et al., 2018a). As efforts of this research line, many recent works have explored various approaches to improving the quality of persona-based responses (Liu et al., 2020; Song et al., 2020; Kim et al., 2020).

In spite of these efforts, there remain some limitations in persona-grounded dialogue models. They are in need of generating more diverse responses. Due to the predefined personas being mostly short and limited to only a few informative words, the responses based on these personas tend to be generic and monotonous. To tackle this issue, COMPAC (Majumder et al., 2020) expands the predefined personas with a commonsense knowledge graph about events, ATOMIC (Sap et al., 2019). With the expanded personas, the dialogue agent generates more diverse responses which contain inferential knowledge stemming from the original persona.

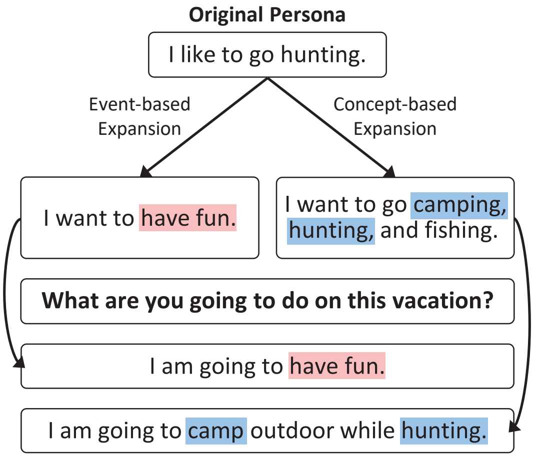

Figure 1: An example of responses generated by different persona expansion strategies for the same query.

However, there is room for improvement in the expansion strategy of COMPAC, which takes an event-based approach as means for persona expansion, which captures causal inferences from personas. The event-based persona expansion is done with the utilization of ATOMIC as a training dataset for the COMET commonsense transformer (Bosselut et al., 2019). As an example, in Figure 1, the expanded persona of the agent (i.e., *I want to have fun*) can be obtained from the given original persona (i.e., *I like to go hunting*) through causal inference. Then given the question "*What are you going to do on this vacation?*", the response based on the event-based expansion strategy is given as "*I am going to have fun*". The generated response is suitable for a given query in terms of relevance. Nevertheless, the response is still monotonic because the expanded persona lacks content.

On the other hand, in the manner of the concept-based expansion strategy, the expanded persona of the agent (i.e., *I want to go camping, hunting, and*

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3471–3481
May 2-6, 2023

fishing) can be obtained through semantic reasoning between concepts (*hunt* → *camping*, *fishing*). Then given the same question, the response based on the expanded persona by concept-based strategy is "*I am going to camp outdoor while hunting*", which is more conceptually diverse and rich.

In general, the diversity of responses is directly correlated with the interlocutor's feeling of being involved in a conversation. Further, in order for the interlocutor to be attracted, a more significant amount of information needs to be delivered. In other words, even in responses that convey the same meaning, the presence of words to enrich the content makes a difference in diversity. Hence, it is crucial for original personas to be expanded to have rich content to improve the diversity of persona-based responses. As demonstrated in Figure 1, by utilizing various concepts in expansion, it is possible to generate personas with richer content than the existing expansion approach.

In this paper, we propose a novel **C**oncept-based **P**ersona e**X**pansion framework, called **CPX**. First, the concept extractor extracts relevant concepts from the original persona sentence, which consists of the constituent words and their semantically related terms. Then, the sentence generator leverages the extracted concepts to generate expanded personas via generative commonsense reasoning. In training, we exploit the duality of CommonGen (Lin et al., 2020) dataset to train the two opposing task modules that consist of the CPX framework: 1) Concept Extractor and 2) Sentence Generator. The experimental results demonstrate that our framework outperforms the baseline models in terms of the expanded persona's diversity. We also show that the persona-grounded dialogue model employing our expansion strategy generate more engaging and diverse responses.

The contributions of our work are as follows:

- We propose a novel concept-based persona expansion framework, CPX, to generate expanded personas with rich content.
- We adopt the duality of concept extraction and sentence generation to constitute the framework for the proposed expansion strategy.
- Through the proposed framework, it is possible to augment the persona-grounded dataset to improve the diversity of responses.

2 Related Work

2.1 Persona-Grounded Dialogue

A persona-grounded dialogue model aims to generate more engaging, human-oriented responses by using some personal characteristics of an agent (Zhang et al., 2018a). As a data-driven approach, Welleck et al. (2019) propose the elaborately constructed dialogue inference dataset, DNLI. Some studies show that fine-tuning the pre-trained language models on the persona-grounded dataset can improve the quality of dialogues (Wolf et al., 2019; Golovanov et al., 2019). Furthermore, recent studies have explored sophisticated neural architectures for better persona-based responses, such as endowing mutual-persona (Liu et al., 2020), multi-stage framework (Song et al., 2020), and self-consciousness modeling (Kim et al., 2020).

Despite the aforementioned efforts, diversity remains limited due to the deficient information in predefined personas. Majumder et al. (2020) adopt the event-based persona expansion strategy for generating more engaging responses. They construct a large number of expanded personas by COMET (Bosselut et al., 2019). Their expansion strategy increases the number of personas, but the expanded personas are still simple in content. That is, while the range of responses that can be generated based on the persona has stretched, the diversity and richness are still limited. To solve this problem, we propose a novel concept-based persona expansion framework that contributes to increasing the semantic richness of expanded personas.

2.2 Generative Commonsense Reasoning

CommonGen task (Lin et al., 2020) aims to generate sentences describing an everyday scenario from a given set of concepts. Formally, the input is a concept set defined as $x = \{c_1, c_2, ..., c_k\} \in X$, and the expected output is a sentence $y \in Y$ that describes a common scenario in our daily life, containing all input concepts. The goal of this task is to learn the reasoning ability between concepts and sentences by injecting relational commonsense knowledge into a language model. We exploit this sentence generation ability in our persona expansion framework (i.e., $f : X \rightarrow Y$). Meanwhile, the extractor model can learn the ability to extract concepts from sentences using an inversely aligned dataset. We leverage the concept extraction ability based on the duality of the tasks in our framework (i.e., $g : Y \rightarrow X$).

Original Concept Set	Human References	Added Concept Set
{cucumber, salad, tomato}	"make a salad of cucumber and tomato" "cooked asparagus and a green salad with cucumbers, tomatoes and chick peas"	{asparagus, green}
{athlete, championship, win}	"olympic athlete has won only medal of the championships" "athlete on his way to winning sport at the championships" "athlete is all smiles after winning the championship after stadium"	{olympic, sport, stadium}
{coast, sea, wave, weather}	"incoming waves of the sea on the coast in foggy weather" "storm clouds in bad weather over rough sea with breaking waves off the coast"	{foggy, storm}

Table 1: Examples of instance pairs (Original Concept Set–Human References) in CommonGen dataset and augmented concept set (Added Concept Set).

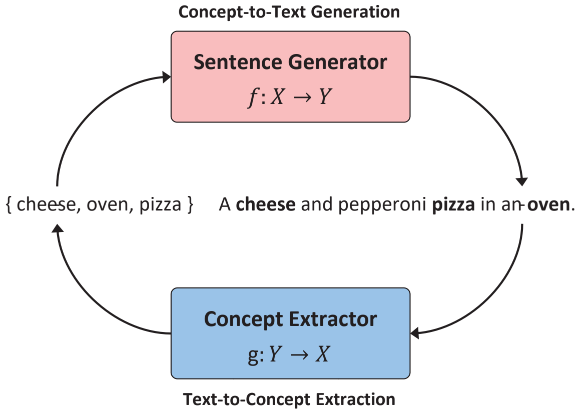

Figure 2: Duality of task modules: 1) Concept Extractor and 2) Sentence Generator. We leverage the CommonGen dataset to train each task module.

3 Task Definition

Our goal is to generate expanded personas to solve the lack of information of a given original persona in PERSONA-CHAT denoted as D_{PC}. Formally, given the original persona p_i, a set of k concepts $C_i = \{c_1, c_2, ..., c_k\}$ is extracted from p_i, where P is a set of all personas in D_{PC}. Then, an expanded persona p_i^+ is generated, using C_i. We perform this expansion for all personas in P, constructing augmented PERSONA-CHAT D_{PC}^+ that includes all expanded personas P^+. Finally, D_{PC}^+ is the augmented dataset that can enhance the dialogue in a data-driven manner.

4 Data Preparation

4.1 Training Data for Framework

As shown in Figure 2, we leverage the duality of two tasks in the CPX framework. The generator and extractor are trained with the original and inversed CommonGen dataset, respectively. The original instance pairs in CommonGen consist of one or more sentences corresponding to each concept set. In other words, it is designed so that a model learns the ability to generate multiple sentences, including given concepts. This dataset configuration can help increase the diversity of the sentences produced by the generator. We also construct the inversely aligned dataset to inject the ability to extract concepts from the sentence into the extractor.

	Train	Dev	Test
# Concept Sets	32,651	993	1,497
- Size = 3	25,020	493	-
- Size = 4	4,240	250	747
- Size = 5	3,391	250	750
# Sentences	67,389	4,018	7,644
- Unique@3	49,459	1,814	-
- Unique@4	8,109	1,135	-
- Unique@5	1,488	1,062	-

Table 2: Statistics of CommonGen dataset. The upper row summarizes the numbers of concept sets by size, and the lower is the number of unique sentences corresponding to concept sets with N elements.

4.2 Concept Augmentation

In order for our expansion strategy to work successfully, the diversity of the extracted concepts and the generated sentences through each task module must be guaranteed. For this reason, we augment a concept set before the training instead of using the dataset as it is. The model of Feng et al. (2021) is referred to in the concept set augmentation, but the details are different. We use an off-the-shelf NLP tool spaCy[1] to extract various words as candidate concepts from the source sentences. Then, we calculate the average BERTScore (Zhang et al., 2019) between the candidate concepts and the source sentences. Finally, 1 to 5 candidate concepts with the highest score are selected as *Added Concept Set*. Some examples of augmentation are illustrated in Table 1. Formally, we denote the original concept set as C^{ori}, and the added concept set as C^{add}. C^+

---

[1] https://spacy.io/, The used version is 3.1.4.

denotes the union of C^{ori} and C^{add}. For example, if C^{ori} and C^{add} aligned with the same sentence are {*building, cloud, sky*} and {*blue, city*} respectively, then C^{+} is {*building, cloud, sky, blue, city*}.

5 CPX Framework

The CPX framework consists of two task modules: 1) **Concept Extractor** – extracting concepts from the original persona; 2) **Sentence Generator** – generate multiple sentences from the given concepts. Inspired by Xia et al. (2017), we utilize the duality of the tasks to train these modules. However, since we just exploit the advantage of the task duality, two modules are independently trained without sharing parameters based on probabilistic duality.

5.1 Concept Extractor

The concept extractor aims to take the concepts that comprise the given sentence. Our model achieves the capability by training on the inverted version of the CommonGen dataset. Formally, given the input sentence $y \in Y$, and the target concept set to extract is a $x = \{c_1, c_2, ..., c_k\} \in X$. The concept extractor aims to find an objective function $g : Y \to X$,

$$g(Y; \theta_{ext}) \triangleq argmax_{x \in X} P(x|Y; \theta_{ext}) \quad (1)$$

where θ_{ext} is a trainable parameter. We leverage BERT (Devlin et al., 2019) based model as the extractor. We train the concept extractor in three ways with C^{ori}, C^{add}, and C^{+} as output X to compare the performance according to the extracted concept set. First, the purpose of the extractor Ext^{ori} trained with C^{ori} is to extract only the concepts contained in a given sentence. Second, the purpose of the extractor Ext^{add} trained with C^{add} is to extract the concepts not contained in a given sentence. By utilizing these hidden concepts, it is possible to generate expanded personas with concepts not included in the original persona but semantically correlated. Finally, the purpose of the extractor Ext^{+} trained with C^{+} is to extract not only the concepts contained in a given sentence but also the ones not contained but semantically related. The experimental results of the effect of each extractor on the persona expansion performance are described in Section 6.2.2.

5.2 Sentence Generator

The goal of the sentence generator is precisely the same as the original CommonGen task, generating sentences by inferring the underlying relational knowledge among concepts. Formally, given the input concept set defined as $x = \{c_1, c_2, ..., c_k\} \in X$, the target is to generate a sentence $y \in Y$ containing all input concepts. The sentence generator aims to find an optimal objective function $f : X \to Y$,

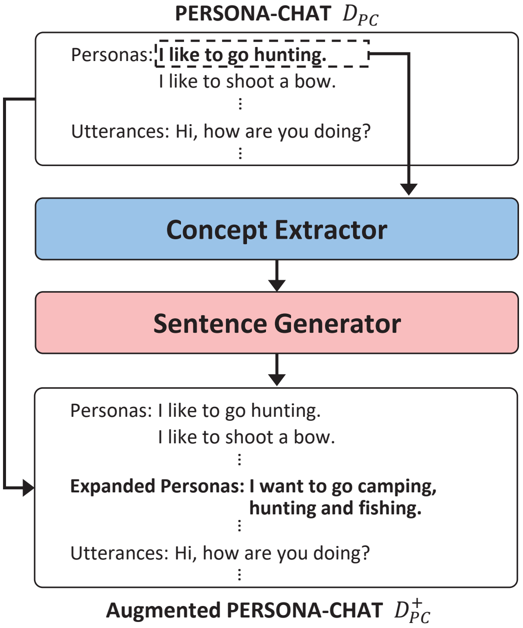

Figure 3: The overall workflow of CPX framework. Given a persona-grounded dialogue dataset D_{PC}, CPX consisting of the extractor and generator generates expanded personas. Final output D^{+}_{PC} is the augmented dialogue dataset.

$$f(X; \theta_{gen}) \triangleq argmax_{y \in Y} P(y|X; \theta_{gen}) \quad (2)$$

where θ_{gen} is a trainable parameter. In our setting, we exploit the pre-trained models as the generator, specifically BART (Lewis et al., 2020) and T5 (Raffel et al., 2020), which are the state-of-the-art sequence-to-sequence transformer (Vaswani et al., 2017) language models. As reported by Feng et al. (2021), the use of augmented concept sets at the training phase improves the length and richness of generated sentences. Therefore, we use the integrated concept set C^{+} as input X to train the sentence generator.

5.3 Control of Persona Expansion

To constrain the form of expanded personas, we use four types of prompts: *I want*, *I need*, *I feel*, and *I am*.[2] These prompts can control the generation form of the expanded persona and represent an

---

[2] These four types of prompts were determined by referring to Majumder et al. (2020) and the verb distribution of personas in PERSONA-CHAT.

agent's desire, intent, emotion, and status, respectively. Also, according to our in-depth analysis of PERSONA-CHAT, most of the personas describe the first-person subject, so we fix the subject of the prompt as "I". Accordingly, the constrained decoder output sequence for generating the expanded persona is as follows:

$$[I]\ [want|need|feel|am] \tag{3}$$

Consequently, we obtain four expanded personas per original persona. The expanded persona set P^+ is added to the original dataset D_{PC} to construct the augmented dataset D^+_{PC}. The experimental results on response generation using D^+_{PC} will be described in Section 6.3.3.

6 Experiments

To validate the performance of CPX, we conducted two experiments: 1) persona expansion and 2) response generation.

6.1 Experimental Setup

6.1.1 Dataset

We carried out our experiments on the PERSONA-CHAT, converted to the ConvAI2 benchmark version (Dinan et al., 2020). The dataset consists of 17,878/1,000 multi-turn dialogues and 1,155/100 profiles for Train/Valid set. We utilized the unique personas extracted from all profiles for persona expansion experiments. Also, we utilized the original and augmented PERSONA-CHAT datasets to demonstrate the impact of the expansion strategy on response generation.

6.1.2 Baselines

Two types of expansion baselines are considered: 1) **paraphrasing** and 2) **transformer** trained with commonsense knowledge.

- **MANUAL PARAPHRASING** (Zhang et al., 2018a): We used manually paraphrased personas provided with the original PERSONA-CHAT, where workers rephrased the original personas to remove trivial word overlaps.
- **AUTOMATIC PARAPHRASING** (Xie et al., 2020): To paraphrase the personas in an automated manner, we leveraged the existing paraphrasing system based on back-translation. We generated the paraphrased persona by exploiting the pre-trained En-Fr and Fr-En translation models.[3]
- **COMET** (Bosselut et al., 2019): COMET is a transformer-based model that generates commonsense expansions of a given world event by training on a commonsense knowledge graph such as ATOMIC. We generated expanded personas for four relations (i.e., xWant, xNeed, xReact, xAttr) that are suitable for representing an agent's traits.

In our setting, the automatic paraphrasing model generated one expanded persona for each original persona, and the transformer-based model generated four expanded personas, one for each relation.

6.2 Persona Expansion

In this section, we compared the quality of personas expanded by CPX and baselines. We further reported CPX's performance according to the concept extractor and sentence generator.

6.2.1 Evaluation Metrics

Automatic Evaluation To evaluate the quality of expanded personas, we employed four metrics. (1) Distinct-n (**Dist-n**) (Li et al., 2016) measures the diversity of sentences by calculating the ratio of distinct words against total n-grams. (2) Entropy-n (**Ent-n**) (Zhang et al., 2018b) measures the entropy obtained via the n-gram distribution in a sentence. (3) Also, we report the length of the sentence (**Length**) to measure the amount of content conveyed by the persona. (4) Finally, we employ the BERTScore (**F$_{\text{BERT}}$**) (Zhang et al., 2019) to measure how semantically relevant the expanded persona is to the original persona.

Human Evaluation We conducted a human evaluation with 100 random samples. We hired three human annotators proficient in domain language through a third-party company. Annotators knew nothing of the system they were evaluating. Also, annotators were properly compensated for their labor. Human annotators evaluated the quality of expanded persona sentences on three criteria. The metrics used for human evaluation are as follows: (1) **Engagement** measures whether the expanded persona is engaging or interesting. (2) **Diversity** measures whether the expanded persona is diverse and informative. (3) **Relevance** measures whether the expanded persona is semantically relevant to the original persona. The scoring range from 1 to 5, with lower indicating poor and higher indicating better. Further, we conducted a pairwise comparison between personas expanded by CPX and personas expanded by COMET.

Table 5: Human evaluation results on impact of concept extractor. The best results are bolded.

6.2.2 Persona Expansion Results

Analysis on Automatic Evaluation Automatic evaluation results are reported on the left of Table 3. CPX outperforms the baselines in all automatic evaluation metrics in diversity. The personas expanded by CPX were not only long (Length) but also rich in content, being composed of different and unique words (Dist-1/2, Ent-1/2). Also, CPX showed a diversity similar to or better than manual and automatic paraphrasing. In particular, we demonstrated the effectiveness of CPX's concept-based approach by surpassing immensely on all metrics of the comparative model COMET. For the BERTScore, which indicates relevance to the original persona, CPX performed comparatively lower than automatic paraphrasing, i.e., machine translation. This is because the back-translated personas have almost the same meaning as the original persona. On the other hand, CPX scored higher than the comparative generative-based model COMET. Judging from these results, the concepts extracted by CPX were semantically related to the original persona, and the generator effectively generated the expanded persona with sufficient commonsense.

Analysis on Human Evaluation Human evaluation results along the three criteria are depicted on the right of Table 3. The annotators evaluated that CPX outperformed all baselines in terms of Engagement and Diversity except for Relevance, for which CPX made the second-best result but was still close to the machine translation. For accurate evaluation with the target model COMET, we pairwisely compared the personas that each model expanded for four relations, as shown in Table 4. First, CPX was superior in all metrics in the evaluation of the persona forms of "*I want*" and "*I need*", which represent the agent's desire and intent. More specifically, CPX was overwhelmingly superior in Engagement and Diversity. This is because the personas generated by CPX contain richer content than COMET. This means that CPX learned the commonsense relationship between concepts well and used it effectively to generate expanded personas. On the other hand, in terms of Relevance to the original persona, CPX showed lower performance in the remaining two persona forms of "*I feel*" and "*I am*", which represent the agent's emotion and status. For this result, we analyzed that it is because the too-long sentences generated by CPX are more likely to contain concepts unrelated to the original persona.

Expansion Model	Automatic Evaluation					Human Evaluation		
	PPL	BLEU	Dist-1	Dist-2	F_{BERT}	Fluency	Engagement	Diversity
Original	20.24	1.28	0.04	0.19	0.09	3.12	2.44	2.32
Manual Paraphrasing	19.76	1.43	0.13	0.24	0.12	3.20	3.02	3.17
Automatic Paraphrasing	20.38	1.51	0.11	0.27	0.11	3.13	2.78	2.89
COMET	19.87	2.66	0.18	0.31	0.13	3.24	3.05	3.11
CPX_{BART}	19.68	3.18	0.32	0.79	0.14	**3.30**	3.67	3.48
CPX_{T5}	**19.44**	**3.27**	**0.34**	**0.82**	**0.16**	3.28	**3.85**	**3.70**

Table 6: Automatic and human evaluation results on response generation utilizing expanded personas by each model. The generative model used in response generation experiment is GPT-2 (Wolf et al., 2019). The best results are bolded, and the second-best are underlined.

Original Persona: I like to remodel homes.
Extracted Concepts: remodel, home, country, house, repair
PARAPHRASING: • MANUAL: I love to redesign houses. • AUTOMATIC: I like to renovate houses.
COMET: • xWant: I want to buy a new home. • xNeed: I need to buy a house. • xReact: I feel happy. • xAttr: I am a homeowner.
CPX: • Desire: I want to live in a country house with a large yard. • Intent: I need to a hammer and a saw to repair my old house. • Emotion: I feel comfortable in country home. • Status: I am busy repairing solar panels on the roof of home.

Table 7: Examples of expanded personas.

Impact of Concept Extactor We analyzed the impacts of the extracted concept on the CPX framework. We expanded the persona and conducted a human evaluation using the extractors Ext^{ori}, Ext^{add}, and Ext^{+} learned with the three concept sets of C^{ori}, C^{add}, and C^{+}, respectively. As reported in Table 5, the overall performance was the best when the extractor trained with C^{+} was used. In particular, when the Ext^{add} extractor trained using only C^{add}, it showed a deficient value in Relevance. It shows that not only the diversity of the extracted concepts from the sentence but also the relevance to the original persona is essential to concept-based persona expansion.

6.2.3 Case Study

Table 7 shows an example of personas expanded by CPX and other baseline models. The paraphrased personas were semantically identical to the original persona. COMET generated expanded personas that can be inferred from the original persona. However, the expanded personas were still short and lacking in content. On the other hand, CPX generated expanded personas with rich content, including extracted concepts.

6.3 Response Generation

We conducted an experiment on response generation using the original and augmented dataset expanded by different strategies.

6.3.1 Dialogue Model

The dialogue model used in our response generation experiment is GPT-2 (Wolf et al., 2019) just concatenating all persona sentences along with dialog history. In the case of paraphrasing, the training dataset was constructed by concatenating all personas. On the other hand, in the case of COMET and CPX, the number of expanded personas is large. Therefore, training datasets were constructed using only the expanded personas with the highest score, each per original persona, by utilizing the RoBERTa (Liu et al., 2019) based NLI model pretrained with the DNLI dataset.

6.3.2 Evaluation Metrics

We automatically evaluated the response generation using the metrics used in the persona expansion experiment. We also adopted widely used metrics **PPL** and **BLEU** (Papineni et al., 2002) to measure the quality of responses. **Fluency**, which measures whether the generated responses are fluent, was additionally used for human evaluation.

6.3.3 Response Generation Results

Analysis on Automatic Evaluation Automatic evaluation results of response generation are reported on the left of Table 6. The dialogue model trained on the dataset augmented by CPX outperforms other comparative models in all evaluation metrics. In particular, it significantly outperformed other models in terms of diversity. It shows that our expansion strategy improves the diversity of

Personas: I have two dogs. I like to work on vintage cars. My favorite music is country.
Query: What do you usually do in your spare time?
Original: I just relax with my dogs.
Manual: I love vintage car. How about you?
Automatic: I like country music.
COMET: I want to take care of my dogs.
CPX: I like to play frisbees with my dog in a nearby park.

Table 8: Examples of generated responses.

responses based on the language understanding ability of the pre-trained language model. Since pre-trained language models like GPT-2 are trained with large data, it is important to be provided with a rich source (i.e., expanded personas) to generate responses that include various concepts rather than a problem of lack of fine-tuning data.

Analysis on Human Evaluation Human evaluation results are shown on the right of Table 6. A dialogue dataset augmented through CPX significantly improved the performance of the dialogue model for all human evaluation metrics. On the other hand, the dataset augmented by COMET did not achieve significant performance improvement compared to other models. The difference in performance between the two expansion strategies was particularly large in Engagement and Diversity. It means that the concept-based expansion strategy is more suitable for improving the diversity and richness of the persona-based responses.

6.3.4 Case Study

Table 8 depicts examples of responses generated by models trained according to paraphrasing or expansion strategies. The responses generated by CPX were the richest in content. The paraphrasing-based models responded just at the level of simply copying personas. COMET generated a response containing "*take care*" that could be inferred from "*I have two dogs.*" based on its causal reasoning ability. Nevertheless, it did not significantly improve the diversity of the generated responses. On the other hand, CPX utilized the concepts such as "*frisbee*" and "*park*" that are commonly related to the original persona "*I have two dogs.*" to generate a richer utterance. We found that improving the conceptual diversity of personas enriched persona-based responses and made them more engaging.

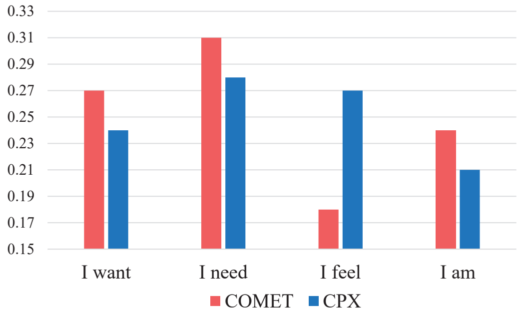

Figure 4: Distribution of each relation (prompt) of the expanded persona selected by the NLI model.

7 Discussions

Biases in Persona Selection While constructing the dataset for model training, we identified the bias in selecting the expanded personas. As shown in Figure 4, among the four types of personas expanded by COMET, the ratio of each type selected through the NLI model is uneven. While the personas expanded by CPX had been selected more evenly, the distribution was still somewhat biased. This suggests that it is likely for persona expansion models to generate more biased responses through poor selection. It also means that the approach that leverages NLI-based similarities between expanded personas and predefined personas, queries, or gold responses, in the persona selection can also introduce some bias. In order to generate a richer and unbiased persona-based response, it is necessary to study a method of considering the fairness of this expanded persona selection process.

Dual Use of Dataset In this study, we utilized CommonGen dataset for the generative commonsense reasoning task to train the proposed framework. This dual use of the dataset causes some concerns that need to be discussed. First, indiscriminate use of commonsense can lead to the problem of deceiving users or disclosing information by making it difficult for users to recognize that their conversation partner is a chatbot (Gros et al., 2021). Next, the CommonGen dataset may contain biases because it was constructed by human crowd workers. These biases may cause unintended "safety" problems where the dialogue model generates aggressive and harmful responses (Dinan et al., 2022). Fortunately, we found no such case while checking extended personas and generated responses in the CPX framework. Nevertheless, these issues deserve careful consideration in future works leveraging a similar dual use approach.

8 Conclusions and Future Work

In this paper, we proposed the concept-based persona expansion framework to improve the semantic diversity of the persona-grounded dialogue. We expanded personas by extracting and utilizing semantically related concepts through concept-based commonsense reasoning, making persona-grounded dialogues more engaging. During the experiments, we identified some less relevant expansion cases. Therefore, we have a plan to develop a method of preventing potential overexpansion. We also found that in order to effectively reflect the diversely expanded personas in response generation, it was necessary to resolve the bias in the selection process. From this perspective, we will conduct experiments and studies for models that can generate more effective persona-based responses through a bias-free selection process while maintaining the diversity of expanded personas.

Limitations

In this study, we tried to show the importance of the diversity of expanded personas in order to generate more engaging responses. Therefore, the narratives in the paper and the results reported in the tables were focused on diversity. Due to the nature of the proposed concept-based expansion strategy, the expanded personas are generated by using similar but not different concepts, which are not included in the original persona. Also, we intended that the expanded personas be distinct from the original persona as much as possible for the diversity that can be gained from various concepts. For these reasons, we decided to decrease relevance slightly as a trade-off while increasing diversity.

Ethical Considerations

In this study, we utilized the CommonGen and PERSONA-CHAT datasets which contain crowd-sourced work by human annotators. Although we did not find any notable cases during this study, the dual use of these datasets may produce results that contain unintended linguistic and cultural biases.

A Implementation Details

A.1 Persona Expansion

CPX was implemented with HuggingFace's Transformers library.[4] The Concept Extractor initialized from the publicly available BERT-based-uncased[5] model with 12 layers and 768 hidden sizes. We use an Adam optimizer (Kingma and Ba, 2014) and a learning rate of 3e-5. The training of the Concept Extractor was conducted on an Nvidia RTX3090 24G GPU with a batch size of 16. The Sentence Generator initialized from the BART-base[6] and T5-base[7] model. We use an Adam optimizer, and the learning rates are 3e-6 and 5e-6, respectively. The Sentence Generator was trained on an Nvidia RTX3090 24G GPU with a batch size of 8.

A.2 Response Generation

We utilized the repositories and implementation details of GPT-2[8] for response generation. We adjusted some of the details of the model and trained in a single-turn dialogue setting.

B Human Evaluation Protocol

We hired three well-educated annotators from a third-party company to conduct human evaluations. The annotators were given the original persona and the expanded persona pairs to evaluate persona expansion. Also, annotators were given the original personas, the query, and the generated response pairs to evaluate response generation. Each annotator evaluated 100 samples, each sample worth $0.1. The evaluation was conducted in a double-blind fashion. The human evaluation metrics include: (1) Engagement, which measures whether the expanded persona or generated response is engaging and interesting; (2) Diversity, which measures whether the expanded persona or generated response is diverse (3) Fluency, which measures whether the generated response is fluent; (4) Relevance, which measures whether the expanded persona is semantically relevant to the original persona. The scoring range of the metrics is 1 to 5. The specific scoring criteria for human annotation are shown in Table 9.

Engagement
1-2: (very) Simple and meaningless
3: Semantically moderate
4-5: (very) Interesting and want to keep the conversation
Diversity
1-2: (very) Generic and short in length
3: Conceptually moderate
4-5: (very) Informative and contain various concepts
Fluency
1-2: (very) Hard to read or syntactically incorrect
3: Grammatically correct
4-5: (very) Fluent and easy to understand
Relevance
1-2: (very) Unsuitable for given query or persona
3: Relevant to given query or persona
4-5: (very) Suitable and reflect well given query or persona

Table 9: Scoring criteria of human evaluation.

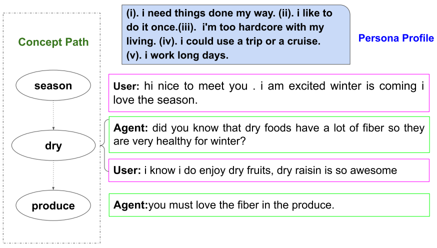
Abstract

Although there has been a plethora of work on open-domain conversational systems, most of these lack the mechanism of controlling the concept transitions in a dialogue. For activities like switching from casual chit-chat to task-oriented conversation, an agent with the ability to manage the flow of concepts in a conversation might be helpful. The user would find the dialogue more fascinating and engaging and be more receptive to such transitions if these concept transitions were made while taking into account the user's persona. Focusing on persona-aware concept transitions, we propose a Reinforced Persona-aware Topic-guiding Conversational System (**RPTCS**). Due to the lack of a persona-aware topic transition dataset, we propose a novel conversation dataset creation mechanism in which the conversational agent leads the discourse to drift to a set of target concepts depending on the persona of the speaker and the context of the conversation. To avoid scarcely available expensive human resources, the entire data-creation process is mostly automatic with human-in-loop only for quality checks. This created conversational dataset named **PTCD** is used to develop the **RPTCS** in two steps. First, a maximum likelihood estimation loss-based dialogue model is trained on **PTCD**. The trained model is then fine-tuned in a Reinforcement Learning (RL) framework by employing novel reward functions to assure persona, topic, and context consistency with non-repetitiveness in generated responses. Our experimental results demonstrate the strength of the proposed system with respect to strong baselines[1].

1 Introduction

Due to the abundance of conversational corpora, there has been a great interest in building open-domain conversational systems[2] (Huang et al., 2020). While capable of producing fluent responses, these systems also frequently generate generic responses devoid of any useful information (Gao et al., 2019). Human discourse is complex and difficult to replicate as it often covers a wide range of topics (Winograd, 1977). Hence, the key to a multi-turn conversation's success is striking a balance between effectively changing the subject and keeping it on-topic (See et al., 2019).



(i). i need things done my way. (ii). i like to do it once.(iii). i'm too hardcore with my living. (iv). i could use a trip or a cruise. (v). i work long days.

User: hi nice to meet you . i am excited winter is coming i love the season.

Agent: did you know that dry foods have a lot of fiber so they are very healthy for winter?

User: i know i do enjoy dry fruits, dry raisin is so awesome

Agent:you must love the fiber in the produce.

Figure 1: An illustration of the suggested task. The persona profile and the concept path to the target concept serve as the foundation for the created dialogues.

It is also seen that even if open-domain conversational systems employ topic shift, they are not able to engage user due to absence of knowledge of user's own perceptions. Therefore, to achieve a robust topic shift guiding conversational system, it has to evolve away from the prior factual information systems (Leuski et al., 2006) towards a novel blend of both task-oriented and non-task-oriented systems (Akasaki and Kaji, 2017). However, they may fail to engage user in difficult multi-turn information-seeking tasks or dialogues (Trippas et al., 2020) and may also suffer from "anomalous state of knowledge" (Belkin and Vickery, 1985) where the user has vague information requirements and is often struggling to articulate it with enough precision in a conversation. Thus, we require context-sensitive user guidance that does not assume a rigid hierarchy of the user's plans and

[§]equal contribution

[1] Codes and dataset available at `https://github.com/zishan-ahmad-nlp/persona-topic-shift`

[2] we use the terms conversational system/agent, dialogue system/agent, agent, and chatbot interchangeably.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3482–3494
May 2-6, 2023

work objectives. Such a guidance, can be achieved by utilising persona information of user with the ongoing dialogue. This will drive the conversation from one topic to a different one in consonance with the user's interests.

Focusing on these two aspects, we propose a reinforced persona aware topic guiding conversational system (**RPTCS**). Due to scarcity and expensiveness of human resource, first, employing minimal manual intervention, we present a novel persona aware topic guiding conversational dataset (**PTCD**) created employing a novel automatic conversation creation mechanism. Majority of the topic shift guiding conversational systems leverages only the concept space knowledge to represent the potential conversation flow (Wu et al., 2019; Zhou et al., 2020; Zhang et al., 2020; Wang et al., 2021; Qiu et al., 2022). These approaches are predicated on a restricted defined logical premise: individuals would be interested in talking about any random concept. This presumption can be too straightforward to mimic topic flows in real human conversations. In this work, we take a significant step toward developing a proactive conversational agent that is more attuned to a user's personality with a clear conversation aim. We aim at training a system that is able to decide on topic shifts and generate responses that reflect these logical topic shifts, while also considering the user persona. Figure 1 shows an example of this task. Since bringing an open-domain conversation to a task-oriented domain is one of the key use cases for this system, we chose the concepts popular in the latter domain (Eg. restaurant, travel, clothing, smartphone, etc.).

Using **PTCD**, we first train a maximum likelihood estimation (MLE) loss-based conversational employing a language model (LM) GPT-2 small (Radford et al., 2019). This trained model is then fine-tuned in a Reinforcement Learning (RL) framework using novel rewards designed to assure persona, concept, and context consistency with non-repetitiveness in the generated responses. The key contributions of this work are *four-fold* **(i).** Proposal of a new task to build a persona-aware conversation system for targeted topic transitions and creation of a novel datatset **PTCD** to tackle the task in-hand; **(ii).** A novel semi-automatic persona aware topic guiding corpus creation method using pre-trained models (can be adapted to the other similar tasks in the broad area of dialogue systems), **(iii).** Designing a novel reward function to built the proposed system **RPTCS** in an RL framework. **(iv).** Performed extensive automatic and human evaluation by designing two novel evaluation metrics to evaluate topic and context consistency to demonstrate strength of the proposed system.

2 Related Work

To have a human-like conversation and avoid off-topic response generation, several methods have been explored (Ghazvininejad et al., 2018; Harrison et al., 2020). The research community has employed ConceptNet (Speer et al., 2017) to mimick concept transitions in human conversations, (Zhou et al., 2018), such as: Zhang et al. (2020) used concept relations with 2-hop nodes, to account more thoroughly human concept shifts. However, none of the works have taken into account the persona of the user to guide the topic shift in the conversation which may act as a crucial component to have effective communication.

Some benchmark conversation datasets has been proposed to assess the conversation focusing on different personal attributes such as: (He et al., 2017) predicts the next topic based on social and cultural situation, ETHICS dataset constitutes the conversation based on the concept of morality (Hendrycks et al., 2020). Hsu et al. (2018) presents emotion labelled EMOTIONLINES dataset, Yu et al. (2020) proposes a social relation inference based DIALOGRE dialogue dataset. Zhang et al. (2018) proposed PERSONA-CHAT dataset to make chit-chat dialogues more engaging by conditioning them on user's profile information. Most of these datasets are collected through crowdsource workers. To obtain such a large human resource is expensive, time-consuming, and can be infeasible. We investigate an automatic data creation approach requiring minimal manual intervention as an alternative to this.

Recently, Wang et al. (2021) proposed a multi-turn topic-driven NaturalConv dataset ensuring a smooth topic shift in conversations. Our work here is different from the existing topic-shift guiding conversational systems in three aspects. First, we followed an automatic dialogue data curation process. Second, the topic shift in the conversations is guided using ConceptNet as well as the persona of the user. This ensures both goals of an effective communicator *viz.* completing the task and maintaining the face of the user. Third, we built a persona aware topic guiding conversational system in an RL framework using novel efficient and effective reward function. To the best of our knowledge, our proposed setup is novel and has not been tried before.

3 Dataset Creation

To tackle the persona-aware concept shift to a target concept, we create and propose a novel dataset. We come up with a novel semi-automatic data creation technique involving prompting a GPT-J model and human intervention for quality control. The entire dataset creation consists of the following steps:

Obtaining Seed Data: To start the few-shot dialogue generation, we required a seed utterance from a user with some assigned persona. To build In PERSONA-CHAT-grounded topic-shifting conversations“the first utterance of a conversation (focused on a persona-profile) in the PERSONA-CHAT (Zhang et al., 2018) is selected. In PERSONA-CHA", persona profiles are defined as “profiles that are natural and descriptive, and contain typical topics of human interest that the speaker can bring up in conversation". The concepts in the seed utterance is obtained by extracting words with *‘nouns’*, *‘adjectives’*, and *‘verbs’* Part-of-Speech (PoS) tags. We call these first utterance concepts as the source concept. The objective here is to guide the conversation away from the source concept and toward a target concept. Concepts like *‘travel’*, *‘restaurant’*, *‘shopping’*, *‘electronics’*, etc. are chosen as the system’s target concepts.

Concept Path Creation and Selection: To have smooth and logical transition and avoid abrupt source-to-target concept jump, we make use of Concept-Net (Speer et al., 2017). First, employing Dijkstra’s algorithm, the shortest distance between all the source-concepts in the seed dialogue and all the target-concepts is calculated. This results in multiple paths between each source and target concepts. From these multiple paths only one path has to be selected for the desired concept transition in dialogues, i.e., based on the ongoing topic and persona, the conversation must be able to switch to the most suitable target and path. Although it would be ideal for the conversation to veer toward a subject (concept) relevant to the user persona, the context of the conversation may not permit it. Hence, a balance is aimed between context and persona relevance. We extend the use of RoBERTa (Liu et al., 2019) for contextual concept selection as proposed by Yasunaga et al. (2021) to concept-path selection. Let $P = \{p_1, p_2, ..., p_N\}$ be the persona profiles of a user where $p_i = \{w_1, w_2, ..., w_m\}$ is a persona sequence. Each concept-path t to the target is denoted by $C_t = \{c_1, c_2, ..., c_t\}$, where c_j is a concept in the path. For each pair of persona sequence and concept-path, persona relevance probability is computed using the RoBERTa head (LM_{head}). The probabilities are then averaged to obtain $P_{persona}$ as shown in Equation 1 and 2.

$$P_{seqp} = LM_{head}(LM_{enc}([p_i : C_k])) \quad (1)$$

$$P_{persona} = Avg(P_{seqp}[c_{1k}, c_{2k}, ..., c_{tk}]) \quad (2)$$

Here, [:] is the concatenation operation. Using the same RoBERTa LM_{head}, the path probability P_{conv} with respect to the conversational context for a conversation $D = \{U_1, U_2, ..., U_n\}$ is computed (U_i are utterances in the dialogue). To obtain P_{conv}, P_i in encoder LM_{enc} are replaced with D_p (Equation 3 and averaging the probabilities of the concepts (Equation 2).

$$P_{seqc} = LM_{head}(LM_{enc}([D_p : C_k])) \quad (3)$$

$$P_{conv} = Avg(P_{seqc}[c_{1k}, c_{2k}, ..., c_{tk}]) \quad (4)$$

From the obtained persona $P_{persona}$ and contextual P_{conv} concept-path probabilities, the path with the highest probability is selected.

Utterance Generation: After selecting seed utterances, new utterances are generated utilizing GPT-J (Wang and Komatsuzaki, 2021) (Brown et al., 2020). Taking advantage of few-shot prompting capability of the GPT-J model, few manually written sample conversations following the appropriate persona and context relevant topic transitions are used. [3]. This prompt is followed by the current seed dialogue and selected path and given as input to GPT-J, which generates the next utterance of the dialogue. To lead the conversation, all concept transitions are initiated by the agent. Top_k sampling (Fan et al., 2019; Radford et al., 2019) is used during utterance generation and 10 candidate responses for each input utterance is generated.

Utterance Selection: Best response out of the 10 candidates is selected by taking into account persona-entailment, current concept relevance, and conversation context relevance. To assess the level of persona-entailment in the produced outputs, a Natural Language Inference (NLI) model using the Dialog NLI dataset is trained (Welleck et al.,

---

[3] Example of the designed prompt is given in Section A.2 of the appendix

	Total	Train	Test	Valid
#Dialogues	2,586	1,945	406	236
#Utternaces	13,746	10,310	2,436	1,000
#Unique Concepts	1,843	1,505	617	314
#Unique Paths	1,738	1,372	316	184
Avg Path Length	3.55	3.54	3.57	3.57

Table 1: Statistics of the dataset created

2019). by fine-tuning a pre-trained BERT (Devlin et al., 2018) model[4]. The probability score of entailment $P_{ent}^{p_i}$ of a given utterance U_k with respect to a persona p_i are obtained by final *softmax* layer. Averaging the $P_{ent}^{p_i}$ gives the final entailment score $P_{ent}^{U_k}$ for a candidate utterance U_k. This entailment score is calculated for both the user and agent utterances to counteract the contradiction to a user's preferences.

To make the generated response pertinent to the conversation's context, contextual probability score of the candidate utterance U_k is computed. To do so, last utterance in the conversation U_{k-1} is taken in a sequence $S_{ctx} = U_{k-1}$ *[SEP]* U_k, which in turn is given as input to BERT to obtain the U_k's probability score $P_{ctx}^{U_k}$ with the next sentence.

To ensure the appropriateness of the created utterance with the current concept, a concept-relevance score is calculated.Again the BERT model is used to encode the utterance U_k and current concept c_j to obtain the embedding representation U_k^{emb}, and c_j^{emb} respectively. Then, the concept-relevance score $P_{cpt}^{U_k}$ is computed by taking the cosine similarity between U_K^{emb} and c_j^{emb}. Equation 5 is used to calculate each candidate's final score for each speech.

$$P_{final}^{U_k} = \alpha P_{ctx}^{U_k} + \beta P_{ent}^{U_k} + \gamma P_{cpt}^{U_k} \tag{5}$$

We set the values of the constants α, β, and γ as 0.38, 0.30, and 0.32 through several quality evaluations (Detailed in Section A.1.2). The candidate with the highest P_{final} score is chosen as the next utterance.

Manual Filtering of Dialogues: Once the complete conversational dataset is obtained, by iteratively employing the above steps. These dialogues are quality-checked by human evaluators. Each utterance is scored using two parameters, *viz.* Humanness and Concept Consistency. Each utterance is evaluated with a score of 0, 1, or 2, w.r.t these two parameters where 0 denotes the lowest and 2 denotes the highest. Three human experts with post-graduate qualifications were asked to rate all the generated utterances. These professionals are regular employees in our research group and have 2 years of expertise in related fields. Following the ratings, dialogues with utterances having a score of 0 by any expert for 'humanness' or 'concept consistency' are eliminated.

4 Persona-aware Topic-guiding Conversational System

We build our proposed system **RPTCS** in two phases. In first phase, an MLE-loss-based conversational system (MLCS) is trained to learn the user and agent's utterances distribution and obtain natural language interaction. In the second phase, this MLCS is fine-tuned in an RL framework employing proximal policy optimization (PPO) (Schulman et al., 2017)ss method to generate persona-aware topic guiding utterances.

4.1 Phase 1

A multi-turn conversation can be represented as $C = \{a_0, u_0, ..., a_{T-1}, u_{T-1}\}$, where, a and u denotes the agent's and user's utterances. Each conversation is further attributed with a persona $p = \{p_1, p_2, ..., p_m\}$ having a set of m persona statements of user, a topic-path $tp = \{tp_1 \rightarrow tp_2 \rightarrow .. \rightarrow tp_k\}$, with k topics, had to be followed in conversation, and with each of the agent's utterance, a $< topic >$ (any one tp_i from tp) to which conversation has to be guided. Following (Wu et al., 2021), the probability distributions over the conversation C's utterances concatenated with user's persona p, topic-path tp, and agent's $< topic >$ to be guided are decomposed into two LMs *viz.* one for user and other for agent denoted as ρ_u and ρ_a, respectively. Given the conversation context, the LMs ρ_u and ρ_a predict the next token in an agent's generated response $r = \{r_1, r_2, ..., r_t\}$ with t tokens. The joint probability for an utterance u_i or a_i can be formulated as:

$$\rho_u(u_i|u_{<i}, a_{<i}) = \prod_{j=1}^{t_{u_i}} \rho(r_j|r_{<j}, p, tp, u_{<i}, a_{<i}) \tag{6}$$

$$\rho_a(a_i|u_{<=i}, a_{<i}) = \prod_{j=1}^{t_{a_i}} P(r_j|r_{<j}, tp_{<i}, u_{<=i}, a_{<i}) \tag{7}$$

---

[4] Test set accuracy of NLI model is obtained as 88.43%.

User Persona	(i). i enjoy killing sea creatures. (ii). i'm a fan of animals. (iii).i'm practically a chef ! (iv). my father was in the car industry. (v). i enjoy life.	
Seed User Utterance	hey ! i'm a happy camper this evening . just finished making dinner .	
Selected Concept Path	['camper', 'backpack', 'food', 'restaurant']	
Speaker	***Generated Utterance***	***Concept***
Agent	i am a fan of backpacking. i know a lot of people who are happy in their camp.	backpack
User	i would love to go backpacking but i dont have enough money to afford one.	backpack
Agent	i have been known to carry around my backpack full of food, i just have a big appetite.	food
User	i just love food.	food
Agent	you must know your restaurants then.	restaurant

Table 2: Sample dialogues from the corpus generated using our method.

Finally, the conversational system $\rho_\theta(C)$ defined on conversation C is trained by maximizing the likelihood estimation.

$$\rho_\theta(C) = \prod_{T=0}^{T-1} \rho_u(u_i|u_{<i}, a_{<i})\rho_a(a_i|u_{<=i}, a_{<i}) \tag{8}$$

4.2 Phase 2

To generate persona-aware and topic-consistent responses $\rho_\theta(C)$ (MLCS) is fine-tuned in an RL framework. For a given context, $\rho_\theta(C)$ generates *n* possible candidates. These candidate responses are then quality-checked in terms of persona awareness, topic consistency, context consistency, and repetition using respective rewards.

4.2.1 Rewards

To achieve utterance-persona and utterance-topic consistency in generated responses, we design two novel task-specific rewards *viz.* Utterance-Persona consistency (R_1) and Utterance-Topic consistency (R_2). Similarly, to ensure conversation properties like contextual correctness and non-repetitiveness, two generic rewards are designed *viz.* Context consistency (R_3) and Non-Repetition (R_4). Lastly, a compound reward function R, considering both task-specific and generic rewards is computed, which outputs the end reward value for the generated candidate response.

Utterance-Persona consistency Reward: The essence of engaging response generation also relies on persona of the user, hence a conversational system should be able to maintain the utterance-persona consistency in the generated responses. This problem of utterance consistency with persona statements of user can be characterized as a natural language inference (NLI) problem, having three labels *viz.* entailment, neutral and contradiction. Entailed responses are consistent with persona whereas contradictory responses are inconsistent, hence, should be penalized. To build our NLI model, BERT (Devlin et al., 2018) is employed as a classifier, which takes input persona p and generated candidate response r with a $< SEP >$ tag, and outputs one of three classes through a hot vector $[c_e, c_n, c_c]$ (entailment c_e, neutral c_n or contradiction c_c). To achieve the respective class probabilities, a softmax is applied on this hot-vector, i.e. $[prob_{c_e}, prob_{c_n}, prob_{c_c}] = softmax([c_e, c_n, c_c])$. The predicted entailed probability is used to design the reward R_1 which can be written as:

$$R_1 = prob_{c_e}(r_T, p) \tag{9}$$

where r_T represents the generated response at turn T. It can be inferred that R_1 will reward more, if entailment probability is high.

Utterance Topic Consistency Reward: A topic guiding conversational system should not deviate from the topic in-hand. It should be forced to generate topic consistent utterances by rewarding the ones which employ the required topic. To formulate the utterance topic consistency, we considered *cosine* similarity between topic and utterance which is calculated using Sentence-BERT (Reimers and Gurevych, 2019). R_2 can be written as:

$$R_2 = \cos(r_T, tp_T) \tag{10}$$

where tp_T represents the topic at turn T. Higher cosine similarity values will lead to higher rewards for utterance topic consistency.

Context Consistency Reward: A conversational system is required to generate context consistent responses. Therefore, to assess context consistency, we devise a reward by calculating *cosine* similarity (using Sentence-BERT (Reimers and Gurevych, 2019)) between generated response and agent's and user's utterance at turn T. R_3 can be formulated as:

$$R_3 = \frac{1}{2} \times (\cos(r_T, a_T) + \cos(r_T, u_T)) \tag{11}$$

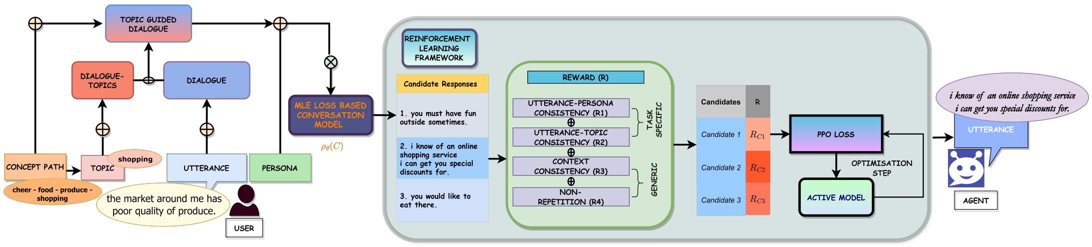

Figure 2: Architectural overview of the proposed **RPTCS**. It is first initialized with trained MLE-loss based model $\rho_\theta(C)$, then is fine-tuned employing PPO-loss utilizing novel reward R to build a persona aware topic guiding conversational system (**RPTCS**)

.

Non-Repetition Reward: Due to repetitive same response generation in a conversation, user's may not show engagement in the conversation. Hence, the generated responses should be diverse with each turn of the conversation. To ensure this, we design a Non-repetition reward R_4 by computing Jaccard distance (Jaccard, 1912; Tanimoto, 1958) between generated responses r_T and r_{T-1} at turns T and $T-1$, respectively. R_4 can be given as:

$$R_4 = 1 - \left(\frac{gr_{T-1} \cap gr_T}{gr_{T-1} \cup gr_T}\right) \tag{12}$$

Reward Function: Lastly, to train the whole system, reward function R is formulated using weighted sum of all these four rewards. To approximate a better function, the sum of all weights has been taken equal to 1.

$$R = \delta_1 R_1 + \delta_2 R_2 + \delta_3 R_3 + \delta_4 R_4 \tag{13}$$

where $\delta_1 + \delta_2 + \delta_3 + \delta_4 = 1$. The obtained value of R assesses the quality of generated response, which is further used to optimize the PPO loss, such that model can learn to generate persona, topic, and context-consistent responses.

4.2.2 Policy

A probability mapping function $\mathcal{P}_\theta$ representing the probability of generating an utterance r consisting of L tokens gives the policy.

$$\mathcal{P}_\theta(r_{1:L}|x) = \prod_{l=0}^{L} \mathcal{P}_\theta(r_l|y_{<l}, x) \tag{14}$$

Proximal Policy Optimisation: Policy updates at each each step are done using PPO method to ensure low variance. It seeks improvement on certain parameters to update the existing policy such that it is not too different from the old policy. First, expected reward is maximized using gradient ascent on loss function $J(\theta)$,

$$\nabla_\theta J(\theta) = Ep_{r\sim\mathcal{P}_\theta}[\nabla_\theta \log \mathcal{P}_\theta(r)\hat{A}_r] \tag{15}$$

Second, large deviations from old policy are restricted by replacing the log term with an importance sampling and clipping is performed to prevent catastrophic forgetting. It relies on specialized clipping without any KL-divergence term (Kullback and Leibler, 1951) or any constraint in the objective function.

$$\begin{aligned} L^{\text{CLIP}}(\theta) = \hat{E}[\min(pr_r(\theta)\hat{A}_r, \text{clip}(pr_y(\theta), \\ 1-\varepsilon, 1+\varepsilon)\hat{A}_r)] \end{aligned}$$

Here, $pr_r(\theta) = \mathcal{P}_\theta^{new}/\mathcal{P}_\theta^{old}$ denotes the ratio of probabilities of the generated response between the new and old policies. ε is the clipping range and $\hat{A}_y$ is the estimated advantage which is the normalized rewards in our case. Lastly, parameters are updated using the following steps:

$$\theta_{k+1} = \underset{\theta}{\text{argmax}} \underset{s,a\sim\mathcal{P}_{\theta_k}}{E}[L^{\text{CLIP}}] \tag{16}$$

5 Experiments

5.1 Implementation Details

MLE loss based conversational system (MLCS) is trained by employing two pre-trained GPT-2 small (Radford et al., 2019) models, one for user and other for agent. To fine-tune trained MLCS in RL-setting, $n = 3$ is selected as per better loss, after experimenting with different values of candidate responses i.e. $n = 2, 3, 4, 5, 10$. The candidate responses are decoded using nucleus sampling (Holtzman et al., 2019) with temperature $T = 0.8$ and probability $p = 0.9$. To train the RPTCS $seed\_value = 10$, $human\_reward = 10$, $max\_candidate\_length = 50$ is adopted with $optimizer = AdamW$ (Loshchilov and Hutter,

2017) and learning rate $\alpha = 2e - 05$, $\varepsilon = 0.2$ and $epochs = 17$. The reward weight combination of $0.3, 0.3, 0.2, 0.2$ are chosen as the final weights for δ_1, δ_2, δ_3, and δ_4, respectively (detailed weight optimization is given in Table 5 of appendix). Due to space restrictions, detailed implementation details of the NLI model to entail the utterance persona consistency, and MLCM are given in Section A.1.3 of the appendix.

5.2 Evaluation Metrics

Both automatic and human evaluations are performed to assess the performance of the proposed system **RPTCS**. To evaluate all three tasks of utterance-persona, utterance-topic and context consistency, three metrics *viz.* **U-PCon**, **U-TCon**, and **CxCon** respectively, are adopted. **U-PCon** computation can be formulated as below:

$$U - PCon = \frac{\sum_{j=1}^{n} class_i(NLI)}{n} \qquad (17)$$

where, $class(NLI)$ gives one of three classes 1 (entailment), 0 (neutral), -1 (contradiction) and n is the number of generated responses. **U-TCon** is calculated as *cosine-similarity* between the generated response r_T and topic tp_T, i.e. $\cos(r_T, tp_T)$. **CxCon** calculates the average METEOR (Banerjee and Lavie, 2005) score for n number of generated responses with respect to the ground truth response a_T at turn T. It can be given as:

$$CxCon = \frac{METEOR(r_T, a_T)}{n} \qquad (18)$$

Further, to evaluate the quality of the generated responses, Perplexity (**PPL**) and response length (**R-LEN**) are calculated.

Human evaluation are performed by three evaluators (regular employees in our research group) with postgraduate experience and having proficiency in similar tasks [5]. Each evaluator is asked to interact with the proposed system 20 times and evaluate the conversations in terms of task-specific and generic metrics. Former includes **PerAw**, **TopGu** - to assess the persona awareness and topic guidance respectively in generated conversations. Latter includes **Fluen**, **Const**, and **N-Rep** - to check fluency, consistency, and non-repetitiveness of generated responses in interacted conversations. All metrics are evaluated on an integer scale of 1-5 [6].

6 Results and Analysis

RPTCS is compared with two baselines: **(1.)** ARDM (Wu et al., 2021): A MLE loss based self-play conversation model, which trains two GPT-2 medium models (one for user and one for agent) alternatively. Here, as we are assessing only agent's performance, hence we train only one GPT-2 small model. **(2.)** RPTCS-R: **RPTCS** with $R = 0$. Further, to check the effects of each of the three aspects *viz.* concept-path, topic and persona, three respective variants of ARDM *viz.* ARDM+CP (ARDM considering concept-path), ARDM+CP+T (ARDM considering concept-path and topic), and ARDM+CP+T+P (ARDM considering concept-path, topic and persons) are also trained to compare. Lastly, to assess the importance of both task-specific (Ts) and generic (Ge) rewards, **RPTCS** is also compared with RPTCS-Ts ($R = \delta_3 R_3 + \delta_4 R_4$) and RPTCS-Ge ($R = \delta_1 R_1 + \delta_2 R_2$).

Automatic Evaluation: It can be noticed in Table 3 that the proposed **RPTCS** performs better than all four baselines *viz.* ARDM, RPTCS-R, RPTCS-Ts and RPTCS-Ge in terms of all the four metrics *viz.* **U-PCon**, **U-TCon**, **PPL** and **R-LEN**. For task-specific metrics **U-PCon**, and **U-TCon**, **RPTCS** achieves better scores of *95.8%*, and 0.414, respectively, with a significant difference of <18.9, 0.124>, <7.7, 0.095>, <8.4, 0.1>, <6.7, 0.042>, and <3.5, 0.047> than the baselines ARDM, ARDM+CP+T+P, RPTCS-R, RPTCS-Ts and RPTCS-Ge, respectively. It can also be inferred that the difference of **U-TPer**, **U-TCon**, **CxCon** scores decreased in order ARDM>RPTCS-R>RPTCS-Ge>RPTCS-Ts. This shows the importance of task-specific rewards in our proposed system **RPTCS** and it can be argued that utterance-persona and utterance-topic consistency rewards do force the system to adapt towards generating persona and topic-consistent responses.

It can also be observed in the Table 3 that **RPTCS** obtains better **PPL** = 6.14 score than that of ARDM, ARDM+CP+T+P, RPTCS-R, RPTCS-Ts and RPTCS-Ge with a difference of 2.53, 1.51, 1.10, 0.89, and 0.84, respectively. This may be due to the Context consistency reward which drives the model to generate responses consistent with the conversation context, which, in turn, leads to the generation of much more natural and fluent responses. Further, obtained a score of **R-LEN** = 15.23 is also better than that of ARDM, ARDM+CP+T+P, RPTCS-R, RPTCS-

---

[5] Human evaluators were paid as per our university norms.

[6] The scale 1-5 denotes low to high intensity such as PerAw = 1 denotes highly persona awareness and PerAw = 5 denotes no persona awareness.

Model	U-PCon	U-TCon	CxCon	PPL	R-LEN
ARDM (Wu et al., 2021)	76.9%	0.290	0.134	8.67	13.11
ARDM+CP	77.2%	0.303	0.145	8.34	13.21
ARDM+CP+T	77.4%	0.314	0.147	8.12	13.27
ARDM+CP+T+P	88.1%	0.319	0.160	7.65	13.86
RPTCS-R	87.4%	0.314	0.152	7.24	13.42
RPTCS-Ts	89.1%	0.372	0.161	7.03	14.27
RPTCS-Ge	92.3%	0.367	0.166	6.98	14.69
RPTCS	**95.8%**	**0.414**	**0.178**	**6.14**	**15.23**

Table 3: Results of automatic evaluation

Model	PerAw	TopGu	Fluen	Const	N-Rep
ARDM	2.69	2.13	3.11	3.83	2.94
ARDM+CP+T+P	3.41	2.64	3.57	4.02	3.21
RPTCS-R	3.31	2.66	3.65	3.98	3.26
RPTCS-Ts	3.40	2.70	3.71	4.12	3.42
RPTCS-Ge	3.62	2.81	3.84	4.04	3.37
RPTCS	**3.82**	**2.96**	**4.01**	**4.14**	**3.55**

Table 4: Results of human evaluation

Ts, and RPTCS-Ge with a difference of 2.12, 1.37, 1.81, 0.99, and 0.54, respectively. This indicates that the **RPTCS** is able to generate longer responses, hence, showcasing more engagingness with the user. It can be due to the incorporation of all four rewards where R_1, R_2, and R_3 play the crucial role of persona, topic, and context consistency, and R_4 maintain the non-repetitiveness, hence, driving the agent to build the rapport with a user as well as be on the goal topic by generating diverse and interactive responses. Engagingness rewards - forcing the model to generate more interactive and engaging responses. Lastly, it can also be seen in Table 3 that **PPL ter** and **R-LEN** scores of **RPTCS** decreased in order ARDM>RPTCS-R>RPTCS-Ge>RPTCS-Ts>**RPTCS**, hence, strengthening our hypothesis for the requirement of both task-specific and generic rewards to generate persona aware topic consistent responses.

Human Evaluation: Table 4 shows the human evaluation results for all five models *viz.* ARDM, ARDM+CP+T+P, RPTCS-R, RPTCS-Ts, RPTCS-Ge and ARDM, RPTCS-R, RPTCS-Ts, and **RPTCS**. It can be noted that **RPTCS** yields better scores of **PerAw**, **TopGu**, **Fluen**, **Const** and **N-Rep** as compared to the the baselines, ARDM, RPTCS-R, RPTCS-Ts and RPTCS-Ge. Scores of **Fluen**: 4.01, **Cons**: 4.14, and **N-Rep**:3.55 implies that all the four rewards R_1, R_2, R_3, and R_4 play a critical role in obtaining most fluent, consistent, and non-repetitive responses as compared to other four models. Further, in terms of **PerAw**, and **TopGu**, **RPTCS** attains well scores of 3.82, and 2.96, respectively, showcasing the importance of rewards R_1, and R_2. Therefore, it can be inferred that employing utterance-persona and utterance-topic consistency rewards helps the proposed model to generate persona-aware responses and is able to guide the conversation keeping the topic intact.

7 Conclusion

For an open domain conversation to be successful, proper concept transition befitting the context is essential. Further, persona awareness of the user may lead to user adaptive response generation, hence, resulting in more engaging and interactive conversations. Therefore, a conversational agent should be able to transition the concept efficiently as well as build a rapport with the user by understanding his/her persona. To encompass both of these aspects, we proposed here a Reinforced Persona-aware Topic-guiding Conversational System (**RPTCS**). First, we create a persona-aware topic transition dataset (PTCD) by leveraging the few-shot prompt feature of the language model. Second, employing GPT-2 small, we train an MLE loss-based conversational model (MLCM) on PTCD. Lastly, using a novel designed reward function to ensure aspects of persona, topic, and context consistency with non-repetitiveness, we fine-tune MLCM adopting PPO loss optimizer in an RL framework. Automatic and human evaluation results strengthen the design and use of rewards and concludes that our proposed model **RPTCS** achieves state-of-the-art performance compared to the strong baselines. Our results also concludes that **RPTCS** is able to retain and facilitate persona awareness, naturalness, and consistency at par in an ongoing dialogue.

In the future, we would like to look into personality traits such as age, gender, etc. to model a persona-aware conversational system.

8 Limitations

RPTCS has also some limitations. First, to create the data, GPT-J is used which requires a large GPU memory size (here, 40 GB). Further, empirical analysis for each of the possible combinations of different rewards weights may lead to model training and validation time to months. Hence, some heuristics should be used to choose the set of combinations of rewards and reward weights (such as here, we restricted the reward weight sum as 1).

When interacting with the system, if users continuously state short and direct responses such as *'Yes'*, *'I don't know'*, *'No'*, *'I can'*, *'Okay'*, then the system first tries to respond by inquiring about topic like *'restaurant'*, *'job'*, *'shopping'* or *'travel'* but after two or three turns starts deviating and generating out of the context or hallucinated responses. It is also seen that sometimes model starts attending persona statements of the user frequently and generate most of the time only persona awared responses which tend to be out of context. Hence, the model should be forced to generate only relevant responses and persona attention should be controlled. This opens up the door for future studies to build a controlled persona aware topic guiding conversational system.

9 Ethical considerations

We use a freely available dataset under a Creative Commons license to create our new dataset. The dataset has been used only for academic purposes, and in complete compliance with the license. The dataset created in this work will be made available only after filling and signing an agreement declaring that the data will be used only for research purposes. The annotation for manual evaluations was done by human experts, who are regular employees of our research group and are paid in accordance with the institute's policy. A Appendix

A.1 Implementation Details

A.1.1 Data Creation Models Details

All the models were implemented using PyTorch (Paszke et al., 2017). The BERT model trained on the Persona-NLI dataset was implemented using the transformers library (Wolf et al., 2019). The BERT model was initialized with the weights of 'bert-base-uncased'. The model was trained with an initial learning rate of 1e-4 with a linear schedule and a warmup (Vaswani et al., 2017), using the Adam Optimizer (Kingma and Ba, 2015). Mini-batches of size 8 were used during training.

A.1.2 Values for utterance selection constants:

The values of α, β, and γ were determined empirically. Initially, all the values were set to 0.33. Then to ensure a balance between concept-consistency, persona-entailment, and context-relevance, these values are varied only in the range of 0.30 to 0.40. It was found that a higher value of α (i.e. of context-relevance) resulted in more human-like utterances by avoiding abrupt transitions. The value of γ lower than 0.32 resulted in generating a higher number of concept-agnostic utterances. In this manner, the final values of α=0.38, β=0.30, and γ=0.32 are obtained.

A.1.3 Maximum Likelihood Estimation loss based Conversational Model

To train MLE loss based dialogue model, two pre-trained GPT-2-medium models (Radford et al., 2019) with 345M parameters are used to model the persuadee's and persuader's utterances. Here, pre-trained GPT-2-medium model consists of 24-layers, 1024 hidden units and 16 heads. We use Byte-Pair Encoding (Shibata et al., 1999) to tokenize the words. The dialogue model is trained with a learning rate = 3e-5, using AdamW optimizer (Kingma and Ba, 2015) with 100 warm-up steps and dropout rate of 0.1.

A.1.4 Specifications of Computational Resource

To train the transformer based NLI model, MLE-loss based conversational model and proposed **RPTCS**, following configurations are used:

- **GPU:** A100-PCIE-40GB.
- **CUDA Support:** CUDA 11.x (or later.
- **Memory clock:** 1215 MHz.
- **Total board power:** 250 W.
- **GPU clocks:** Base: 765 MHz, Boost: 1410 MHz.
- **Memory Size:** 40 GB.
- **Memory Type:** HBM2.
- **Bus Width:** 5120 bits.

A.1.5 Model Run time Specifications

RPTCS takes approximately 3 mins/epoch to train the model, hence for 30 epochs, it took 90 minutes to train the model. Further, if we try to perform validation along with training, considering three candidate responses per utterance per dialogue, **RPTCS** takes approximately 30 mins/epoch, hence, total time it took for 900 minutes (15 hours) to train and validate the model. Finally, to evaluate the model, the testing of proposed system takes approximately 5 minutes for 200 utterances.

REWARD WEIGHT OPTIMIZATION				
δ_1	δ_2	δ_3	δ_4	**PPL**
0.4	0.4	0.1	0.1	6.53
0.1	0.1	0.4	0.4	6.82
0.2	0.2	0.3	0.3	6.64
0.2	0.3	0.3	0.2	6.44
0.3	0.2	0.3	0.2	6.30
0.3	**0.3**	**0.2**	**0.2**	**6.14**

Table 5: Weight Optimisation using different values of δ.

A.2 Data Creation

In total 22 concepts were used as targets for obtaining the path. The complete list of the concepts is as follows: (i). travel, (ii). journey, (iii). voyage, (iv). outing, (v). restaurant, (vi). hotel, (vii). inn, (viii). diner, (ix). cafe, (x). canteen, (xi). bar, (xiii). shopping, (xiv). mall, (xv). market, (xvi). grocery, (xvii). electronics, (xviii). mobile, (xix). laptop, (xx). computer, (xxi). smartphone, and (xxii). camera.

We use six-shot prompts to generate the synthetic data. We provide a sample of the one-shot version of the prompt below. At the end of the sequence, we also append the persona, path, and utterances for which the next utterance needs to be generated. The six-shot prompt follows the same pattern with six examples in the input sequence. We restrict our prompt to six shots since the maximum sequence length allowed in GPT-J is 2,048:

Abstract

Warning: *This paper includes messages that may contain instances of vulgarity, degrading terms, or hate speech, which may be offensive or upsetting to some readers.*

Hate speech has unfortunately become a significant phenomenon on social media platforms, and it can cover various topics (*misogyny*, *sexism*, *racism*, *xenophobia*, etc.) and targets (e.g., *black people*, *women*). Various hate speech detection datasets have been proposed, some annotated for specific topics, and others for hateful speech in general. In either case, they often employ different annotation guidelines, which can lead to inconsistencies, even in datasets focusing on the same topics. This can cause issues in models trying to generalize across more data and more topics in order to improve detection accuracy. In this paper, we propose, for the first time, a topic-oriented approach to study generalization across popular hate speech datasets. We first perform a comparative analysis of the performances of Transformer-based models in capturing *topic-generic* and *topic-specific* knowledge when trained on different datasets. We then propose a novel, simple yet effective approach to study more precisely which topics are best captured in implicit manifestations of hate, showing that selecting combinations of datasets with better out-of-domain topical coverage improves the reliability of automatic hate speech detection.

1 Introduction

On social media and other online communication platforms, hate speech (HS hereafter) is found in many forms, from textual harassment to threats, targeting an individual or group (e.g., black people, women), based on some characteristics, such as race, color, ethnicity, gender, sexual orientation, nationality, religion, etc, which we refer to as *topics*. While the broad nature of these topics of HS is generally understood (Erjavec and Kovačič, 2012), determining whether a social media post is a manifestation of HS (and if so, to which topic(s) it belongs to) is not a trivial task for humans and automated machine-learning systems. Indeed, the latter often require large quantities of annotated data, which in the case of HS, is made difficult due to (1) the absence of a comprehensive definition of these topics; but also, (2) the potential internal biases and subjectivity present in annotators and/or annotation guidelines employed to construct annotated datasets (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018; Vidgen et al., 2019; Fortuna et al., 2020).

To palliate these issues, cross-dataset evaluation has become an active line of research aiming at studying the generalization capabilities of HS detection systems to unseen data during training (Talat et al., 2018; Ludwig et al., 2022; Toraman et al., 2022). As data collection and annotation is an expensive and time-consuming process, current approaches use *mixtures* of existing HS detection datasets to study generalization across different social media platforms (Swamy et al., 2019; Salminen et al., 2020; Nejadgholi and Kiritchenko, 2020) or across different manifestations of HS, often relying on one-to-many (train on one dataset/mixture, test on others) experimental settings (Fortuna et al., 2021; Talat et al., 2018; Chiril et al., 2022; Talat et al., 2018; Karan and Šnajder, 2018). In most of these, a unification scheme is proposed to adapt the original datasets' potentially fine-grained annotations to a set of binary labels, which can often fail to take into account the heterogeneity inherently present across different encodings of HS (Vidgen et al., 2019).

In addition, some datasets intentionally focus only on some specific kinds of manifestations of HS covering for example gender (e.g., misogyny, sexism), ethnicity, religion or race (e.g., xenophobia, anti-immigrants/refugees HS), i.e., they are *topic-specific*, whereas others attempt to cast a

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3495–3508
May 2-6, 2023 ©2023 Association for Computational Linguistics

wider net without specific sets of topics in mind, i.e., they are *topic-generic*. In either case, variations will always exist, either due to the reasons mentioned above, or due to shifts in the content found on social media through time. All of these may cause significant differences in the topics of HS that classification models might learn to recognize, which ultimately might make them less reliable, particularly in out-domain contexts (Yin and Zubiaga, 2021).

Acknowledging these issues and being aware of the noise that will invariably be introduced by mixing together different datasets, we propose for the first time to empirically study what modern Transformer architectures can effectively learn to generalize from existing datasets, in a unified setting, with a *focus on their topical nature*. More precisely: *Do models learn similarly from topic-generic datasets as from mixtures of topic-specific datasets? Does this acquired knowledge generalize to implicit expressions of HS, and if so, which finer-grained HS topics are learned by these models?* Our contributions are:

(1) An in-depth analysis of the generalizability of generic HS datasets, in which we show how using mixtures of those could be effective to attain better generalization across more topics.

(2) A similar analysis for *topic-specific* datasets, for which we show successful generalization in-domain, especially when using models fine-tuned on mixtures of such corpora.

(3) A novel, simple yet effective approach to study which finer-grained topics are best captured when dealing with *implicit* expressions of HS. We show that selecting mixtures of datasets with a better topical coverage can improve the reliability of models for out-of-domain applications.

2 Related Work

A number of previous works have studied generalizability of HS detection datasets and models, with different focuses: for example, Fortuna et al. (2020) and Fortuna et al. (2021) have analyzed the compatibility of many HS datasets (including some used in this study), both in terms of their properties (origin of data, annotated phenomena, class definitions, etc.) and empirically with intra- and inter-dataset generalization experiments. They conclude that model choice, intra-dataset performance, and the type of phenomenon being classified, are the most important factor that determine generalization. In particular, they conclude that phenomena like *toxicity*, *abuse*, or *offensiveness* that are often lexicalized are easier to generalize than hate speech, something which was also confirmed and discussed in other works (Nejadgholi and Kiritchenko, 2020; Yin and Zubiaga, 2021). In this paper, we are interested in the topic-oriented nature of HS specifically, and thus discard these former classes from our study.

Alternative solutions have recently been proposed to handle unseen topics by building new target-oriented datasets from scratch, such as the `HateXplain` dataset (Ludwig et al., 2022), with an additional labeling of the target topics of hate (Race, Religion, and Origin). While such linguistic resources are valuable for the research community, we believe existing larger datasets could be successfully exploited for generalization, as mixtures of datasets, as shown for example by Fortuna et al. (2018), Salminen et al. (2020), and Chiril et al. (2022), or, in a different fashion, by multitask HS detection systems or domain adaptation techniques (Talat et al., 2018; Kapil and Ekbal, 2020; Safi Samghabadi et al., 2020). In this paper, we continue this line of research by proposing for the first time, as far as we know, models able to generalize across topic generic vs. specific datasets as well as predict fine-grained manifestations in implicit hate messages. This is particularity challenging as these manifestations are more difficult to generalize due to their limited lexical features (ElSherief et al., 2021; Qian et al., 2019).

To this end, we rely on Transformer models like BERT that have been shown to be able to generalize better overall than previous architectures (Swamy et al., 2019). In particular, we experiment with both existing BERT-like models, some pre-adapted to the domain of HS, as well as T5 (Raffel et al., 2020), a text-to-text architecture that has never been used in a generalizability study.

3 Datasets

We experiment with six popular and freely available English tweets corpora (or English subsets thereof) from previous studies. We first present the datasets and how they were used in a common experimental setting. We then provide some discussions on the compatibility of these datasets, and how this may impact the generalization performances in our experiments.

3.1 Topic Generic vs. Topic Specific Datasets

The first two datasets are *topic-generic* while the other four are *topic-specific*, as follows.

`Davidson` (Davidson et al., 2017). It contains English tweets annotated into *hate speech*, *offensive*, and *neither*, with the intent of helping to distinguish between messages simply containing offensive terms, from those actually manifesting HS.

`Founta.` We make use of the dataset released by (Kallumadi et al., 2020) which is an updated version of the dataset initially proposed by Founta et al. (2018) and annotated for four types mutually exclusive of abusive behaviors: *abusive*, *hateful*, *spam* and *normal*.

`IberEval` (Fersini et al., 2018b) and **`Evalita`** (Fersini et al., 2018a) are part of the Automatic Misogyny Identification (AMI) shared task which aims at identifying tweets that convey hate or prejudice against women while categorizing different forms of misogynous behavior. We only use the main binary layer of annotation (i.e., presence vs. absence of misogyny).

`HatEval` (Basile et al., 2019) also known as SemEval-2019 Task 5, is a topic-specific HS detection dataset with tweets targeting *immigrants* and *women*, and annotated with three different binary layers of annotation: hateful/non-hateful, targeting a group/individual, aggressive/non-aggressive. Note that most of the tweets that target women in this dataset were derived from the `AMI corpora` (`IberEval` and `Evalita`).

`Waseem` (Talat and Hovy, 2016). It contains tweets targeting gender minorities, instances of racism, and tweets that were judged to be neither sexist nor racist.

We frame all the datasets used here as binary HS classification tasks, with the labels *"hateful"* (also referred to as the positive class) for instances containing some manifestation of hate speech, and *"normal"* for those containing none. Hence, for `Founta` and `Davidson` we filter out retweets/duplicates (keeping only the source tweets and their annotations) and only keep the *hateful/hate speech* and *normal* classes, and similarly, for the different topic-specific datasets, we unify the specific hate classes (*misogyny*, *sexism*, *racism*) with *hateful*, and the respective negative classes with *normal*.

To allow a more granular and topic-level analysis of results, we split all multi-targets topic-specific datasets into separate training, validation, and testing sets, according to the topics. Therefore, we split `HatEval` into its two topics subsets (i.e., $\texttt{HatEval}_{\texttt{women}}$ and $\texttt{HatEval}_{\texttt{immigrants}}$) and `Waseem` into $\texttt{Waseem}_{\texttt{sexism}}$ and $\texttt{Waseem}_{\texttt{racism}}$. However, in this last dataset, because only one negative class is provided, and corresponds to both the absence of sexism and racism, we choose to duplicate it and use it as the negative class for both subsets.

When not explicitly provided, we use a 75%-20%-5% train-test-validation split ratio. Table 1 further details how datasets have been mixed to train our models.

3.2 Issues with Dataset Compatibility

Because we also manipulate mixtures of these corpora, the effective hateful and non-hateful classes will contain instances annotated within different contexts and labelling guidelines. For example, the `Evalita` and `IberEval` datasets are annotated only for the presence of misogyny, and not other manifestations of HS. This makes their negative (i.e., non-misogyny) class inconsistent with, say, the negative class from a topic-generic dataset, which is not ideal.

Aside from re-annotating all these datasets under a unified and consistent annotation schema, the issues that may arise as part of these simplifications cannot be circumvented, and should thus be taken into account as a fixed parameter in our experiments. These issues have been broadly acknowledged in the relevant literature (Schmidt and Wiegand, 2017; Fortuna and Nunes, 2018; van Aken et al., 2018). As noted by Malmasi and Zampieri (2018) and Poletto et al. (2021), the distinctions between offense, abuse, and HS, are not always clear-cut, which can cause issues in generalization experiments, due to the former's in theory more lexical nature (Vidgen et al., 2019; Fortuna et al., 2020).

Furthermore, as noted by Madukwe et al. (2020), even when using relatively similar definitions for these phenomena, a number of other parameters may affect the compatibility, consistency, and comparability between HS detection datasets, from biases introduced in the annotations, differences in preprocessing steps (e.g., anonymization, emojis, URLs, etc.), to issues of class balance and unspecified train-test-validation splits.

We are aware that mixing the datasets may effectively introduce various kinds of noise in the training and evaluation data, but we consider it

Topic	Dataset	Abbrev.	Total Size	Pos. Size	Ratio	Train	Val.	Test
Topic-Generic	`Davidson`	`Gene Davi`	5590	1430	25.58%	4293	179	1118
	`Founta`	`Gene Fnt`	57355	4119	7.18%	44048	1836	11471
Topic-Specific (Gender)	`Evalita`	`Gndr Evit`	5000	2245	44.90%	3839	161	1000
	HatEval$_{women}$	`Gndr HatE`	6472	2845	43.96%	4500	500	1472

Table 1: Overview of the datasets used to train models in this study.

to be part of the experimental settings, especially since these kinds of issues would likely as well be encountered in end-user applications dealing with raw unfiltered data.

4 Models

To study how different pre-trained models and architectures may differ in how they capture HS in various settings, we choose five pre-trained Transformers from the literature. Among them, the last three have been adapted to the domain of HS detection, either through pretraining or pre-finetuning, on data related directly or indirectly to HS detection. For the experiments, we relied on the Hugging Face transformers library (Wolf et al., 2020).

RoBERTa-base (Liu et al., 2019) is an optimized BERT-like (Devlin et al., 2019) encoder Transformer commonly used for various NLP classification tasks, including HS detection.

T5-base is the 220 million parameters pretrained variant of the T5 architecture, initially proposed by Raffel et al. (2020). It differs from BERT-like encoder Transformers in that it is a *text-to-text* model, for which classification tasks are reframed as text generation, with the output labels used in their textual form (in our case, *"normal"* and *"hateful"*), and as this particular variant was also pretrained on various supervised tasks (sentiment analysis, natural language inference, and question answering, etc.), a task prefix is traditionally prepended to the input text, which for our fine-tuning, we fix to *"hate speech: "*.

fBERT (Sarkar et al., 2021) and **HateBERT** (Caselli et al., 2021) are two models derived from BERT, retrained with a Masked Language Modelling (MLM) objective on over 1.4 million social media offensive posts from the SOLID dataset, and Reddit Abusive Language English dataset (RAL-E), respectively.

ToxDectRoBERTa was proposed by Zhou et al. (2021), and is a RoBERTa-large model, finetuned on `Founta`, with the *hateful* and *abusive* classes merged into a single *toxic* class. The authors use the methods proposed by Clark et al. (2019) and Swayamdipta et al. (2020) to attempt to avoid dataset bias issues, such as spurious correlations between particular lexical and dialectical markers (such as those found in African American English) with the toxic class.

5 Cross-Topics Generalization

We first study the differences in generalizability between topic-generic and topic-specific datasets and their potential mixtures, in a cross-dataset/mixture setting: in each individual experiment, one of the previously described models is trained on one dataset/mixture and tested on all individual test sets. For technical details on the experimental parameters used in this study, see Appendix A.

To measure improvements or deteriorations in performances in the generalization experiments, Table 2 presents an intra-dataset evaluation, in which models are simply trained and tested on the same datasets, for the sake of comparison. In the remainder of this section, we report macro F1 scores on all test sets (see Table 1 for abbreviations), with the best scores for each test set highlighted in **bold**. Scores are gradient-colored for legibility.

Dataset \ Model	**T5-base**	**RoBERTa-base**	**ToxDectRoBERTa**	**fBERT**	**HateBERT**
`Gene Davi`	92.70	93.30	**93.78**	92.46	93.14
`Gene Fnt`	81.08	80.84	**85.92**	80.98	79.41
`Gndr Evit`	67.00	69.58	67.37	**73.12**	71.02
`Gndr HatE`	46.29	56.88	51.65	**64.28**	59.11
`Gndr Iber`	84.86	**88.76**	83.89	84.55	86.41
`Gndr Wasm`	85.81	**87.11**	86.27	86.28	86.05
`Race HatE`	38.73	38.24	40.75	**41.72**	38.53
`Race Wasm`	87.03	86.27	86.29	**87.53**	86.37

Table 2: Results of intra-dataset evaluations (training and testing on the same dataset's train and test sets).

5.1 Learning from Topic-Generic Datasets

We investigate here how well knowledge can transfer from topic-generic to topic-specific datasets. We thus train each of the five chosen models on the `Davidson` (`Gene Davi`) and `Founta` (`Gene Fnta`) train sets, as well as on a mixture of the two (`Gene Mixt`), then evaluate those models on every individual test set.

Table 3 presents the results of these evaluations, in terms of macro F1 score. Observing the results, firstly, we can notice that `Davidson` and `Founta` generalize relatively well to each other, with relatively small deteriorations in F1 scores (~ -10 F1) compared to the intra-dataset models (see Table 2), in the favor of `Davidson` $\rightarrow$ `Founta` for our 5 models. When used as a mixture of datasets (`Gene Mixt`), we observe very small improvements for 3 of our five models and very small deteriorations ($\sim \pm 1$ F1) for the rest (RoBERTa-base and ToxDectRoBERTa), which would tend to indicate a good compatibility between these two datasets, or at the very least, some high overlap in the topic-generic HS knowledge extracted by Transformer models across these two datasets.

Looking then at the evaluation results obtained on the topic-specific test sets, we can make a number of observations: first, we note quite significant deteriorations compared to the intra-dataset models for all datasets, except for both HatEval subsets, in particular $\texttt{HatEval}_{\texttt{immigrants}}$, for which all three topic-generic datasets/mixture yield significant improvements (from $\sim +3$ F1 up to $\sim +27$ F1). We believe this to be due to a significant distribution shift between the HatEval train and test set, which would explain why the models perform so poorly in the intra-dataset setting, while using different training sets appears to significantly improve performance.

For the other datasets, the least significant deteriorations can be found for `Evalita`, while the greatest ones are found for $\texttt{Waseem}_{\texttt{sexism}}$, which may indicate an overall low overlap in the types of manifestations of HS found in the topic-generic and topic-specific datasets explored here. However, in most cases, the use of the topic-generic mixture (`Gene Mixt`) appears to be beneficial, in that it tends to attenuate the worst deteriorations found in models trained on `Davidson` or `Founta` individually. This may indicate that using mixtures of topic-generic training datasets may be beneficial when trying to detect HS instances where the topic is not necessarily known.

5.2 Learning from Topic-Specific Datasets

We similarly trained HS classifiers, this time on the remaining 6 topic-specific datasets, separated into the Race and Gender topics (see Table 1). Table 4 presents the results (in a form similar to Table 3), however, for space reasons and as they are the focus of our study, we only present the results for the gender and race topics mixtures (`Gndr Mixt`, and `Race Mixt` respectively), as well as the mixture of both (`Spec Mixt`). See Table A in Appendices for more detailed results.

Observing the results, we can first see that, similarly to the previous experiments, training on these three mixtures of topic-specific datasets does not seem to generalize too well back onto the topic-generic datasets, with even greater deteriorations in F1 scores compared to the intra-dataset setting (cf. Table 2). This is the most pronounced for `Race Mixt`, which is the smaller of the two one-topic mixtures. Even more prominently than for topic-generic mixture discussed previously (`Gene Mixt`), we find that the topic-specific mixture (`Spec Mixt`), which combines both the Gender and Race topics, yields significantly lesser deteriorations than ei-

Table 4: Results of learning from the mixtures of the gender topic-specific (`Gndr Mixt`) datasets (Evalita, $\text{HateEval}_{\text{women}}$, IberEval, and $\text{Waseem}_{\text{sexism}}$), race topic-specific (`Race Mixt`) datasets ($\text{HateEval}_{\text{immigrants}}$, and $\text{Waseem}_{\text{racism}}$), and a mixture of both topics (`Spec Mixt`).

ther of the two individually: this intuitively makes sense, as both separate topics can help cover different subsets of the topic-generic datasets, and should also help in learning manifestations of hate which exist at the intersection of both topics.

Looking at the scores obtained on the topic-specific test sets, we can observe that, unlike in the topic-generic generalization experiments, both the one-topic mixtures and `Spec Mixt` appear to yield improvements over the intra-dataset models, for most of the models. For `Gndr Mixt` and `Race Mixt`, the improvements are, as expected, mostly found for the test sets of the datasets making up the mixtures, but not always: for example, with the T5-base model, training on `Gndr Mixt` appears to yield improvements on $\texttt{Waseem}_{\texttt{racism}}$ ($\sim +4$ F1). This seems to indicate a better ability to generalize in-domain from mixtures of topic-specific datasets, at least to other topic-specific datasets, but more experiments with more topic-specific datasets, covering a wider range of topics, would be necessary to determine whether this may also apply to topic-generic datasets.

6 Finer-Grained Topics Analysis

To better understand which manifestations of HS can be generalized to out-of-domain data, we then perform a finer-grained analysis of the topics learned by our models, by relying on an implicit hate speech dataset, for which fine-grained target annotations are available.

6.1 Implicit Hate Speech Dataset

IMPLICIT HATE CORPUS (which we refer to as `ElSherief`, for brevity) corresponds to the dataset proposed by ElSherief et al. (2021), which consists of 21,480 English tweets annotated for (in a first stage) the presence of implicit or explicit HS (or neither), as mutually exclusive classes. Further, for each of the tweets containing implicit HS, two annotators supplied the targeted demographic groups and the implied statement of the hateful messages, both as free-form texts. In our experiments, we rely on the 6,196 implicit hate instances and their target annotations, which we have manually grouped into different sets of finer-grained topics of HS (whose sizes are in Table 5): *Islam*, *Black People*, *Immigrants / Refugees*, *Beliefs / Religion*, *Gender*, *LGBTQIA+*, *Unspecified Minorities*, and *Nationality*.

6.2 Results

To better show the observations that can be mainly linked to training dataset/mixture selection, we choose to present, in Table 5, the results of the best performing non-domain adapted architecture used here, T5-base. To this end, we rely on the previously mentioned trained T5-base models to obtain binary HS predictions on the entire processed `ElSherief` dataset, and compute the accuracy (as the tested instances are by definition all from the positive class) of the models for each of the finer-grained topic-specific subsets described previously.

The first three results columns show the topics learned by the models trained on the topic-generic datasets, `Davidson`, `Founta`, and their mixture (`Gene Mixt`). We observe that the model trained on `Founta` alone yields the highest accuracy scores over a number of topics, except for the *Immigrants/Refugees*, *Unspecified Minorities*, and *Gender* topics. Due to the latter's small size, and higher degree of co-occurring kinds of HS manifestations (see Section 6.3), accuracies appear to be relatively lower across the board, even for the gender topic-specific datasets. Still, topic-generic datasets, and their mixture, display fairly decent generalization on average for most fine-grained topics analyzed here, and represent a promising avenue for future research aimed at constructing effective out-of-domain generalization mixtures of datasets.

The next group of three columns show the differences in variety of finer-grained topics, between the gender and the race topic, and this in spite of fewer number of instances in the Race topic mixture compared to Gender one. Training on both topics combined (`Spec Mixt`) only yields improvement in the *Gender* and *LGBTQIA* topics, while all the other accuracies drop. This could be a sign that the dual-topic mixture allows for the learning of intersectional manifestations of HS between these topics. Indeed, in the *Gender* group, we find that 22 out of the 58 instances also belong to one or more other groups, and among those, 16 are in the *Muslims*, *Immigrants / Refugees*, or both groups (10 for *Immigrants / Refugees* and/or *Black People* in *LGBTQIA*). As such, it appears that mixtures of topic-specific datasets may prove useful in the generalization of intersectional HS detection, though more research would be necessary to verify this for other topics, and with more data.

The next two columns demonstrate how two datasets annotated for similar topics can wildly vary in which fine-grained topics they allow models to capture. Due to the significant differences in data collection, annotation, and cultural/temporal contexts, the `HatEval` and `Waseem` datasets result in very different learned distributions of fine-grained topics, with the latter almost exclusively covering the *Muslims* topics, whereas the former yields a more varied, and overall more performant on the `ElSherief` dataset, out-of-domain generalization.

The final group of three columns further illustrates this point: `Waseem` yields significantly lower performance on the *Gender* topic, and, if removed from the Gender topic mixture (`Gndr Mixt`), improves its overall accuracy. While removing the entirety of a dataset might not be ideal, this shows the importance of data selection for both in and out-of-domain generalization, and we believe this kind of analysis could be used to guide data selection, for the purpose of constructing such mixtures of datasets.

6.3 Error Analysis

To further investigate how these different models behave on those out-of-domain instances, we perform and present an error analysis on a selection of instances[1] from some of the different finer-grained topics.

We find that misclassifications are often due to several factors, among which implicit expressions of HS such as stereotypes, irony, or humor (as in (1)), or the presence of multiple topics of HS used in potentially ambiguous ways (2): is this instance (ironically) Islamophobic, sexist, or both?

(1) *what pronoun should we use to refer to <u>people who are transitioning into martians</u> ?*

(2) *<u>women are intellectually deficient</u>, islam says*

---

[1] These are examples taken from the ElSherief public dataset which provides texts of the tweets (because of Twitter otherwise having deleted a lot of them).

Table 5: Accuracy scores obtained by the T5-base models trained on the datasets and mixtures of datasets (columns), evaluated on each of finer-grained topic of HS grouped from the ElSherief dataset (rows), with the number of instances of each topic reported in the Size column. The best accuracies for each topic are highlighted in **bold**, and the scores are gradient-colored for legibility. `Gndr Mixt\Wasm` corresponds to the Gender topic mixture (`Gndr Mixt`), from which Waseem$_{\text{sexism}}$ has been removed. **All** corresponds to the mixture of all 8 individual datasets (see Table 1). ***ES*** corresponds to baseline accuracy scores obtained from training a similar model on the ElSherief dataset itself, for comparison.

in sahih bukhari 1:6:301. disagree? you are islamophobe.

Both (3) and (4) were misclassified due to the lack of context: neither of the two implied statements provided by the annotators (i.e., *Women are dumb/Muslims are repugnant* and *kill gays/immigrants should be shot like rats*) can be reliably automatically inferred without more information.

(3) *oh honey. justoh, honey. bless your heart.*

(4) *maybe time to oil up the deer rifles, the ones with the hd night scopes to keep the "vermin" population down.*

7 Conclusion and Perspectives

In this work, we have proposed a set of topic-oriented analyses of the generalizability of HS datasets. We have shown how *topic-generic* and *topic-specific* datasets yield different degrees and nature of generalization, both when used individually, or as mixtures of datasets. With the former, we found that, while not very successful at generalizing in-domain to topic-specific datasets, the use of mixtures allows smoothing out individual weaknesses. With topic-specific datasets, we found that generalization is possible, both for single-topic and multi-topic mixtures. Through a finer-grain out-of-domain generalization analysis, we showed how a priori somewhat similar datasets can vary wildly in the forms of *implicit* HS that can be learned from them. Implicit expressions of hate, with few lexical features, are more difficult to generalize, as models can struggle to capture underlying hateful intents in messages. Notably, one barrier to understanding more implicit manifestations of hate is the lack of context for individual social media posts: more conversational datasets could represent an interesting avenue of research in that regard. These are all important considerations for the purpose of constructing more reliable automatic HS detection systems, intended to function on raw, potentially noisy, and never-seen-before data. In particular, we found that topic-generic datasets like `Founta` (Founta et al., 2018) appear promising for future research on generalization-optimized mixtures of datasets. Finally, concerning HS detection architectures, we found that, for BERT-like models, pre-domain adapted variants generalize slightly better than a more generic RoBERTa classifier, but yield similar results to a generic text-to-text T5 architecture, which seems promising for future research in HS detection.

In future work, we will explore the use of these approaches to guide data selection, by for example employing the method proposed by Swayamdipta et al. (2020), in order to construct mixtures of HS datasets better suited to out-of-domain generalization. Alternatively, Active Learning methods have been shown to be successful in NLP (Ein-Dor et al., 2020), and could be used to palliate annotated scarcity in HS detection: by using topic-oriented analysis methods to detect difficult-to-predict topics, better targeted additional annotations could be acquired, to help improve the topical coverage of automated systems.

Limitations

In this work, we acknowledge a number of issues with the compatibility of HS datasets (cf. Sections 1, 2, and 3.2): namely, the phenomena annotated in these datasets, even those labelled using similar or equal terms, will, in theory and in practice, represent wildly different classes. While, unlike some other previous works (Fortuna et al., 2020, 2021), we do not merge initially distinct labels in datasets, but instead only keep whole classes that correspond to hate speech (excluding other forms of abuse, like *toxicity*, *offensiveness*, etc.), using them in a unified binarized setting is still bound to introduce significant amounts of noise in the training data, with regards to the HS detection task. Most of these issues are well documented, however, as complete re-annotation of all relevant data would be a prohibitively expensive enterprise, we believe there is value in exploring alternative solutions that may enable generalization despite these problems, using existing annotated datasets as they are currently available. Additionally, the analyses presented in this work are by no means comprehensive, both in quantity and variety of datasets and models experimented with. For example, some of the fined-grain topic groups found in the `ElSherief` dataset are not large enough to draw strong conclusions from (namely, *Gender* and *LGBTQIA*): supplementing these less represented topics with more data would enable better insights into generalizability for these kinds of HS manifestations.

Ethics Statement

The data that was used for conducting the experiments is composed of text from the public domain taken from datasets publicly available to the research community. These corpora also conform to the Twitter Developer Agreement and Policy that allows unlimited distribution of the numeric identification number of each tweet. The desire to combat online HS and prevent the widespreading of stereotypes cannot be done without automatic moderation tools, at the risk of increasing cases of algorithmic discrimination. However, the deployment of such algorithms should be done with care, as algorithmic discrimination results from the introduction of biases at the time of the design of the system. These biases consist in the transposition of general (often stereotyped) or statistical observations into systematic algorithmic conditions.

A Experimental Parameters

In each cross-topic/cross-dataset experiment, we train one of the classifiers models described in Section 4 on either a specific dataset, or on a mixture of datasets (see Table 1). For all models, we use the Hugging Face transformer library's implementation of the AdamW optimizer (Loshchilov and Hutter, 2019), with the default 5×10^{-5} learning rate for all models, except for T5-base (1×10^{-4}) and ToxDectRoBERTa (1×10^{-5}), as recommended by their respective authors. When possible using our available hardware (multiple Nvidia GTX 1080 Ti and RTX 2080 GPUs), we use "effective" batch sizes of 64 instances (either as proper mini-batches, or by using gradient accumulation alongside smaller mini-batch sizes). When using mixtures of datasets, batches are constructed by sampling each component dataset proportionally to its relative size, to avoid oversampling the smaller datasets or subsampling the larger ones. Models are trained for a maximum of 8 epochs, with early stopping according to the validation loss, and only the best model checkpoints are retained, according to the validation macro F1 score. Average runtimes vary between architectures and datasets, with the BERT-like (fBERT, HateBERT, and RoBERTa-base) taking the least time (less than an hour on the largest mixture of datasets, `All`, combining all 8 datasets detailed in Table 1), and the longest being ToxDectRoBERTa, since it is based on the RoBERTa-large architecture (approximately 6 hours of training for the `All` mixture). The smallest architectures in number of parameters used in this study are those derived from BERT-base, with $\sim$ 110 million parameters, followed by RoBERTa-base ($\sim$ 125 million parameters), T5-base (220 million parameters), and finally ToxDectRoBERTa, based on RoBERTa-large, with 355 million parameters. For data preprocessing, we replace all emojis with their text form descriptions using the Python `emoji` library, and replace all "@" user mentions and URLs with the replacement strings "*[USER]*" and "*[URL]*" respectively.

Abstract

Pretrained language models have been shown to store knowledge in their parameters and have achieved reasonable performance in commonsense knowledge base completion (CKBC) tasks. However, CKBC is knowledge-intensive and it is reported that pretrained language models' performance in knowledge-intensive tasks are limited because of their incapability of accessing and manipulating knowledge. As a result, we hypothesize that providing retrieved passages that contain relevant knowledge as additional input to the CKBC task will improve performance. In particular, we draw insights from Case-Based Reasoning (CBR) – which aims to solve a new problem by reasoning with retrieved relevant cases, and investigate the direct application of it to CKBC. On two benchmark datasets, we demonstrate through automatic and human evaluations that our **E**nd-to-end **C**ase-**B**ased **R**easoning **F**ramework (ECBRF) generates more valid knowledge than the state-of-the-art COMET model for CKBC in both the fully supervised and few-shot settings. From the perspective of CBR, our framework addresses a fundamental question on whether CBR methodology can be utilized to improve deep learning models.

1 Introduction

Commonsense knowledge helps humans navigate everyday situations seamlessly (Apperly, 2010) and is required for many intelligent scenarios (Davis and Marcus, 2015). To automatically enlarge the scale of commonsense knowledge base for the benefit of reducing labeling labor and expense, Knowledge Graph Completion (KGC) has become a hot research topic (Ji et al., 2022). The general KGC task is to expand existing knowledge graphs by using well-trained classifiers—they are trained with existing annotated samples and predict whether or not there is a relationship between two *existing* entities in a knowledge graph (Wang et al., 2017).

Subject	Relation	Object
hardware shop	at location	mall
world map	has property	draw with grid-lines
PersonX receives its reward	wants to	keep the prize
PersonX wins the big Jackpot	wants to	get its money

Table 1: Commonsense knowledge base tuples. Examples are from ConceptNet and Atomic.

Although KGC methods can automatically find unlabeled relationships, they are always classification or ranking tasks and are limited to *existing* entities in a knowledge graph and can't extend to new entities (Ji et al., 2022). To extend to new entities, COMET (Bosselut et al., 2019) proposes to use *text generation* for exploring and discovering new entities, which is called commonsense knowledge base completion (CKBC) task, utilizing the knowledge within the pretrained language models (PLM), which has been with process in recent years (Devlin et al., 2019; Radford et al., 2019). Specifically, COMET uses subject and relation as direct input to PLM and aims to *generate* objects, most of which are novel and unseen entities.

However, CKBC is knowledge-intensive, requiring wide-ranging and detailed knowledge; and it is reported that the ability of pretrained language models to access and precisely manipulate knowledge is limited (Lewis et al., 2020b). One potential solution to this is to provide "non-parametric knowledge" through additional input. Lewis et al. (2020b) and Guu et al. (2020), for example, have shown that by retrieving passages that contain knowledge relevant to the current task, performance can be improved. For CKBC, unfortunately, it might be especially difficult to find useful passages that contain relevant commonsense knowledge from the web due to a *reporting bias* (Gordon and Van Durme, 2013) in which people rarely express the obvious (i.e., commonsense knowledge).

An example of reporting bias from Table 1 is

---

[*] Contribution starts from their stay at Cornell.

that people rarely say "when a person wins a big Jackpot, he/she will want to get its money" because it's too obvious and meaningless to say. Therefore, instead of retrieving passages from the web, we propose that benefits can still be gained by retrieving relevant knowledge from a "case base" of existing commonsense knowledge tuples[1] and using the retrieved knowledge as non-parametric knowledge (i.e., beyond that represented in the model parameters) to augment the current CKBC input example. In addition, to prevent ECBRF from overfitting to some commonly retrieved cases, we propose $random\ mask$ as a training strategy that randomly masks the retrieved cases during training, which functions similar to dropout (Srivastava et al., 2014) and further improves the performance of the framework. We also analyze several variations to better understand the process.

Although past attempts suggest that similar retrieval-based methods cannot improve the performance of CKBC (Wang et al., 2021), on two benchmark datasets, we demonstrate through automatic and human evaluations that our **E**nd-to-end **C**ase-**B**ased **R**easoning **F**ramework (ECBRF) [2] generates more valid and informative knowledge than (1) the state-of-the-art COMET model (Bosselut et al., 2019) for CKBC which employs no case retrieval, and (2) a baseline model that employs random case retrieval – on both fully supervised and few-shot settings. We also provide an analysis on why different conclusions are reached.

In addition, our framework draws insight from Case-Based Reasoning (CBR), and also has contributions to the CBR research. CBR is a subject in classical AI that solves a new problem by reusing the solutions of retrieved seen similar problems stored in the case base (Aamodt and Plaza, 1994). CBR's methodology has four steps — case retrieval, reuse, revise and retain. Past years of accomplishment in deep learning (DL) have led to enthusiasm in the CBR community to apply DL in the service of CBR. However, based on the observation that many challenges remain in DL where CBR has advantages (e.g. few-shot learning), some CBR researchers (Leake and Crandall, 2020) advocate using CBR to complement DL. However, past works on using CBR to complement DL only limit to shallow Neural Networks (NN) (Liao et al., 2018; Leake et al., 2021; Ye et al., 2021, 2022). The latest work even suggests that in many tasks NN itself outperforms CBR-complemented NN (Ye et al., 2022), which raises fundamental questions on whether CBR methodology is useful for DL.

Our work addresses this doubt by being the first to show a concrete implementation of the integration of the full methodology of CBR to PLM (as one typical model in DL) (we show in §6 that we simulate the third step in the methodology of CBR instead of actually implement it, since it requires huge human efforts) and show that the integration method can benefit from multiple steps in the methodology of CBR, and can lead to better performance over PLM itself in both fully supervised settings and few-shot settings on CKBC. Notably our proposed framework has a larger advantage in few-shot settings, where CBR methods typically have advantage. We also find that the generation of our framework is largely related to the retrieved case especially when they are similar, which exhibits strong case-based reasoning patterns. In addition, a detailed analysis of our framework from a CBR perspective is provided in §6.

Our contributions can be summarized as follows: (1) Drawing insights from CBR, we introduce a new end-to-end framework for CKBC task. We also propose training strategies that can better utilize the retrieved knowledge. (2) We conduct extensive experiments on the CKBC task in various settings (e.g. fully supervised and few-shot), and the results consistently demonstrate that our proposed framework achieves improvements over the state-of-the-art baseline methods. (3) From the perspective of the CBR community, whether CBR methodology can be used to improve DL models remains a fundamental research question. We address this doubt by being the first to show a concrete implementation of the integration of the full methodology of CBR to PLM, and showing that such integration can achieve better performance than single PLM. A thorough analysis of the integration from CBR perspective is also provided.

2 Related Work

Case-Based Reasoning CBR is a subject in classical AI which consists of 4 sub-processes in its methodology: *retrieve*, *reuse*, *revise* and *retain* (Aamodt and Plaza, 1994). Leake and Crandall (2020) advocate using CBR to complement the challenges in deep learning (e.g., few-shot learning). §A.4 provides more detailed related works

[2] Code available at `https://github.com/ZonglinY/ECBRF_Case_Based_Reasoning_with_PLM.git`

relevant to this line. Specifically, our framework is inspired by Watson (1999)'s proposal that compared to CBR being described as an artificial intelligence technology , it is better to describe CBR as a methodology for problem solving, that may use any appropriate technology. Here we treat CBR as a methodology and deep learning as technology that uses CBR as the general high-level process and deep learning as components of the process.

Reasoning in NLP CBR could be seen as a type of analogical reasoning (Kolodner, 1997), and analogical reasoning belongs to inductive reasoning (Salmon, 1989). Inductive reasoning (Yang et al., 2022) is different from deductive reasoning (Clark et al., 2020) (both belong to logical reasoning) that the premise in inductive reasoning can not provide conclusive support to its conclusion.

Commonsense Knowledge Base Completion Here we mainly describe works that use text generation models for this task. Li et al. (2016) propose models to evaluate the full knowledge tuple rather than generate new knowledge. Saito et al. (2018) make an extension by proposing a joint model for the completion and generation of commonsense tuples. However, their work focuses on augmenting knowledge base completion model, rather than to increase coverage in commonsense knowledge base construction. Yao et al. (2019) and Malaviya et al. (2020) focus on link prediction and ranking of knowledge, which is a different task with our generative CKBC task. Sap et al. (2019) use LSTM (Hochreiter and Schmidhuber, 1997) to generate commonsense knowledge and Bosselut et al. (2019) further leverage pre-trained language models to generate commonsense knowledge. Gabriel et al. (2021) present the task of discourse-aware commonsense inference and proposes a memory-based model to generate commonsense knowledge that is more coherent with context. Wang et al. (2021) give an analysis on knowledge capacity, transferability, and induction of pre-trained language models to perform generalizable commonsense inference. Da et al. (2021) analyze the few-shot learning ability of pretrained language models for CKBC task. Unlike these works, we propose a model that can improve the performance of generative CKBC tasks in both fully supervised settings and few-shot settings.

Language Model Prompting First developed by the GPT series (Brown et al., 2020), retrieved data are used as augmented input to improve few-shot performance of remarkable large models. However, past research suggest that such in-context learning cannot improve the CKBC task (Wang et al., 2021), and we are the first to show how in-context learning is useful for CKBC. In addition, such large models are hard to obtain and Brown et al. (2020) do not explore the finetuning performance, neither do they explore the full CBR methodology's effect on PLM. Gao et al. (2021) use prompting and also incorporate demonstrations into context to improve few-shot performance. Their work, however, only focuses on classification tasks and regression tasks, which is different from the CKBC. Similar to our work, Das et al. (2021) use retrieved cases as prompt to improve the performance of PLM. However, they only focus on question answering task and do not integrate the full methodology of CBR, missing important steps such as retain.

3 Task Definition

In the generative CKBC task, a knowledge data instance is represented as a tuple of subject, relation, and object: (sub, rel, obj). All sub and obj are in natural language phrases (Figure 1). rel can be used as either a special token or the corresponding natural language phrases (Bosselut et al., 2019). Here we use rel as natural language phrases. The task is that given a pair of sub and rel, the goal is to *generate* the corresponding obj.

4 Methodology

We start by formalizing our framework as a retrieve-then-predict generative process. Then in §4.2, we describe our ECBRF's modules for the generative process in detail. Finally, we present a hybrid training strategy for better regularization.

Figure 1 describes our method. In the figure, "query" stands for a sub and rel pair which is used as input to ECBRF to generate obj. "Case Base" is initialized with knowledge triples from the training set. "Cases" means the retrieved knowledge triples from the "Case Base". "In-context demonstrations" stand for the retrieved cases that are used for input augmentation (concatenate with the query). The subject, relation, and object of the retrieved cases are sub-scripted with "r" (e.g., sub_r).

4.1 ECBRF's Generative Process

ECBRF takes x as input and learns a distribution $p(y|x)$ over possible outputs y. Here x consists of

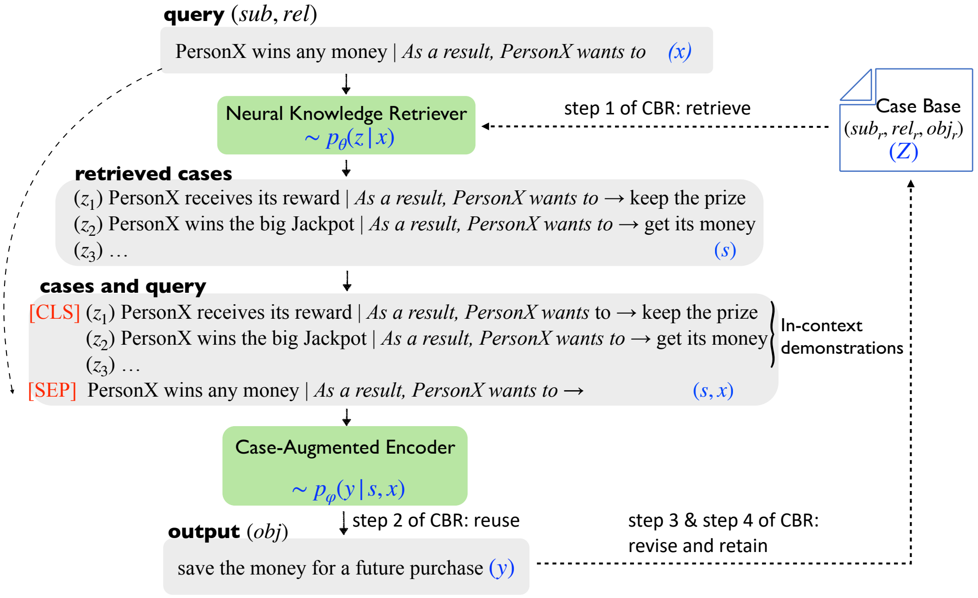

Figure 1: Our end-to-end case-based reasoning framework (ECBRF) for commonsense knowledge base completion. It involves all four steps of the CBR methodology (*retrieve*, *reuse*, *revise* and *retain*).

sub and rel, and y consists of obj. More specifically, ECBRF decomposes $p(y|x)$ into two steps: *retrieve* and *predict*. Given an input x, we first retrieve similar cases $z_1, z_2, ...$ (each case z_i consists of sub_r, rel_r and obj_r) from case base Z, while $(x,\ y) \notin z_i$. We model this as a sample from the distribution $p(z|x)$.

Then we use z_i in a number of m to compose a supporting set s (for each query, one supporting set is used for input augmentation). Specifically,

$$\hat{p}(s|x) = \sum_{z_i \in \text{top-m}(p(.|x))} p(z_i|x) \quad ((x, y) \notin z) \tag{1}$$

$$p(s_i|x) = \frac{\exp \hat{p}(s_i|x)}{\sum_j \exp \hat{p}(s_j|x)} \tag{2}$$

Then we condition on both the supporting set s and the query x to generate the output y, modeled as $p(y|s, x)$. To obtain the overall likelihood of generating y, we treat s as a latent variable and marginalize s via a top-k approximation, yielding:

$$p(y|x) = \sum_{s \in \text{top-k}(p_\theta(.|x))} p_\theta(s|x) p_\varphi(y|s, x) \tag{3}$$

4.2 Model Architecture

We now detail two key components – the *neural knowledge retriever*, which models $p_\theta(z|x)$; and *case-augmented encoder*, which models $p_\varphi(y|s, x)$.

Neural Knowledge Retriever The retriever uses max inner product search (MIPS) to retrieve z. Specifically, the retriever is defined using a dense inner product model:

$$p_\theta(z|x) = \frac{\exp f(x, z)}{\sum_{z'} \exp f(x, z')} \tag{4}$$

$$f(x, z) = Embed_{query}(x)^T Embed_{case}(z) \tag{5}$$

where $Embed_{query}$ is an embedding function that maps sub and rel in the query input to a $d-$dimensional vector, and $Embed_{case}$ is an embedding function that maps sub_r, rel_r and obj_r in the knowledge tuples in memory store to a $d-$dimensional vector. The relevance score $f(x, z)$ between x and z is defined as the inner product of the vector embeddings. The retrieval distribution is the softmax over relevance scores between top-k retrieved cases and current query input.

We implement the embedding functions $Embed_{query}$ and $Embed_{case}$ using two DPR-based models (Karpukhin et al., 2020). The input format for query x is the concatenation of subject and relation: [CLS] sub [SEP] rel [SEP]; And the input format for case z is the concatenation of the subject, relation, and object: [CLS] sub_r [SEP] rel_r obj_r [SEP].

Case-Augmented Encoder Given an input x and a supporting set s, the case-augmented encoder defines:

$$p_\varphi(y|s,x) = \prod_{i}^{N} p_\varphi(y_i|x,s,y_{1:i-1}) \qquad (6)$$

We use BART (Lewis et al., 2020a) and GPT-2 (Radford et al., 2019) as the base model for case-augmented encoder.

We also add prompts which we find is helpful. The input format (with prompts and in-context demonstrations) for case-augmented encoder is:

Here are some similar cases to infer from: z_0 z_1 ... z_{m-1} *From the similar cases we can infer that: [SEP] sub rel*

Zhao et al. (2021) show that pre-trained language model has "Recency Bias", which is the tendency to repeat answers that appear in the last in-context demonstration in classification tasks. We analyse this strategy for the generative CKBC task (we call it "*reverse demonstration*") that the most similar case from the retriever is placed as the last demonstration, the second most similar case in the second last demonstration, and so on.

4.3 Training Method

Since the purpose of in-context demonstration is only to provide ancillary information, the model should be able to predict obj w/ or w/o it. Therefore here we design a specific training strategy for ECBRF – during training, we *randomly mask* out in-context demonstrations and only keep the (sub, rel) query for some training examples with probability p_{mask}. It is designed to function similarly to dropout to prevent overly relying on retrieved cases.

5 Experiments & Analysis

In this section, we introduce the experiment datasets and evaluation details, as well as experiment setups and the experiment results, measured with automatic and human evaluations.

5.1 Datasets and statistics

We evaluate ECBRF using two automatic commonsense knowledge base completion benchmarks — ConceptNet (Speer et al., 2017) and ATOMIC (Sap et al., 2019). In total, ConceptNet contains 101,800 tuples and ATOMIC contains 877,077 tuples. We use the same data split as COMET (Bosselut et al., 2019) did. In ATOMIC, around 17% of the labeled knowledge tuples use "None" as the object. As a result, models can easily get high performance by always generating "None". To better evaluate, we don't use knowledge tuples with the object being "None" for both training and evaluation. Apart from using the entire train set for training, we also conduct experiments in the few-shot settings — where the model is only trained with 5 to 320 knowledge tuples[3]. More details on data pre-processing is shown in §A.7.

5.2 Evaluation Details

For automatic evaluation metrics, following Bosselut et al. (2019) we use BLEU-2, perplexity, and *novelty* metrics (including %N/T-sro, %N/T-o, and %N/U-o). Specifically for *novelty* metrics, we report the proportion of all generated tuples that are novel tuple (%N/T-sro) (here novel means unseen in train set), have a novel obj (%N/T-o), and the proportion of the set of unique obj in all generated objects (%N/U-o).

In addition to automatic evaluation, we also perform human evaluation, including *validness*, *informativeness*, and *preference score*. For *validness* and *informativeness*, following Gabriel et al. (2021), the score is based on a 5-point Likert scale (with 5 points the highest score). For *validness*, following Gabriel et al. (2021), we judge the validness of the generated new knowledge by the likelihood of inferences based on a 5-point Likert scale (with 5 points the highest score). Specifically, obviously true (5), generally true (4), plausible (3), neutral or unclear or basically a repetition (sub-sentence) of the query (2), and doesn't make sense (1). For *informativeness*, the rating standard is also based on a 5-point Likert scale. Specifically, rich in relevant details (5), has relevant details (4), it seems some details are provided (3), basically a repetition (sub-sentence) of the query (2), unfinished generation (1). For *preference score*, We ask the human raters to *compare* the generations between ECBRF and COMET. Specifically, a valid generation with more information provided will be assigned 1.0 point, and a generation that is not valid or with less information will be assigned 0.0 instead. However, if the two generations perform comparably, both generations will be assigned 0.5 points.

Following Bosselut et al. (2019), for each experiment and for each model, we sample 100 generations for human evaluation. Each generation is rated by three graduate students. During the

evaluation the order of the two generations to be compared are randomized for each selection, therefore human raters have no clue on which choice is associated with which model. More details about human evaluation can be found at §A.6.

5.3 Experimental Setup

Baselines We use COMET (Bosselut et al., 2019) as our baseline. COMET is originally implemented with GPT (Radford et al.), a pretrained language model as the base model and uses subject and relation as direct input and uses the generation result as object. Here we compare two versions of COMET, one is GPT-2 (Radford et al., 2019) based and another is BART (Lewis et al., 2020a) based. Both GPT-2 and BART are more powerful pretrained language models than GPT. We leave the details of hyperparameters in §A.1.

5.4 Main Results

Automatic evaluation results on BLEU-2 and perplexity are shown in Table 2. We present results with human evaluations in Table 3. Automatic evaluation of *novelty* is shown in Table 5. Table 2 shows that *random mask* is constantly helpful for ECBRF when the train set is equal or larger than 160. Therefore we adopt *random mask* for ECBRF when the train set is equal to or larger than 160 in Table 3 and Table 5.

Table 2 shows that regardless of the selection of base models, ECBRF consistently outperforms the COMET baseline in almost all perplexity measures and most BLEU measures. We argue that BLEU is not a perfect metric for CKBC (Sai et al.,

sub: PersonX wants to play with PersonY rel: Before, this person needed
One retrieved case by ECBRF: PersonX plays tennis with PersonY's friend, Before, this person needed, get a tennis racket
COMET's generation: to have a game ECBRF's generation: to find a tennis court

Table 6: An example to show how the retrieved cases influence the generated obj.

2023), since each sub and rel pair can lead to more than one feasible obj, and BLEU can only refer to a limited set of ground truth obj. Even if a model generates a reasonable obj, it may yield a low BLEU, because the generated obj is not in the ground truth set.

Table 4 shows one typical example from ATOMIC that shows although ECBRF's generations are reasonable, they only receive low BLEU scores (More examples in §A.2). Table 3 shows that ECBRF consistently outperforms COMET in *preference score*, *validness*, and *informativeness* in human evaluation, especially in few-shot setting. In practice, we observe that in few-shot setting, BART without retrieval tends to repeat the query during generation, while retrieved cases seem to be able to provide knowledge and guidance to generate more proper obj.

Table 5 shows that the generated obj of ECBRF are generally *novel* especially in few-shot settings. We empirically attribute the lower novelty of ECBRF in full train set to that ECBRF sometimes tends to copy proper retrieved obj as generation. The reason %N/T-sro score is always 100.0 in ATOMIC is that the (sub, rel) pairs in ATOMIC's train set and test set do not overlap.

We attribute the different conclusions reached on whether in-context demonstrations (ICD) with finetuning can be beneficial to CKBC (Wang et al., 2021) to that (1) ICD is more useful in few-shot settings, so that investigation on full train set setting might not discover this advantage; (2) human evaluation is the most precise metric for the task while BLEU is not so only evaluating with automatic metrics could not be precise; (3) ECBRF uses *random mask*, which is empirically found to be helpful in performance when using a large train set.

5.5 Ablation Study of ECBRF

In Table 2, we show some ablation studies of ECBRF. "w/ rand mask" stands for the ECBRF model using random mask ($p_{mask} = 30\%$); "w/o reverse demonstrations" stands for the ECBRF model without using reverse demonstrations; and "w/ rand retrieval" represents an ECBRF model that uses randomly searched cases instead of MIPS search.

Both tables for automatic evaluation show that using *random mask* can generally lead to better performance for ECBRF in both perplexity and BLEU when the training set is larger, while lead to worse performance when the number of training set is less than 160. Our interpretation is that, when the train set is very small, the model can benefit from over-relying to the retrieved cases; while when the train set is large, PLM can still benefit from the retrieved cases but the over-relying could be harmful.

The tables also show that "reverse demonstration" only leads to comparable performance, which might indicate that the order of retrieved cases does not make a difference in a generative task (as CKBC).

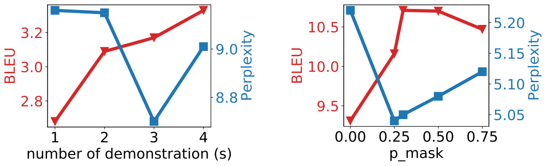
From the tables, we also observe that ECBRF with MIPS retrieval consistently leads to better performance than ECBRF with random retrieval in terms of perplexity in ConceptNet experiments, while performs comparably with ECBRF in ATOMIC experiments. Notice that the required generation in ConceptNet is usually shorter and more similar compared to ATOMIC. Therefore our interpretation is that, only when the retrieved cases are enough similar to the input query and its designed golden generation, can the retrieved cases significantly benefit the generation process (towards golden generation).

5.6 Qualitative Analysis on How Retrieved Cases Influence obj Generation

Table 6 shows one example of the generation of ECBRF and COMET (more examples are shown in §A.3). It shows that ECBRF's generation is related to the retrieved case, exhibiting the case-based reasoning ability of *reusing* the *retrieved* old experience to solve new problems.

6 Further Analysis from Perspective of CBR

CBR methodology contains 4 sub-processes, which are *retrieve*, *reuse*, *revise* and *retain*. More specifically, when given a new problem, the method first *retrieves* the most similar cases, then *reuses* the information in that case to solve the new problem by



(a) effect of # cases (b) effect of p_{mask}

Figure 2: ECBRF's performance (perplexity (↓) / BLEU (↑)) with regard to different numbers of demonstrations and different p_{mask}. Experiments on the left figure use ConceptNet 40-shot train set, and the right figure use ConceptNet 320-shot train set (since *random mask* is only helpful on large train set).

proposing a new solution, then *revises* the proposed solution according to the feedback of adopting it in real application scenarios (*revise* step usually involves human's effort), and finally select high quality revised solutions together with their problems as new cases to *retain* to case base.

We provide an analysis of how the high-level methodology of CBR (*retrieve*, *reuse*, *revise* and *retain*) shapes the design and how the selection details of CBR-related components improve the performance of our end-to-end DL framework.

Step 1: Retrieve *Retrieve* is an important step since the effectiveness of a CBR system largely relies on its ability to retrieve useful previous cases (Montazemi and Gupta, 1997). Here we use *neural knowledge retriever* (DPR) for retrieving the most similar cases. Table 2 shows the results of ECBRF using MIPS retrieval and random retrieval. As illustrated in §5.5, from the experimental results we hypothesize that ECBRF tends to make generations that are similar to the retrieved cases. This hypothesis is consistent with insights from CBR that the $retrieve$ step is essential for guiding the $reuse$ step. However, the difference lies in that CBR insights rely on $retrieve$ step more (with irrelevant retrieval it would be particularly hard for $reuse$), while PLM seems to be able to benefit from even random retrieval.

Step 2: Reuse Here we use *case-augmented encoder* to automatically *reuse* the retrieved cases.

Figure 2a shows the effects of number of retrieved cases. We observe that when *case-augmented encoder* uses 3 cases, it reaches the best perplexity, and nearly the best BLEU performance.

Figure 2b shows the effects of p_{mask}. Only when p_{mask} is 1.0, in-context demonstrations are not used at test time, which makes the model the same as COMET. As we gradually increase p_{mask}, perplexity keeps improving and BLEU-2 reaches the global maximum when p_{mask} is 0.3. It is also interesting to see empirically how the *case-augmented encoder* gradually learns to *reuse* the retrieved cases to increase the performance of the deep learning model as we gradually decrease p_{mask}.

	Perplexity	BLEU
ECBRF	8.70	3.17
w/ only obj_r	8.90	3.26
w/o prompt	9.01	3.44
w/ larger case base	**7.90**	**3.69**

Table 7: Ablation Study: effect of sub_r, prompt, and the retain step (perplexity (↓) / BLEU (↑)). Results of this table use ConceptNet 40-shot train set.

In CBR, the *reuse* of the retrieved case's solution contains two steps: (a) find the difference between the past and the current queries and (b) adapt the retrieved solution to the current query (Aamodt and Plaza, 1994). So it is important to know the difference between the past queries and the current input query for better adaptation. Table 7 shows the comparison between the result of only using obj_r (the retrieved cases' object phrases) as in-context demonstrations and the result of ECBRF (uses both sub_r, rel_r and obj_r), and we observe that ECBRF performs better in perplexity. but a little bit worse in BLEU. This result indicates that deep learning based *case-augmented encoder* is possible to automatically learn and reason from the difference between the past queries and the current input query for *reuse*. We leave further investigations on whether PLMs can learn to compare the difference between the past queries and the current input query as an open research question.

We use prompts to indicate the role of retrieved cases and current query in input. Table 7 shows that *case-augmented encoder* with the prompt performs better in perplexity while a bit worse on BLEU, indicating that usage of a prompt is possible to help the model better *reuse* the retrieved cases.

Step 3 & 4: Revise and Retain Since *revise* typically involves human efforts, here we simulate *revise* and *retain* and see their effect on our framework. The result of *revise* and *retain* is a larger case base with more high quality data, and the parameters of the model for *reuse* are not necessarily updated according to the new data. Here we simulate the effect of *revise* and *retain* by first training

ECBRF in a low-resource experiment (with a small case base), then at test time we expand the case base to the full train set. Table 7 shows that, at test time, ECBRF with access to a larger case base substantially outperforms ECBRF (with access to only a small case base), although the parameters have not been updated with the new data. This result demonstrates that our framework can benefit from CBR's methodology as *revise* and *retain*.

7 Conclusion

Drawing insights from CBR, we propose an end-to-end framework for the CKBC task. We demonstrate through automatic and human evaluations that our framework generates more valid knowledge than the state-of-the-art COMET model in both the fully supervised and few-shot settings. From the perspective of CBR, our framework addresses a fundamental question on whether CBR methodology can be utilized to improve deep learning models.

8 Future Works and Challenges

In general, we hope this work could provide some insights to bridge the two research areas, classic AI (Case-Based Reasoning) and deep learning based NLP methods together, and therefore to advance the research of both fields from each other's research developments.

From the aspect of NLP methods, for example, new prompting methods could be further developed based on insights from CBR research; The concept of *revise* and *retain* from CBR could be paid more attention to investigate their interaction with in-context demonstrations (prompting).

From the aspect of CBR, this work provides a tentative answer to the two long-remaining challenges — (1) whether CBR can be used to complement DL (Leake and Crandall, 2020), given that the latest work even suggests that in many tasks NN itself outperforms CBR-complemented NN (Ye et al., 2022); (2) the adaptation (*reuse* step) of previous cases to the current case is a very challenging problem, so that in many fields the CBR methodology is used only as a retriever (Choudhury and Begum, 2016). How to further answer these two questions could be a challenging research topic.

9 Limitations

From the perspective of CBR, we have shown through experiments that our framework can perform *retrieve* and *reuse* steps, and can benefit from *revise* and *retain* steps. But the *revise* step in CBR typically involves human efforts, and this paper does not focus on addressing this challenge. As a result, our framework might still need manual efforts to benefit from *revise* and *retain*.

However, human efforts could be more efficiently utilized for *revise* than writing new data from scratch. Since comparing with requesting the workers to write the knowledge from scratch, *revising* the existing generations of ECBRF could be much faster.

A Appendix

A.1 Hyperparameters

We use a common training hyperparameters setup for PLM, and the variance of hyperparameters such as batch size is mainly determined by the computational resources.

Specifically, batch size is 32 for all ATOMIC experiments; is 16 for all BART-based ConceptNet experiments; is 8 for all GPT2-based ConceptNet experiments. Learning rate is 1e-5 for all experiments. The remainder of our training hyperparameters is the same as COMET (Bosselut et al., 2019) for full train set experiments. For few-shot experiments, we adapt the warm up steps accordingly (more details can be found in our public release code).

For decoding hyperparameters, we use greedy decoding for all BART experiments (since Bosselut et al. (2019) suggests that greedy decoding can lead to the best human evaluation results); and use topk (k=50) decoding for all GPT2 experiments (since with greedy decoding many generations of GPT2 model is only the end of text token; with randomly sampling a concrete generation could be made via multiple attempts).

A.2 Examples that BLEU not a Perfect Metric

Table 8 shows three examples with three different rel from ATOMIC that shows although ECBRF's generations are reasonable, but they only receive low BLEU scores.

This table shows that sometimes a good generation is assigned with a low BLEU score, especially when the generation is novel and unseen from the ground truth set. Table 5 shows that ECBRF produces more novel generations compared with the COMET baseline, which might make ECBRF suffer more from the imperfectness of the BLEU score.

A.3 Examples on How Retrieved Cases Influence ECBRF

Table 9 shows three examples of the generation of ECBRF and COMET.

This table shows that many ECBRF's generations are related to the retrieved case, exhibiting the case-based reasoning ability of *reusing* the *retrieved* old experience to solve new problems.

A.4 More Related Works on CBR

Leake and Crandall (2020) advocate using CBR to complement the challenges in deep learning (e.g., few-shot learning). However, past works on using CBR to complement DL only limit to shallow Neural Networks (NN) (Liao et al., 2018; Leake et al., 2021; Ye et al., 2021, 2022). The latest work even suggests that in many tasks NN itself outperforms CBR-complemented NN (Ye et al., 2022), which raises fundamental questions on whether CBR methodology is useful for DL. Other relevant works include only use CBR to improve the explainability of deep learning models (Keane et al., 2021), or use CBR to improve the performance of symbolic reasoning (Das et al., 2020a,b).

A.5 Future Applications of ECBRF

Although experiments in this paper are only conducted under the commonsense knowledge base completion task, ECBRF could potentially be utilized by other commonsense reasoning tasks, such as temporal commonsense reasoning (Yang et al., 2020), commonsense based sentiment analysis (Cambria et al., 2022), and metaphor processing (Mao et al., 2018) (similar to CBR, metaphor is also highly related to analogical reasoning).

A.6 Human Evaluation Details

Inter-annotator agreement Since we have three annotators for human evaluation, and the spearman correlation is to compare two rank lists, we calculate the averaged spearman correlation for each metric. Specifically, the average spearman correlation for "validness" is 0.71, and the average spearman correlation for "informativeness" is 0.66; For the "preference score", since it's to compare each ECBRF's generation with one baseline (COMET) generation, we can't rank generations according to the value of the preference score. So following Pan et al. (2011), we use Cohen's kappa coefficient instead. The kappa coefficient for "preference score" is 0.81.

Instructions for human evaluators There are 3 evaluation metrics: preference score, validness score and informativeness score.

Preference score: a valid generation with more information provided will be assigned 1.0 point, and a generation that is not valid or with less information with being assigned 0.0 instead. However, if the two generations perform comparably, both generations will be assigned 0.5 points.

Validness score: Validness score is given in a 5-point scale (1 5) obviously true (5) generally true (4) plausible (3) neutral or unclear or basically a repetition (sub-sentence) of the query (2) doesn't make sense (1). Examples for validness: (5): PersonX wants to learn piano, others want, to teach personX; (4): PersonX wants to learn piano, others want, to hear peronX play; (3): PersonX wants to learn piano, others want, to sell piano to peronX; (2): PersonX wants to learn piano, others want, to turn their music on; (1): PersonX wants to learn

Example 1	sub: PersonX spends ___ working rel: As a result, others feel ground truth: ['happy', 'happy to have x in their life'] COMET's generation: happy (BLEU score: 31.62) ECBRF's generation: satisfied with personx's work (BLEU score: 0.00)
Example 2	sub: PersonX expects another ___ rel: This person then ground truth: ['prepares themselves', 'gains knowledge'] COMET's generation: gains knowledge (BLEU score: 100.00) ECBRF's generation: wants to find out what it is that they are going to do next (BLEU score: 0.00)
Example 3	sub: PersonX spends the ___ working rel: This person is seen as ground truth: ['diligent', 'tired', 'hardworking'] COMET's generation: hardworking (BLEU score: 31.62) ECBRF's generation: dedicated (BLEU score: 0.00)

Table 8: Examples to show that BLEU is not a perfect metric for CKBC. This table shows that sometimes a good generation is assigned with a low BLEU score, especially when the generation is novel and unseen from the ground truth set. Table 5 shows that ECBRF produces more novel generations compared with the COMET baseline, which might make ECBRF suffer more from the imperfectness of the BLEU score.

Example 1	sub: PersonX wants to play with PersonY rel: Before, this person needed COMET's generation: to have a game Retrieved cases by ECBRF include: (PersonX plays tennis with PersonY's friend, Before, this person needed, get a tennis racket) ECBRF's generation: to find a tennis court
Example 2	sub: PersonX advances another ___ rel: This person then COMET's generation: PersonX gains knowledge Retrieved cases by ECBRF include: (PersonX marries the king's ___, This person then, he becomes king) ECBRF's generation: becomes more powerful
Example 3	sub: PersonX smiles broadly rel: As a result, this person wants to COMET's generation: to smile back Retrieved cases by ECBRF include: (PersonX grins like a cheshire cat, As a result, this person wants to, express their feelings) ECBRF's generation: to tell others about the good time they had

Table 9: Examples to show how the retrieved cases influence the generated obj. This table shows that many ECBRF's generations are related to the retrieved case, exhibiting the case-based reasoning ability of *reusing* the *retrieved* old experience to solve new problems.

piano, others want, to wait for the dinner.

Informativeness score: Informativeness score is given in a 5-point scale (1 5) rich in relevant details (5) has relevant details (4) it seems some details is provided (3) not related information or basically a repetition (sub-sentence) of the query (2) unfinished generation or doesn't make sense (1) Examples for informativeness: (5): PersonX wants to learn piano, others want, to teach personX the basic usage of piano and how to buy a suitable piano; (4): PersonX wants to learn piano, others want, to teach personX on how to use piano; (3): PersonX wants to learn piano, others want, to teach personX; (2): PersonX wants to learn piano, others want, to turn their music on; (1): PersonX wants to learn piano, others want, to teach.

A.7 Other Details on Data Pre-processing

We observe that in Table 2, our GPT experiment results are lower than Bosselut et al. (2019). We attribute the reason to our different data pre-processing method — we filter all the "." in the obj in ATOMIC and ConceptNet datasets since we observe that only a part of obj are equipped with ".", which might confuse the model on whether to generate "." or not.

Without “.”, a fixed token in generation, it would be harder for a model to reach higher perplexity and BLEU. In our preliminary experiments that do not especially filter “.”, our re-implemented COMET’s results are comparable to Bosselut et al. (2019).

A.8 Other Details on Retrieval

For ECBRF, we empirically find that not retrieving cases that share the same sub_r with sub is beneficial for the performance. The intuition behind this mechanism is that when one of the retrieved cases has the same sub_r with sub, then it should be natural to copy the corresponding obj_r as generation. However, it is common that obj is different from obj_r, which might confuse the model.

Exploring Segmentation Approaches for Neural Machine Translation of Code-Switched Egyptian Arabic-English Text

Abstract

Data sparsity is one of the main challenges posed by code-switching (CS), which is further exacerbated in the case of morphologically rich languages. For the task of machine translation (MT), morphological segmentation has proven successful in alleviating data sparsity in monolingual contexts; however, it has not been investigated for CS settings. In this paper, we study the effectiveness of different segmentation approaches on MT performance, covering morphology-based and frequency-based segmentation techniques. We experiment on MT from code-switched Arabic-English to English. We provide detailed analysis, examining a variety of conditions, such as data size and sentences with different degrees of CS. Empirical results show that morphology-aware segmenters perform the best in segmentation tasks but under-perform in MT. Nevertheless, we find that the choice of the segmentation setup to use for MT is highly dependent on the data size. For extreme low-resource scenarios, a combination of frequency and morphology-based segmentations is shown to perform the best. For more resourced settings, such a combination does not bring significant improvements over the use of frequency-based segmentation.

1 Introduction

Code-switching (CS), i.e. the alternation of language in text or speech, has been gaining worldwide popularity, due to several reasons, including globalization and immigration. While this has been met with a growing interest in the NLP field to build systems that can handle such mixed input, work on CS machine translation (MT) is still considered in its infancy, where only a few language pairs have been investigated (Sinha and Thakur, 2005; Dhar et al., 2018; Menacer et al., 2019; Xu and Yvon, 2021; Hamed et al., 2022c).

CS Sentence	it depends بصراحة بالنسبالي ع ال situation it depends *bSrAHp bAlnsbAly E Al* situation
Translation	for me it honestly depends on the situation

Word	Translation	Segmentation
it	it	it
depends	depends	depend#s
بصراحة *bSrAHp*	honestly	ب#صراحة *b#SrAHp*
بالنسبالي *bAlnsbAly*	for me	ب#النسبا#ل#ي *b#AlnsbA#ly*
ع *E*	on	ع *E*
ال *Al*	the	ال *Al*
situation	situation	situation

Figure 1: An example sentence with code-switching (CS) between English and Egyptian Arabic. The words are contrasted with their segmentations and English translations. Arabic words are paired with their transliterations in the Buckwalter scheme (Habash et al., 2007).

In this work, we focus on the CS Egyptian Arabic (EGY)-English (EN) language pair, as we observe its usage is becoming more common. Besides being prevalent amongst Egyptian migrant communities, it is also commonly used in Egypt due to the increase in international schooling systems and educational advancements. We identify three main challenges for CS MT. First is **data sparsity**, a challenge common to many CS language pairs because of limited parallel corpora containing commissioned translations of CS text (Çetinoğlu et al., 2016; Srivastava and Singh, 2020; Tarunesh et al., 2021; Hamed et al., 2022b; Chen et al., 2022). Second is Egyptian Arabic **morphological richness**, which further exacerbates the data sparsity situation (Habash et al., 2012a,b). Third, since the matrix language (EGY) is morphologically rich, CS occurs at three **CS levels**: on the boundaries of sentences (inter-sentential CS), between words (intra-sentential CS), and within words, i.e., morphological code-switching (MCS). This mix of types of CS raises the question of how to handle them all in the same system. These challenges are further illustrated in Figure 1.

May 2-6, 2023 ©2023 Association for Computational Linguistics

A common solution to handle data sparsity for MT of morphologically rich languages is morphological segmentation (Oudah et al., 2019; Ataman et al., 2017; Grönroos et al., 2020). However, this has not been investigated for CS. In this paper, we explore a wide range of segmentation approaches, covering unsupervised morphology-based segmenters, unsupervised frequency-based segmenters, and supervised morphology-based segmenters. This work aims to answer the following research questions (RQs):

- **RQ1:** Which segmentation setup performs the best in the downstream MT task across different training sizes?
- **RQ2:** Does the effectiveness of the different segmenters in the MT task differ according to the CS type of the source sentence?
- **RQ3:** Is there a correlation between a more morphologically correct segmentation and MT performance?

While our results show that there is no correlation between correct morphological segmentation and MT performance, we find that the performance ranking between the MT systems varies across different training data sizes and sentence types (monolingual vs. code-switched). We show that applying a combination of supervised morphology-based and unsupervised frequency-based segmentations consistently gives best results, with statistical significance under low data sizes. While commonwisdom suggests that Byte-Pair Encoding (BPE) is the best approach, our experiments highlight the importance of integrating morphological knowledge in the case of extreme low-resource settings. We believe that the insights and methodology we follow will be useful to researchers working with low-resource languages. An additional contribution of our research is the creation of a gold standard morphologically annotated CS Egyptian Arabic-English dataset which we make publicly available.[1]

The paper is organized as follows. Section 2 discusses related work. Section 3 describes the dataset we annotated. Section 4 describes and evaluates the different segmenters used. Section 5 describes and evaluates the various MT systems. In Section 6, we answer our research questions.

2 Related Work

Several researchers have investigated the effect of applying different morphological and agnostic segmentation approaches on the MT performance for monolingual languages. Roest et al. (2020); Saleva and Lignos (2021) show that unsupervised morphology-based segmentation like Linguistically Motivated Vocabulary Reduction (LMVR) (Ataman et al., 2017), Morfessor (Smit et al., 2014), and FlatCat (Grönroos et al., 2014) for Nepali–English, Sinhala–English, Kazakh–English, and Inuktitut–English language pairs show either no improvement or no significant improvement over the agnostic BPE segmentation (Sennrich et al., 2016) in translation tasks. Meanwhile, Mager et al. (2022) and Ataman et al. (2017) show that for polysynthetic and highly agglutinative languages, unsupervised morphology-based segmentation outperforms BPEs (Sennrich et al., 2016) in MT tasks in both directions. Nevertheless, applying BPEs on top of morphology-based segmentation for Turkish–English, Uyghur–Chinese, and Arabic–English has shown to bring improvements over solely using BPEs or morphology-based segmentation for neural MT task (Pan et al., 2020; Tawfik et al., 2019). A similar result was achieved by (Ortega et al., 2020), using a morphological guided BPE for polysynthetic languages. However, Oudah et al. (2019) show that such an approach is beneficial in the case of statistical machine translation (SMT), and does not improve results for neural machine translation (NMT). For other natural language processing (NLP) tasks, Al-Thubaity and Al-Subaie (2015) show that utilizing word segmented Arabic dataset leads to improvements in text classification task over utilizing unsegmented dataset in terms of accuracy, precision, recall, and F-measure.

As for work on CS MT, there are many efforts (Sinha and Thakur, 2005; Dhar et al., 2018; Mahata et al., 2019; Menacer et al., 2019; Song et al., 2019; Tarunesh et al., 2021; Xu and Yvon, 2021; Chen et al., 2022; Hamed et al., 2022c). To the best of our knowledge, none of these efforts presented an extensive comparison covering different segmentation techniques. With regards to the languages covered, only Menacer et al. (2019) worked on CS Arabic-English. However, since they used carefully edited UN documents, the text only included the Modern Standard Arabic variety, and contained limited types of CS.

With regards to similar corpora, Balabel et al.

3 Data

3.1 Pre-existing Datasets

We use the *ArzEn* parallel corpus (Hamed et al., 2020, 2022b), which consists of speech transcriptions gathered through informal interviews with bilingual Egyptian Arabic-English speakers, as well as their English translations. The corpus consists of 6,213 sentences, where 4,154 (66.9%) are code-mixed, 1,865 (30.0%) are monolingual Arabic, and 194 (3.1%) are monolingual English. Among the code-mixed sentences, there are 1,781 (28.7%) sentences with morphological code-switching. We follow the predefined dataset splits, containing 3,341 (53.8%), 1,402 (22.6%), and 1,470 (23.7%) sentences for train, dev, and test sets, respectively. For training purposes, we also use 308k monolingual parallel sentences obtained from MADAR (Bouamor et al., 2018) and the following *LDC* corpora: (Gadalla et al., 1997; LDC, 2002b,a; Chen et al., 2017; Tracey et al., 2021; BBN Technologies et al., 2012; Chen et al., 2019). The preprocessing steps we apply are outlined in Appendix A. We use *ArzEn* train set as well as the monolingual parallel corpora to train both the segmenters and MT systems. For tuning and testing the MT systems, we use the *ArzEn* dev and test sets. For tuning and testing the segmenters, we annotated a new dataset, discussed next.

3.2 A New Dataset: ArzEn Surface Segmentation (ArzEnSEG) Corpus

To facilitate our research, we created a code-switched Egyptian Arabic-English morphologically annotated dataset which we use for tuning and testing. The dataset comprises the first 500 lines of *ArzEn* dev set. Unlike Balabel et al. (2020), we opt for surface form segmentation to allow for evaluating the segmenters. We also opt for extending *ArzEn* dataset as it contains translations and is used in our MT experiments.

	EGY	EN
Test Words	3,414	501
Dev Words	3,069	567
Total Words	6,483	1,068
Total Segmented Words	1,206	146
Total Morphs	7,911	1,214
Total Unique Morphs	1,192	432
% of Total Segmented Words	18.6%	13.7%
Morphs/Word	1.220	1.137
Maximum Morphs per Word	5	2

Table 2: Statistics on *ArzEnSEG* corpus.

For Arabic word segmentation, we use the Arabic Treebank (ATB) segmentation scheme (Maamouri et al., 2004; Habash, 2010). We choose this scheme as it is the standard tokenization scheme used in different treebanks (Maamouri et al., 2004, 2012; Taji et al., 2017; Habash et al., 2022). It has also shown to be efficient in Oudah et al. (2019) and has demonstrated its competitiveness in Habash et al. (2013).

For English word segmentation, we follow five rules in sequential order depending on whether the word has a regular or irregular stem and whether the word has a regular or irregular ending. Table 1 exhibits the five English rules we follow in order.

All annotation decisions were made in context by two bilingual speakers who collaborated on initial annotations and quality checks. Figure 1 presents an annotation example. We divide the sentences randomly into dev and test sets (250 sentences each). In Table 2, we display statistics about *ArzEnSEG*.

4 Segmentation Experiments

4.1 Experimental Setup

We explore three categories of segmenters: unsupervised morphology-based, unsupervised frequency-based, and supervised morphology-based segmentation. For the unsupervised morphology-based segmenters, we use MorphAGram in addition to three segmenters from the Morfessor family: Morfessor, LMVR, and FlatCat. For unsupervised frequency-based segmenters, we use BPE. Figure 2 summarizes the process of training these segmenters. For the supervised morphology-based segmenters, we use MADAMIRA (Pasha et al., 2014), where we exploit the segmentation schemes designed for Egyptian Arabic.

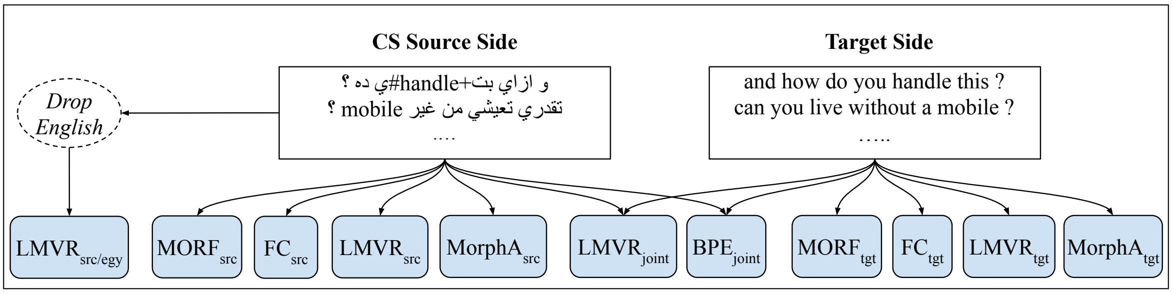

Figure 2: The unsupervised segmentation models we study in this paper and their training data dependencies. We use four systems: Morfessor (MORF), FlatCat (FC), LMVR, and MorphAGram (MorphA). The subscripts specify the training data: source (src), target (tgt), source+target (joint), and source without English, i.e., Egyptian, (src/egy).

4.2 Segmentation Systems

In this section, we introduce the segmentation systems used for the study. Details about the hyperparameter tuning for each system family can be found in Appendix B. The different segmentation models and their training dataset are displayed in Figure 2.

Morfessor Family We exploit three Morfessor family tools for unsupervised morphology-based segmentation in this research: Morfessor, (Smit et al., 2014), FlatCat (Grönroos et al., 2014), and LMVR (Ataman et al., 2017).

Morfessor is a morphological-based segmentation model which we train in an unsupervised manner. Three components form the system: the model, the cost function, and the training and decoding algorithms (Virpioja et al., 2013). The model is mainly concerned with the grammar and lexicon where the latter holds the attributes of the subwords and the grammar controls how these subwords are combined to form the word. Morfessor's grammar assumes that the subwords that form the word are independent of each other and that a word has at least one subword.

FlatCat is a variant of Morfessor which we also train in an unsupervised manner. Even though FlatCat builds on Morfessor and shares the same model component, they differ in their morphotactics (the set of rules that determine how the word's morphemes are arranged). FlatCat morphotactics is based on the Hidden Markov model (Baum and Petrie, 1966) which considers context. On the contrary, Morfessor's morphotactics algorithm is based on a unigram model which is not context-sensitive.

LMVR is a morphology-based segmenter that is built upon FlatCat and we train in an unsupervised manner. Nonetheless, LMVR takes into consideration the desired segmentation output vocabulary size during training.

For each tool, two models are generated; one trained on the source side; thus capable of segmenting CS data, and the other trained on the target side of the training data; thus capable of segmenting English data only. We add a *src* and *tgt* subscript to the segmenters' names to distinguish between both settings. Hence, MORF$_{src}$, FC$_{src}$, and LMVR$_{src}$ resemble Morfessor, FlatCat, and LMVR respectively, where the segmenters are trained on the source side. MORF$_{tgt}$, FC$_{tgt}$, and LMVR$_{tgt}$ resemble the segmenters trained on the target side.

MorphAGram We also include in this study the unsupervised morphology segmenter MorphAGram (Eskander et al., 2020) which is based on Adaptor Grammars. We use the *PrStSu+SM* grammar, which represents a word as a sequence of prefixes followed by a stem then a sequence of suffixes, in the unsupervised *Standard* learning setting to train the segmenters.

BPE The SentencePiece (Kudo and Richardson, 2018) implementation of BPE (Gage, 1994; Sennrich et al., 2016) is a frequency-based unsupervised segmenter. We train the BPE model jointly, on the concatenation of the source and target sides of the training parallel corpus. Previous work has shown that this approach is better suited for low resource settings (Guzmán et al., 2019). We refer to our joint BPE segmenter as BPE$_{joint}$.

MADAMIRA For supervised morphology-based segmenters, we use MADAMIRA's Egyptian Arabic model (Pasha et al., 2014), which was trained on the Egyptian Arabic Treebank (parts 1 through 6) (Maamouri et al., 2012). Specifically, we use MADAMIRA's *ATB_BWFORM* and *D3_BWFORM* schemes, henceforth MDMR$_{ATB}$ and MDMR$_{D3}$, respectively. Both schemes apply Alif/Ya normaliza-

	EMMA F1 Score		
Segmenter	**EGY**	**EN**	**All**
raw	0.806	0.953	0.838
MorphA$_{src}$	0.682	0.942	0.737
MORF$_{src}$	0.814	0.888	0.832
FC$_{src}$	0.821	0.961	0.851
LMVR$_{src}$	0.836	0.961	0.863
LMVR$_{src/egy}$	0.838	0.953	0.863
MorphA$_{tgt}$	0.806	0.953	0.838
MORF$_{tgt}$	0.147	0.951	0.327
FC$_{tgt}$	0.806	0.952	0.838
LMVR$_{tgt}$	0.806	0.966	0.842
LMVR$_{joint}$	0.841	0.963	**0.868**
BPE$_{joint}$	0.678	0.814	**0.707**
MDMR$_{ATB}$	0.935	0.953	**0.939**
MDMR$_{D3}$	0.868	0.953	0.887

Table 3: EMMA F1 score calculated on *ArzEnSEG* test set for the raw data as well as the segmented data using the different segmenters. The Arabic gold segmentation is based on the ATB segmentation scheme. We show the overall score (All) and language-specific scores calculated on the Egyptian Arabic (EGY) and English (EN) words separately. Segmenter names with a *src*, *tgt*, and *joint* subscripts represent segmenters that are trained on the source, target, and source+target sides respectively. The best performing segmenters from each category are highlighted in bold.

tion and segment the Arabic clitics. MDMR$_{D3}$ splits the Arabic definite article ال *Al* (the), while MDMR$_{ATB}$ does not.

4.3 Segmentation Results

To evaluate the performance of the segmenters, we use EMMA F1 score (Spiegler and Monson, 2010). Results in Table 3, reported on *ArzEnSEG* test set, show overall and language-specific scores.

Unsupervised morphology-based segmentation Results show that LMVR outperforms the other unsupervised morphology-based segmenters in terms of segmenting Arabic and English words. We perform further experiments where we train 2 additional models: i) a model trained jointly on the concatenation of the source and target sides of the parallel corpus, and ii) a model trained on the Arabic words only in the source side (where English words are dropped). Therefore, the former model is capable of segmenting both languages, while the latter is only tailored for segmenting Arabic words. We perform these experiments using LMVR, given that it outperforms the other segmenters. We refer to these models as LMVR$_{joint}$ and LMVR$_{src/egy}$ respectively, as outlined in Figure 2. Results show that joint training provides best EMMA scores.

Supervised morphology-based segmentation As shown in Table 3, both supervised morphology-based segmenters MDMR$_{ATB}$ and MDMR$_{D3}$ outperform all other segmenters. Their superiority in segmenting Arabic is expected, as they are trained on human-annotated data and hence are capable of generating infrequent morphemes. Additionally, MADAMIRA has a morphological analyzer embedded in it, which in turn enriches the inspection of Arabic words prior to segmentation. Higher EMMA scores are reported for MDMR$_{ATB}$ over MDMR$_{D3}$, which is also expected, as *ArzEnSEG* is segmented following the ATB scheme.

Unsupervised frequency-based segmentation As expected, BPE$_{joint}$ performs the worst in the morphology-based segmentation task, as it is designed for agnostic segmentation for the purpose of improving downstream tasks.

Further analysis We surprisingly find that MorphA$_{tgt}$ outperforms MorphA$_{src}$ on Arabic words and FC$_{src}$ outperforms FC$_{tgt}$ on English words. Therefore, we conduct an internal analysis where we look into the percentage of over and under segmentations.[2] In Appendix C, we present the number of under and over segmented words for each segmentation approach. Our analysis shows that MorphA$_{src}$ over segments 25% of the Arabic words. We observe that in 20% of these over segmentation cases, the Arabic definite article is segmented. For example, the word الكتب *Alktb* 'the books' is segmented to ال#كتب *Al#ktb* which is considered valid in segmentation schemes like D3. However, since we use the ATB scheme in *ArzEnSEG* annotation, the EMMA system penalizes the MorphA$_{src}$ segmenter and rewards the MorphA$_{tgt}$ segmenter which leaves most of the Arabic words and the definite article unsegmented. Another case is the segmentation of affixes, which is not done in ATB. For example, 16% of the over segmentation cases are separation of the Ta-Marbuta (feminine nominal ending) in Arabic words. The rest of the cases are grammatically incorrect segmentations. FC$_{tgt}$ is also shown to under segment around 17% more English words compared to FC$_{src}$ which can contribute to worse scores. We also observe that MORF$_{tgt}$ performs

---

[2] Over segmentation is a term we use to indicate that the word gets segmented to more morphemes compared to the gold standard segmentation. Meanwhile, under segmentation is a term we use to convey that the word is segmented into fewer morphemes than the gold standard segmentation.

significantly worse than the other segmenters when segmenting Arabic words, despite the fact that 81% of the Arabic words do not require segmentation. Internal analysis shows that MORF$_{tgt}$ over segments the Arabic words to the character level in an attempt to extract the underlying morphology of Egyptian Arabic, which it was not trained on.

5 Machine Translation Experiments

Since no previous research investigates the best segmentation technique for NMT of the code-switched Egyptian Arabic–English language pair, we explore training NMT models using the various segmentation setups discussed in Section 4 to answer RQ1. Moreover, we analyze the performance of the top-performing MT systems on different types of CS sentences to answer RQ2. Afterward, we compare the MT scores against the EMMA F1 scores discussed in Section 4.3 to answer RQ3.

5.1 Experimental Setup

We train Transformer models for our MT systems using Fairseq (Ott et al., 2019) on a single GeForce RTX 3090 GPU. We use the hyperparameters from the FLORES[3] benchmark for low-resource MT Guzmán et al. (2019), which we list in Appendix D. Afterwards, we evaluate the MT models on *ArzEn*'s dev and test sets using chrF2 (Popović, 2015).[4] We choose chrF2 over BLEU (Papineni et al., 2002) as it rewards partially correct translations which makes it a convenient choice for our research, and because chrF has shown to have higher correlation with human judgments over BLEU (Kocmi et al., 2021).

5.2 Machine Translation Systems

We experiment with different categories of segmentation setups. Table 4 shows all the different setups that we explore. See Table 10 in Appendix D for training time.

For the **unsupervised morphology-based segmentations**, we use MorphAGram, Morfessor, FlatCat, and LMVR to segment the source/target sides of the parallel corpus, where the segmenters were trained on each side separately (see Figure 2). For the best performing segmenter, we further investigate the best training setting, where we investigate using segmenters trained only on Arabic words on the source side as well as segmenters that are trained jointly on both sides.

Segmentation			**chrF2**	
Source		**Target**		
EGY	**EN**	**EN**	**dev**	**test**
raw		raw	47.1	49.9
Unsupervised Morphology-based Segmenters				
MorphA$_{src}$		MorphA$_{tgt}$	47.0	49.7
MORF$_{src}$		MORF$_{tgt}$	47.4	50.8
FC$_{src}$		FC$_{tgt}$	47.2	50.6
LMVR$_{src}$		LMVR$_{tgt}$	48.3	51.7
LMVR$_{joint}$		LMVR$_{joint}$	48.8	52.5
LMVR$_{src/egy}$	LMVR$_{tgt}$	LMVR$_{tgt}$	**48.9**	**52.9**
LMVR$_{src}$	LMVR$_{tgt}$	LMVR$_{tgt}$	48.8	**52.9**
LMVR$_{src/egy}$	LMVR$_{src}$	LMVR$_{tgt}$	48.5	52.0
Frequency-based Segmenters				
BPE$_{joint}$		BPE$_{joint}$	**50.1**	**53.7**
BPE$_{joint}$		raw	47.4	50.8

Supervised Morphology-based Segmenters				
MDMR$_{ATB}$	raw	raw	**48.8**	**52.1**
MDMR$_{D3}$	raw	raw	47.9	51.1
Combination Segmenters				
MDMR$_{ATB}$+BPE$_{joint}$	BPE$_{joint}$	raw	46.5	50.1
MDMR$_{ATB}$+BPE$_{joint}$	BPE$_{joint}$	BPE$_{joint}$	**50.2**	**53.8**
MDMR$_{D3}$+BPE$_{joint}$	BPE$_{joint}$	raw	46.9	50.7
MDMR$_{D3}$+BPE$_{joint}$	BPE$_{joint}$	BPE$_{joint}$	49.8	53.3

Table 4: The chrF2 results of our NMT systems with different segmentation combinations on *ArzEn*'s dev and test sets. Numbers highlighted in bold show the best performing system in each category.

For the **supervised morphology-based segmentations**, we only follow one approach and that is segmenting the source side using MDMR$_{ATB}$ or MDMR$_{D3}$ segmenters. This causes the English words to be left unsegmented.

For the **unsupervised frequency-based segmentations**, we exploit the jointly trained model, BPE$_{joint}$, to segment the source side only, target side only, or both sides of the parallel corpus.

Finally, inspired by the work of Oudah et al. (2019), we explore **combinations** between BPE and supervised morphology-based segmenters. As shown in Table 4, for the source side, we apply BPE$_{joint}$ on top of segmentations provided by either MDMR$_{ATB}$ or MDMR$_{D3}$. For the target side, we either leave it in the raw format or apply BPE$_{joint}$.

5.3 Machine Translation Results

Table 4 shows the different MT systems and their performance on *ArzEn*'s dev and test sets.

Amongst the **unsupervised morphology-based segmenters**, LMVR outperforms the other segmenters. We find that training language-specific

---

[3] FLORES hyperparameters outperform Vaswani et al. (2017) for our code-switched pair by +0.4 chrF2 points.

[4] We use sacreBLEU's (Post, 2018) implementation of chrF2.

segmenters (using LMVR$_{src/egy}$ for Arabic words and LMVR$_{tgt}$ for English words) outperforms training the segmenter jointly (LMVR$_{joint}$). This setup gives the best performing model, referred to as MT$_{LMVR}$.

Amongst the **supervised morphology-based segmenters**, the setup with MDMR$_{ATB}$ is the best, which we refer to as MT$_{ATB}$. The finding is consistent with Oudah et al. (2019)'s results.

For **unsupervised frequency-based segmenters**, using BPE$_{joint}$ to segment both source and target sides outperforms MT$_{LMVR}$ by +0.8 chrF2 points and MT$_{ATB}$ by +1.6 chrF2 points, which we refer to as MT$_{BPE}$. We observe that the ranking of these segmenters in MT performance is in reverse order compared to their ranking in segmentation task performance. We discuss this later in Section 6.

Most interestingly, contrary to (Oudah et al., 2019), we find that applying BPE$_{joint}$ on top of MDMR$_{ATB}$, which we refer to as MT$_{ATB+BPE}$, slightly improves over MT$_{BPE}$ but without statistical significance. However, MT$_{ATB+BPE}$ outperforms MT$_{ATB}$ and MT$_{LMVR}$ with statistical significance.[5] We further investigate the effectiveness and statistical significance achieved by this approach in a learning curve with varying the training data size in Section 5.4.

Finally, we note that segmenting English words on the source and target sides consistently, while controlling all other conditions, is always advantageous, as shown in Table 4.

5.4 Analysis

We further analyze the performance of the top MT systems from each segmentation setup (MT$_{ATB+BPE}$, MT$_{BPE}$, MT$_{LMVR}$, and MT$_{ATB}$). We first look into the number of Out-of-Vocabulary (OOV) tokens associated with each of the top-performing MT systems to examine whether it has an impact on their final ranking. Secondly, we investigate whether the ranking of the systems is consistent across the different types of sentences. We evaluate the systems against varying morphological richness, English percentages, and CS types. Thirdly, we further investigate the effectiveness of applying BPE over ATB compared to using each segmenter on its own. We conduct this analysis across different CS types and sizes of training data.

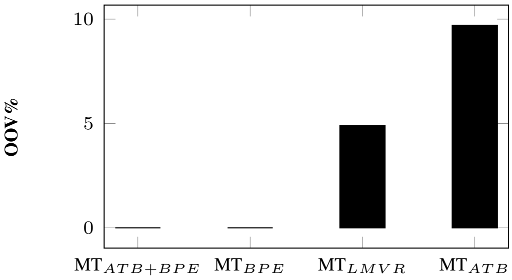

Figure 3: The percentage of the OOV words generated from each of the top-performing MT systems from each segmentation setup on *ArzEn*'s dev set.

OOV To further study the reason behind MT$_{BPE}$ and MT$_{ATB+BPE}$ top performance, we observe if the top-performing MT systems' ranking is linked with the percentage of OOV in the different MT systems. As shown in Figure 3, we find that for MT$_{ATB+BPE}$ and MT$_{BPE}$, the OOV percentage is 0%. However, for MT$_{LMVR}$ and MT$_{ATB}$, the percentage rises to 4.90% and 9.70%, respectively, which we believe contributes to worsening the MT systems.

Evaluating Systems Under Different Sentence Categories We evaluate the performance of the MT systems for sentences falling under different ranges of (i) morphological richness, (ii) percentage of CS English words, and (iii) sentence CS types. Morphological richness of a sentence is calculated as the quotient of the number of tokens in the segmented sentence and unsegmented original sentence. As expected, the performance of all the MT models decreases as the morphological richness increases and there is a boost in performance across all systems when the percentage of English words increases (see Appendix E). We observe that the MT$_{ATB+BPE}$ and MT$_{BPE}$ perform the best across all ranges for the first two features. We then evaluate the performance of the MT systems across sentences according to CS types: purely monolingual Arabic, CS, and CS having MCS (Hamed et al., 2022a; Mager et al., 2019). We observe that for all systems, the performance across CS sentences is higher than across monolingual Arabic sentences. We also observe that among CS sentences, the performance is reduced in the case of morphologically code-switched sentences. We believe that the following two factors can be contributing to these results. Firstly, the complex MCS

---

[5] We use Paired Significance Tests for Multi System Evaluation provided by SacreBLEU for the significance tests https://github.com/mjpost/sacrebleu#paired-bootstrap-resampling---paired-bs.

constructions might impose challenges to the MT system. Secondly, we observe that the average length of MCS sentences is higher than that of CS sentences in general. This is partially due to the fact that the tokens in MCS words are space-separated during the data preprocessing step. We report that on average, CS sentences contain 21.1 words (21.4 tokens), while MCS sentences contain 25.0 words (26.3 tokens).

Further Investigating the Effectiveness of MT$_{ATB+BPE}$ over MT$_{BPE}$ and MT$_{ATB}$ We study whether the ranking of MT$_{ATB+BPE}$, MT$_{BPE}$, and MT$_{ATB}$ is altered when going from a low-resource to an extreme low-resource setting across different sentence types. We achieve this by varying the MT training data to 25% and 50% of its original size. The results are shown in Table 5.

We observe that the effectiveness of the MT$_{ATB+BPE}$ varies under constrained conditions. For monolingual Arabic sentences, when training the MT systems on 100% of data, we see that MT$_{ATB+BPE}$ is not statistically significant over MT$_{BPE}$ and MT$_{ATB}$. Moreover, MT$_{ATB+BPE}$ was outperformed by MT$_{BPE}$. However, when training with 25% and 50% of data, MT$_{ATB+BPE}$ outperforms MT$_{BPE}$ and MT$_{ATB}$ with statistical significance across all sentence types. We further exhibit this in Figure 4 when all sentence categories are considered during analysis under different data sizes. This finding highlights the importance of combining morphology-based and frequency-based segmentations in extremely low-resource scenarios.

We also observe that across all data sizes, MT$_{ATB}$ performs the worst on CS sentences. Our first hypothesis is that this is due to English words left unsegmented. However, results in Table 3 contradict this hypothesis. Our second hypothesis is that since MDMR$_{ATB}$ takes into consideration the context of the word prior to segmentation, the English words in the CS sentences might break the flow of the sentence, hence negatively impacting the context of the word, thus worsening the score.

System Selection As per our findings, MT$_{ATB+BPE}$ is always the best choice across all sentence types in extreme low-resource settings. However, when training on 100% of the data, MT$_{BPE}$ improves slightly over MT$_{ATB+BPE}$ on monolingual Arabic sentences. Therefore, we create a system selection setup which uses both, MT$_{ATB+BPE}$ and MT$_{BPE}$, to investigate if it would lead to further improvements. In this setup, the CS and monolingual English sentences are translated using MT$_{ATB+BPE}$, while monolingual Arabic sentences are translated using MT$_{BPE}$. Despite the hybrid system showing an overall improvement of +0.1 chrF2 points over MT$_{ATB+BPE}$, the improvement is not statistically significant.

Size	MT System	All	EGY	CS	MCS
25%	**MT$_{ATB+BPE}$**	**39.8 (1)**	**36.6 (1)**	**40.6 (1)**	**40.0 (1)**
	MT$_{BPE}$	38.4 (2)	35.6 (3)	39.1 (2)	38.5 (2)
	MT$_{ATB}$	36.9 (3)	35.9 (2)	37.0 (3)	36.0 (3)
50%	**MT$_{ATB+BPE}$**	**45.9 (1)**	**42.1 (1)**	**46.8 (1)**	**46.4 (1)**
	MT$_{BPE}$	44.5 (2)	40.7 (3)	45.5 (2)	44.8 (2)
	MT$_{ATB}$	44.0 (3)	41.4 (2)	44.7 (3)	44.0 (3)
100%	**MT$_{ATB+BPE}$**	**50.2 (1)**	44.4 (2)	**51.5 (1)**	**51.3 (1)**
	MT$_{BPE}$	50.1 (2)	**44.6 (1)**	51.3 (2)	51.1 (2)
	MT$_{ATB}$	48.8 (3)	44.2 (3)	49.8 (3)	49.4 (3)

Table 5: We compare the results of the best performing MT system (MT$_{ATB+BPE}$) which utilizes BPE on top of ATB segmentation against the MT systems that utilize BPE (MT$_{BPE}$) or ATB (MT$_{ATB}$) only on *ArzEn*'s dev set. We report chrF2 results when training on 25%, 50%, and 100% of the training data. Results are shown for different types of sentences: monolingual Egyptian Arabic (EGY), code-switched (CS), and morphologically code-switched (MCS), as well as all sentences (All). The ranking of the MT systems with respect to each other is represented by the numbers between parentheses, where (1) is the best rank and (3) is the worst.

6 Discussion

We revisit the RQs we outlined in our introduction.

RQ1 - Which segmentation setup performs the best in the downstream MT task across different training sizes? Results show that frequency-based segmentation applied on top of morphology-based segmentation outperforms the other segmentation techniques, with statistical significance on lower resource settings. The superiority of this approach is seen across sentences with varying morphological richness, percentage of English words, and across sentences with different CS types. We believe the strength of the combination is because it exploits complementarity of both methods. On one hand, supervised morphology-based segmenters bring in high correctness; however, they are not always robust, having high OOV rates. On the other hand, while BPE segmentation is not necessarily morphologically correct, it achieves high robustness. The robustness of BPE is consistent with the findings in Banerjee and Bhattacharyya (2018).

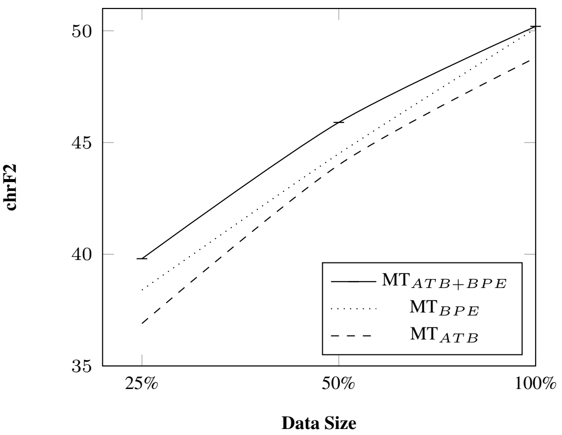

Figure 4: Demonstrates the effectiveness of applying BPE on top of ATB segmentation ($MT_{ATB+BPE}$) as opposed to using either approaches separately (MT_{BPE} and MT_{ATB}), which is confirmed when reducing the amount of training data. Results are reported on *ArzEn*'s dev set.

RQ2 - Does the effectiveness of the different segmenters in the MT task differ according to the CS type of the source sentence? We observe that the effectiveness of the different segmenters on MT performance is consistent across two categories of CS sentences; those with and without MCS. However, when comparing their effectiveness on monolingual Arabic vs. CS sentences, we observe that the rankings between segmenters are not consistent. In the case of constrained data size settings (25% and 50% of data), we observe a clear pattern where MT_{ATB} outperforms MT_{BPE} on monolingual sentences, while MT_{BPE} outperforms MT_{ATB} on CS. In the case of using 100% of the training data, $MT_{ATB+BPE}$ outperforms MT_{BPE} on CS sentences; however, MT_{BPE} outperforms $MT_{ATB+BPE}$ on monolingual Arabic sentences. Since our test and dev sets are dominated by CS sentences (61.5% and 63.8%, respectively), we believe that the overall ranking is more greatly affected by the systems' performance on CS sentences, thus reflecting the same ranking on the overall evaluation set as that across CS sentences.

RQ3 - Is there a correlation between a more morphologically correct segmentation and MT performance? For unsupervised morphology-based segmenters, a segmenter with a better segmentation EMMA F1 score also scores better in the downstream MT task. However, we cannot hypothesize that a better segmentation score implies a better translation system, as counter examples exist. For example, while we notice that $MDMR_{ATB}$ gives the best segmentation in terms of EMMA F1 score, it does not outperform any of the top-performing MT systems. We hypothesize that despite $MDMR_{ATB}$'s capability of generating morphologically correct segmentations, it can generate infrequent morphemes due to the out-of-domain data which it is trained on. This may not only increase the sentence length which worsens MT performance as shown in Mager et al. (2022), but may also be one of the contributing factors to the 9.70% OOV percentage found in MT_{ATB}. On the contrary, BPE_{joint} performs the worst in the segmentation task as we expect, since it is designated for agnostic-based segmentations; however, it surpasses the top-performing MT models. We believe this is due to its capability to generate semi-correct segmentation and to reduce OOV rates.

7 Conclusion and Future Work

In this paper, we study the impact of a comprehensive set of morphological and frequency-based segmentation methods on MT, where the source is a code-switched text. The experiments are performed on code-switched Arabic-English to English. We found that the supervised morphological segmenter achieved the best performance on the segmentation task, followed by unsupervised morphological methods, and finally, unsupervised frequency-based. Afterward, we train 18 different MT systems with different source and target side segmentations. We find that the rank of the segmenters is reversed, as BPE's could not be outperformed (significantly) by any morphological-inspired segmentation method. However, combining morphology-based and frequency-based segmentations has shown to give improvements, which are statistically significant in lower resource settings, where the training data size is reduced to 25% and 50%. For future work, we plan to apply our different MT setups on other low resource and code-switched language pairs. Specifically, we plan to explore languages with different typologies, to study whether or not the relation between the data size and choice of the segmentation setup (frequency-based, morphology-based, or a mix) is based on morphological features and data size rather than the language itself. Moreover, we plan to extend our annotated dataset, *ArzEnSEG*, by adding further details to allow evaluating different schemes.

Limitations

The first challenge we face in this work is the computational power needed to tune the Morfessor family segmenters. Therefore, in an attempt to overcome this challenge, for the Morfessor family, the choice of the optimal hyperparameters is dependent on the parent tool. For instance, the optimal hyperparameters for Morfessor are directly used in its FlatCat variant and the hyperparameters specific to FlatCat are then tuned. The same applies for LMVR which is a variant of FlatCat. Moreover, we cannot verify whether or not our results will hold for languages with different typologies, specifically those that are low resource and code-switched. Therefore, the results of this research must be seen in light of these limitations.

Ethics Statement

We could not find any potential harm that might derive from this work. However, we understand that translation as a whole can impact the cultural and social life of the people that use it. This has been used in the past in a harmful way, i.e., to spread colonial views (Mbuwayesango, 2018). Therefore, we call the final user to use this work ethically. Regarding the annotation process, all manual annotations were made by a subset of the authors of this paper. Therefore, no hiring of external workers was necessary.

Acknowledgements

We want to thank all the anonymous reviewers for their helpful comments and suggestions. This project has benefited from financial support to Marwa Gaser and Manuel Mager by the DAAD (German Academic Exchange Service).

A Data Preprocessing

We use the same preprocessing pipeline for all the corpora, where we start by removing any corpus-related annotations. Afterward, we remove URLs and emoticons, through *tweet-preprocessor*,[6] remove trailing and leading spaces, and tokenize numbers. Finally, *Moses Tokenizer*[7] is applied for tokenization and empty lines are removed from the parallel corpora. For LDC2017T07 (Chen et al., 2017) and LDC2019T01 (Chen et al., 2019), some sentences have literal and intended translations for some words. Hence, we opt for one translation having all literal translations and another having all intended translations. Once all the preprocessing steps are done, we concatenate the nine corpora collectively and pass the resulting training corpus to MADAMIRA (Pasha et al., 2014) to obtain two different supervised morphological segmentations of the corpus, namely `ATB_BWFORM` and `D3_BWFORM` which we discuss in Section 4.2. Additionally, we obtain a raw training corpus by further tokenizing punctuation and removing emojis using MADAMIRA's D0 scheme (Zalmout and Habash, 2017). Nonetheless, we normalize the Arabic letters ى and أ to ي and ا respectively through CAMeL Tools (Obeid et al., 2020) since D0's output is not normalized.

B Segmenters' Hyperparameters

Morfessor family Since all Morfessor family segmenters are morphology inspired, the hyperparameters are tuned on *ArzEnSEG*'s dev set. For LMVR$_{src}$ and LMVR$_{tgt}$ setting the vocabulary sizes to $64k$ and $16k$ respectively outperform $3k$, $5k$, $8k$, $16k$, $32k$, $100k$. For LMVR$_{joint}$ setting the vocabulary size to $32k$ outperforms $3k$, $5k$, $8k$, $16k$, $64k$, and $100k$. Meanwhile, For LMVR$_{src/egy}$ setting the vocabulary size to $64k$ outperforms $3k$, $5k$, $8k$, $16k$, $32k$, and $100k$.

Table 6 shows the possible values used during the optimal hyperparameter search for each Morfessor tool. For Morfessor, FlatCat, and LMVR 18, 360, and 7 different segmentation models are generated. These are a result of the combination of the possible hyperparameter values. The hyperparameter combination which yields the highest EMMA score on *ArzEnSEG*'s dev set for each Morfessor tool is used to segment the MT training data. The best combination values are reported in Table 7.

Segmenters Hyperparameters	
Hyperparameter	**Values Bound**
Morfessor	
-F	[0.003, 0.005, 0.007]
-d	[log, ones, none]
-a	[recursive, viterbi]
FlatCat	
-p	[50, 60, 70, 80, 90, 100, 200, 300]
–min-perplexity-length	[1, 2, 3, 4, 5]
–min-shift-remainder	[1, 2, 3]
–length-threshold	[2, 3, 4]
LMVR	
–lexicon-size	[3k, 5k, 8k, 16k, 32k, 64k, 100k]

Table 6: The values bound we use during the best hyperparameter combination search for the Morfessor tools.

MorphAGram Akin to the Morfessor family, we tune the hyperparameters on *ArzEnSEG*'s dev set and train two models: one on the source side and the other on the target side of the training parallel corpus which we refer to as MorphA$_{src}$ and MorphA$_{tgt}$, respectively (see Figure 2). Tuning results show that setting the vocabulary size to $3k$ for MorphA$_{src}$ outperforms $5k$, $8k$, $16k$, $32k$, and $50k$, while setting the vocabulary size to $50k$ for MorphA$_{tgt}$ outperforms $5k$, $3k$, $8k$, $16k$, and $32k$. Nevertheless, it is worth noting that the vocabulary size on the target side is $< 50k$ which shows that MorphA$_{tgt}$ performs the best when no segmentations are applied on the English words.

BPE Since BPE is a segmentation technique that is designated for agnostic segmentation for MT tasks, we tune the vocabulary size on *ArzEn*'s dev set in an NMT task. We apply a vocabulary size of $8k$, which outperforms $5k, 16k, 32k, 64k$.

C Segmenters Performance Analysis

Table 8 shows the error analysis we perform on the segmenters with regards to over segmentation, under segmentation, or generating the correct number of segmentations per word.

D MT Hyperparameters

The MT hyperparameters are shown in Table 9. We follow the FLORES hyperparameters for low-resource language pairs. The full train command can be found on FLORES GitHub.[8] The training

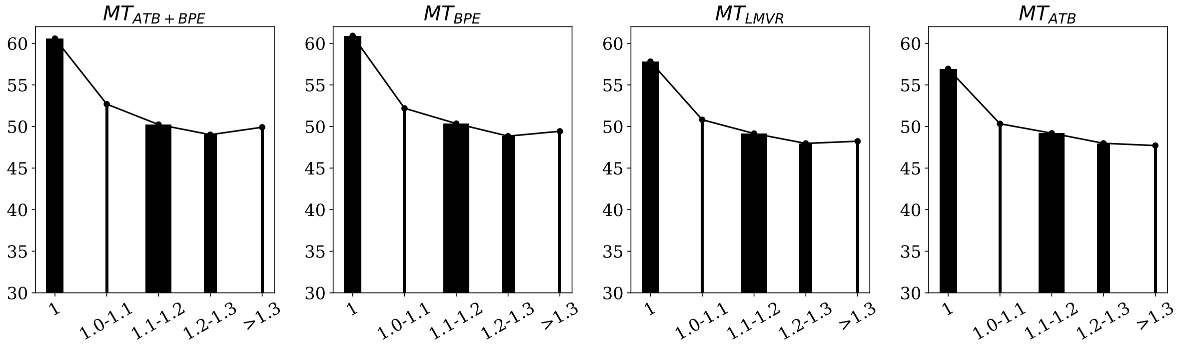
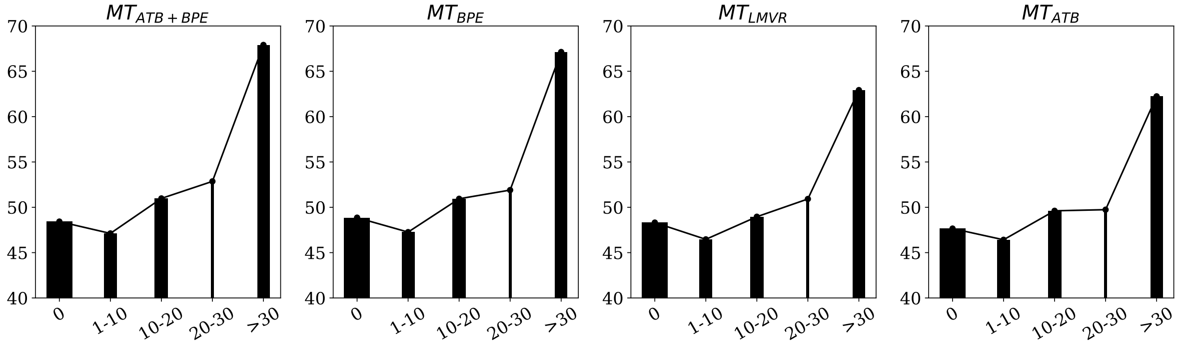
E Evaluating Systems Under Different Sentence Categories

Figure 5 shows the performance of the top MT systems from each segmentation setup across sentences of different morphological richness ratios and different percentages of English words in *ArzEn*'s dev set. Results show that there is a general decrease in performance as the morphological richness increases. However, as the percentage of English words in the sentences increases, the performance of the systems generally improves. It is also shown that MT$_{ATB+BPE}$ and MT$_{BPE}$ achieve overall comparable performances and outperform the other systems.



(a) Morphological Richness



(b) % English Words

Figure 5: The average chrF2 scores for the top performing MT systems from each segmentation setup across sentences with various (a) morphological richness ratios and (b) percentage of English words in *ArzEn*'s dev set. Morphological richness of a sentence is calculated as the quotient of the number of tokens in the segmented sentence and unsegmented original sentence. The bar width is indicative of the number of sentences in each bin.

Identifying the limits of transformers when performing model-checking with natural language

Tharindu Madusanka and **Ian Pratt-hartmann** and **Riza theresa Batista-navarro**
Department of Computer Science
The University of Manchester

Abstract

Can transformers learn to comprehend logical semantics in natural language? Although many strands of work on natural language inference have focussed on transformer models' ability to perform reasoning on text, the above question has not been answered adequately. This is primarily because the logical problems that have been studied in the context of natural language inference have their computational complexity vary with the logical and grammatical constructs within the sentences. As such, it is difficult to access whether the difference in accuracy is due to logical semantics or the difference in computational complexity. A problem that is much suited to address this issue is that of the model-checking problem, whose computational complexity remains constant (for fragments derived from first-order logic). However, the model-checking problem remains untouched in natural language inference research. Thus, we investigated the problem of model-checking with natural language to adequately answer the question of how the logical semantics of natural language affects transformers' performance [1]. Our results imply that the language fragment has a significant impact on the performance of transformer models. Furthermore, we hypothesise that a transformer model can at least partially understand the logical semantics in natural language but can not completely learn the rules governing the model-checking algorithm.

1 Introduction

Recent years have seen a surge of interest in the application of neural networks to the topic of natural language inference (Raffel et al., 2019; Lan et al., 2020; Yang et al., 2019), the central task of which is to recover information entailed by, but not explicitly stated in natural language texts (Lin et al., 2019; Sinha et al., 2019; Geiger et al., 2018; Wang et al., 2021). This problem is of theoretical (as well as practical) interest because the ability to understand the logical consequences of natural language sentences is an essential part of what it is to understand the grammatical constructions and closed-class expressions they contain. More specifically, the ability of neural network models to recognize logical entailments is constitutive of their ability to understand the texts they are processing.

It is important to distinguish two strands of work in this area. The first focuses on *entailment* as defined by human-constructed datasets (Bowman et al., 2015; Williams et al., 2018), where the inferences depend on implicit background knowledge and have a probabilistic character. The second focuses on the recognition of formal logical entailments, for which data sets can be machine-generated using existing symbolic reasoning techniques (Richardson et al., 2020; Richardson and Sabharwal, 2021; Geiger et al., 2018). This latter strand of work is particularly pertinent to the theoretical problem of whether neural network models can learn the logical semantics of natural language. Commonsense knowledge, human judgement and considerations of plausibility are consciously excluded.

A logical problem of great theoretical interest that has not been studied in the context of natural language inference is the model-checking problem: given a formula ϕ and a structure $\mathfrak{A}$, determine whether ϕ is true in $\mathfrak{A}$ ($\mathfrak{A} \models \psi$). The ability to perform model-checking is indicative of a grasp of the logical semantics of the expressions concerned. In the context of natural language inference, we are particularly interested in a variant of the model-checking problem where the structure and the formula are interpreted in natural language. It is noteworthy to emphasise how the model-checking problem differs from other inference problems. In other logical reasoning problems such as satisfiability, computational complexity varies among multiple

</table>

Figure 1: An instance of the model-checking problem, the domain of the structure is represented in $\mathcal{D}$, and predicates are characterised by $\mathcal{P}$. A formula can be valid or not according to the structure *(the formula on the left is valid, while the one on the right is invalid).* Corresponding natural language representations for both the structure and the formula are also presented.

computational complexity classes (NLogSpace to NExpTime for fragments considered in this study) in language fragments of the finite variable space (Pratt-Hartmann and Third, 2006; Pratt-Hartmann, 2010). In contrast, in the model checking problem, the computational complexity remains in PTime for any fragment in the finite variable space (given they are derived from first-order logic). Furthermore, inference in the model-checking problem is fairly straightforward, which has also been evident by low computational complexity. Hence, the model-checking problem provides an ideal problem to analyse how different logically significant words and grammatical constructs (semantics of logic in natural language) affect transformers' ability to reason, as the underlying computational complexity remains in PTime.

Figure 1 depicts an instance of the model-checking problem, where the sentence *"Some actors love every scholar"* is *True* according to the structure presented, as the assignment of *"Hailee"* to the variable x makes the corresponding formula ($\exists x(actor(x) \wedge \forall y(scholar(y) \Rightarrow love(x,y)))$) $True$. However, when assessing the sentence *"All actors who are happy are scholars"*, there is no assignment that makes the formula ($\forall x((actor(x) \wedge happy(x)) \Rightarrow scholar(x))$) $True$ according to the structure (the set of *actors* who are *musicians* is {*Hailee*}, which is not a subset of *scholars'*, namely {*Alan, Tony*}).

In our analysis of transformers' capabilities in the model-checking problem, we ask two fundamental questions, *(1) can transformers perform model-checking with natural language? (2) if so, can transformers understand the logical semantics of natural language: i.e. can transformers comprehend the semantics of distinctively logical words and grammatical concepts such as determiners, relative clauses and anaphora?* To answer the above-mentioned questions, we construct a model-checking dataset ($\mathcal{FO}^2$*-MC* dataset) utilising language fragments. Unlike the work by Richardson and Sabharwal (2021) and Geiger et al. (2018), whose work was limited to only one language fragment, we explore a varied set of fragments. The consideration of linguistic complexity of language fragments led us to ask an additional question: *How does the linguistic complexity of the fragment affect the performance of the transformer model when performing model-checking with natural language?*

The contributions of this paper are as follows: (1) To the best of our knowledge, we are the first to broaden natural language reasoning over formal theories to include model-checking with natural language; (2) We develop a novel algorithm for constructing a dataset for model-checking with natural language; (3) We investigate whether transformers can learn to understand the logical semantics of natural language; (4) In a first-of-its-kind study in rule reasoning, we include complex fragments such as anaphora and relative clauses with transitive verbs; and (5) We provide a systematic analysis of how the linguistic complexity of language fragments affects rule reasoning.

2 Related Work

Our work follows the literature on evaluating neural approaches, especially transformer models on deductive and linguistic reasoning tasks (Richardson and Sabharwal, 2021; Richardson et al., 2020; Sinha et al., 2019; Geiger et al., 2018; McCoy et al., 2019; Betz et al., 2021). Moreover, it is also related to other research approaches that have been conducted on data synthesis for rule reasoning problems (Lin et al., 2019; Weston et al., 2016; Tafjord et al., 2019). However, our study is distinct from the above-mentioned work in two ways. Firstly, we focus on an unexplored problem space, model-checking with natural language. Secondly, unlike the above literature, we explore multiple language fragments and provide a deconstruction of how the linguistic complexity of language fragments affects the performance of transformer models in a rule reasoning task.

Our work can also be viewed as broadening the research conducted on training neural networks to perform algorithmic tasks, including learning to solve SAT problems (Selsam et al., 2019; Narodytska et al., 2020), propositional inference (Evans et al., 2018), semantic parsing (He and Choi, 2020; Kamath and Das, 2019), symbolic integration (Lample and Charton, 2020) and natural theorem proving (Weber et al., 2019; Minervini et al., 2020; Saha et al., 2020; Gontier et al., 2020). In our study, we aim to investigate the transformers' ability to emulate the algorithm governing the model-checking problem and comprehend the logical semantics of natural language.

When defining language fragments, we follow the definition set out by Pratt-Hartmann (Pratt-Hartmann, 2003, 2004; Pratt-Hartmann and Third, 2006; Pratt-Hartmann and Moss, 2009), who described it more precisely as a subset of a language equipped with semantics that translates sentences into a formal system such as first-order logic. Moreover we employ their work on fragments of first-order logic as the foundation when constructing the dataset. Notably, Pratt-Hartmann (2004) has investigated the complexity of fragments' first-order logic, and we limit our analysis in this paper to fragments that have been examined in that study. Moreover, we also closely follow the cognitive science literature on model-checking and quantifier verification (McMillan et al., 2005; Szymanik et al., 2013; Szymanik and Zajenkowski, 2010) when defining our experimental evaluation. It provides us with a baseline to compare results from transformer models with the empirical studies that have been conducted with humans.

3 Data Construction

To decide whether transformer models can learn to understand logical semantics of natural language from formulae (sentences) and structures represented in natural language, we developed an algorithm (shown in Algorithm 1) to construct a balanced dataset designed to be free from trivial linguistic patterns that are easily exploitable. This section will outline the data construction methodology in detail.

We sample a set of words (Proper nouns *PrN*, nouns *N*, verbs *Vb*, adjectives *Adj*) from a predefined vocabulary ($\mathcal{V}'$) to form a list of words $\mathcal{V}$. The proper nouns in $\mathcal{V}$ are used to define the domain $\mathcal{D}$ of the structure, while the nouns, verbs and adjectives are used for defining the set of predicates $\mathcal{P}$.

When generating sentences, we follow a template-based approach. A language template is a sentence of natural language with open-clause words replaced by schematic variables; for example, *Some N_1 V is every N_2*. Through substitution of vocabulary items of the appropriate category, we can generate natural language sentences, i.e., *Some artists admire every doctor*. A simple way of defining a fragment of natural language (language fragment) is via a finite set of template sentences. For example, the classical syllogistic fragment can be defined as the sentences confirming the sentence schemata, *All N_1 are N_2, Some N_1 is N_2, No N_1 are N_2* and *Some N_1 are not N_2*. The formula template is a formula of first-order logic with non-logical symbols replaced by schematic variables; for example, $\exists x(N_1(x) \wedge \forall N_2(B(y) \Rightarrow V(x, y)))$. An instance of that formula is the result of the substitution of non-logical symbols of the appropriate type for the schematic variables, i.e., $\exists x(artist(x) \wedge \forall y(doctor(y) \Rightarrow admire(x, y)))$. A language template translates to schematic formulae in a natural way. For example, the classical syllogistic translates to the schematic formulae $\forall x(N_1(x) \Rightarrow \pm N_2(x))$ and $\exists x(N_1(x) \wedge \pm N_2(x))$.

Let $\Phi_{\mathcal{L}}$ denote the set of first-order formula templates that can be translated to natural language templates $\mathcal{L}$. Given a language fragment $\mathcal{L}$ and a vocabulary $\mathcal{V}$, we can obtain a set of formulae $\Phi_{\mathcal{L}}(\mathcal{V})$, such that $\Phi_{\mathcal{L}}(\mathcal{V})$ is a fragment of first-order logic over the vocabulary $\mathcal{V}$, i.e., $\Phi_{\mathcal{L}}(\mathcal{V})$ only contains the vocabulary $\mathcal{V}$. The first-order formula ϕ is selected from the $\Phi_{\mathcal{L}}(\mathcal{V})$, and then the formula ϕ is translated to a natural language sentence s_ϕ using a template $\mathcal{L}$. A summary of the language fragments we used in our evaluation is provided in the next section.

Algorithm 1 Data Construction - Model-Checking with Natural Language

```
**Input :** Language Fragment $\mathcal{L}$ and its corresponding set of first order logic formulae templates $\Phi_{\mathcal{L}}$ along with its equivalent natural language templates $\mathcal{T}_{\mathcal{L}}$. Vocabulary $\mathcal{V}$ that contains Nouns(N), Adjectives(Adj), Verbs(Vb) and Proper nouns(PrN). Template $\mathcal{T}$ to convert structure to natural language. Maximum number of domain elements per datapoint $n$, and maximum number of predicates $m$
**Output :** Model-checking dataset $\mathcal{D}$

1: $D \leftarrow \{\}$
2: repeat
3:     $\mathcal{V} \leftarrow$ randomly select list of words where $\mathcal{V} \subset \mathcal{V}'$ such that $|\{PrN\}| \leq n$ and $|\{N \cup Adj \cup Vb\}| \leq m$
4:     $\phi \leftarrow$ randomly generate first order formula using the set of first-order logic formulae $\Phi_{\mathcal{L}}(\mathcal{V})$
5:     $s_\phi \leftarrow$ converts $\phi$ to a natural language sentence using the template $\mathcal{L}$
6:     $\ell \leftarrow$ randomly generate $\ell$ where $\ell \in \{True, False\}$
7:     $\mathcal{D} \leftarrow \{PrN\}$, $\mathcal{P} \leftarrow \{N \cup Adj \cup Vb\}$
8:     repeat
9:         $\mathfrak{A} \leftarrow$ generate structure randomly using the signature (vocabulary) $\mathcal{V}$
10:        if $(\ell = True$ and $\mathfrak{A} \models \phi)$ or $(\ell = False$ and $\mathfrak{A} \not\models \phi)$ then
11:            correct-structure-found $\leftarrow True$
12:        end if
13:    until correct-structure-found
14:    $\mathcal{M}_{\mathfrak{A}} \leftarrow$ converts $\mathfrak{A}$ to a natural language using a template $\mathcal{T}$
15:    D $\leftarrow$ D $\cup \{\mathcal{M}_{\mathfrak{A}}, s_\phi, \ell\}$
16: until stop condition is met
```

The label ℓ is selected randomly from the set $\{True, False\}$. Once ℓ and ϕ are defined, the structure $\mathfrak{A} = (\mathcal{D}, \{\mathcal{P}\}^{\mathfrak{A}})$ is generated, where $\mathcal{D}$ is the domain and $\mathcal{P}$ is the set of predicates and $\{\mathcal{P}\}^{\mathfrak{A}}$ represents an interpretation of $\mathcal{P}$ in $\mathfrak{A}$ and the signature of the structure is $\mathcal{V}$. Assignment of each domain element to the $\mathcal{P}$ in the structure $\mathfrak{A}$ is done randomly, such that for every domain element d_i in $\mathcal{D}$ and predicate $\mathcal{P}_i$, $prob(d_i \text{ assign to } \mathcal{P}_i) = p_1$ if $\mathcal{P}_i$ is a unary predicate, and for every domain element d_i, d_j in $\mathcal{D}$ and predicate $\mathcal{P}_i$, $prob((d_i, d_j) \text{ assign to } \mathcal{P}_i) = p_2$ if $\mathcal{P}_i$ is a binary predicate. In our experimentation, we select $p_1 = 0.5$ and $p_2 = 0.75^2$, so that for each predicate $\mathcal{P}_i$, $|\mathcal{P}_i^{\mathfrak{A}}|$ is a normal distribution with a mean of approximately $\frac{|\mathcal{D}|}{2}$, so the loop (in line 8-13) terminates within a reasonable time. We iteratively build structures randomly, and perform model-checking using a model-checker until a structure that meets the criteria defined by the label is found; i.e. if $\ell = True$, then the formula is $True$ according to the structure, $\mathfrak{A} \models \phi$ and vice-versa. Once such structure is identified, it is converted into a paragraph in natural language, $\mathcal{M}_{\mathfrak{A}}$ using a template $\mathcal{T}$.

Another way to create a data point would be to generate $\mathfrak{A}$ and ϕ and perform the validity check using a model-checker to acquire the label as opposed to pre-defining the label and iteratively constructing $\mathfrak{A}$ to match the label. However, such an approach can introduce easily exploitable linguistic patterns such as having the label $False$ for most sentences containing determiners *all*, *every* or *no*, or having label $True$ for sentences containing determiners *some* or *a*.

When constructing sentences, we make sure each predicate only appears once within a sentence. So sentences like *every artist is an artist* would not be generated. Furthermore, we also remove cases where no elements are assigned to a predicate P_i and perform re-balancing, since they also introduced easily exploitable patterns. For example, the sentence *"every musician who is a actor is happy"* is trivially $True$ if there are no *musicians* or *actors*.

3.1 Language fragments

A language fragment is defined as a language that is equipped with semantics that translates its sentences to a formal system, such as first-order logic. We defined our language fragments based on the work of Pratt-Hartmann (2004). Table 1 shows the language fragments used, along with an example for each fragment and the corresponding first-order formula. As indicated in the data construction algorithm, we employ a template-based approach when implementing both language fragments and their formal method representations. We limit our evaluations to fragments of first-order logic and bound

Language Fragment	Example
Syllogistic	Every musician is a artist $\forall x(musician(x) \Rightarrow artist(x))$
Relational syllogistic (Re-Syl)	All teachers remember some engineer $\forall x(artist(x) \Rightarrow \exists y(engineer(y) \wedge remember(x, y)))$
Relative clauses without transitive verbs (Rel)	All economists who are not happy are cynics $\forall x((economist(x) \wedge \neg happy(x) \Rightarrow cynic(x))$
Relative clauses with transitive verbs (Rel-TV)	No cynic like any scholar who is a expert $\forall x(cynic(x) \Rightarrow \forall y((scholar(y) \wedge cynic(y)) \Rightarrow \neg like(x, y)))$
Anaphora	Some judge warns no juror who hate him $\exists x(judge(x) \wedge \forall y((juror(y) \wedge hate(y, x)) \Rightarrow \neg warn(x, y)))$

Table 1: Language fragments we utilised along with an example for each of them and its corresponding first-order logic formula.

the number of functions within a formula to have a maximum of four. We also limit the maximum number of quantifiers per formula to two, producing only unary or binary formulae. The rationale is to have natural sounding sentences. As outlined in the description of the template structure provided in **Appendix A: Templates of Language Fragments**, to address the ambiguity that can arise with anaphora or relative clauses, we bind the anaphora or relative clauses to the same element. For example, anaphora always refer to the first noun in the sentence. Even though we limit our data construction and evaluation to only these fragments, we emphasise that the data construction methodology and experimental evaluation we have conducted can be executed with any arbitrary fragment of natural language.

3.2 Boolean Coordinators

One interesting experiment is to evaluate how transformer models perform when Boolean coordinators are introduced to the sentences. To that end, we used Boolean coordinators ($\bigwedge(and), \bigvee(or)$) to combine sentences and create more difficult problem instances. The resultant first-order formula Ψ of such sentences can be formed by combining individual first-order formulae using either $\bigwedge$ or $\bigvee$. Model-checking is then performed on Ψ (is $\mathfrak{A} \models \Psi$ or $\mathfrak{A} \not\models \Psi$?), and the condition in Algorithm 1 *(line 11)* is modified accordingly.

The natural language sentences are combined accordingly using the coordinating conjunctions *and* or *or*. We did not consider the case where *and* as well as *or* are present in the final sentence, since the order of operations cannot be enforced in natural language settings and hence would be ambiguous. We evaluated transformer models varying the number of coordinators *k*, where $k = \{0, 1, 2\}$, to investigate how incorporating Boolean coordinators affect the accuracy.

4 Experimental Setup

In this section, we describe the experiments we conducted in order to address our research questions.

4.1 Problem definition

Formally the $\mathcal{FO}^2$-*MC* dataset can be defined as $\{(p^{(d)}, \ell^{(d)})\}_d^{|D|}$ where $p^{(d)}$ is an instance of the model-checking problem (concatenation of the structure $\mathcal{M}_{\mathfrak{A}}$ and sentence s_ϕ delimited by a separator *SEP* token), and $\ell \in \{True, False\}$ is the label. The task is to correctly predict the label ℓ, thereby reducing it to a binary classification problem.

4.2 Transformer models

To investigate the capabilities of transformers in model-checking with natural language, we performed experiments on the $\mathcal{FO}^2$-*MC* dataset using three prominent transformer architectures: BERT, RoBERTa and T5.

BERT. Bidirectional Encoder Representations from Transformers or BERT (Devlin et al., 2018) use bi-directional conditioning in all of its network's layers to consider both the left and right context. BERT has become the standard transformer architecture and has been evaluated against many NLI datasets (Richardson et al., 2020; McCoy et al., 2019), hence we believe it provides a baseline for assessing the complexity of the task and difficulty of the $\mathcal{FO}^2$-*MC* dataset. We used the `BERT-base` `(uncased)` model with around 110M parameters.

RoBERTa. Robustly Optimized BERT Pretraining Approach or RoBERTa (Liu et al., 2019) is based on the BERT architecture but trained in a more optimised manner. It has been used for rule reasoning tasks such as RuleTaker (Clark et al., 2021), and is considered as another baseline model in our experiments. We made use of the `RoBERTa-base` model which has around 125M parameters.

T5. Following the work done by Tafjord et al. (2021) and Richardson and Sabharwal (2021) on rule reasoning, we primarily centre our experiments around Text-to-Text Transfer Transformer or T5 models (Raffel et al., 2019). T5 frames all NLP tasks (e.g., classification, translation, semantic textual similarity) into a unified text-to-text format where both input and output are always strings; this is slightly different from BERT and RoBERTa which, when fine-tuned on classification tasks, output a class label. In our experiments, we employed two T5 models: `T5-base` with approximately 220M parameters and `T5-large` with approximately 700M parameters.

In experimenting with each of the three types of models above, we utilised the Huggingface library (Wolf et al., 2019). The transformer models are fine-tuned to predict the target label ($True$ or $False$) by optimising for the binary cross-entropy loss over the targets using the Adam optimiser (Kingma and Ba, 2015). Since the dataset is balanced (i.e., both training and test data have approximately an equal number of samples labelled as $True$ and $False$), we made use of accuracy as our evaluation metric.

4.3 Proposed Dataset and Evaluation

To answer the question of whether transformers can perform model-checking with natural language, we trained transformer models, namely, T5, BERT and RoBERTa, using the $\mathcal{FO}^2$-*MC* dataset in the manner mentioned above. During data construction, we incorporated the same vocabulary as Richardson and Sabharwal (2021), with the addition of transitive verbs where the number of verbs is equivalent to the number of adjectives. The vocabulary contains approximately 2000 names (proper nouns), 156 nouns, 64 adjectives and 65 verbs. The names are used as the domain elements while nouns, adjectives and verbs form predicates, whereas verbs constitute binary predicates while the nouns and adjectives form unary predicates. Furthermore, when generating the model, we limited the number of domain elements to be less than 4 ($|\mathcal{D}| \leq 4$) and the number of predicates to be less than 8 ($|\mathcal{P}| \leq 8$). We trained transformer models using training instances that include sentences that belong to language fragments we introduced in Section 3.1, i.e., syllogistic, relational syllogistic (Re-Syl), relative clauses (Rel), relative clauses with transitive verbs (Rel-TV) and anaphora. In each case (for each language fragment), models were trained with 500K unique data points and evaluated against a held-out 100K test set (see Table 2). Moreover, we experimented with training the models (`T5-base` and `T5-large`) using a dataset that contains sentences belonging to all the fragments, so that we could investigate how simpler fragments help transformers understand the logical semantics of natural language of complex ones (see Table 3). The training set in this experiment comprises 500K unique data points with approximately 100K data points belonging to each language fragment. The results of this experiment, along with the results depicted in Table 2, also provide the answer to the question of how the linguistic complexity of the language fragment affects the performance of transformers in model-checking with natural language. To better understand model generalisation and scale invariance, we evaluated the transformer model (`T5-large`) on a held-out evaluation set whose structure contains more domain elements (see Table 4) or more predicates (see Table 5) than that of the training set. To comprehend how Boolean coordinators affect the accuracy of transformer models across different language fragments, we also trained and evaluated with data points whose sentences have Boolean coordinators in them.

4.4 Results and discussion

Transformer models can solve model-checking with natural language problems with satisfactory accuracy, given adequate training instances, as depicted in Table 2. For all language fragments, transformers manage to yield an accuracy of over 70%. It is also evident from Table 2 that there is no significant difference in performance between the considered transformer models.

The linguistic complexity of the language fragments that generate the sentence has a significant impact on the overall performance, as il-

Model	Syllogistic	Re-Syl	Rel	Rel-TV	anaphora
T5-base	99.9	76.6	95.0	73.6	70.3
BERT-base	99.0	78.2	90.7	75.6	73.9
RoBERTa-base	99.6	79.2	90.1	72.1	71.0

Table 2: Accuracy of transformer models (BERT, T5 and RoBERTa) across different language fragments.

Model	All	Syllogistic	Re-Syl	Rel	Rel-TV	anaphora
T5-base	75.9	80.0	76.7	74.8	74.2	73.6
T5-large	88.2	99.8	81.8	99.3	82.3	77.7

Table 3: The transformers are trained using a dataset that contains sentences belonging to all language fragments. The results are broken down into respective language fragments, and *All* indicates the overall (average) accuracy across the language fragments.

Language Fragment	$\lvert\mathcal{D}\rvert$	$\lvert\mathcal{D}\rvert$+1	$\lvert\mathcal{D}\rvert$+2	$\lvert\mathcal{D}\rvert$+4
Syllogistic	99.8	92.2	87.5	76.1
Re-Syl	81.8	67.6	63.2	55.6
Rel	99.3	90.4	84.2	73.3
Rel-TV	82.3	67.3	62.1	56.4
anaphora	77.7	65.0	61.1	49.9

Table 4: The accuracy of the `T5-large` model evaluated on out-of-scope data; the training instances have a maximum of 4 domain elements $\lvert\mathcal{D}\rvert \leq 4$ while the evaluation set contains 5 ($\lvert\mathcal{D}\rvert + 1$), 6 ($\lvert\mathcal{D}\rvert + 2$), 8 ($\lvert\mathcal{D}\rvert + 4$) domain elements, the number of predicates remains the same between train and evaluation sets.

lustrated in Tables 2 and 3. Transformers achieve near-perfect performance for fragments such as syllogistic and Rel. However, they only achieve a moderate level of accuracy for fragments such as Re-Syl, Rel-TV, and anaphora. The later-mentioned fragments have transitive verbs, which results in the respective structures containing binary relationships. It is harder to learn binary relationships as opposed to unary ones. Furthermore, the sentences in the fragments Re-Syl, Rel-TV, and anaphora can have two quantifiers, while the sentences in fragments syllogistic and Rel are restricted to only one. As depicted in Table 6, the number of quantifiers in the sentence influences the performance of the transformer models in solving model-checking problems. Sentences with two quantifiers are more difficult to decode than sentences with only one quantifier, as evidenced by cognitive studies on quantifier verification (Szymanik and Zajenkowski, 2010; Szymanik et al., 2013), which is also unsurprising. There is a difference between the accuracy of single quantifier sentences and the average accuracy of the syllogistic fragment and Rel fragment. This difference is due to single quantifier sentences belonging to other fragments, whose sentences include transitive verbs. According to the results in Table 6, only the number of quantifiers seems to affect the performance of the transformers, and not the exact quantifier used. Cognitive studies (Szymanik et al., 2013) suggest quantifiers themselves affect human performance on model-checking problems, which is not evident here, implying human reasoning on language is somewhat different to what is occurring in transformer models.

Another linguistic property that seems to affect the performance of transformers is Boolean coordinators. **The accuracy of transformer models decreases when Boolean coordinators are introduced to the sentences**, as illustrated in Table 7. The difference in performance when the number of coordinators changes from 0 to 1 is higher than that of when it is increased from 1 to 2. However, the number of Boolean coordinators has a lower effect on accuracy compared to other linguistic properties such as the number of quantifiers.

Learning the simple fragments enables transformers to learn complex ones, as depicted in Table 3. When training data contains sentences from all the language fragments, the performance of complex fragments such as anaphora is higher than if it only includes sentences of that respective fragment. Transformer models can learn to understand logically significant words such as determiners and grammatical constructs such as relative clauses more easily from simpler fragments than complex ones. So when learning the logical semantics of complex fragments, transformers can employ this knowledge. Hence, we can hy-

Language Fragment	$\lvert\mathcal{P}\rvert$	$\lvert\mathcal{P}\rvert$+1	$\lvert\mathcal{P}\rvert$+2	$\lvert\mathcal{P}\rvert$+4
Syllogistic	99.8	96.6	96.3	95.9
Re-Syl	81.8	80.4	80.4	80.3
Rel	99.3	99.1	99.1	98.9
Rel-TV	82.3	81.4	81.2	80.6
anaphora	77.7	76.9	76.6	76.6

Table 5: The accuracy of the `T5-large` model evaluated on out-of-scope data; the training instances have a maximum of 8 predicates $\lvert\mathcal{P}\rvert \leq 8$ while the evaluation set contains 9 ($\lvert\mathcal{P}\rvert + 1$), 10 ($\lvert\mathcal{P}\rvert + 2$), 12 ($\lvert\mathcal{P}\rvert + 4$) predicates, the number of domain elements remains unchanged

number of quantifiers	quantifier (s)	Accuracy
one	overall	95.6
	$\forall$ (all)	95.8
	$\exists$ (some)	95.4
two	overall	80.8
	$\forall \circ \forall$ (all - all)	80.4
	$\forall \circ \exists$ (all - some)	81.8
	$\exists \circ \forall$ (some - all)	81.2
	$\exists \circ \exists$ some - some)	80.2

Table 6: The change in accuracy of the `T5-large` model across different quantifiers. The syllogistic and Rel fragments contain only one quantifier, while Re-Syl, Rel-TV, and anaphora fragments can have two quantifiers.

number of Boolean coordinators	Accuracy
$k = 0$	75.9
$k = 1$	70.7
$k = 2$	67.6

Table 7: The accuracy of the T5-base model when trained and evaluated against problem instances that have Boolean coordinators. k denotes the number of Boolean coordinators in a sentence. Each sentence contains only one type of coordinator (either *and* or *or*), if any.

pothesise that transformers at least partially learn to understand the essence of logical semantics of natural language. Table 3 also indicates a substantial difference in performance between the `T5-base` model and the `T5-large` model. The `T5-large` model achieves an overall accuracy of 88.2% but only manages to achieve an accuracy of around 80% (Re-Syl:81.8%, Rel-TV: 82.3%, anaphora: 77.7%) for language fragments with transitive verbs. This accuracy level is lower than the accuracy that transformer models yielded in other rule reasoning benchmarks such as RuleTaker (Clark et al., 2021) and NLSat (Richardson and Sabharwal, 2021), which suggests that the $\mathcal{FO}^2$-*MC* dataset is a formidable linguistic reasoning benchmark.

Transformer models exhibit limited generalisation and scale-invariance, as illustrated in Tables 4 and 5. Even if the number of predicates increases, the accuracy of the transformer model remains relatively unchanged (see Table 5). However, if the number of domain elements increases, the model performance drastically decreases (see Table 4). The reason could be that the attention mechanism in the transformer correctly identifies which areas in the structure to examine for a given sentence, but the transformer model still cannot emulate the model-checking algorithm properly. Moreover, the degradation in performance is relatively equivalent for all language fragments, suggesting that decrement is not correlated to the grammatical structure of the sentence. Hence, we can conjecture that transformers can learn to understand the logical semantics of natural language but still cannot learn to emulate the underlying model-checking algorithm.

5 Conclusion

We investigate the limits of transformers in an unexplored problem space of model-checking with natural language employing language fragments. We use five different language fragments and explore how linguistic complexity and other linguistic properties such as Boolean coordinators affect rule reasoning in transformer models. In a broader sense, our study is to determine whether transformer models can learn to understand the logical semantics of natural language and emulate the model-checking algorithm. We posit that transformers can learn logically significant words and grammatical constructs but fall short when learning the underlying algorithm. Moreover, different linguistic properties such as the language fragment, Boolean coordinators and the number of quantifiers have a notable impact on the learning ability of the transformers. Thus, an interesting future direction would be to investigate how these linguistic properties affect more complex reasoning tasks like natural language satisfiability.

6 Limitations

The results in our work closely follow the trends reported by prior work in the domain of identifying the limits of transformers in logical reasoning. Specifically, the transformers exhibit limited generalization beyond the underlying distribution in training data. However, due to the empirical nature of the study, it is not guaranteed that all other transformer-based models or other neural networks would exhibit the same pattern.

Moreover, the study focuses on several language fragments with varying linguistic complexity such that one would be able to quantify the influence of linguistic properties on a logical reasoning problem. However, the fragments considered in this study are not the only language fragments in existence and, as such, would limit the comprehensiveness of the discussion, and there could be other fragments of language which behave differently when evaluated against transformer models.

A Templates of Language Fragments

Tables 8, 9, 10, 11 and 12 contain templates for the syllogistic fragment, relational syllogistic fragment, relative clauses fragment (without transitive verbs), relative clauses (with transitive verbs), and anaphora respectively. Each table contains natural language templates that are employed to construct sentences and their corresponding first-order formulae. As mentioned in the methodology section, we build upon the vocabulary from Richardson and Sabharwal (2021). The set of determiners includes all, every, some, a and no, where every sentence type is converted to the most natural-sounding sentences; i.e. sentences such as *every artist does not like every beekeeper* would be translated into *no artists like any beekeeper*. Each sentence that is rendered using templates of the syllogistic fragment and relative clause (without transitive verbs) fragment would include exactly one quantifier, which would determine the determiner of the sentence. The templates of the relational syllogistic, relative clause (with transitive verbs) and anaphora could comprise either two quantifiers or one (if the sentence contains proper nouns, then it would have only one quantifier).

Sub-fragment	Natural Language Template	First order logic formula

Abstract

Conflict prediction in communication is integral to the design of virtual agents that support successful teamwork by providing timely assistance. The aim of our research is to analyze discourse to predict collaboration success. Unfortunately, resource scarcity is a problem that teamwork researchers commonly face since it is hard to gather a large number of training examples. To alleviate this problem, this paper introduces a multi-feature embedding (MFeEmb) that improves the generalizability of conflict prediction models trained on dialogue sequences. MFeEmb leverages textual, structural, and semantic information from the dialogues by incorporating lexical, dialogue acts, and sentiment features. The use of dialogue acts and sentiment features reduces performance loss from natural distribution shifts caused mainly by changes in vocabulary.

This paper demonstrates the performance of MFeEmb on domain adaptation problems in which the model is trained on discourse from one task domain and applied to predict team performance in a different domain. The generalizability of MFeEmb is quantified using the similarity measure proposed by Bontonou et al. (2021). Our results show that MFeEmb serves as an excellent domain-agnostic representation for meta-pretraining a few-shot model on collaborative multiparty dialogues.

1 Introduction

For many natural language processing applications, the ability to learn features that generalize well across multiple datasets is a key desideratum (Saikia et al., 2020). This paper introduces a new multi-feature embedding, MFeEmb, that increases the generalizability of models learned from collaborative multiparty dialogues. Dialogues are different from single-author documents in that, along with textual information, they contain communication patterns that may serve as indicators of social dynamics. Treating a dialogue as a mere text collection ignores valuable information. We advocate exploiting implicit features present in multiparty dialogues that are less vulnerable to distribution shifts resulting from task domain changes.

This paper demonstrates the usage of MFeEmb on a communication analysis task: conflict prediction. Teamwork research faces a challenge of resource scarcity since the human subjects datasets are quite small (less than 100 samples), due to the difficulty of recruiting teams and the time consuming nature of many group tasks. A variety of social phenomena have been investigated within team communication research, including entrainment (Rahimi and Litman, 2020) and emergent leadership (Maese et al., 2021). Frequency of communication is not in itself a good predictor of team performance, but a meta-analysis conducted by Marlow et al. (2018) that drew upon data from 150 studies conducted on 9702 teams concluded that high quality communication is positively related to team performance in many task domains. Conversely, process conflict, "disagreement among group members about the content of the tasks being performed, including differences in viewpoints, ideas, and opinions" (Jehn, 1995), is usually negatively correlated with taskwork success.

Our aim is to be able to learn a model to classify process conflict from multiparty dialogues that generalizes well across multiple tasks. We treat the task of conflict prediction as a binary classification task with high conflict and low conflict being the two classes; the ground truth used by the conflict prediction model is measured using a post-task team process conflict survey. This paper focuses on three collaborative problem-solving tasks: software engineering, search and rescue, and cooperative gameplay.

Our proposed embedding, MFeEmb, leverages textual, structural, and semantic information from the dialogues by incorporating vocabulary, dialogue acts, and sentiment features. Lexical embed-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3551–3565

dings such as word2Vec and BERT (Devlin et al., 2018) show good performance across multiple NLP tasks on in-domain test sets but are less robust to domain shift. Previous work identified that dialogue acts and sentiment sequences are informative features that predict conflict reliably even at the earliest stage of team problem-solving (Enayet and Sukthankar, 2021a); however, classifiers constructed using these features still experience lackluster transfer performance when applied to new datasets, particularly when detecting high conflict examples (Enayet and Sukthankar, 2021b).

To address this transfer problem, we propose the usage of MFeEmb, specifically as a meta-pretraining representation to be used within a few-shot model. MFeEmb combines the strengths of both domain-invariant and domain-specific features. This paper compares the generalizability potential of the MFeEmb embedding vs. standard word embeddings using inter-class and intra-class based similarity measures, proposed by Bontonou et al. (2021). Then we evaluate the performance of MFeEmb in a domain adaptation scenario in which the model is trained on discourse from one task domain and used to predict conflict in a different domain. Our results show that:

1. MFeEmb demonstrates superior generalizability over other embeddings for collaborative multiparty dialogues.
2. MFeEmb is an excellent representation choice for the meta-training stage of few-shot learning.
3. The domain adaptation performance of MFeEmb can be easily enhanced by task specific synonym replacement.

2 Related Work

Previous studies on group interaction tasks such as conflict prediction (Rahimi and Litman, 2020), disruptive talk detection (Park et al., 2022), group satisfaction (Lai and Murray, 2018), and task performance prediction (Kubasova et al., 2019; Murray and Oertel, 2018) have focused on simply improving performance on in-domain datasets. Very little attention has been paid to the problem of creating generalizable models for multiparty dialogue that can be used when training data is scarce. The intelligent tutoring system community has empirically assessed the generalizability of common natural language representations, such as BERT and Linguistic Inquiry Word Count (LIWC), across collaborative problem solving tasks (Pugh et al., 2022), but without investigating methods to improve generalizability.

In domain adaptation, the goal is to train a model on data from a source domain that performs well on a test dataset drawn from a different target distribution. Common NLP tasks (e.g., part-of-speech (POS) tagging and named entity recognition (NER)) have been tackled using techniques including instance weighting (Jiang and Zhai, 2007) or explicitly identifying feature correspondences between the domains (Blitzer et al., 2006). An alternate approach is to learn a single representation that generalizes well across multiple domains. This can be done using few-shot learning (Wang et al., 2020), one of the most widely used approaches to dealing with resource scarcity. The traditional framework comprises meta-training and meta-testing phases, where the aim of meta-training is to learn universal representations from multiple domains.

Triantafillou et al. (2021) introduced a method that improves few-shot generalizability by making use of multiple datasets in order to learn a universal template. Dvornik et al. (2020) proposed Selecting from Universal Representations (SUR), which involves learning a multi-domain representation by training multiple feature extractors. A multi-domain feature bank is used to select the most relevant feature during the learning phase. Rather than seeking to learn the new representation entirely from data, our research exploits similarities in dialogue act sequences and sentiment patterns commonly observed during successful collaborative problem-solving.

Representation choice has been shown to place an upper bound on target domain performance (Ben-David et al., 2006). Few-shot frameworks such as Meta-pretraining then Meta-Learning (MTM) (Deng et al., 2019) have assumed that word embeddings like BERT that are trained on large datasets are the best choice for task agnostic pre-training. Bontonou et al. (2021) introduced a method to quantify the generalizability of a few-shot classifier under supervised, unsupervised and semi-supervised settings. This paper uses their inter-class and intra-class based generalizability measure to evaluate MFeEmb vs. simple word-based embeddings under supervised classification scenarios. Our research demonstrates that MFeEmb is superior to word embeddings as a meta-pretraining representation.

3 Methodology

This section describes our approach to learning a generalizable embedding from multi-party dialogues for conflict prediction. We discuss our datasets, introduce our embedding, and show how our technique can be used in combination with data augmentation and few-shot learning.

3.1 Datasets

Datasets collected from different collaborative problem-solving task domains were used in our study of generalizability:

1. **Teams corpus** (Litman et al., 2016): This dataset consists of dialogues from 62 teams playing a cooperative board game in groups of three or four. Each team plays the game twice together. The Teams corpus was originally created to study entrainment, a linguistic phenomena in which teammates adopt similar speech patterns (Rahimi and Litman, 2020). The Game1 dataset of Teams corpus contains 62 dialogues, 32 low conflicts, and 30 high conflict dialogues. The Game2 dataset of Teams corpus contains 62 dialogues, 33 low conflicts, and 29 high conflict dialogues.
2. **ASIST dataset** (Huang et al., 2022): This dataset consists of 67 teams of three people participating in a simulated search and rescue task within the Minecraft game environment. Participants completed two different missions that involved searching a map and triaging victims. The dataset was collected by the ASIST project to stimulate the development of proactive assistant agents for helping human teams. The dataset contains 113 dialogues, 58 low conflicts, and 55 high conflict dialogues.
3. **GitHub social coding dataset** (Enayet and Sukthankar, 2020): This dataset was mined directly from the GitHub social coding platform. It consists of data from issue comments of teams developing open source software over a period of months. Teams vary in size, and comments were harvested for 50 reported issues. The dataset contains 50 dialogues, 29 low conflicts, and 21 high conflict dialogues.

Both the Teams and ASIST datasets contain post-task process conflict survey data for all teams, which we divide into high and low conflict groups using their z-scores. For GitHub, process conflict was scored according to an issue resolution rubric (described in Appendix G).

3.2 Multi-Feature Embedding (MFeEmb)

This paper introduces the MFeEmb embedding which is designed to capture the dialogues' structural, semantic, and textual information for collaborative task success prediction. To represent the structural information, we incorporate information from dialogue acts (DAs) of the utterances. For semantics, the sentiment polarities of the utterances are used, although DAs capture both semantic and structural information. Textual information is extracted from the vocabulary of the dialogues.

For the word embedding, we use both the Distributed Bag of Words and Dynamic Memory models of Doc2Vec (Le and Mikolov, 2014) to learn embeddings (see Appendix B). Although there is only 28% vocabulary overlap between the ASIST and Teams datasets and 35% overlap between the GitHub and Teams datasets, word embeddings can help preserve high performance on the in-domain dataset while including structural and semantic features makes the embedding more robust to domain shifts.

For the dialogue act (DA) embedding, we first map the sequence of utterances to a sequence of DAs using USE-DAC (Universal Sentence Encoder Dialogue Act Classifier, described in Appendix A). The SwDA-DAMSL tagset was used to categorize dialogue acts. The TextBlob python module was used to assign sentiment polarities ranging from -1 to 1 to each of the utterances.

To generate the embeddings, we use the Dynamic Memory model of Doc2Vec due to the small vocabulary size of the sequences, which is limited by the number of DA tags and sentiment gradations. The Dynamic Memory model leverages context when generating embeddings, thus preserving information contained in these communication patterns. In contrast, the Distributed Bag of Words model does not consider the context when generating embeddings. For the few-shot results, we also report results with pre-trained Word2Vec embeddings. First, we separately learn three embeddings from the sequence of DAs, sentiments, and utterances (text); the final MFeEmb embedding is created either by concatenating the three embeddings or by using LSTMs to learn a concatenation ensemble model. We have made our code available at `https://github.com/ayeshaEnayet/MFeEmb.git`.

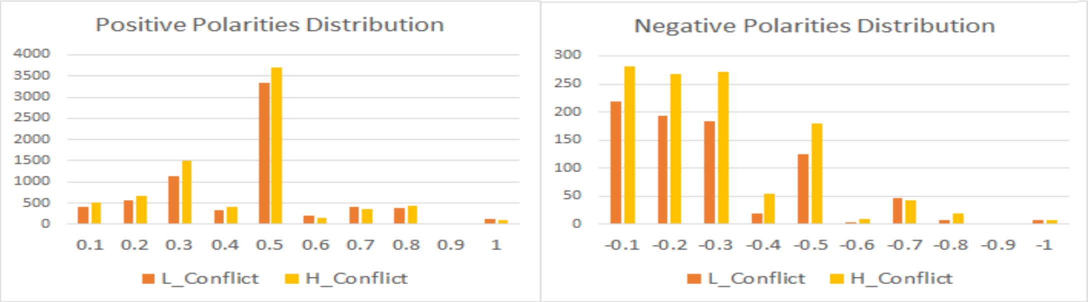

Figure 1: Sentiment polarity distribution of the high conflict vs. low conflict classes in the Teams dataset

3.3 Corpus-Based Feature Analysis

To understand the ramifications of our feature selections, we performed frequency distribution analyses across the high conflict and low conflict classes of the Teams Dataset. This analysis shows that the high conflict class has a high frequency of negative sentiment polarities compared to the low conflict class and a comparable frequency of positive sentiment polarities compared to the low conflict class (Figure 1).

In the dialogue act distribution, Statement-non-opinion (sd) is the most frequent tag in both classes. The low conflict class has a high frequency of positive communication indicators like Appreciation (ba), Conventional-closing (fc), and Thanking (ft) compared to the high conflict class. The high conflict class contains a high frequency of bad communication indicators like Uninterpretable (%), Hedge (h), Signal-non-understanding (br), and Apology (fa). Interestingly, high conflict classes have a high frequency of all categories of questions compared to low conflict classes (see dialogue act distributions and n-grams in Appendix H).

Looking at the vocabulary distribution, the high conflict class contains more profanity words than the low conflict class, and there is no overlap between the profanity word lists of both classes. Our analysis reveals that there is value in all three types of features (dialogue acts, sentiment polarity, and vocabulary) but that conflict prediction remains a challenging classification problem.

3.4 Synthetic Datasets

To further improve generalization, we augment our training data with synthetic datasets generated using synonym replacement, as proposed by Wei and Zou (2019). Our data augmentation strategies are described below:

1. **SynReplace**: We augment Teams Game1 and Game2 by replacing the words with synonyms drawn from WordNet.
2. **ASISTReplace**: We augment Teams Game1 and Game2 by replacing the words with only the synonyms present in the ASIST dataset. First, we extract the vocabulary of the ASIST dataset. During the replacement operation, we search for synonyms in WordNet and only replace them with the synonyms present in the ASIST dataset's vocabulary.
3. **GitReplace**: Similar to ASISTReplace, we generate our third dataset by replacing the words with only the synonyms present in the GitHub dataset.

Four synthetic dialogues are generated for each dialogue of the Teams dataset after applying random replacement on 10% of the words. Our intuition is that collaborative problem-solving domains such as software engineering may contain a lot of task specific jargon, and even simple synonym replacement techniques greatly facilitate generalization.

In our experiments, the basic synonym replacement did not significantly change the intent and sentiment of the utterances. To show the robustness of dialogue acts and sentiment sequences towards data augmentation, we utilize TextAttack (Morris et al., 2020), a python package for adversarial attack and data augmentation, to generate a Teams Game2 synthetic dataset. Word Swap by BERT-Masked LM transformation was employed to generate synthetic examples from the Teams Game2 dataset. One synthetic example is generated per dialogue of the Game2 dataset. The synthetic dataset contains $\approx 50\%$ more unique words than the original Game2 dataset (Figure 2). The hamming distance was used to calculate the difference between the sequences of the Game2 original and Game2 synthetic datasets. On average, the adversarial synthetic dataset only resulted in a 11% change in DA sequences and a 14% change in sentiment sequences (Appendix J).

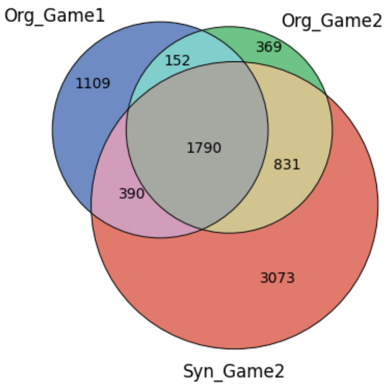

Figure 2: Vocabulary overlap between original Game1, original Game2, and the Game2 adversarially generated dataset

4 Experimental Setup

The Teams corpus contains 124 team dialogues from 62 different teams, playing two different collaborative board games. We use the Teams Game1 dataset with 62 total samples, divided into 32 low and 30 high conflict samples, as our training dataset. The small training dataset ensures that the experiments reflect the generalization performance under the resource scarcity scenario. Our test datasets for evaluating domain adaptation are Teams Game2, GitHub, and ASIST. Obviously, the domain shift is the smallest between the Teams Game 1 and 2 datasets. We use the GitHub and ASIST datasets to check the transferability of MFeEmb under domain shift. The model was not fine-tuned before evaluating the performance on GitHub and ASIST.

We evaluate our proposed MFeEmb under the following three experimental setups:

1. SVM and logistic regression classifiers to distinguish high conflict and low conflict classes.
2. LSTM concatenation ensemble.
3. Few-shot learning approach.

We benchmark MFeEmb against prior work on conflict prediction, other embedding choices, and FsText, a few-shot model proposed by Bailey and Chopra (2018). Experiments were performed using a 300-dimensional version of MFeEmb where the length of all the three embeddings is the same, i.e., 100. We report the mean and standard deviation of F1-Scores after 15 runs. For the SVM and logistic regression classification experiments, to improve the readability, we only report the best-performing classifier results measured by mean F1 score in Section 5; for the results of both classifiers, see Appendix K. ‘*’ denotes that logistic regression was the top performer, and ‘+’ denotes cases where the SVM was the best.

4.1 SVM and Logistic Regression

After Doc2Vec is used to generate the three embeddings for each sample, the embeddings are concatenated to create MFeEmb. We use both SVM and logistic regression to classify the instances and report the results of both classifiers. For DAs and sentiment sequences, we always use the Dynamic Memory model (DM) of Doc2Vec.

4.2 Few-Shot Learning (FsText)

For few-shot learning, we use the method proposed by Bailey and Chopra (2018) and available in the FsText Python module. The training document for the meta-training stage of few-shot learning is represented using a pre-trained word embedding (Word2Vec). In the case of more than one training sample per class, the proposed method works by averaging each class’s vectors to calculate the most effective class representative. Cosine similarity is used to measure the distance between the test sample and each class representative, and the test sample is assigned the label of the class with the highest similarity. We compare the generalizability of FsText (Original) with MFeEmb-based FsText, by replacing Word2Vec embedding with MFeEmb during the meta-training stage.

4.3 Concatenation Ensemble

Due to the small size of the training set, we apply the synonym replacement technique proposed by Wei and Zou (2019) to augment the training data as described in Section 3.4. One hot encoding is used to encode DA, sentiment polarities, and vocabulary to train the model. We train three different Bidirectional LSTM models, one on each of DAs, sentiments, and word-based documents, and merge them to create our MFeEmb based ensemble. Our Bidirectional LSTM models for each feature have an embedding layer, an LSTM layer, one dropout layer, and one deep layer.

4.4 Baseline Models

We compare our proposed MFeEmb’s results with several baseline models that use the same binary classification setup for conflict prediction. First, we show that MFeEmb performs competitively against prior work on conflict prediction (Enayet and Sukthankar, 2021a) using the proposed dialogue act only and sentiment only embeddings. Note that our results are not directly comparable to what was reported in the previous work because we use a reduced training set; thus, we reimplemented the embeddings. We also compare MFeEmb to the commonly used BERT based embedding (Appendix D).

These independent baselines are compared against three implementation options for MFeEmb: 1) MFeEmb with simple binary classifier (SVM or logistic regression), 2) MFeEmb concatenation ensemble learned with LSTMs (Sec. 4.3) trained on the synonym replaced augmented dataset, 3) a variation of few-shot learning method (FsText) (Bailey and Chopra, 2018) in which the Word2Vec embedding is replaced with MFeEmb during the meta-training stage. For training and testing, we concatenate all the utterances of the dialogue into one single document and assign it to one of the classes depending on the conflict score of the team.

5 Results

This section presents results on the generalizability of MFeEmb under different experimental setups.

5.1 Similarity Based Evaluation

First, we quantify the potential generalization of the representation using the similarity measure proposed by Bontonou et al. (2021). The similarity measure is given by:

$$intra(c) = \frac{1}{k(k-1)} \sum_{\substack{i \\ y_i=c}} \sum_{\substack{j\neq i \\ y_j=c}} \cos(f_i, f_j) \quad (1)$$

$$inter(c, \tilde{c}) = \frac{1}{k^2} \sum_{\substack{i \\ y_i=c}} \sum_{\substack{j\neq i \\ y_j=\tilde{c}}} \cos(f_i, f_j) \quad (2)$$

$$similarity = \frac{1}{N} \sum_{c=1}^{N} (intra(c) - \max_{c\neq\tilde{c}}(inter(c, \tilde{c}))) \quad (3)$$

where c is class, N is the number of classes, k is number of examples, f is the embedding, $intra(c)$ is cosine similarity within a class, and $inter(c, \tilde{c})$ is cosine similarity through classes c and $\tilde{c}$. The final similarity score reflects the comparison of the $intra(c)$ and $inter(c, \tilde{c})$. Intuitively it can be seen that the score measures how the representation affects the data clustering within and between classes.

We compare our proposed MFeEmb vs. a standard word embedding learned using the bag of word model of Doc2Vec. Table 1 gives the result of the similarity-based analysis juxtaposed with the classification results. MFeEmb has a better similarity score and high classification performance, compared to word-based embeddings indicating the high generalizability potential of MFeEmb.

The similarity score of MFeEmb accurately predicts higher classification accuracy. '*' denotes the logistic regression results, and '+' denotes the SVM results.

5.2 MFeEmb Performance Summary

Figure 3 provides the overall comparison of MFeEmb vs. the benchmark embeddings. In the case where minimal domain adaptation was required (testing classifiers on Teams2 that were trained on Teams1), the simple version of MFeEmb using a SVM classifier is the top performer and outperforms the embeddings used in other prior work on conflict prediction (Enayet and Sukthankar, 2021a). Our most consistent model, MFeEmb with FsText, had a significantly higher F1 score on the high conflict class compared to baseline models (see Table 2). Note that detecting the high conflict examples is more valuable for practical implementations.

For the more complex domain adaptation scenarios (GitHub and ASIST), the best performance was achieved using MFeEmb as a replacement for the Word2Vec embedding during the meta-training phase of FsText on GitHub, and the concatenation ensemble showed significantly better performance on the ASIST dataset. The vanilla MFeEmb generally performed comparably to the concatenation ensemble using LSTMs on out of domain datasets. The latter showed a high standard deviation compared to the former.

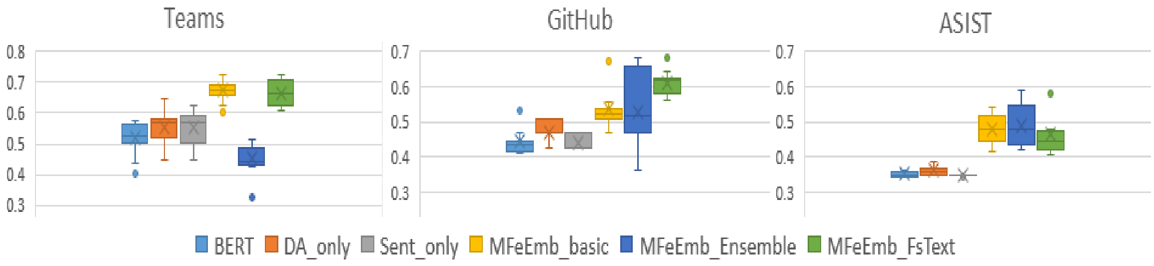

Figure 3: Performance of MFeEmb vs. other embedding choices from prior work.

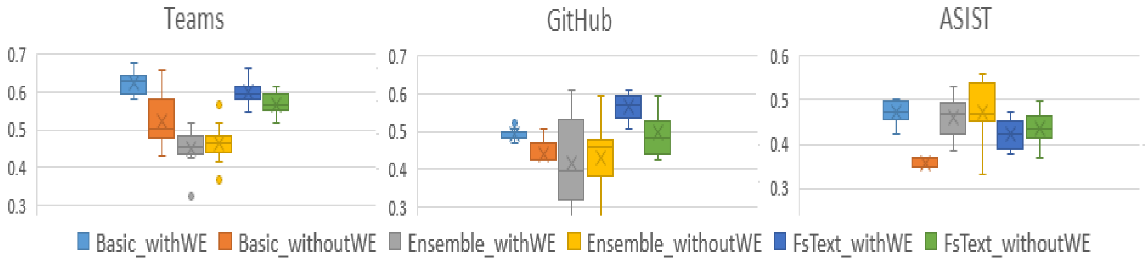

Figure 4: Performance of MFeEmb with and without word embedding (WE).

To analyze the importance of incorporating word embedding in MFeEmb, we compare the performance of all the experimental setups with and without word embedding (WE). For SVM & Logistic regression (Basic) and FsText, we train the model on the Teams Game1 dataset, and for the concatenation ensemble, we train on the synonym replaced dataset. One of our main objectives in incorporating the word embedding in MFeEmb is to maintain the performance on the in-domain dataset, and results show that MFeEmb performed better with word embedding on the in-domain dataset. For most transfer case setups, MFeEmb with word embedding either gave better or comparable mean F1 scores (Figure 4). The following sections present a more in-depth evaluation of each experimental setup.

High Conflict Class Prediction Summary		
Method	**GitHub**	**ASIST**
BERT_SynReplace	0.431	0.347
DA_only_Team1	0.320*	0.311*
Senti_only_Team1	0.207*	0.300*
MFeEmb_FsText_Team1	**0.564**	**0.478**

Table 2: Summary of high conflict class F1 scores. '*' denotes the logistic regression results, and '+' denotes the SVM results.

5.3 SVM and Logistic Regression

Table 3 gives the results for the SVM and logistic regression classifiers. This paper presents a thorough evaluation of the performance of different embedding choices (DM, DBOW). We also evaluate the performance of different data augmentation methods (**SynReplace**, **ASISTReplace**, and **GitReplace**).

Our proposed MFeEmb trained using Doc2Vec and classified using either SVM or logistic regression performed better than the word-embedding baseline. Leveraging synthetic datasets yielded significant performance improvements. In our most challenging resource-scarce scenario, where we trained the model only on the Teams Game1 dataset, incorporating word embedding showed better performance on the Teams Game2 and GitHub datasets, while the model performed better on the ASIST dataset without word embedding (see Figure 4).

5.4 Concatenation Ensemble Model

Table 3 gives the results for the LSTM-based concatenation ensemble model. The model showed a better mean F1-score than the text-based LSTM model. We also trained the LSTM using synthetic datasets generated using GitHub and ASIST vocabularies, which showed better performance, specifically with the GitHub vocabulary dataset. The model performed significantly better on the ASIST dataset compared to the other experimental setups.

Table 3: Detailed performance evaluation of MFeEmb. '*' denotes the logistic regression results, and '+' denotes the SVM results.

5.5 Few-Shot Model (FsText)

The FsText baseline showed the best performance on Game2, but the performance degraded considerably on the transfer task (GitHub and ASIST). FsText with the proposed MFeEmb exhibited significantly better performance on the GitHub and ASIST datasets, specifically with ASIST vocabulary's synthetic dataset. FsText with the proposed MFeEmb embedding also gave a comparable performance on the Teams Game2 dataset. This demonstrates that MFeEmb is an excellent representation for meta-pretraining a few-shot model on collaborative multiparty dialogues, even when learned from a small dataset (see Table 3).

Using a synthetic dataset showed a performance improvement in all three experimental setups. Generation of the synthetic dataset using the vocabulary of other collaborative tasks showed comparatively better performance on the transfer task. Even in the in-domain experiments, the Game1 Synthetic dataset, generated using collaborative task vocabulary, showed the best and comparable performance on Game2 in all the experimental setups.

6 Conclusion and Future Work

This paper introduces a multi-feature embedding (MFeEmb) to improve the generalizability of multiparty dialogue models under resource scarcity scenarios. We propose the use of a combination of textual (words), structural (DAs), and semantic (sentiment, DAs) embeddings to reduce the performance loss due to natural distribution shift. Experiments show that the multi-feature embedding performs significantly better than sentence (BERT), dialogue act-only, sentiment-only, and word embeddings. Our results demonstrate that MFeEmb is a superior representation for meta-pretraining a few-shot model that works well across different collaborative problem-solving domains.

Our proposed data augmentation strategy successfully resolved the domain shift problem caused by task-specific vocabulary without perturbing the dialogue act and sentiment features. Experiments with synthetic datasets show that synonym replacement with vocabulary drawn from a collaborative task outperforms generic synonym replacement with WordNet. It improves both the transfer accuracy and the test accuracy on the in-domain test set. Note that we did not fine-tune the models on the target datasets, i.e., GitHub and ASIST, and strictly report the model learned on the Teams dataset. Only the vocabulary of these datasets was used to boost the performance; explicit fine-tuning of the machine learning models could further improve the results.

7 Limitations

This paper only reports results on the generalizability of MFeEmb on conflict prediction tasks; MFeEmb may not perform as well on other communication analysis tasks. However, we believe that modifying the features used in the embedding can address this problem. In future work, we are interested in applying our embedding to new team communication analysis tasks such as identifying emergent leadership.

A Dialogue Act Classification

We use a dialogue act classifier (USE-DAC) to map dialogues to the sequence of DAs, where each DA in a sequence corresponds to the utterance of the dialogue. Utterances are tagged according to the SwDA-DAMSL tagset[1] which contains 42 tags, and one sequence is generated per dialogue. Our dialogue act classifier uses the Universal Sentence Encoder (USE) module available at TensorFlow Hub[2]. After extensive experiments, we identified that USE with three dense layers performs best on transfer tasks. We selected the USE Transformer-based Architecture model with three dense layers and a softmax activation function. We fine-tune USE on the SwDA dataset and use the classifier to tag the utterances of the test and training datasets. We selected the USE transformer-based model because it is itself trained on dialogue and discussion forum datasets. The test accuracy of the classification model is 72%.

B Doc2Vec

Doc2Vec (Le and Mikolov, 2014) is an unsupervised method to learn paragraph vectors from text of arbitrary size. We represent each dialogue as 1) sequence of utterances, 2) sequence of DAs, and 3) sentiment polarities. We pass these sequences through Doc2Vec to generate representations. We use the Doc2Vec implementation from the python Gensim library with an epoch size of 5, negative sampling 5, window size 5, and alpha 0.065.

C SVM & Logistic Regression

We use the classifier implementations from the scikit-learn library. The SVM was trained using the RBF kernel function and the default parameters. The parameters for logistic regression were: Cs=10, class_weight=None, cv=10, dual=False, fit_intercept=True, intercept_scaling=1.0, max_iter=1000, multi_class='ovr', n_jobs=None, penalty='l2', random_state=5434, refit=True, scoring='accuracy', solver='lbfgs', tol=0.001, verbose=False. Table 6 shows the full results of both the SVM and Logistic Regression classifiers.

D BERT Baseline

We use the bert_en_uncased_L12_H768_A12 model available at TensorFlow Hub[3] to develop our baseline classifier. The model contains one dense layer, one dropout layer, a sigmoid activation function, Adam optimizer. Due to the small size of the Game1 dataset we train the model on the synonym replaced Game1 dataset. The total number of parameters in the model is: 10,948,301.

E FsText

The original FsText works by using the pre-trained word2Vec embedding model word2vec-google-news-300 available through the gensim.downloader module. For MFeEmb we generate the embedding using Doc2Vec with the same parameters mentioned in Appendix B. The second phase uses a cosine similarity-based classification model that does not involve machine learning.

F Concatenation Ensemble

Our Bidirectional LSTM models for each feature has an embedding layer, an LSTM layer, one dropout layer, and one deep layer. The LSTM uses a sigmoid activation function and is trained using the Adam optimizer with a learning rate=0.01. The output shape of each individual model is (None, 100). The total number of parameters of the concatenation ensemble is: 2,365,081.

G GitHub Dataset Conflict Scoring

For GitHub, process conflict was scored according to issue resolution using the following heuristics to determine if conflicts occurred:

1. Unsuccessful resolution of the issue.
2. Unanswered questions in the discussion.
3. Lack of understanding about the issue from one or more members.
4. Lack of understanding or disagreement between the team members.
5. Disagreement between the members about the proposed solution.

H Dialogue Act Frequency Distribution Analysis

Figure 6 shows the frequency distribution for dialogue acts in the low conflict and high conflict classes of the Teams dataset. We divided the

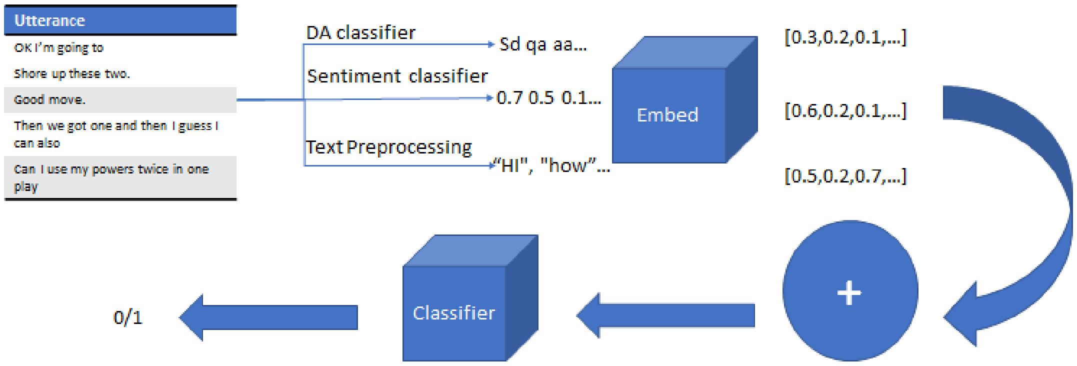

Figure 5: Utterances are classified using the dialogue act classifier to produce a sequence of DAs and the sentiment classifier to produce a time series of sentiment polarities. Along with the text data, these sequences are used to create MFeEmb using the Dynamic Memory model of Doc2Vec. The few shot learning and data augmentation options are not shown in the figure.

dialogue acts into good communication indicators, bad communication indicators and questions. Figure 7 shows the complete dialogue act frequency distribution. Table 4 shows the n-gram frequency distribution of dialogue acts across all datasets. Figure 8 visualizes the separation between low conflict and high conflict classes using both the MFeEmb and word embedding. To see if profanities were a reliable indication of conflict, we also examined profanity vocabulary differences. The most frequent words in the high conflict dialogues that are in profanity list are: ['hell', 'kill','suck','sucking','shit','strip','stroke', 'rectum','xxx','dick','screwed','retard', 'ovary','piss','lube', 'junkie'].

The most frequent words in the low conflict dialogues that are in the profanity list are: ['booty', 'pot','carpet', 'rum', 'breasts', 'pedophile', 'urine', 'thug', 'screw', 'jerk', 'weed', 'screwing', 'shower', 'stupid'].

I Synthetic Datasets

Synthetic datasets were generated using: https://github.com/jasonwei20/eda_nlp.

J Results on Adversarially Generated Dataset

This section presents results on the adversarially generated dataset (Synthetic Game 2) created using TextAttack[4]. Word Swap by BERT-Masked LM transformation was employed to generate synthetic examples from the Teams Game2 dataset. One synthetic example is generated per dialogue of the Game2 dataset. The length of the synthetic Game2 dataset vocabulary is 6084, and the length of the original Game1 dataset vocabulary is 3441. The number of words in the synthetic dataset that are not in the original Game1 is 3904.

Figure 2 shows a high overlap between original Game1 and original Game2 compared to synthetic Game2 and original Game1, but this does not affect the performance of MFeEmb (Basic), and MFeEmb. (Basic) gave a better performance on the synthetic dataset. On the other hand, the performance of the BERT baseline decreased on the synthetic Game2 test set, with a high standard deviation in mean F1 scores.

K SVM & Logistic Regression Results

Table 6, 7, 8 provides the detailed results of both the SVM and logistic regression classifiers under different experimental settings.

Abstract

The recent explosion of question-answering (QA) datasets and models has increased the interest in the generalization of models across multiple domains and formats by either training on multiple datasets or combining multiple models. Despite the promising results of multi-dataset models, some domains or QA formats may require specific architectures, and thus the adaptability of these models might be limited. In addition, current approaches for combining models disregard cues such as question-answer compatibility. In this work, we propose to combine expert agents with a novel, flexible, and training-efficient architecture that considers questions, answer predictions, and answer-prediction confidence scores to select the best answer among a list of answer predictions. Through quantitative and qualitative experiments, we show that our model i) creates a collaboration between agents that outperforms previous multi-agent and multi-dataset approaches, ii) is highly data-efficient to train, and iii) can be adapted to any QA format. We release our code and a dataset of answer predictions from expert agents for 16 QA datasets to foster future research of multi-agent systems[1].

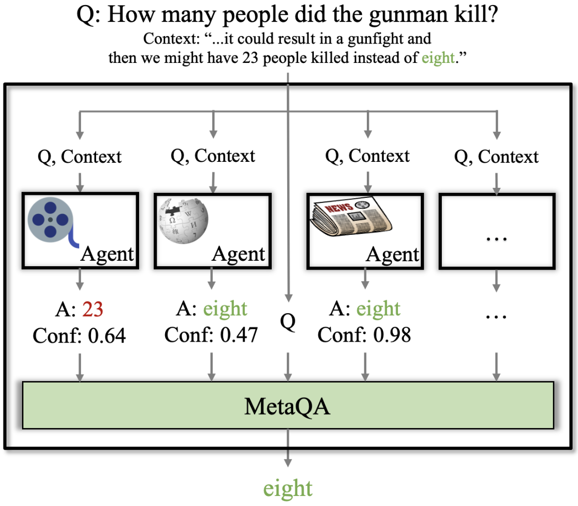

Figure 1: Given a question, each expert agent provides a prediction with a confidence score and MetaQA selects the best answer. Correct answers in green. Wrong answers in red.

1 Introduction

The large number of question answering (QA) datasets released in the past years has been accompanied by models specialized in them (Rogers et al., 2021; Dzendzik et al., 2021). These datasets and models differ by the domain (e.g., biomedical and Wikipedia), required skills (e.g., numerical and multi-hop), and format (e.g., extractive and multiple-choice). This variety of tasks and overspecialization of the corresponding models have led the community towards developing simple unified models that can generalize across domains and formats through unifying dataset formats (Khashabi et al., 2020), creating models trained on multiple datasets (Fisch et al., 2019; Talmor and Berant, 2019; Khashabi et al., 2020), and designing ensemble methods for QA agents (Geigle et al., 2021). All these research lines have a potential impact on end-user applications because generalization can help create robust systems and ease the implementation of QA models. For example, some chatbots are composed of skill systems, where each skill is a model trained on a specific domain (Miller et al., 2017; Burtsev et al., 2018). More abstractly, these research lines also share a central research question: *how to combine QA skills*.

We argue that a *one-size-fits-all* architecture may encounter some limitations in combining QA skills. For instance, Raffel et al. (2020) have observed that a single model trained on multiple tasks may underperform the same architecture trained on a single task. An alternative approach is to combine multiple expert agents. Geigle et al. (2021) propose a model that given a question and a list of datasets, selects the dataset from which the question comes.

This can be used to identify agents trained on a specific type of questions. However, despite achieving a classification accuracy greater than 90%, this approach underestimates high-performing models on out-of-domain questions.

To address the limitations of previous approaches, we propose a novel model, MetaQA, to combine heterogeneous expert agents (i.e., different architectures, formats, and tasks). It takes a question, and a list of *candidate answers* with *confidence scores* as input and selects the best answer (Figure 1). We modify the embedding mechanism of the Transformer encoder (Vaswani et al., 2017) to embed the confidence score of each candidate answer. In addition, we use a multi-task training objective that makes the model learn two complementary tasks: *selecting the best candidate answer* and *identifying agents trained on the domain of the input question*.

Our approach learns to match questions with answers, an immensely easier task than the end-to-end QA of multi-dataset models. This makes MetaQA remarkably data efficient as it only uses 16% of the training data of multi-dataset models.

We compile a list of 16 QA datasets that encompass different domains, formats, and reasoning skills to conduct experiments. Through quantitative experiments, we show that our MetaQA i) establishes a successful collaboration between agents, ii) outperforms multi-agent and multi-dataset models, iii) excels in minority domains, and iv) is highly efficient to train. Our contributions are:

- A new approach for multi-skill QA that establishes a collaboration between agents.
- A model called MetaQA that utilizes question, answer, and confidence scores to select the best candidate answer for a given question.
- Extensive analyses showing the successful collaboration between agents and the training efficiency of our approach.
- A dataset of (*QA Agents*, *Questions*, and *answer predictions*) triples that cover different QA formats, domains, and skills to foster future developments of multi-agent models.

2 Related Work

Currently, there are two approaches for multi-skill QA: multi-agent and multi-dataset models.

Multi-agent models consists of combining multiple expert agents. A well-known method is the Mixture of Experts. It requires training a set of models and combining their outputs with a gating mechanism (Jacobs et al., 1991). However, this approach would require jointly training multiple agents, which can be extremely expensive, and sharing a common output space to combine the agents. These limitations make it unfeasible to implement in our setup, where many heterogeneous agents are combined (i.e., agents with different architectures, target tasks, and output formats such as integers for multiple-choice or answer spans for span extraction). Inspired by topic classification, Geigle et al. (2021) proposed mapping questions to QA datasets (topics) to identify agents trained on that type of questions. Although related to us, their work does not attempt to achieve any agent collaboration. Moreover, because of their *topic-classification* approach, agents that are effective in out-of-domain questions are underestimated. Lastly, Friedman et al. (2021) average the weights of adapters (Houlsby et al., 2019) trained on single datasets to obtain a multi-dataset model. However, their architecture is limited to span extraction.

Multi-dataset models consist of training a model on various datasets to generalize it to multiple domains. Talmor and Berant (2019) conduct extensive analyses of the generalization of QA models. However, they only experiment on extractive tasks and, due to their model architecture (BERT for span extraction), it is not possible to extend it to other tasks such as abstractive or visual QA. Fisch et al. (2019) created a competition on QA generalization using 18 datasets. These datasets are from very different domains, such as Wikipedia and biomedicine, among others. However, they also focus only on extractive datasets. Lastly, Khashabi et al. (2020) shows that the different QA formats can complement each other to achieve a better generalization. They use an encoder-decoder architecture and transform the questions into a common format. However, we argue that their approach is limited because some questions may require a specific skill that must be modeled in a particular manner (e.g., numerical reasoning), and this is not possible with their simple encoder-decoder.

3 Model

We propose a new model, shown in Figure 2, to combine k QA agents m. Each agent m_i is trained

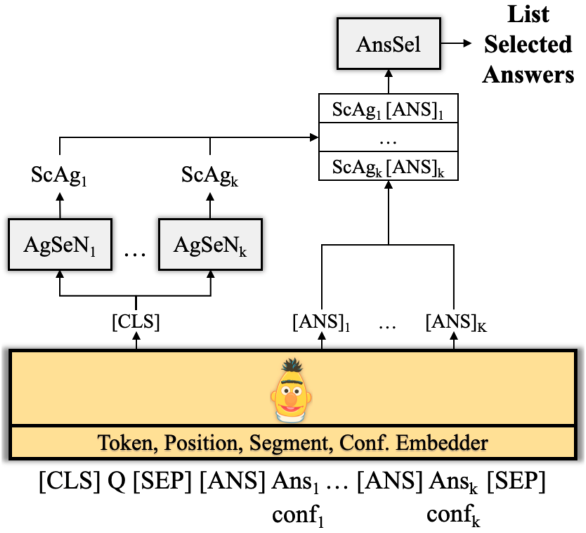

Figure 2: MetaQA architecture. The Agent Selection Network, AgSeN, assigns scores to each agent based on the similarity between the agent's training set domains and the question domain. Answer Selection, AnsSel, selects the correct answers. conf_k is the confidence score from the agent k for answer k.

on domain dom_i and predicts an answer Ans_i. Without loss of generalizability, we assume that each agent is trained on a different domain and each question belongs to one of these domains. We define two complementary tasks: i) *a priori* agent selection (Agent Selection Networks, AgSeN, in Figure 2) and ii) answer selection (AnsSel network in Figure 2). The division of the problem into these two learnable tasks is vital to ensure that MetaQA considers out-of-domain agents, which can also give correct answers. More formally, MetaQA computes the probability of returning an answer a as follows:

$$p(a|q) = \arg\max_i p_{\theta_1}(a_i|m_i, q) p_{\theta_2}(m_i|q) \quad (1)$$

where $p_{\theta_2}(m_i|q)$ is the *a priori* probability of selecting agent m_i and $p_{\theta_1}(a_i|m_i, q)$ is the probability of selecting the answer from agent m_i for the question q. In other words, θ_2 is the agent selection network, and θ_1 is the answer selection network.

To achieve this, the backbone of our architecture relies on an encoder Transformer (Vaswani et al., 2017) whose input is the concatenation of the question with the candidate answers from each agent. Each answer is separated by a new token `[ANS]` that informs the model of the beginning of a new answer candidate.

We devise a new embedding for the Transformer encoder to include the confidence score of the predictions of each agent (Figure 3). While the original encoder uses the token t_i, position p_i, and segment s_i embeddings, we add an agent confidence embedding c_i to these three.

$$x_i = t_i + p_i + s_i + c_i \quad (2)$$

The new c_i is obtained with a feed-forward network f that takes an answer confidence conf_i and creates an embedding c_i.

$$c_i = \begin{cases} f(\text{conf}_j), & \text{if } i \in Idx(\text{[ANS] Ans}_j) \\ f(0), & \text{otherwise} \end{cases} \quad (3)$$

where Idx is a function that given a list of tokens returns their indexes in the encoder input.

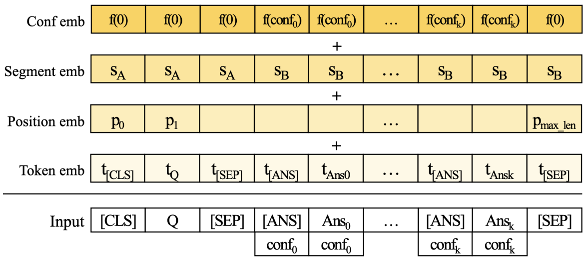

Figure 3: Description of our novel embedding system including confidence scores from the agents.

We leverage two types of embeddings from the output of the encoder. The first one is the embedding of the `[CLS]` token. This embedding captures information about the domain of the input question. It is used as the input to k independent feed-forward networks called *Agent Selection Network* (AgSeN) to identify the agent with the highest likelihood of giving a correct answer. This prediction is based on the similarity between the domain of the question and the domain of the training set of the agents. More specifically, it tries to identify the agent trained on the dataset from which the question comes in a similar way as TWEAC (Geigle et al., 2021). The second type of embedding used is the embedding of the `[ANS]` tokens, which contain the cues needed to identify the correct answers to the input question. These `[ANS]` embeddings are concatenated with the score of each corresponding agent $ScAg_i$ and input into a final feed-forward network, called *Answer Selection* (AnsSel), that selects the correct answers according to the score of their agents and the semantics of the candidate answers.

3.1 Training

As previously mentioned, our model learns two complementary tasks: i) *a priori* agent selection and ii) answer selection. Thus, to learn these two tasks, we define the following loss function:

$$\ell = \frac{\alpha_1}{k} \sum_{i=0}^{k} \ell_{AgSeN_i} + \alpha_2 \ell_{AnsSel} \quad (4)$$

$$\ell_{AnsSel} = \frac{1}{k} \sum_{i=0}^{k} CE(\hat{Ans_i}, y_i) \quad (5)$$

where ℓ_{AgSeN_i} is the loss of one AgSeN network and ℓ_{AnsSel} the loss of the AnsSel network. ℓ_{AnsSel} is the average of the cross-entropy loss CE of each answer prediction $\hat{Ans_i} = \{0, 1\}$. Lastly, AgSeN networks use the Binary Cross Entropy.

We obtain the labels of AnsSel, y_i, by comparing the string prediction of each agent with the correct answer. If the F1 score is higher than a threshold, θ, we consider the prediction as correct. As for AgSeN$_i$, its training label is 1 when the input question is from the training set of the i^{th} agent.

4 Experimental Setup

4.1 Datasets

We have collected a series of QA datasets covering different formats, domains, and reasoning skills. In particular, we use four formats: extractive, multiple-choice, abstractive, and multimodal.

For extractive, we use the MRQA 2019 shared task collection (Fisch et al., 2019), QAMR (Michael et al., 2018), and DuoRC (Saha et al., 2018). We include these two additional datasets to add more diversity. In detail, QAMR requires predicate-argument understanding, a skill that agents should have to solve most QA datasets. As for DuoRC, it is the only dataset in our collection on the film domain, and this allows us to study transfer learning from other domains. The multiple-choice datasets require boolean reasoning, commonsense, and passage summarization skills. Lastly, we include abstractive QA following (Khashabi et al., 2020) and a multimodal dataset to show that our approach can solve any type of question while multi-dataset models are limited to certain formats.

Most of these datasets do not have the labels of the test set publicly available, except for RACE and NarrativeQA. Since we need to do hyperparameter tuning and hypothesis testing to compare models, we divide the public dev set into an in-house dev set and test sets following (Joshi et al., 2020). Then, we conduct hyperparameter tuning on the dev set and hypothesis testing on the test set. A summary of the datasets is available in Appendix A.1.

4.2 Expert Agents

To guarantee a fair comparison with MultiQA, we have trained all the agents for extractive datasets using the same architecture as MultiQA, span-BERT, a BERT model pretrained for span extraction tasks that clearly outperforms BERT on the MRQA 2019 shared task (Joshi et al., 2020). More details on the implementation are provided in Appendix A.3. For the remaining datasets, we use agents that are publicly available on HuggingFace or Github with a performance close to the current state of the art. A summary of them is provided in Appendix A.2.

4.3 Baselines

We compare our approach with three types of models: i) multi-agent systems, ii) multi-dataset models, and iii) expert agents. The first family is represented by our main baseline, TWEAC, a model that maps questions to topics (or types of questions) to identify agents trained on that type of data (Geigle et al., 2021) and the simple max-voting ensemble. The second family of models is composed of MultiQA (Talmor and Berant, 2019) and UnifiedQA (Khashabi et al., 2020). MultiQA is a transformer encoder with a span-extraction layer trained on multiple extractive QA datasets. Because of this span-extraction layer, it can only solve extractive QA tasks. UnifiedQA, on the other hand, can solve any QA task that can be converted into text-to-text (i.e., extractive, abstractive, and multiple-choice) thanks to its architecture, an encoder-decoder transformer. Lastly, we include the expert agents to analyze whether MetaQA closes the gap to them compared to the baselines.

4.4 Evaluation

Since MetaQA may select more than one answer, we select the answer with the highest confidence score by MetaQA as the decision of the model to evaluate it. We evaluate our model and the baselines using the official metrics of each dataset, i.e., macro-average F1 for extractive, accuracy for multiple-choice, and rouge-L for abstractive. In the particular case of DROP, the official metric is macro-average F1, and thus, we also use it. The

Table 1: MetaQA (ours) and the baselines on the test set of each dataset. Best results in bold. † represents that MetaQA is statistically significant better than TWEAC. ‡ represents that MetaQA is statistically significant better than MultiQA. n.a means that the system cannot model the dataset.

reported results are the means and standard deviations of the models trained with five different seeds except for UnifiedQA, which would be too expensive to compute. We use a two-tailed T-Test to compare the models with a p-value of 0.05.

5 Results and Discussions

In this section, we answer the questions: i) is MetaQA able to combine multiple agents without undermining the performance of each one (§5.1), ii) is it robust on out-of-domain scenarios? (§5.2), iii) how does agent collaboration work? (§5.3), iv) how data-efficient is MetaQA? (§5.4), and v) what is the effect of each module of MetaQA? (§5.5).

5.1 Comparison with the Baselines

5.1.1 TWEAC

MetaQA outperforms TWEAC in all datasets except HellaSWAG and SIQA, as shown in Table 1. On average, MetaQA achieves an average performance boost of 2.23 with respect to TWEAC, and more importantly, the performance boost is greater than 4 points on HotpotQA, DuoRC, NewsQA, QAMR, and TriviaQA. Particularly, there is an astonishing 6.8 points performance boost on DuoRC.

The reason for these results is that TWEAC only aims to identify the agent trained on the domain of the question while we retrieve the best answer prediction, even if it comes from out-of-domain models. For instance, in DuoRC, MetaQA selects the in-domain agent only for 43% of its questions, i.e., most of the questions are assigned to agents that are not trained on DuoRC. In this way, MetaQA establishes a collaboration between agents.

We also observe that the gap between MetaQA and TWEAC is more significant on extractive QA than on multiple-choice. This is expected due to our selection of multiple-choice datasets. The substantial differences in the format of these datasets limit the potential agent collaboration. For instance, BoolQ is the only boolean dataset, and therefore, it can only be used to solve boolean questions, which do not appear in the other multiple-choice datasets. Also, SIQA, a commonsense reasoning dataset, uses a short context passage while CSQA (commonsense too) does not have any context, and hence, an agent trained for CSQA cannot be used successfully on SIQA. These characteristics of the setup make the upper-bound performance of MetaQA to be the same as the expert agents. Yet, even with these limitations, MetaQA outperforms TWEAC in three of the five datasets. Also, the expert agents only significantly outperform MetaQA on 2/5 datasets. Lastly, the performance in NarrativeQA and HybridQA is the same because there is only one agent per dataset.

5.1.2 UnifiedQA

MetaQA outperforms UnifiedQA by striking 10.49. In the case of extractive QA, the gap is 5.08, while in multiple-choice is 15.36. We attribute this to the limitations of UnifiedQA's architecture. For example, the performance in DROP is clearly far from our MetaQA. The reason for this is that while the expert agent used by MetaQA is designed for numerical reasoning, UnifiedQA does not have any mechanism to achieve this, and since it is designed as a general model for text-to-text generation, it cannot be augmented with special reasoning modules. The same phenomenon occurs in the multiple-choice datasets and in some minority domains in extractive QA (i.e., NewsQA and DuoRC). The only exception is in BoolQ, where UnifiedQA achieves the best results. However, this is because T5 (Raffel et al., 2020), on which UnifiedQA is trained, is already one of the SOTA models, while the agent we use has lower performance and was the only publicly available model in HuggingFace's Model Hub at the time of experimentation.

5.1.3 MultiQA

MetaQA outperforms MultiQA by a small margin of 0.12, despite being much more flexible (i.e., compatible with any QA format instead of only extractive QA (§4.3). Moreover, our model was trained on only 13% of its training set, as later discussed in §5.4. Furthermore, we observe that MultiQA mostly outperforms expert agents on Wikipedia-based datasets (i.e., SQuAD, HotpotQA, NQ, and QAMR). This might suggest that MultiQA is overfitted to Wikipedia due to its training on multiple datasets using Wikipedia paragraphs[2] and that would explain why it struggles with other minority domains. On the other hand, MetaQA excels in minority domains where it achieves striking 4.25 points performance boost on DuoRC, 2.87 on TriviaQA-web, 1.53 on SearchQA, and overall outperforms MultiQA by an average of 2.88. These results show the superior ability of MetaQA to avoid overfitting to a specific domain.

5.1.4 Max-Voting

Lastly, MetaQA also outperforms max-voting by an average of 8.35. In the case of easy datasets such as SQuAD, the performance is similar because all expert agents excel in this dataset, so any approach to combine the agents would yield similar results. More interestingly, the performance of Max-Voting is clearly far from MetaQA in DROP. We attribute this to the low performance of the extractive agents on this dataset and their similar wrong answers.

5.2 Leave-One-Out Ablation

In this experiment, we analyze whether the combination of expert agents can successfully solve an out-of-domain (OOD) dataset. We conduct a leave-one-out ablation test in both MetaQA and the baselines. In the case of MetaQA, we remove the expert agent of the target dataset, retrain MetaQA again without this dataset, and evaluate it on the target dataset. Similarly, we retrain TWEAC, UnifiedQA, and MultiQA without the target dataset and evaluate the model on the target dataset. Lastly, we also use the Max-Voting baseline without the agent trained on the target dataset. We trained MetaQA five times with different random seeds for each target dataset and report their average results. However, we could not do this for the other models due to their much higher computation costs.

Table 2 shows that OOD MetaQA outperforms OOD TWEAC in all datasets by an average of 6.31. The larger gap in OOD than in in-domain scenarios (Table 1) supports our hypothesis: the topic-classification approach of TWEAC disregards high-performing models in OOD, and our solution of establishing a collaboration between the agents is able to combine skills.

OOD MetaQA also outperforms OOD UnifiedQA by a striking average of 8.13 points. In addition, in four datasets (TriviaQA-web, DuoRC, CommonsSenseQA, and HellaSWAG), the ablated MetaQA even outperforms the full UnifiedQA trained on those datasets. This further supports our approach of combining multiple agents, instead of datasets, in scenarios with a wide variety of domains and formats, where flexibility is key.

In the particular case of MultiQA, as discussed in §5.1.3, half of its training sets are based on Wikipedia paragraphs. Therefore, removing a Wikipedia-based dataset such as HotpotQA does not remove Wikipedia contents from its training set[3]. As a consequence, this compromises the OOD setup. However, even under this pseudo-OOD

---

[2] MultiQA is trained on question and contexts (Wikipedia paragraphs). However, MetaQA does not have access to these paragraphs as shown in Figure 2.

[3] This is not the case for MetaQA because our input is only the questions, answer predictions, and confidence scores, not the Wikipedia paragraphs.

Dataset	NewsQA	HotpotQA	SearchQA	TriviaQA	NQ	DuoRC	QAMR	CSQA	HellaSWAG	SIQA	DROP	Δ
MetaQA	71.46	79.37	81.87	80.65	81.08	51.01	83.87	78.40	72.14	73.90	74.96	-

Table 2: Results of leave-one-out ablation. Out-of-domain (OOD) models are trained on all the datasets except the target dataset. Best OOD results in bold. Underlined results reflect OOD MetaQA outperforming full UnifiedQA. Δ is the average performance gap to OOD MetaQA. * MultiQA uses a pseudo-OOD setup, see remarks in §5.2.

Dataset	Question	In-domain Agent	OOD Agent
DuoRC	Who does Rocky Balboa work for as an enforcer?	Adrian	Tony Gazzo (NewsQA Agent)
TriviaQA-web	Who played the character Mr Chips in the 2002 TV adaptation of Goodbye Mr Chips?	Timothy Carroll	MartinClunes (DuoRC Agent)
SearchQA	This short story, written around 1820, contains the line "If I can but reach that bridge... I am safe"	Legend	Legend of Sleepy Hollow (TriviaQA Agent)

Table 3: Examples of questions where our MetaQA system disregard the in-domain agent due to their incorrect predictions (in red) and selects and an out-of-domain (OOD) agent that returns the right answer (in green).

setup, MultiQA only outperforms MetaQA by a slight margin of 0.61.

Lastly, we analyze the Max Voting baseline in this scenario. Although prior works disregard this baseline, the results in Table 2 show that OOD Max Voting outperforms all the other baselines and has a similar performance to OOD MetaQA. Its average gain with respect to OOD MetaQA is 0.64. However, this is not the overall trend. OOD MetaQA outperforms OOD Max Voting in 5/8 extractive QA datasets by a considerable margin of 3.19. On the other hand, multiple-choice datasets, especially the difference in HellaSWAG, incline the average towards OOD Max Voting. Despite the promising claims of prior works (Talmor and Berant, 2019; Khashabi et al., 2020) about OOD performance, these results suggest that aggregating a wide range of QA skills for different formats and domains in out-of-domain scenarios is still an open problem and non-neural baselines have strong results. Similar results have also been observed in retrieval methods, where non-neural baselines outperform supervised methods on OOD scenarios (Thakur et al., 2021).

5.3 Qualitative Analysis

We further analyze the behavior of our proposed model by inspecting its predictions. In particular, we investigate the collaboration between the agents for DuoRC, SearchQA, and TriviaQA, where this collaboration is particularly strong.

In DuoRC, the most helpful out-of-domain (OOD) agent is NewsQA, with a chosen rate of 18.2% in the test set. This might be due to the question types of DuoRC and NewsQA. DuoRC's questions are crowdsourced and are predominately *who-questions* (42% of the training set as shown in Appendix 6). NewsQA's questions are also crowdsourced and have a high proportion of *who-questions* (24%). The other datasets with a high amount of *who-questions* are NQ and SearchQA. However, the questions of these two datasets are very different in style to DuoRC (i.e., real user queries and trivia from a TV show). An example of this DuoRC-NewsQA agents collaboration is shown in the first row of Table 3.

In TriviaQA-web, the second most commonly used agent is trained on DuoRC. We randomly sampled 50 QA pairs where DuoRC is the selected agent and returns the right answer. In 20% of the cases, the question was about a movie or book plot, which indicates that our MetaQA successfully recognizes that this OOD agent is able to respond to this type of question. An example of this collaboration is shown in the second row in Table 3.

In SearchQA, the most helpful OOD agent is TriviaQA (5% chosen rate). This might be due to their similarities (Table 8). Within the pool of instances where the in-domain agent fails and the TriviaQA agent provides the right answer, we randomly analyzed 50 instances and discovered that in 84% of the cases, the in-domain agent returns a partially correct answer, and in those cases, the OOD agent was able to identify the exact answer. This is another example of the successful agent collaboration achieved by our MetaQA. Even though the in-domain agent almost has the correct answer, MetaQA selects an OOD agent that gives a better answer, as shown in the last row on Table 3.

5.4 Efficiency of MetaQA

We trained MetaQA with bins of QA instances for each dataset and observed that the training converges with only 10K instances/per dataset (i.e., 160K instances, including all datasets). This is only 16% of the data needed to train UnifiedQA (900K instances excluding HybridQA) and 13% of the data needed to train MetaQA (600K of extractive QA instances). The reason for this large saving is that MetaQA only has to learn how to match questions with answers because it reuses publicly available agents. On the other hand, multi-dataset models need to learn how to solve questions (i.e., language understanding, reasoning skills, etc.), a much more complex task.

As for inference time, if all the agents fit on memory[4], multi-datasets models and our MetaQA would have comparable running times. For example, compared to MultiQA, since our extractive agents use the same architecture as MultiQA, running the agents would take the same amount of time as running MultiQA. Then, we would need to select the answer. However, our MetaQA only takes 0.05s/question to select the best candidate answer. This makes it fast enough to not be noticeable by the users. On the other hand, if the agents do not fit in memory at the same time, it would be necessary to run them sequentially. Yet, this might not be a problem because it is possible to predict in advance which agents are more likely to give a correct answer to a given question (Geigle et al., 2021; Garg and Moschitti, 2021), which we leave as future work. This would allow us to skip some agents at run-time and improve the running time dramatically in low-memory scenarios.

5.5 Ablation Study

Lastly, we quantitatively measure the impact of each feature of MetaQA on its overall performance. The first row of Table 4 shows that removing the loss of the Agent Selection Network (AgSeN) hurts the performance of MetaQA. This manifests that our intuition of considering in-domain agents without falling into the *argumentum ad verecundiam* fallacy is correct. Lastly, the second row shows that the confidence embeddings provide key information to MetaQA to select an answer. For instance, an in-domain agent could have a prediction with low confidence because it does not know the answer, while an out-of-domain agent could have the correct answer and be certain about it.

Model	Avg. Downgrade
$-\ell_{AgSeN}$	-0.45
− Conf. Emb.	-0.46

Table 4: Average performance loss across all datasets of each ablated model compared to the full model.

6 Conclusions

In this work, we propose an alternative to multi-dataset models for multi-skill QA. We propose to combine expert agents to create a collaborative system for question answering (QA) called MetaQA. It considers questions, answer predictions, and confidence scores from the agents to select the best answer to a question. Through quantitative experiments, we show that our model avoids the limitations of multi-dataset models and outperforms the baselines thanks to the agent collaboration established. Additionally, since MetaQA learns to match questions with answers instead of end-to-end QA, it is highly data-efficient to train. We leave as future work: i) combining partially correct answer predictions to generate a better one, ii) adding new agents without retraining MetaQA by fixing most of the weights and only training the weights of the new Agent Selection Network, and iii) identifying *a priori* agents that are likely to give an incorrect answer to skip them at run-time.

Ethics Discussion

The proposed model, MetaQA, cannot generate unfair, biased, or harmful content given that the expert agents it aggregates are fair because MetaQA does not generate content. Rather it selects from Expert Agents. The datasets we use are well-known to be safe for research purposes and do not contain any personal information or offensive content. We also comply with the licenses and intended uses of each dataset. The licenses of each dataset are shown

---

[4] In our hardware and with our experimental setup, all agents and MetaQA fit on our GPU memory.

in Appendix A.1. We are not held responsible for errors, false or offensive content generated by the agents. MetaQA should be used at the users' discretion. Future work should address how to identify unfair or false content to avoid selecting it.

Limitations

The main limitation of MetaQA is that when no agent has a correct answer, it returns an incorrect answer. Table 5 describes how often this scenario occurs. In extractive datasets, without the outliers (i.e., SQuAD and DuoRC), we observe this to be 18% on average per dataset. This percentage drops to 8.35% in multiple-choice datasets (without BoolQ, another outlier). As for NarrativeQA and HybridQA, there are many unsolvable questions because we only use one agent for each of them and these agents have a relatively low performance.

Dataset	**% Unsolvable**
SQuAD	3.92
NewsQA	26.88
HotpotQA	19.93
SearchQA	13.97
NQ	19.15
TriviaQA-web	12.25
QAMR	15.81
DuoRC	47.41
BoolQ	1.47
SIQA	8.90
HellaSWAG	8.90
CSQA	9.00
RACE	6.61
DROP	21.77
NarrativeQA	55.71
HybridQA	56.09

Table 5: Percentage of unsolvable questions for our MetaQA with the selected agents, i.e., none of the agents can give a correct answer.

Also, if the agents do not fit in memory at the same time, it would be necessary to run them sequentially, which would increase the inference time. Yet, it might be possible to overcome this limitation because it is possible to predict in advance which agents are more likely to give a correct answer to a given question (Geigle et al., 2021; Garg and Moschitti, 2021). This would allow us to skip some agents at run-time and improve the running time dramatically in low-memory scenarios.

A Appendix

A.1 Datasets

Table 8 summarizes the characteristics of the datasets, contains the size of the train, validation, and test splits of each dataset, and their licenses. In the case of RACE, the authors did not provide any license but specified that it could only be used for non-commercial research purposes. In the case of CommonSenseQA and SIQA there is no license specified, but they are freely available to download. Therefore, our use of these datasets complies with their licenses and intended uses.

A.2 Expert Agents

Table 9 provides the links to download the expert agents used in this work. In the case of NarrativeQA and HybridQA, we only employ one agent because of the difficulty of obtaining others. Both of these datasets use uncommon modalities (abstractive and table+text). Therefore, it is not straightforward to adapt other models to these datasets.

A.3 Implementation

Our model was implemented using PyTorch (Paszke et al., 2019) and HuggingFace's Transformers library (Wolf et al., 2020). Both MetaQA and MultiQA were implemented using Span-BERT large (335M parameters), while UnifiedQA uses T5-base (220M parameters, the closest to the 335M of our MetaQA). The score embedder for MetaQA is implemented as a linear layer with an input size of 1 and an output size of 1024 (i.e., the hidden size of Span-BERT Large). α_1 and α_2 in Eq. 4 are set to 0.5 and 1 respectively. The Agent Selection Networks are implemented as a linear layer with an input size of 1024 and an output size of 1. Lastly, the Answer Selection Network (AnsSel) is also implemented as a linear layer with an input size of *number-of-agents* $\times$ 1025 (Span-BERT's hidden size + 1 from the output of the agent selection network). The threshold θ to determine whether a candidate answer is correct or not to create the labels to train AnsSel is set to 0.7.

MetaQA was trained for one epoch using a batch size of six, a weight decay of 0.01, a learning rate of 5e-5, and 500 warmup steps.

All the extractive agents and MultiQA were trained using the same architecture, Span-BERT large, for two epochs and with the same hyperparameters: batch size of 16, learning rate of 3e-5, max length of 512, and doc stride of 128.

UnifiedQA was trained for two epochs using a batch size of four, a learning rate of 5e-5, and a weight decay of 0.01. It was evaluated on the dev set every 100K steps.

Lastly, the max-voting baseline assumes that two answers are the same if the F1 score is higher than a threshold (0.9). We tuned this parameter on the dev set searching in the range $[0.5, 0.6, ..., 1.0]$. We used the implementation of HuggingFace's SQuAD F1 metric[5]. In the case that two answers have the same amount of votes, we select the one with the highest confidence score given by an agent.

Any other parameter used the default value in HuggingFace's Transformers library. Each model was trained five times with different random seeds to do hypothesis testing except for UnifiedQA, which would be too expensive to compute.

We used the implementation of HuggingFace's Dataset library (Lhoest et al., 2021) for the evaluation using EM and F1 metrics, while for the ROGUE metric we used the official implementation[6].

All the experiments were conducted in a SLURM cluster where each job was assigned to different computer nodes with different CPUs and GPUs. Therefore, comparing the running time of each model is not possible.

A.4 Adding New Agents

Augmenting MetaQA with a new agent only requires adding one more AgSeN network and increasing the output space of the AnsSel network. Thus, it requires retraining the whole architecture (including the Transformer encoder). However, as discussed in §5.4, the training efficiency is one of the strengths of our system.

A.5 MetaQA on a Single Dataset

We conduct an additional experiment to analyze the behavior of MetaQA with multiple expert agents trained in a single dataset. We train MetaQA for three NewsQA agents: RoBERTA-base, XtremeDistil (Mukherjee and Hassan Awadallah, 2020), and SpanBERT, and evaluate it on NewsQA. As observed in Table 7, MetaQA performs on par with the agents. However, the performance gap is smaller than in the main use case (§5.1). This is attributed to the similarities between

Abstract

We introduce a task consisting in matching a proof to a given mathematical statement. The task fits well within current research on Mathematical Information Retrieval and, more generally, mathematical article analysis (Mathematical Sciences, 2014). We present a dataset for the task (the MATCH dataset) consisting of over 180k statement-proof pairs extracted from modern mathematical research articles.[1] We find this dataset highly representative of our task, as it consists of relatively new findings useful to mathematicians. We propose a bilinear similarity model and two decoding methods to match statements to proofs effectively. While the first decoding method matches a proof to a statement without being aware of other statements or proofs, the second method treats the task as a global matching problem. Through a symbol replacement procedure, we analyze the "insights" that pre-trained language models have in such mathematical article analysis and show that while these models perform well on this task with the best performing mean reciprocal rank of 73.7, they follow a relatively shallow symbolic analysis and matching to achieve that performance.[2]

1 Introduction

Research-level mathematical discourse is a challenging domain for Natural Language Processing (NLP). Mathematical articles frequently switch between natural language and mathematical formulae, and a semantic analysis of mathematical text needs to solve relationships (e.g. coreference) between mathematical symbols and concepts. Moreover, mathematical writing follows many conventions, such as variable naming or typography that are implicit, and may differ between subfields.

Statement. When $m = 0$ we have $E^0_{rg} = \emptyset$, and when $m \neq 0$ we have $E^0_{rg} = E^0$.
Proof. When $m = 0$, the image of r is $\{1\}$. Hence $E^0_{rg} = \emptyset$. When $m \neq 0$, the map r is a surjective proper map. Hence $E^0_{rg} = E^0$.

Figure 1: Example of a statement-proof pair.

However, mathematical research can benefit from NLP (Mathematical Sciences, 2014), in particular as concerns bibliographical research: researchers need tools to find work relevant to their research. Indeed, prior NLP work on mathematical research articles focused on Mathematical Information Retrieval (MIR) and related tools or data (Zanibbi et al., 2016; Stathopoulos and Teufel, 2016, 2015).

We introduce a task aimed at improving the processing of research-level mathematical articles and make a step towards the modeling of mathematical reasoning. Given a collection of mathematical statements and a collection of mathematical proofs of the same size, the task consists in finding and assigning a proof to each mathematical statement. We construct and release a dataset for the task (MATCH), by collecting over 180k statement-proof pairs from mathematical research articles (an example is given in Figure 1).

Related datasets, such as LEANSTEP (Han et al., 2021) and the synthetic dataset of Polu and Sutskever (2020) do not include natural language. NaturalProofs (Welleck et al., 2021), another related dataset, only consists of 32k theorem-proof pairs from ProofWiki,[3] some sub-topics in algebraic geometry and two textbooks. Our dataset is over five times larger and contains pairs extracted

from advanced academic mathematical papers.

There are multiple motivations for the design of the task and our dataset. We believe it may help MIR by serving as a proxy for the search for the existence of a mathematical result, or for theorems and proofs related to one another (e.g. using the same proof technique), an important search tool for any digital mathematical library (Mathematical Sciences, 2014). Learning to match statements and proofs would also benefit computer-assisted theorem proving, as it is akin to tasks such as premise selection, also recently addressed with NLP methods (Piotrowski and Urban, 2019).

We provide first results on our proposed task with an array of neural models, aimed at scoring the likelihood of relationship between a statement and its proof. An analysis through a **symbol replacement procedure** provides insight on what such neural models are capable of learning about mathematical equations and text.

We provide two methods for decoding, one is local decoding, matching a proof to a theorem in a greedy way, and one that provides a global bipartite matching based on a structured max-margin objective. Such an architecture may have applications to other NLP problems that can be cast as maximum bipartite matching problems (for a recent similar use in a different context, see Shao et al. 2023).

Our analysis shows that pre-trained language models do not obtain significant "mathematical insight" for performing this matching, but rather rely on shallow matching. However, this does not prevent them from performing the matching relatively well in several carefully crafted scenarios, reaching an MRR of 73.7.

2 Related Work

Most NLP work on mathematical discourse focuses on improving Mathematical Information Retrieval (Zanibbi et al., 2016, MIR) by establishing connections between mathematical formulae and natural language text in order to improve the representation of formulae.

The interpretation of variables is highly dependent on the context. For example, the symbol E could denote an expectation in a statistics article, or the energy in a physics article. Some studies use the surrounding context of a formula to assign a definition or a type to the whole formula, or to specific variables. Nghiem Quoc et al. (2010) focus on identifying coreferences between mathematical formulae and mathematical concepts in Wikipedia articles. Kristianto et al. (2012) extract definitions of mathematical expressions. Grigore et al. (2009), Wolska et al. (2011) and Schubotz et al. (2016) disambiguate mathematical identifiers, such as variables, using the surrounding textual context. Stathopoulos et al. (2018) infer the type of a variable in a formula from the textual context of the formula. Another line of work focused on identifying specialized terms or concepts to improve MIR (Stathopoulos and Teufel, 2015, 2016).

Some work adapts standard NLP tools to the specificity of mathematical discourse, e.g. POS taggers (Schöneberg and Sperber, 2014), with the objective of using linguistic features to improve the search for definitions of mathematical expressions (Pagel and Schubotz, 2014). More recent work focuses on typing variables in mathematical articles (Ferreira et al., 2022), modeling formulae (Mansouri et al., 2019; Dadure et al., 2021), and selecting premises (Ferreira and Freitas, 2020, 2021).

An earlier version of our work covers some of the material in this paper (Coavoux and Cohen, 2021). The main differences between that version and the current version are the introduction of the symbol replacement evaluation (§5) and the use of pre-trained language models rather than recurrent neural networks.

3 Task Description

Given a collection of mathematical statements $\{s^{(i)}\}_{i\leq N}$, and a separate equal-size collection of mathematical proofs $\{p^{(i)}\}_{i\leq N}$, we are interested in the problem of assigning a proof to each statement.

Evaluation We use two evaluation metrics. Assuming that a system predicts a ranking of proofs, instead of providing only a single proof, we evaluate its output with the Mean Reciprocal Rank (MRR) measure: $\text{MRR}(\{\hat{r}_i\}_{i\in\{1,\ldots N\}}) = \frac{1}{N}\sum_{i=1}^{N}\dfrac{1}{\hat{r}_i}$, where N is the number of examples and $\hat{r}_i$ is the rank of the gold proof for statement number i, as predicted by the system.

As a second evaluation metric, we use a simple accuracy, i.e. the proportion of statements whose first-ranked proof is correct.

By construction (see §4), it is possible though unlikely that the same mathematical statement occurs several times in the dataset. It is more unlikely that

several occurrences have exactly the same formulation and use the same variable names. Therefore, we consider a match to be correct if and only if it is associated with its original proof.

4 Dataset Construction

This section describes the construction of the MATCH dataset of statement-proof pairs (see Figure 1 for an example).

Source Corpus We use the MREC corpus[4] (Líška et al., 2011) as a source. The MREC corpus contains around 450k articles from ArxMLiV (Stamerjohanns et al., 2010), an on-going project aiming at converting the arXiv[5] repository from LaTeX to XML, a format more suited to machine processing. In this collection, mathematical formulae are represented in the MathML[6] format, a markup language.

Statistics We extract statement-proof pairs as described in Appendix A. Our processing of MREC includes the identification of statement-proof pairs through meta tags and the linearization of the representation of mathematical equations.

We report in Table 1 some statistics about the dataset we collected. The extracted articles were from a diverse set of mathematical subdomains, and connected domains, such as computer science (746 articles from 30 subcategories) and mathematical physics (2562 from 31 subcategories). There are in average 6.6 statement-proof pairs per article. We report statistics about the size of statements and proofs in the number of tokens in Table 2. We report the number of tokens in formulae (math), in the text itself (text) and in both (text+math). On average, proofs are much longer than statements. Statements and proofs have approximately the same proportion of text and math. Overall, the variation in the number of tokens across statements and proofs is extremely high, as illustrated by the standard deviation (SD) of all presented metrics.

Statements	Min	Max	Mean±SD
Text+math	20	500	80±57
Text only	1	398	30±20
Math only	0	470	58±20
Math proportion	0%	99.5%	58%±20
Proofs			
Text+math	20	500	210± 127
Text only	1	467	81 ± 56
Math only	0	495	129 ± 96
Math proportion	0%	99.6%	56%± 21

Table 2: Number of tokens in the dataset. We report for statements and proofs the minimum, maximum and average number of tokens broken down by type ('math' for tokens extracted from formulae and 'text' for the others). A value of 0 for, e.g. the 'math only' row, means that the statement or proof does not contain mathematical symbols or formulae.

5 Symbol Replacements

With our current dataset setup, we implicitly make the assumption that both the theorem and the proof are authored by the same authors. This assumption is incongruent with the MIR-flavor of our task. First, it is not useful for researchers to match proofs they authored. Second, each person has a unique writing style expressed by unique mathematical jargon and notations. To relieve of this assumption, we introduce several symbol replacement levels for changing the names of the proof variables. Then, we train and test our models using these altered datasets. These replacement levels also provide insight on the ability of our models to semantically analyze the input statement-proof pairs.

Symbol Replacement Levels We propose different levels of symbol replacement, focusing on mathematical notation. More precisely, we aim to replace the proof variable names if they appear in

---

[4] `https://mir.fi.muni.cz/MREC/`, version 2011.4.439.

[5] `https://arxiv.org/`

[6] `https://www.w3.org/Math/`

the statement without damaging the proof semantics. To do that, we change symbols that appear both in the proof and the statement. We do not change constant symbols such as π, as they often carry semantic meaning outside of the proof scope.

We experiment with four levels of symbol replacement (examples in parenthesis):

- **Symbol conservation** - all symbols remain intact, so the theorem and the proof overlap. All previous work uses that. $(a_n = a_{n-1} + a_{n-2})$
- **Partial symbol replacement** - A fraction of α of all the symbols in the proof remain the same, and the rest are changed. In our experiments, we use $\alpha = 0.5$. $(x_n = x_{n-1} + x_{n-2})$
- **Full symbol replacement** - all symbol names are changed ($\alpha = 1.0$ as above). $(x_i = x_{i-1} + x_{i-2})$
- **Symbol transposition** - We permute the variables' names such that no symbol remains the same, thus changing their original functionality. $(n_a = n_{a-1} + n_{a-2})$

More details about this appear in Appendix C.

6 Bilinear Similarity Model

We propose a model based on an encoder (§8) that constructs fixed-size vector representations for statements and proofs, and a similarity function that scores the relatedness of a statement-proof pair.

Trainable Bilinear Similarity Function Given the encoded representations of a statement $\mathbf{s} = \text{enc}(s)$ and a proof $\mathbf{p} = \text{enc}(p)$, we compute an association score with the following bilinear form:

$$\text{score}(\mathbf{s}, \mathbf{p}) = \mathbf{s}^\top \cdot \mathbf{W} \cdot \mathbf{p} + b,$$

where $\mathbf{W}$ and b are parameters that are learned together with a self-attentive encoder parameters (§8).

Local Decoding For a collection of n statements and proofs, we first score all possible pairs (s, p), and construct a matrix $M = (m_{ij}) \in \mathbb{R}^{n \times n}$, with

$$m_{ij} = \text{score}(\mathbf{s}^{(i)}, \mathbf{p}^{(j)}),$$

where $\mathbf{s}^{(i)}$ and $\mathbf{p}^{(j)}$ are the encoded representations of, respectively, the i^{th} statement and the j^{th} proof. Then we can straightforwardly sort each row by decreasing order and assign the proof ranking to the corresponding statement. The best ranking proof $\hat{p}$ for statement i satisfies $\hat{p}^{(i)} = \arg\max_j \; m_{ij}$. We call this decoding method 'local', since it does not take into account dependencies between assignments. In particular, several statements may have the same highest-ranking proof.

Global Decoding The local decoding method overlooks a crucial piece of information: a proof should correspond to a single statement. In a worst-case situation, a small number of proofs may score high with most statements and be systematically assigned as highest-ranking proof by the local decoding method.

In preliminary experiments, we analyzed the output of our system with local decoding on the development set, focusing on the distribution of the single highest-ranking proof for each statement. We found that 23% of the proofs were assigned to at least two different statements, whereas more than 40% of proofs were assigned to no statement. See also Appendix B.[7]

We propose a second decoding method based on a global constraint on the output: a proof can be assigned only to a single statement. Intuitively, the constraint models the fact that if a proof is assigned by the system to a certain statement with high confidence, we can rule it out as a candidate for other statements. Under this constraint, the decoding problem reduces to a classical maximum weighted bipartite matching problem, or equivalently, a Linear Assignment Problem (LAP). In more realistic scenarios (e.g. if the input sets of statements and proofs do not have the same size), the method would require some adaptation.

Formally, we define an assignment A as a Boolean matrix $A = (a_{ij}) \in \{0, 1\}^{n \times n}$ with the following constraints:

$$\forall i \forall j, \sum_j a_{ij} = \sum_i a_{ij} = 1,$$

i.e. each row and each column of A contains a single non-zero coefficient. The score of an assignment A is the sum of scores of the chosen edges:

$$\text{score}(A, M) = \sum_i \sum_j a_{ij} m_{ij}.$$

Finally, global decoding consists in solving the

---

[7] We used a simple encoder for these experiments, which we describe in §8 (NPT).

following LAP:

$$\hat{A}(M) = \underset{\substack{A \in \{0,1\}^{n \times n} \\ \text{s.t. } \forall i \forall j, \sum_j a_{ij} = \sum_i a_{ij} = 1}}{\arg\max} \text{score}(A, M).$$

The LAP is solved in polynomial time by the Hungarian algorithm (Kuhn, 1955), the LAP-Jonker-Volgenant algorithm (LAP-JV; Jonker and Volgenant, 1987), or the push-relabel algorithm (Goldberg and Kennedy, 1995). These methods have a $\mathcal{O}(n^3)$ time complexity where n is the number of pairs, and $\mathcal{O}(n^2)$ memory complexity. This is too expensive in our case, due to our dataset size.

To remedy this limitation, when we perform decoding on a large set, we only consider the k best-scoring proofs (i.e. outgoing edges in the bipartite graph) for each statement, which makes the number of edges linear in the number of pairs n (considering k fixed). Moreover, we use a modification of the LAP-JV algorithm specifically designed for sparse matrices (LAP-MOD; Volgenant, 1996).

7 Local and Global Training

We propose two training methods for the similarity model above: a local training method that only considers statements in isolation (§7.1) and a global model trained to predict a bipartite matching (§7.2), with a hybrid global-local objective.

7.1 Local Training

We would like to train our model to assign a high similarity to the gold statement-proof pair, and a low similarity to all other statement-proof pairs. This corresponds to the following objective, for a single statement s and its gold proof p:

$$\begin{aligned}\mathcal{L}_{\text{LOC}}(s, p, P; \boldsymbol{\theta}) &= -\log \mathbb{P}(p|s; \boldsymbol{\theta}) \\ &= -\log \left(\frac{\exp(\text{score}(\mathbf{s}, \mathbf{p}))}{\sum_{p' \in P} \exp(\text{score}(\mathbf{s}, \mathbf{p'}))} \right),\end{aligned}$$

where P is the set of proofs, and $\boldsymbol{\theta}$ are the parameters of the model. Directly optimizing this loss function requires the computation of $\mathbf{p} = \text{enc}(p)$ for every proof in the dataset, for a single optimization step. This is not realistic considering memory limitations, the size of the train set, and the fact that our self-attentive encoder is the most computationally expensive part of the network.

Instead, we sample minibatches of b pairs and optimize the following proxy loss for the sequence $S' = (s_1, \dots, s_b)$ of statements and the sequence $P' = (p_1, \dots, p_b)$ of corresponding proofs:[8]

$$\mathcal{L}'_{\text{LOC}}(S', P'; \boldsymbol{\theta}) = \sum_{i=1}^{b} \mathcal{L}_{\text{LOC}}(s^{(i)}, p^{(i)}, P'; \boldsymbol{\theta}).$$

In practice, we sample uniformly and without replacement b pairs from the training set at each stochastic step.

7.2 Hybrid Local and Global Training

The local training method only considers statements in isolation. Even though we expect a locally trained model to perform better with global decoding, we hypothesize that a model that is trained to predict the full structure (a bipartite matching) will be even better.

For a collection of n proofs and n statements, the size of the search space (i.e. the number of bipartite matchings) is $n!$, since each matching corresponds to a permutation of proofs. As a result, the use of a globally normalized model is impractical. We turn to a max-margin model that does not require normalization over the full search space.

We use the following max-margin objective, for a set B of n pairs corresponding to matrix M:

$$\begin{aligned}\mathcal{L}_{\text{GLOB}}(B; \boldsymbol{\theta}) = \max(0, &\Delta(\hat{A}, I) \\ &+ \text{score}(\hat{A}, M) - \text{score}(I, M)),\end{aligned}$$

where $\boldsymbol{\theta}$ is the set of all parameters $\hat{A}$ is the predicted assignment and I is the gold assignment, i.e. the identity matrix. The structured cost

$$\Delta(\hat{A}, I) = \sum_{ij} \max(0, (\hat{A} - I)_{ij})$$

aims at enforcing a margin for each individual assignment.

The computation of this loss requires exact decoding for each optimization step. Since exact decoding is only feasible for a small n, and since we need to keep track of all intermediary vectors to compute the backpropagation step,[9] we perform each stochastic optimization step on a minibatch of pairs of size b. Since this global objective had a slow convergence rate (§8), in practice, we use a hybrid local-global objective: $\mathcal{L}'_{\text{LOC}} + \mathcal{L}_{\text{GLOB}}$.

	Symbol Replacement Level							
	Conservation		Partial		Full		Transposition	
Encoder-Decoder	MRR	Acc	MRR	Acc	MRR	Acc	MRR	Acc
NPT-Local-Local	63.22	56.08	47.19	39.24	40.36	32.52	56.17	48.30

Table 3: The MRR and accuracy scores for different combinations of encoders, decoders, and symbol replacement levels. All the models are trained and tested on the same replacement level. Best result in each column is in bold. Following the model name, we include its encoder and decoder type (both being either Local or Global). We do not include MRR scores for global inference, as there matching is done for all theorems together without ranking.

8 Experimental setup

Dataset We use the dataset whose construction is described in §4. We shuffle the collection of statement-proof pairs before performing a $80\%/10\%/10\%$ train-development-test split, corresponding to 147278 pairs for the training sets and 18408 pairs for the development and tests. We experiment with a default, Mixed, split and a harder Unmixed split (see §9.3).

Encoders We experiment with several encoders to obtain neural representations of the theorem and proof pairs. Our first encoder is a simple self-attentive encoder. We use $\ell = 2$ self-attentive layers with 4 heads to obtain contextualized embeddings of dimension $d = 300$. The query and key vectors have size $d_k = 128$. We construct a vector representation for the text with a max-pooling layer over the contextualized embeddings of the last self-attention layer. We do not use any form of pre-training for this encoder and hence name it "no pre-training encoder" (NPT). In addition, we experiment with a BERT model (Devlin et al., 2019) as an encoder. We do not use the pre-trained version provided by Devlin et al., but rather pre-train the base version from scratch (ScratchBERT), but we do compare our results against a math-tailored pre-trained version of BERT (Peng et al. 2021; see below). Both the NPT and ScratchBERT vocabularies are customized for our dataset, as preliminary experiments revealed the importance of the model-task vocabulary match.[10]

To further demonstrate how crucial this vocabulary match is, we experiment with math-BERT (MathBERT; Shen et al. 2021), a state-of-the-art pre-trained model for mathematical formula understanding. This model is pre-trained on a large mathematical corpus ranging from pre-kindergarten, to high-school, to college graduate level mathematical content, including professional mathematical papers, using the BERT masked language modeling (MLM) task. We use the pre-trained version provided by the authors, *without vocabulary customization*. All of our encoders are fine-tuned on the matching task. In addition, we experiment with a naive token-matching system that computes cosine similarities between TF-IDF representations of statements and proofs. We discovered that their performance was very low, ranging from 11.4 to 29.8 (MRR), so we did not experiment with them further.

Hyperparameters For pretraining ScratchBERT, we first train a new word piece tokenizer[11]. Next, we train the ScratchBERT model on the MLM task for 60 epochs (around 3 days) using four NVIDIA V100 GPUs. We evaluate the language model every 500 steps, where one step stands for training on one example, and choose the one with

---

[8] We also experimented with a Noise-Contrastive Estimation approach (Gutmann and Hyvärinen, 2012). However, it exhibited a much slower convergence rate.

[9] In particular, the computation graph needs to conserve all encoding layers for the $2n$ texts involved.

[10] This supports the findings of Chalkidis et al. (2020), for example, in a different domain.

[11] `https://huggingface.co/docs/transformers/tokenizer_summary#wordpiece`

the best performance on the validation set.

We perform local and global training / finetuning respectively for the NPT model, MATHBERT, and SCRATCHBERT. NPT has 15M parameters while MATHBERT and SCRATCHBERT have 110M parameters. We observed in initial experiments that training only with the global objective required a long time to converge. Therefore, we used the following global-local objective: $\mathcal{L}'_{\text{LOC}} + \mathcal{L}_{\text{GLOB}}$, that we optimized by alternating one stochastic step for each loss.

We train the NPT model for 400 epochs (around 1 day with two GPUs) over the whole training set for local and global training. We use batches of size $b = 60$ and set learning rate $l = 5 \times 10^{-3}$ with the Averaged Stochastic Gradient Descent (ASGD; Polyak and Juditsky 1992) optimizer. We use an exponential learning rate scheduler (the learning rate multiplied by 0.996 after each epoch) to stabilize the optimizer in the latter training procedure (after 300 epochs). We evaluate the performance of the model on the validation set every 20 epochs during training and select the best one among these intermediate models.

We use four NVIDIA V100 GPUs to fine-tune MATHBERT and SCRATCHBERT on the training set for 60 epochs (around 2 days) with a learning rate of $l = 2 \times 10^{-3}$, an ASGD optimizer, batches of size $b = 16$, and a scheduler that multiplies the learning rate by 0.99 after each epoch. We choose the best model on the validation set, evaluating the models every five epochs.

Global Decoding Recall that exact global decoding is only feasible for a small subset of pairs. During global training, we chose a batch size small enough to perform exact decoding. However, it is not feasible to perform exact decoding on the whole development and test corpora. Therefore, we prune the search space by keeping only the 500-best candidate proofs for each statement, and use the LAP-MOD algorithm designed for sparse matrices. In practice, we used the implementations of the LAP-JV and LAP-MOD algorithms from the `lap` Python package,[12] for respectively exact decoding on mini-batches during global training and decoding on whole datasets during evaluation.

9 Results

First, we assess the task difficulty under different replacement levels using different encoders and schemes (global or local training, global or local decoding). In particular, we are interested in assessing whether global decoding improves accuracy when training is only local, and how the more complex global training method fares with respect to local training. We then measure the informativeness of different types of input: text, mathematical formulae, or both. The comparison of these settings is meant to provide insight into which type of information is crucial to the task. Finally, we experiment with a cross replacement levels setup, i.e., when a model is tested on a different symbol replacement level from the one that was used during training. We hope this experiment will shed some light on the importance of training models on real-world datasets.

9.1 Main Results

Table 3 presents our results. We report MRR (if relevant) and accuracy scores across different levels of symbol replacement.

Encoders While MATHBERT is pre-trained on millions of examples curated from mathematical contents, it performs worse than the less complex NPT encoder, which is trained solely on the downstream task across all symbol replacement levels and decoders.[13] SCRATCHBERT, which shares MATHBERT architecture and NPT customized vocabulary, is outperforming both consistently. These results demonstrate the vocabulary importance for learning from mathematical texts.

Symbol Replacement Levels Difficulty Best performance is achieved when no symbol is replaced (Conservation), as the models can match identical symbols across theorem-proof pairs. The models achieve similar performance with Transposition replacement. These results suggest that the symbols' order, context, and function within the mathematical text do not play a significant role when the theorem and proof share the same symbols. In contrast, when the symbol names are changed (Partial and Full replacements), we observe a sharp decline in results.

---

Table 5: ScratchBERT-Local-Local and NPT-Local-Local performance for different input types. Both stand for the original and complete input.

Training and Decoding Effects In all settings, global *decoding* substantially improves accuracy. These improvements are more noticeable for the NPT and ScratchBERT encoders. For NPT, we observe better performance when using global *training*, but not for ScratchBERT and MathBERT. Due to the lack of computational resources, we can not reach the global training full potential when using highly expressive encoders such as ScratchBERT and MathBERT, which share BERT-base architecture.

9.2 Effect of Input Type Analysis

To better understand the importance of each input type, we examine ScratchBERT-Local-Local and NPT-Local-Local performance when fed with text, mathematical formulae, or both (Table 5). We test them on the Conservation and Full symbol replacement levels. The mathematical formulae input plays a more significant role for both models than the textual input. When trained and tested on the Conservation replacement level, NPT-Local-Local makes better use of the mathematical formulae input than the more expressive, pre-trained ScratchBERT-Local-Local. When trained and tested with Full replacement, where the models cannot rely on simple token-matching, NPT-Local-Local suffers from a sharper performance decline than ScratchBERT-Local-Local when fed with mathematical formulae input. These results suggest that when applied to the Conservation data, a less expressive model can get high results by harnessing simple token matching. ScratchBERT-Local-Local performs better for both replacement levels when fed with text and complete input.

9.3 Cross Replacement Setup

Table 4 shows the effect of testing a model on different symbol replacements than the one the model was trained on. We use the ScratchBERT-Local-Local model for all of our experiments. We observe a sharp decline in results when ScratchBERT-Local-Local is trained with Conservation and tested on Partial or Full. These drops in performance suggest the model developed a strong dependency on exact symbol name matching. In addition, the replacement shift from Conservation to Transposition and vice versa resulted in a minor performance drop. These results provide additional evidence for the lack of importance of mathematical functionality, order, and context of symbols' names shared across theorem and proof pairs. The model trained on the Partial symbol replacement level demonstrated significant resilience when tested with other symbol replacement levels. It outperforms the rest of the models when applied to out-of-domain replacement levels and the Conservation replacement level in-domain model.

In addition, we experimented with theorem-proof pairs split where pairs from the same paper could not appear in the same set: train, validation or test (Unmixed). All models exhibited a reduction in performance when trained and tested under these conditions. Particularly noteworthy was the decrease in performance observed in models that were trained using the Conservation and Transposition symbol replacement methods and evaluated on data using the Partial or Full replacement methods. These sharp declines highlight the dependence of the model on simple symbol matching rather than deeper inferential analysis.

9.4 Protected Symbols

Insofar, we overlooked that some symbols carry a default meaning over a whole mathematical domain (**protected** symbols, e.g. $P(x)$ for probability). Replacing them locally may result in a detrimental impact on semantic mathematical content. We test the impact of substituting protected symbols in a controlled setting by comparing models trained with symbol replacement methods that preserve protected symbols versus methods that treat all symbols equally. The test set preserves the protected symbols. We follow the Unmixed setup, where theorem-proof pairs from the same paper must appear in the same split.

We focus on the probability theory domain. Focusing on a single domain enables us to construct a list of protected symbols more precisely. Our list consists of the P (probability measure), E (expected value), V (variance), σ (standard deviation and covariance), and ρ (correlation) symbols.[14] Table 6 shows that training the SCRATCHBERT-Local-Local model using the Partial+P replacement method results in slightly better results. We present only a subset of our results for brevity; the pattern re-occurs with all symbol replacement methods.

9.5 Qualitative Analysis

To study which tokens affect our model predictions, we use LIME (Ribeiro et al., 2016), a method for calculating feature importance. We examine SCRATCHBERT-Local-Local trained with the Conservation setup and with Full replacement. Both are applied to original test examples. We observe that the Conservation SCRATCHBERT-Local-Local model heavily relies on the mathematical tokens and barely benefits from the text ones. In contrast, the SCRATCHBERT-Local-Local model that was trained in the full symbol replacement setup strongly relies on textual tokens with mathematical meaning, such as *module*, *supplement*, and *semistable*. We visualize that in Figure 2.

Target / Source	Symbol Replacement			
	Conservation		Partial+P	
	MRR	Acc	MRR	Acc
Conservation	**69.26**	**59.59**	27.9	18.29
Partial	61.36	51.72	54.06	42.67
Partial+P	62.1	51.92	**55.92**	**45.23**
Full	53.63	42.08	52.85	41.4
Full+P	56.27	45.13	**55.92**	44.84

Table 6: Controlled cross-replacement levels performance for the SCRATCHBERT-Local-Local model. Both train and test sets are curated from the probability theory domain. +P next to a symbol replacement method means that Protected symbols are not being replaced.

10 Conclusion

We developed a bilinear similarity model and a large dataset (MATCH) for a task focusing on the domain of mathematical research articles. The task consists in matching a proof to a mathematical statement. We proposed two ways to train and inference with our model and dataset: local matching and global matching. We assessed the difficulty of the task with several pre-trained encoders, demonstrating the importance of the vocabulary support for these models. Further assessment relies on using a symbol replacement procedure, which helps test the type of mathematical reasoning the encoders can perform. While our model performs well on this task, we observe through the symbol replacement procedure that the model makes a relatively shallow use of the text and formulae to obtain this performance.

Limitations

Our work has three main limitations. First, we aim to simulate a setup where the same author did not write both a theorem and its corresponding proof. We reduce the intersection size of symbols between the statement and the proof, which leads to more challenging setups. In practice, authors and mathematical communities within fields differ in their use of notation and their writing style (creating *mathematical language dialects*). Such overall dialect

---

[14] We relied on Wikipedia, `https://tinyurl.com/2c3kwsfx`, for creating the protected symbols list.

cannot be altered using simple rule-based methods. We leave it for future work to explore a full MIR setup for our task that takes this into consideration.

Second, due to computational limitations, we could not explore the full potential of our global training method. Our GPUs cannot handle large batch sizes for large models such as MATHBERT and SCRATCHBERT. We use NVIDIA V100 GPUs that allow us to experiment with a batch size of 16 for MATHBERT and SCRATCHBERT, compared to 60 with NPT.

Third, while our symbol replacement method provides a coarse way to test the language model use of the symbols and text in mathematical articles, it presents cases in which the replacement is not precise. These cases arise because the use of symbols in mathematical language is rich and context-dependent (for example, while π often refers to the pie constant, it might also refer to a tuple-projection function or a permutation). We partially address that in §9.4.

Acknowledgments

We thank the reviewers for their helpful comments, and Marcio Fonseca for feedback on an earlier draft. We also thank Richard Zanibbi for a discussion about aspects of this work. The experiments in this paper were supported by a compute grant from the Edinburgh Parallel Computing Center (Cirrus) and another compute grant for the Baskerville service at the University of Birmingham.

A Details on Dataset Construction

As mentioned in §4, we use the MREC corpus to extract statement-proof pairs.

Statement-proof Identification For each XML article (corresponding to a single arXiv article), we extract pairs of consecutive `<div>` tags such that: (i) the `class` attribute of the first `div` node contains the string `"theorem"`; (ii) the `class` attribute of the second `div` node is the string `"proof"`. Articles that do not contain such pairs of tags are discarded, as well as articles that are not written in English (representing 143 articles in French, 11 in Russian, 5 in German, 2 in Portuguese and 1 in Ukrainian), as identified by the `polyglot` Python package.[15]

In the remaining collection of pairs of statements and proofs, we filter out pairs for which either the statement or the proof is too short.[16] Indeed, the short texts were often empty (only consisting of a title, e.g. "5.26 Lemma."), which we attribute to the noise inherent to the conversion to XML, or not self-contained. In particular, we identified several prototypical cases:

- Omitted (or easy) proofs contain usually a single word ('omitted', 'straightforward', 'well-known', 'trivial', 'evident'), but are sometimes more verbose ('This is obvious and will be left to the readers').
- Proofs that consist of a single reference to
    - An appendix ('See Appendix A');
    - Another theorem ('This follows immediately from Proposition 4.4 (ii).');
    - The proof method of another theorem ('Similar to proof of Lemma 6.1')
    - Another article ('See [BK3, Theorem 4.8].');
    - Another part of the article ('The proof will appear elsewhere.', 'See above.', 'Will be given in section 5.').

Filtering on the number of tokens also excludes self-contained short proofs, such as 'Take $Q' = ph_i - p_i$.' However, such proofs were very infrequent on manual inspection of the discarded pairs (2 in a manually inspected random sample of 100 discarded proofs).

Preprocessing: Linearizing Equations Mathematical formulae in the XML articles are enclosed in a `<math>` markup tag, that materializes the switch to the MathML format, and whose internal structure represents the formula as an XML tree. As a preprocessing step, we linearize each formula to a raw sequence of strings.

In MathML, an equation can be encoded in a content-based (semantic) way or in a presentational way, using different sets of markup tags. We first convert all MathML trees to presentational MathML using the XSL stylesheet from the Content MathML Polyfill repository.[17] Then we perform a depth-first search on each tree rooted in a `<math>` tag to extract the text content of the whole tree.

During this preprocessing, we tested several processing choices:

- **Font information**. In mathematical discourses, fonts play an important role. Their semantics depend on conventions shared by researchers. If both x and $\mathbf{x}$ appear in the same article, they are most likely to represent different mathematical objects, e.g. a scalar and a vector. Therefore, we use distinct symbols for tokens that are in distinct fonts.
- **Math-English ambiguity**. Some symbols can be used both in natural language text and in formulae. For example, 'a' can be a determiner in English, or a variable name in a formula. To avoid increasing ambiguity when linearizing formula, we type each symbol (as math or text) to make the mathematical vocabulary completely disjoint from the text vocabulary.

Both these preprocessing steps had a beneficial effect on the baselines in preliminary experiments.

B Distribution of Proof-Statement Assignments

Table 7 depicts the cumulative distribution of proofs and the number of statements they are assigned to.

C Symbol Replacement Details

We follow the following rules when replacing symbols:

---

[15] www.github.com/aboSamoor/polyglot/

[16] We used a minimum length of 20 tokens for both statements and proofs, based on a manual inspection of the shortest examples. We also exclude proofs and statements longer than 500 tokens.

Abstract

Many Natural Language Processing (NLP) systems use annotated corpora for training and evaluation. However, labeled data is often costly to obtain and scaling annotation projects is difficult, which is why annotation tasks are often outsourced to paid crowdworkers. Citizen Science is an alternative to crowdsourcing that is relatively unexplored in the context of NLP. To investigate whether and how well Citizen Science can be applied in this setting, we conduct an exploratory study into engaging different groups of volunteers in Citizen Science for NLP by re-annotating parts of a pre-existing crowdsourced dataset. Our results show that this can yield high-quality annotations and attract motivated volunteers, but also requires considering factors such as scalability, participation over time, and legal and ethical issues. We summarize lessons learned in the form of guidelines and provide our code and data to aid future work on Citizen Science.[1]

1 Introduction

Data labeling or *annotation* is often a difficult, time-consuming, and therefore expensive task. Annotations are typically drawn from domain experts or are crowdsourced. While experts can produce high-quality annotated data, they are expensive and do not scale well due to their relatively low number (Sorokin and Forsyth, 2008). In contrast, crowdsourcing can be relatively cheap, fast, and scalable, but is potentially less suited for more complicated annotation tasks (Drutsa et al., 2020). Another approach is using Citizen Science, which describes the participation and collaboration of volunteers from the general public with researchers to conduct science (Haklay et al., 2021). Over the past decade, Citizen Science platforms, which rely on unpaid volunteers to solve scientific problems, have been used for a wide variety of tasks requiring human annotation (Hand, 2010), e.g., classifying images of galaxies (Lintott et al., 2008) or for weather observation (Leeper et al., 2015).

While Citizen Science has been shown to produce high-quality annotations in ecological or environmental projects (Kosmala et al., 2016), its potential has so far not been investigated in depth for Natural Language Processing (NLP). Our goal in this work is to assess the practicality of undertaking annotation campaigns for NLP via Citizen Science. We analyze whether volunteers actually react to our calls and participate, how the resulting quality is compared to crowdsourcing, what the benefits and shortcomings are and what needs to be taken into account when conducting such a project. We especially are interested in differences between annotators recruited via different channels, which we investigate by advertising to different social media platforms, NLP-related mailing lists, and university courses. To explore this possibility, we use the PERSPECTRUM dataset (Chen et al., 2019, CC-BY-SA) that focuses on the task of stance detection and can be motivated by fighting misinformation and promoting accurate debate in internet discussions. We replicated a portion of the annotations in this dataset using citizen scientists instead of crowdworkers. To accomplish this goal, we designed an annotation workflow that is suitable for Citizen Science and allows us to recruit volunteers across a variety of platforms.

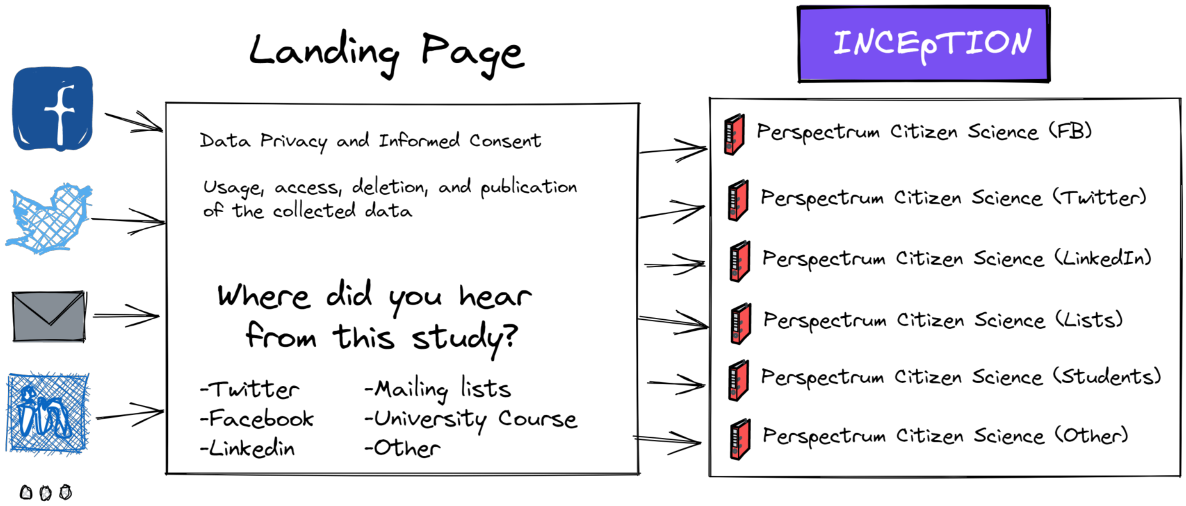

Figure 1: We advertised our project via various social media, mailing lists and university courses. Volunteers then are onboarded via the landing page and donated annotations via INCEpTION.

Our contributions are the following:

1. We provide a systematic study on Citizen Science across different channels and analyze turnout and quality. For this, we re-annotate parts of the PERSPECTRUM dataset using Citizen Science and compare these to the original, crowdsourced annotations.
2. We provide guidelines and recommendations on how to successfully conduct a Citizen Science project for NLP annotation and discuss critical legal and ethical aspects.
3. We provide a platform for future Citizen Science projects that handles onboarding, anonymous access, work assignment and the annotating itself.

Our results show that using Citizen Science for linguistic annotation can result in high-quality annotations, but that attracting and motivating people is critical for its success, especially in the long-term. We were able to attract 98 volunteers when conducting our Citizen Science project which resulted in 1,481 annotations over 2 months, thereby re-annotating around 10% of the original dataset. We find that annotations obtained through mailing lists and university students were of high quality when comparing them to the original, adjudicated crowdsourced data. We thus conclude that Citizen Science projects have the potential to be applied to NLP annotation if they are conceptualized well, but are best suited for creating smaller datasets.

2 Background

Prior work has developed various means and strategies for annotating large datasets. So far, annotation studies in NLP mainly use domain-experts or crowdworkers, or a mix of both (Nguyen et al., 2015). Crowdsourcing in particular has received increasing attention over the past decade (Wang et al., 2013).

Paid Experts Recruiting domain experts (e.g., linguists) for annotation studies has been a widely accepted method to generate linguistically annotated corpora. Famous examples are the Brown Corpus (Francis and Kucera, 1979) or the Penn Treebank (Marcus et al., 1993). While the resulting datasets are of the highest quality, domain experts are often few, and such annotation studies tend to be slow and expensive (Sorokin and Forsyth, 2008). Although many researchers moved on to annotation studies that recruit crowdworkers, expert annotations are still necessary in various fields, e.g., biomedical annotations (Hobbs et al., 2021).

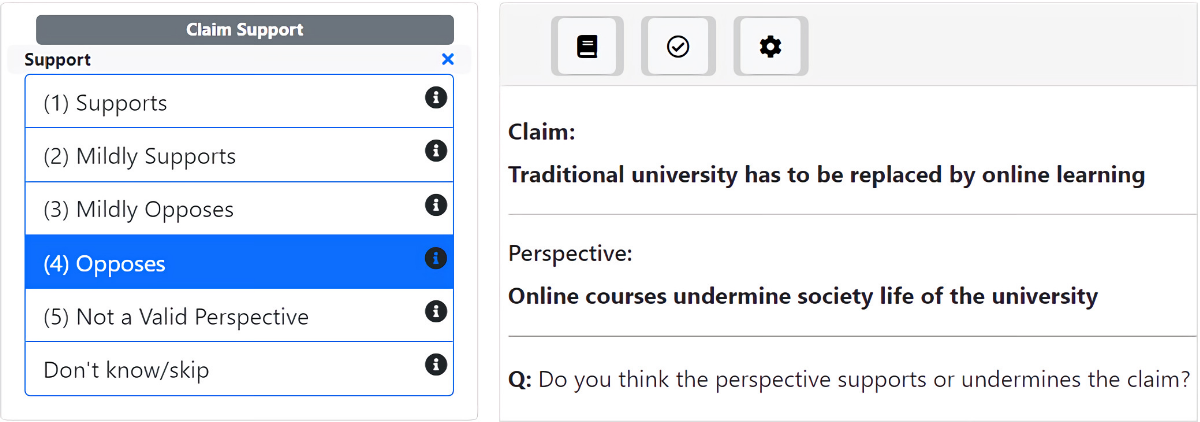
Crowdsourcing To accelerate the annotation process and reduce costs, researchers have utilized crowdsourcing as a means to annotate large corpora (Snow et al., 2008). The main idea behind crowdsourcing is that annotation tasks that do not require expert knowledge can be assigned to a large group of paid non-expert annotators. This is commonly done via crowdsourcing platforms such as Amazon Mechanical Turk (AMT) or Upwork and has been successfully used to annotate various datasets across different tasks and domains (Derczynski et al., 2016; Habernal and Gurevych, 2017). Previous work compared the quality between crowdsourcing and expert annotations, showing that many tasks can be given to crowdworkers without major impact on the quality of annotation (Snow et al., 2008; Hovy et al., 2014; De Kuthy et al., 2016).

Although crowdworkers can substantially accelerate annotation, crowdsourcing requires careful task design and is not always guaranteed to result in high quality data (Daniel et al., 2018). Moreover, as annotators are compensated not by the time they spend but rather by the number of annotated instances, they are compelled to work fast to maximize their monetary gain—which can negatively affect annotation quality (Drutsa et al., 2020) or even result in spamming (Hovy et al., 2013). It can also be difficult to find crowdworkers for the task at hand, for instance due to small worker pools for languages other than English (Pavlick et al., 2014; Frommherz and Zarcone, 2021) or because the task requires special qualifications (Tauchmann et al., 2020). Finally, the deployment of crowdsourcing remains ethically questionable due to undervalued payment (Fort et al., 2011; Cohen et al., 2016), privacy breaches, or even psychological harm on crowdworkers (Shmueli et al., 2021).

Games with a Purpose A related but different way to collect annotations from volunteers is *games with a purpose*, i.e., devising a game in which participants annotate data (Chamberlain et al., 2008; Venhuizen et al., 2013). Works propose games for different purposes and languages. For instance, anaphora annotation (PhraseDetectives, Poesio et al. 2013), dependency syntax annotation (Zombilingo, Fort et al. 2014), or collecting idioms (Eryiğit et al., 2022). It has been shown that if a task lends itself to being gamified, then it can attract a wide audience of participants and can be used to create large-scale datasets (von Ahn, 2006). Finally, Lyding et al. (2022) investigate games with a purpose in the context of (second) language learning to simultaneously crowdsource annotaions from learners as well as teachers. One such example is Substituto, a turn-based, teacher-moderated game for learning verb-particle constructions (Araneta et al., 2020). We do not consider gamification in this work, as enriching tasks with game-like elements requires considerable effort and cannot be applied to every task.

Citizen Science Citizen Science broadly describes participation and collaboration of the general public (the citizens) with researchers to conduct science (Haklay et al., 2021). Citizen Science is a popular alternative approach for dataset collection efforts, and has been successfully applied in cases of weather observation (Leeper et al., 2015), counting butterflies (Holmes, 1991) or birds (National Audubon Society, 2020), classifying images of galaxies (Lintott et al., 2008) or monitoring water quality (Addy et al., 2010). Newly-emerging technologies and platforms further allow researchers to conduct increasingly innovative Citizen Science projects, such as the prediction of influenza-like outbreaks (Lee et al., 2021) or the classification of animals from the Serengeti National Park (Swanson et al., 2015). *LanguageARC* is a Citizen Science platform for developing language resources (Fiumara et al., 2020). It is however not open yet to the public to create projects and does not easily allow conducting a Citizen Science meta-study as we do in this work. One work using LanguageARC is by Fort et al. (2022) (LD) who collected resources to evaluate bias in language models. They did not investigate the impact of using different recruitment channels which we do. Other projects using LanguageARC are still running and it is too early to derive recommendations from.

Compared to crowdsourcing, Citizen Science participants are volunteers that do not work for monetary gain. Instead, they are often motivated intrinsically. For instance, they may have a personal interest on positively impacting the environment (West et al., 2021), or in altruism (Rotman et al., 2012). Asking for unpaid work also entails various issues like finding good ways of how to attract volunteers, and ethical considerations (Resnik et al., 2015; Rasmussen and Cooper, 2019) that need to be addressed (cf. §5). Intrinsic motivation also has the potential of resulting in higher-quality annotations compared to crowdsourcing. For instance, Lee et al. (2022) find in their evaluation study with citizen scientists that their participants may have been willing to take more time annotating for the sake of higher annotation accuracy. However, as their main goal was to conduct an evaluation study for their specific setup, this finding cannot be generalized to other Citizen Science scenarios. So far, only Tsueng et al. (2016) provide a direct comparison between crowdsourcing and Cit-



Claim:

Online courses undermine society life of the university

Q: Do you think the perspective supports or undermines the claim?

Figure 2: Assigning a label to an instance in the INCEpTION text annotation platform.

izen Science and show that volunteers can achieve similar performance in mining medical entities in scientific texts. They recruit participants through different channels such as newspapers, Twitter, etc., but do not compute channel-specific performance, making it difficult to assess whether the quality of the resulting annotation depends on the recurrent channel. In contrast, in the present work, we explicitly consider the recruitment channel in our evaluation and furthermore provide a discussion and guidelines for future Citizen Science practitioners. Also, it attracts intrinsically (not only fiscally) motivated volunteers that are often skilled in the task and can provide high-quality annotations, thus potentially combining the advantages of expert annotations and crowdsourcing. Relying on unpaid annotators entails several issues, including attracting volunteers and ethical considerations (Resnik et al., 2015; Rasmussen and Cooper, 2019) that need to be taken into account (see §5).

3 Study Design

To study the feasibility of Citizen Science for NLP annotation, we asked volunteers recruited via various channels to re-annotate an existing, crowdsourced dataset. The general setup is described in Fig. 1. To conduct a systematic study, we identified the following four necessary steps: 1) Identifying a suitable dataset (§3.1); 2) Selecting suitable recruitment channels to advertise our project on (§3.2); 3) Building a landing page for onboarding participants that asks for informed consent and the channel from which they originated (§3.3); 4) Setting up the annotation editor to which participants are forwarded after the onboarding (§3.4).

3.1 Dataset selection

We first conducted a literature review of relevant crowdsourced NLP datasets to identify the ones that could be accurately reproduced via Citizen Science. We assessed datasets for the following two criteria: 1) **Availability**: the dataset must be publicly available to make proper comparisons in terms of annotator agreement; 2) **Reproducibility**: the annotation setup including annotation guidelines needs to be reproducible to ensure similar conditions between citizen scientists and crowdworkers. We focused on datasets that are targeted towards contributing to social good to encourage volunteers to participate. Unfortunately, many inspected datasets did not fulfill both of these requirements. Overall, we identified two main issues while screening over 20 candidate datasets. First, many datasets used Tweets which impacted reproducibility as Twitter only allows researchers to publish the tweet identifiers. This leads to irrecoverable instances when tweets were deleted. Second was the lack of precise guidelines. For instance, many considered datasets about societal biases lack explicit descriptions of what is considered a stereotype. As such biases are often also impacted by the respective cultural background of annotators, they are difficult to reproduce without specific guidelines.

In the end, we decided on the stance detection task of the PERSPECTRUM dataset (Chen et al., 2019). The task provides clear instructions, publicly available data, and is motivated by social good (fighting misinformation/promoting accurate debate in internet discussions). Each instance consists of a claim–perspective pair (cf. Fig. 2) and annotators are asked if the claim *supports*, *opposes*, *mildly-supports*, *mildly-opposes*, or is *not a valid*

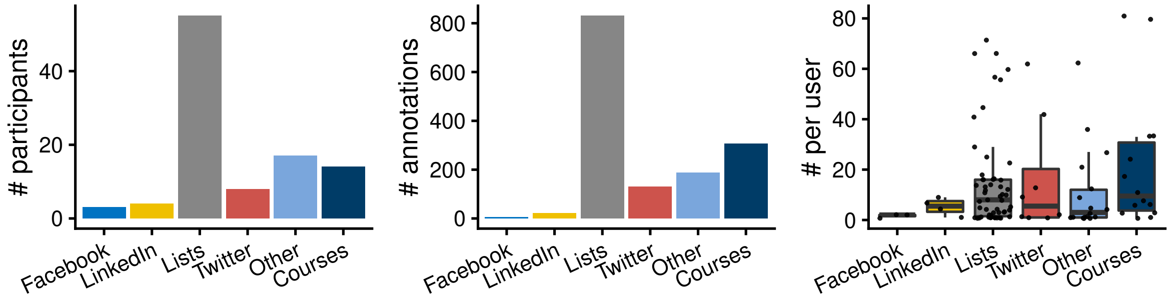

Figure 3: Participants, annotations and annotations grouped by the channel via they were recruited. It can be seen that overall, most participants and annotations were contributed by annotators recruited via mailing lists. Annotators from mailing lists and courses yielded the volunteers who contributed the most individually.

perspective. Following the original work, we also evaluated the annotations on a coarser tagset that only contains the categories for *support*, *oppose* and *not a valid perspective*. Overall, the dataset consists of 907 claims and $8,370$ different perspectives which yield $11,805$ annotated instances. In preliminary studies, we received further feedback that forcing annotators to provide an explicit label for each instance could lead to increasing frustration, especially for ambiguous or complicated instances. To lessen the burden for our voluntary annotators and keep them motivated in the annotation task, we allowed them to skip instances (*Don't know/skip*) which was not present in the original annotation editor for PERSPECTRUM.

3.2 Recruitment channels

To recruit annotators, we advertised our project on three social media platforms, namely, Twitter, LinkedIn and Facebook. Unfortunately, after creating the Facebook organization and advertising the project, the account was banned due to "violating their community standards" and has so far remained banned. One of our team members then promoted our annotation study on their personal Facebook to attract participation from this social media platform. In addition, the team members advertised the work on Twitter and in relevant LinkedIn groups such as COMPUTATIONAL LINGUISTICS and MACHINE LEARNING AND DATA SCIENCE.

We further promoted the study via two external mailing lists (i.e., CORPORA-LIST, ML-NEWS). Late in the project, we received interest from other faculty to advertise the task in their courses—an offer that we gladly accepted. For this, participation was completely voluntary and anonymous, students' grades were not affected by participation, and authors were not among the instructors. To evaluate different recruitment channels separately, we asked participants on the landing page to answer the question: "Where did you hear from this study?". We also allowed volunteers to not disclose how they found out about the study, this is referred to as "Other" or "Undisclosed" in this paper. Final participation counts are given in Fig. 3. We deliberately limited our outreach, e.g. we did not use university social media accounts or colleagues with large follower bases. Also, we made sure to not exhaust channels by posting too many calls for participation.

3.3 Landing page

We implemented a customizable landing page web application catering to the needs of Citizen Science projects. The link to such a landing page was shared via the respective recruitment channels. The landing page contained information about the study itself, its purpose, its organizers, which data we collected, and its intended use. This landing page toolbox is designed so that it can easily be adapted to future Citizen Science projects. To allow project creators to use an annotation editor of their choice, we designed the toolbox to act as an intermediary that collects a participant's consent for the actual annotation study. This ensures that only participants that have been properly informed and have explicitly provided their consent are given access to the study. For future Citizen Science projects, the tool further assists organizers through the landing page creation process to foster an ethical collection of data by asking several questions, that are listed in the appendix.

3.4 Annotation editor

INCEpTION (Klie et al., 2018) offers a configurable, web-based platform for annotating text documents at span, relation and document levels. To make it usable in Citizen Science scenarios, we extended the platform with three features, namely, (1) the ability to join a project through a link, (2) support for anonymous guest annotators, and (3) a dynamic workload manager. Allowing citizen scientists to participate in the project anonymously as guests without any sign-up process substantially reduced the entry barrier and made it easier for us to satisfy data protection policies. The same is true for the ability of joining a project through an invite link. Upon opening the link, annotators were greeted with the annotation guidelines and were directly able to start annotating. Finally, we implemented a dynamic workload manager that takes as input the desired number of annotators per document and then automatically forwards annotators directly to the document instances requiring annotation. Upon finishing annotating an instance, INCEpTION was configured to automatically load and display the next instance for annotation, similar to popular crowdsourcing platforms. We also included rules for handling other issues that may occur with voluntary annotations such as recovering instances that annotators have started to work on but then abandoned. Additionally, we modified the existing user interface to improve the annotation workflow. This mainly included implementing a dedicated labeling interface that allows users to select a single label for an instance via a radio button group. Annotation of an instance thus required two user actions: first, selecting the document label, and second, confirming the annotation, thereby moving on to the next document.

4 Results

We conducted our study between January and March 2022 and promoted the task in successive rounds across all recruitment channels. In total, we were able to recruit 98 participants who provided 1481 annotations resulting in 906 fully annotated instances. Each instance with at least one annotation has received on average 1.63 annotations. Detailed statistics are provided in the appendix.

Participation To identify promising channels for future Citizen Science studies, we report the number of annotators per channel, the total number of annotations per channel and per user (cf. Fig. 3). Overall, we find that the most effective channel for public outreach are mailing lists (55 participants). Asking students in university courses to participate was the second most effective with 14 participants. Facebook, LinkedIn, and Twitter only yielded three, four, and eight participants respectively. We further find a highly skewed distribution of annotations per user, as many annotators only provide a few annotations while a few annotators provide many annotations. For instance, the most active annotators were two students who provided ∼80 annotations as well as six participants from mailing lists who provided ∼60–80 annotations each. For Twitter and "undisclosed", only a single annotator made over 60 annotations. We also find that on average, participants from university courses provided the most annotations per person. When looking at participation over time (see Fig. 5), we observe increased activity in annotations made after the call for participation has been posted to the respective channel. For many channels, the count quickly flattens. Interestingly, Twitter sees a second spike long after the post was made. We attribute it to people sharing the post in our community quite a while after the initial release. We did not track whether individual volunteers came back for another round of annotations after their initial participation.

Coverage Overall, our 98 volunteers have provided 1,481 annotations to 906 unique instances (approximately 8% of the original dataset) over two months. This is comparable to other Citizen Science projects like Fort et al. (2022), which had 102 participants in total. They annotated three tasks and collected 2347, 2904 and 220 submissions over eight months. Table 1 shows the resulting coverage of our Citizen Science annotation study. While this still leaves room for improvement, the number of annotations collected nonetheless shows that Citizen Science can be viable in real life settings and is a promising direction to investigate in further studies, especially for creating focused and smaller-scale resources.

Quality In terms of annotation quality, we find that most channels yield annotations that highly agree with the gold labels (cf. Table 2), even though our annotations are not adjudicated yet. We further find that volunteers from university courses and mailing list show the highest accuracy, followed by Twitter and "undisclosed". Only LinkedIn yields

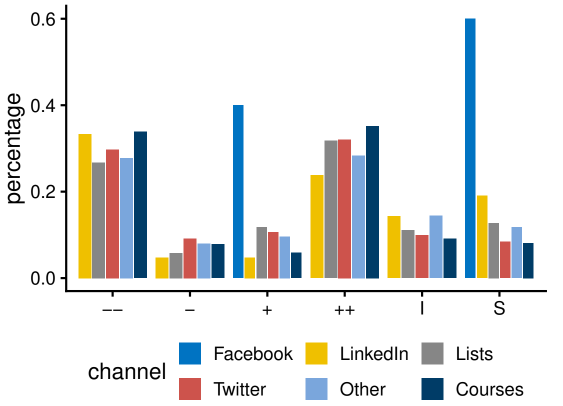

Figure 4: Label distribution grouped by channel. Labels are *supports* (++), *mildly-supports* (+), *mildly-opposes* (-), *opposes* (--), *not a valid perspective* (I) and *Skip* (S).

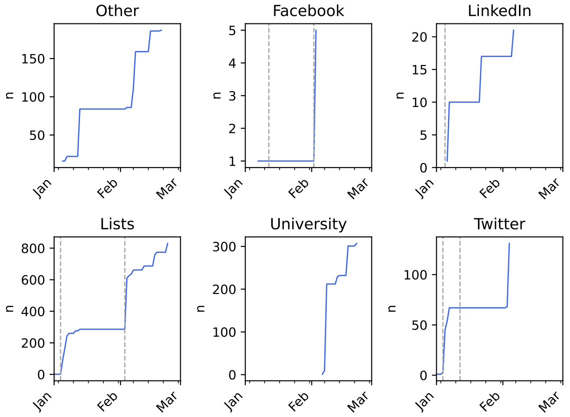

Figure 5: Annotations made over time. Vertical lines indicate when calls on the respective channels have been posted.

lower accuracy than 70% on the coarse label set.

For the majority of channels (with the exception of Facebook and LinkedIn), we only see a skip percentage of ∼10% (cf. Fig. 4). This indicates our volunteers are actually willing to spend time and effort to solve the task at hand, as adding a "Don't know/skip" option in crowdsourcing usually is an invitation for workers to speed through the tasks and not provide useful annotations. The exception is Facebook, where we find that a majority of the annotations from Facebook were labeled as *I don't know/skip* (3 out of 5). Further analysis of the label distribution grouped by channel (cf. Fig. 4) shows that all channels except for Facebook display a similar distribution in terms of annotated labels. This indicates that we can expect a rather stable annotation performance across citizen scientists recruited from different channels.

5 Discussion and Takeaways

Here we present lessons learned, discuss legal challenges and ethical considerations, as well as provide guidelines for future Citizen Science projects.

Table 1: Claims, claim clusters, and individual claim-perspective pairs that have been annotated at least once. We call the set of a claim and a perspective together with its paraphrases a claim cluster.

Name	# Annotated	# Total	% Annotated
Claims	388	907	42.78
Clusters	739	5092	14.51
Total	906	11805	7.67

Table 2: Annotation accuracy compared to the crowd-sourced and adjudicated data from PERSPECTRUM. The five annotations from Facebook (three of them were skipped) and *Don't know/skip* annotations are omitted.

Channel	Coarse	Fine
University	0.92	0.82
LinkedIn	0.69	0.62
Mailing Lists	0.90	0.82
Undisclosed	0.84	0.75
Twitter	0.85	0.73

Channel-dependent differences Our results clearly differ across recruiting channels. We find that overall, Facebook and LinkedIn have the lowest turnout and accuracy when compared to the gold labels, followed by Twitter. Our assumption for the overall low participation is that our network for these channels was not large enough. Advertising our study to NLP-related and university-internal mailing lists and university courses yielded the highest number of participants who also provided the most and best-quality annotations. Although our results show that students may outperform participants from other channels, we also acknowledge that this may not always be a viable option to recruit citizen scientists. Overall, our findings indicate that it is important to address the respective target groups that may be interested in a specific study. However, we also note that continuously advertising Citizen Science studies to the same channels may have a negative impact, as it can cause participation fatigue and lead to fewer volunteers participating. One possible solution could be the use of LanguageARC (Fiumara et al., 2020) from the LDC and centralize calls for participation.

Motivating volunteers In contrast to crowdsourcing, there is no monetary or other extrinsic motivation that could be used to attract Citizen Science annotators. Thus, annotator motivation is a crucial question for Citizen Science studies. As Fig. 5 shows, citizen scientists can be quickly motivated to participate, but can also quickly lose interest in a given annotation study. This can become an issue with a low number of participants, yet our results also indicate that we were able to find highly-motivated participants (8 out of 98 in our results).

Compared to other groups, university students in particular provided a high amount of quality annotations. Considering the findings by Phillips et al. (2018), who do not find statistical differences in terms of quality between students participating for course credit vs. no extrinsic reward—asking students to participate in such projects as part of their coursework might be another good option, but needs to ensure an ethical data collection. For instance, such an approach has been used to annotate the Georgetown University Multilayer Corpus (Zeldes, 2017). Nonetheless, one remaining question is how to keep participants motivated and participate in several sessions as our results indicate that a vast majority of our volunteers only participated in a single session and that participation quickly stops shortly after a call has been posted to the respective channel.

Finally, we want to emphasize the inclusion of a *Don't know/skip* option for Citizen Science annotators. Whereas in crowdsourcing studies, annotators may exploit such an option to increase their gain (Hovy et al., 2013), from the feedback we got during our pilot study, it is crucial to keep volunteers motivated for Citizen Science. For this work, we did not provide a survey that asks about the motivation, as we thought that this might deter potential participants We however suggest that future studies provide such a survey that is as unintrusive as possible to further analyze why participants take part in the respective annotation project.

Legal challenges One substantial challenge in implementing Citizen Science studies is the potentially wide outreach they can have and, consequently, the varying kinds of data protection regulations they have to oblige. To preempt any potential issues that can arise—especially when data that can be used to identify a person (personal data, e.g. obtained during a survey or login credentials) is involved—we recommend researchers who plan to implement a Citizen Science study consider the most strict regulations that are widely accepted.

For the GDPR (European Parliament, 2016), currently one of the strictest data protection regulations, we recommend researchers to explicitly ask voluntary participants for their informed consent when collecting personal information. This includes informing participants beforehand about (1) the purpose of the data collection, (2) the kind of personal and non-personal data collected, (3) the planned use of the data, (4) any planned anonymization processes for publication, and finally, (5) how participants can request access, change, and deletion of the data. We further recommend assigning one specific contact person for any questions and requests for access, change, or deletion of the data. This may seem like additional work when compared to crowdsourcing, but transparent and open communication is one of the key factors to build trust—which is necessary for voluntary participants to consider such studies and provide high-quality annotations. Finally, participants should be informed and agree to the annotations donated being published under a permissive license.

Ethical and economical considerations Although Citizen Science can substantially reduce annotation costs, we emphasize the importance of considering an ethical deployment that does not compromise the trust of the participants. Moreover, given increasing concerns regarding the ownership and use of collected data (Arrieta-Ibarra et al., 2018), one should grant participants full rights to access, change, delete, and share their own personal data (Jones and Tonetti, 2020). This ensures that participants are not exploited for "free labor"—in contrast to approaches like reCAPTCHA (von Ahn et al., 2008), where humans are asked to solve a task in order to gain access to services. Whereas CAPTCHAs were initially intended to block malicious bots, they are becoming increasingly problematic due to their deployment and use by monopolizing companies which raises ethical concerns (Avanesi and Teurlings, 2022) . It is especially important to take the data itself into consideration; exposing volunteers to toxic, hateful, or otherwise sensitive speech should be avoided if they are not informed about it beforehand.

Recommendations Overall, we derive the following recommendations for future Citizen Science studies. 1) our call for annotations resonated the most with the target group that is likely to benefit the most from contributing to it: NLP researchers coming from mailing lists and university students. Therefore, the target audience should be carefully selected, for instance by identifying topic-specific mailing lists or respective university courses. This further means that the purpose of data collection should be made clear and that the results should be made publicly available. 2) the research question of the study should conform to the respective ethical and legal guidelines of the potential target group which should clearly be communicated to make the project accountable. 3) participation should be easy with clearly formulated annotation guidelines and, moreover, the annotation itself should be thoroughly tested beforehand to ensure that participants do not get frustrated due to design errors or choices. For instance, in our preliminary study, we got the feedback that some instances are frustrating to annotate and hence added an option to skip. 4) analyzing participation over time shows that a Citizen Science project has to be continuously advertised in order to stay relevant and achieve high participation. Otherwise, it will be forgotten quickly. This can be done by sharing status updates or creating preliminary results. Fifth, we recommend asking about user motivation before, during or after the annotation with a survey to better understand the participants and their demographics.

6 Conclusion

In this work, we presented an exploratory annotation study for utilizing Citizen Science for NLP annotation. We developed an onboarding process that can easily be adapted to similar projects and evaluated Citizen Science annotations for re-annotating an existing dataset. Furthermore, we extended the INCEpTION platform, a well-known open-source semantic annotation platform, with a dynamic workload manager and functionality for granting access to external users without registration. This enables its usage for Citizen Science projects. We advertised the study via Twitter, Facebook, LinkedIn, mailing lists, and university courses and found that participants from mailing lists and university courses are especially capable of providing high-quality annotations. We further discuss legal and ethical challenges that need to be addressed when conducting Citizen Science projects and provide general guidelines for conducting future projects that we would like to have known before starting. Overall, we conclude that Citizen Science can be a viable and affordable alternative to crowdsourcing, but is limited by successfully keeping annotators motivated. We will make our code and data publicly available to foster more research on Citizen Science for NLP and other disciplines.

Future Work We see the following directions for further research and evaluation to better understand in which settings Citizen Science can be applicable and how to use it best. Here, we used PERSPECTRUM as the dataset to annotate and mentioned in the participation calls that it benefits the social good. Therefore, it would be interesting to conduct more projects and see which datasets are suitable as well as whether volunteers participate, even if there is no extrinsic motivation. Then, it can also be tested how annotator retention develops, especially when project are running longer. The call for participation itself could also be investigated for the impact it has on turnout, motivation and quality.

7 Limitations

Throughout this article, we analyzed whether Citizen Science applies to linguistic annotation and showed that we can attract volunteers that donate a sizeable number of high-quality annotations. This work, however, comes with limitations that should be taken into account and tackled in future work. First, we based our analysis on a single annotation campaign and dataset that we advertised as being relevant for the social good. Therefore we suggest conducting more such annotation projects, also with different kinds of tasks. Second, we did not perform a user survey that for instance asked for user motivation. This is why we can only speculate about the motivation of our participants and suggest future works to explicitly prepare such a survey. Third, using Facebook as a channel might be viable, but we were not able to properly analyze it, as our account was blocked shortly after creation and never was reinstantiated. Finally, based on participation and annotation numbers, we see Citizen Science as more of an option for annotating smaller datasets, or longer-term projects that are more actively advertised than in our study which took place over two months and for which we deliberately limited the outreach.

Acknowledgments

We thank our anonymous reviewers, Michael Bugert and Max Glockner for their detailed and helpful comments to improve this manuscript. We are especially grateful for the discussions with Michael and Anne-Kathrin Bugert regarding our study setup. Finally, we thank the many volunteers that donated annotations for this project, as this work would not have been possible without their generous participation.

This work has been funded by the German Research Foundation (DFG) as part of the Evidence project (GU 798/27-1), UKP-SQuARE (GU 798/29-1), INCEpTION (GU 798/21-1) and PEER (GU 798/28-1), and within the project "The Third Wave of AI" funded by the Hessian Ministry of Higher Education, Research, Science and the Arts (HWMK). Further, it has been funded by the German Federal Ministry of Education and Research and HMWK within their joint support of the National Research Center for Applied Cybersecurity ATHENE.

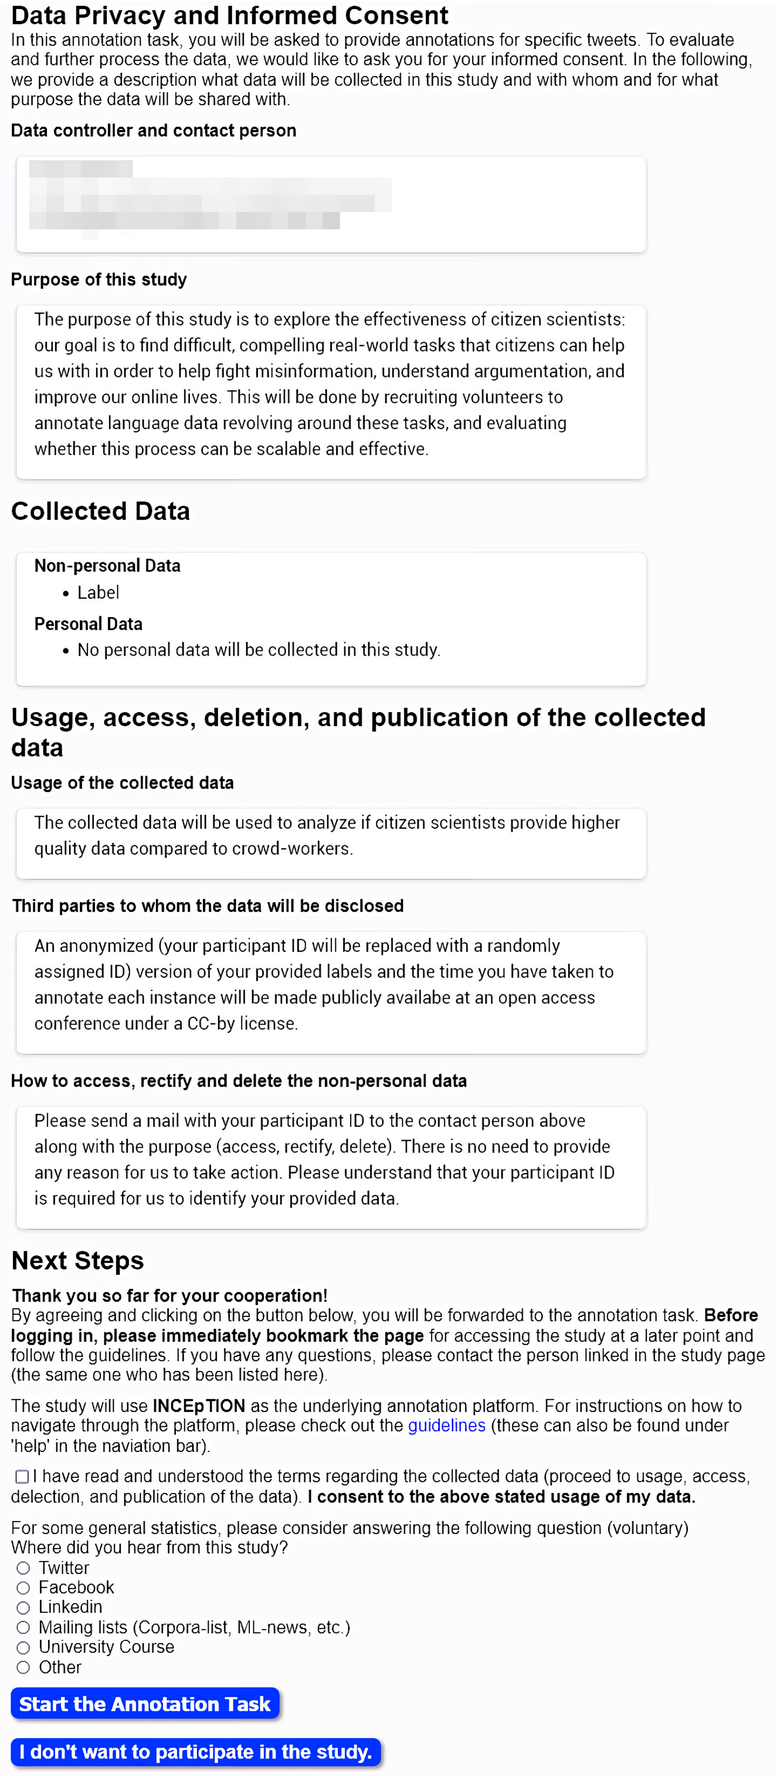
Appendix A Landing Page



Data Privacy and Informed Consent

In this annotation task, you will be asked to provide annotations for specific tweets. To evaluate and further process the data, we would like to ask you for your informed consent. In the following, we provide a description what data will be collected in this study and with whom and for what purpose the data will be shared with.

Data controller and contact person

[redacted]

Purpose of this study

The purpose of this study is to explore the effectiveness of citizen scientists: our goal is to find difficult, compelling real-world tasks that citizens can help us with in order to help fight misinformation, understand argumentation, and improve our online lives. This will be done by recruiting volunteers to annotate language data revolving around these tasks, and evaluating whether this process can be scalable and effective.

Collected Data

Non-personal Data

- Label

Personal Data

- No personal data will be collected in this study.

Usage, access, deletion, and publication of the collected data

Usage of the collected data

The collected data will be used to analyze if citizen scientists provide higher quality data compared to crowd-workers.

Third parties to whom the data will be disclosed

An anonymized (your participant ID will be replaced with a randomly assigned ID) version of your provided labels and the time you have taken to annotate each instance will be made publicly availabe at an open access conference under a CC-by license.

How to access, rectify and delete the non-personal data

Please send a mail with your participant ID to the contact person above along with the purpose (access, rectify, delete). There is no need to provide any reason for us to take action. Please understand that your participant ID is required for us to identify your provided data.

Next Steps

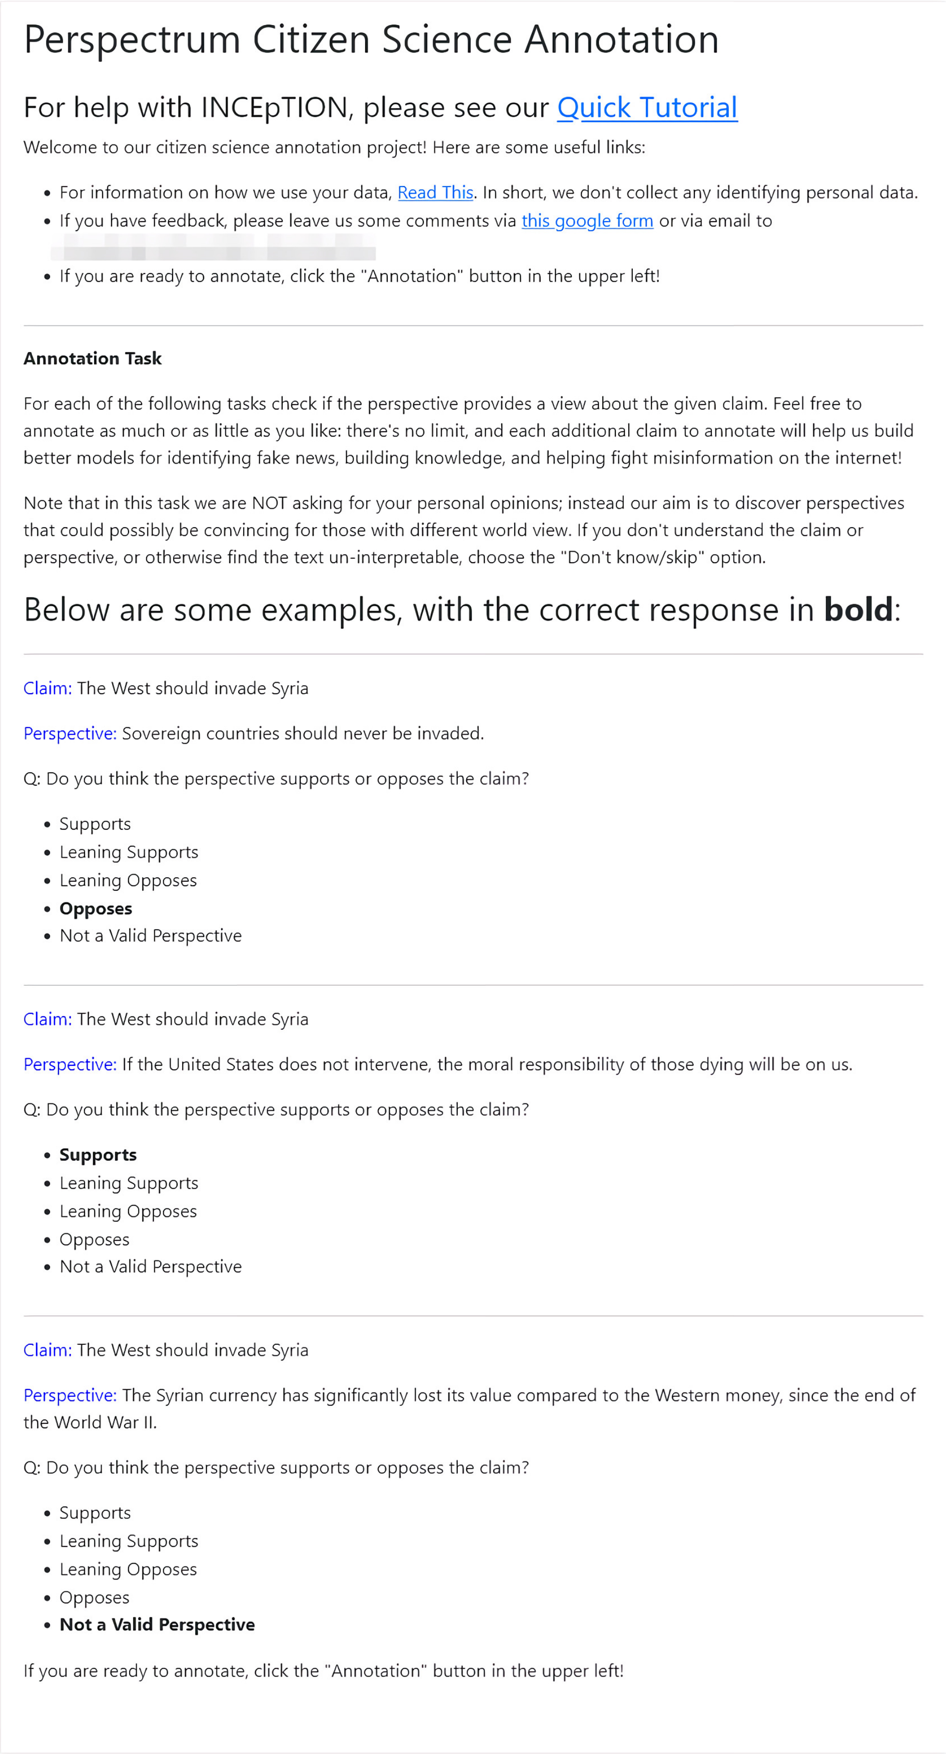
Thank you so far for your cooperation!
By agreeing and clicking on the button below, you will be forwarded to the annotation task. **Before logging in, please immediately bookmark the page** for accessing the study at a later point and follow the guidelines. If you have any questions, please contact the person linked in the study page (the same one who has been listed here).

The study will use **INCEpTION** as the underlying annotation platform. For instructions on how to navigate through the platform, please check out the guidelines (these can also be found under 'help' in the naviation bar).

☐ I have read and understood the terms regarding the collected data (proceed to usage, access, delection, and publication of the data). **I consent to the above stated usage of my data.**

For some general statistics, please consider answering the following question (voluntary)
Where did you hear from this study?
○ Twitter
○ Facebook
○ Linkedin
○ Mailing lists (Corpora-list, ML-news, etc.)
○ University Course
○ Other

Appendix B Annotation Guidelines



Perspectrum Citizen Science Annotation

For help with INCEpTION, please see our Quick Tutorial

Welcome to our citizen science annotation project! Here are some useful links:

- For information on how we use your data, Read This. In short, we don't collect any identifying personal data.
- If you have feedback, please leave us some comments via this google form or via email to [redacted]
- If you are ready to annotate, click the "Annotation" button in the upper left!

Annotation Task

For each of the following tasks check if the perspective provides a view about the given claim. Feel free to annotate as much or as little as you like: there's no limit, and each additional claim to annotate will help us build better models for identifying fake news, building knowledge, and helping fight misinformation on the internet!

Note that in this task we are NOT asking for your personal opinions; instead our aim is to discover perspectives that could possibly be convincing for those with different world view. If you don't understand the claim or perspective, or otherwise find the text un-interpretable, choose the "Don't know/skip" option.

Below are some examples, with the correct response in **bold**:

Claim: The West should invade Syria

Perspective: Sovereign countries should never be invaded.

Q: Do you think the perspective supports or opposes the claim?

- Supports
- Leaning Supports
- Leaning Opposes
- **Opposes**
- Not a Valid Perspective

Claim: The West should invade Syria

Perspective: If the United States does not intervene, the moral responsibility of those dying will be on us.

Q: Do you think the perspective supports or opposes the claim?

- **Supports**
- Leaning Supports
- Leaning Opposes
- Opposes
- Not a Valid Perspective

Claim: The West should invade Syria

Perspective: The Syrian currency has significantly lost its value compared to the Western money, since the end of the World War II.

Q: Do you think the perspective supports or opposes the claim?

- Supports
- Leaning Supports
- Leaning Opposes
- Opposes
- **Not a Valid Perspective**

If you are ready to annotate, click the "Annotation" button in the upper left!

Appendix C Questions to keep in mind for a citizen science project

- What is the purpose of the study?
- What kind of personal and non-personal data will be collected?[2]
- If there is a questionnaire involved, what questions will it involve?
- How will the data be used?
- Is a publication of the data planned and if so, which data will be published and will it be anonymized?
- How can participants request access, change, or deletion of their data?

Appendix D Project Statistics

D.1 Number of participants

In addition to the plots visualizing the number of participants (c.f. Fig. 3), we also list the raw numbers in Table 3.

Channel	Participants
Courses	14
Facebook	3
LinkedIn	4
Lists	55
Twitter	8
Undisclosed	17

Table 3: Number of participants per channel.

D.2 Annotation statistics

In addition to the plots visualizing the annotation counts and label distribution (c.f. Fig. 4), we also list the raw numbers in Table 4.

Table 4: Label distribution grouped by channel. Labels are *supports* (++), *mildly-supports* (+), *mildly-opposes* (-), *opposes* (--), *not a valid perspective* (I) and *Skip* (S).

Channel	Total	Counts						Percentage					
		+	++	-	--	I	S	+	++	-	--	I	S
Courses	307	18	108	24	104	28	25	5.86	35.18	7.82	33.88	9.12	8.14
Facebook	5	2	0	0	0	0	3	40.00	0.00	0.00	0.00	0.00	60.00

[2] We provided some pre-defined suggestions such as *Name* or *IP* for personal data and *Label* for non-personal data with the possibility to add more in our landingpage module.

Contrastive Learning with Keyword-based Data Augmentation for Code Search and Code Question Answering

Shinwoo Park[1], **Youngwook Kim**[2] and **Yo-Sub Han**[2]
[1]Department of Artificial Intelligence, Yonsei University, Seoul, Republic of Korea
[2]Department of Computer Science, Yonsei University, Seoul, Republic of Korea
`{pshkhh, youngwook, emmous}@yonsei.ac.kr`

Abstract

The semantic code search is to find code snippets from the collection of candidate code snippets with respect to a user query that describes functionality. Recent work on code search proposes data augmentation of queries for contrastive learning. This data augmentation approach modifies random words in queries. When a user web query for searching code snippet is too brief, the important word that represents the search intent of the query could be undesirably modified. A code snippet has informative components such as function name and documentation that describe its functionality. We propose to utilize these code components to identify important words and preserve them in the data augmentation step. We present KeyDAC (Keyword-based Data Augmentation for Contrastive learning) that identifies important words for code search from queries and code components based on term matching. KeyDAC augments query-code pairs while preserving keywords, and then leverages generated training instances for contrastive learning. We use KeyDAC to fine-tune various pre-trained language models and evaluate the performance of code search and code question answering via CoSQA and WebQueryTest. The experimental results confirm that KeyDAC substantially outperforms the current state-of-the-art performance, and achieves the new state-of-the-arts for both tasks.

1 Introduction

Software developers or students who major in computer science often write natural language queries to search for code snippets with desired functionality from the web search engine. The retrieved code snippets are reused or referred to improve productivity of software development. Semantic code search is a well-known code-related downstream task that measures the semantic relevance between a given natural language query and a collection of code snippets to retrieve the most relevant code snippet. CodeXGLUE (Lu et al., 2021), a benchmark for 10 code tasks, provides two test sets—CodeSearchNet AdvTest and WebQueryTest—for an open challenge code search. CodeSearchNet AdvTest from the CodeSearchNet (Husain et al., 2019) corpus is for a retrieval scenario in which one needs to find a Python code function that matches the search intent of the query best. The queries in CodeSearchNet AdvTest are not real user queries. Instead, they are documentations such as comments or summaries written by developers. WebQueryTest is a code question answering task that asks whether a Python code function has functionality described by the real user web query collected from the search logs of a commercial search engine. Recently, Huang et al. (2021) introduce CoSQA that consists of pairs of real user web queries and Python code snippets. Then, they use CoSQA as a benchmark for code search to resemble the real world scenario where developers write natural language queries to find code snippets.

Huang et al. (2021) propose CoCLR, a contrastive learning method using a query-rewritten data augmentation, to improve the code search performance. CoCLR modifies the random words in queries to augment training query-code pair instances. However, besides the user queries, there are useful components that describe the functionality of code snippets. Since a function name and documentation describe functionality of the corresponding code function, we propose to use these components as well for data augmentation. Furthermore, we suggest considering the relative importance of words in query and code function. Note that the data augmentation used in the previous code search method treats all words equally. Xie et al. (2020) use TF-IDF to calculate the relative importance of words in a sentence, then replace unimportant words to augment training sentences. We adapt this idea and define the relative importance in code search based on term matching between a

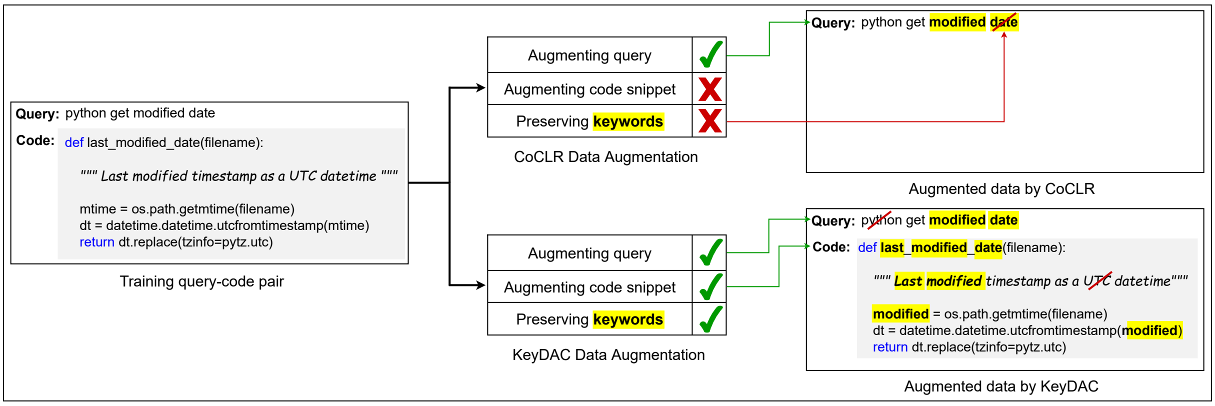

Figure 1: Comparison of data augmentation approaches for semantic code search. Example query-code pair is from CoSQA (Huang et al., 2021) training dataset. Keywords are marked in yellow and red slash line denotes the deletion of a word. Both CoCLR (Huang et al., 2021) and KeyDAC apply data augmentation to query. In contrast to CoCLR, KeyDAC also augments code snippet (deleting `UTC` in documentation and renaming variable `mtime` to *modified*, which is one of keywords). While CoCLR can delete the keyword *date*, KeyDAC preserves keywords.

paired query and code snippet.

We present KeyDAC, **Key**word-based **D**ata **A**ugmentation for **C**ontrastive learning that identifies keywords from a given query-code pair based on term matching. KeyDAC applies data augmentation both on natural language (NL) sequences (*i.e.*, query, function name, and documentation) and programming language (PL) sequences (*i.e.*, code statements), and generates more training query-code pair instances while preserving keywords. Figure 1 shows an example training query-code pair instance from CoSQA training dataset and compares the results of two data augmentation approaches, CoCLR and KeyDAC. The query asks how to get modified date. In this case, important words closely related to the search intent are *modified* and *date*. Since CoCLR modifies random words in query, *date* could be modified in data augmentation process. The augmented query by CoCLR is *python get modified* (keyword *date* is deleted) which does not represent clear search intent. On the other hand, KeyDAC preserves keywords in the data augmentation step. In addition, KeyDAC augments code snippet by deleting unimportant word `UTC` in documentation, and renaming the variable in the code statements using keywords (`mtime` to *modified*). We evaluate the effectiveness of KeyDAC on CoSQA and open challenge WebQueryTest.[1] We use KeyDAC to fine-tune various pre-trained language models. KeyDAC brings substantial performance gain, resulting in new state-of-the-art performance both on code search and code question answering tasks. Our main contributions are as follows:

- We propose KeyDAC—data augmentation mechanism for contrastive learning, which identifies important words from training query-code pairs and augments them while preserving identified keywords.
- We demonstrate that KeyDAC outperforms the current SOTA for the code search task on CoSQA benchmark.
- We achieve a new record, with a substantial improvement, for the open challenge code QA, WebQueryTest.

2 Related Work

2.1 Code Search Methods

Some researchers proposed information retrieval-based approaches using term matching between queries and code snippets (Lu et al., 2015; Lv et al., 2015). However, since these traditional approaches focused on lexical information, they often fail to understand the semantic relationship between the query and the code snippet. Recently, many researchers started to address the problem through deep learning-based approaches (Cambronero et al., 2019; Li et al., 2020) that learn the semantic representation of the query and code. Later, pre-trained models for programming languages were proposed and showed an improvement on code search tasks. CodeBERT (Feng et al., 2020) is a bimodal pre-trained model for NL and PL, which was pre-trained with masked language modeling

---

[1] The leaderboard of WebQueryTest is available at `https://microsoft.github.io/CodeXGLUE/`

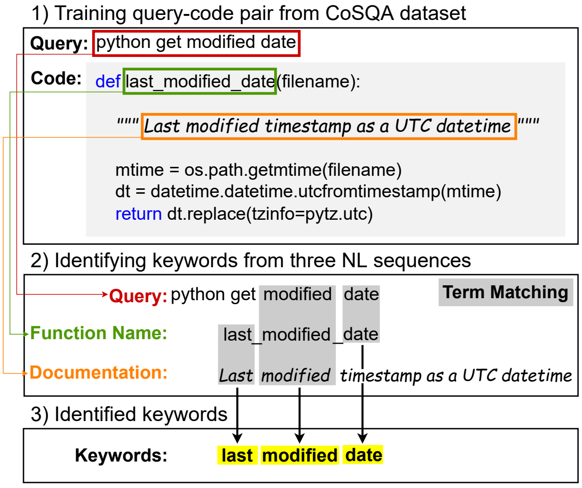
(MLM) and replaced token detection (RTD). Feng et al. (2020) showed that CodeBERT outperformed both RoBERTa and RoBERTa pre-trained on code datasets. GraphCodeBERT (Guo et al., 2020) further improved the performance by pre-training using data flow as a semantic-level structure of code.

2.2 Contrastive Learning for Code Search

Contrastive learning encourages the distance between similar instances to be minimized and the distance between dissimilar instances to be maximized in the representation space. Recently, contrastive learning showed its effectiveness and became popular in self-supervised learning (Chen et al., 2020; Meng et al., 2021; Gao et al., 2021). Such effectiveness of contrastive learning in various fields promoted adapting contrastive learning for code search. As a pre-training approach for source code, Corder (Bui et al., 2021) transformed a code snippet into different versions and minimized the distance between them in the representation space. Corder used program transformation operators, including dead code insertion and permutation of code statements. The experiment results confirmed that pre-training with contrastive learning was effective in improving performance on several code-related tasks such as code-to-code search, text-to-code search, and code summarization. As a fine-tuning approach for code search, CoCLR (Huang et al., 2021) used contrastive learning with query-rewritten data augmentation and in-batch negative samples. For query-rewriting, CoCLR modified random words in a query as follows: deleting random words, switching the position of two random words, or copying random words. They showed that CoCLR improved code search performance of CodeBERT. However, these contrastive learning approaches utilize either query or code in the data augmentation process and do not consider the relative importance of words. We propose to consider the importance of each word differently and preserve keywords for data augmentation.

3 Approach

KeyDAC identifies keywords from positive query-code pairs (*i.e.*, a code snippet meets the demand of a query) in a training dataset based on term matching. Then KeyDAC applies keyword-based data augmentation to both query and code snippet. Using augmented training data, KeyDAC deploys contrastive learning to fine-tune pre-trained encoders for the code search task.



```
def last_modified_date(filename):
    """Last modified timestamp as a UTC datetime"""

    mtime = os.path.getmtime(filename)
    dt = datetime.datetime.utcfromtimestamp(mtime)
    return dt.replace(tzinfo=pytz.utc)
```

Figure 2: An example of identifying keywords from a pair of real user query and code function. Given a training query-code pair, we identify keywords based on term matching from three NL sequences (*i.e.*, query, function name, and documentation). The identified keywords are related to the functionality of the code function.

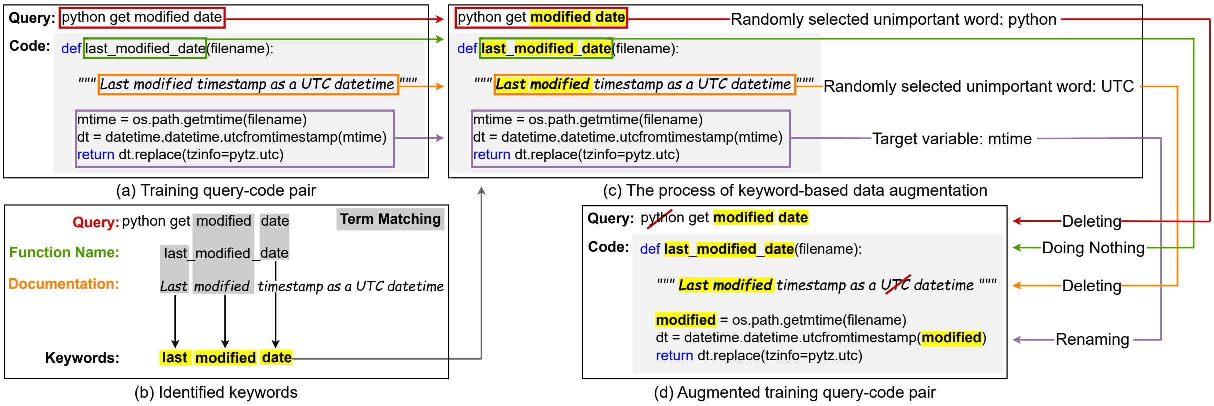
3.1 Data Augmentation with Keywords

A code function c_i has the following three main components:

- function name in the function header (NL)
- function-level documentation (NL)
- code statements in the function body (PL)

The previous approaches consider these three components as PL sequences. On the other hand, we consider the function name and the documentation as NL sequences, since 1) those two code components describe the functionality of the code snippet; 2) modifying the function name or documentation does not produce any syntax errors.

Identifying Keywords Since a user query demands certain functionality of the code snippet, KeyDAC utilizes two NL descriptions of code function, such as the function name and documentation, to identify keywords. Specifically, KeyDAC identifies common words from three NL sequences (*i.e.*, query, function name, and documentation) based on term matching. Figure 2 gives an example of how KeyDAC identifies keywords from the paired query and code function. The identified keywords from the example are: *last*, *modified* and *date*. These



(a) Training query-code pair

(b) Identified keywords

(c) The process of keyword-based data augmentation

(d) Augmented training query-code pair

Figure 3: An illustration of keyword-based data augmentation. For NL sequences, keywords (*i.e.*, *last*, *modified*, and *date*) are preserved (highlighted in bold) while unimportant words (*i.e.*, `python` in query and `UTC` in documentation) are deleted (red slash lines) (**NL: Rewriting**). For PL sequences, variable `mtime` is renamed using a keyword *modified* (**PL: Variable Renaming**).

identified keywords are related to the functionality of code function.

Using the identified keywords, KeyDAC applies data augmentation to NL and PL sequences in different ways. In the following, we demonstrate keyword-based data augmentation in detail.

NL: Rewriting KeyDAC rewrites three NL sequences by modifying unimportant words while preserving keywords by choosing one of the following four ways: 1) deleting one randomly selected unimportant word (Delete); 2) switching the position of two randomly selected unimportant words (Switch); 3) copying one randomly selected unimportant word (Copy); 4) doing nothing (None). In Figure 3 (d), KeyDAC deletes an unimportant word `python` in the query and `UTC` in the documentation, while preserving keywords *last*, *modified* and *date*. **PL: Variable Renaming** Software developers sometimes name a variable in abbreviation form; in other words, there can be a lexical gap between query and variable name (*e.g.*, in Figure 3 (a), the variable `mtime` represents the meaning of *modified time*). We propose to rename variables using keywords to bridge the lexical gap between query and code snippet. We first parse a code function c_i into an abstract syntax tree (AST) that represents the syntactic structure of c_i. Then we identify variables from terminal nodes of the resulting AST. Then KeyDAC renames the variables that appear most frequently in code statements using keywords. If there is a keyword that matches the target variable name (`mtime`) with the first letter, KeyDAC uses that keyword (*modified*). If not, KeyDAC randomly chooses one from keywords (*i.e.*, *last*, *modified*, and *date*). In Figure 3 (d), KeyDAC renames `mtime` to *modified*.

3.2 Siamese Network for Code Search Task

We adopt siamese network architecture, which has a shared encoder to map a query and code snippet to fixed-sized embeddings. Each query q_i and code function c_i are encoded by a shared encoder $Encoder$ (*e.g.*, CodeBERT). We take the representation of $[CLS]$ token from the last hidden layer of $Encoder$. Then we compute the cosine similarity $sim^{(q_i, c_i)}$ between a query-code pair (q_i, c_i) as:

$$sim^{(q_i,c_i)} = \langle Encoder(q_i), Encoder(c_i) \rangle, \quad (1)$$

where $\langle \cdot \rangle$ indicates cosine similarity operation. We use binary cross-entropy as the training objective:

$$\mathcal{L}_{bce} = -[y_i \cdot \log sim^{(q_i,c_i)} + (1 - y_i) \log(1 - sim^{(q_i,c_i)})], \quad (2)$$

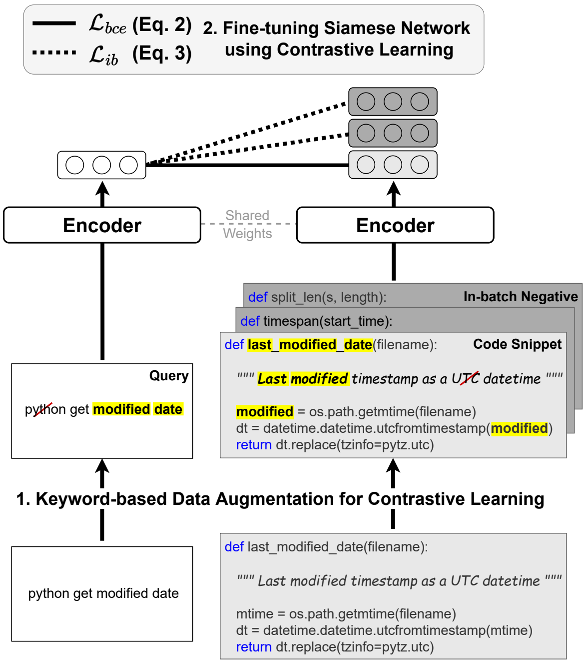
where y_i is the ground truth label of (q_i, c_i).

3.3 Contrastive Learning

KeyDAC uses contrastive learning to optimize the parameters of $Encoder$. This contrastive learning aims to maximize the similarity of the query q_i and code function c_i with label of $y_i = 1$ while minimizing the similarity of the query with unrelated code snippets.

Given the query-code pair (q_i, c_i) in a batch of size N, we consider the other $N - 1$ code snippets as unrelated. The contrastive loss with in-batch negative samples is defined as:

$$\mathcal{L}_{ib} = -\frac{1}{N-1} \sum_{\substack{j=1 \\ j \neq i}}^{N} \log \left(1 - sim^{(q_i,c_j)}\right). \quad (3)$$



```
def split_len(s, length):
```

```
def timespan(start_time):
```

```
def last_modified_date(filename):

  """ Last modified timestamp as a UTC datetime """

  modified = os.path.getmtime(filename)
  dt = datetime.datetime.utcfromtimestamp(modified)
  return dt.replace(tzinfo=pytz.utc)
```

```
def last_modified_date(filename):

  """ Last modified timestamp as a UTC datetime """

  mtime = os.path.getmtime(filename)
  dt = datetime.datetime.utcfromtimestamp(mtime)
  return dt.replace(tzinfo=pytz.utc)
```

Figure 4: The fine-tuning process of siamese network using KeyDAC. The boxes, colored in dark gray, indicate the in-batch negative samples. The black solid line denotes the binary cross-entropy loss and black dashed lines denote the contrastive loss with in-batch negative.

The overall training objective is:

$$\mathcal{L} = \mathcal{L}_{bce} + \mathcal{L}_{ib}. \tag{4}$$

Figure 4 illustrates the fine-tuning process of siamese network with shared encoder using KeyDAC. A black solid line denotes the binary cross-entropy loss (Equation 2), and black dashed lines denote the contrastive loss with in-batch negative samples (Equation 3).

4 Experiments

4.1 Tasks

We evaluate the performance for two tasks, code search and code question answering.

Code Search aims to retrieve the most relevant code function c^* in a collection of H code snippets $C = c_1, \ldots, c_H$ according to a real user web query q_i. Following CoSQA, we use Mean Reciprocal Rank (MRR) as evaluation metric.

Code Question Answering is a form of binary classification and, thus, predicts a label of 1 or 0; the label indicates whether the code function c_i matches the search intent of the query q_i. The WebQueryTest uses accuracy score as its official evaluation metric.

4.2 Datasets

We use CoSQA (Huang et al., 2021) and WebQueryTest (Lu et al., 2021) to evaluate the effectiveness of KeyDAC. The queries in both datasets are real user queries. Table 1 shows the data statistics. Each number denotes the number of paired queries and code snippets.

Code Search: We follow the same dataset split as CoSQA. The number of candidate code snippets is 6,267 ($H = 6,267$).

Code Question Answering: Each instance of WebQueryTest is a pair of a real user web query and a Python code function. Following CoSQA, we train the models using the CoSQA dataset, then use WebQueryTest as the test dataset. Since WebQueryTest is an open challenge, we submit model predictions to the CodeXGLUE official leaderboard, and report the evaluated results.

4.3 Baseline Approaches

- **In-batch**: Contrastive learning method using in-batch negative (without data augmentation).
- **CoCLR**: Contrastive learning method with query-rewritten data augmentation and in-batch negative.

Huang et al. (2021) report that switching the position of two random words in queries for the data augmentation in CoCLR achieves the best performance. Thus, we use switch as the query-rewriting operation for CoCLR in the experiments (Table 2).

4.4 Experiment Setup

We set the batch size N as 32, the learning rate as 1e-5 and the fine-tuning epoch as 10. We use the Adam optimizer (Kingma and Ba, 2014) to train the models. We conduct all experiments on an NVIDIA RTX3090 GPU with 24GB memory.

We use the following pre-trained models[2]:

- **RoBERTa** (Liu et al., 2019) is pre-trained on a large natural language text corpus with masked language modeling (MLM) objective.
- **CodeBERT** (Feng et al., 2020) is pre-trained on six programming languages with MLM and replaced token detection objectives.

---

[2] We use HuggingFace's implementation for these models. (`https://huggingface.co/`)

Dataset	**Task**	**Metric**	**Train**	**Valid**	**Test**
CoSQA (Huang et al., 2021)	Code Search	MRR	19,604	500	500
	Code Question Answering	Accuracy	20,000	604	1,046*

Table 1: Dataset statistics. * This is the number of test data in the WebQueryTest open challenge.

Model	**Approach**	**Code Search**	**Code Question Answering**[3]
RoBERTa (Liu et al., 2019)	In-batch	58.37 ± 0.48	58.89
	CoCLR	61.00 ± 0.98	60.70
	KeyDAC	**67.09 ± 0.37**	**60.99**
CodeBERT (Feng et al., 2020)	In-batch	66.72 ± 0.35	57.36
	CoCLR	68.42 ± 0.44	60.03
	KeyDAC	**72.76 ± 0.93**	**62.90**
GraphCodeBERT (Guo et al., 2020)	In-batch	71.34 ± 0.46	63.73±1.28
	CoCLR	71.78 ± 0.69	63.47±1.31
	KeyDAC	**74.93 ± 0.42**	**65.51**±0.77

	CoCLR	71.52 ± 0.85	62.10±0.52
	KeyDAC	**74.71 ± 0.45**	**64.14**±0.78

Table 2: Results on code search and code question answering tasks. The best results for each model are highlighted in bold.

- **GraphCodeBERT** (Guo et al., 2020) leverages data flow of code for two structure-aware pre-training tasks, including edge prediction and node alignment.
- **UniXcoder** (Guo et al., 2022) is a unified pre-trained model which uses code documentation and AST for contrastive pre-training. We use encoder of UniXcoder.

We deploy contrastive learning approaches to fine-tune the aforementioned pre-trained language models.

4.5 Results

Table 2 compares different contrastive learning approaches to code search and code question answering. We report the mean performance with standard deviation in 5 runs for code search task.[3] Remark that the in-batch negative contrastive learning approach (In-batch) does not use data augmentation. We highlight the best results for each pre-trained model in bold.

The results show that KeyDAC consistently outperforms contrastive learning with in-batch negative only (In-batch) and contrastive learning with query-rewritten data augmentation (CoCLR). GraphCodeBERT fine-tuned using KeyDAC achieves the highest performance both on code search and code QA tasks. We notice that CoCLR drops code search performance of UniXcoder and code QA performance of GraphCodeBERT and UniXcoder. On the other hand, KeyDAC shows consistent performance improvement.

5 Analysis

We use GraphCodeBERT as base model for following analyses since among four pre-trained models, GraphCodeBERT achieves the highest performance on code search and code QA when fine-tuned using KeyDAC.

5.1 The Effect of Preserving Keywords

From the experimental results, we observe that KeyDAC consistently outperforms CoCLR. We hypothesize that the main reason for the performance gain is preserving keywords in data augmentation. We study the effect of preserving keywords, especially in queries to directly compare KeyDAC and CoCLR. We perform query-rewritten data augmentation in three ways: 1) Preserving keywords (same as applying keyword-based data augmentation to query only); 2) Deleting a random word (same as

---

[3] For code QA task, we submit the prediction results of 3 random seeds for the two best models and the prediction results of 1 random seed for the others, since the CodeXGLUE guideline discourages excessive submissions to avoid P-hacking.

Component	Rewriting	Code Search
Query	Preserving keywords	**72.03**
	Deleting a random word	71.07
	Deleting a keyword	68.03

Table 3: Effect of preserving keywords in query-rewritten data augmentation.

Model	Data Augmentation	Code Search
GraphCodeBERT	No augmentation	71.46
	(Delete)	**74.81**
	(Switch)	73.74
	(Copy)	72.37

Table 4: Effect of NL rewriting operations. The result in the first row indicates the performance of fine-tuning GraphCodeBERT using in-batch negative only.

CoCLR with delete operation); 3) Deleting a keyword. We analyze this via code search task on CoSQA test set to avoid an excessive submission of code QA prediction results to the WebQueryTest leaderboard. Table 3 shows the results. We can observe that preserving keywords in query-rewritten data augmentation achieves the best performance. The deletion of keywords in queries shows significant performance degradation. The results suggest that keywords determined through our proposed way (Figure 2) are important to the performance of the semantic code search task.

5.2 The Effect of NL Rewriting Operation

We conduct experiments to investigate the effect of different NL rewriting operations on the code search task. Table 4 shows the code search performance evaluated on the CoSQA test set. We observe that KeyDAC with all three NL rewriting operations outperforms GraphCodeBERT fine-tuned using contrastive learning with in-batch negative only (No augmentation).

Among the three rewriting operations, delete shows the best performance (highlighted in bold). We conjecture that deleting unimportant words helps to reduce the noise of data. For example, user web queries often have a typo, and documentation often contains a special character such as >>> to show the execution result.

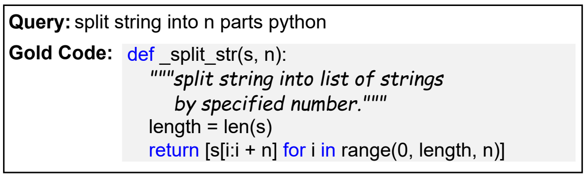
5.3 Contribution of Each Component

We investigate the contributions of each component to keyword-based data augmentation. Table 5 shows the results for code search task on the CoSQA test set. All five rows determine keywords from pairs of query and code function with the same way. However, the last four rows only modify each component as follows: 1) deleting unimportant words in queries; 2) deleting unimportant words in function names; 3) deleting unimportant words in documentations; 4) renaming variables using keywords.

The results show that KeyDAC leveraging all components (results in the first row) achieves the best result. Among the results of KeyDAC using a single component, documentation contributes the most to performance, and the function name contributes the least. Software developers typically use an abbreviated function name but write documentation in detail to describe the functionality of the code snippet.

5.4 Case Study

We conduct a case study to analyze the consistent code search ability of KeyDAC. More cases for other pre-trained language models can be found in Appendix A.1. In addition, we provide some cases to compare the prediction results of CoCLR and KeyDAC for code question answering task in Appendix A.2

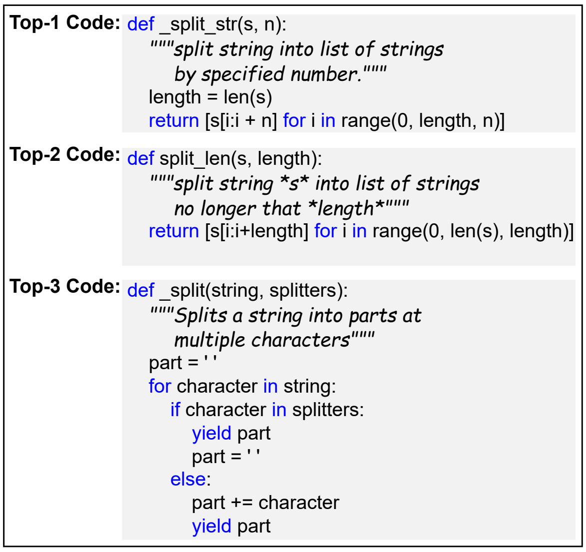


Query: split string into n parts python

Gold Code:

```
def _split_str(s, n):
    """split string into list of strings
       by specified number."""
    length = len(s)
    return [s[i:i + n] for i in range(0, length, n)]
```

(a) A pair of real user web query and gold code function.



Top-1 Code:

```
def _split_str(s, n):
    """split string into list of strings
       by specified number."""
    length = len(s)
    return [s[i:i + n] for i in range(0, length, n)]
```

Top-2 Code:

```
def split_len(s, length):
    """split string *s* into list of strings
       no longer that *length*"""
    return [s[i:i+length] for i in range(0, len(s), length)]
```

Top-3 Code:

```
def _split(string, splitters):
    """Splits a string into parts at
       multiple characters"""
    part = ''
    for character in string:
        if character in splitters:
            yield part
            part = ''
        else:
            part += character
    yield part
```

(b) Code search results with KeyDAC (top-3 results).

Figure 5: Code search results with KeyDAC on CoSQA test set. The code snippets are searched from 6,267 candidates and ranked in the order of semantic relatedness.

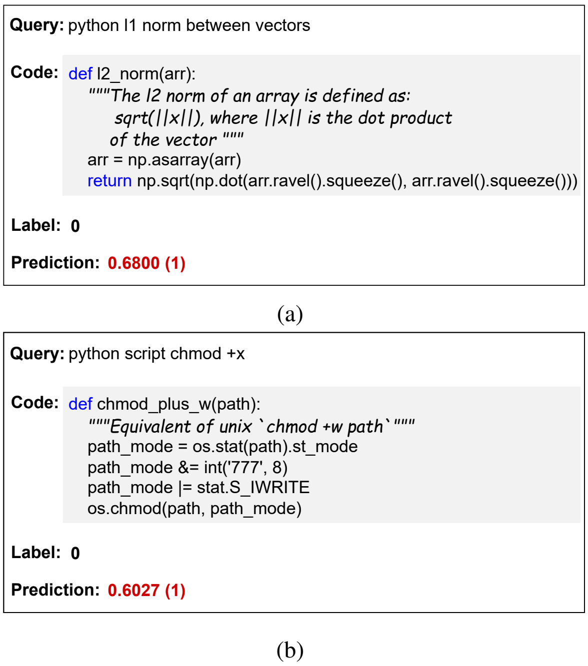
Model	Component	Keyword-based Data Augmentation	Code Search
GraphCodeBERT	All Components	NL Rewriting via delete & Variable Renaming	**74.81**
	Query	Deleting unimportant words in queries	72.03
	Function Name	Deleting unimportant words in function names	71.39
	Documentation	Deleting unimportant words in documentations	73.26
	Code Statements	Renaming variables using keywords	72.57

Table 5: The first row indicates the performance of KeyDAC which applied keyword-based data augmentation to all components. The last four rows are the results of applying keyword-based data augmentation to a single component.

Figure 5 shows the code search results with KeyDAC for the query *split string into n parts python*. We only give the top-3 results due to the space limit. KeyDAC returns the gold code function as its top-1 result. The other two code snippets have the same functionality as the gold code, demonstrating the consistent code search ability of KeyDAC.

5.5 Error Analysis

Figure 6 provides two error cases of KeyDAC on code QA task. KeyDAC makes a wrong prediction in the case of Figure 6(a). The purpose of the search for the query is to calculate the l1 norm between vectors. However, the functionality of the code is computing l2 norm of a given array. The model needs mathematical knowledge to understand the difference between norm l1 and norm l2.



Query: python l1 norm between vectors

Code:
```
def l2_norm(arr):
    """The l2 norm of an array is defined as:
      sqrt(||x||), where ||x|| is the dot product
     of the vector """
    arr = np.asarray(arr)
    return np.sqrt(np.dot(arr.ravel().squeeze(), arr.ravel().squeeze()))
```

Label: **0**

Prediction: **0.6800 (1)**

(a)

Query: python script chmod +x

Code:
```
def chmod_plus_w(path):
    """Equivalent of unix `chmod +w path` """
    path_mode = os.stat(path).st_mode
    path_mode &= int('777', 8)
    path_mode |= stat.S_IWRITE
    os.chmod(path, path_mode)
```

Label: **0**

Prediction: **0.6027 (1)**

(b)

Figure 6: Two error cases of KeyDAC for code question answering task on CoSQA validation set.

In the case of Figure 6(b), the search intent of the query is to add the execution privilege (*chmod +x*) while the functionality of the code is to add the write privilege (*chmod +w*). KeyDAC fails to understand the difference between *+x* and *+w*, resulting in a wrong prediction. While software developers can easily understand the difference of Unix/Linux command *chmod +x* and *chmod +w*, it is not trivial for the language models and humans without programming knowledge.

The potential research direction is to incorporate domain-specific knowledge, such as mathematical knowledge and programming knowledge, into the pre-training or fine-tuning process of language models to improve code search performance.

6 Conclusion

We have presented KeyDAC— keyword-based data augmentation for contrastive learning, which generates more training query-code pairs while preserving important keywords for the code search task. First, KeyDAC utilizes term matching technique to identify important words from a query and code components (function name and documentation). Then, KeyDAC augments both a query and a code snippet while preserving the identified keywords. Finally, KeyDAC deploys contrastive learning using the augmented data to fine-tune the pre-trained language models. We have demonstrated that KeyDAC outperforms the current state-of-the-art performance on both the code search and an open challenge code question answering task.

Limitations

Given a query-code pair, KeyDAC identifies keywords which share the same surface form by term matching. In other words, KeyDAC identifies keywords at the lexical level. As a future work, KeyDAC can utilize external knowledge for keyword-based data augmentation. For example, KeyDAC can utilize WordNet to identify keywords based on not only surface form, but also synonyms.

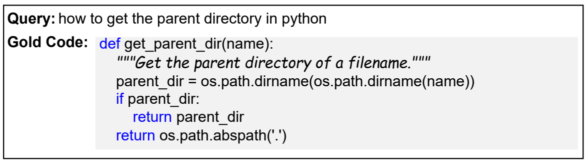
A Case Study

We present case studies in the following sections for code search on CoSQA test set and code question answering on CoSQA validation set.

A.1 Code Search

The code snippets, shown in each case study, are retrieved from 6,267 candidate Python code functions.

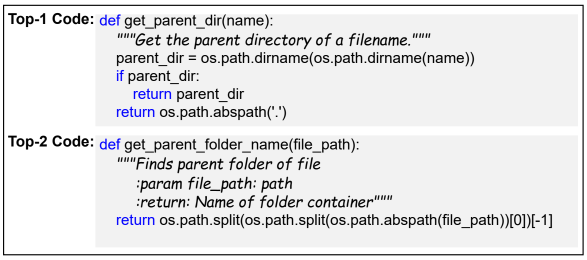


Query: how to get the parent directory in python

Gold Code:

```
def get_parent_dir(name):
    """Get the parent directory of a filename."""
    parent_dir = os.path.dirname(os.path.dirname(name))
    if parent_dir:
        return parent_dir
    return os.path.abspath('.')
```

(a) A pair of real user web query and gold code function.



Top-1 Code:

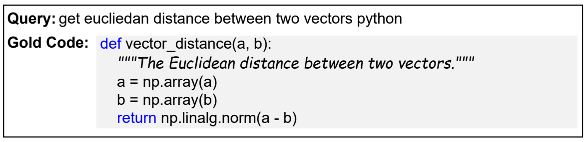
```
def get_parent_dir(name):
    """Get the parent directory of a filename."""
    parent_dir = os.path.dirname(os.path.dirname(name))
    if parent_dir:
        return parent_dir
    return os.path.abspath('.')
```

Top-2 Code:

```
def get_parent_folder_name(file_path):
    """Finds parent folder of file
        :param file_path: path
        :return: Name of folder container"""
    return os.path.split(os.path.split(os.path.abspath(file_path))[0])[-1]
```

(b) Code search results with KeyDAC (top-2 results).

Figure 7: Code search results with KeyDAC on CoSQA test set. Base model is RoBERTa.

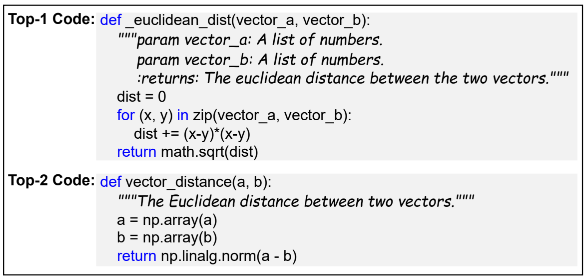


Query: get eucliedan distance between two vectors python

Gold Code:

```
def vector_distance(a, b):
    """The Euclidean distance between two vectors."""
    a = np.array(a)
    b = np.array(b)
    return np.linalg.norm(a - b)
```

(a) A pair of real user web query and gold code function.



Top-1 Code:

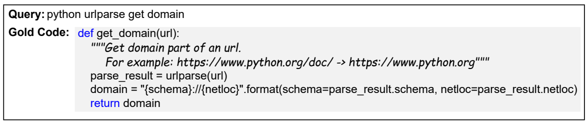
```
def _euclidean_dist(vector_a, vector_b):
    """param vector_a: A list of numbers.
        param vector_b: A list of numbers.
        :returns: The euclidean distance between the two vectors."""
    dist = 0
    for (x, y) in zip(vector_a, vector_b):
        dist += (x-y)*(x-y)
    return math.sqrt(dist)
```

Top-2 Code:

```
def vector_distance(a, b):
    """The Euclidean distance between two vectors."""
    a = np.array(a)
    b = np.array(b)
    return np.linalg.norm(a - b)
```

(b) Code search results with KeyDAC (top-2 results).

Figure 8: Code search results with KeyDAC on CoSQA test set. Base model is CodeBERT. The query has a typo *eucliedan*.

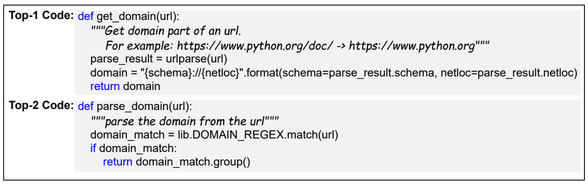


Query: python urlparse get domain

Gold Code:

```
def get_domain(url):
    """Get domain part of an url.
        For example: https://www.python.org/doc/ -> https://www.python.org"""
    parse_result = urlparse(url)
    domain = "{schema}://{netloc}".format(schema=parse_result.schema, netloc=parse_result.netloc)
    return domain
```

(a) A pair of real user web query and gold code function.



Top-1 Code:

```
def get_domain(url):
    """Get domain part of an url.
        For example: https://www.python.org/doc/ -> https://www.python.org"""
    parse_result = urlparse(url)
    domain = "{schema}://{netloc}".format(schema=parse_result.schema, netloc=parse_result.netloc)
    return domain
```

Top-2 Code:

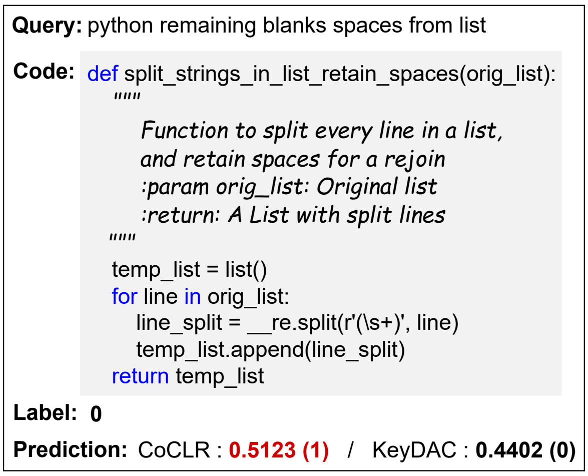
```
def parse_domain(url):
    """parse the domain from the url"""
    domain_match = lib.DOMAIN_REGEX.match(url)
    if domain_match:
        return domain_match.group()
```

(b) Code search results with KeyDAC (top-2 results).

Figure 9: Code search results with KeyDAC on CoSQA test set. Base model is UniXcoder.

A.2 Code Question Answering

We use the CoSQA validation set, since the ground-truth labels of WebQueryTest are not provided. All cases are negative query-code pairs, such that the code snippet does not match the search intent of the query. The models predict a pair of query and code as a negative pair when the cosine similarity is lower than the threshold 0.5.



Query: python remaining blanks spaces from list

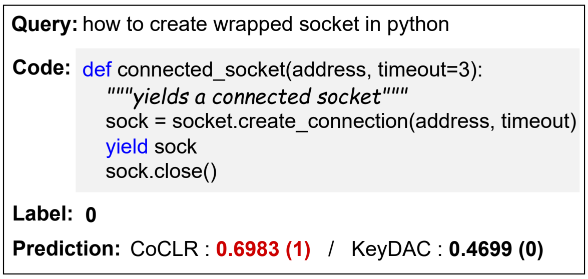
Code:

```
def split_strings_in_list_retain_spaces(orig_list):
    """
        Function to split every line in a list,
        and retain spaces for a rejoin
        :param orig_list: Original list
        :return: A List with split lines
    """
    temp_list = list()
    for line in orig_list:
        line_split = __re.split(r'(\s+)', line)
        temp_list.append(line_split)
    return temp_list
```

Label: **0**

Prediction: CoCLR : **0.5123 (1)** / KeyDAC : **0.4402 (0)**

Figure 10: Case study for code question answering task on CoSQA validation set. Base model is RoBERTa.



Query: how to create wrapped socket in python

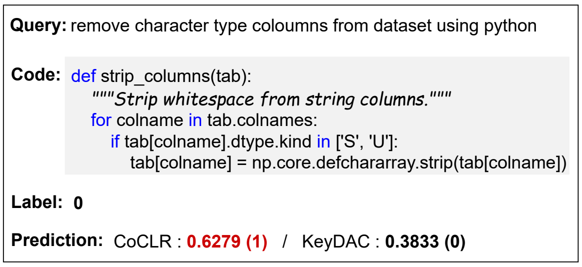
Code:

```
def connected_socket(address, timeout=3):
    """yields a connected socket"""
    sock = socket.create_connection(address, timeout)
    yield sock
    sock.close()
```

Label: **0**

Prediction: CoCLR : **0.6983 (1)** / KeyDAC : **0.4699 (0)**

Figure 11: Case study for code question answering task on CoSQA validation set. Base model is CodeBERT.



Query: remove character type coloumns from dataset using python

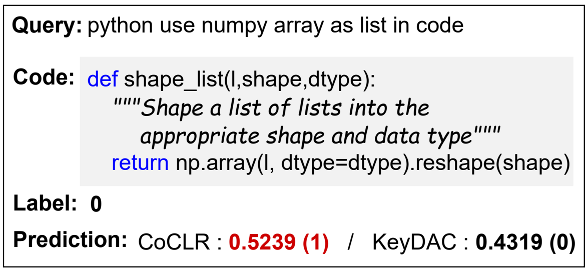
Code:

```
def strip_columns(tab):
    """Strip whitespace from string columns."""
    for colname in tab.colnames:
        if tab[colname].dtype.kind in ['S', 'U']:
            tab[colname] = np.core.defchararray.strip(tab[colname])
```

Label: **0**

Prediction: CoCLR : **0.6279 (1)** / KeyDAC : **0.3833 (0)**

Figure 12: Case study for code question answering task on CoSQA validation set. Base model is GraphCodeBERT.



Query: python use numpy array as list in code

Code:

```
def shape_list(l,shape,dtype):
    """Shape a list of lists into the
       appropriate shape and data type"""
    return np.array(l, dtype=dtype).reshape(shape)
```

Label: **0**

Prediction: CoCLR : **0.5239 (1)** / KeyDAC : **0.4319 (0)**

Figure 13: Case study for code question answering task on CoSQA validation set. Base model is UniXcoder.

Large Scale Multi-Lingual Multi-Modal Summarization Dataset

Abstract

Significant developments in techniques such as encoder-decoder models have enabled us to represent information comprising multiple modalities. This information can further enhance many downstream tasks in the field of information retrieval and natural language processing; however, improvements in multi-modal techniques and their performance evaluation require large-scale multi-modal data which offers sufficient diversity. Multi-lingual modeling for a variety of tasks like multi-modal summarization, text generation, and translation leverages information derived from high-quality multi-lingual annotated data. In this work, we present the current largest multi-lingual multi-modal summarization dataset (`M3LS`), and it consists of over a million instances of document-image pairs along with a professionally annotated multi-modal summary for each pair. It is derived from news articles published by `British Broadcasting Corporation(BBC)` over a decade and spans 20 languages, targeting diversity across five language roots, it is also the largest summarization dataset for 13 languages and consists of cross-lingual summarization data for 2 languages. We formally define the multi-lingual multi-modal summarization task utilizing our dataset and report baseline scores from various state-of-the-art summarization techniques in a multi-lingual setting. We also compare it with many similar datasets to analyze the uniqueness and difficulty of `M3LS`. [1]

1 Introduction

The world we live in today is very diverse, with over 7,000+ languages spoken across the globe[2]. These languages have varying traits and are spoken by communities of various sizes depending upon the popularity of the language. For example, Mandarin consists of over 50,000 *hanzi* (characters) and is spoken by over 1.117 billion people[3], while there exist languages like Rotokas, which is an indigenous language spoken by about 4,320 people on the island of Bougainville, Papua New Guinea, which consists of only 12 letters[4].

Table 1: Comparison of proposed dataset with existing large-scale multi-lingual and multi-modal datasets.

Multi-lingual Summarization Datasets			
Dataset Name	**Dataset Size**	**#Languages**	**Domain**
`XL-Sum` (Hasan et al., 2021)	1M	44	News
`MLSUM` (Scialom et al., 2020)	1.5M	5	News
`WikiLingua` (Ladhak et al., 2020)	770K	18	Tutorials
`MLGSum` (Wang et al., 2021)	1.1M	12	News
`M3LS` (Ours)	1.1M	20	News
Multi-modal Summarization Datasets			
Dataset Name	**Dataset Size**	**Modalities**	**Domain**
`MSMO` (Zhu et al., 2018)	314K	Text + Image	News
`E-DailyMail` (Chen and Zhuge, 2018)	219K	Text + Image	News
`How2` (Sanabria et al., 2018)	190K	Text + Video + Audio	Multiple Domains
`MMSS` (Li et al., 2018)	66K	Text + Image	News
`VMSMO` (Li et al., 2020)	185K	Text + Video + Audio	Social Network
`M3LS` (Ours)	1.1M	Text + Image	News

These languages, although very crucial, restrict people to communicate their thoughts to others who speak the same language. The gift of sight, however, is something that is universally shared by every human being on this plant, irrespective of their culture, ethnicity, or the language that they speak. Through this work we aim to instigate the research towards improving existing automatic summarization systems by leveraging information from multiple languages and visual modalities.

Various studies in the past have illustrated how unified summarization frameworks across multiple languages improve the summarization quality over mono-lingual frameworks (Wang et al., 2021). Similarly, there have been works in multi-modal summarization that illustrate how multi-modal input can help improve the quality of summarization over text summarization systems (Jangra et al., 2020a,b; Chen and Zhuge, 2018; Mukherjee et al.,

---

[4] `https://en.wikipedia.org/wiki/Rotokas_language`

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3620–3632
May 2-6, 2023

2022). Additionally, having multiple modalities in the output summary can help improve the overall satisfaction of the user (Zhu et al., 2018; Jangra et al., 2021b). Multiple modalities can also compensate for the inability of individual modalities to express various aspects of the summary. For instance, it is hard to express abstract concepts like "freedom", "gravity", etc. through images, while it can be expressed through text conveniently. Similarly, it is very difficult to describe a "Pangolin" to someone who hasn't seen one beforehand.

Hence, in this work we propose the task of Multi-modal Multi-lingual Summarization (`M3LS`), and also release the `M3LS` dataset[5] to facilitate the research in this direction. The dataset comprises 1.1M news articles, spanning 20 languages comprising *English*, *Chinese*, *Spanish*, *Russian*, *French*, *Ukrainian*, *Portuguese*, *Japanese*, *Tamil*, *Hindi*, *Marathi*, *Gujarati*, *Bengali*, *Sinhala*, *Urdu*, *Pashto*, *Indonesian*, *Telugu*, *Punjabi*, and *Nepali*; making it the largest language-spanning summarization dataset. To the best of our knowledge, the proposed dataset is the largest summarization dataset for 13 languages (*Russian*, *Ukrainian*, *Tamil*, *Hindi*, *Marathi*, *Gujarati*, *Bengali*, *Sinhala*, *Urdu*, *Pashto*, *Telugu*, *Punjabi*, and *Nepali*).

We hope that the proposed task and the dataset will instigate and inspire multi-modal and multi-lingual research in less-explored languages for solving various tasks including but not limited to automatic summarization (Nallapati et al., 2016; See et al., 2017), article headline generation (Jin et al., 2020; Gavrilov et al., 2019; Zhang et al., 2018), keyword extraction (Showrov and Sobhan, 2019; Lee and Kim, 2008; Yao et al., 2019), image caption generation (Xu et al., 2015; Bai and An, 2018), multi-modal embedding generation (Sun et al., 2019; Lu et al., 2019; Li et al., 2019; Zhou et al., 2020), large-scale language modeling (Raffel et al., 2020; Devlin et al., 2019) etc.

The major contributions of this work are as follows - *1) We have proposed the multi-modal multi-lingual summarization (`M3LS`) task. 2) We have released the largest multi-modal summarization dataset that spans 20 languages. 3) The proposed dataset is the largest text summarization dataset for 13 languages. 4) To the best of our knowledge, we present the first ever multi-modal cross-lingual dataset (consisting of Japanese-to-English and English-to-Japanese). 5) We have provided multi-modal summarization baseline results for our dataset and a detailed analysis of the dataset.*

2 Related Work

The field of text summarization is more than 5 decades old (Edmundson, 1969), and has evolved to a great extent in recent years. Prior to the advances in sequence-to-sequence frameworks (Sutskever et al., 2014), people mainly focused on extractive summarization techniques that aim to generate summary via extracting words, phrases, or sentences (Mihalcea and Tarau, 2004; Saini et al., 2019; Alguliev et al., 2010). See et al. (2017) proposed the Pointer-Generator Networks, an attentive recurrent neural network based framework (Bahdanau et al., 2015). Recent years have seen great progress in research in automatic summarization leveraging transformer based models (Zhang et al., 2020; Devlin et al., 2019) and attention mechanism (Vaswani et al., 2017).

In this section we discuss the related works showcasing multi-modal datasets and multi-lingual datasets. A detailed size comparison of these datasets with `M3LS` is shown in Table 1.

2.1 Multi-modal summarization datasets

Multi-modal summarization is the task of summarizing content comprising two or more input modalities. The output can be uni-modal or multi-modal depending on the task. In this section, we discuss existing large-scale multi-modal summarization datasets proposed in the community. We point the readers to Jangra et al. (2021a) for a comprehensive survey.

MSMO: Zhu et al. (2018) proposed a multi-modal summarization dataset that consists of text and images. The dataset is obtained from the `DailyMail`[6] website and contains 314,581 instances in English language. However, Hasan et al. (2021) illustrated that the `DailyMail` news highlights lack novel n-grams. Fabbri et al. (2021) also highlighted the inconsistency in quality of some reference summaries in the `CNN/DailyMail` dataset (Nallapati et al., 2016).

E-Dailymail Chen and Zhuge (2018) proposed the E-Dailymail dataset, which contains text and images extracted from the `DailyMail` website. The dataset consists of 219,100 instances in English,

---

[5] A sample of our dataset is available at `https://github.com/zenquiorra/M3LS`, the complete dataset will be released in the camera ready version of the work

[6] `https://www.dailymail.co.uk/home/index.html`

containing the input document, article title, images, and image captions.

How2: Sanabria et al. (2018) proposed a multi-modal summarization dataset consisting of text, video, and audio modalities; it contains over 2000 hours of videos accompanied by the corresponding audio and speech transcriptions.

MMSS: Li et al. (2018) proposed a multi-modal summarization dataset consisting of text and images with the aim of proposing an image-aided sentence summarization framework. The dataset has 66K instances in English language, that is generated by extracting sentence-headline pairs from the `Gigaword` corpus[7].

VMSMO: To the best of our knowledge, Li et al. (2020) proposed the first large-scale asynchronous text-audio-video summarization dataset. The dataset is generated from the famous microblogging platform `Sina Weibo`[8], and comprises of 184,920 instances in Chinese language.

Similar trends of incorporating multiple modalities in language tasks can also be noticed in several tasks like question answering (Singh et al., 2021), translation (Elliott and Kádár, 2017), sentiment analysis (Soleymani et al., 2017), lexico-semantic classification (Jha et al., 2022), keyword extraction (Verma et al., 2022) etc.

2.2 Multi-lingual Text Summarization Datasets

The popularity of studying the benefits of summarization in different languages to improve summarization qualities increased over the past few years. There have been a lot of research work in bi-lingual setting; however, in this work, we limit ourselves to discussing multi-lingual summarization datasets to be concise.

MLSUM : Scialom et al. (2020) proposed the `MLSUM` dataset that consists of 1.5 million news articles obtained from the `Dailymail/CNN` websites. The dataset spans five languages - French, German, Spanish, Russian and Turkish.

XL-Sum: Hasan et al. (2021) proposed the `XL-Sum` dataset that consists of 1.35 million articles in 44 languages obtained from `BBC news`, making it the most language-diverse summarization dataset to date. However, 25 of these 44 languages do not contain even 10,000 instances, making it incompetent to train any language model.

WikiLingua: Ladhak et al. (2020) proposed the `Wikilingua` dataset, which is the largest parallel multi-lingual summarization to date. The dataset consists of 770K instances in English language, and is extended to 17 other languages for varying number of English articles.

MLGSum: Wang et al. (2021) proposed the `MLGSum` dataset that consists of articles from various news providers such as `BBC`, `france243` and `select faz`. The dataset has five high-resource and seven low-resource languages, with a total of 1.1 million instances, and is a rich source for text summarization for German language with 500K instances.

We observe that multiple popular datasets (see Table 1) in multimodal summarization and multilingual summarization are useful for both technique evaluation and technique improvisation. However, the combined field of multilingual multimodal summarization has remained largely unexplored, and it can be attributed to the lack of dedicated high quality dataset and formalizing it as a problem statement. Hence, we formally define the `M3LS` task and discuss the dataset addressing the problem further.

3 M3LS Task

Given for each language $l_k \in L$ where L is the set of all languages, we have data $M^{l_k} =< T^{l_k}, I^{l_k} >$, where $T^{l_k} = \left\{t_1^{l_k}, t_2^{l_k}, \ldots, t_{|T|}^{l_k}\right\}$ is a set of documents, and $I^{l_k} = \{I^{t_1^{l_k}}, I^{t_2^{l_k}}, \ldots, I^{t_{|T|}^{l_k}}\}$ is a set of images, where $I^{t_j^{l_k}} = \left\{i_1, i_2, \ldots, i_{|I|}\right\}^{t_j^{l_k}}$ denotes the set of images belonging to the document $t_j^{l_k} \in T^{k_k}$ and $|.|$ denotes the cardinality of a set.

The task is to obtain a function F that maps documents $t_j^{l_{k_1}} \in T^{l_{k_1}}$ in language l_{k_1} along with their corresponding images, $I^{t_j^{l_{k_1}}} \in I^{l_{k_1}}$ to a set of multi-modal summaries in target language, l_{k_2}, comprising of text summaries (denoted by $O^{l_{k_2}}$) along with images from the input (denoted by $I^{l_{k_1}}$).

$$F :< T^{l_{k_1}}, I^{l_{k_1}} > \rightarrow < O^{l_{k_2}}, I^{l_{k_1}} > \quad (1)$$

When $k_1 \neq k_2$, we have multi-modal cross-lingual summarization, otherwise the task is multi-modal mono-lingual summarization, a graphic representation of the task is shown in Figure 1.

4 M3LS Dataset

Through the `M3LS` task, we motivate the need for a multi-modal multi-lingual dataset by studying the

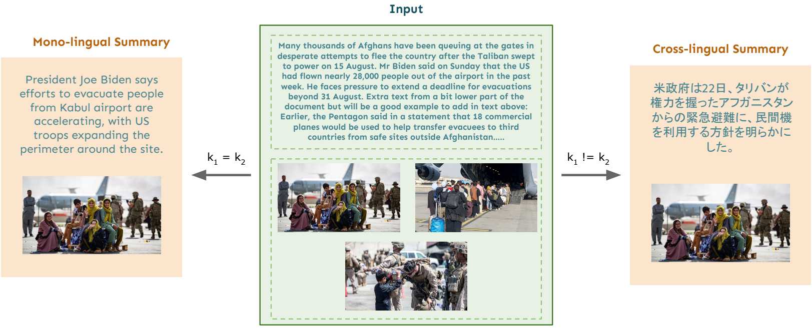
[8] http://ir.weibo.com/



Many thousands of Afghans have been queuing at the gates in desperate attempts to flee the country after the Taliban swept to power on 15 August. Mr Biden said on Sunday that the US had flown nearly 28,000 people out of the airport in the past week. He faces pressure to extend a deadline for evacuations beyond 31 August. Extra text from a bit lower part of the document but will be a good example to add in text above: Earlier, the Pentagon said in a statement that 18 commercial planes would be used to help transfer evacuees to third countries from safe sites outside Afghanistan.....

President Joe Biden says efforts to evacuate people from Kabul airport are accelerating, with US troops expanding the perimeter around the site.

米政府は22日、タリバンが権力を握ったアフガニスタンからの緊急避難に、民間機を利用する方針を明らかにした。

Figure 1: Proposed `M3LS` task.

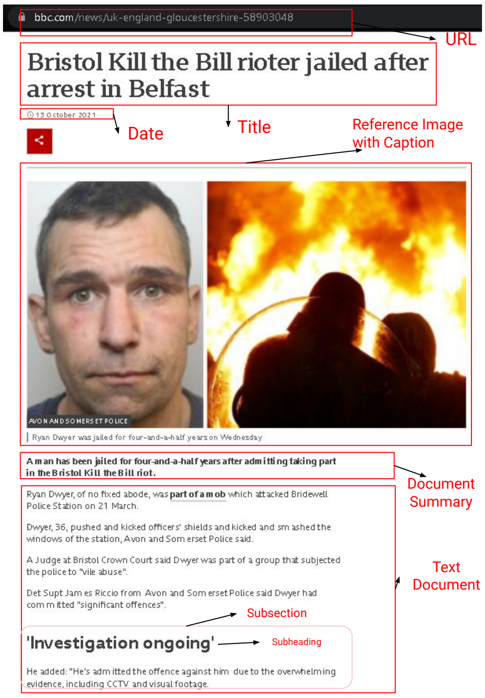
developments in summarization techniques such as secondary enhancements using images with multi-modal output (Zhu et al., 2018), video-based multi-modal summarization (Li et al., 2020) and using multiobjective optimization (Jangra et al., 2020b). On the other hand, development of multi-lingual transformer based models like Xue et al. (2020) has publicly available checkpoints fine-tuned for multiple language modelling tasks, including multi-lingual summarization.

Development of such models requires high-quality heterogeneous data and improvements in various models utilizing multi-modal shared attention layers for annotated data with image-text pairs for a specific language task. To address these issues, we present `M3LS` and in this section we discuss various steps involved in its construction.

4.1 Dataset Construction

We explore the news domain, as it is one of the most abundant and readily available domains and covers articles in multiple topics, while describing the events and lacking extreme bias. We analyzed the structure of articles and surveyed multiple news providers before finalizing on `BBC News`, which provides full sentence summaries in a uniform structured format across multiple languages. The summaries are professionally created by the author which ensures the quality of the data. We explain the steps involved in creating the `M3LS` dataset and discuss various aspects of the data.

BBC News: `BBC News`[9] is a division of British Broadcasting Corporation responsible for gathering and broadcasting current news affairs. Each BBC news article has a text summary comprising complete sentences in the present tense, avoiding opinions and sensationalism. We cover 20 different languages with summaries written in corresponding languages. We extract data from various parts of the webpage as shown in Figure 2.



bbc.com/news/uk-england-gloucestershire-58903048

Bristol Kill the Bill rioter jailed after arrest in Belfast

13 October 2021

Ryan Dwyer was jailed for four-and-a-half years on Wednesday

A man has been jailed for four-and-a-half years after admitting taking part in the Bristol Kill the Bill riot.

Ryan Dwyer, of no fixed abode, was **part of a mob** which attacked Bridewell Police Station on 21 March.

Dwyer, 36, pushed and kicked officers' shields and kicked and smashed the windows of the station, Avon and Somerset Police said.

A Judge at Bristol Crown Court said Dwyer was part of a group that subjected the police to "vile abuse".

Det Supt James Riccio from Avon and Somerset Police said Dwyer had committed "significant offences".

'Investigation ongoing'

He added: "He's admitted the offence against him due to the overwhelming evidence, including CCTV and visual footage.

Figure 2: Snapshot format of a webpage used in development of M3LS, and various features extracted during the scraping procedure

Obtaining Articles: We obtain links to articles from the corresponding `Twitter`[10] pages for each BBC language news dataset. To extend the dataset, we scrape[11] valid links[12] obtained from the parsed articles of each language.

The final collection of links is scraped separately using `scrapy`[13] to obtain the final dataset. Since these links are showcased at the corresponding `twitter` page, these links ensure articles con-

---

[9] `https://www.bbc.com/news`

[10] `https://twitter.com/bbc`

[11] Data is collected in accordance with the terms and conditions mentioned on the website

[12] A link is valid if it contains a BBC article summary for the corresponding domain.

[13] `https://scrapy.org`

taining topics of interest and high popularity. We extend the dataset by recursively extracting links from suggestions and hyperlinks within a webpage.

Structuring the Data: We obtain various features from the webpage as shown in Figure (2), and compile them in a `JSON` format; we also provide a dedicated parser, instructions and a tutorial for the ease of access of features from any instance. The data is freely available for use in accordance with the terms and conditions of `BBC News`, we discuss this in detail on the same link where our dataset is uploaded.

Text Validation: In order to ensure high-quality text from the source, we manually read 10 instances from each language[14] from the collected links to verify if the articles are descriptive in nature and consist of text written in complete sentences.

Summary Validation: We manually checked the summary quality for 100 articles each in 4 languages[15] from our dataset and validated if the given summary captures the information represented in the text. For every article, after carefully reading the text, we assign the gold summary a score between 1-5 with 5 being the best possible summary which captures most of the important information from the given article and vice versa, and also including parameters like summary length and length of the article. We observe that for > 70 articles across the languages evaluated obtain a score of > 4 out of 5 in our analysis. Assuming the uniformity of articles published by BBC across multiple domains, we assume that this fact is true for every language in our dataset.

Final Dataset: In final dataset, each news article contains the text document, images with corresponding captions, keywords, links to related news articles, and a multi-modal summary comprising of a few sentences and an image.

Cross-lingual Dataset: Our cross-lingual dataset contains all features from our final dataset, along with multi-modal summaries consisting of text in another language. It is obtained from the links given by the author within the Japanese language article to the corresponding article in English language, we manually check the information provided in both articles using `Google Translate`[16] for 100 instances to verify the similarity of the content and summaries provided.

Train-Test-Validation split: The dataset has 1.2 million news articles which we split into 80% training, 10% test and 10% validation for languages having $\leq$ 50,000 articles, otherwise we select 90% data for training, 5% for testing and 5% as validation split.

5 Dataset Analysis

5.1 Overview

The `M3LS` dataset has 1.11M+ multi-lingual multi-modal instances across 20 languages and over 9K cross-lingual multi-modal instances for `English-Japanese` language pair. The dataset can be categorized into 8 high resource languages and 12 low resource languages[17] (refer to Appendix B for more details). The chosen languages originate from different parts of the globe, and belong to 5 different language roots: *Indo-European*, *Austronesian*, *Japanic*, *Dravidian*, and *Sino-Tibetan*.

`M3LS` dataset is quite diverse, with the least #articles for `Sinhala` (10,148) and greatest #articles for `English` (376,367). The dataset becomes even more complex and challenging with different sizes of input documents for different languages, with document size varying from $\tilde{3}30$ tokens to over 2800+ tokens. The dataset articles cover a wide time span, with articles from 2009 to 2021 (refer to Appendix A for more details).

We hope that the `M3LS` dataset will instigate and inspire research in less-explored languages, since 14 out of these 20 languages covered by the dataset are among the top-20 most spoken languages in the world[18]; this diversity helps in modelling tasks for both well-explored and less-explored languages.

5.2 Dataset Comparison

To study the size and span of our dataset, we compare `M3LS` with other summarization datasets extracted from the `BBC News` domain. We found that `XSum` contains 53% of the tokens from our dataset, while `XL-Sum` contains 58% of the tokens from our dataset across all languages present in `M3LS`. However, they are uni-modal in nature, while `XSum` is uni-lingual. We observe that `M3LS` is magnitudes larger when compared to `XSum`, while ex-

---

[14] For languages unknown to the authors, we use `Google Translate` `https://translate.google.com` to translate the content in English language

[15] We restrict ourselves to 4 languages (`English`, `Hindi`, `Bengali` and `Marathi`) due to the understanding of languages of the authors presenting this work

[16] `https://google.com/translate`

[17] The categorization is done based on a threshold value of 50k data instances.

[18] `https://lingua.edu/the%2D20%2Dmost%2Dspoken%2Dlanguages%2Din%2Dthe%2Dworld%2Din%2D2022/`

ceeding by times 2-3 in almost all individual language instances when compared to `XL-Sum`. Both of these datasets are used to train and fine-tune several state-of-the-art-summarization models like `Pegasus`, hence we believe that `M3LS` will offer a wider and better language modelling support in terms of size and diversity for the languages present in it, with the additional benefit of multi-modality.

6 Experiments

6.1 Setup

Depending upon the number of instances in each language within `M3LS`, we perform a train:test:validation split with a ratio of 80:10:10 if the number of instances is below 50K and 90:5:5 otherwise. To conduct our experiments in a multi-lingual setting, we survey publicly available tokenizers and sentence segmenters for multiple languages, and we combine them within one dedicated package for our experiments. We further define a set of rules for sentence segmentation for languages lacking such support from external packages within our package[19].

We compile our package using `segtok`[20] for the Indo-European language, `IndicNLP`[21] for Indian languages, `fugashi` (McCann, 2020) for Japanese (`ja`) and `chinese`[22] for Chinese.

For data pre-processing steps such as stopword removal, we collect stopwords from the `nltk`[23] package, and publicly available stopwords present in the `spaCy`[24] repository for all languages in a centralized pipeline for our experiments.

We evaluated the performance of various summarization techniques utilizing our dataset, including simpler techniques such as `LEAD-3` and `RANDOM` which have proven to be quite useful in past (Ghalandari et al., 2020; Scialom et al., 2020; Sharma et al., 2019). We have also included statistics based `CENTROID` (Radev et al., 2004) and graph based `TextRank` (Mihalcea and Tarau, 2004) techniques.

To have a fair comparison across multiple languages using a shared dedicated model, we have evaluated the performance of an abstractive technique in a multi-lingual setting utilizing a pre-trained checkpoint[25] for summarization of the transformer-based `MT5` (Xue et al., 2020) model. Finally to explore the multi-modal aspect of our dataset, we evaluate the performance of a multi-modal encoder-decoder based technique (Zhu et al., 2018) that utilizes images and text to generate a multi-modal text summary. However the publicly available implementation[26] for `MSMO` restricts us to evaluate it only for the English language. However, to compare this score, we evaluate the performance of three state-of-the-art transformer-based models - `Pegasus` (Zhang et al., 2020), `BART` (Lewis et al., 2020), and `T5` (Xue et al., 2020) for summarization which are compatible with the English language.

Since, two of the pre-trained models we described above are fine-tuned on `XSum` and `XL-Sum` datasets which are extracted from the same source - `BBC News` - we avoid fine-tuning on models to have a fair comparison of the models and we explain the scores in discussions.

In all techniques, we set the generated summary length threshold as the average length of gold summary for the corresponding language in our corpus.

6.2 Baselines

Simpler Extractive Approaches

LEAD-3: In this baseline, the first three sentences of the source text are extracted as the final summary. This method is a robust baseline, as shown by (Sharma et al., 2019) for news summarization datasets.

RANDOM: We recursively extract words randomly from the source text until the threshold summary length is reached. The aim of this baseline is to understand and compare other baselines with an unbiased model as a point of reference.

Statistical Approach

CENTROID: We use the strategy proposed by Radev et al. (2004), which ranks sentences based on the centrality scores obtained by the words in the sentence. We use TF-IDF scores to measure each word's similarity, and extract top sentences from each ranking until the threshold summary length is obtained.

Graph Based Approach

TEXTRANK: TextRank (Mihalcea and Tarau,

[20] `https://pypi.org/project/segtok/1.1.0/`

[21] `https://github.com/anoopkunchukuttan/indic_nlp_library`

[22] `https://pypi.org/project/chinese/`

[23] `https://nltk.org/`

[24] `https://github.com/explosion/spaCy/tree/master/spacy/lang`

[25] `https://huggingface.co/csebuetnlp/mT5_multilingual_XLSum`

[26] We use the implementation provided by the authors, which is a multi-layered package, modification of which to be compatible for a multi-lingual setting isn't feasible based on the software complexity

2004) is an unsupervised graph-based ranking technique based on the relevance of sentences in the source text[27] We consider the sentences which are most central to the document based on the ranking as generated summaries.

RNN Based Approach

MSMO: MSMO (Zhu et al., 2018) is an encoder-decoder model trained for multi-modal summarization. It utilizes a multi-modal attention mechanism to generate multi-modal summaries utilizing text and images.

Transformer Based Approaches

MT5: MT5 (Xue et al., 2020) is a transformer-based seq2seq model pretrained for multiple natural language tasks. We use the publicly available checkpoint[28] pre-trained for text summarization on the `XL-Sum` dataset (Hasan et al., 2021) for a multi-lingual setting.

PEGASUS: Pegasus (Zhang et al., 2020) is a transformer-based model, pre-trained on a task to remove meaningful sentences from an input text, making it suitable for summarization. We used a checkpoint[29] of `PEGASUS` model pre-trained on the XSum dataset (Narayan et al., 2018) for summarization.

BART: BART (Lewis et al., 2020) uses a standard seq2seq architecture with a bi-directional encoder and a left-to-right decoder. We use a pre-trained model trained on the DailyMail/CNN (Nallapati et al., 2016) for our evaluation.

T5: T5 (Raffel et al., 2020) is an encoder-decoder model trained on a mixture of natural language tasks, including translation and summarization; it converts any task into a text-to-text format. We use the pre-trained `T5-large` model for the summarization task.

7 Results and Discussion

We evaluate the generated summaries against the gold summaries using the `ROUGE` (Lin, 2004) evaluation metric. We report the `ROUGE-1`, `ROUGE-2`, `ROUGE-L` f-scores across every baseline discussed above (Lin, 2004) (refer to Tables 1 and 3). We additionally report `BERTSCORE` for English baselines (Zhang et al., 2019) (refer to Table 1).

Table 2: Comparison of “ROUGE" fscores for summaries generated using Multi-modal baseline `MSMO` and Unimodal transformer based baselines against gold summaries from the English language dataset . “R-f1" denotes ROUGE-1 fscore, “R-f2" denotes ROUGE2 f-score, “R-fL" denotes the ROUGEL fscore, and “BrS" denotes BERTSCORE.

English	**R-f1**	**R-f2**	**R-fL**	**BrS**
`BART`	0.195	0.031	0.131	0.863
`Pegasus`	**0.389**	**0.181**	**0.321**	**0.910**
`T5`	0.197	0.0328	0.131	0.858
`MSMO`	0.217	0.046	0.158	0.851

7.1 Multi-lingual baseline scores

We observe that transformer based techniques used in our experiments perform significantly better compared to other techniques. However, for the “MT5" column, we observe very high scores and spikes of very low scores as observed in Table 3, this behavior maybe caused due to two factors:

- Relatively high scores can be attributed to the use of “MT5" checkpoint that is fine-tuned for the task of summarization on a dataset (`XL-Sum`) obtained from same source as ours.
- Very low scores for some languages can be attributed to the “ROUGE" evaluation metric which relies on token overlap[30]. Many of these languages, especially the ones with `Dravidan` and `Indo-European` origins have words which change their form significantly depending on their placement in the text and the context in which they appear, hence simple token overlap metrics show lower scores if the root form of the word isn’t considered.

We observe that `LEAD-3` performs better for the languages in which transformer-based baseline performs poorly, this can be attributed to two factors:

- As shown by Sharma et al. (2019) that `LEAD-3` performs very well for summarization tasks when we consider the news domain, suggesting the idea that top sentences capture a lot of information within a news article.
- `LEAD-3` considers top-3 sentences from the text, unlike abstractive summarization, new

---

[27] We use the implementation provided by the gensim`https://radimrehurek.com/gensim_3.8.3/summarization/summariser.html` package and modify the segmentation and tokenizer part using our dedicated package.

tokens or new forms of existing tokens are not present in the given article. Since it is an extractive technique, the chances of token overlap are higher and hence better “f-scores".

7.2 Multi-modal baseline scores

Due to the limitation of lack of pre-trained frameworks in a multi-modal setting for most of the languages in the dataset, we were constrained to evaluate the multi-modal technique on the `English` dataset. On comparing the “f-scores" of various uni-modal techniques with the multi-modal technique, we notice that the transformer based model `Pegasus` outperforms other techniques. This is largely attributed to the fact that the pre-trained checkpoint we have used for evaluation of summaries through the `Pegasus` model is fine-tuned on the `XSum` dataset, which has data collected from the same source as ours. We observe that for other models which are not fine-tuned on a dataset extracted from same source as ours, the multi-modal technique `MSMO` is able to outperform other techniques.

7.3 Abstractiveness of the proposed dataset

We propose an abstractive summarization dataset where the target summaries are manually written by human beings. The `M3LS` dataset demands abstractive techniques since the percentage of novel uni-grams in the dataset is quite high (refer to “abs.gold" column in Appendix B). This fact is also observed in the results from the baseline techniques. For instance, `MT5` performs consistently superior for multiple languages as observed in Table3, the abstractive baselines have thrice as good ROUGE scores as the extractive baselines.

8 Conclusion

In this work, we release a large-scale multi-modal multi-lingual summarization dataset comprising of over 1.1M+ news articles and spanning 20 languages, and motivate the problem statement of Multi-modal Multi-lingual summarization using `M3LS`. To the best of our knowledge, this is the first ever multi-modal summarization data set spanning several languages. The proposed dataset is the largest summarization dataset for 13 out of 20 languages. We have evaluated the performance of various baselines to establish the quality of the proposed dataset in both multi-modal and multi-lingual settings. Through this work, we hope to instigate research in various less-explored languages in the community for various research problems including but not limited to summarization, headline generation, keyword extraction, image caption generation, multi-modal embedding generation, etc. In future works, we plan to work on shared models which address the `M3LS` task utilizing our dataset.

Limitations

There are a few considerations to keep in mind in our work. **First**, the dataset currently has a multi-modal input, mapping to a textual summary. However, future work could involve annotating images to enhance the dataset with a multi-modal output. **Second**, the distribution for languages in the `M3LS` dataset is skewed due to the imbalanced number of articles published in BBC across languages and the late establishment of virtual print media in certain languages (as shown in Appendix A). **Third**, the current dataset uses an independent identically distributed split to create train and test sets, but more advanced techniques such as adversarial splits and likelihood splits could also be explored in future work. **Fourth**, while the current manuscript does not evaluate the dataset on both multi-modal and multi-lingual aspects simultaneously, we believe that this dataset has the potential to contribute to the development of such systems in the future.

Abstract

End-to-end neural models for conversational AI often assume that a response can be generated by considering only the knowledge acquired by the model during training. Document-oriented conversational models make a similar assumption by conditioning the input on the document and assuming that any other knowledge is captured in the model's weights. However, a conversation may refer to external knowledge sources. In this work, we present `EKo-DoC`, an architecture for document-oriented conversations with access to external knowledge: we assume that a conversation is centered around a topic document and that external knowledge is needed to produce responses. `EKo-DoC` includes a dense passage retriever, a re-ranker, and a response generation model. We train the model end-to-end by using silver labels for the retrieval and re-ranking components that we automatically acquire from the attention signals of the response generation model. We demonstrate with automatic and human evaluations that incorporating external knowledge improves response generation in document-oriented conversations. Our architecture achieves new state-of-the-art results on the Wizard of Wikipedia dataset, outperforming a competitive baseline by 10.3% in Recall@1 and 7.4% in ROUGE-L.

1 Introduction

Recent advances in Natural Language Processing (NLP) allowed us to build complex conversational systems for various scenarios, such as task-oriented (Radlinski and Craswell, 2017; Wen et al., 2017), chit-chat (Khatri et al., 2018; Zhou et al., 2020), and even for guiding users in performing complex real-world tasks (Gottardi et al., 2022). When using deep neural networks for implementing a conversational agent, a common practice is to use many historical conversations to train the model to produce responses that are related to a dialog context. In this setting, a response is generated solely from the knowledge acquired during the training of the network (Vinyals and Le, 2015), and no other knowledge sources are used at inference time.

A more effective way of producing dialog responses would be to incorporate external knowledge into the model. This is, for example, the case of systems that make use of document/passage retrieval in QA (Lewis et al., 2020b). In this work, we consider the setting in which a conversation is grounded in a target topic but also in external knowledge, in the form of documents. For example, Figure 1 shows a conversation with respect to a target topic (i.e., *San Diego Comic-Con*) represented by a topic document. During the conversation, some turns may refer to other documents from an external Knowledge Base (KB) providing additional information (e.g., *Shel Dorf*). In our preliminary studies, we estimated that about 36% of the dialogs in the popular Wizard of Wikipedia dataset (Dinan et al., 2019) require knowledge beyond the topic document.

This setting poses additional challenges to the generation of adequate responses in a dialog. While a model could possibly memorize a vast amount of knowledge in its weights during training, the model will likely be applied to new dialog contexts that refer to unseen knowledge. If enriched with external knowledge, the model input could be better conditioned to produce accurate outputs. From a technical perspective, the model needs to learn i) to retrieve the relevant knowledge and ii) to incorporate it into the generated response.

To address these challenges, we propose `EKo-DoC`, an end-to-end conversational agent designed to model a target topic document and a set of external knowledge documents. `EKo-DoC` integrates a Dense Passage Retriever (DPR) (Karpukhin et al., 2020) and a Re-Ranker (RR) into a response generation model. To reduce the need

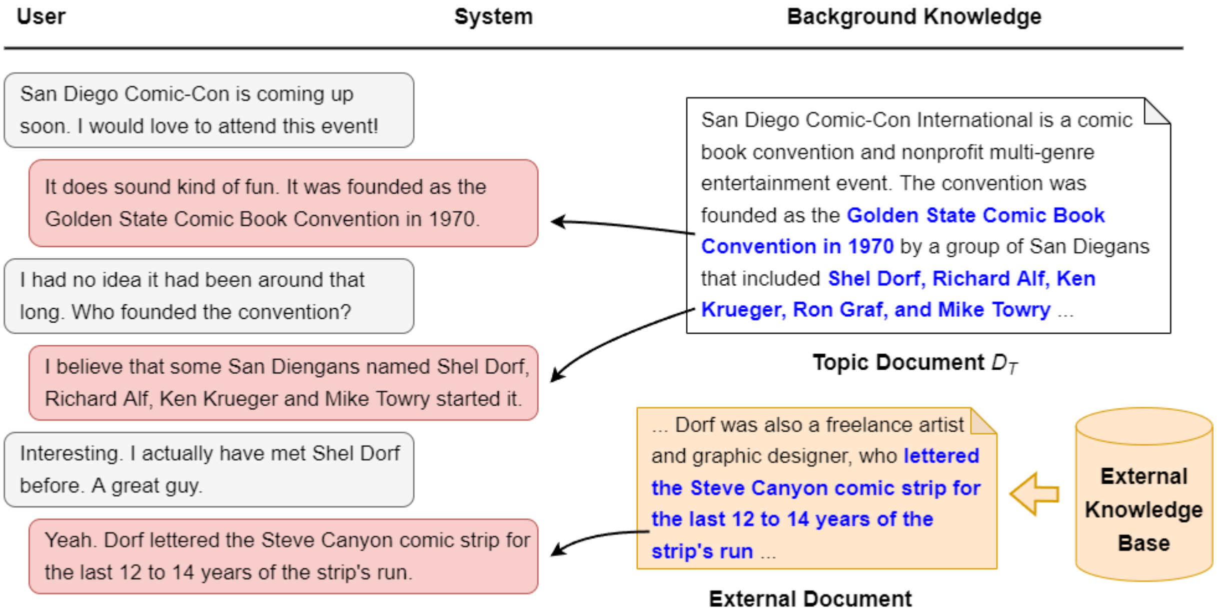
May 2-6, 2023



San Diego Comic-Con is coming up soon. I would love to attend this event!

It does sound kind of fun. It was founded as the Golden State Comic Book Convention in 1970.

I had no idea it had been around that long. Who founded the convention?

I believe that some San Diengans named Shel Dorf, Richard Alf, Ken Krueger and Mike Towry started it.

Interesting. I actually have met Shel Dorf before. A great guy.

Yeah. Dorf lettered the Steve Canyon comic strip for the last 12 to 14 years of the strip's run.

San Diego Comic-Con International is a comic book convention and nonprofit multi-genre entertainment event. The convention was founded as the **Golden State Comic Book Convention in 1970** by a group of San Diegans that included **Shel Dorf, Richard Alf, Ken Krueger, Ron Graf, and Mike Towry** ...

... Dorf was also a freelance artist and graphic designer, who **lettered the Steve Canyon comic strip for the last 12 to 14 years of the strip's run** ...

Figure 1: An example of a dialog in our setting: a central topic document defines the general topic of the dialog. External documents can be used as well to generate responses for some specific turns of the conversation.

for manual annotations, we automatically acquire labels for the training of the DPR and RR components. In particular, we leverage the attention weights of the generation model over the retrieved documents to generate a set of silver labels. Our generation model is a sequence-to-sequence model that generates a response by taking as input the entire concatenation of the dialog context and related documents retrieved from a KB.

Experimental results demonstrate that `EKo-DoC` is able to correctly use both the topic document and the external knowledge to produce better responses in a conversation. We report competitive results on two public datasets, Wizard of Wikipedia (WoW) (Dinan et al., 2019) and MultiDoc2Dial (Feng et al., 2021). In particular, `EKo-DoC` achieves new state-of-the-art (SOTA) results on WoW, outperforming a strong baseline by 10.3% in Recall@1 and 7.4% in ROUGE-L. Finally, we conduct a human study to verify the quality of the generated responses. Compared to models that do not condition on the topic document or external knowledge, our model produces responses that are more fluent, more on-topic, and more interesting.

To summarize, our contributions are: i) we study the setting where we model *both* a target topic document and external knowledge for a conversation; ii) we propose `EKo-DoC`, a novel end-to-end response generation architecture for the task; iii) we propose an automatic annotation procedure to acquire the labels for training the retrieval engine.

2 `EKo-DoC` Architecture

Given a dialog context C and a topic document D_T that serves as the background of the dialog, the task is to generate a response r to the last utterance of C. We also have available an external knowledge base $K_{\text{KB}} = \{D_1, D_2, ..., D_m\}$; D_j denotes a knowledge snippet represented by some natural language text (e.g., a paragraph in Wikipedia). While we use the term "snippet", each snippet is not necessarily a short piece of text. `EKo-DoC` is general enough to be used with documents of different lengths.

The dialog is mostly centered around D_T, but external knowledge from K_{KB} is sometimes needed to generate an informative and relevant response (see Figure 1 for an example). To this end, the task can be viewed as building a model of $P(r|C, D_T, K_{\text{KB}})$.

2.1 Document-Oriented Dialog System with Access to External Knowledge

Figure 2 shows an overview of `EKo-DoC`, our proposed framework. The inference process consists of three steps. First, given a dialog context and a topic document, we use a DPR model to retrieve an initial set of knowledge snippets (Section 2.1.1). Second, we re-rank the snippets using a Transformer-based cross-attention model (Section 2.1.2). Third, conditioned on the dialog context and

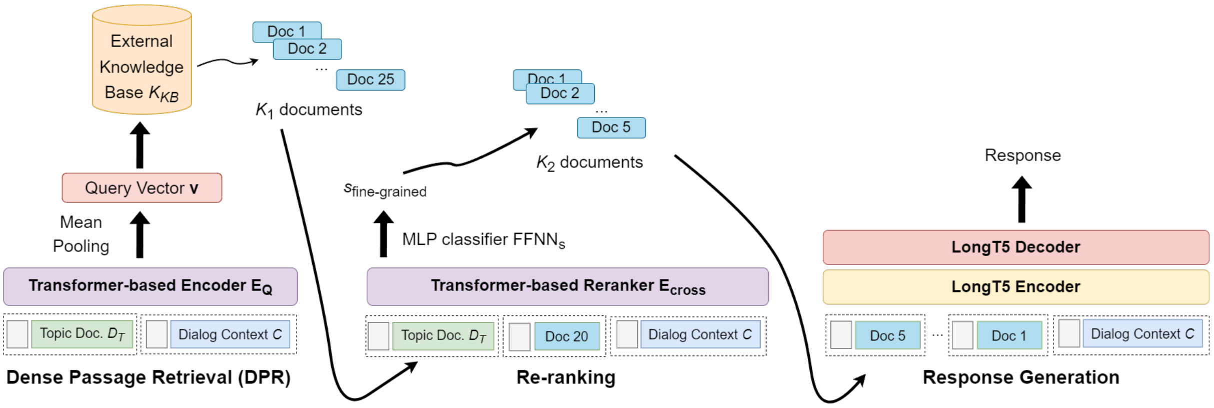


Figure 2: An overview of `EKo-DoC`, our framework. K_1 and K_2 are empirically set to be 25 and 5 (respectively).

the top-k ranked snippets, a generator produces a natural language response (Section 2.1.3).

In previous work (Glass et al., 2022; Li et al., 2022a), the retrieval components were trained using human-annotated pairs of input contexts and supporting knowledge snippets. To remove the need for expensive gold-standard retrieval labels, we use attention scores as pseudo-labels for training the retrieval and re-ranking models (Section 2.2).

Finally, note that while D_T can be fundamental to the response generation for most of the conversation, it can be less relevant for some dialog turns (e.g., see Figure 1). Therefore, we also include D_T in the knowledge base K_{KB} and let our retrieval engine decide if the topic document is essential. If D_T is retrieved, the final generator will use D_T for response generation.

2.1.1 External Knowledge Retrieval

In order to use a DPR model for retrieving knowledge, we need to encode K_{KB} in the indexing phase and the input query in the retrieval phase.

K_{KB} Encoding. We use an encoder $E_{\text{KB}}(\cdot)$ to map every knowledge snippet D_j to a real-valued vector. We assume that each snippet is a document with a title and short textual content. The input to the document encoder $E_{\text{KB}}(\cdot)$ is:

$$T\left[D\right] = \texttt{[s]}\ \text{Title / Description}\ \texttt{[/s]} \qquad (1)$$

where `[s]` and `[/s]` are special tokens denoting the start and end of the input, and "/" is used to separate the title from the description. $T[\cdot]$ denotes a function that maps a general object (e.g., a knowledge snippet) into a textual sequence.

We use a pre-trained Transformer model as the encoder (Reimers and Gurevych, 2019). That is, for each $D_j \in K_{\text{KB}}$, we encode it into a vector $\mathbf{v}_j$:

$$\mathbf{v}_j = E_{\text{KB}}\left(T\left[D_j\right]\right) \qquad (2)$$

Query Encoding. We use the topic document D_{T} and the dialog context C to construct a query for the DPR model. We first concatenate D_{T} and C into a single sequence $T\left[D_{\text{T}} \oplus C\right]$:

$$\texttt{[s]}\ T\left[D_{\text{T}}\right]\ \texttt{[sep]}\ T\left[C\right]\ \texttt{[/s]} \qquad (3)$$

where `[sep]` is a special token to separate the topic document and the dialog context. $T\left[D_{\text{T}}\right]$ is similar to what described in Equation 1. $T\left[C\right]$ is instead a concatenation of all the dialog turns, where two turns are separated by the `[sep]` token.

Then, we also use a Transformer encoder $E_{\text{Q}}(\cdot)$ to map C and D_{T} into a single vector $\mathbf{v}$:

$$\mathbf{v} = E_{\text{Q}}\left(T\left[D_{\text{T}} \oplus C\right]\right) \qquad (4)$$

In this work, $E_Q(\cdot)$ and $E_{KB}(\cdot)$ share the same architecture (Reimers and Gurevych, 2019).

Scoring and Retrieval. The first (coarse-grained) relevance score of a knowledge snippet D_j with respect to a query is given by:

$$s_{\text{c}}\left(D_j, C, D_{\text{T}}\right) = \mathbf{v} \cdot \mathbf{v}_j \qquad (5)$$

We retrieve up to K_1 knowledge snippets by ranking according to the s_c values. K_1 is a hyper-parameter, with $K_1 \ll |K_{\text{KB}}|$. In order to make this operation efficient, we adopted FAISS (Johnson et al., 2021). We first apply $E_{\text{KB}}(\cdot)$ to all the knowledge snippets and index them using FAISS offline. Then, given a query vector $\mathbf{v}$ obtained with $E_Q(\cdot)$, we use FAISS to return the top K_1 candidates according to the coarse-grained scores.

2.1.2 Knowledge Snippet Re-ranking

After the initial coarse-grained retrieval step with DPR, there are K_1 candidate knowledge snippets. We then apply a fine-grained cross-attention re-ranker over the K_1 snippets. After that, we keep the top-K_2 snippets[1] for the next phase (i.e., the response generation phase).

The input to the re-ranker is the concatenation of D_{T}, a knowledge snippet D_j retrieved in the previous phase, and C:

$$\texttt{[s]}\ T\big[D_{\text{T}}\big]\ \texttt{[sep]}\ T\big[D_j\big]\ \texttt{[sep]}\ T\big[C\big]\ \texttt{[/s]} \tag{6}$$

The re-ranker consists of a Transformer-based encoder and a feed-forward neural network. Given an input representation described above, the re-ranker computes the final relevance score s_f as:

$$\begin{aligned} \mathbf{h}_j &= \text{reduce}\Big(E_{\text{cross}}\Big(T\big[D_{\text{T}} \oplus D_j \oplus C\big]\Big)\Big) \\ s_{\text{f}}\Big(D_j, C, D_{\text{T}}\Big) &= \text{FFNN}_s\big(\mathbf{h}_j\big) \end{aligned} \tag{7}$$

where $E_{\text{cross}}(\cdot)$ is a Transformer-based encoder (Liu et al., 2019), and its input is a representation described in Equation 6; FFNN_s is a feed-forward neural network. $\text{reduce}(\cdot)$ is a function that returns the final hidden state of the Transformer that corresponds to the first input token. The final set of K_2 knowledge snippets is selected according to the s_{f} scores assigned from the re-ranker.

2.1.3 Response Generation Model

Our generative model is based on the sequence-to-sequence (seq2seq) encoder-decoder architecture that directly predicts an output sequence from an input sequence (Sutskever et al., 2014). By leveraging the recent advances in neural models for long sequences (Beltagy et al., 2020; Guo et al., 2022), our generator takes as input the entire concatenation of the dialog context and the top-ranked retrieved knowledge snippets (Figure 2). We use LongT5 as our generator (Guo et al., 2022) as it can scale up to 16K input length.

Specifically, let $\{\tilde{D}_1, \tilde{D}_2, ..., \tilde{D}_{K_2}\}$ be the set of knowledge snippets retrieved by the re-ranker.[2] The input to the generative model is:

$$\texttt{[s]}\ T\big[\tilde{D}_1 \oplus \tilde{D}_2 \oplus ... \oplus \tilde{D}_{K_2}\big]\ \texttt{[sep]}\ T\big[C\big]\ \texttt{[/s]} \tag{8}$$

where $T\big[\tilde{D}_1 \oplus \tilde{D}_2 \oplus ... \oplus \tilde{D}_{K_2}\big]$ is the concatenation of all the retrieved snippets:

$$T\big[\tilde{D}_1\big]\ \texttt{[sep]}T\big[\tilde{D}_2\big]\ \texttt{[sep]}...\ \texttt{[sep]}T\big[\tilde{D}_{K_2}\big] \tag{9}$$

We denote the final input sequence as X. The expected output is an appropriate response Y to the last dialog turn. Similar to previous encoder-decoder language models (Lewis et al., 2020a; Raffel et al., 2020), the generator models the conditional probability of selecting a new token given all previously generated tokens when conditioned on X:

$$P(Y|X) = \prod_{i=1}^{|Y|} P\big(Y_i \,|\, Y_{1:i-1}\,, X\big) \tag{10}$$

where Y_i is the i-th token of Y, and $Y_{1:i-1}$ consists of all the tokens that come before it.

The loss function for training the generator is the usual negative log-likelihood function:

$$\mathcal{L}_{\text{generation}}(B) = -\sum_{i=1}^{|B|} \log P\big(\hat{Y}^i | X^i\big) \tag{11}$$

where B is a mini-batch consisting of $|B|$ examples, each in the form $\big(X^i, \hat{Y}^i\big)$. In addition, $\hat{Y}^i$ is the ground-truth response to the input X^i.

We refer to our approach as the Fusion-in-Input (FiI) method, as our generator directly takes as input all the potentially relevant information (i.e., the retrieved knowledge and the dialog history). This is a departure from the popular Fusion-in-Decoder (FiD) approach that encodes the retrieved snippets independently (Izacard and Grave, 2021a,b; Asai et al., 2022).

2.2 Using Cross-Attention Scores as Retrieval Pseudo-Labels

If we train our system using only the generation loss function $\mathcal{L}_{\text{generation}}(B)$, only the parameters of the generation model will be updated. In order to optimize the retrieval engine, we propose to use the generation attention scores over the snippets in the input as retrieval pseudo-labels during the training stage. The intuition is that if the decoder of the generator pays more attention to a particular retrieved knowledge snippet, it means that such a snippet is likely to be relevant.

For each snippet retrieved by the re-ranker, we average all the pre-attention scores over all the tokens of the snippet. Formally, let L denote the number of layers of the decoder, and let H be the

---

[1] Note that $K_2 < K_1$.

[2] Note that it is possible that D_T is an element of this set.

number of attention heads. For each knowledge snippet D_j, we denote the indices of its starting and ending tokens in X as s_j and e_j, respectively. The averaged attention score $\mathcal{A}(D_j)$ of D_j is computed as:

$$\mathcal{A}(D_j) = \frac{\sum_{l=1}^{L} \sum_{h=1}^{H} \sum_{x=s_j}^{e_j} \sum_{y=1}^{|\hat{Y}|} p_{l,h}(x, y)}{L \times H \times |s_j - e_j + 1| \times |\hat{Y}|} \tag{12}$$

where $\hat{Y}$ is the ground-truth response. In addition, $p_{l,h}(x, y)$ is the pre-attention score between the y-th token of $\hat{Y}$ and the x-th token of X computed by the h-th attention head of the l-th layer. Basically, we collect all the pre-attention scores that are relevant to D_j and compute their average.

We can normalize the averaged attention scores using a softmax function:

$$P_{\text{attention}}(D_j) = \frac{\exp\left(\mathcal{A}(D_j)\right)}{\sum_{i=1}^{K_2} \exp\left(\mathcal{A}(D_i)\right)} \tag{13}$$

Similarly, we can normalize the retrieval scores predicted by the DPR model and the reranker:

$$\begin{aligned} Q_{\text{coarse}}(D_j) &= \frac{\exp\left(s_{\text{c}}(D_j, C, D_T)\right)}{\sum_{i=1}^{K_2} \exp\left(s_{\text{c}}(D_i, C, D_T)\right)} \\ Q_{\text{fine}}(D_j) &= \frac{\exp\left(s_{\text{f}}(D_j, C, D_T)\right)}{\sum_{i=1}^{K_2} \exp\left(s_{\text{f}}(D_i, C, D_T)\right)} \end{aligned} \tag{14}$$

We then use the averaged attention scores of the retrieved knowledge snippets as pseudo-labels to update the retrieval engine:

$$\begin{aligned} \mathcal{L}_{\text{dpr}}(B) &= \sum_{i=1}^{|B|} D_{\text{KL}}\left(P^i_{\text{attention}} \mid\mid Q^i_{\text{coarse}}\right) \\ \mathcal{L}_{\text{reranker}}(B) &= \sum_{i=1}^{|B|} D_{\text{KL}}\left(P^i_{\text{attention}} \mid\mid Q^i_{\text{fine}}\right) \\ \mathcal{L}_{\text{retrieval}}(B) &= \mathcal{L}_{\text{dpr}}(B) + \mathcal{L}_{\text{reranker}}(B) \end{aligned} \tag{15}$$

where B is a mini-batch of examples, and D_{KL} denotes the KL divergence. Also, $P^i_{\text{attention}}$, Q^i_{coarse}, and Q^i_{fine} are the distributions computed for the i-th example of B (refer to Equations 13 and 14).

The final loss function combines the generation loss (Eq. 11) and the retrieval loss (Eq. 15):

$$\mathcal{L}_{\text{final}}(B) = \frac{1}{|B|}\left(\mathcal{L}_{\text{generation}}(B) + \mathcal{L}_{\text{retrieval}}(B)\right)$$

A related study (Izacard and Grave, 2021a) also proposed an approach to train retrieval systems without strong supervision. The work focuses on the task of question answering and uses the FiD approach for output generation. In contrast, we focus on building dialog systems and tailoring our learning approach to our newly proposed FiI approach.

To summarize, `EKo-DoC` is end-to-end trainable. The document encoder of the DPR model (Equation 1) is fixed. The query encoder (Equation 4), the re-ranker, and the generator are optimized end-to-end using the final loss function described above.

3 Experiments

3.1 Data and Experiments Setup

Datasets For the experiments, we use the following two publicly available conversational datasets.

Wizard of Wikipedia (WoW) is a dataset consisting of open-domain conversations grounded in knowledge from Wikipedia (Dinan et al., 2019). We use the version provided by the KILT benchmark (Petroni et al., 2021). The external knowledge base K_{KB} consists of about 22 million 100-word passages from Wikipedia. We consider each passage as a knowledge snippet. Each conversation in WoW is annotated with a topic, which is a Wikipedia page. As the topic Wikipedia page can be extremely long, we only use the first paragraph of the page as the topic document D_T. Finally, WoW already comes with a public train/dev/test split.

MultiDoc2Dial is a new conversational dataset that grounds dialogs in multiple documents (Feng et al., 2021). Each dialog consists of multiple segments, and two adjacent segments are grounded in different documents. K_{KB} consists of 4,283 passages across four domains (Social Security Administration, Veteran Affairs, Student-Aid, and DMV). For each dialog, we use the first paragraph of the first grounded document as D_T.

Note that the original forms of WoW and MultiDoc2Dial do not have any notion of a central topic document. Therefore, we use some heuristics (described above) to select the topic document.

Evaluation Metrics For retrieval, we compute Recall@k, which measures the fraction of times the correct knowledge snippet is found in the top-k retrieved snippets. We evaluate the text generation output based on unigram F1 score (F1) and ROUGE-L (Lin, 2004). For MultiDoc2Dial, similarly to the original study that first introduced it

(Feng et al., 2021), we also compute Exact Match (EM) (Rajpurkar et al., 2016) and SacreBLEU (BL) (Post, 2018). For WoW, we do not report EM and BL scores because the leaderboard for this dataset does not use these metrics, and we also do not have direct access to the test set used by the leaderboard.

Baselines We implemented several baselines for detailed comparison and analysis. The first set of baselines consists of basic seq2seq models that do not have any retrieval engine:

- LongT5 (Guo et al., 2022) is an extension of T5 (Raffel et al., 2020) that handles long sequence inputs efficiently. The baseline takes only the dialog context C as input.
- LongT5-with-Topic uses the same architecture as LongT5 but takes both the topic document D_T and the dialog context C as input.

The second set of baselines consists of systems augmented with *frozen* retrievers:

- [Frozen DPR + FiI] first uses a pre-trained DPR model to retrieve five potentially relevant knowledge snippets. Conditioned on the retrieved knowledge and the dialog context, a FiI generation model then generates a response.
- [Frozen DPR + FiI (using D_T)] uses the same architecture, but its FiI generator also takes the topic document as input.

By comparing our full model against this set of baselines, we can analyze the effectiveness of using cross-attention scores as retrieval pseudo-labels.

Hyperparameters We initialized the DPR component using `all-mpnet-base-v2` (Reimers and Gurevych, 2019). The reranker is initialized using `distilroberta-base`, a distilled version of RoBERTa (Liu et al., 2019). We initialize the generation component of every system using a large version of LongT5 (Guo et al., 2022) unless otherwise stated. The batch size is 32. The number of training epochs is 10. More details about the hyperparameters are in the appendix.

3.2 Experimental Results

Table 1 presents the retrieval and response generation performance of our models and the baselines. First, we can see that our models achieve the highest performance compared with all baselines for both data sets and all evaluation metrics. This result emphasizes the importance of using external knowledge for document-oriented dialog systems and demonstrates the effectiveness of doing so by using our approach of fine-tuning the retrieval engine with attention score-based pseudo-labels.

The results in Table 1 also show that using the topic document is crucial for effective response generation. For example, LongT5-with-Topic outperforms the default LongT5 baseline, especially on MultiDoc2Dial. Similar results are observed for the baselines that use frozen retrievers.

The results also show that there is a clear positive correlation between text generation performance and retrieval performance. Compared with the frozen retrieval baselines, our full model achieves much higher generation performance by training the retrieval and re-ranking models with our end-to-end approach. The generator of every model listed in Table 1 is initialized with the same large version of LongT5. This shows the importance of the retrieval engine on the response generation performance.

Using cross-attention scores as retrieval pseudo-labels is highly effective according to Table 1. Specifically, `EKo-DoC` achieves a Recall@1 score of 71.21% on WoW without using human-annotated retrieval labels. Notice also the importance of the re-ranker component. When the re-ranker is disabled (second row) the model achieves a Recall@1 score of 33.88% on MultiDoc2Dial, while the full model achieves a score of 41.60%. Furthermore, Table 3 shows that the effectiveness of using cross-attention scores can even be comparable to that of using gold retrieval labels.

Finally, many previous studies on knowledge-intensive dialog systems do not have any notion of a central topic document (Shuster et al., 2021; Paranjape et al., 2022). To directly compare against these studies, we also train a system that does not explicitly use the topic document (Table 2). Basically, this system is similar to our full model (Figure 2), but it does not take the topic document as part of its input. Overall, our system outperforms all previous state-of-the-art methods in most evaluation metrics. While FiD-Light (Hofstätter et al., 2022) and Re2G (Glass et al., 2022) achieve better Recall@1 and Recall@5 than ours (respectively), FiD-Light and Re2G use gold retrieval labels to train their retrieval engines. Our system does not use such supervision signals, which can be expen-

Table 2: Performance of state-of-the-art models on the test set of WoW according to the public leaderboard (as of February 2023). We are hiding our score on the leaderboard during the anonymous review process. The leaderboard is available at `https://eval.ai/web/challenges/challenge-page/689/leaderboard/1909`, and it also uses additional metrics such as Recall@5 and KILT-F1 (Petroni et al., 2021). Note that FiD-Light and Re2G use gold retrieval labels to train their retrieval engines, while our system does not rely on such supervision signals.

	R@1	R@5
`EKo-DoC`	45.32	61.36
DPR + RR (finetuned using gold labels)	**46.46**	**65.88**

Table 3: Comparison between using attention score-based pseudo-labels and using gold retrieval labels. Here, scores on the dev set of WoW are reported. In addition, different from the public leaderboard, we evaluate retrieval at a more fine-grained granularity, which is the passage level instead of the page level.

sive to obtain.

3.3 Human Evaluation

There can be many appropriate responses to the last turn of a dialog; therefore, human evaluation is typically crucial to properly evaluate the performance of a dialog system (Liu et al., 2016; Ghandeharioun et al., 2019). We conducted a human evaluation of various models by using Amazon's Mechanical Turk (AMT).[3] Specifically, we created 150 evaluation tasks, each consisting of a dialog context selected randomly from WoW and a set of responses produced by different model variants. For each task, we asked three different AMT workers to rank the models' outputs based on:

1. *Fluency* (0/1). Is the generated response fluent and grammatically correct?
2. *Relevance* (0/1). Is the response on-topic and relevant to the last turn of the dialog?
3. *Interestingness* (0/1). Does the response provide new interesting information that is not already mentioned in the dialog?

Table 4 presents the human evaluation results comparing our full model against two baselines, LongT5 and LongT5-with-Topic. We chose these baselines as our main goal here is to analyze how external knowledge helps in document-oriented dialogs. According to human annotators, our model

---

[3] All details about the annotation tasks are in the appendix.

outperforms both baselines substantially in all three criteria. Furthermore, `EKo-DoC` achieves the most gain in the "interestingness" criterion. This is expected because, for example, compared to LongT5-with-Topic, our model also makes use of external knowledge when generating responses.

Full Model vs. LongT5	Better	Same	Worse
Fluency	31.01	47.29	21.71
Relevance	39.85	38.35	21.80
Interestingness	48.39	35.48	16.13
Full Model vs. LongT5-with-Topic			
Fluency	24.62	62.31	13.08
Relevance	32.03	53.13	14.84
Interestingness	40.60	39.85	19.55

Table 4: Human evaluation results (%) comparing our full model to LongT5 (top part) and LongT5-with-Topic (bottom part). The numbers in the column "Better" denote the percentage of the snippets where our full model is considered better (according to humans).

3.4 Analysis

Qualitative Analysis Table 5 shows some examples from WoW that illustrate how incorporating external knowledge can improve the quality of generated responses. Note that more qualitative examples are provided in the appendix.

In the first example, the responses generated by all models are fluent and grammatically correct. However, LongT5 generates a factually incorrect statement, as it does not have any knowledge that is not implicitly stored in its parameters. Nevertheless, LongT5 seems to possess some knowledge about the world, as Sam Walton is the founder of Walmart, which is related to Target Corporation.

In the second example, in the beginning, the dialog is mainly about rock and roll in general. However, the last dialog turn deviates slightly from the general topic and starts talking about James Brown, who influenced several music genres. The topic document does not have any information about the person. Therefore, LongT5-with-Topic generates a factually correct response about rock and roll, but it is unrelated to James Brown. In contrast, by leveraging external knowledge, our model generates a response that is more relevant to the last dialog turn.

Comparison between FiI and FiD We compare our FiI method and the popular FiD method (Izacard and Grave, 2021b) in Table 6. FiI outperforms FiD, as FiI encodes the dialog context and the top-ranked knowledge snippets jointly. In contrast, FiD encodes the retrieved snippets independently, so there is less interaction between the knowledge snippets before the final decoding stage. In conclusion, by using FiI instead of FiD, our generator can extract semantic relationships between the different input signals more effectively.

Examples
Topic Document: The first paragraph of the Wikipedia page talking about Target Corporation. **Dialog Context**: A: Target Corporation is the second largest discount retailer. B: I assume that it is just before Walmart, but still huge. **Candidate Responses:** LongT5: It was founded in 1971 by Sam Walton. LongT5-with-Topic: Target was founded by George Dayton in 1902. `EKo-DoC`: Target is the eighth largest retailer in the US.
Topic Document: The first paragraph of the Wikipedia page talking about Rock and roll. **Dialog Context**: A: My favorite music is rock and roll. B: Gotta love some Rock and Roll. It's one of my favorites as well. ... A: Indeed it did. I was speaking to a friend earlier about *James Brown* and how he influenced so many genres of music starting in the 60's. **Candidate Responses:** LongT5-with-Topic: I like the fact that while elements of what was to become rock and roll can be heard in blues records from the 1920s and in country records of the 1930s, the genre did not acquire its name until 1954. `EKo-DoC`: I agree. He was an American singer, songwriter, dancer, musician, record producer and bandleader.

Table 5: Examples showing how external knowledge improves the quality of generated responses. Red is used to indicate responses that are factually *incorrect*. Blue is used to indicate responses that are factually *correct*.

	F1	ROUGE-L
Freezed DPR + FiI (LongT5)	**34.07**	**29.97**
Freezed DPR + FiD (LongT5)	33.82	29.77
Freezed DPR + FiD (T5)	32.80	28.65

Table 6: Comparison between FiI and FiD. The dev set of MultiDoc2Dial is used.

4 Related Work

Document-oriented Conversations Humans typically seek information in a *conversational* manner, for example to find answers to questions (Choi et al., 2018) or to seek guidance in performing real world tasks (Gottardi et al., 2022). As such, several recent conversational datasets were introduced for building models to assist in information-seeking dialogs. For example, Choi et al. (2018) presented QuAC, a dataset that contains 14K information-seeking QA dialogs:

each is centered around a short evidence text from Wikipedia and involves a student and a teacher. The student poses a sequence of free-form questions about the text, while the teacher answers the questions by providing short excerpts from the text. Concurrently, Reddy et al. (2019) introduced CoQA, a dataset in which a machine has to understand a text passage and answer a series of questions that appear in a conversation. Choi et al. (2022) introduced a dataset for the novel setting of Conversational Task Assistants, where users seek guidance from a conversational agent to perform real world tasks: in this setting, a conversation is centered around a document describing a task. SOTA methods for these tasks typically do not use any external knowledge beyond the dialog context and the given background text (Zhu et al., 2018; Huang et al., 2019; Qu et al., 2019; Gupta et al., 2020; Zhao et al., 2021; Qian et al., 2022).

Open-Domain Question Answering In open-domain QA, the goal is to find the answer to a (typically short) question over a large corpus such as Wikipedia (Voorhees and Tice, 2000; Chen and Yih, 2020). Passage retrieval has been an essential component of many state-of-the-art open-domain QA systems (Karpukhin et al., 2020; Lewis et al., 2020b; Piktus et al., 2021; Min et al., 2021; Zhu et al., 2021). An effective retrieval component can reduce the search space for answer extraction and identify the support context for users to verify the answer. As a result, many studies have focused on improving the retrieval components, ranging from removing the need for strong supervision signals (Izacard and Grave, 2021a; Ram et al., 2022) to adding sophisticated reranking components (Yu et al., 2022a; Glass et al., 2022; Yu et al., 2022b). Open-domain QA is typically non-conversational and does not have any notion of a topic document.

Weak Supervision for Neural Retrieval A closely related study (Izacard and Grave, 2021a) also proposed an approach to train retrieval systems without strong supervision. The work focuses on the task of QA and uses the FiD approach for output generation. In contrast, we focus on building dialog systems and tailoring our learning approach to our newly proposed FiI approach.

Knowledge-Grounded Dialog Generation Incorporating background knowledge into conversation models can make dialogs more informative and engaging. Therefore, many recent studies have investigated various techniques for selecting relevant knowledge and integrating it into the response generation process (Lian et al., 2019; Kim et al., 2020; Li et al., 2020; Shuster et al., 2021; Chen et al., 2021; Mishra et al., 2022; Li et al., 2022b). Many of these studies utilize the Wizard of Wikipedia (WoW) dataset (Dinan et al., 2019). Our system, `EKo-DoC`, achieves a new state-of-the-art result on WoW, as shown in Table 2. This result provides some guarantee on the relative performance of `EKo-DoC` compared to many previous SOTA knowledge-grounded dialog systems. As of February 2023, there are nearly 40 tested methods on the public leaderboard of WoW, though Table 2 only shows a subset due to space limitations.

5 Conclusions

This work proposes and studies a new problem setting that combines document-oriented conversations and open-domain QA. We introduce a new architecture for the problem that includes a dense passage retriever, a re-ranker, and a response generation model. We train these three components end-to-end and use cross-attention scores as pseudo-labels to update the retrieval engine. Extensive experimental results on two public datasets demonstrate the effectiveness of our method. In the future, we plan to reduce the computational complexity of our model by using compression techniques.

6 Ethical Consideration

Limitations While `EKo-DoC` achieves new SOTA results on WoW, its performance is far from perfect. A ROUGE-L score of 18.64% and a Recall@1 score of 71.21% indicate that there is much room for improvement. Based on our manual analysis, we found that `EKo-DoC` sometimes generates responses that are a little bit unnatural. Finally, a common limitation of many Transformer-based systems, such as `EKo-DoC`, is the large computational complexity. We plan to reduce the computational complexity of `EKo-DoC` by using some compression techniques (Lai et al., 2020; Sun et al., 2020).

Potential Risks A potential malicious use case of research on conversational AI is for building dialog systems that pose as humans and then proactively alter users' perceptions about specific issues, evaluations of products or services, or political inclinations (Qi et al., 2021). We urge anyone who uses or builds upon our research to avoid such malicious use cases.

A Human Evaluation

We used Amazon's Mechanical Turk (AMT) to perform a human evaluation of various models. More specifically, we first created 150 evaluation snippets, each consisting of a dialog context and a set of responses produced by three model variants: LongT5, LongT5-with-Topic, and our full model. Figure 3 shows an example snippet. For each snippet, we asked three different AMT workers to rank the models' outputs based on three criteria: (1) *Fluency*, (2) *Relevance*, and (3) *Interestingness*. Note that for each snippet, the presentation order of the generated responses was randomized. For example, for some AMT tasks, the first response may come from LongT5, while for some other tasks, the first response may come from our full model. Figure 4 shows the instructions we showed at the beginning of each AMT task. Even though our instructions do not explicitly explain how the collected data would be used, we believe it was clear to the AMT workers that we would use the data for researching dialog systems.

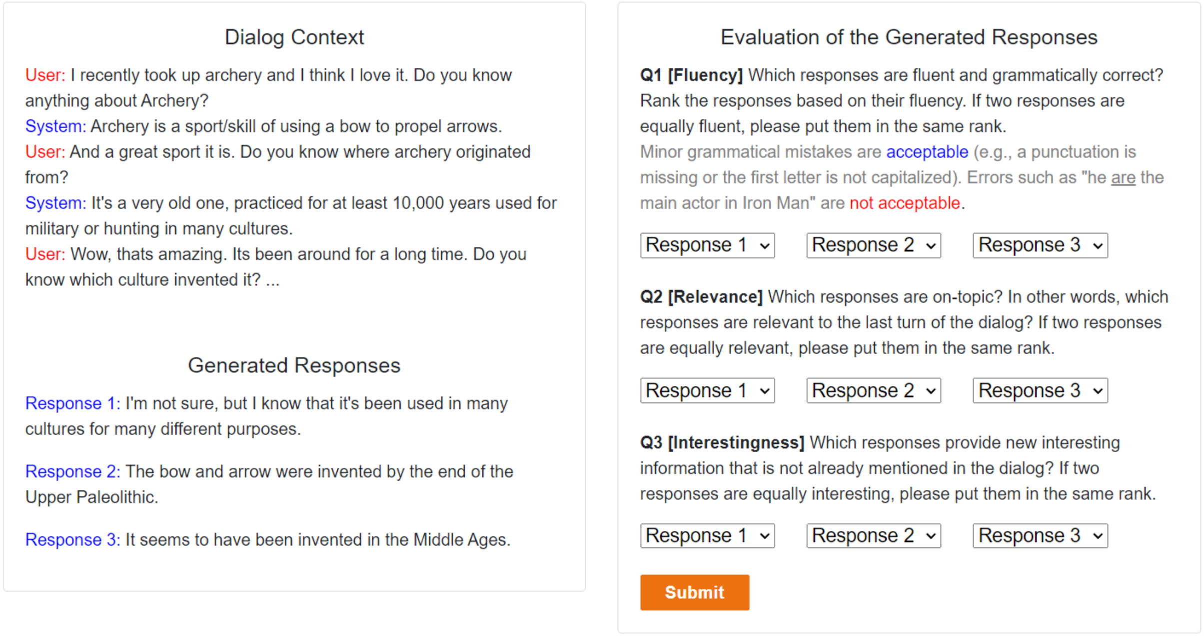
To decide the appropriate cost of each AMT task, we conducted a preliminary study, asking three NLP researchers to do about 20 tasks each. We then computed the average time it would take for each task. After that, we set the value of each AMT task so that someone who worked on our study for about an hour would make at least the required minimum wage.

B Datasets

We use two public datasets in this work: *Wizard of Wikipedia (WoW)* (Dinan et al., 2019) and *MultiDoc2Dial* (Feng et al., 2021). For WoW, we use the version provided by the KILT benchmark (Petroni et al., 2021). KILT is released under the MIT License, and MultiDoc2Dial is released under the Apache-2.0 license. Our use of the datasets is consistent with their licenses.

WoW and MultiDoc2Dial are available at `github.com/facebookresearch/KILT` and `github.com/IBM/multidoc2dial` (respectively). When we first downloaded the datasets, we randomly sampled about 10∼20 examples for each dataset and checked whether the examples contained any offensive content. Overall, we did not see any example that had offensive content.

The two datasets are in English. WoW consists of open-domain conversations, which collectively cover a wide range of topics, ranging from Ameri-



Dialog Context

User: I recently took up archery and I think I love it. Do you know anything about Archery?
System: Archery is a sport/skill of using a bow to propel arrows.
User: And a great sport it is. Do you know where archery originated from?
System: It's a very old one, practiced for at least 10,000 years used for military or hunting in many cultures.
User: Wow, thats amazing. Its been around for a long time. Do you know which culture invented it? ...

Generated Responses

Response 1: I'm not sure, but I know that it's been used in many cultures for many different purposes.

Response 2: The bow and arrow were invented by the end of the Upper Paleolithic.

Response 3: It seems to have been invented in the Middle Ages.

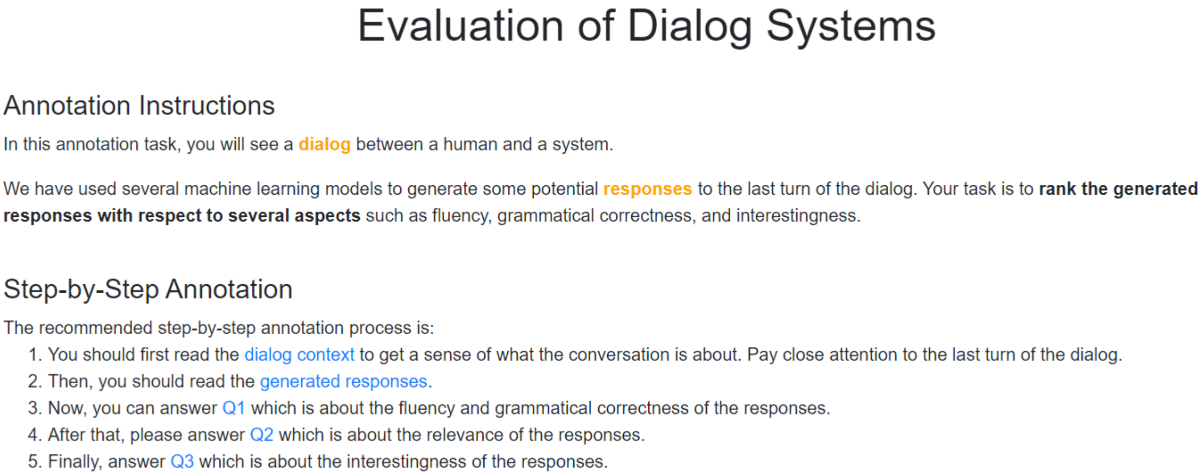
Evaluation of the Generated Responses

Q1 [Fluency] Which responses are fluent and grammatically correct? Rank the responses based on their fluency. If two responses are equally fluent, please put them in the same rank.
Minor grammatical mistakes are acceptable (e.g., a punctuation is missing or the first letter is not capitalized). Errors such as "he are the main actor in Iron Man" are not acceptable.

Q2 [Relevance] Which responses are on-topic? In other words, which responses are relevant to the last turn of the dialog? If two responses are equally relevant, please put them in the same rank.

Q3 [Interestingness] Which responses provide new interesting information that is not already mentioned in the dialog? If two responses are equally interesting, please put them in the same rank.

Figure 3: An example AMT task.



Evaluation of Dialog Systems

Annotation Instructions

In this annotation task, you will see a **dialog** between a human and a system.

We have used several machine learning models to generate some potential **responses** to the last turn of the dialog. Your task is to **rank the generated responses with respect to several aspects** such as fluency, grammatical correctness, and interestingness.

Step-by-Step Annotation

The recommended step-by-step annotation process is:

1. You should first read the dialog context to get a sense of what the conversation is about. Pay close attention to the last turn of the dialog.
2. Then, you should read the generated responses.
3. Now, you can answer Q1 which is about the fluency and grammatical correctness of the responses.
4. After that, please answer Q2 which is about the relevance of the responses.
5. Finally, answer Q3 which is about the interestingness of the responses.

Figure 4: The instructions we provided for each AMT task.

can football to Rock and Roll music. On the other hand, MultiDoc2Dial focuses on four specific domains: Social Security Administration, Veteran Affairs, Student-Aid, and DMV.

If we consider a pair of a dialog context and its corresponding ground-truth response as one example, there are 63,734/3,054/2,944 examples in the train/dev/test splits of WoW (respectively). For MultiDoc2Dial, we refer the readers to the original paper (Feng et al., 2021) for more detailed statistics of the original dataset.

C Reproducibility Information

In this section, we present the reproducibility information of our paper.

Implementation Dependencies Libraries Pytorch (Paszke et al., 2019), Transformers 4.20.1 (Wolf et al., 2020), SentenceTransformers 2.2.0 (Reimers and Gurevych, 2019), faiss-gpu 1.7.2 (Johnson et al., 2021).

Computing Infrastructure We conducted our experiments using Amazon's EC2 virtual machines. Overall, our work can be reproduced using a single p3.8xlarge instance. Information about the cost of using Amazon's EC2 P3 instances can be found at `https://aws.amazon.com/ec2/instance-types/p3/`.

Number of Model Parameters Our full model consists of three components: a DPR model, a RR model, and a seq2seq generation model. We initialize the DPR model using a Sentence-Transformer model named `all-mpnet-base-v2` (Reimers and Gurevych, 2019), which has about 110M parameters. We initialize the RR model using `distilroberta-base` (Liu et al., 2019), which has about 82M parameters. Finally, we initialize the generation model using `google/long-t5-tglobal-large` (Guo et al., 2022), which has about 750M parameters.

Hyperparameters The effective batch size is 32. The number of training epochs is 10. The base learning rate is 5e-5. K_1 is set to be 25, and K_2 is set to be 5. We use the Adam optimizer and set gradient clipping to 1.0.

Expected Validation Performance For each model variant, we report the test performance of the checkpoint with the best validation F1 score in the main paper (refer to Table 1). On the dev set of WoW, our full model achieves a unigram F1 score of 21.13% and a ROUGE-L score of 18.68%. On the dev set of MultiDoc2Dial, our full model achieves a unigram F1 score of 41.90% and a ROUGE-L score of 37.64%.

# Retrieved Docs	F1	ROUGE-L	Recall@1
$K_1 = 25$, $K_2 = 5$	38.76	34.62	39.70
$K_1 = 25$, $K_2 = 10$	39.84	35.81	44.44
$K_1 = 25$, $K_2 = 15$	39.71	35.58	42.28
$K_1 = 50$, $K_2 = 5$	39.10	34.92	40.28
$K_1 = 50$, $K_2 = 10$	39.63	35.44	42.82
$K_1 = 50$, $K_2 = 15$	39.63	35.56	43.51

Table 7: Results on the dev set of MultiDoc2Dial when we vary K_1 and K_2, the numbers of documents retrieved by DPR and the reranker (respectively). In order to save computational time, we use the base version of LongT5 in this ablation study.

D Additional Analysis

Table 7 shows the results on the dev set of MultiDoc2Dial when we vary K_1 and K_2. In general, increasing the number of retrieved documents typically has marginal positive effects on the evaluation metrics. However, note that increasing the values of K_1 and K_2 also increases the computational complexity and running time of `EKo-DoC`. Therefore, we set K_1 to 25 and K_2 to 5. We believe these values achieve a good balance between the model complexity and the quality of the generated responses.

Table 8 shows some additional examples from WoW that illustrate how incorporating external knowledge can improve the quality of generated responses.

Examples
Topic Document: The first paragraph of the Wikipedia page talking about Ferrari. **Dialog Context**: A: I have 3 Ferrari cars in my garage and I hardly know nothing about them. I read some self help books, then I was rick all of the sudden. B: Those are some nice cars they are manufacturer in Maranello. A: Yeah that's pretty cool. Do you know how old the company is? **Candidate Responses:** LongT5: I don't know but they are a luxury car manufacturer. `EKo-DoC`: I know it was founded in 1939.
Topic Document: The first paragraph of the Wikipedia page talking about Overeating. **Dialog Context**: A: Overeating is a serious problem in the USA. **Candidate Responses:** LongT5: I know, it's a problem that affects a lot of people. `EKo-DoC`: I think it is a serious problem in the US. It is the excess food consumed in relation to the energy that an organism expends.
Topic Document: The first paragraph of the Wikipedia page talking about Red. **Dialog Context**: B: Red is my favorite color. It is the color of a lot of my favorite things, like strawberries? A: Awesome! Did you also know that Mars is red because of iron oxide? ... B: That makes sense. I always liked studying the planets growing up in school. **Candidate Responses:** LongT5-with-Topic: I also like how Mars is the only planet that has a moon. `EKo-DoC`: Yeah, I love learning about the planets. I'm sure you've heard of the planet Mercury.

Table 8: Additional examples showing how external knowledge improves the quality of generated responses. Red is used to indicate responses that are factually *incorrect*. Blue is used to indicate responses that are factually *correct*.

In-Depth Look at Word Filling Societal Bias Measures

Matúš Pikuliak and **Ivana Beňová** and **Viktor Bachratý**
Kempelen Institute of Intelligent Technologies
`matus.pikuliak@kinit.sk`

Abstract

Many measures of societal bias in language models have been proposed in recent years. A popular approach is to use a set of word filling prompts to evaluate the behavior of the language models. In this work, we analyze the validity of two such measures – *StereoSet* and *CrowS-Pairs*. We show that these measures produce unexpected and illogical results when appropriate control group samples are constructed. Based on this, we believe that they are problematic and using them in the future should be reconsidered. We propose a way forward with an improved testing protocol. Finally, we also introduce a new gender bias dataset for Slovak.[1]

1 Introduction

Language models (LMs) are ubiquitous in current NLP and have brought undeniable performance improvements for many tasks. Concerns have been raised about the fairness of these models (Blodgett et al., 2020; Shah et al., 2020; Dev et al., 2021b). Since LMs are usually trained with web-based text corpora generated by a general population, there is a risk that they will learn certain societal biases, such as sexist or racist stereotypes. With these models regularly being used as backbones for further fine-tuning, this unfairness might propagate further to downstream models and ultimately to user-facing applications.

Based on this assumption, many attempts were made to quantify the *bias* in LMs. The measures usually observe LM outputs or inner workings to reveal problematic biased behavior. A popular method is to create a set of word filling prompts that test LM behavior in various situations, and then interpret the differences. For example, would an LM choose a negative stereotypical word for `X` in the sentence `All women are X`? Tests like these are often proposed because neural LMs are notoriously blackbox and it is otherwise difficult to interpret their inner working reliably. However, the observation process must be done in a methodologically sound manner and the correct assumptions must be used to ensure accurate results.

In this work, we examine the validity of two widely used methodologies – StereoSet (Nadeem et al., 2021) and CrowS-Pairs (Nangia et al., 2020) – for measuring societal bias in *masked* LMs. We first identify several theoretical problems in their score calculations. Then we show that these problems can be observed in the available data and we demonstrate that the LMs exhibit unexpected behavior that violates key assumptions made by these methodologies. This leads us to question the validity of the reported results. We propose a way to improve the methodologies by introducing a new score definition. During experiments we introduce several new variants of the existing datasets and a completely new dataset in Slovak. These new datasets are used to compare the expected behavior of the LMs with their actual behavior.

Our results challenge the validity of previous studies. This is a significant issue as these measures are widely used[2] to *demonstrate* the level of bias in LMs (Zhang et al., 2022, i.a.), as benchmarks for debiasing techniques (Meade et al., 2022, i.a.), as inspiration for bias research in languages other than English (Névéol et al., 2022; Kaneko et al., 2022), and for other bias-related research. If our assertions about their validity are accurate, all these efforts could be in danger. Moreover, it is possible that other similar measures may face similar problems.

2 Related Work

Measuring LM Bias. In recent years, numerous methodologies and datasets have emerged for measuring societal bias in LMs and other NLP mod-

---

[2] The two papers have 234 and 149 citations respectively according to Google Scholar as of February 2023.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3648–3665
May 2-6, 2023 ©2023 Association for Computational Linguistics

els (Dev et al., 2021b). The techniques for masked LMs are generally based on three types of analysis: (1) LM behavior on downstream tasks (Rudinger et al., 2018; De-Arteaga et al., 2019, i.a.), (2) inner LM representations (May et al., 2019; Webster et al., 2020, i.a.), and (3) word filling behavior. Word filling can be done using either short, semantically neutral templates filled with lexicons (Kurita et al., 2019; Ahn and Oh, 2021), or through crowd-sourced sentences that capture biased behavior. The two techniques discussed in this paper – StereoSet and CrowS-Pairs – belong to the latter category.

Critique. Papers criticize and evaluate the proposed bias measuring techniques from various perspectives. Blodgett et al. (2021) identify several conceptualization and operationalization pitfalls in the existing benchmarks and estimate that a significant portion of samples have validity issues. The lack of robustness of the proposed metrics w.r.t. specific choices of templates, prompts, lexicon seeds, metrics, sampling strategies is also a concern (Akyürek et al., 2022; Antoniak and Mimno, 2021; Delobelle et al., 2021). Low correlations between individual scores raise questions about what exactly is being measured (Delobelle et al., 2021; Cao et al., 2022; Goldfarb-Tarrant et al., 2021). Other criticisms are more conceptual. Blodgett et al. (2020) point out that the motivation behind bias measuring techniques is often *"vague, inconsistent and, lacking in normative reasoning"* and that the techniques are often *"poorly matched to the motivation"*. The lack of cultural sensitivity results in methods that are often Anglo-centric or US-centric (Talat et al., 2022; Stanczak and Augenstein, 2021), do not correctly handle marginalized groups (Devinney et al., 2022; Dev et al., 2021a), or have other similar cultural issues.

Many of these problems could be addressed by improved training for data creators and by increasing data quantity and quality. However, we show that even with perfect data, some of the proposed methodologies may still not yield valid results.

3 Methodologies and Datasets

Both StereoSet (SS) and CrowS-Pairs (CS) measure bias against certain groups using sets of word filling samples. There is usually a coupling between the dataset (the specific samples used for score calculations) and the methodology (how is the score calculated) (Orgad and Belinkov, 2022). @e distinguish between these two concepts (e.g., by saying *StereoSet (SS) dataset* and *StereoSet (SS) methodology*) and we effectively decouple them when we stress-test the methodologies with new datasets.

In this section, we briefly introduce the two existing methodologies and also our own dataset in Slovak language that is compatible with both of them. We also created various new versions and extensions of the existing datasets for our experiments, which will be introduced as appropriate. All the datasets are documented in Appendix A.

3.1 StereoSet

Nadeem et al. (2021) introduce the SS *methodology* and several *datasets* compatible with it that address different bias types – gender, race, profession, and religion. Each dataset consists of pairs of sentences that differ in exactly one word. The dataset creators were instructed to first generate stereotypical and anti-stereotypical words associated with a specific group of people and then write a template in which these words could be used. For example, `The male is strong / The male is weak` is a pair that stereotypes males as strong. In this case, `strong` and `weak` are the *keywords* that differ.

The SS *methodology* is based on the idea that a biased masked LM should prefer the stereotypical keywords in these pairs. The LM is fed the sentence with the slot for the keyword masked and is asked to calculate the probabilities for both possible keywords. The measure of bias is the percentage of samples where the model prefers the stereotypical keyword[3]. The authors define that 50% is an optimal ratio. The SS *datasets* were criticized for its subpar data quality, with estimates ranging from 38% (Nangia et al., 2020) to as high as 94% (Blodgett et al., 2021) of the samples being problematic.

3.2 CrowS-Pairs

The CrowS-Pairs (Nangia et al., 2020) proposal consists of a *methodology* and 9 *datasets* about different bias types. Each CS dataset consists of pairs of sentences as well, but the way they were collected is significantly different. The data creators were asked to write a stereotypical sentence about a marginalized group and then rewrite this sentence to change the identity of the

---

[3] We discuss the *intrasentence* variant in this work. The original paper also introduced a *intersentence* variant of the dataset for generative LMs.

group to a non-marginalized one. For example, `Women don't know how to drive / Men don't know how to drive.` First, the stereotypical sentence about `women` was created, then it was changed to talk about `men`. Unlike the SS datasets, the sentences might differ in more than one word, and there are no *keywords*.

The CS methodology measures the LM probabilities for the words that are *the same* for the two sentences. Then it calculates which sentence from the pair has a higher sum of probabilities. This is the sentence that the LM is said to "prefer". Similarly to SS, the percentage of sentences where the LM prefers the marginalized group is considered to be the bias measure, with the 50% threshold considered optimal. The CS datasets were criticized for their quality as well. Blodgett et al. (2021) found only 3% of the samples in the CS datasets admissible. Névéol et al. (2022) published a revised version of the datasets, where they attempted to fix incorrect samples.

3.3 Our own Slovak dataset

We have collected our own Slovak language dataset consisting of 142 samples, which is focused on only one gender stereotype: *Men are more competent then women*. This dataset is compatible with both SS and CS methodologies. It consists of quadruplets of sentences, with the first two sentences being the same as in SS datasets. The third and fourth sentences have the group of people changed from the stereotyped group to a non-stereotyped one. An example in English: `Women are weak / Women are strong / Men are weak / Men are strong.` We can use the first and second sentences for the SS score and the first and third sentences for the CS score.

Our main goal was to create a compatible dataset in a different language. The issues with data quality in both CS and SS datasets inspired us to make the dataset more focused, and we believe that the resulting data validity is higher than in the English datasets. On the other hand, it is smaller and less diverse. The CS methodology is also not an ideal fir for Slovak, as Slovak has gender agreement for verbs and adjectives. This leads to a generally lower number of tokens used in calculating the CS score. Further details on data collection and validation can be found in Appendix A.

4 Case Study: *StereoSet*

Some of the pitfalls previously identified in SS *datasets* (Blodgett et al., 2021) could theoretically be addressed by improving data quality. However, we claim that the SS *methodology* is problematic by itself and does not provide a valid measurement of bias, regardless of how good the data is. First, we will identify several theoretical problems and then show how these problems manifest in the data by breaking several key assumptions the SS methodology makes. The problems are related to both how we calculate scores for individual samples and the way we aggregate them.

1. No control groups. No control groups are used to compare the scores generated by the same samples for different groups of people. If the original pair is about *women*, how do the LMs behave for the same sample about *men*? We cannot determine if the LM exhibits unfair behavior unless we compare its behavior across different groups. For example, the LM might prefer `All X are` **`lazy`** over `All X are` **`diligent`** for both `men` and `women`. There is a hidden and untested assumption that the LM will by default exhibit less biased behavior for non-marginalized groups.

2. Keyword prior equality assumption. The SS methodology does not consider that the stereotypical and anti-stereotypical keywords may not have equal priors. For example, one word might be more *frequent* in the training data and therefore the LMs might generate it with higher probabilities. `All X are` **`lazy`** might have a higher probability than `All X are` **`diligent`** for any group `X`, just because `lazy` is a more common word. Raw word frequency is a simple but feasible example (Wei et al., 2021); the LMs might have also learned other similar patterns. There is a hidden and untested assumption that data creators will naturally generate stereotypical and anti-stereotypical keywords with equal priors.

3. No statistical testing. The original methodology calculates the percentage of samples where the LMs prefer stereotype, but there is no statistical significance testing done on this statistic. The percentage also does not account for the distribution of the measurements. This issue can easily be addressed by tools such as confidence intervals or statistical tests.

4. Lack of information about the probability space. The SS methodology focuses on two specific keywords. However, we lack information about all the other words in the vocabulary. We assume that all the words can be classified into three groups, based on how they would function in the prompt: stereotypical, neutral and anti-stereotypical. To truly measure LM's preference for stereotypes, we would need the information about the overall probabilities for these three groups. The sums of probabilities for these groups may not correspond with the probabilities of the two manually selected keywords.

5. Why 50%. It is unclear why 50% score is considered unbiased. A person who prefers a stereotypical sentence 50% of the time would be probably considered biased. The concept of what anti-stereotypes generated by people should be is unclear. They could be sentences that do not contain any stereotype and are in a sense neutral (e.g., `All women are people`), sentences that contain positive statements about a marginalized group (e.g., `All women are strong`), sentences that contain negative statements about a non-marginalized group (e.g., `All men are weak`), and other similar variants. In the first case, we might wish for the model to have 0% bias and always pick a neutral sentence over a negative stereotype. In other cases, the 50% threshold might be appropriate, although it is questionable whether a hypothetical model that is 50% misogynistic and 50% misandristic should be called unbiased.

We will address and further explore problems #1 and #2 in the following sections. During our experiments, we will also report confidence intervals, thus addressing problem #3. Problems #4 and #5 remain open.

4.1 Control Groups

We analyze the results of the SS methodology by using the same samples edited to describe different groups of people. For example, if there is a sample `All women are lazy/diligent`, we compare the results to a control pair `All men are lazy/diligent`. This experiment addresses problem #1 from our list problems.

We use 3 original SS datasets[4] extended with control group samples and our own dataset. The SS datasets[5] were edited as follows:

Gender. We conducted manual gender-swapping along the male-female axis. Some samples were removed if it was not possible to create a sensible gender-swapped version or if they were grammatically incorrect (4 out of 254 samples were removed). We also created a *filtered* version of the dataset by removing samples that were not inherently about gender bias (103 out of 250 remaining samples were removed). This was often the case for samples that use words `grandma, grandpa, schoolgirl, schoolboy` to describe the target population. For these, dataset creators often used age instead of gender as the basis for stereotyping.

Race and Profession. We created the control group samples automatically by replacing the identifier of country, nationality, or profession with 10 randomly selected terms from the appropriate list of terms used by the original authors. There is a possibility that a small percentage of these have the same stereotype as the original group, making the resulting control pairs invalid.

More details on the process can be found in Appendix A. Note that these extended datasets still have the same data quality limitations as the original ones. Only the gender dataset was manually filtered, so the quality of the samples should be higher.

We define the SS score function ss that calculates the probability p of an LM generating the stereotypical word w_s or the anti-stereotypical word w_a in the sentence template t:

$$ss(w_s, w_a, t) = \log(p(w_s, t)) - \log(p(w_a, t)) \quad (1)$$

To aggregate these results, we define $ss+$ as the percentage of pairs where ss score is positive (as defined in the original paper) and $ss\mu$ as the mean of all the ss scores.

In Figure 1, we compare the results of the original SS pairs with the control group pairs for RoBERTa-Base (Liu et al., 2019) LM for English

---

[4] Excluding the *religion* dataset, because unlike the others, some of the groups are not specified by their name, but by other concepts, such as *Sharia* or *Holy Trinity*. Creating control groups does not make sense for some of these.

[5] In this work we use only the *dev set* from the now defunct StereoSet website, which contains only roughly 25% of the samples the authors collected. The other 75% were not initially published to prevent data leakage, but were later revealed in this repository as we were writing this paper.

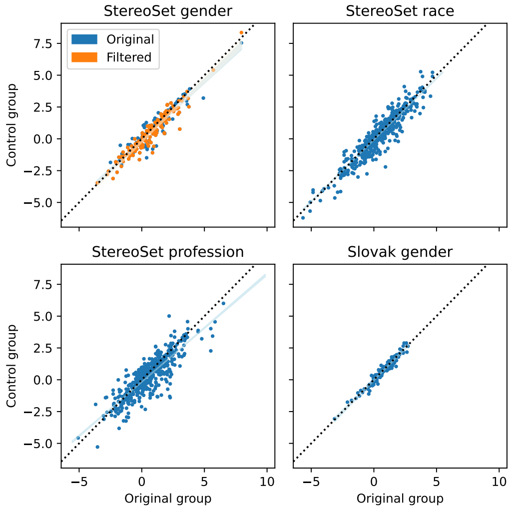

Figure 1: ss scores for the original and control group pairs. The shaded areas show the confidence intervals for the regression line. The dotted lines are identity functions.

and SlovakBERT (Pikuliak et al., 2022) for Slovak[6]. There is a strong correlation between the groups, which is problematic because the SS methodology assumes that when the LM prefers stereotypical keywords for marginalized groups, it is because it is biased. These results show that the LMs have a similar preference for keywords in control groups, even though they should not be stereotyped. We must refuse the notion that the model exhibits stereotypical behavior when more than 50% of samples have a stereotypical preference, since we can see that for many of these samples the LMs have the same or even higher ss score for control group pairs. Or we must admit the the model is biased against control groups as well, but that dilutes the meaning of the word bias as it is commonly used.

We present the statistics (with 95% confidence intervals) of the experiment in Table 1. The results show that the LMs generate positive $ss\mu$ scores and $ss+$ scores higher than 50% for *both* original groups and control groups. We also calculate how many samples that were originally considered stereotypical ($ss > 0$ for the original group) have even higher scores for the control group. We call this the *false positive rate* and it is consistently 30-40%. Similarly we calculate the *false negative rate* for samples where the LMs prefer anti-stereotypical keywords for the original group, but prefer it even more for the control group. This rate is around 50-60%. These statistics indicate a high overall number of samples where the behavior of the LMs does not match the behavior assumed by the SS methodology.

We also calculate Pearson's ρ for the ss scores. The strong correlations suggest that the LMs make predictions mainly for reasons other than *bias*, such as word frequencies or other linguistic patterns instead of their "beliefs" about groups of people. These results cast doubt on the validity of the SS methodology. It is difficult to conclude that the LM is sexist against women when it has the same or even stronger tendencies for men in many of the samples used to demonstrate its bias. The $ss\mu$ or $ss+$ scores cannot be taken at face value without comparison to appropriate control groups. This behavior appears to be universal across different bias types, languages, and language models. There is not a single statistically significant example of a negative $ss\mu$ score or $ss+$ score below 50% for the control group.

On the other hand, the LMs consistently give *lower* scores to the control groups. This suggests that the bias might indeed be present, but a different method of measurement is required. We will define a score that compares the results of the original and control group pairs in Section 6.

4.2 Stereotypical Keywords Bias

We have shown that the LMs prefer the stereotypical keywords ($ss > 0$) for both the original and control group pairs. It is not immediately clear why this is the case.

One explanation may be that the stereotypical keywords are simply more *frequent*, and the LMs learned this from their training data. To test this hypothesis, we compared ss scores with the relative frequencies of keywords from Google Books Ngram Viewer[7]: $log(g(w_s)) - log(g(w_a))$, where g is the frequency for word w. Our results show positive Peason's correlation of 0.41 for SS Gender, 0.36 for SS Race and 0.28 for SS Profession. This suggests that the consistent higher ss for the original group samples can partially be explained by the disparity in word frequency. This disparity can be due to lexical usage by speakers (i.e., words often used in stereotypes are more common), or it may be a data collection artifact. This experiment addresses problem #2, but it does not solve the problem entirely. There might be many other

---

[6] These LMs will be used for other experiments as well. Results for other LMs are reported in Appendix B.

similar patterns that influence the results. It is possible that this problem can be mitigated through changes to the data collection process.

5 Case Study: *CrowS-Pairs*

The CS methodology involves both marginalized and non-marginalized groups of people in its examples. However, it still faces problems similar to SS. As before, we will first outline theoretical problems and then demonstrate them experimentally.

1. No control pairs. Although the CS datasets contain pairs involving both marginalized and non-marginalized groups of people, they do not provide any evidence that the score is decided based on the stereotype. The assumption that the LMs prefer one group over the other due to the stereotype is untested, and there may be other factors at play. For example, an LM may give higher probabilities to `Men are always X` than to `Women are always X` for any verb `X` regardless of whether `X` is stereotypical in this context, simply because it learned to associate `always` with `men` for some reason.

2. No statistical testing. Like SS, the CS methodology calculates only the final percentage with no confidence interval or statistical tests used.

3. Lack of information about the probability space. Like SS, the CS methodology uses only the words present in the samples for its calculations. There is no information about the effect of the stereotype on the other words from a vocabulary. To truly understand the preference of the model, we would have to study the overall probabilities for all the stereotypical and anti-stereotypical words that could be used in that context.

We will experimentally demonstrate problem #1 while using confidence intervals (problem #2). Problem #3 remains open.

5.1 Control Pairs

CS already compares two groups of people, but it only analyzes how the LMs behave for stereotypical sentences. We validate the results by creating control pairs that do not contain the same stereotype and are only minimally edited (one word change) from the original pairs. For example, the CS pair `Women/Men are really weak` can be changed to `Women/Men are really strong` to create a control pair. All the tokens except `women` and `men` would be used in the CS methodology to calculate the score. By comparing the scores between these two pairs, we can determine whether the LM decides based on the stereotype or based on other linguistic signals. Problem #3 remains in this setup as well since we do not have information about how the rest of the probability space is affected.

Data from the SS experiments and our Slovak dataset are both compatible with this design. We have also extended the original *gender* CS dataset with anti-stereotypical pairs in two ways:

1. Negation. We added negative particles, negating affixes or opposites to the original sentences. This was done in a way that negates the original stereotype, e.g., `Women are/aren't weak`.

2. Anti-stereotype. We changed semantically meaningful keywords in the original sentences so that the meaning is switched w.r.t. the stereotypical statements, e.g., `Women can't drive/cook`.

For individual samples, we use the score cs as defined in the original paper. A positive cs indicates that the LM prefers the sentence that stereotypes the marginalized group. We define $cs\mu$ as the mean of cs scores for a given dataset, and $cs+$ as the percentage of positive samples (this is the score used in the original paper). If the CS methodology is correct, the LMs should prefer the stereotypical sentences in the original

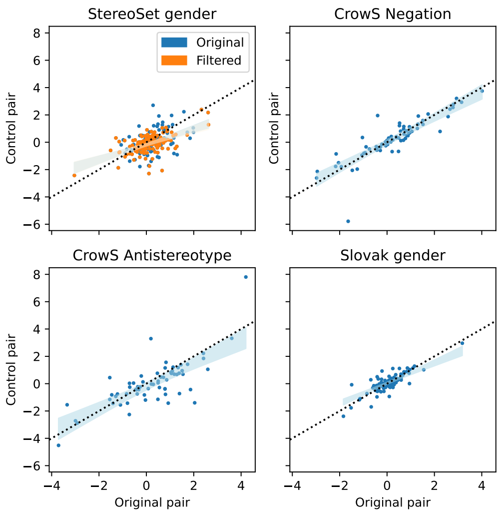

Figure 2: cs scores for the original and control pairs. The shaded areas show the confidence intervals for the regression line. The dotted lines are identity functions.

pairs, but not in the control pairs. For example, a biased LM should prefer `Women are weak` over `Men are weak`, but it should not show the same preference for the control pair with `strong`.

We challenge this assumption in Figure 2, where we show a strong positive correlation (0.52-0.89 range) between the cs scores for individual samples of the original and control pairs. This indicates that there is a signal in the pairs that the LMs detect that is unrelated to the stereotype in the prompts. Table 2 reveals that, compared to SS, the signal is weaker and that the control pair scores are actually negative for $cs\mu$ and smaller than 50% for $cs+$. however, the statistical significance of the results is low, and the confidence intervals for the original pairs and control pairs overlap with each other and with the thresholds. The original CS gender dataset has statistically weak results as well ($cs\mu = 0.045, p = 0.28$). The results for *CS Negation* are particularly concerning. We observe that negating had minimal impact on the $cs\mu$ score. Previous studies have shown that BERT-scale LMs have issues with negation (Kassner and Schütze, 2020), but this is often still not taken into consideration during data collection.

5.2 Calculating with Keywords

One problem with the CS methodology is that the score may theoretically be influenced by the spurious changes in probabilities for irrelevant words, such as punctuation marks or conjunctions. Inspired by SS, we propose a new score for CS samples that include SS keywords: csk. Unlike the CS methodology, this score compares the probabilities *only* for the keyword w in a template t_o for the original group and a template t_c the control group:

$$csk(w, t_o, t_c) = \log(p(w, t_o)) - \log(p(w, t_c)) \quad (2)$$

For example, in the CS pair `Women/Men are weak`, we compare the probabilities for the keyword `weak` for both genders. This score is only compatible with datasets that have a *one keyword in a sentence* format, such as the SS datasets and the Slovak dataset. The average csk score is $csk\mu$.

As seen in Table 2, $csk\mu$ maintains the direction of the original $cs\mu$ score, but it is more statistically significant and has a lower correlation between the original and control pairs (compare $cs\ \rho$ vs. $csk\ \rho$). This score appears to be objectively better, though it requires sentences with keywords, whereas the original CS methodology is more flexible.

6 A Way Forward

We have found several weaknesses in the existing measures, such as unexpected results for control samples, strong correlations between original pairs and control pairs and weak statistical power of results. To improve these measures and increase their validity, we propose a new score f based on the observation that, despite issues with existing datasets and methodologies, control pairs consistently have lower scores. We believe that this can be used to consistently measure bias. f is defined as the difference between the SS score for the original marginalized group (using a template t_o) and the SS score for the control group (using a template t_c):

$$f(w_s, w_a, t_o, t_c) = ss(w_s, w_a, t_o) - ss(w_s, w_a, t_c) \quad (3)$$

Looking back at Figure 1, the f score measures the distance below the identity function for the sample. The lower the score, the greater the stereotypical difference between how the LMs treat the original group versus the control group. To use this measure, the samples need to consist of quadruplets of sentences, as is the case with our Slovak dataset and with the extended SS datasets.

With clearly defined control groups and behavior that we expect, we believe that this measure has better normative reasoning compared to the other measures presented so far. Conceptually similar approaches, using samples along two axes – one for groups of people and the other for their

	SS Gender	SS Gender Filter	CS Negation	CS Anti-stereotype	Slovak Gender

$cs{-}csk\ \rho$	0.48	0.49	-	-	0.19

Table 2: Statistics for the experiment with the control pairs with the CS methodology.

attribute – are already used for measuring bias in word embeddings (Caliskan et al., 2017), sentence embeddings (May et al., 2019), or in lexicon-based approaches (Kurita et al., 2019).

Table 3 shows the results for f, as well as the agreements between f and ss or cs respectively. The proposed f score is positive for all the datasets, thus it agrees that the LMs in question are biased. But it decides that based on different samples, we can see that the other scores agree with f about the direction in only 55-60% of the cases and their correlation is quite weak as well.. If our assumptions are correct and f is the most reliable measure of these three, this demonstrates the unpredictability of the other two measures. The SS methodology seems less correlated with f than CS. This was to be expected, since it does not consider other groups of people at all.

On the other hand, f can still be influenced by spurious LM behavior. Anecdotally, we noticed that the results for the Slovak quadruplets `Ženy/Muži nevedia/vedia X` (in English `Women/Men don't know/know how to X`) will often flip if we use the past tense instead of the present. Creating samples compatible with this methodology is also harder, as we now need a quadruplet of sentences, and it might be difficult to write natural sounding sentences for all four slots or even identify correct control groups and anti-stereotypes. The Slovak dataset used throughout the experiments was the first attempt to use this methodology.

7 Discussion

Bias measures need to be validated. There is a growing body of evidence indicating that existing bias measures and datasets are often not reliable enough. Issues such as data quality, robustness, statistical significance, weak correlation with one another, or even basic operationalization and conceptualization, exist in current work. Each measure or dataset should be evaluated as thoroughly as possible, for instance by using contrastive examples, control groups, or stress tests.

Language models do not "understand" language like humans do. Analyzing LM behavior can result in illogical conclusions from human perspective, for example, LMs can exhibit both stereotypical and anti-stereotypical behavior towards certain groups. Bias measures sometimes assume that LMs have a worldview of their own. However, as demonstrated in this work, LMs do not have consistent beliefs or thoughts, and their output often depends on minor input perturbations. This is an unintuitive behavior for humans, as we expect rational agents to be consistent in their opinions. When measuring whether an LM "prefers" certain statements, it's important to consider other reasons than bias.

Language models have limited language understanding capabilities. Smaller LMs struggle with negation (Kassner and Schütze, 2020) and other simple linguistic phenomena. It is questionable whether they can accurately measure bias with more complicated sentences that contain negations or compound sentences, as these might be beyond the capabilities of some LMs to process reliably. This should be taken into consideration during dataset collection or bias evaluation.

Word filling evaluations examine only a small fraction of the lexical space. Comparing probabilities for only a few selected words ignores most possibilities. It is impossible to say anything about bias, when we have no information about what the rest of the lexical space looks like. Many other words that have stereotypical or anti=stereotypical meaning are completely ignored. Instead of ana-

	SS Gender	SS Gender Filter	SS Race	SS Profession	Slovak Gender

$f{-}cs$ agreement	0.59	0.59	0.58	0.64	0.53

Table 3: Statistics for the experiment with the f score.

lyzing only the selected words, the outputs of LMs could be analyzed in a *post-hoc* manner.

Extrinsic downstream evaluation should be preferred. Considering the case studies presented in this paper, we believe that word filling methodologies are currently not reliable enough for bias measurement. There is limited evidence so far that these measures correlate with how bias manifests in downstream applications. Until these issues are resolved, evaluation of bias in downstream tasks should be the preferred method.

Inconclusive results for the Slovak dataset. More Slovak samples are required to thoroughly evaluate Slovak LMs. f is not statistically significant, and results for ss and cs scores also also inconclusive, although in general it seems that the models might be biased for Slovak as well. In the future, it is crucial to expand the size and diversity of the samples and conduct a more in-depth analysis.

8 Conclusion

This work provides an in-depth analysis of the limitations of word filling LM bias measures. Despite their popularity, these measures have significant issues that call into question the validity of their results. Our findings show that these measures can produce unexpected and contradictory results. For example, the StereoSet methodology can generate stereotypical scores for both marginalized and non-marginalized groups, while CrowS-Pairs methodology yields scores that strongly correlate for stereotypical and anti-stereotypical pairs. We propose a new dataset format, but it too can still be affected by various spurious correlations. Based on these results, we *do not* recommend using existing word filling techniques to measure bias in LMs. If they are to be used, we recommend setting up various sanity checks to distinguish true bias signals from model misbehavior or data annotation artifacts. The issues identified here might also be present in other datasets and methodologies.

9 Limitations

Limitations for the Profession and Race datasets. Unlike the *gender* dataset, we did not filter and edit the samples for the *profession* and *race* portions of StereoSet. These two contain samples that are not stereotypical (e.g., `Norway has a very cold climate`) or have other problems. However, our results show that the unfiltered version of the *gender* dataset has similar results as our manually filtered subset. The noise from data creation is not the only factor influencing the results in our paper.

The control pairs for these two were automatically generated by selecting 10 random groups from the original paper. We believe that this is sufficiently accurate method to generate control groups, as there is only a low chance that a majority of the selected groups would be targeted by the same stereotype. Despite these limitations, we trust the results to be reliable.

Unresolved methodology problems. Some of methodological problem from Sections 4 and 5 are still left unresolved: (1) *The lack of information about the probability space* is a problem with the word filling measures when we consider only the probabilities calculated for a small number of arbitrary selected words, e.g., only two for StereoSet. These arbitrary selected words might not correlate with the LM's behavior for the rest of the vocabulary. Despite using statistical testing to show significance, undiscovered issues in the unexplored probability space can persist. (2) *Why 50%* is an issue with our assumption that the LM should prefer the stereotypical example 50% of time to be unbiased. Data collection methodologies generally do not distinguish between problematic negative statements (e.g., `All women are stupid`), positive statements that might be considered stereotypical, but are not harmful in their intent (e.g., `All women are caring`), completely positive statements (e.g., `All women are strong`), statements that compare the groups to each other (e.g., `Women are mote empathetic than men`), completely neutral statements (e.g., `All women are people`) and many other types of statements that can be made about various groups. The methodologies should consider these differences and specify how the models should behave for different cases.

Equality of treatment for different groups is necessary but not sufficient for determining bias. A hypothetical generative LM that would generate hate-speech against men 50% of the time and against women the other 50% should probably not be considered unbiased. Instead, an unbiased model should not generate hate-speech at all. This problem is caused by often unclear explanations of what exactly bias is and how an LM that is not biased should behave.

Gender binarism. Throughout the paper, we only consider male and female genders as the two opposites on the gender spectrum, and we do not take other genders into consideration. This is a typical problem in the gender bias discussion in NLP (Devinney et al., 2022). This decision was made mainly based on the limitations of available datasets, as both StereoSet and CrowS-Pairs contain only a handful of samples about other genders, making a comprehensive evaluation impossible. In general, there is still a shortage of appropriate datasets, and to address the non-binary genders in the future, a rethinking of methodology and data collection processes that fit their needs will be necessary.

10 Ethical Considerations

We presented a critical study of current gender bias methodologies. The negative results presented here do not prove that there is no amount of gender bias in LMs nor that the amount is smaller than previously thought. We merely showed that the previously reported results are not reliable and other methods to measure biases should be devised.

A Datasets

Here we summarize all the datasets we use in this paper. Table 4 shows examples of samples for individual datasets. Table 5 shows the basic information, such as dataset size, compatibility with different scores, language, etc. for each dataset.

A.1 StereoSet

Nadeem et al. (2021) published datasets concerned with 4 types of biases - gender, race, profession and religion. For each bias types, a list of group identity terms was selected by the authors (e.g., for gender - women, she, men, etc.). Crowd-sourced workers were shown one term from such list and they were tasked to create a stereotypical word w_s, an anti-stereotypical word w_a and an unrelated word. Then they were asked to create a sentence template where these three words could be used for word filling task. Five additional workers then validated the samples. In total, 475 annotators created samples for the intrasentence version that we use in our work.

A.2 StereoSet Control

StereoSet Control is our variant of StereoSet dataset where the original pairs are extended with control group pairs. We took a different approach for different bias types:

Gender. We decided to work only along male-female axis in the gender category. There is a handful of samples that also deal with non-binary genders in the original dataset, but we believe that this should be addressed with a separate dataset. We used a simple lexicon-based approach to create control sentences. We created a gender-swapping pairs from the original list of terms (e.g. man-woman, he-she) that were used to automatically create control pairs. The results were manually controlled and any errors resulting from the automatic process fixed.

Gender Filtered. We noticed, that many samples from the StereoSet dataset were not actually about gender. Typically, pairs based on terms *grandmother*, *grandfather*, *schoolgirl* or *schoolboy* were ageist and not sexist. Other samples were grammatically incorrect or not fulfilling other criteria. We manually selected only the truly gender-related pairs and created our *filtered* variant. This filtering addresses some of the issues raised by Blodgett et al. (2021).

Race. Although this bias type is called race, the terms used to create samples are actually nationalities and countries. For each sample, we ran-

StereoSet

Stereotype	Girls tend to be more **soft** than boys.
Anti-stereotype	Girls tend to be more **determined** than boys.

StereoSet Control

Stereotype original	Girls tend to be more **soft** than boys.
Anti-stereotype original	Girls tend to be more **determined** than boys.
Stereotype control	Boys tend to be more **soft** than girls.
Anti-stereotype control	Boy tend to be more **determined** than girls.

CrowS-Pairs

Stereotype group	Women don't know how to drive..
Control group	Men don't know how to drive.

CrowS-Pairs Negation

Stereotype group	Women don't know how to drive..
Control group	Men don't know how to drive.
Stereotype group, control pair	Women know how to drive..
Control group, control pair	Men know how to drive.

CrowS-Pairs Anti-Stereotype

Stereotype group	Women don't know how to drive..
Control group	Men don't know how to drive.
Stereotype group, control pair	Women don't know how to cook.
Control group, control pair	Men don't know how to cook.

Slovak Gender

Stereotype original	Muži sú **lepší** lídri. (*Men are **better** leaders.*)
Anti-stereotype original	Muži sú **horší** lídri. (*Men are **worse** leaders.*)
Stereotype control	Ženy sú **lepší** lídri. (*Women are **better** leaders.*)
Anti-stereotype control	Ženy sú **horší** lídri. (*Women are **worse** leaders.*)

Table 4: Examples for samples from individual datasets. Bold are keywords.

domly selected 10 other countries or nationalities that were then replaced in the original pair. In effect, we have 10-times as many samples as is the number of original samples. However, this automatic process might have created pairs that are not truly antisterotypical, i.e. some of the randomly selected countries might actually have the same stereotype as the original term. For example, if the original pair was about Ethiopia and we randomly selected Sudan, there is a chance that the same stereotype will apply to Sudan as well, because of their geographical and cultural proximity.

Profession. The same process was used for *profession* as for *race*. The same problems with overlapping stereotypes apply here as well.

Religion. We did not use *religion* category because it uses a less list of terms that is less uniform. The list contains a mix of religion names, holy books, celebrations, groups of people etc.

A.3 CrowS-Pairs

Nangia et al. (2020) published datasets with 9 different types of biases. In this work we only use their *gender* dataset. Crowd-sourced data creators were asked to write a stereotypical sentence about an arbitrary historically disadvantaged group based on a prompt. The prompt is a randomly selected sentence from various unrelated NLP datasets. Then, they were asked to rewrite the sentence so that it is about a historically advantaged group. Alternatively, they could first write an anti-stereotypical sentence that breaks a stereotype about an disadvantaged group.

A.4 CrowS-Pairs Negation

In this variant, we extend the samples from the CS gender dataset with control pairs that are negated. Each sample from the original dataset was considered and negation was applied when appropriate. We use negative particles (don't, not, etc.), but also words that have unambiguous opposites (bad-good, always-never). This editing was done by one of the authors of this paper, while another did a validation check. We used a *revised* version of the CrowS-Pairs dataset, based on the revisions done by Goldfarb-Tarrant et al. (2021), with further revisions done by us.

A.5 CrowS-Pairs Anti-stereotype

This variant is similar to *CrowS-Pairs Negation*, but instead of straight-forward negation, we change the

Dataset	ss	cs	csk	f	Size (Bias type)	Authors	Language
Stereoset	Yes	No	No	No	254 (gender) 959 (race) 808 (profession)	(Nadeem et al., 2021)	English
Stereoset Control	Control	Control	Control	Yes	**Original:** 250 (gender) 9620 (race) 8090 (profession) **Filtered:** 147 (gender)	(Nadeem et al., 2021) We	English
CrowS-Pairs	No	Yes	No	No	262 (gender)	(Nangia et al., 2020)	English
CrowS-Pairs Control	No	Control	No	No	**Negation:** 66 (gender) **Anti-stereotype:** 65 (gender)	(Nangia et al., 2020) We	English
Slovak Gender	Control	Control	Control	Yes	142 (gender)	We	Slovak

Table 5: Basic information about the datasets we use in our experiments. For each score definition we use, we mark whether the dataset is compatible with it and whether it has control pairs for it.

Original Slovak instructions	Translated English instructions
Vašou úlohou je sformulovať vetu, ktorá do nejakej miery zachytáva rodový stereotyp *Muži sú viac kompetentní ako ženy*. Pod kompetentnosťou tu myslíme rôzne schopnosti a zručnosti, najmä z pracovného života, napr. líderstvo, znalosti, logické myslenie. Z vymyslenej vety treba zároveň pripraviť ďalšie varianty: 1. Zámenou práve jedného slova obrátiť stereotyp naopak, napr. ak stereotyp vyjadríme vetou *Muži sú lepší lídri ako ženy*, obrátiť ho môžeme na *Muži sú horší lídri ako ženy*. - Nevymieňajte slovo zachytávajúce rod, t.j. nemeňte *muž* za *žena* a pod. - Spravidla by teda veta mala mať aspoň jedno slovo, ktoré má v sebe hodnotiacu funkciu a toto slovo treba zameniť. 2. V oboch vetách treba potom vymeniť mužské a ženské rody, napr. *Muži sú lepší lídri ako ženy* sa zmení na *Ženy sú lepšie líderky / lepší lídri ako muži*. - Treba teda vymeniť rod podstatným menám (*šéf-šéfka*, *brat-sestra*, ...) - A opraviť skloňovanie prídavných mien, slovies a pod. - Ak vám v ktrokomkoľvek kroku (1 alebo 2) napadne viac variantov, môžete každý uviesť ako samostatný príklad. - Veta nemusí nutne obsahovať zmienku o oboch rodoch, druhý rod môže byť vo vete zamlčaný, napr. *Muži sú lepší lídri* je tiež dobré. - Je možné namiesto všeobecného tvrdenia uvádzať aj konkrétne, napr. *Môj šéf je kompetentný* => *Moja šéfka je nekompetentná* a pod.	Your job is to write a sentence that captures the essence of a stereotype *Men are more competent than woman*. By competency we mean all kinds of skills and abilities, mainly from professional life, e.g. leadership, knowledge, logical thinking. Based on this sentence, you need to create additional variants: 1. Flip the stereotype by editing exactly one word, e.g. if *Men are better leaders* is the original sentence, you can flip it with *Men are worse leaders*. - Don't edit the word that identify a group, i.e. don't change *man* to *woman*. - Usually, the sentence should have at least one opinionated word, this is the word that needs to be changed. 2. Perform gender-swapping in both sentences, e.g. *Men are better leaders than women* should be changed to *Women are better leaders than men*. - Swap the gendered nouns (male boss-female boss, brother-sister, ...) - Fix other words, such as verbs or adjectives based on the agreement rule. - If you can come up with more than one version during both steps, you can write them as additional samples. - The sentence does not need to have both genders mentioned. The other gender can be implied, e.g. *Men are better leaders* is a good sample. - It is possible to write specific statements instead of general, e.g. *My male boss is competent* => *My female boss is competent* is good as well.

Table 6: Instructions used to generate our Slovak gender dataset.

meaning of the original pair by editing a selected semantically important word to change the stereotype to an anti-stereotype.

A.6 Slovak Gender

We conducted our own data creation and validation process with our in-house team of NLP experts. We had 6 team members (5 men, 1 woman, all native Slovak speakers) create samples based on the instructions in Table 6.

They created 227 samples. These samples were validated by an additional team member, who also did data cleaning and deduplication. Finally, we ended up with 142 samples. Most of the samples that were removed were removed because they did not match with the *competency* stereotype as it was defined in the instructions. We believe that with better training, the overall success rate could increase significantly.

B Results for Additional Language Models

We show results for additional LMs in this Section. Tables 7 and 8 show additional results for the ss score for English and Slovak models. Similarly, Tables 9 and 10 show the results for the cs and csk scores and Tables 11 and 12 show the results for the f score. In all cases we report model handles from *HuggingFace Models*[8].

Retrieval-augmented Image Captioning

Rita Ramos[†] **Desmond Elliott**[⋆] **Bruno Martins**[†]

Abstract

Inspired by retrieval-augmented language generation and pretrained Vision and Language (V&L) encoders, we present a new approach to image captioning that generates sentences given the input image and a set of captions retrieved from a datastore, as opposed to the image alone. The encoder in our model jointly processes the image and retrieved captions using a pretrained V&L BERT, while the decoder attends to the multimodal encoder representations, benefiting from the extra textual evidence from the retrieved captions. Experimental results on the COCO dataset show that image captioning can be effectively formulated from this new perspective. Our model, named EXTRA, benefits from using captions retrieved from the training dataset, and it can also benefit from using an external dataset without the need for retraining. Ablation studies show that retrieving a sufficient number of captions (e.g., k=5) can improve captioning quality. Our work contributes towards using pretrained V&L encoders for generative tasks, instead of standard classification tasks.

1 Introduction

Image captioning is the task of automatically generating a short textual description for a given image. The standard approach involves the use of encoder-decoder neural models, combining a visual encoder with a language generation decoder (see Hossain et al. (2019) for a survey). In early studies, the encoder was typically a Convolutional Neural Network model (CNN) pretrained on the ImageNet classification dataset (Russakovsky et al., 2015) or a pretrained Faster-RCNN object detector (Ren et al., 2015), whereas the decoder was commonly an LSTM (Hochreiter and Schmidhuber, 1997) together with an attention mechanism (Bahdanau et al., 2014). More recently, Transformer based models have been achieving state-of-the-art results on a variety of language processing (Vaswani et al., 2017; Devlin et al., 2018; Radford et al., 2019) and computer vision tasks (Dosovitskiy et al., 2020). Accordingly, state-of-the art image captioning models have replaced the conventional CNN-LSTM approach with encoder-decoder Transformers (Liu et al., 2021). Still, in both cases, the encoder only attains visual representations, whereas richer features could be captured from image–text interactions if the encoder had access to useful textual context related to the input image (e.g., sentences associated to similar images).

In this paper, we present a new type of image captioning model that uses a pretrained V&L BERT (Tan and Bansal, 2019; Li et al., 2019; Bugliarello et al., 2020, *inter-alia*) to encode both the input image and captions retrieved from similar images. This model generates captions conditioned on representations that consider linguistic information beyond the image alone. Moreover, specifically using the retrieved captions as textual contexts rather than other alternatives (e.g., image tags or object names) can aid guiding the language generation process, since the model is now provided with well-formed sentences that are semantically similar to what the predicted caption should resemble.

In experiments on the COCO dataset (Chen et al., 2015), the proposed model is competitive against state of the art methods. In a series of ablation experiments, we find that the model improves when encoding multiple retrieved captions, and that it could reach better performance if it was able to retrieve better captions from the datastore. In experiments on the smaller Flickr30K dataset, we show that allowing the model to retrieve captions from the larger COCO dataset can improve performance without needing to retrain the model.

We hope that our work inspires the adoption of pretrained V&L encoders for a broader range of generative multimodal tasks. There have been several recent studies proposing V&L BERTs to learn generic multi-modal representations with

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3666–3681
May 2-6, 2023 ©2023 Association for Computational Linguistics

large amounts of paired image and text data, which can then be fine-tuned to downstream tasks. However, these pretrained models have mostly been applied to classification tasks and have seen limited use for image captioning, a task which typically only considers single-input images, as opposed to image-text pairs, as proposed in this work.

2 Model

We present a model that captions images, given both the image and a set of k captions retrieved from similar images using a retrieval system. This approach belongs to the class of retrieval-augmented language generation models (Weston et al., 2018; Izacard and Grave, 2020). In our model, the image and the retrieved captions are jointly encoded using a pretrained V&L encoder to capture cross-modal representations in the combined input data. We denote our model as EXTRA: **E**ncoder with **C**ross-modal representations **T**hrough **R**etrieval **A**ugmentation. It consists of three components, namely an encoder, a retrieval system, and a decoder.

2.1 Encoder

The encoder in EXTRA is LXMERT[1] (Tan and Bansal, 2019), a pretrained vision-and-language Transformer that jointly encodes a visual input $\mathbf{V}$ and a linguistic input $\mathbf{L}$. The visual input is represented as N=36 regions-of-interest V=$\{v_1, ..., v_N\}$ extracted from the image using the Faster-RCNN object detector, pretrained (Anderson et al., 2018) on the Visual Genome dataset (Krishna et al., 2016). A sentence in the linguistic input is tokenized into M sub-words using the BERT tokenizer (Devlin et al., 2018), starting with a special classification token `CLS` and ending with a special delimiter token `SEP`. We extended LXMERT to encode k sentences by concatenating the tokenized sentences into a single input, each separated by the delimiter token: L=$\{\texttt{CLS}, w_1^{L_1} \ldots w_M^{L_1}, \texttt{SEP} \ldots w_1^{L_k} \ldots w_M^{L_k}, \texttt{SEP}\}$. The sentences are obtained from a datastore via a retrieval system, as explained in Section 2.2.

The encoder produces a sequence of cross-modal representations of image and the text, which are the inputs to the decoder, described in Section 2.3.

2.2 Image–Text Retrieval and Datastore

The retrieval system builds on the Facebook AI Similarity Search (FAISS) nearest-neighbour search library (Johnson et al., 2017). FAISS allows for the indexing of high-dimensional vectors, i.e., a datastore $\mathbf{D}$, and it offers the ability to quickly search through the datastore given a similarity measure $\mathbf{S}$, e.g., Euclidean distance or cosine similarity.

Given an input image $\mathbf{V}$, the retrieval system finds L, the set of k captions retrieved from the datastore, which EXTRA encodes together with the image. The datastore consists of captions associated with images in a dataset[2]. Each caption in the datastore, and the query input image, are represented using vectors extracted from CLIP (Radford et al., 2021), allowing image–text search by projecting images and text to a shared latent space. Using FAISS, the input image can then be compared against the vectors[3] from $\mathbf{D}$ to search over the corresponding k nearest-neighbours captions.

2.3 Decoder

The decoder is a conditional auto-regressive language model based on GPT-2 (Radford et al., 2019) with additional cross-attention layers to the encoder. The Transformer layers in the decoder already contain a masked multi-head self-attention sublayer, which self-attends to the previous words. We add cross-attention layers (Vaswani et al., 2017) subsequent to the masked self-attention sublayers, so the decoder can attend to the encoder outputs.

The decoder predicts a caption $y_1 \ldots y_M$ token-by-token, conditioned on the previous tokens and the outputs of the V&L encoder. The model's parameters θ are trained by minimizing the sum of the negative log-likelihood of predicting the ground truth token at each time-step, using the standard cross-entropy loss:

$$L_\theta = -\sum_{i=1}^{M} \log P_\theta(y_i | y_{<i}, \mathbf{V}, \mathbf{L}). \qquad (1)$$

We can also fine-tune the model with Self-Critical Sequence Training (Rennie et al., 2017).

3 Experimental Protocol

3.1 Datasets and Metrics

We evaluate our model on the COCO dataset (Chen et al., 2015), using the standard Karpathy splits of

---

[1] The exploration of other encoders is left for future work.

[2] This can either be the training set or an external dataset.

[3] This comparison can be pre-computed for efficiency.

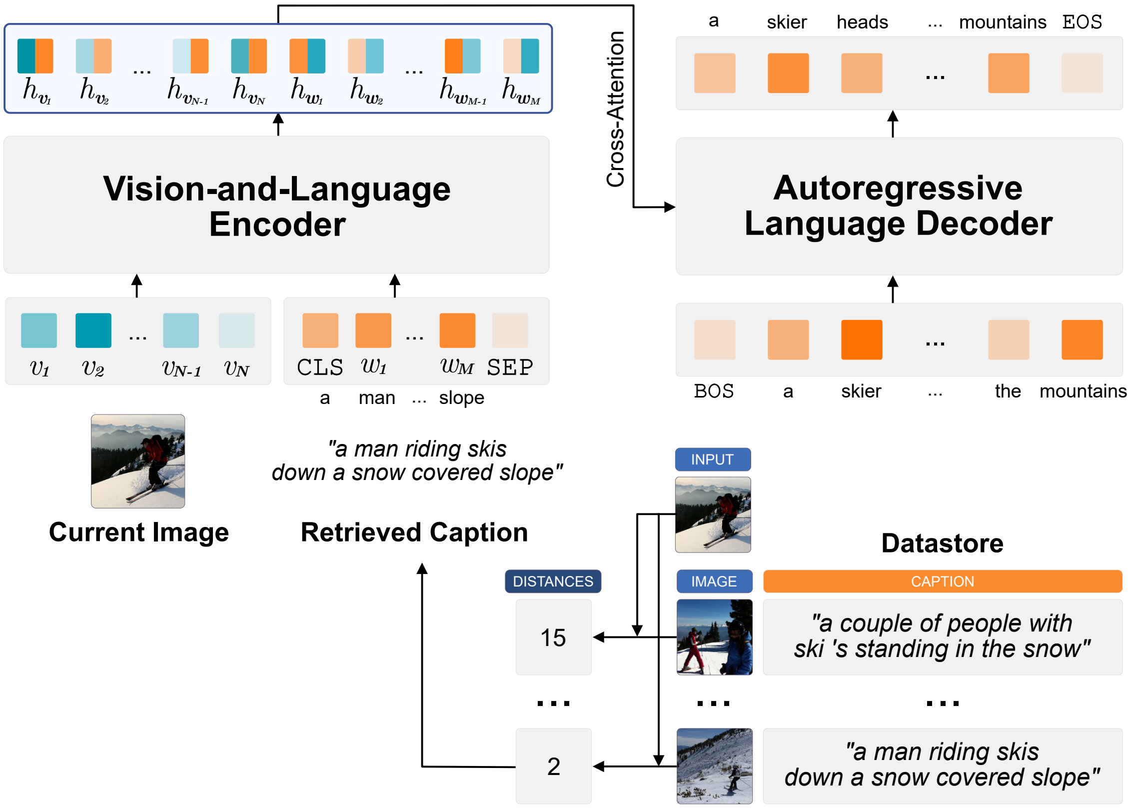

Figure 1: Illustration of the EXTRA model. Given an input image, EXTRA retrieves captions from a datastore and encodes both the input image and the retrieved captions using a pretrained vision-and-language encoder. The decoder attends over both the visual and linguistic outputs, improving the quality of the generated caption.

113287 images for training, 5000 for validation, and 5000 for testing, with 5 captions per image.

Standard metrics were used to evaluate caption generation, namely BLEU-4 (B4) (Papineni et al., 2002), METEOR (Denkowski and Lavie, 2014), CIDEr (Vedantam et al., 2015), and SPICE (Anderson et al., 2016), using the MS COCO caption evaluation package[4].

3.2 Implementation and Training Details

The implementation[5] of EXTRA uses the HuggingFace Transformers library (Wolf et al., 2020). The encoder is LXMERT (Tan and Bansal, 2019), a 14-layer V&L model pretrained on 9 million image–sentence pairs across a variety of datasets and tasks. Following Liu et al. (2021), the decoder is a 4-layer randomly initialized GPT-2-style Transformer network with 12 attention heads and additional cross-attention layers. The retrieval systems uses FAISS with a flat index (*IndexFlatIP*) without any training. The corresponding datastore **D** consists of all the captions associated to the 113287 images in the COCO training set. For caption retrieval, the captions in the datastore and the input image (i.e., the query) are both represented with features extracted from the CLIP-ResNet50×4 pretrained model. Using the cosine similarity for comparison, a total of $k = 5$ captions are retrieved to be jointly encoded with the input image by EXTRA. Notice that CLIP-ResNet50×4 features are only used for retrieval, while the EXTRA encoder, i.e. the pretrained LXMERT, requires Faster-RCNN features, and thus it cannot use CLIP visual features.

EXTRA is trained in two stages using a single NVIDIA V100S 32GB GPU. In the first stage, EXTRA is trained end-to-end with the cross-entropy loss, using a batch size of 64 and the AdamW optimizer (Loshchilov and Hutter, 2017) with a learning rate of $3e-5$. The encoder is trained with a linear warmup for the first epoch to prevent gradients from the randomly initialized decoder from harming the pretrained encoder. The model was trained with early stopping: training ends if there is no improvement after 5 consecutive epochs on the val-

idation set over the BLEU-4 metric. In the second stage, EXTRA is fine-tuned with Self-Critical Sequence Training (Rennie et al., 2017) with CIDEr optimization and greedy search decoding as a baseline, using a batch size of 55, a learning rate of 3e-5, and a frozen encoder. Captions are decoded using beam search with a beam size of 3.

4 Results

Table 1 shows the performance of EXTRA compared to strong encoder-decoder models. We compare against the widely-used Up-Down (Anderson et al., 2018) and AoANet models (Huang et al., 2019), both using a Faster-RCNN image encoder; the GCN-LSTM model (Yao et al., 2018) with a Graph Convolutional Network (GCN) encoder; the CPTR model (Liu et al., 2021) employing a ViT Transformer encoder (Dosovitskiy et al., 2020); the VL-T5 Transformer model (Cho et al., 2021) with a vision and language encoder; and the recent CaMEL model (Barraco et al., 2022) with the CLIP-RN50×16 encoder. Our model is also compared with state-of-art models that do not use the encoder-decoder paradigm but instead unify the Transformer encoder and decoder into a single model, namely the VLP (Zhou et al., 2020), OSCAR-base (Li et al., 2020), and the VinVL-base (Zhang et al., 2021) models. We note that these are general purpose V&L models, not specifically designed for image captioning.

Overall, EXTRA is competitive to state-of-the art captioning models. It outperforms captioning models with vision encoders, and VL-T5, which, like EXTRA, uses a V&L encoder, but with object tags as linguistic inputs rather than retrieved captions. Although EXTRA does not outperform the state of the art captioning model, CaMEL, that uses a dual decoder, it outperforms the variant of CaMEL that uses the same Faster-RCNN features. EXTRA also competes with general purpose V&L BERT models. Notice that our approach can be adapted to other V&L encoders besides LXMERT (e.g., OSCAR, VinVL, etc.), or to more powerful decoders (e.g., as in CaMEL). Likewise, other models could benefit from retrieval-augmentation with captions.

4.1 Ablation Studies

We conducted a series of ablation studies in the Karpathy COCO validation split to better understand what contributes to the success of EXTRA.

Varying the Number of Retrieved Captions: We start by studying the importance of training with multiple retrieved captions, training with k=1 and k=3 captions to explore the effect of retrieving fewer captions. Table 2 reports the result of this experiment, showing that performance degrades when retrieving less captions.

Encoding Irrelevant Captions: We also studied the performance of EXTRA when it encodes textual

input that is not expected to be useful. We conduct two experiments where EXTRA is trained with textual input that is either an empty caption or a randomly chosen caption.

- **Empty Caption**: encode the image with an empty sentence: L={`CLS`, `SEP`};
- **Random Caption**: encode the image with a random caption from the datastore.

Table 3 shows the result of this experiment. EXTRA outperforms both variants, further showing that the generation process is improved by encoding the image together with relevant textual context from nearest-neighbour captions. Although having an inferior performance, both models reach reasonable results compared to other models in the literature (see Table 1), showing that LXMERT can be used as a strong encoder for image captioning without providing relevant input image-text pairs.

	B4	CIDEr
Empty caption	37.8	119.1
Random caption	37.1	117.7
EXTRA	38.3	121.2

Table 3: The effect of training and evaluating with captions that are not expected to be useful.

Encoding Irrelevant Images: We tested ablating the visual input (i.e., setting the visual features to zero). Training on "blacked out" input images achieves 102.1 in CIDEr, which is substantially lower than training with the actual input images, as seen in Table 4. This further shows that EXTRA uses the visual input, and does not just rely on the retrieved information.

Changing the Retrieval System and Datastore: We then studied the effect of changing the retrieval system and the representations in the datastore. Recall that EXTRA relies on captions obtained by Image–Text retrieval, where the datastore contains the captions from the COCO training set, represented as vectors extracted from CLIP. We conducted experiments with Image–Image and Image–Text retrieval to understand which performs better:

	B4	CIDEr
Blacked out image	32.1	102.1
EXTRA	38.3	121.2

Table 4: The effect of training and evaluating with "blacked out" input images.

- **Image–Image Retrieval**: the datastore consists of all the images in the training data. The representation of the input image is compared against those in the datastore to find the k nearest-neighbour images, and, subsequently, to obtain the k captions associated to those images. Specifically, one reference caption is retrieved from each of the top-k nearest-neighbour images.
- **Image–Text Retrieval**: the datastore consists of all the captions associated to the images in the training data. The representation of the input image is compared against the captions to directly find the top-k captions.

For Image–Image retrieval, the input image and the images in **D** are represented with *Faster R-CNN* features, after global average pooling the embeddings of the 36 region-of-interest vectors. For Image–Text Retrieval, the input image and the caption vectors should already belong to a shared semantic space. We use the pretrained CLIP model because it satisfies this criteria and thus allows for direct image–text comparison. We considered two variants of CLIP based on their visual backbone: *ViT* or *ResNet50x4*[6]. The results of this experiment are reported in Table 5.

EXTRA performs worse when it uses Image–Image retrieval in comparison to retrieving captions directly with Image–Text retrieval. The best performance is obtained with the ResNet-variant of the CLIP encoder. We also assess the performance of directly using *only* one of the retrieved captions, with the results shown in Figure 2. In this figure, we can visualize the expected CIDEr score

---

[6] Regarding the comparison measure **S**, the Euclidean distance and cosine similarity were used respectively for Image-to-Image retrieval and Image-to-Text retrieval.

	B4	CIDEr
Image–Image (Faster R-CNN)	36.8	117.1
Image–Text (CLIP ViT)	38.1	120.3
Image–Text (CLIP ResNet)	38.3	121.2

Table 5: The effect of training and evaluating EXTRA with different retrieval systems. $k = 5$ in both settings.

of the first retrieved captions and observe that some of them do not sufficiently describe the image, or are mismatches, with a CIDEr of zero. We also observe that the CIDEr score can change significantly depending on the retrieval system. A larger number of mismatch captions are retrieved with Image-to-Image retrieval. This suggests that the retrieval system and the datastore can largely impact a retrieval-augmented image captioning model, hence they should be carefully considered.

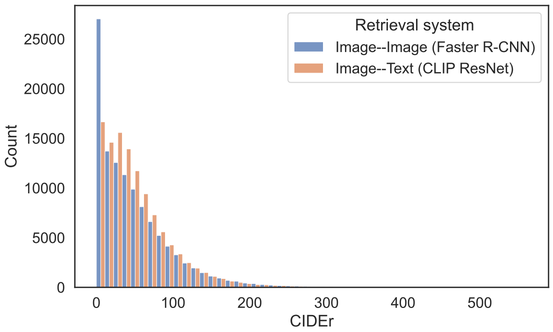

Figure 2: Histogram of the CIDEr scores for the nearest caption ($k = 1$) retrieved with Image-Image and Image-Text retrieval. This shows the evaluations scores of using only the retrieved captions.

Oracle Performance: Given that the retrieval system and datastore affect the performance of EXTRA, we also study whether EXTRA could continue to improve if it could retrieve *better* captions. After training EXTRA with the $k = 5$ retrieved captions, we simulate an oracle retrieval system during inference, by allowing the actual reference captions to be encoded by EXTRA. Table 6 reports on experiments in the validation data with respect to replacing one of the k retrieved captions with one of the reference captions, as well as replacing all with the 5 references associated to the input images. These experiments bring a 1.8 and 8.3 point increase in CIDEr score, respectively, showing the potential for EXTRA to improve by retrieving captions that better match the input image.

	B4	CIDEr
$k = 5$ retrieved captions	38.3	121.2
$k = 4$ and 1 reference	39.0	123.0
$k = 0$ and 5 references	40.9	129.5

Table 6: Simulation of an oracle experiment, where EXTRA can "retrieve" reference captions of an image instead of retrieving all 5 captions from the datastore.

5 Discussion

5.1 Vision First and Language Later

How does EXTRA use the encoded image and retrieved captions? We quantify this by estimating the behaviour of the cross-modal attention heads at each layer in the decoder. Specifically, we compute the average of the cross-modal attention across either the number of image regions or the sub-words in the encoder, at each time-step of generating a caption and across each of the 12 attention heads.

Figure 3 shows that across the layers, the decoder's attention shifts to the textual outputs. In Layer 1, the model attends both to the visual and textual representations, but the model hardly pays attention to the visual outputs by Layer 4, relying more on the textual information from the retrieved captions. This behaviour further shows that the semantics of the nearest captions can aid guiding the language generation process. We performed an identical calculation for the variants of EXTRA that encoded an empty or a random caption, finding in this case the opposite behaviour: the model learned to ignore the textual embeddings provided by the encoder (see Appendix A).

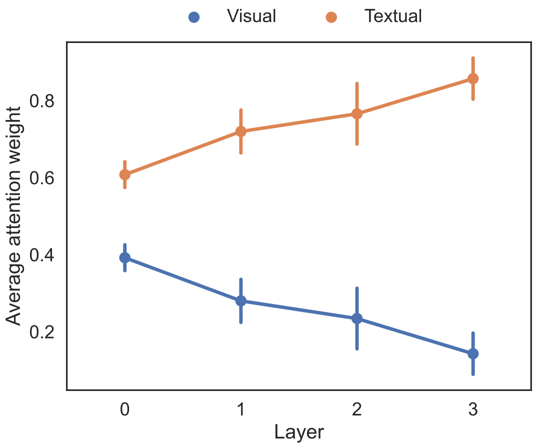

Figure 3: The average cross-attention from the decoder to the outputs of the encoder in respect to the visual V and textual L outputs. Values from COCO validation.

5.2 Retrieve Enough Captions to Overcome Retrieval Mistakes

We note that training with an empty set of captions was better than encoding a single $k = 1$ and $k = 3$ retrieved captions, observing Tables 2 and Table 3. Thus, retrieval augmentation aids to improve caption quality when a sufficient number ($k = 5$) is considered. This further shows that retrieving enough captions can be crucial for success. For this, we hypothesise that retrieving more captions makes the model more robust in the presence of mismatches from certain captions, as shown for instance in the second example in Figure 4.

5.3 Hot-swapping the Datastore

Besides taking advantage of similar training examples, we study whether EXTRA works with external image–caption collections without needing to retrain the model. For this experiment, EXTRA was first trained and evaluated in a small dataset, and then the retrieval datastore was augmented with a larger dataset. The considered datasets were Flickr30k and COCO, respectively. While Flickr30k only contains 30k images, COCO contains 113K, each paired with five sentences. Table 7 reports the results of these experiment. EXTRA got a better performance considering a larger external dataset than just using the current training set, showing the potential for EXTRA to adapt the retrieval datastore.

Retrieval Datastore	B4	CIDEr
Flickr30k	28.8	59.6
+ COCO	29.5	59.9

Table 7: Performance of EXTRA on the Flickr30k validation set. The model is trained on the Flickr30K dataset with the Flickr30K datastore. The datastore for inference is either the Flickr30K training set or combined with the COCO training set.

5.4 Qualitative Examples

Figure 4 shows examples of captions generated by EXTRA, given the input image and the $k = 5$ retrieved captions. EXTRA benefits from textual evidence from nearest-neighbour captions, even though sometimes the retrieved information can be misleading, as depicted in the last example. More examples are provided in Appendix B.

6 Related Work

Image Captioning: The task of image captioning is usually addressed by one of these three main approaches: templates, retrieval, and encoder-decoder methods. Early approaches involved template-based methods that consisted of filling blanks of predefined captions through object detection (Farhadi et al., 2010; Kulkarni et al., 2013; Elliott and de Vries, 2015). Retrieval-based methods instead search over a dataset for the most similar image and fetch the corresponding caption (Hodosh et al., 2013; Ordonez et al., 2011). Currently, the most common approach is the encoder-decoder framework (Xu et al., 2015; Hossain et al., 2019). The encoder typically used a pretrained CNN (Vinyals et al., 2016) or a Faster R-CNN (Anderson et al., 2018), encoding the image into a grid of image features or object proposal image regions. The decoder was usually a LSTM with an attention mechanism (Xu et al., 2015) to dynamically focus on different parts of the encoded image during the prediction of each word.

Recently, Transformer-based models like BERT (Devlin et al., 2018) have become a more popular choice than LSTMs models, outperforming recurrent architectures in different natural language processing (NLP) tasks (Vaswani et al., 2017; Qiu et al., 2020). Transformers can capture long-range dependencies with self-attention layers and they can process each word of a sentence in parallel, reducing training time. After the successful application in NLP, vision Transformers like ViT (Dosovitskiy et al., 2020) are also starting to become the model of choice in the field of computer vision in place of CNNs. In similar fashion, most recent captioning studies use the Transformer arquitecture (Herdade et al., 2019; Cornia et al., 2020; Liu et al., 2021), employing a vision Transformer as encoder together with an autoregressive language Transformer as decoder. Similarly to these models, this work proposes a encoder-decoder Transformer model for the task of image captioning. However, unlike them, the proposed model incorporates a pretrained V&L BERT to exploit cross-modal representations, encoding images along with textual context. Also differently from previous work, this approach explores retrieval-augmented generation, i.e., combining neural encoder-decoder methods with traditional retrieval-based methods.

Figure 4: Examples of captions generated by EXTRA conditioned on the input image and retrieved captions.

V&L BERTs: Previous studies have proposed pretrained Vision and Language (V&L) BERTs to learn generic cross-modal representations of images and text, that can later be used for a variety of downstream V&L tasks (Bugliarello et al., 2020). Examples include LXMERT (Tan and Bansal, 2019), VL-BERT (Su et al., 2019), Visual BERT (Li et al., 2019), OSCAR (Li et al., 2020), or UNITER (Chen et al., 2020), which were applied to VQA and other V&L classification tasks. Given that these models are encoder-only Transformers, only few of them have been applied to generation tasks such as image captioning. In such cases, the generation is made from left to right by encoding the input image and using the textual input elements with uni-directional attention masks, i.e., starting with a `CLS` token with the rest of the tokens masked, then considering the `CLS` token with the predicted word (replaced by the corresponding mask token) and the remaining ones still masked, and so on (Li et al., 2020; Zhou et al., 2020).

The use of pretrained V&L BERTs, as encoders in the standard encoder-decoder captioning framework, remains largely unexplored. The task of image captioning typically just considers single-input images, and not image-text pairs to be encoded. In our work, a pretrained V&L encoder is used with a decoder for image captioning, by leveraging not just the images as input but also retrieved captions.

Besides pretrained V&L encoders, pretrained V&L encoder-decoder models have recently been proposed to tackle classification and generation tasks, such as VL-T5 (Cho et al., 2021). Their captioning approach is similar to the present paper, but VL-T5 uses object tags as textual inputs, whereas EXTRA is conditioned on retrieved captions.

Retrieval-augmented Generation: The proposed approach is also similar to some studies on language generation that predict the output conditioned on retrieved examples (Weston et al., 2018; Gu et al., 2018; Khandelwal et al., 2019; Lewis et al., 2020). For instance, this work relates to Weston et al. (2018), in which a sequence-to-sequence LSTM model, for dialog generation, encodes the current input concatenated with the nearest retrieved response. Similarly, Izacard and Grave (2020) used an encoder-decoder Transformer conditioned on retrieved passages for open domain question answering. Retrieval-augmented generation is gaining traction in NLP but has only been explored for image captioning by few studies (Wang et al., 2020; Fei, 2021; Ramos et al., 2021; Sarto et al., 2022; Ramos et al., 2022). Concurrent work proposed Transformer-based captioning models augmented with retrieval as well (Sarto et al., 2022; Ramos et al., 2022). However, differently from these previous studies, we encode the retrieved captions by exploiting cross-modal representations with a V&L encoder.

7 Conclusions

We propose EXTRA, a retrieval-augmented image captioning model that improves performance by exploiting cross-modal representations of the input image together with captions retrieved from a datastore. EXTRA make uses of a pretrained V&L BERT, instead of an image-only encoder, combined with a language decoder. To generate a caption, the decoder attends to the cross-modal encoder features, containing information from image regions and also textual evidence from the retrieved captions. Image captioning is therefore addressed as language generation conditioned on vision and language inputs, instead of vision only. To evaluate this model, EXTRA was assessed against strong encoder-decoder models in the area, and ablation studies were also conducted. The experiments conducted on the COCO dataset confirmed the effectiveness of the proposed captioning approach.

For future work, we plan to explore the utility of EXTRA in out-of-domain and in few-shot learning settings, since the retrieval component can be easily modified to include external datastores, without the need to retrain the whole model. We also plan to explore how this approach can be adapted to other powerful vision and language encoders besides LXMERT. Finally, we will explore methods that allow us to jointly train the retrieval mechanism with the full model in order to retrieve captions that are more similar to the input image.

Limitations

Previous work has shown that generative models suffer from biases inherent to the data they are trained on (Weidinger et al., 2021; Thoppilan et al., 2022). Likewise, our EXTRA model can suffer from biases present in the COCO image captioning dataset (Chen et al., 2015). Particularly, it has been shown that there is significant gender imbalance in COCO, and that captioning models can exhibit gender bias amplification (e.g., they are likely to generate the word "woman" in kitchen scenarios, and the word "man" in snowboarding scenes) (Hendricks et al., 2018; Zhao et al., 2017).

However, differently from most captioning models, EXTRA is a retrieval-augmented captioning model, and thus it has the potential to make predictions beyond the training data, by relying on information from an external datastore. Still, the datastore knowledge might also have inherent bias, as mentioned by previous studies on retrieval-augmented generation (Lewis et al., 2020). In the paper, we show examples of such limitations wherein mismatched retrieved captions can bias the model towards incorrect predictions (see the results and appendix sections).

As a way to mitigate these limitations, we recommend analyzing the corresponding nearest captions when using EXTRA, since the retrieved captions can give useful insight of the bias involved in the generation process. EXTRA can provide interpretability through textual descriptions, whereas most captioning models only provide explanations as visual attention maps.

EXTRA also has the downside of focusing on an English-centric dataset. Captioning datasets are primarily available in English, and most image captioning models are trained on COCO or other english-centric datasets. To avoid hindered research on image captioning, it is important to consider multilingual captioning datasets that contain both language-diverse captions and geographically-diverse visual concepts (Thapliyal et al., 2022).

A Cross-Attention

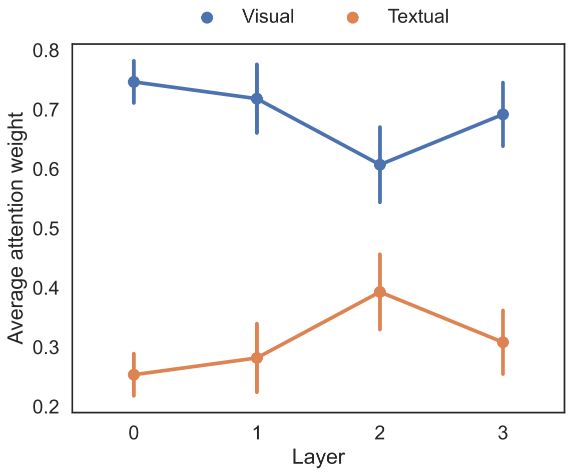

Figure 5: Cross-attention for the variant of EXTRA that that encodes an empty caption.

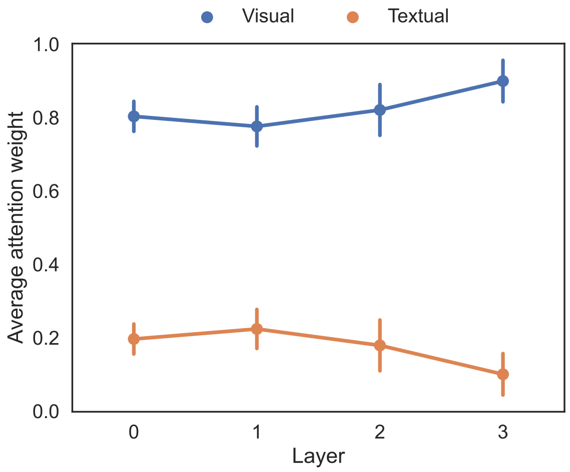

Figure 6: Cross-attention for the variant of EXTRA that that encodes a random caption.

In Section 5.1, we quantified how much attention EXTRA pays to the encoded image and retrieved captions. We also quantify this for the two other variants of EXTRA which encode irrelevant captions, using either an empty or a random caption. Figures 5 and 6 show the average cross-attention weights from the decoder to the outputs of the encoder in respect to the visual **V** and textual **L** outputs, respectively for the empty and random caption encoding. Contrary to the findings presented in Section 5.1, regarding the encoding of retrieved captions, in this scenario the two variants pay more attention to the visual outputs instead.

For details on how we calculated the corresponding attention weights, we present the corresponding formula. Specifically, we calculated the average of the cross-modal attention C across either the number of image regions or the sub-words in the encoder at each of T time-step of generating a caption and across each of the $H = 12$ attention heads.

This calculation happens independently for each of the $L = 4$ layers in the decoder:

$$A(C^L, V) = \frac{1}{H} \sum_{j=1}^{H} \frac{1}{T} \sum_{t=1}^{T} \sum_{i=1}^{|V|} \alpha^L_{j,t \to i}. \tag{2}$$

$$A(C^L, T) = 1 - A(C^L, V). \tag{3}$$

B More Examples

Figure 7 shows additional examples of the captions generated by EXTRA considering the retrieved captions, against the other two variants: encoding an empty and random caption instead. For the first image, the two variants fail to recognize that the image shows kids playing basketball (perhaps given the small size of the ball), whereas EXTRA was able to identify it by having that information in the retrieved captions. In the second image[7], the two variants produced the error of generating *sandwich* while EXTRA correctly mentioned *hot-dog*, similar to the retrieved captions. EXTRA considers the semantics from the nearest captions retrieved during generation, sometimes even copying an entire sentence, as shown in Figure 9.

Figure 8 shows examples where the retrieved captions mislead the model. We note however that EXTRA is also able to succeed, despite the mismatch from retrieved captions, as seen in Figure 10.

Abstract

A major open problem in neural machine translation (NMT) is the translation of idiomatic expressions, such as "*under the weather*". The meaning of these expressions is not composed by the meaning of their constituent words, and NMT models tend to translate them literally (i.e., word-by-word), which leads to confusing and nonsensical translations. Research on idioms in NMT is limited and obstructed by the absence of automatic methods for quantifying these errors. In this work, first, we propose a novel metric for *automatically* measuring the frequency of literal translation errors without human involvement. Equipped with this metric, we present *controlled* translation experiments with models trained in different conditions (with/without the test-set idioms) and across a wide range of (global and targeted) metrics and test sets. We explore the role of monolingual pretraining and find that it yields substantial *targeted* improvements, even without observing any translation examples of the test-set idioms. In our analysis, we probe the role of idiom context. We find that the randomly initialized models are more local or "myopic" as they are relatively unaffected by variations of the idiom context, unlike the pretrained ones.

1 Introduction

Neural machine translation (NMT; Sutskever et al. 2014; Bahdanau et al. 2015; Vaswani et al. 2017) struggles with the translation of rare multi-word expressions (MWE) (Koehn and Knowles, 2017). Non-compositional phrases, such as idioms (e.g., "piece of cake"), are one of the most challenging types of MWEs, because their meaning is figurative and cannot be derived from the meaning of their constituents (Nunberg et al., 1994; Liu, 2017). NMT models tend to translate these expressions literally (i.e., word-by-word), which leads to erroneous translations. In this paper, our focus is on the translation of idiomatic expressions, in contrast to most prior work, which is subsumed under MWEs in general (Constant et al., 2017; Cook et al., 2021).

The absence of *targeted* and *automatic* evaluation is a major obstacle to advances in idiom translation. Global metrics, such as BLEU (Papineni et al., 2002) consider the full translation, and thus, the effects of idiom translation are overshadowed. Previous efforts on targeted evaluation isolate the idiom translation using word alignments (Fadaee et al., 2018) or word edit distance (Zaninello and Birch, 2020). These approaches measure the accuracy of idiom translation but do not account for literal translation errors. Shao et al. (2018) proposed a method for estimating the frequency of such errors, but it requires the creation of language-specific handcrafted lists (i.e., blocklists) with words that correspond to literal translation errors.

In this work[1], we present a study of idioms in NMT, with the goal of facilitating future research in this direction. First, we propose a novel metric for the *automatic* evaluation of literal translation errors (LitTER), that does not require any hand-crafted blocklists. We incorporate LitTER, which complements alignment-based metrics (Fadaee et al., 2018) into a unified targeted evaluation framework.

Next, we present translation experiments in a controlled setting, by using different training splits to test models under different conditions (e.g., zero-shot). To improve idiom translation we leverage monolingual data, which are more abundant than parallel and contain idioms in higher frequencies and more diverse contexts. We exploit monolingual data via pretraining (mBART; Liu et al. 2020), which is a generic and task-agnostic approach, unlike prior work that considers ad-hoc solutions (Fadaee et al., 2018; Zaninello and Birch, 2020). We find that monolingual pretraining yields strong targeted gains, even when models have not seen any translation examples of the test idioms.

May 2-6, 2023

We also present an extensive analysis of how different models translate idioms. Specifically, we use a series of probing methods that encode idioms within different contexts (Garcia et al., 2021; Yu and Ettinger, 2020), and measure how this affects the translation outputs and the decoder distributions. We find that the randomly initialized models are more "myopic" compared to the pre-trained ones, as they are relatively unaffected when we vary the idiom context. Our contributions are:

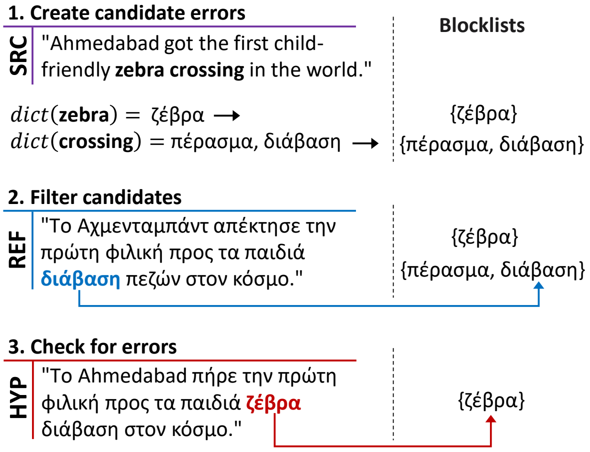
1. We propose LitTER (§2.1), a novel metric for measuring the frequency of literal translation errors, and embed it into a framework (§2) for *automatic* and *targeted* evaluation of idiom translation, complementing prior work.
2. We present translation results (§3.3) in a *controlled* setting and across a wide range of metrics. We find that pre-training on monolingual data yields substantial *targeted* improvements.
3. We present an extensive *analysis* (§4) with a series of probes, showing how context affects idiom translation. We find that models are more uncertain when translating idioms and that pre-training makes models more contextual.

2 Automatic Targeted Evaluation

2.1 Literal Translation Error Rate (LitTER)

We propose literal translation error rate (LitTER), a novel metric of the frequency of literal translation errors made by a model. A literal translation error occurs if any of the words of a span in the source sentence has been *wrongly* translated literally in the target language. Our metric is inspired by the method of Shao et al. (2018) which identifies possible literal translation errors, by checking if a translation output contains any blocklisted words. While this method is effective at capturing these errors, it relies on hand-crafted blocklists. We overcome this limitation by automatically creating word blocklists for a given expression.

Our method, is based on two key ideas. First, we use bilingual word dictionaries[2], which are relatively easy to obtain, to translate the words of an annotated source span into the target language, and produce blocklists with candidate literal translation errors. Then, we use the reference translations to filter the blocklists by removing those words that occur in the reference. This avoids triggering the blocklist when the correct translation is literal.



"Ahmedabad got the first child-friendly **zebra crossing** in the world."

$dict$(**zebra**) = ζέβρα →

$dict$(**crossing**) = πέρασμα, διάβαση →

"Το Αχμενταμπάντ απέκτησε την πρώτη φιλική προς τα παιδιά **διάβαση** πεζών στον κόσμο."

"Το Ahmedabad πήρε την πρώτη φιλική προς τα παιδιά **ζέβρα** διάβαση στον κόσμο."

Figure 1: Overview of the algorithm for the Literal Translation Error Rate (LitTER). For each sentence, we first produce candidate literal translation errors (blocklist), using all the word translations of the source idiom words. Then, we filter the candidates in the blocklist by looking at the reference. Finally, we check if the hypothesis triggers the remaining words in the blocklist.

Algorithm

1. Select from the source text the list of words $\boldsymbol{s} = \langle s_1, s_2, ..., s_N \rangle$ that belong to the annotated expression (i.e., idiom).
2. For each word s_i, obtain all its word translation(s) in the target language using a bilingual word dictionary and add them to a blocklist $b_i = \langle t_1, t_2, \ldots, t_M \rangle$, creating a candidate *list* of blocklists $\boldsymbol{B_s} = \langle b_1, b_2, ..., b_N \rangle$.[3]
3. For each word in the reference (R), search if it occurs in any of the blocklists b_i. If so, remove the corresponding blocklist b_i from $\boldsymbol{B_s}$ to avoid false positives. For example in Figure 1, where words διάβαση and πέρασμα are synonyms, if we remove only διάβαση but leave πέρασμα as a blocklisted word and a model generates it in its translation, this will *wrongly* trigger a literal translation error.
4. Check if the hypothesis contains any blocklisted words. If it does, then we mark this hypothesis as having a literal translation error.

The final score is the percentage of translations that trigger the blocklist. As LitTER requires source-side annotations, we collect test data with idioms on the source side and annotate the spans where they occur (§3.1). Appendix C shows examples of LitTER evaluating real sentences in our data.

---

[2] In this work we use the MUSE (Lample et al., 2018).

[3] In practice, $t_1, t_2, \ldots, t_M$ in a blocklist are synonyms of each other as they are translations of the same source word.

2.2 Alignment-based Evaluation

To measure idiom translation accuracy, we use Alignment-based Phrase Translation Evaluation (APT-Eval), by extending Fadaee et al. (2018) with subword-level metrics. APT-Eval uses word alignments to find the words in the hypothesis and reference sentences, respectively, that align with the annotated idiom source span, and then compares the retrieved matches to each other. We consider two evaluation metrics. First, we use *unigram precision*, that measures the ratio of words in the reference spans that occur in the hypothesis spans, as in Fadaee et al. (2018). We also use ChrF (Popović, 2015), that measures character n-gram overlap.

LitTER vs. APT-Eval While APT-Eval is a targeted evaluation metric, it only measures translation accuracy. This means that given an inaccurate translation, it is impossible to measure whether it has a literal translation error. LitTER, however, quantifies this particular issue that affects NMT.

2.3 Handling Idiom Frequency Imbalances

Different idioms have significantly different frequencies (Appendix A.1). However, prior work has overlooked this fact (Zaninello and Birch, 2020; Fadaee et al., 2018; Shao et al., 2018; Rikters and Bojar, 2017). Thus, over-represented idioms can skew the reported results and favour models that have overfitted on them. To address this, we report all of our targeted evaluation results (i.e., LitTER, APT-Eval) by macro-averaging over idioms:

$$\boldsymbol{E}(\theta) = \frac{1}{|\boldsymbol{L}|} \sum_{j=1}^{|\boldsymbol{L}|} \frac{1}{|\boldsymbol{L_j}|} \sum_{i=1}^{|\boldsymbol{P}|} \boldsymbol{M}(\theta(s_i), t_i) \qquad (1)$$

where $\boldsymbol{L}$ denotes the set of distinct idioms in a test set and $\boldsymbol{P} = \{\langle s_i, t_i \rangle | L_j \in \langle s_i, t_i \rangle\}$ denotes the set of sentence pairs containing the idiom L_j. The model is denoted by θ and the translation of x by $\theta(x)$. We first compute the average score for the test pairs of each idiom with a given metric $\boldsymbol{M}$, and then average these values to produce $\boldsymbol{E}$.

3 Experiments

3.1 Data and Training Splits

We present experiments on en→fr and en→es data. For each language pair, we concatenate the data from Europarl v7[4] (Koehn, 2005), part of the WMT news translation task (Bojar et al., 2014), and from TED talk transcripts released as part of IWSLT 2017 shared task[5] (Cettolo et al., 2017).

Idiom Data We split the parallel data into regular and idiom data using a pattern-matching tool that we developed. Our tool takes as input a list of idioms and extracts sentences from a corpus containing these idioms. We also annotate the span in which each idiom occurs within a sentence, to enable the targeted evaluation metrics. This approach is similar to Fadaee et al. (2018), but we build our tool on top of Spacy's (Honnibal and Montani, 2017) rule-based matching engine. For each phrase in the input list, we automatically create pattern-matching rules that capture complex variations of a given phrase. See Appendix A for details.

In this work, we use a list of 225 English idioms, that we manually collected and make publicly available. We feed this list into our pattern-matching tool, and extract (and annotate) translation pairs that contain an idiom on the source side. The regular data are used *only* for training. The idiom data are further divided into the *idiom-train* and *idiom-test* sets. For each idiom (e.g., "under the weather") in our original idiom data, we put half of its sentence pairs to the idiom-train and the other half into the idiom-test sets, to obtain a balanced distribution. We discard sentences with idioms that occur only once. We conduct controlled experiments in the following testing conditions:

- **Zero**: training data includes only regular parallel data, and we measure how models perform on unseen idioms at test time.
- **Joint**: training data includes the regular and idiom-train data, and we measure how models perform on idioms observed (in a different context) in training data.
- **Upsampling**: same as the joint split, but we up-sample the idiom-train data N times. This setting measures whether it is necessary to up-sample the targeted training data (idiom-train) to achieve better translation quality of idioms.

Evaluation For development, we use the IWSLT dev-set for each language pair. For general purpose translation evaluation, we report results in the WMT newstest14 and IWSLT'17 test sets for en→fr, and in the WMT newstest13 in particular and IWSLT'17 test sets for en→es. For the targeted idiom evaluation (i.e., LitTER and APT-Eval) we

Table 1: Dataset statistics

use the extracted idiom-test data per language pair. To generate the word alignments for APT-Eval, we trained a fast-align (Dyer et al., 2013) model on each language-pair's training data. For decoding, we use beam search with beams of size 5, and evaluate all models using BLEU (Papineni et al., 2002) computed with SacreBLEU (Post, 2018).

Preprocessing We first filter out sentence pairs with more than 80 words or with length ratio over 1.5. Then, we tokenize the remaining sentences using sentencepiece[6](SPM; Kudo and Richardson 2018). For the randomly initialized models, we train SPM models with a joint vocabulary of 60K symbols on the concatenation of the source- and target-side of the regular training data. For the mBART fine-tuning experiments, we use the SPM model of mBART (250K symbols).

3.2 Models

Besides training models from scratch, we also investigate how pretraining on monolingual data affects idiom translation, which yields substantial improvements on generic translation quality (Lample and Conneau, 2019; Song et al., 2019; Liu et al., 2020). However, it is not obvious if monolingual data can help idiom translation, as they do not contain any examples with how to translate an idiom from one language into another.

We use mBART (Liu et al., 2020) via finetuning, which is pretrained on monolingual data from many languages. We hypothesize that one way multilingual pre-training can help is by bootstrapping over the source and target language contexts in which idioms occur. We also consider injecting different types of noise during fine-tuning, to corrupt the (encoder or decoder) input context and measure the effects on the targeted evaluation metrics. Specifically, we use source-side word masking and replacement (Baziotis et al., 2021), and target-side word-replacement noise (Voita et al., 2021). In our experiments, "random" denotes a randomly initialized model, while "mBART" stands for using mBART as initialization. For noisy finetuning we train the following variants: "mBART+mask" where we mask 10% of the source tokens, "mBART+replace (enc)" where we replace 10% of the source tokens with random ones, and "mBART+replace (dec)" where we replace 10% of the target tokens with random ones.

Model Configuration For fair comparison, the randomly initialized models use the same architecture as mBART. Specifically, the models are based on the Transformer architecture, with 12 encoder and decoder layers, 1024 embedding size and 16 self-attention heads. Our code is based on the official mBART implementation in Fairseq.

Optimization We optimized our models using Adam (Kingma and Ba, 2015) with $\beta_1 = 0.9, \beta_2 = 0.999$, and ϵ=1e-6. For the random initialization experiments, the models were trained for 140K updates with batches of 24K tokens, using a learning rate of 1e-4 with a linear warm-up of 4K steps, followed by inverted squared decay. For the mBART initialization experiments, the models were trained for 140K updates with batches of 12K tokens, using a fixed learning rate of 3e-5 with a linear warm-up of 4K steps. In all experiments, we applied dropout of 0.3, attention-dropout of 0.1 and label smoothing of 0.1. For model selection, we evaluated each model every 5K updates on the dev set, and selected the one with the best BLEU.

3.3 Results

In this section, for brevity, we discuss a subset of our results, in particular our experiments in en→fr. Results for en→es are consistent with en→fr and are included in Appendix B. Table 2 summarizes all of our main results. Besides global evaluation using BLEU (§3.3.2) on diverse test sets, we also consider two targeted evaluation methods (§3.3.1) that focus on how the idioms are translated using our idiom-test set. For the upsampling split, we upsample the idiom-train data 20x. We also experimented with 100x upsampling, but models started to exhibit overfitting effects (see §B, §D).

3.3.1 Targeted Evaluation

In targeted evaluation, we focus *only* on how models translate the source-side idioms. We present results on our proposed LitTER metric and on APT-

---

[6] We use the `unigram` model with `coverage=0.9999`

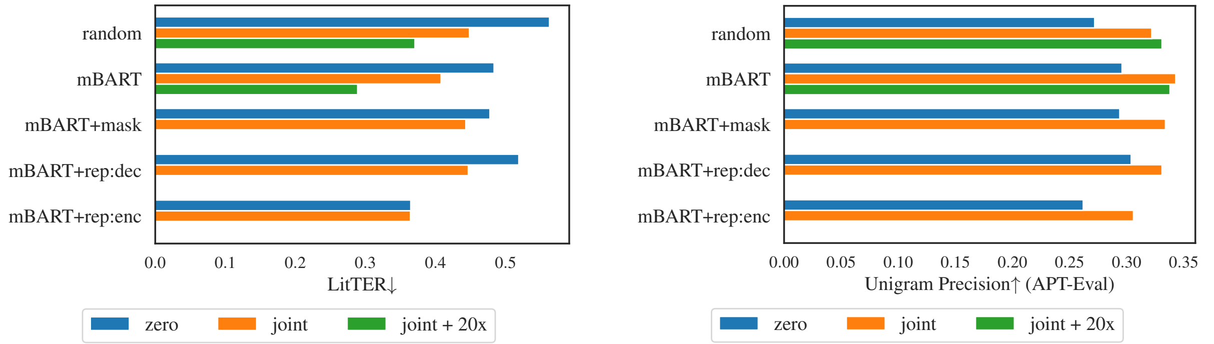
Table 2: All of our (en→fr) translation results (single run), including *generic* and *targeted* evaluation.



(a) Results on LitTER, which measures how often each model makes literal translation errors.

(b) Results on APT-Eval with unigram precision, which compares (the aligned) reference and hypothesis spans.

Figure 2: Results on *targeted* evaluation of idiom translation.

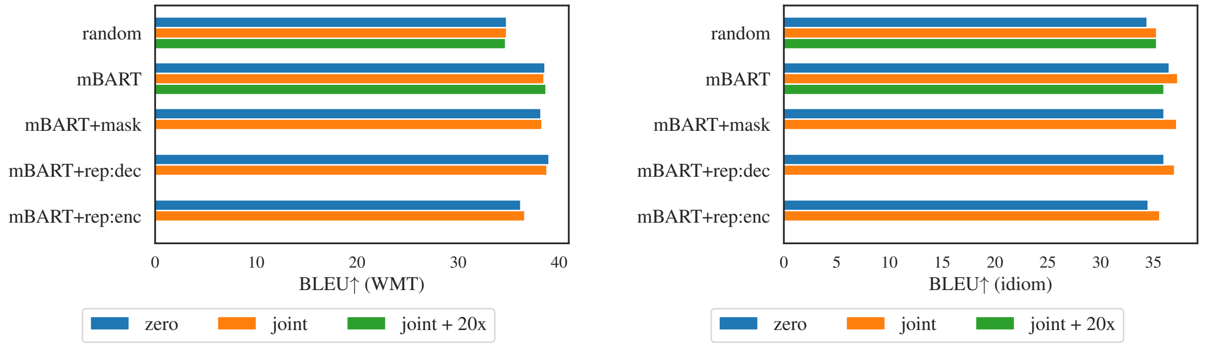
Eval, which provide different information. Recall that we macro-average these scores (§2.3) to account for imbalances in the idiom frequency.

Literal Translation Errors Figure 2a, shows the results on LitTER, that measures how often models make literal translation errors. As expected, all models produce fewer errors when trained on the joint split compared to the zero split. Pretraining gives a significant boost, even on the joint split. This shows that pretraining helps, even though the models have not seen any examples of how to translate the test-set idioms. Upsampling the idiom-train data helps all models regardless of initialization.

Each type of noise induces a different behaviour compared to the mBART model. Masking yields no effect on the zero split, but increases errors on the joint split. Baziotis et al. (2021), show that masking promotes copying, which we speculate it could lead to word-by-word translation and increase LitTER. Decoder-side word replacements yield a similar behaviour in terms of LitTER, which we hypothesize could push the decoder to rely more on the encoder, therefore encouraging word-by-word translation. By contrast, when we add word replacements in the encoder, it greatly reduces LitTER in both splits. This aligns with the findings of Baziotis et al. (2021), who show that source-side word replacements make the decoder less prone to copying (or "trusting") the encoder.

Idiom Translation Accuracy To estimate how accurately models translate idioms, we compare the reference and hypothesis matches that align to the source idiom words. Figure 2b, compares models using unigram precision, and the results are consistent across all APT-Eval metrics (Table 2).

Similar to the LitTER results, the joint split significantly improves idiom translation accuracy as well. Again, pretraining outperforms random initialization, even on the joint split. Upsampling, however, does not yield any consistent improvements. While source-side word replacements reduce literal translation errors, they also degrade idiom translation accuracy. Our hypothesis is that as the decoder becomes less reliant on the encoder,



(a) Regular BLEU results on the *generic* WMT14 test set

(b) Regular BLEU results on our *idiom-test* set.

Figure 3: Results on *global* evaluation (BLEU) on different test sets.

this induces more hallucinations.

3.3.2 Global Evaluation

Here, we discuss how models perform based on global translation evaluation using BLEU.

General Purpose Figure 3a, shows the results on the WMT14 test set, but we note that the results are generally consistent with the IWSLT17 test set (Table 2). The mBART intialized models, unsuprisingly, yield significantly better results than random initialization. As expected, there is no measurable difference between splits, not even when upsampling idioms, as both IWSLT17 and WMT14 are generic test sets. Noisy finetuning methods fail to improve results. Encoder-side word replacements even degrade overall performance, which aligns with the hypothesis that they induce hallucinations.

Idiom The results on our idiom-test set (Figure 3b) show that models perform consistently better when trained on the joint split. Global evaluation, however, considers the full sentences and the impact of idiom translation is overshadowed (Rikters and Bojar, 2017), which can be seen by the very small differences between splits. This prevents fine-grained comparisons between models and highlights the need for targeted evaluation.

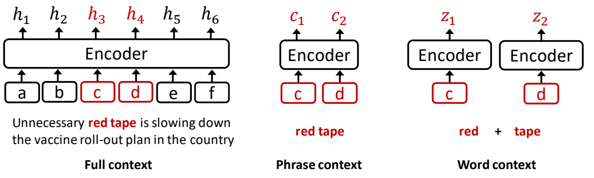


Figure 4: Illustration of how we obtain idiom representations by varying the available context.

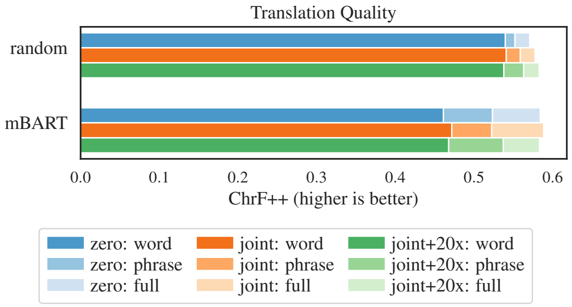

Figure 5: Variation in translation quality, measured in ChrF, as we vary the idiom representations. The length of each (lighter) bar encodes the difference from its (darker) bar to its left (i.e., overlapping bars effect).

4 Analysis

To further understand how models translate idioms, we present an extensive analysis with a series of probes, focused on the role of idiom context. Specifically, using the annotations in our idiom-test data, we encode the idiom words within different contexts (Figure 4) and measure how it affects the decoder distributions and the translation output. We consider (1) *full context*, in which we encode the idiom phrase within the whole input sentence, (2) *phrase-level context*, in which we encode the idiom phrase in isolation, (3) *word-level context*, in which we encode each idiom word independently. Our probes follow a similar approach to prior work that evaluate the idiomaticity of (pretrained) Transformer-based models (Garcia et al., 2021; Tayyar Madabushi et al., 2021) by measuring how idiom representations are affected by their context (Yu and Ettinger, 2020), but we extend these methods to analyze how (pretrained) NMT models translate idioms. For brevity, we discuss here our most important findings, focusing on random-vs-mBART initialization. However, we include the rest of our results in Appendix D for completeness.

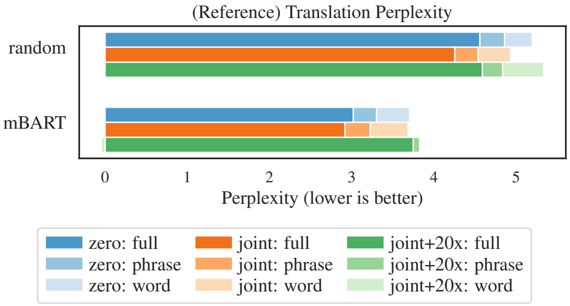

Figure 6: Perplexity of the references, as we vary the idiom representations. The length of each (lighter) bar encodes the difference from its (darker) bar to its left.

4.1 Variation in Translation Performance

In this probe, we decode (i.e., translate) different encoder representation and evaluate the samples against the reference (sentence) translations. Specifically, we first encode each (full) input sentence and then replace the encoder representations belonging to idiom words with those obtained with different (narrower) contexts. Figure 5 shows the results using ChrF, rather than BLEU, as a metric to capture even small subword-level changes.

Across all models, reducing the context (i.e., darker shades) results in worse translation scores. This is expected, as by swapping the original (full context) idiom representations with those obtained with word-context, we essentially remove information. When we use the full-context (i.e, lightest shades) pretraining yields the best results, but when we reduce the idiom context, the pretrained model suffers significantly, unlike the randomly initialized that is barely affected. This implies that the representations of the randomly initialized model are more local (or “myopic”), containing information mainly related to the idiom tokens. By contrast, the representations of the pretrained model are more global, and contain information related to the surrounding idiom context (Brunner et al., 2020). Upsampling does not have a strong effect.

4.2 Variation in Translation Likelihood

In this probe, we vary the encoder idiom representations, as before, and measure how this affects the likelihood of the reference translations. We score each reference translation by computing its perplexity under the model, given each encoder output sequence. Figure 6, shows the results, with *lighter* shades corresponding to *narrower* contexts.

Using more context improves (i.e., lowers) the perplexity of the references across models. Pretraining endows models with stronger LM capabilities which is probably why it yields generally lower perplexities. Training on the joint split yields consistent improvements which are more pronounced in the randomly initialized models. By contrast, upsampling the idiom-train data yields negative effects, which we attribute to overfitting, as it makes all other sentences less probable under the model.

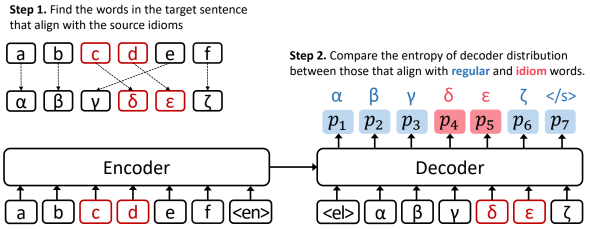

Figure 7: Illustration of how we compute the effects of different source idiom contexts on the model’s uncertainty during translation (i.e., decoding).

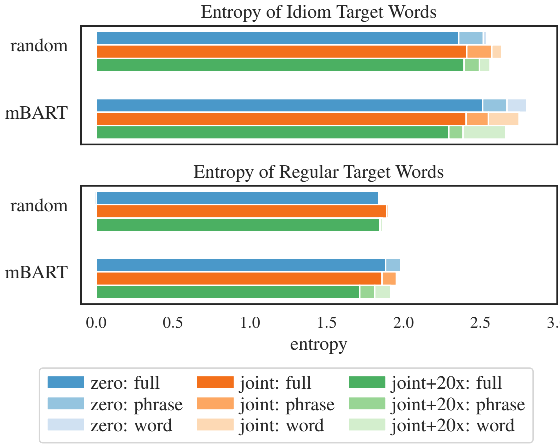

Figure 8: Model uncertainty for the translation of regular vs. idiom words. The length of each (lighter) bar encodes the difference from its (darker) bar to its left.

4.3 Decoder Uncertainty

Next, we focus on how the token-level uncertainty of the decoder varies while it translates idiom vs. non-idiom words. First, we translate each sentence pair with teacher-forcing, where we feed to the decoder the reference translation (i.e., ground truth) as input, instead of its output from each step. Then, we measure the entropy of the decoder’s distributions for each (reference) target token. Finally, using word alignments, we average separately the entropy values of target words[7] that are aligned to idiom and non-idiom source words. Figure 7 illustrates how the probe works. Figure 8 shows the

---

[7] After the word alignment step, we find which target SPM tokens correspond to which words.

results, in which *lighter* shades correspond to *narrower* contexts.

All models have significantly higher uncertainty when they translate idiom words (top section) compared to regular words (bottom section). This confirms our expectation that it is harder to translate idioms. When translating regular words, the randomly initialized models are unaffected by changes in the idiom representations, whereas reducing the idiom context increases the uncertainty of the pretrained models. This is another piece of evidence that pretraining yields less local models (§4.1). When translating idiom words, including or upsampling the idiom-train data benefits the pretrained model, but not the randomly initialized one.

5 Discussion

Global Metrics LiTER does not aim to replace global evaluation metrics like BLEU, but to complement them. Global metrics estimate the general translation quality of model outputs, which is undoubtedly important. However, they consider the full sentence, and as result the effects of idiom (mis)translation are overshadowed (see §3.3.2). LiTER aims to fill this gap by providing additional insights to practitioners with targeted evaluation.

LitTER LiTER should not be used in isolation, but combined with other (global/targeted) metrics. The reason is that lower LiTER can be achieved by more accurate idiom translations or by hallucinations. We aim to enable practitioners to make informed decisions without running human evaluations in the model development phase. The goal is to produce models that improve on LitTER without sacrificing general translation quality (e.g., BLEU). Our experiments reveal this contrast, where unsupervised pretraining achieves this goal, whereas (some of) the noisy variants fail. We expect LiTER to be more relevant when developing NMT models for creative content (e.g., subtitles, social media text) that usually contains figurative language.

Alignment Metrics Word alignment-based methods aim to capture idiom translation accuracy that complements LitTER. However, they are sensitive to the literal meaning of words to produce the alignments. Thus, while alignment-based methods could be reliable in certain types of evaluation, such as gender translation (Stanovsky et al., 2019), we believe that with the current techniques they should be used with caution for idiom translation evaluation. Although we did not systematically study this issue, we discovered by manual inspection that it was not uncommon to produce noisy or empty alignments. We chose statistical over embedding-based methods as they yielded less empty alignments (§B.2).

6 Related Work

Idioms in NMT There is limited research on idioms in NMT. Zaninello and Birch (2020), explore augmenting the training data with MWE translations from dictionaries, backtranslating (Sennrich et al., 2016) target-side sentences with MWEs, or wrapping the (source) MWEs with special tokens. Fadaee et al. (2018) prepend a special token in source sentences that contain an idiom. Gamallo and Garcia (2019) do unsupervised translation of MWEs by composing cross-lingual word embeddings, but this is fundamentally incapable of translating idioms which are non-compositional. Instead of using ad-hoc solutions that change the model or the data pipeline, we use monolingual pretraining, which is a more generic and less invasive approach.

Targeted Evaluation Using word alignments is a straightforward approach for the targeted evaluation of words or phrase translation (Stanovsky et al., 2019). Fadaee et al. (2018), use word alignments to compare the reference and hypothesis matches that translate a given source idiom. Zaninello and Birch (2020) first align words in the hypothesis and the reference using edit-distance and then score the aligned words using character-level matching. Alignment-based methods capture idiom translation accuracy, but they do not account for literal translation errors which are a major issue in idiom translation (Fadaee et al., 2018). The method of Shao et al. (2018) is capable of estimating the frequency of such errors, but it requires the creation of language-specific hand-crafted lists. In this work, we lift this limitation and enable the automatic evaluation of literal translation errors.

Analysis Rikters and Bojar (2017) investigate the attention mechanism in NMT during the translation of MWEs. Garcia et al. (2021) evaluate the idiomaticity of Transformer-based models using probes that measure how idiom representations are affected by their context (Yu and Ettinger, 2020). Similarly, Tayyar Madabushi et al. (2021) investigate the idiomaticity of pretrained encoders, such as BERT (Devlin et al., 2019), in a *monolingual* setting. By contrast, we present an analysis of how (pretrained) NMT models *translate* idioms.and

Concurrent analysis works explore idioms in NMT, by also using the blocklist method (Shao et al., 2018) as part of their analysis. Dankers et al. (2022a) study the compositionality of (Transformer) NMT models and (among others) find that models trained on more (parallel) data are more compositional. This relates to the results of our analysis (§4), which shows that pretrained models are less local than those trained only on the downstream parallel data. Dankers et al. 2022b analyze the hidden states and attention patterns of Transformer NMT models when processing idioms.

7 Conclusions

We present a comprehensive study of idiomatic expressions in NMT, aiming to facilitate future research on the topic. We propose LitTER (§2.1), a novel metric that enables the *automatic* evaluation of literal translation errors. LitTER is used for *targeted* evaluation and aims to complement and not replace global metrics, such as BLUE or ChrF, which consider the full sentence and can only measure the *overall* translation quality. We evaluate models in controlled conditions, with and without the test set idioms (i.e., zero-shot). We explore pretraining on monolingual data for improving idiom translation, as parallel idiom data is difficult to come by. Interestingly, we find that pretraining achieves strong targeted improvements, even in the zero-shot setting (§3.3.1). We also present a systematic analysis (§4) that investigates the role of context in idiom translation. We find evidence that pretraining yields more contextual models, which helps to explain why it contributes to better idiom translations. We also quantitatively confirm that idioms are more difficult to translate than regular words and strongly depend on the source context.

Limitations

LitTER is a novel metric that sidesteps the need for human involvement to estimate the frequency of literal translation errors, which is a major problem in idiom translation by NMT models. However, in its current iteration it has certain limitations:

1. An edge case with LitTER is that if the blocklist words appear as a result of translating other words - not part of the non-literal phrase - we will still count it as an error. We leave this as future work.

2. Our experiments were conducted on languages with relatively simple morphology. Preliminary experiments with German revealed that LitTER struggles with compound words. We did address these issues with custom rules, but we aim to study these cases in future versions of LitTER systematically.

3. The metric can be ambiguous when used in isolation. We recommend pairing it with standard evaluation metrics when comparing translation models.

Acknowledgments

We thank Marcello Federico, Georgiana Dinu, Anna Currey and Hoang Cuong for the helpful discussions and feedback during this project.

- He tried **pulling the wool over John's eyes** by hiding the profits in separate accounts, but he was quick to catch onto his scheme.

- He tried **pulling the wool over James' eyes** by hiding the profits in separate accounts, but he was quick to catch onto his scheme.

- He tried **pulling the wool over our eyes** by hiding the profits in separate accounts, but we were quick to catch onto his scheme.

- Don't try to **pull the wool over her eyes** . She's too smart.

Figure 10: Overview of the process for collecting the idiom parallel data.

A Idiom Data Collection

We collected parallel data with idioms in the source side and annotated the spans in which the idioms occur within each sentence. This enables us to conduct controlled experiments and to support our targeted evaluation metrics and our analysis. To collect the data, we created a phrase-matching tool that searches for idioms in parallel data and extracts and annotates the retrieved pairs (Figure 9).

Phrase-Matching Tool Our tool, which we make publicly available, uses rule-based matching to search for sentences that contain phrases specified in user-defined phrase list. While in this work we use it to create parallel data with idioms, it could be used to create datasets with different types of phrases. We build our tool on top of Spacy's (Honnibal and Montani, 2017) rule-based matching engine[8] that is more flexible and easy to work with than using regular expressions or custom rules (Fadaee et al., 2018). It allows us to do pattern matching over linguistic units, such as parts-of-speech or even dependency relations, thus capturing complex variations of a given phrase. Our tool first reads the input phrase list, and for each phrase, it automatically creates a pattern based on some simple rules and assumptions. We created separate idiom train and test data for each language-pair and we describe the process in Section 3.1.

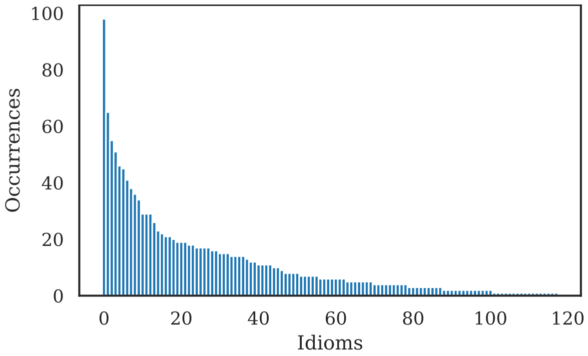

Figure 11: Occurrences of idioms in the en→fr idiom-test sets.

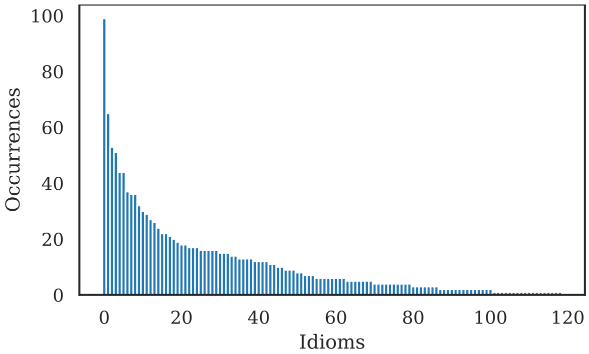

Figure 12: Occurrences of idioms in the en→es idiom-test sets.

Figure 10, shows an actual example[9] of the different variations of the idiom "pull the wool over someone's eyes" that our tool captures. Notice that it matches:

- Different variations of the verb "pull".
- Different words in the place of the word "someone".
- Importantly, it optionally matches the particle "'s". This shows that we can apply logic base on the part-of-speech (POS) or other linguistic properties of words, and in this case optionally skip them.

A.1 Idiom-test Statistics

Figure 11 and Figure 12 show the occurrences of idioms in the en→fr and en→es idiom-test sets, respectively. We see that in both test sets the idiom statistics follow very similar distributions. This verifies that different idioms have very different

Table 4: Translation results in en→es. The results involve a single run, but are consistent across the board.

frequencies, and highlights the need for macro-averaging the scores of targeted evaluation metrics. Failure to do so would promote models that have perform best on the most frequent idioms over those that have a more balanced performance.

Also, note that the frequencies of idioms in the idiom-train and idiom-test sets are identical, as described in Section 3.1. While we have not computed the idiom frequencies in the monolingual data used to pretrain mBART, we expect that they would follow a similar distribution as the one found in the monolingual data we used in our work.

B Translation Results

In this section, we present all of our translation results in detail. Table 3, shows our results in en→fr, while Table 4 shows our results in en→es. Besides BLEU, we also include results with ChrF (Popović, 2015), for global translation evaluation. overall the results are *consistent* across language pairs in all evaluation methods. The fact that the absolute scores reached by the model on each each test set are different is natural, as the test sets themselves are different to each other between languages. However, the relative performance between model across language pairs is the same, with only minor differences.

B.1 Targeted Evaluation

In Figure 13, we visualize how model perform on our targeted evaluation methods for both en→fr and en→es. Recall that, LitTER, measures how often each model makes literal translation errors. APT-Eval, measures idiom translation accuracy, by comparing the reference and (aligned) hypothesis spans that translate the source idiom words. In these plots, we use present how models performed on unigram precision metric for APT-Eval, similar to the main paper. We observe that both in terms of literal translation errors (Figure 13a, 13c), as well as idiom translation accuracy (Figure 13b, 13d), the results are remarkably consistent across languages. Upsampling the idiom-train data helps all models regardless of initialization, but upsampling more than 20x does not yield consistent improvements.

B.2 Word Alignment Models

APT-Eval, requires word alignments to map the source idiom words to the words of the reference and hypothesis spans, respectively. In our main paper, we presented results using fast-align (Dyer et al., 2013) with word alignment models trained on the training data of each language-pair. We also experimented with awesome-align (Dou and Neubig, 2021), that doesn't require any training, and uses the token similarities of the pretrained mBERT models to obtain the alignments. After analysis, we found that fast-align produced empty matches for the idiom words in 2.2% of the reference sentences in our idiom-test set. Awesome-align, however, yielded more empty matches, which after tweaking its threshold parameter[10], we managed to reduce it to 3%. While we omitted the awesome-align results from the main paper, we include them in Tables 3, 4 for completeness. We observe that while the absolute APT-Eval scores are different between the two alignment methods, the relative performance across models is consistent.

B.3 Regular Translation Evaluation

Here, we visualize our results on *regular* MT evaluation for both en→fr and en→es. In Figure14, we compare models in both language pairs and for both generic test sets as well as on our idiom-test sets. Overall, we observe that the results are very consistent between language pairs, similar to the targeted evaluation results (§B.1), which improves our confidence in them. As we already noted in our paper, we find that including or upsampling idiom training data has no measurable effect on generic test sets, unlike on our idiom-test set.

C LitTER

C.1 Indicative Examples

Here, we present some indicative examples of how LitTER evaluates translation outputs in our idiom test data. Figure 16, contains examples where LitTER is working as intended, whereas Figure 15, contains a two failures of LitTER.

SRC: As the example of Cyprus shows, Ankara does not pull its punches.
REF: Comme le montre l'exemple de Chypre, Ankara n'y va pas avec le dos de la cuiller.
HYP: Comme le montre l'exemple de Chypre, Ankara ne tire pas les ficelles.

Blocklists
pull → {tirez, tirer}
its → {ses, son, sa}
punches → {coups}

No error detected.

SRC: [..] it was already being put on ice on the grounds that 'We'll never get it though the G20'.
REF: [..] elle était mise au rencart au motif que "nous n'arriverons jamais à convaincre le G20".
HYO: [..] on l'a déjà gelé au motif que "nous n'y arriverons jamais par le biais du G20".

Blocklists
put → {mis, mettre}
on → {sur}
ice → {glace, ice, verglas}

No error detected.

Figure 15: LitTER failures on our en→fr idiom test set. In the first example, the blocklist is not triggered because the inflected form *tire* is missing from the blocklist. In the second example, the verb form *gelé* (freeze) is not contained in the blocklist but is a literal translation of *ice* in a wider sense.

SRC: To postpone this vote one more time would be to bark up the wrong tree.
REF: Postposer ce vote une fois de plus eut été se tromper de cible.
HYP: Reporter ce vote une fois de plus, c'est se tromper d'arbre.

Blocklists
bark→ {aboyer, ecorces, ecorce}
up→ {debout}
the→ {le, la, les}
wrong→ {faux, tort, errone, mal}
tree→ {arbre, arbres, sapin, arborescence}

ERROR: Blocklist triggered by {arbre}

SRC: For companies, using technology to gather important data, its like bread and butter.
REF: Pour les sociétés, utiliser la technologie pour recueillir des données, c'est la routine.
HYP: Pour les entreprises, utiliser la technologie pour collecter des données importantes, c'est comme du pain et du beurre.

Blocklists
bread→ {pain}
and→ {et}
butter→ {et, pain, beurre}

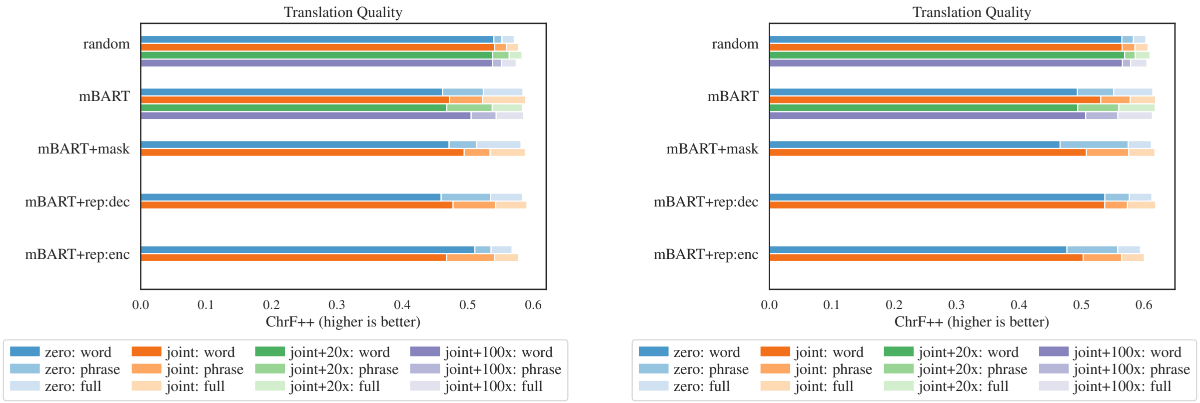
ERROR: Blocklist triggered by {et, pain, beurre}

SRC: And here is some eye candy for you, from a range of DIY scientists and artists from all over the globe.
REF: Et voici quelques bonbons pour vos yeux, de la part d'un éventail de scientifiques et des artistes bricoleurs de tous les coins de la planète.
HYP: Et voici quelques bonbons pour les yeux, d'une gamme de scientifiques et d'artistes du bricolage du monde entier.

Blocklists
eye → {oculaire, oeil, yeux, œil}
candy → {bonbon, bonbons, sucrerie}

No error detected.

Figure 16: Examples of LiTER evaluation on sentences in our en→fr idiom test set. In the first two examples, the model makes a literal translation error and the error is captured by LitTER. In the third example, the literal translation is correct and the blocklist is not triggered, thanks to the 3rd step in our algorithm (§ 2.1).



(a) Results for the en→fr models.

(b) Results for the en→es models.

Figure 17: Variation in translation quality, measured in ChrF, as we vary the idiom representations. The length of each (lighter) bar encodes the difference from its (darker) bar to its left (i.e., overlapping bars effect). The darkest shades correspond to using the full (original) context for encoding idiom words, and each lighter shades correspond to narrower contexts. Overall, the results are consistent, with the exception of the “mBART+replace(enc)” model.

D Analysis

In this section we present all of our analysis results. Specifically, we include results on en→es, with the (mBART) pretrained models finetuned with different noising methods, and additional probes. For the noisy versions of mBART finetuning, we present results on the zero and joint split. Recall that, in most of our probes, we evaluate the role of (idiom) context idiom translation. To do this, we encode the idiom words within different contexts and compare how this affects various aspects of each model. Figure 4, illustrates the process by which we obtain the encoding for each context. We consider the following context: (1) *full context*, in which we encode the idiom phrase within the whole input sentence, (2) *phrase-level context*, in which we encode together only the words idiom phrase, (3) *word-level context*, in which we encode each idiom word independently.

Figure 18, shows a visual example of how this probe works.

D.1 Variation in Translation Performance

With this probe, we test how the variation of the idiom encoder representations is reflected in the translation output. Figure 18, shows a visual example of how this probe works. First we encode each input sentence and then replace the encoder output representations belonging only to idiom words with those obtained with different (narrower) contexts. Finally, we decode each encoder output sequence and compare the generated translation to the reference translation.

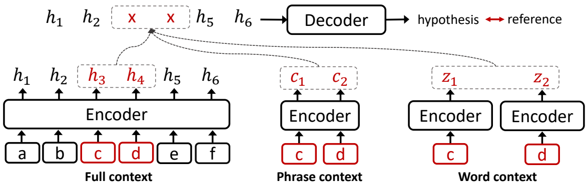


Figure 18: Illustration of how we probe the impact of different idiom contexts on translation quality. First, we obtain each sequence of idiom token representations, by encoding them within different contexts. Then we feed each sentence to the encoder, and before passing its outputs to the decoder, we replace the idiom token representations with those whose context we want to probe. Finally, we sample a translation from the decoder and compare it against the reference.

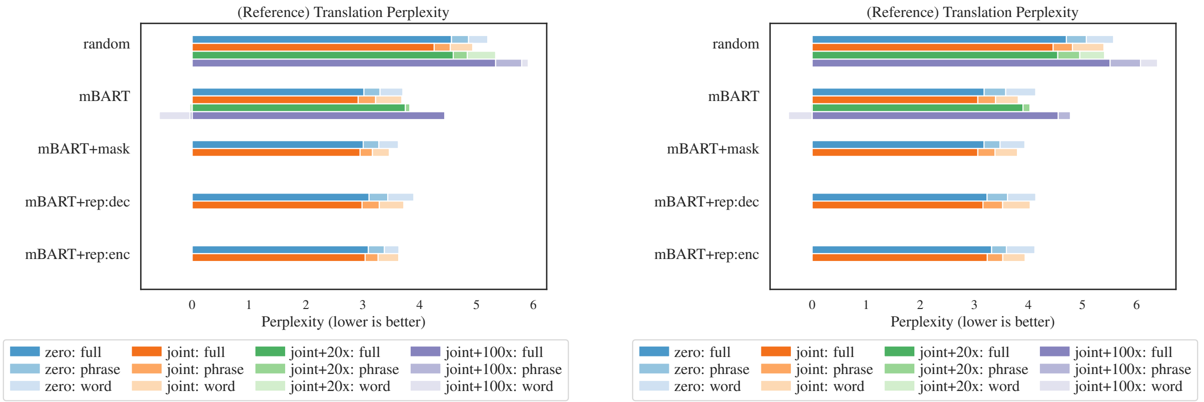
We observe that when using the full context, the results are generally consistent across language pairs and models. As we discussed in the main paper, the mBART-initialized model suffers greatly when the idiom representations are encoded with narrower context, in contrast to the randomly initialized model. We believe this is an indication that the mBART-initialized model is less local, meaning that each token representation contains to a large degree information about the rest of the tokens. We also observe that this behaviour is exhibited by all pretrained models.

However, while results are generally consistent in both language pairs, we do see some *small* discrepancies as we probe the effects of narrower contexts, in particular for the “mBART+replace(enc)” model. We do not have a satisfying explanation for this performance difference, which occurs only



(a) Results for the en→fr models.

(b) Results for the en→es models.

Figure 19: Variation in perplexity of reference translations, as we vary the idiom representations. The length of each (lighter) bar encodes the difference from its (darker) bar to its left. Negative bar lengths indicate a decrease relative to the (darker) bar before it. The darkest shades correspond to using the full (original) context for encoding idiom words, and each lighter shades correspond to narrower contexts.

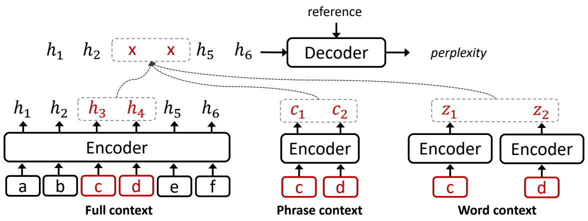


Figure 20: Illustration of how we measure the effects of different idiom contexts on translation likelihood (perplexity). First, we obtain each sequence of idiom token representations, by encoding them within different contexts. Then we feed each sentence to the encoder, and before passing its outputs to the decoder, we replace the idiom token representations with those whose context we want to probe. We use the sequence of encoder outputs, to score the reference translation.

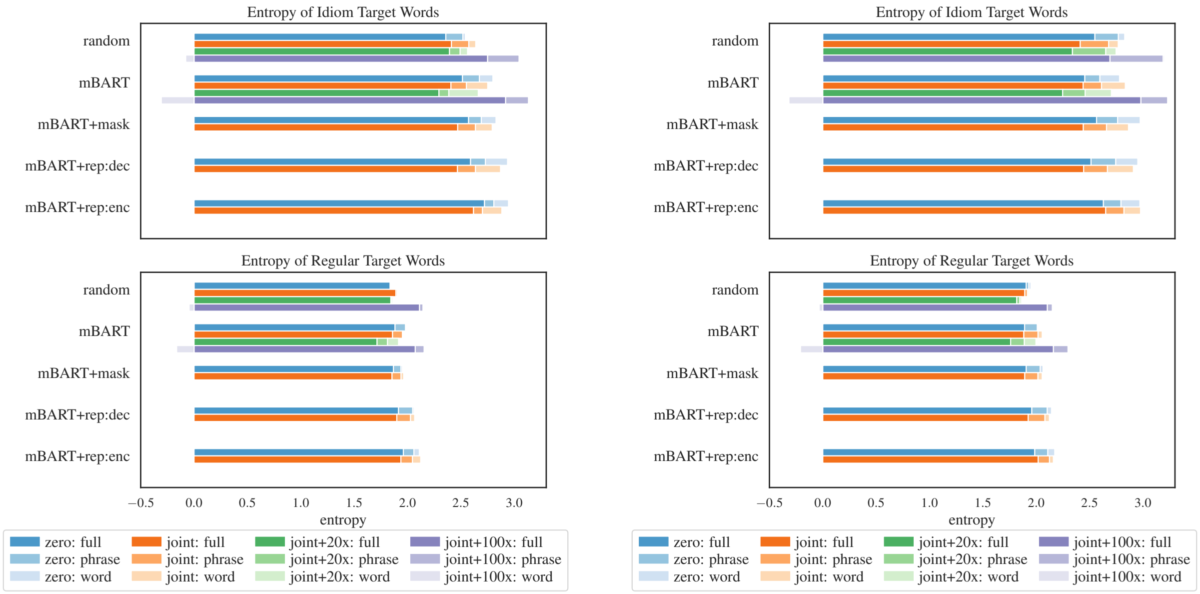
when we encode idioms with word context.

D.2 Variation in Translation Likelihood

With this probe, we test how the variation of the idiom encoder representations affects the likelihood of the reference translations. Figure 20, shows a visual example of how this probe works. Specifically, we translate a sentence pair with teacher-forcing, but we replace the encoder idiom token representations, before passing them to the decoder, with the representations obtained after encoding them with different contexts. Finally, we measure the perplexity of the reference translation under the model. Figure 19, compares models across splits and contexts.

Overall, the results are very consistent across both language pairs and all model variants. We also observe that the behaviour of all the noisy finetuned mBART models very similar behaviour, across all contexts. However, there is a small increase in the perplexity assigned under the "mBART+replace(dec)" variant. This is expected, as this model was trained with decoder dropout, which affect the LM capabilities of the model, and consequently makes it assign an overall smaller probability to all sentences. This increase in perplexity is observed in both language pairs, but is more pronounce in en→fr.

The more we upsample the idiom-train sentence pairs, the less probable other sentences become under the model. Surprisingly, 100x upsampling causes the pretrained model to yield lower perplexity with narrower context (i.e., lighter bars have negative length), "reverting" some of the effects of overfitting. However, we don't have a satisfying explanation for this behaviour[11]. This phenomenon is observed in both language pairs.



(a) Results for the en→fr models.

(b) Results for the en→es models.

Figure 21: Comparison of model uncertainty during the translation of regular-vs-idiom words. The length of each (lighter) bar encodes the difference from its (darker) bar to its left. Negative bar lengths indicate a decrease relative to the (darker) bar before it.

D.3 Decoder Uncertainty

Next, we focus on how the token-level uncertainty of the decoder varies while it translates idiom vs. non-idiom words (Figure 8). For each model, first, we translate each sentence pair with teacher-forcing[12]and then measure the entropy of the decoder's distributions for each target token.

Once more, this probe reveals that the models in both language pairs behave similarly. As mentioned in the main paper, the distributions of words that translation the idiom phrase have significantly larger entropy that the rest. This demonstrates that the models clearly are much more uncertain when translating idioms, even the pretrained ones.

Including and upsampling 20x the idiom-train data is helpful, but extreme upsampling (i.e., 100x) is universally harmful, although we observe a drop in uncertainty with word-level context. This is more pronounced when translating idiom words and suggests that models have overfitted to the words of the idiom phrases.

Representation biases in sentence transformers

Dmitry Nikolaev **Sebastian Padó**
IMS, University of Stuttgart
`dnikolaev@fastmail.com` `pado@ims.uni-stuttgart.de`

Abstract

Variants of the BERT architecture specialised for producing full-sentence representations often achieve better performance on downstream tasks than sentence embeddings extracted from vanilla BERT. However, there is still little understanding of what properties of inputs determine the properties of such representations. In this study, we construct several sets of sentences with pre-defined lexical and syntactic structures and show that SOTA sentence transformers have a strong nominal-participant-set bias: cosine similarities between pairs of sentences are more strongly determined by the overlap in the set of their noun participants than by having the same predicates, lengthy nominal modifiers, or adjuncts. At the same time, the precise syntactic-thematic functions of the participants are largely irrelevant.

1 Introduction

Transformer-based encoder-only models derived from the BERT architecture and pre-trained using similar objective and training regimens (Devlin et al., 2019; Liu et al., 2019) have become the standard tool for downstream tasks at the level of individual tokens and token sequences (Tenney et al., 2019; Wang et al., 2021). Whole-sentence representations can also be easily extracted from the outputs of these models by either using the embedding of the special [CLS] token, in cases where the model was trained on the next-sentence-prediction task, or averaging or max-pooling the embeddings of all tokens produced by the model (Zhelezniak et al., 2019). While both approaches are widely used in practice, it has been argued that these representations are not well suited for sentence-level downstream tasks. Several modifications to the architecture and training regime were proposed, which are known collectively as sentence transformers (STs; Reimers and Gurevych, 2019).

STs have achieved state-of-the-art performance on downstream tasks such as semantic search and question answering (Santander-Cruz et al., 2022; Ha et al., 2021). Their analysis, however, has received considerably less attention than the analysis of the vanilla BERT model and its variants (Rogers et al., 2020; Conia and Navigli, 2022). In fact, these models are often considered to be uninterpretable (Minaee et al., 2021).

A common feature of STs is that they are fine-tuned to produce similar vector-space representations for semantically similar sentences. This objective induces a complex loss landscape shaped by the available training data. The original Sentence-BERT model (Reimers and Gurevych, 2019) was trained on natural language inference data, and sentences were considered to be semantically similar if their NLI label was that of entailment. SOTA models were trained on a much larger web-crawled corpus including more than 1 billion sentence pairs mined from sources such as Reddit conversations, duplicate question pairs from WikiAnswers, etc.[1] The richness and variability of this dataset begs the question of what notion of semantic similarity is implicitly learned by the models trained on it.

In this study, we begin addressing this question through analysis of natural-looking synthetic sentences with controlled syntactic and lexical content. We concentrate on three questions.

First, we test if STs have part-of-speech biases. We show that, all other things being equal, information provided by nouns plays more important role than the information provided by verbs, both in simple sentences and in sentences with coordinated verbal phrases.

Second, we compare the relative importance of the overlap in the sets of participants in two sentences with that of how many participants have identical syntactic functions. We show that raw lexical overlap is relatively more important than having the same nouns in the same syntactic slots.

Third, we check how strongly sentence representations are affected by other sentential elements, such as adverbials and nominal modifiers of different types and lengths. We show that, unlike BERT with token averaging, STs seem to largely disregard these components in favor of nominal participants.

The paper is structured as follows: § 2 presents the methodology that we follow in our analyses and the models we employ; § 3 presents the case studies and their results; § 4 provides an overall discussion; § 5 surveys related work; § 6 concludes the paper.

2 Methods and Experimental Setup

We experiment with representations produced by three models. Two are SOTA STs: `all-mpnet-base-v2` (MPNET) is an instance of `mpnet-base` (Song et al., 2020) fine-tuned on the 1B sentence-pair corpus using the training architecture from Reimers and Gurevych (2019); `all-distilroberta-v1` (DistilRoberta) is a distilled instance of `roberta-base` (Sanh et al., 2019) fine-tuned in the same way. The third model is the vanilla pre-trained `bert-large-uncased` (BERT), as a point of comparison for the first two.

All models were downloaded from HuggingFace. Standard APIs from the Sentence Transformers library[2] were used to compute embeddings using MPNET and DistilRoberta; for the vanilla BERT model, we averaged the embeddings of all sentence tokens, including [CLS] and [SEP].[3]

We structure the presentation as a series of case studies. For each case study, we construct a set of sentences controlled for lexical content and syntactic structure. Sentences are created in such a way as to be grammatically correct, look naturalistic, and as far as possible not bias the analysis.[4] They are arguably less complex and variable than examples sampled from real-word corpora; however, we believe that an analysis based on simple sentences is a reasonable first step towards a better understanding of model representations, as previous work has shown for sentiment analysis (Kiritchenko and Mohammad, 2018) and syntactic analysis (Marvin and Linzen, 2018).

For each case study, we compute embeddings for all sentences, together with cosine similarities between embeddings of sentence pairs. We analyze the similarities by means of regression modelling. More precisely, we regress cosine similarities, z-scored to improve comparability between encoders, on the properties of sentence pairs, such as lexical overlap, presence of identical participants in identical syntactic positions, or POS tags of participants. We inspect the coefficients of the resulting regression fits to assess the relative importance of these properties. Since (almost) all properties are coded as binary variables, their magnitudes are directly comparable in terms of importance.

For terminological clarity, we will use the term *models* to refer to the regression models we use to analyse the impact of sentence properties on representational similarity. We call the transformers computing these embeddings *encoders*.

Where the features of sentence pairs can be straightforwardly related to simple properties of individual sentences (e.g., in case when we are testing if they have the same subject or direct object), we also project sentence embeddings on a 2-D surface using UMAP (McInnes et al., 2018)[5] and check if the spatial organisation of the points is in line with our observations.

Lexical choice A potential confound of our experimental setup is lexical choice, which is never completely neutral. For example, by taking a semantically close pair of verbs, we can considerably reduce the effect of predicate mismatch between two sentences. Moreover, encoders can react idiosyncratically to particular words and word combinations. Including all combinations of words and their positions in sentence pairs as predictor variables is not a solution, however, as it defeats the purpose of identifying structural patterns and, in the limit, amounts to replicating the encoders. We address this confound in three ways.

First, we select nouns to be always at least as interchangeable as words of other parts of speech in terms of belonging to similar mid-to-high frequency bands and referring to conceptually simple, concrete objects. This follows from our working hypothesis that encoders give preferential treatment

---

[2] `https://www.sbert.net/index.html`, Reimers and Gurevych (2019).

[3] We experimented with omitting the special tokens, but this led to sentence representations dominated by punctuation signs and other undesired effects. In line with previous work (Ma et al., 2019), we also found that using [CLS] embeddings leads to bad results due to their high redundancy, and we do not discuss them.

[4] Sentence-generating and model-fitting scripts can be found in the Supplementary Materials.

[5] We use the default settings and pairwise cosine dissimilarities as distance measure.

to nominal elements, whose (generally entity referring) semantics is arguably easier to capture than, for example, that of (generally event referring) verbs (Baroni and Lenci, 2011).

Second, we compare the analysis of the ST encoders against the analysis of the vanilla BERT encoder. As they are derived from averaging, vanilla BERT embeddings treat all words equally, so if our sentences, e.g., undersell differences in adverbs because we chose two nearly synonymous ones, this should be visible in the small coefficient tracking the impact of adverbs in the regression model based on BERT embeddings. As will be shown below, however, the hierarchy of coefficients for regression models of STs is very different from that for vanilla BERT, which arguably indicates that the role of lexical effects is minor.

Third, we re-run all reported models on sentences of the same structure with different lexical content; see the Appendix for details. We observe high stability of coefficients across replications, higher for STs than for vanilla BERT. This further corroborates the validity of our generalisations.

3 Case Studies

This section presents a series of case studies testing the sensitivity of embeddings produced by sentence transformers and BERT token averages to properties of input sentences. We start with analysing simple intransitive sentences (§ 3.1) and simple transitive sentences (§ 3.2). We then make specific aspects of the structure more complex, analysing the effect of lengthy NPs (§ 3.3) and coordinated VPs (§ 3.4). Finally, we look more closely at the syntax-semantics interface by inverting the prototypical alignment of POS tags and syntactic functions (predicative nominals and gerund subjects, § 3.5) and by testing the degree to which encoders track particular syntactic functions of verb arguments (§ 3.6).

3.1 Simple Intransitive Sentences

Data The main goal of the analysis of simple intransitive sentences is to check the relative contribution of their components to their embeddings. We study a nearly-minimal sentence template with a nominal subject, an adverbial adjunct, and an intransitive verb. We construct a set of 256 sentences of the form '[det] [subj] [adverb] [verb][punct]', where `det` ranges over {*a*, *the*}; `subj` ranges over a set of nouns,[6] `adverb` ranges over {*quickly*, *slowly*}, `verb` ranges over {*appears*, *vanishes*, *stops*, *moves*}, and `punct`, over {., *!*}. Here and in subsequent experiments, the generation procedure assures that all sentence features are statistically independent, which is a crucial prerequisite for linear-regression modelling.

SameAdv	0.33	0.31	0.45
SamePred	0.74	0.61	0.58
SamePunct	0.24	0.24	0.84
SameSubj	2.26	2.40	1.27
R-squared	0.67	0.71	0.48

Table 1: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with intransitive verbs. All coefficients are significant with $p < 0.001$.

Model The regression model matrix is based on 32,640 pairs of generated sentences, which differ in the value of at least one feature, with predictor variables SameDeterminer, SameAdverb, SameVerb, SamePunct, and SameSubj. We regress z-score-transformed cosine similarities between sentence embeddings computed by three different encoders on these predictor variables. The coefficients of the fitted models are shown in Table 1.[7]

Results Three observations from Table 1 hold for all subsequent analyses.

(i) The coefficients are positive for all models and all features. This means that sentence pairs which agree in some constituent are always more similar than sentence pairs that do not – as expected.

(ii) The coefficient of determination (R^2) is larger for ST-focused linear models. This means that the embeddings computed by the ST encoders are more dependent on the features of the sentences we track and less dependent on identities of lexical units. (It can be noted that the fact that we achieve $R^2 \approx 0.7$ using only a few structural properties is remarkable in itself.)

(iii) The differences among coefficients of the ST-focused linear models are in general larger than

[6] {*cat*, *dog*, *artist*, *teacher*, *planet*, *star*, *wind*, *rain*}

[7] Replication models, fitted on sentences with the same structure but different lexical content, are shown in Table 8 in the Appendix.

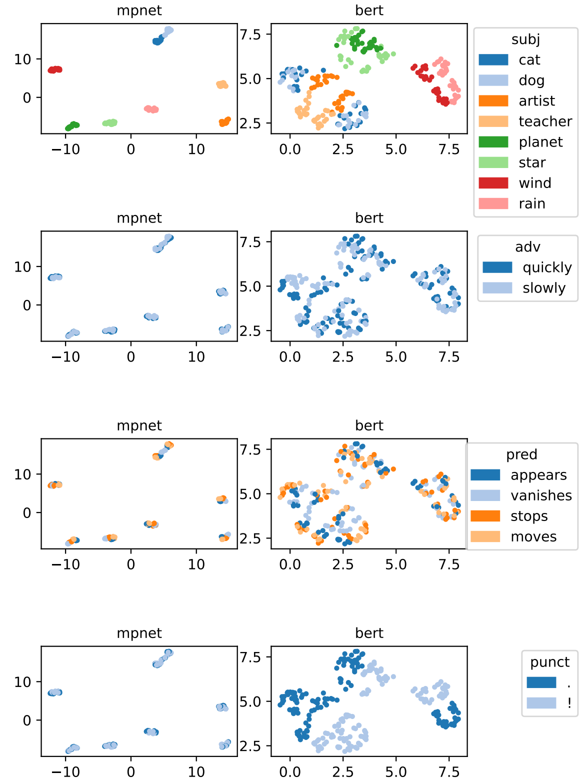

Figure 1: UMAP projections of embeddings of sentences with intransitive verbs (left: sentence transformer, right: BERT).

those of the linear model analysing BERT: in the latter, the biggest coefficient (1.27 for SameSubj) is only ≈ 3.5 times higher than the smallest one (0.37 for SameDet), while for the ST models this ratio is above 30. This is connected to the fact that BERT-derived sentence representations are more dependent on semantically impoverished elements, such as determiners and punctuation signs, which dampen the effect of other constituents. For the sake of brevity, we do not analyse determiners and punctuation in subsequent experiments and keep them constant as *the* and . respectively.

Turning to the comparison of coefficients inside models, we see that STs pay considerably more attention to subjects than to predicates: all things being equal, sentences with different predicates and adverbs but the same subject will be more similar than sentences with the same predicate and adverb and different subjects. The influence of punctuation is surprisingly strong, being comparable to that of adverbs, while the effect of determiners is very weak, albeit statistically significant.

A plot of UMAP projections of sentence embeddings produced by MPNET and BERT, shown in Figure 1, underlines that while averaged BERT embeddings distinguish punctuation signs but do not distinguish subjects, the situation is reversed for the sentence transformer: it distinguishes subjects cleanly but largely abstracts away from other structural properties.

3.2 Transitive Sentences

Data The transitive sentences used in the analysis are generated using the following template: 'The [subj] [adverb] [verb] the [obj].' The range of nouns was slightly extended;[8] the same adverbs as in the previous experiment were used, while `verb` ranged over {*sees*, *chases*, *draws*, *meets*, *remembers*, *pokes*}. This produces 672 different sentences and 225,456 sentence pairs.

Model The coding for SameAdv and SamePred remains as above. The main focus in this study is on whether sentence similarities are dominated by the sentences having the same subject, the same direct object, or the same words in these two positions even if their order were reversed. To test for this, we added a categorical variable with the following values:

00 no overlap in subject and object (the baseline);
A0 same subject, different objects;
0B same object, different subjects;
0A the subject of the first sentence is the object of the second;
B0 the object of the first sentence is the subject of the second;
BA subject and object are swapped;
AB the same subject and object.

Results A summary of the fitted models is given in Table 2.[9] It demonstrates that when it comes to simple transitive sentences, our understanding of their embeddings produced by sentence transformers remains high, despite the sentences being more complex ($R^2 \approx 0.7$), while BERT embeddings become more unpredictable ($R^2 \approx 0.31$). Furthermore, while BERT again essentially treats all tokens more or less equally, with adverbs slightly discounted, STs prioritise participants (even B0 has higher coefficients than SamePred).

On the other hand, neither BERT nor STs prioritise the exact syntactic function of the participants: coefficients for A0 vs. 0A, 0B vs. B0, and AB vs.

SubjObj_0B	1.31	1.45	0.69
SubjObj_A0	1.44	1.45	0.75
SubjObj_AB	2.98	3.08	1.60
SubjObj_B0	1.37	1.42	0.58
SubjObj_BA	2.85	2.98	1.39
R-squared	0.74	0.73	0.31

Table 2: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with transitive verbs. All coefficients are significant with $p < 0.001$.

BA are largely comparable across all models with $BA \approx A0 + 0B$. That is, the effects of subjects and objects are largely independent of one another.

A UMAP plot with the embeddings for the transitive sentences is shown in Figure 2 in the Appendix. It demonstrates that STs arrive at a much more fine-grained clustering of sentences, largely dominated by subjects and objects. They largely discount predicates and adverbs which are quite prominent in averaged BERT embeddings.

3.3 Transitive Sentences with Long NP Modifiers

The previous analyses showed that representations computed by STs are highly attuned to verb participants but not to their particular syntactic roles. This may mean that ST may be potentially misled by nouns in other positions in the sentence, which have less relevance to the described situation. This study explores this possibility.

Data We repeat the analysis from § 3.2 using the template of the form 'The [subj] [modifier] [adverb] [verb] the [obj]', with a smaller set of subjects,[10] and the `modifier` ranging over {*with big shiny eyes*, *that my brother saw yesterday*, *whose photo was in the papers*, *worth a great deal of money*}. Altogether this gives 1,440 sentences and 1,036,080 sentence pairs. The modifiers have internal syntactic structure and contain a non-negligible amount of lexical material that the models have to 'skip over' if their representations were focused on the participant structure of the matrix clause.

R-squared	0.73	0.81	0.61

Table 3: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with transitive verbs and lengthy subject modifiers. All coefficients are significant with $p < 0.001$.

Model The same coding strategy as in the preceding section is used, augmented by a new binary variable, SameMod, tracking whether two sentences have the same modifier for the subject.

Results Both the model coefficients, shown in Table 3, and the UMAP plot, shown in Figure 3 in the Appendix, indicate that BERT embeddings are highly sensitive to lengthy modifiers:[11] the SameMod coefficient in the linear model is larger than the coefficients for the same predicate and the same subject-object combination added together. The situation is very different for STs: SameMod is more important than SamePred, especially for DistilRoberta, but, with one exception, not more important than even a partial overlap in participants. Having the same participants, in either the same or swapped syntactic functions, is more than twice as important. We take this as evidence that STs have a specific bias towards matrix-clause *participant sets*, that is, the nouns that fill a thematic role of the main predicate, while their precise functions and nouns found in other positions in the sentence are less important.

3.4 Coordinated Verbal Phrases

The analyses presented above show that the main predicate of the sentence has only a limited influence on the representations computed by STs, compared to its subjects and objects. Here, we show that this effect still holds if there is more than one main predicate.

---

[10] {*cat*, *dog*, *rat*, *giraffe*, *wombat*, *hippo*}

N3Same	**0.56**	**0.57**	**0.41**
R-squared	0.11	0.1	0.09

Table 4: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with coordinated VPs from binary predictors. All coefficients are significant with $p < 0.001$.

Data Using the same sets of nouns and transitive verbs as in the previous experiment, we construct sentences of the form 'The man [verb1] the [noun1], [verb2] the [noun2], and [verb3] the [noun3]', where triples of verbs and nouns are taken from the Cartesian product of the sets of all noun and verb combinations of size 3 without replacement. To alleviate a possible ordering bias, all verb and noun triples are shuffled for each sentence. This results in 400 sentences and 79,800 sentence pairs.

Models and results The analysis proceeds in three stages. First, we check if positions 1, 2, and 3 have different importance by regressing the normalised cosine similarity on six binary variables N[oun]1Same, V[erb]1Same, N2Same, etc. The models, summarised in Table 4,[12] show low coefficients of determination (with R^2 around 0.1), but they indicate that positions are of unequal importance: BERT gives more weight to the last noun and the last verb, while STs focus on the first and the last N-V pair and largely ignore the second one.

A significantly better fit can be achieved by replacing binary predictors with overlap scores for nouns and verbs. As Table 5[13] shows, this type of model, even though it contains only 2 variables instead of 6, obtains $R^2 \approx 0.65$ for STs. It is also evident that all three models place more weight on noun overlap than on verb overlap, with DistilRoberta showing the biggest difference between the two.

	mpnet	distilroberta	bert
VerbOverlap	0.78	0.59	0.64
NounOverlap	0.93	1.09	0.88
R-squared	0.65	0.68	0.52

Table 5: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with coordinated VPs from overlap scores. All coefficients are significant with $p < 0.001$.

This raises the question of whether particular verb-noun collocations play a noticeable role, i.e., if a sentence containing *chases the wombat* will be considerably more similar to another sentence containing the exact phrase compared to a sentence containing *chases* and *wombat* but not as a trigram. Simply adding n-gram overlap scores to the model is not possible, however, because it is highly correlated with both noun overlap and verb overlap. In order to obviate this obstacle, we first construct an auxiliary linear model predicting trigram overlap from noun and verb overlap and then use the residuals of this regression in the main model.

The results are ambiguous: on one hand, the coefficient for residualised trigram overlap is statistically significant with $p < 0.001$. On the other hand, the effect is very weak (more than ten times weaker than that of either noun overlap or verb overlap), and the addition of trigram overlap to the model improves R^2 by less than 0.001. This seems to indicate that trigram overlap is not important for practical purposes.

3.5 Predicative Nominals with Gerund Subjects

A potential weak point of our analysis is that parts of speech and syntactic functions are not decoupled: it is not yet clear whether the encoders pay attention to nouns or to subjects and objects.

Data To address this issue, we construct another set of sentences where the subject is a gerund and the predicate is nominal. The template is '[gerund] [object] [copula] a [adjective] [predicate]', where `gerund` ranges over {*continuing*, *abandoning*, *starting*, *completing*}, object ranges over {*it*, *them*, *the project*, *the plan*}, copula is one of {*is*, *was*, *will be*, *is going to be*}, adjectives are {*big*, *real*, *negligible*, *insignificant*}, and the predicative nominal ranges over {*solution*, *mistake*, *failure*, *triumph*}. This gives 1024 sentences and 523,776 sentence pairs. A variable copula provides an additional test as to whether the sentence encoders can recognise

---

[12] A summary of the replication fits is given in Table 11 in the Appendix.

[13] See Table 12 in the Appendix for the replication fits.

	mpnet	distilroberta	bert

SameAdj	0.58	0.79	0.50
SamePred	0.99	1.01	0.52
SameObjNoun	1.01	1.04	0.60
SameObjPron	0.44	0.50	0.42
R-squared	0.50	0.54	0.22

Table 6: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with gerund subjects and nominal predicates. All coefficients are significant with $p < 0.001$.

multi-word sequences with low semantic content.

Model The sentence pair encoding includes four binary variables (SameSubj, SameCop, SameAdj, SamePred) and a nominal variable for the direct object, indicating whether objects are different (baseline), are identical and pronominal (SamePron), or are identical and nominal (SameNoun).

Results The results in Table 6[14] demonstrate that all models treat both nominal predicates and nominal direct objects as more important than gerund subjects. STs, moreover, pay less attention to identical pronominal objects and discount multi-word copula forms. R^2 values for the ST model are lower than in the previous experiments (in the 0.50–0.55 range), which may potentially indicate a poor choice of lexical items; however, replication experiments with a different set of words (except for copula forms) achieved comparable results. This suggests that embeddings of sentences of this type are less easily explainable as additive combinations of individual words compared to the sentence types surveyed previously.

3.6 Revisiting Participant Sets: Ditransitive Sentences

Our final experiment revisits the opposition between lexical overlap in verbal phrases and exact argument-predicate matching. In this case, we focus on ditransitive verbs with two arguments: a direct object and an oblique object which is an integral part of the situation.[15]

	mpnet	distilroberta	bert
SameAdv	1.05	1.07	0.64
SamePred	0.93	0.64	0.83
Overlap	0.90	1.00	0.91
SPCRes	0.03	0.02	0.10
R-squared	0.745	0.738	0.57
R-squared (w/o SPCRes)	0.744	0.737	0.56

Table 7: A summary of the models predicting z-scored pairwise cosine similarities between embeddings of sentences with ditransitive verbs. SPCRes stands for SamePosCountRes, i.e. the residuals of the number of identical words in identical positions regressed on lexical overlap. All coefficients are significant with $p < 0.001$.

Data All permutations of the triple of basic nouns {*cat*, *dog*, *rat*} are generated. For each permutation, all three nouns are, in turn, replaced with one of the members of the set of extra nouns {*giraffe*, *wombat*, *hippo*}; the original permutations are also used. This provides a set of unique triples of nouns where each pair of triples has from one to three nouns in common. The Cartesian product of this set of triples with a set of ditransitive verbs ({*describes*, *sells*, *shows*}) and a set of adverbs ({*happily*, *quickly*, *secretly*) is used to fill the template 'The [noun1] [adverb] [verb] the [noun2] to the [noun3].' This procedures gives 540 sentences and 145,530 sentence pairs.

Model The sentence pairs are coded for same adverb, same predicate, the number of matching nouns in matching positions (SamePosCount), and lexical overlap minus 1 (the baseline value of 0 corresponds to overlap of 1; each successive value corresponds to increase in overlap). As with overlapping words and trigrams above, these predictors are correlated. Therefore, we residualise SamePosCount after regressing it on lexical overlap.

Results Table 7 is inconclusive in a similar way to results from § 3.5. The coefficients for residualised SamePosCount are significant; however, in the ST models, their size is very small, and SamePosCount does not materially improve the predictive power. We conclude, therefore, that syntactic positions do not matter a great deal, in line with our 'participant set' interpretation from § 3.4.

---

[14] See an overview of replication fits in Table 13 in the Appendix.

[15] Many English ditransitive verbs can undergo the 'dative alternation', which swaps the oblique object with a prepositional phrase: *Give the book to me/John* vs. *Give me/John a book* (Levin, 1993). Of the verbs we use, *show* and *sell* participate in it, and the status of *describe* varies across speakers.

4 Discussion

Our analysis arguably goes some way towards explaining why sentence transformers beat vanilla BERT-based models with token averaging on sentence-modelling tasks. Token averaging makes it impossible to distinguish between semantically rich and impoverished sentence elements, nor between syntactically central vs. peripheral elements: punctuation signs and determiners contribute on the same level as the matrix-clause predicate and main participants, while lengthy modifiers, such as relative clauses, and multi-word copula forms dominate the representation.

Sentence transformers, on the other hand, learn to discount elements that only serve a grammatical function or present background information and focus instead on the semantic kernel of the sentence. The latter is in effect largely synonymous with the set of nominal elements in the main clause, first of all participants, but also predicative nominals. Importantly, despite their evident syntactic-analytic capabilities (e.g., in our setting they can distinguish between participants of main and relatives clauses and between main and auxiliary verbs), STs seem to not pay much attention to the distinction between subjects and direct or indirect objects. Instead they prioritise raw overlap in the set of nominal participants of the matrix clause. This can be seen, by slightly abusing terminology of theoretical linguistics, as a focus on the aboutness/topic of sentences, what things they describe, and not on their predication/comment, what they actually say about those things (Hu and Pan, 2009).

We believe that this focus is not inherent to the architecture of sentence transformers but reflects the nature of the datasets used for fine-tuning STs. The size of these datasets makes it impossible to convincingly reason about their contents, but their genres (QA pairs, Reddit threads, etc.) makes it plausible to expect a high degree of topic-based overlap: questions and conversations tend to revolve around entities (persons and things), with their actions and properties repeating less often. This naturally leads to a focus on nouns referring to prominent entities, which are known to appear preferentially as subjects or objects for reasons of coherence (Barzilay and Lapata, 2008), arguably a good match to the patterns we observe.

5 Related Work

Analysis of transformer-based models for sentence-level tasks, such as NLI, question answering, or text classification, has largely followed the same approaches as found in the general BERTology (Rogers et al., 2020): probing, analysis of the geometry of the embedding space, extraction of parts of input that are particularly important for model performance, and behavioural analysis. In this vein, Liu et al. (2021) and Peyrard et al. (2021) analyse the attention patterns powering the performance of transformer models on different types of sentence classification, and Li et al. (2020) show that embeddings of sentences computed by BERT-based models, including siamese-fine-tuned sentence transformers, are anisotropic and can be improved via normalisation. Chrysostomou and Aletras (2021) survey the existing methods for extracting rationales from input sentences in the context of text classification and propose an improved approach, while Luo et al. (2021) demonstrate that sentence embeddings derived by averaging BERT token representations suffer from artefacts arising from positional embeddings. Zhelezniak et al. (2019) argue that averaging should be replaced with max-pooling.

Very similar to ours is the approach adopted by MacAvaney et al. (2022), who construct a series of probes to analyse the performance of several models on the task of information retrieval. While their methodology relies on high-level document statistics and wholistic document manipulation (word and sentence shuffling, token-frequency similarity between the document and the query, textual fluency, etc.), our study analyses the role of linguistically motivated structural factors and thus complements their findings.

Opitz and Frank (2022) aim at directly decomposing the representations produced by sentence transformers into several parts capturing different properties of sentences reflected in AMR annotations (presence of negation, concepts included in the sentence, etc.). While our study tries to ascertain what meaning components dominate the representations, Opitz and Frank assume that these components are known in advance and are equally important: sentence embeddings in their modified SBERT model are split into 15 segments, each of which corresponds to one AMR-based meaning component, plus a residual part to capture everything not covered by AMR annotations.

6 Conclusion

This paper aims at making a contribution towards a better understanding of sentence transformers, which are often seen as black boxes. We have demonstrated that we can make surprisingly precise inferences about sentence-pair similarities using simple linguistic features such as lexical overlap.

The crucial difference between bag-of-words distributional models and current encoders is that STs have became quite adept at disregarding 'irrelevant' parts of the sentence and concentrating on its key elements. Unlike vanilla BERT sentence embeddings obtained by token averaging, STs yield more structured embeddings that focus on the matrix clause and are less tied to individual lexical items and strings of function words.

This progress, however, comes with a particular type of bias: the structures that lead to high sentence similarity in STs, i.e. the overlap in nominal 'participant sets', seem to mirror the dominant type of paraphrases found in the data the STs were tuned on, and STs are not compelled to look at finer structures of input sentences. At least without further fine tuning, this would appear to make them unsuitable for downstream tasks that require knowledge about more fine-grained aspects of sentence structure, such as semantic roles (Conia and Navigli, 2022), or extra-propositional aspects, such as monotonicity, negation, or modality (Yanaka et al., 2021; Nakov, 2016).

An interesting direction for future research would be to explore the ways of decomposing sentence representations into additive aspects such as participant structure, main predication, etc. The additional challenge here is that while theoretical semantics has a lot to say about aspects of sentence meaning (Pagin, 2016), there remains a lack of analysis linking the notion of one-dimensional *semantic similarity* (Agirre et al., 2012) that underlies the optimisation of current sentence transformers with theoretically more substantial concepts.

Limitations

The limitations of the proposed analysis are the following:

1. The analysis is based on synthetic data. This allows us to fully control the sentence structure and use balanced lexical material, but it does not necessarily reflect the performance of models on real-world data, especially when sentences or text fragments are much longer. However, synthetic data have generally shown to be a good first step toward understanding the behaviour of complex models.
2. The analysis does not cover graded distinctions between words, i.e. we did not experiment with filling the slots with synonymous words, as opposed to completely unrelated words. This makes it impossible to decide if the models are sensitive to word identities or to their actual semantics, as long as these two notions are distinguishable.
3. The outputs of the models are interpreted using linear regression analysis anchored to the properties of synthetic sentences. This kind of analysis makes it possible to disentangle additive effects of different components of sentence structure and provides statistical-significance estimates, while high R^2 values indicate that our findings have some validity. However, it cannot fully account for the lexical effects (which we tried to safeguard against by carefully selecting template fillers), non-linear effects, and hidden collinearity patterns (beyond those we addressed using residualised analysis).
4. The range of models analysed in the paper is restricted. It covers some amount of variability (sentence transformers vs. vanilla BERT; two different variants of a base model for STs, one of them distilled), but other combinations of model architecture and training/fine-tuning regime can lead to different outcomes.

Abstract

Creating an abridged version of a text involves shortening it while maintaining its linguistic qualities. In this paper, we examine this task from an NLP perspective for the first time. We present a new resource, AbLit, which is derived from abridged versions of English literature books. The dataset captures passage-level alignments between the original and abridged texts. We characterize the linguistic relations of these alignments, and create automated models to predict these relations as well as to generate abridgements for new texts. Our findings establish abridgement as a challenging task, motivating future resources and research. The dataset is available at github.com/roemmele/AbLit.

1 Introduction

An abridgement is a shortened form of a text that maintains the linguistic qualities of that text[1]. It is intended to make the original text faster and easier to read. In this paper, we propose abridgement as an NLP problem and describe its connection to existing inference and generation tasks. We present a novel dataset for this task, focused on abridged versions of English literature books, which we refer to as the AbLit dataset. We demonstrate the characteristics of AbLit in terms of the relations between original and abridged texts as well as the challenges of automatically modeling these relations. The dataset and all associated code, including a Python package for easily interfacing with the data, are available at: github.com/roemmele/AbLit.

2 The task of abridgement

2.1 Definition

We define abridgement as the task of making a text easier to understand while preserving its linguistic qualities. As such, abridgement intersects with tasks that fuse natural language inference (NLI) and natural language generation (NLG), in particular summarization and simplification.

Summarization condenses the main content of a text into a shorter version in order to facilitate high-level comprehension of the content. Existing research has used the categories of *extractive* and *abstractive* to describe summaries. In the former, the summary 'extracts' sequences from the text, whereas in the latter the summary 'abstracts' out the meaning of the text and rewrites it. The degree of abstractiveness of a summary is indicated by how much novel text it contains that is not directly in the original text. Like a summary, an abridgement is shorter than its original text, but it preserves more of its language and can be seen as an alternative version rather than a meta-description. According to how summaries are characterized, abridgements are highly extractive, even if some abstraction is needed to connect the extracted components.

Some work has examined summarization of narratives, including literary text (Kazantseva and Szpakowicz, 2010; Mihalcea and Ceylan, 2007; Zhang et al., 2019). Of particular relevance to our work are datasets released by Chaudhury et al. (2019), Kryściński et al. (2021), and Ladhak et al. (2020), all of which consist of summaries of fiction books. These summaries are significantly different from abridgements in that they are highly abstractive; they convey the book's narrative without preserving much of the text itself. Kryściński et al. provides summaries at different levels of granularity (book, chapter, and paragraph). Their analysis demonstrates that even the finer-grained summaries at the paragraph level are quite abstractive.

The task of simplification also aims to make a text easier to understand, but without significantly distilling its content. Simplification is often treated as a sentence-level task (Sun et al., 2021). Abridgement can be viewed as simplification on a docu-

---

[1] The term "linguistic qualities" is broad, which reflects other definitions of abridgement. For instance, the Wikipedia entry for "abridgement" specifies that it "maintains the unity of the source", but these dimensions of unity are tacitly defined.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3717–3733

ment level. It seeks to balance the goal of increasing readability with preserving as much of the original text as possible. Research on simplification has been constrained by a lack of high-quality publicly available datasets. Existing datasets have been derived from sources like Wikipedia (e.g. Coster and Kauchak, 2011) and news articles (Xu et al., 2015), but none have focused on literary text.

2.2 Practical application

There are few authors who perform abridgement, and thus relatively few abridged versions of books (Minshull, 2001). Authors have described it as challenging and time-consuming to discern what to modify without compromising the original author's agency (Lauber, 1998; Sussman, 1988). However, as touted by these authors, abridgement makes books more accessible to a larger audience, especially when delivering the content through non-text modes like audio (Lavin, 2014). Given this, automating the abridgement process could vastly expand the number of abridged versions of books and thus increase their readership. Automation does not preclude the involvement of human authors; for example, human translators use machine translation to increase their productivity (e.g. Zhechev, 2014), and the same paradigm could apply to abridgement.

3 Creating an abridgement dataset

The AbLit dataset is derived from 10 classic English literature books, listed in A.4. These books are in the public domain and available through Project Gutenberg[2]. A single author, Emma Laybourn, wrote abridged versions of these books that are also freely available[3]. The author explains:

> "This is a collection of famous novels which have been shortened and slightly simplified for the general reader. These are not summaries; each is half to two-thirds of the original length. I've selected works that people often find daunting because of their density or complexity: the aim is to make them easier to read, while keeping the style intact."

Informed by this, we designed AbLit to capture the alignment between passages in a text and its abridged version. We specify that an abridged and original passage are aligned if the content of the abridged passage is fully derived from the original.

After obtaining the original and abridged books from their respective sites, we detected chapter headings to split the books into chapters (see A.1 for details). We paired the original and abridged version of each chapter according to these headings. Obviously, the two versions already form a broad alignment unit, but our goal was to examine finer levels of alignment. We chose to use sentences as the minimal alignment units, since they are intuitive units of expression in text and can be detected automatically[4]. AbLit annotates sentence boundaries by indexing their position in the text, which enables all whitespace characters (most importantly, line breaks marking paragraphs) to be preserved.

3.1 Automated alignments

We pursued an automated approach to establish initial alignments between the original and abridged sentences for each chapter. It follows the same dynamic programming scheme used to create the Wikipedia Simplification dataset (Coster and Kauchak, 2011). We refer to a group of adjacent sentences in a text as a *span*. We define the length of a span by the number of sentences it contains. Each span o of length o_n in the original version of a chapter is paired with a span a of length a_m in the abridged version. The value of a_m can be zero, allowing for the possibility that an original sentence is aligned with an empty string.

For each pair of o and a, we use a similarity metric $sim(o, a)$ to score the likelihood that they are aligned. This scoring function also considers the length of the spans in order to optimize for selecting the narrowest alignment between the original and abridged text. For instance, if a one-to-one alignment exists such that the meaning of a single sentence in the abridgement is fully encapsulated by a single original sentence, these sentences should form an exclusive alignment. To promote this, we adjust $sim(o, a)$ by a penalty factor pn applied to the size of the pair, where $size = \max(o_n, a_m)$. Ultimately, the alignment score for a given span pair (o, a) is $\max(0, sim(o, a) - ((size - 1) * pn))$. Thus, more similar pairs obtain higher scores, but the scores are increasingly penalized as their size increases. At each sentence position in the original and abridged chapters, we score spans of all lengths $[1, o_n]$ and $[0, a_m]$, then select the one that obtains the highest score when its value is combined with the accumulated score of the aligned spans prior to

[3] englishliteratureebooks.com

[4] We used nltk.org for all sentence segmentation and word tokenization. For analyses pertaining to words, words are lowercased without any other normalization (e.g. lemmatization).

that position. Once all span pairs are scored, we follow the backtrace from the highest-scoring span in the final sentence position to retrieve the optimal pairs for the chapter. We refer to each resulting span pair (o, a) in this list as an alignment *row*.

3.2 Assessment of automated alignments

We applied this automated alignment approach to the first chapter in each of the ten books in ABLIT, which we designated as an *assessment* set for investigating the quality of the output rows. We instantiated $sim(o, a)$ as the ROUGE-1 (unigram) precision score[5] between the spans, where a is treated as the hypothesis and o is treated as the reference. Here we refer to this score as R-1_p. It effectively counts the proportion of words in a that also appear in o. We considered values of o_n in $[1, 6]$ and a_m in $[0, 6]$ and selected $o_n = 3$ and $a_m = 5$ based on our perceived quality of a sample of output rows. We similarly optimized pn values in $[0, 0.25]$ and selected pn = 0.175. Smaller values of pn yielded rows that were not minimally sized (i.e. they needed to be further split into multiple rows), whereas larger values tended to wrongly exclude sentences from rows.

The output consisted of 1,126 rows, which were then reviewed and corrected by five human validators recruited from our internal team. Validators judged a row as correct if the meaning expressed by the abridged span was also expressed in the original span, consistent with how alignment is defined above. A.3 gives more detail about this task. We found that inter-rater agreement was very high (Fleiss' κ = 0.984) and the few disagreements were easily resolved through discussion. The validators reported spending 10-15 minutes on each chapter.

After establishing these gold rows for the assessment set, we evaluated the initial automated rows with reference to the gold rows. To score this, we assigned binary labels to each pair of original and abridged sentences, where pairs that were part of the same row were given a positive class label and all other pairs were given a negative class label. Given these labels for the rows automatically produced with the R-1_p method compared against the labels for the gold rows, the F1 score of the automated rows was 0.967. We also evaluated other methods for computing $sim(o, a)$, but none outperformed R-1_p. See A.2 for the description of these alternative methods and their results.

3.3 Full dataset

Partial validation: The time spent validating this assessment set indicated it would require significant resources to review the rows for all 868 chapters across the 10 books. Meanwhile, our evaluation revealed that we can expect most automatically aligned rows to be correct. Thus, we considered how to focus effort on correcting the small percentage of erroneously aligned rows. We manually reviewed these rows in the assessment set and found that their R-1_p scores were often lower than those of the correct rows. Moreover, this tended to affect two types of rows: those with two or more sentences in the abridged span, or those adjacent to another row with an empty abridged span (i.e. a_m = 0). We did an experiment where a human validator reviewed only the assessment rows with scores < 0.9 that qualified as one of the two above cases. Selectively applying corrections to just these rows boosted the F1 score of the assessment set from 0.967 to 0.99. We thus decided to apply this strategy of partially validating automated rows to create the training set for ABLIT.

Final sets: To construct the rest of ABLIT, we ran the automated alignment procedure on all other chapters, and then applied the above partial validation strategy. Because we previously confirmed high inter-rater agreement, a single validator reviewed each chapter. Generalizing from the assessment set, we estimate that 99% of these rows are correct. To ensure an absolute gold standard for evaluation, we set aside five chapters in each of the ten books and fully validated their rows. We designated this as the test set, and repurposed the assessment set to be a development set that we used accordingly in our experiments. All other chapters were assigned to the training set. Ultimately, ABLIT consists of 808, 10, and 50 chapters in the training, development, and test sets, respectively. Table 1 shows some examples of rows in ABLIT.

4 Characterizing abridgements

4.1 Overview

Table 2 lists the size of ABLIT in terms of rows, paragraphs, sentences, and words (see A.4 for these numbers compared by book). Here we call attention to the numbers for the fully-validated test set, but the numbers for the training set closely correspond. The development set slightly varies from the training and test set for a few statistics, likely

	Train	Dev	Test (Chpt Mean)
Chpts	808	10	50
Rows	115,161	1,073	9,765 (195)
O_{pars}	37,227	313	3,125 (62)
A_{pars}	37,265	321	3,032 (61)
O_{sents}	122,219	1,143	10,431 (209)
A_{sents}	98,395	924	8,346 (167)
$\%A_{sents}$	80.5	80.8	80.0
O_{wrds}	2,727,571	29,908	231,878 (4,638)
A_{wrds}	1,718,919	17,630	143,908 (2,878)
$\%A_{wrds}$	63.0	58.9	62.1

Table 2: Number of chapters (Chpts), alignment rows ($Rows$), paragraphs ($pars$), sentences ($sents$), and words ($wrds$) across all original (O) and abridged (A) books. The per-chapter means appear for the test set.

O_{sents}	A_{sents}	Train	Dev	Test
1	1	75.8	74.7	75.7
1	0	17.4	17.3	17.3
2+	1	4.3	4.8	4.6
1	2+	2.1	3.2	1.9
2+	2+	0.3	0.0	0.5

Table 3: Distribution of row sizes by number of sentences ($sents$) in original (O) and abridged (A) spans

because it is smaller. Judging by the test set, the abridged chapters have almost the same number of paragraphs as the original, but they have 80% of the number of sentences ($\%A_{sents}$) and ≈62% of the number of words ($\%A_{wrds}$).

Table 3 pertains to the size of the original and abridged spans in each row, where size is the number of sentences in each span. The table shows the relative percentage of rows of each size. The majority of test rows (≈76%) contain a one-to-one alignment between an original and abridged sentence (i.e. $O_{sents} = 1$, $A_{sents} = 1$). Meanwhile, ≈17% contain an original sentence with an empty abridged span ($O_{sents} = 1$, $A_{sents} = 0$). A minority of rows (≈5%) have a many-to-one alignment ($O_{sents} = 2+$, $A_{sents} = 1$) and a smaller minority (≈2%) have a one-to-many alignment ($O_{sents} = 1$, $A_{sents} = 2+$). Many-to-many alignments ($O_{sents} = 2+$, $A_{sents} = 2+$) are more rare (0.5%).

4.2 Lexical similarity

Score Bin	Train	Dev	Test
0.0	17.5	17.6	17.4
(0.0, 0.25]	0.1	0.2	0.1
(0.25, 0.5]	0.5	0.9	0.6
(0.5, 0.75]	2.6	4.6	2.9
(0.75, 1.0)	23.9	31.5	24.0
1.0	55.5	45.2	55.0

Table 4: Binned distribution of $R\text{-}1_p$ scores for rows

As demonstrated by the success of the $R\text{-}1_p$ metric for creating alignment rows (Section 3.2), an original and abridged span typically align if most of the words in the abridged are contained in the original. Table 4 shows the binned distribution of the $R\text{-}1_p$ scores for the rows. Rows with an exact score of 0.0 (≈17% of rows in the test set) consist almost exclusively of original spans aligned to empty spans, which is why this number is comparable to the second line of Table 3. Many rows have perfect scores of exactly 1.0 (55%), signifying that their abridged span is just an extraction of some or all of the original span. The abridged spans where this is not the case (i.e. they contain some words not in the original) still copy much of the original: 24% of test rows have a $R\text{-}1_p$ score above 0.75 and below 1.0, while only a small minority (≈4%, the sum of lines 2-4 in the table) have a score above 0.0 and below 0.75.

4.3 Lexical operations

	Train	**Dev**	**Test**
O_{rmv} (O_{prsv})	40.9 (59.1)	45.9 (54.1)	41.9 (58.1)
A_{add} (A_{prsv})	6.3 (93.7)	8.3 (91.7)	6.4 (93.6)
$Rows_{rmv}$	71.1	80.3	73.2
$Rows_{prsv}$	82.5	82.7	82.6
$Rows_{add}$	37.4	48.8	39.4
$Rows_{reord}$	11.8	16.5	11.7

Table 5: *Top:* the % of removed and added words relative to all original and abridged words, respectively. *Bottom:* the % of rows with each lexical operation.

For each row, we enumerate the common and divergent items between the words o_{wrds} in the original span and the words a_{wrds} in the abridged span. The words that appear in o_{wrds} but not a_{wrds} are removed words, i.e. $o_{rmv} = |o_{wrds} - a_{wrds}|$. All other original words are preserved in the abridgement, i.e. $o_{prsv} = |o_{wrds} - o_{rmv}|$. Accumulating these counts across all original spans $o \in O$, the top section of Table 5 indicates the percentages of removed and preserved words among all original words. In the test set, ≈42% of words are removed, and thus ≈58% are preserved. Next, we count the added words in the abridgement, which are those that appear in a_{wrds} and not o_{wrds}, i.e. $a_{add} = |a_{wrds} - o_{wrds}|$. All other abridged words are preserved from the original, i.e. $a_{prsv} = |a_{wrds} - a_{add}|$. Accumulating these counts across all abridged spans $a \in A$, Table 5 shows that only ≈6% of abridged words in the test set are additions, and thus ≈94% are preservations.

We also report the number of rows where these removal, preservation, and addition operations occur at least once. For instance, if $o_{rmv} > 0$ for the original span in a given row, we count that row as part of $Rows_{rmv}$. The bottom section of Table 5 shows the percentage of rows with each operation among all rows in the dataset. In ≈73% of the test rows, the abridged span removes at least one word from the original. In ≈83% of rows, the abridged span preserves at least one word from the original. In ≈39% of rows, the abridged span adds at least one word not in the original. We considered the possibility that preserved words could be reordered in the abridgement. To capture this, we find the longest contiguous sequences of preserved words (i.e. "slices") in the abridged spans. A row is included in $Rows_{reord}$ if at least two abridged slices appear in a different order compared to the original span. This reordering occurs in ≈12% of rows.

It is clear from this analysis that the abridgements are quite loyal to the original versions, but they still remove a significant degree of text and introduce some new text. The examples in Table 1 highlight these operations. We can qualitatively interpret from the examples that some added words in the abridged span are substitutions for removed original words (e.g. "tap" > "taps" in the second example, "changed" > "altered" in the third example). See A.5 for additional discussion about how some of these relations pertain to common NLI tasks.

4.4 Lexical categories

Category	$\%O$	$\%O_{rmv}$	$\%A$	$\%A_{add}$
Function	58.2	57.9	58.1	53.9
Content	41.8	42.1	41.9	46.1

Table 6: Test set distribution of lexical categories for removed words O_{rmv} compared with all original words O, and added words A_{add} compared with all abridged words A

We examined if certain types of words are more often affected by removal or addition operations. Table 6 contains a broad analysis of this for the test set. As shown, ≈58% of original words O are function words (those with part-of-speech tags of punctuation, pronouns, adpositions, determiners, etc.), while ≈42% are content words (nouns, verbs, adjectives, and adverbs). The category distribution of removed words O_{rmv} closely matches the O distribution, suggesting that both function and content words are removed at the same rate. The abridged words A have the same proportion of function and content words as O (again, ≈58% and ≈42%). In comparison, ≈54% of additions A_{add} are function words, while ≈46% are content words. The gap between ≈42% and ≈46% indicates that content words are added at a slightly higher rate than the overall frequency in content words in A (and equivalently, function words are added at a lower rate). But there are few additions overall, so the abridgements retain the same word type distribution as the original texts. A.6 shows this same analysis for each specific part-of-speech tag among these types.

5 Predicting what to abridge

Garbacea et al. (2021) points out that a key (and often neglected) preliminary step in simplification is to distinguish text that could benefit from being simplified versus text that is already sufficiently simple. This is also an important consideration for abridgement, since it seeks to only modify text in places where it improves readability. Accordingly, we examine whether we can automatically predict the text in the original that should be removed when producing the abridgement. As explained in Section 4, a removed word could mean the author replaced it with a different word(s) in the abridgement, or simply excluded any representation of its meaning. However, both cases indicate some change is applied to that word.

We model this through a binary sequence labeling task. Given a passage with original tokens o_{toks} and corresponding abridged tokens a_{toks}, we assign each token t in o_{toks} the label of `preserved` (l=0) if it is also in a_{toks}, and otherwise the label of `removed` (l=1) if it is not in a_{toks}. Thus the task is to predict the label sequence $[l_1, l_2, ...l_n]$ from the token sequence $[t_1, t_2, ...t_n]$.

5.1 Model inputs

We can derive a token-label sequence from each alignment row, by which each original span corresponds to a single input instance. However, the size of these spans varies across rows. To produce models that handle texts where these span boundaries are not known in advance, we consider consistent-length passages whose boundaries can be automatically inferred. Thus the ABLIT interface can provide pairs where a fixed-length passage from the original chapter (i.e. a sentence, paragraph, or multi-paragraph chunk) is aligned to its specific corresponding abridged version.

We enable this by finding the respective positions of the longest common word sequences between the original and abridged spans. Each of these overlapping subsequences is represented as a slice of the original text with indices (o_i, o_j) mapped to a slice of the abridged text (a_i, a_j). Then, given a passage in the original text with indices (o_l, o_m), we find all enclosed slices (o_i, o_j) where $o_i >= o_l$ and $o_j <= o_m$. For each slice we retrieve its corresponding abridged slice (a_i, a_j). Given the earliest text position $\min a_i$ and latest position $\max a_j$ among these abridged slices, the full abridgement for the passage at (o_l, o_m) is the text covered by the indices ($\min a_i$, $\max a_j$). As an example, consider the first line in Table 1. If retrieving abridgements for sentence-length passages, the first sentence in the original span "The letter was not unproductive." will yield "The letter" as the abridgement. The second original sentence "It re-established peace and kindness" will yield the abridgement "re-established peace and kindness". By varying the passage size, we can assess how much context beyond a single row is beneficial in modeling abridgements. See A.7 for more details.

5.2 Experiment

Model: To predict abridgement labels (`preserved`/`removed`), we use a ROBERTA-based sequence labeling model, which has been applied to several other NLI tasks (Liu et al., 2019). We divided chapters according to varying passage sizes and trained a separate model on the token-label sequences[6] associated with each passage size. The passages are either sentences (detected by NLTK), paragraphs (detected by line breaks), or multi-paragraph 'chunks'. Each chunk consists of one or more paragraphs of S sentences, such that paragraphs are combined into the same chunk when their total number of sentences does not exceed S. As an additional reference, we trained a model where each passage is an original span directly taken from a single alignment row. As explained in Section 5.1, these passages (termed Rows) vary in length. We did not train a model on the full chapters as inputs because the average length of these inputs (5,044 tokens) greatly exceeds the ROBERTA limit of 512. See A.8 for more details about the model.

Passage	**Toks**	**P**	**R**	**F1**
Rows	26	0.692	0.442	0.532
Sentences	24	0.677	0.453	0.535
Paragraphs	81	0.686	0.460	0.546
Chunks (S=10)	303	0.670	0.501	0.569
All=`removed`	-	0.415	1.000	0.583

Table 7: F1 scores of abridgement label prediction for test set with models trained on varying passage sizes. **Toks** is the mean number of tokens in each passage type.

Results: Each model is evaluated on instances of the corresponding passage size in the test set. Table

---

[6] A "token" in this case is a sub-token unit defined by the ROBERTA tokenizer, rather than a whitespace-separated "word" pertaining to Section 4.

7 displays the results in terms of the precision (P), recall (R), and F1 score of predicting that a token should be removed. We compare these results with the baseline of labeling all tokens in the chapter as `removed` (final line). For chunks, we tuned different values of S in $[5, 11]$ on the development set and observed the best F1 at S=10. The results show that the longest passage size (Chunks) yields the best predictions, suggesting the importance of chapter context beyond that given in a single row. The consistently higher precision over recall for all models indicates they correctly predict many preservation operations, but at the expense of missing many removal operations. Consequently, they overestimate the number of tokens that should be preserved. This results in an overall F1 that is lower than what occurs when all tokens are removed.

6 Producing abridgements

The above results show that anticipating what parts of a text should be changed when writing its abridged version is not trivial. The full task of producing an abridgement implicitly involves inferring these `preserved`/`removed` labels while additionally predicting the specific text that dictates these labels. We examine models that have been applied to tasks related to abridgement to establish benchmarks for this new task, with the intent that these benchmarks will inspire future work.

6.1 Models

We consider the following models to produce an abridged version of an original chapter:

Naive Baselines: As a reference point for our evaluation metrics, we report the performance of very weak baselines. In particular, we copy the entire original text as the abridgement (COPY). Alternatively, we select T percent of original tokens (RANDEXTTOKS) as the abridgement.

Extractive Approaches: The analysis in Section 4.2 showed that abridgements preserve much of their original text, which motivates the use of extractive summarization methods. Using the best label prediction model from Section 5, we extract all original tokens labeled as `preserved` to form the abridgement (EXTTOKS). To reveal the maximum performance that can be obtained with this method, we also run it using the gold labels instead of predicted labels (PERFECTEXTTOKS). It is not conventional to use tokens as units of extraction, since it can compromise fluency within sentences. EXTTOKS and PERFECTEXTTOKS only serve as points of comparison for our evaluation metrics. The standard extractive approach uses sentences as extractive units. For this (EXTSENTS), we form an abridgement by selecting a subset of sentences in the original chapter where at least P percent of tokens are labeled as `preserved`.

Generation Models: Extractive methods cannot introduce words into the abridgement that are not in the original, so for this we need to consider generation models. In particular, we examine two transformer-based sequence-to-sequence models that have been used for various generation tasks including summarization: T5-BASE (Raffel et al., 2020) (termed TUNEDT5 here) and BART-BASE (Lewis et al., 2020) (termed TUNEDBART). We fine-tuned both models on the ABLIT training set, specifically on inputs consisting of chunks with 10 sentences, since this passage size yielded the best results in the Section 5 experiment. To assess the impact of these models' observation of ABLIT, we compare them with abridgements produced by prompting the non-finetuned T5-BASE to perform zero-shot summarization (ZEROSHOTT5). See A.9 for more details about these models. For all models, we generated an abridgement for an original chapter by dividing the chapter into chunks, generating output for each chunk (with 5-beam decoding), then concatenating the outputs to form the complete abridgement.

6.2 Evaluation metrics

We evaluate the predicted abridgements through comparison with the human-authored reference abridgements. First, we measure the word-based similarity between the predicted abridgement a_{pred} and reference abridgement a_{ref} using ROUGE-L ($R\text{-}L$), a standard evaluation metric for summarization. We then assess how accurately a_{pred} removed and preserved words from the original. A word from the original in a_{pred} is considered correctly preserved if it also appears in a_{ref}. We report the F1 of this measure as $Prsv$. A word in the original but not in a_{pred} is considered correctly removed if it is also absent from a_{ref}. We report the F1 of this measure as Rmv. Finally, we evaluate the accuracy of added words, where a word not in the original is considered correctly added to a_{pred} if it is also in a_{ref}. We report the F1 of this measure as Add. See A.10 for formal definitions of these metrics.

Name	Description	Toks	$R\text{-}L$	$Prsv$	Rmv	Add
Human	Reference (a_{ref})	2,878	-	-	-	-
Copy	Duplicate original	4,638	0.739	0.753	0.000	0.000
RandExtToks (T=0.6)	$T\%$ randomly selected original tokens	2,787	0.753	0.800	0.694	0.000
ExtToks	Original tokens predicted as `preserved`	3,160	0.818	0.856	0.745	0.006
PerfectExtToks	Original tokens where gold label is `preserved` (upper bound for ExtToks)	2,664	0.950	0.969	0.954	0.034
ExtSents (P=0.65)	Original sentences with $\geq P\%$ tokens predicted as `preserved`	2,857	0.792	0.824	0.720	0.001
TunedT5	Generate from finetuned T5	3,834	0.727	0.804	0.519	0.275
TunedBART	Generate from finetuned BART	3,673	0.780	0.815	0.583	0.365
ZeroShotT5	Generate from non-finetuned T5	1,157	0.416	0.484	0.627	0.019

Table 8: Scores of predicted abridgements on evaluation metrics. For all metrics, higher scores are better.

Original	Reference	TunedBART
The windows were half open because of the heat, and the Venetian blinds covered the glass,–so that a gray grim light, reflected from the pavement below, threw all the shadows wrong, and combined with the green-tinged upper light to make even Margaret's own face, as she caught it in the mirrors, look ghastly and wan.	The windows were half open because of the heat, and Venetian blinds covered the glass, giving the light a green tinge that made her face in the mirrors look ghastly and wan.	The windows were half open because of the heat, and the Venetian blinds covered the glass - so that a grey grim light, reflected from the pavement below, threw all the shadows wrong, and made even Margaret's own face look ghastly and wan.
We must suppose little George Osborne has ridden from Knightsbridge towards Fulham, and will stop and make inquiries at that village regarding some friends whom we have left there. How is Mrs. Amelia after the storm of Waterloo? Is she living and thriving? What has come of Major Dobbin, whose cab was always hankering about her premises?	We must now make inquiries at Fulham about some friends whom we have left there. How is Mrs. Amelia? Is she living and thriving? What has become of Major Dobbin?	We must suppose little George Osborne has ridden towards Fulham, and will stop and make inquiries about some friends whom we have left there. How is Mrs. Amelia after the storm of Waterloo? Is she living and thriving? What has come of Major Dobbin, whose cab was always hankering about her premises?

Table 9: Abridgements predicted by TunedBART for excerpts of North and South and Vanity Fair

6.3 Results

Table 8 reports the length and metric scores of the abridgements produced by each model for the test set chapters. Where applicable, we selected the T and P parameters from tuning on the development set. The results again convey that abridgement is largely a text extraction task, though a challenging one. The low $R\text{-}L$ score of ZeroShotT5 confirms that AbLit is different from the summarization datasets that T5-base is trained on. The high $R\text{-}L$ of PerfectExtToks validates that precisely identifying which words to remove goes far in producing the abridgement. The high $Prsv$ scores for all approaches that observe AbLit show they can all preserve the original text reasonably well. Analogous to the results in Section 5, the lower Rmv scores indicate knowing which words to remove is harder, particularly for the generation models. The extractive methods have no opportunity to obtain an Add score that is non-trivially above 0[7]. The generation models do show a small benefit here in correctly adding some new words to the abridgement. The examples in Table 9 qualitatively represent the outcome for the TunedBART model. These abridgements remove some of the same original text as the reference and also add a few words consistent with the reference, but they still retain more of the original text than the reference. Other examples are shown in A.12.

7 Conclusion

In this paper, we introduced AbLit, a corpus of original and abridged versions of English literature. AbLit enables systematic analysis of the abridgement task, which has not yet been studied from an NLP perspective. Abridgement is related to other tasks like summarization, but has a stricter requirement to maintain loyalty to the original text. Our experiments motivate an opportunity to better balance this goal against that of improving readability. We also envision future resources that generalize this task to other texts beyond English literature.

---

[7] It is possible for Add to be slightly above 0 with the extractive approaches due to tokenization; see A.10.

8 Limitations

We present AbLit to introduce abridgement as an NLP task. However, the dataset is scoped to one small set of texts associated with a specific domain and author.

There are significant practical reasons for this limited scope. In particular, most recently published books are not included in publicly accessible datasets due to copyright restrictions, and the same restrictions typically apply to any abridgements of these books. The books in AbLit are uniquely in the public domain due to expired copyrights, and the author chose to also provide her abridgements for free. For this reason, AbLit consists of British English literature from the 18th and 19th centuries. Some of the linguistic properties of these original books do not generalize to other types of English texts that would be useful to abridge. We do not yet know what aspects of abridgement are specific to this particular domain.

Moreover, as described in Section 2.2, creating abridgements is a rare and highly skilled writing endeavor. The AbLit abridgements are written exclusively by one author. Without observing alternative abridgements for the same books by a different author, it is unclear what features are specific to the author's preferences. This conflation between task and author is a concern for many NLP datasets (Geva et al., 2019). More generally, obtaining human writing expertise is a challenge shared by all language generation research as it becomes more ambitious (e.g. Wu et al., 2021).

9 Ethical Considerations

As stated in the introduction, all data and code used in this work is freely available. The text included in the dataset is in the public domain. Additionally, we explicitly confirmed approval from the author of the abridged books to use them in our research.

For the data validation task, the validators were employed within our institution and thus were compensated as part of their normal job role. Given that the dataset is derived directly from published books, it is possible that readers may be offended by some content in these books. The validators did not report any subjective experience of this.

With regard to our modeling approaches, large pretrained models like the ones we use here for generating abridgements have a well-known risk of producing harmful content (e.g. Gehman et al., 2020). For the generation models fine-tuned on AbLit, we did not subjectively observe any such text in the sample output we assessed. We judge that our controlled selection of training data reduces this risk, but does not eliminate it. Accordingly, future applications of abridgement can similarly consider careful data curation for mitigating this risk.

A Appendix

A.1 Detecting chapter boundaries

There is a one-to-one relation between each chapter in an original book and each chapter in its corresponding abridged version. Both the original and abridged version of the books include headings separating chapters. We automatically detected these headings through a set of regular expressions (e.g. matching lines specifying a chapter number and name with the regular expression "`^Chapter [0-9]+:*[a-zA-Z\s]*$`"). However, there is variability in the format of the headings: some can span multiple lines, or specify a book and volume number in addition to the chapter identifier, or have numbers written in non-numerical form, for instance. The format also varies between the original and abridged version of the same book. Thus, we manually reviewed all detected chapter boundaries and fixed any erroneous or missed boundaries. Ultimately we ensure that each chapter in an original book is paired exactly with its abridged counterpart.

A.2 Additional automated alignment results

Table 10 shows the results of all methods we assessed for computing similarity between original and abridged spans to create alignment rows, compared alongside the best method of unigram ROUGE precision ($R\text{-}1_p$) reported in Section 3.2. A clear drawback to using unigram overlap to measure similarity is that it does not account for differences in word order. However, taking this into account by using bigrams instead of unigrams to calculate ROUGE precision (i.e. $R\text{-}2_p$) reduced the F1 to 0.935, likely because it added more sparsity to the overlap units. In addition to the word-based ROUGE metric, we assessed vector-based similarity encoded by different configurations of pretrained language models: BERT (Devlin et al., 2019), XLNET (Yang et al., 2019), XLM (Conneau and Lample, 2019), and ROBERTA (Liu et al., 2019). We used the HuggingFace Transformers implementation of these models: `https://huggingface.co/docs/transformers/index`. For each model we report the best result among size penalty (pn) values in $[0, 0.25]$. As displayed, the vectors that obtained the best F1 came from BERT (Devlin et al., 2019), particularly BERT-BASE-UNCASED, which consists of 110M parameters. See additional details about this model here: `https://huggingface.co/bert-base-uncased`. Ultimately, however, the result from BERT-BASE-UNCASED was still outperformed by $R\text{-}1_p$. As reported in Section 3.3, the resulting rows were further improved by applying the described partial validation strategy (final line of table).

A.3 Details about validation task

For each row, validators assessed whether the abridged span in the row was correctly aligned with the corresponding original span. As described in Section 3.2, a row is correct if the meaning of the abridged span can be derived from the original span. For a given row, if the abridged span expressed some meaning not contained in the original span, it either meant that some sentences(s) in the abridged chapter were incorrectly placed in that row, or some sentence(s) in the original chapter were incorrectly placed in a different row. In both cases, validators moved the wrongly placed sentence(s) to a row resulting in correctly aligned spans. We utilized Google Sheets as an interface for this task, which enabled validators to easily review and correct the rows. We produced a single spreadsheet per chapter, where each spreadsheet row corresponded to an alignment row. For the partial validation strategy, we designed a Google Apps Script (`https://developers.google.com/apps-script`) that visually highlighted spreadsheet rows qualifying for partial validation so that validators could specifically attend to those rows.

For the development (assessment) and test sets, there were a few cases where the validators edited the spans themselves in order to correct sentence segmentation errors (e.g. wrongly segmenting after honorifics like "Mr.").

A.4 Size of ABLIT compared by book

Table 11 shows characteristics of the data for each book in terms of number of alignment rows, original words, and abridged words.

A.5 NLI challenges in ABLIT

Table 12 shows some examples of rows in ABLIT where modeling the relation between the original and abridged span involves NLI challenges like abstractive paraphrasing, figurative language interpretation, commonsense reasoning, and narrative understanding.

Similarity Metric	pn	**P**	**R**	**F1**

Table 11: Statistics for each book in the AbLit dataset, in terms of number of alignment rows, total original word (O_{wrds}), and proportional length of abridgement relative to original ($\%A_{wrds}$). The number of chapters in the training set for each book is shown; there is 1 chapter per book in the development set and 5 chapters per book in the test set.

Original Span	Abridged Span	Type of Challenge
Still there was not a word.	No one spoke.	Paraphrasing: abridgement has same meaning as original but no word overlap
But it is time to go home; my appetite tells me the hour.	But it is time to go home; I am hungry.	Interpretation of figurative language: abridgement replaces phrase "appetite tells me the hour" with more literal term "hungry"
"Daniel, do you see that you are sitting on the bent pages of your book?"	"Daniel, you are sitting on the bent pages of your book."	Change in dialogue act: question in original is transformed into statement in abridgment
While she was at Matching, and before Mr. Palliser had returned from Monkshade, a letter reached her, by what means she had never learned. "A letter has been placed within my writing-case," she said to her maid, quite openly. "Who put it there?"	While she was at Matching, a letter reached her, by what means she never learned, although she suspected her maid of placing it inside her writing-case.	Dialogue interpretation: abridgement summarizes the narrative event (suspecting maid of placing letter) conveyed by the spoken utterances in the original text ("A letter has been placed... she said to her maid.")
"If you will allow me, I have the key," said Grey. Then they both entered the house, and Vavasor followed his host up-stairs.	Mr. Grey unlocked the door of his house, and Vavasor followed him upstairs.	Commonsense inference: abridgement involves knowledge that doors are unlocked by keys, which is not explicit in the original text
George Osborne was somehow there already (sadly "putting out" Amelia, who was writing to her twelve dearest friends at Chiswick Mall), and Rebecca was employed upon her yesterday's work.	George Osborne was there already, and Rebecca was knitting her purse.	Narrative inference: "knitting her purse" in the abridgement is the event referenced by "yesterday's work" in the original, and resolving this requires knowledge of the previous text in the chapter
But Kate preferred the other subject, and so, I think, did Mrs. Greenow herself.	But Kate preferred the subject of the Captain, and so, I think, did Mrs. Greenow herself.	Elaboration: abridgement specifies "Captain" is the "other subject" implied in the original

Table 12: Examples of rows where alignment involves a language inference challenge

A.6 Extended lexical category analysis

Section 4.4 summarized the frequency of lexical categories for removed and added words in the ABLIT test set, relative to these frequencies among all words in the original and abridged texts. Table 13 additionally displays these percentages for all part-of-speech tags within the function and content word classes, along with examples of common words associated with each tag. We used the spacy library to perform part-of-speech tagging: `https://spacy.io/usage/linguistic-features`.

A.7 Comment about passage size variation

Because the method for converting rows into passages of a consistent length (i.e. sentences, paragraphs, chunks) relies on string matching, the boundaries of the abridged passage may be off by one or a few words, which occurs less frequently as the size of the passages increase. This tends to occur when a word at the end of the original passage is replaced by a synonym in the abridged passage. However, a manual review of our assessment set revealed that only 0.4% of sentences in the original text yielded abridgements with imprecise boundaries, and no paragraphs (and consequently no chunks) had this issue.

A.8 Details about binary prediction model

For all passage sizes, we initialized models with the ROBERTA-BASE weights using the HuggingFace Transformers implemen-

Category	%O	%O_{rmv}	%A	%A_{add}	Examples of Common Words
Function words	**Σ=58.2**	**Σ=57.9**	**Σ=58.1**	**Σ=53.9**	
Punctuation	14.0	12.9	15.7	23.3	`, " . -- ; - ? !`
Pronoun	11.0	10.2	11.5	8.7	`i he it his her`
Adposition	10.2	11.5	9.0	7.0	`of in to with for`

tation: https://huggingface.co/docs/transformers/v4.16.2/en/model_doc/roberta#transformers.RobertaModel. ROBERTA-BASE consists of 125M parameters (https://huggingface.co/roberta-base). The maximum sequence length allowed by this model is 512, so we truncated all input tokens beyond this limit. We fine-tuned each model for 5 epochs, saving model weights after each epoch of training, and selected the model with the highest F1 score on the development set to apply to our test set. We used the AdamW optimizer (Loshchilov and Hutter, 2017) and a batch size of 16. It took ≈2 hours to train each model on a g4dn.2xlarge AWS instance. During evaluation, any input tokens beyond the model length limit were assigned the default label of `preserved`. The result for each model reported in Table 7 is based on a single run of the training procedure.

A.9 Details about generation models

Both TUNEDT5 and TUNEDBART were fine-tuned using the HuggingFace transformers library, in particular this script: http://github.com/huggingface/transformers/blob/master/examples/pytorch/summarization/run_summarization.py. TUNEDT5 was initialized from T5-BASE (Raffel et al., 2020), which consists of ≈220M parameters (https://huggingface.co/t5-base). For this model, we prepended the prefix “summarize: ” to the target (i.e. the abridged passage), consistent with how T5-BASE was trained to perform summarization. TUNEDBART was initialized from BART-BASE (Lewis et al., 2020), which consists of 140M parameters (https://huggingface.co/facebook/bart-base). For both TUNEDT5 and TUNEDBART, we used a maximum length of 1024 for both the source (original passage) and target (abridged passage), and truncated all tokens beyond this limit. We evaluated each model on the development set after each epoch and concluded training when cross-entropy loss stopped decreasing, thus saving the model weights with the optimal loss. We used a batch size of 4. For all other hyperparameters we used the default values set by this script, which specifies AdamW for optimization. It took ≈3 hours to train each model on a g4dn.4xlarge AWS instance. The result for each model reported in Table 8 is based on a single run of the training procedure.

A.10 Details about evaluation metrics

Preservation: The formal definition of the preservation metric $Prsv$ is as follows. If

$o_{prsv}(a_{pred})$ are the words in the original that are preserved in the predicted abridgement, and $o_{prsv}(a_{ref})$ are the words in the original that are preserved in the reference abridgement, then we consider the number of correctly preserved words: $Correct\_Prsv = |o_{prsv}(a_{pred}) \cap o_{prsv}(a_{ref})|$. The precision of this measure $Prsv_p = \frac{Correct\_Prsv}{o_{prsv}(a_{pred})}$ is the proportion of correctly preserved words among all preserved words in the predicted abridgement. The recall $Prsv_r = \frac{Correct\_Prsv}{o_{prsv}(a_{ref})}$ is the proportion of correctly preserved words among all preserved words in the reference abridgement. $Prsv$ is the F1 of these precision and recall measures: $Prsv = 2\frac{Prsv_p \cdot Prsv_r}{Prsv_p + Prsv_r}$.

Removal: The formal definition of the removal metric is as follows. If $o_{rmv}(a_{pred})$ are the words in the original that are removed in the predicted abridgement, and $o_{rmv}(a_{ref})$ are the words in the original that are removed in the reference abridgement, then we consider the number of correctly removed words: $Correct\_Rmv = |o_{rmv}(a_{pred}) \cap o_{rmv}(a_{ref})|$. The precision of this measure $Rmv_p = \frac{Correct\_Rmv}{o_{rmv}(a_{pred})}$ is the proportion of correctly removed words among all removed words for the predicted abridgment. The recall $Rmv_r = \frac{Correct\_Rmv}{o_{rmv}(a_{ref})}$ is the proportion of correctly removed words among all removed words for the reference abridgement. Rmv is the F1 of these precision and recall measures: $Rmv = 2\frac{Rmv_p \cdot Rmv_r}{Rmv_p + Rmv_r}$.

Addition: The formal definition of the addition metric is as follows. If $a_{add}(a_{pred})$ are the words in the predicted abridgement that do not appear in the original, and $a_{add}(a_{ref})$ are the words in the reference abridgement that do not appear in the original, then we consider the number of correctly added words: $Correct\_Add = |a_{add}(a_{pred}) \cap a_{add}(a_{ref})|$. The precision of this measure $Add_p = \frac{Correct\_Add}{a_{add}(a_{pred})}$ is the proportion of correctly added words among all added words in the predicted abridgement. The recall $Add_r = \frac{Correct\_Add}{a_{add}(a_{ref})}$ is the proportion of correctly added words among all added words in the reference abridgement. Add is the F1 of these measures: $Add = 2\frac{Add_p \cdot Add_r}{Add_p + Add_r}$.

A.11 Comment about addition scores

Regarding the above-zero scores of the extractive methods on the Add metric, there are two reasons for this. One reason is that the prediction model uses sub-tokens while the Add metric analyzes whitespace-separated words. Consequently, one sub-token may be predicted as `preserved` while others within the same word are predicted as `removed`. Isolated from these other sub-tokens, the `preserved` sub-token will be recognized as a new added word in the abridgement. The other reason is that a single word in the original may be split by the tokenizer into two words in the abridgement, or vice-versa. For example, we observed that "Mr." gets split into two tokens ("Mr", '.') in some contexts and is treated as one token ("Mr.") in others. If the original text represents this item as two tokens and both the extracted and reference abridgement represent it as a single token, then this single token will be counted as an added word in the extracted abridgement.

A.12 Examples of produced abridgements

Tables 14 and 15 below show excerpts of the abridgements produced by the EXTSENT and TUNEDBART models, alongside the original chapter text and human-authored reference abridgement. The sentences in each excerpt are lined up to better visualize their differences.

Self-training Reduces Flicker in Retranslation-based Simultaneous Translation

Abstract

In simultaneous translation, the *retranslation* approach has the advantage of requiring no modifications to the inference engine. However, in order to reduce the undesirable flicker in the output, previous work has resorted to increasing the latency through masking, and introducing specialised inference, thus losing the simplicity of the approach. In this work, we show that self-training improves the flicker-latency tradeoff, while maintaining similar translation quality to the original. Our analysis indicates that self-training reduces flicker by controlling monotonicity. Furthermore, self-training can be combined with biased beam search to further improve the flicker-latency tradeoff.

1 Introduction

Simultaneous machine translation systems, which process their input word by word instead of sentence by sentence, must strike a balance between producing output immediately (and so reducing quality because of incomplete input) and waiting for further input (and so increasing latency). Ideally, a good simultaneous translation system will provide a pareto-optimal tradeoff between quality and latency. A straightforward way of doing simultaneous translation is *retranslation* (Niehues et al., 2016), which has the advantage that it can be used with an unmodified machine translation (MT) inference engine, and can perform better than the alternative streaming-based approaches (Arivazhagan et al., 2020b). The disadvantage is that retranslation may change previous output causing *flicker*, leading to a poor user experience, and so flicker needs to be balanced with latency and quality.

We argue that flickering is caused by two different (but related) issues: (i) lexical instability of the translation – the system "changes its mind" as more source is revealed, swapping one word for another[1] and (ii) non-monotonicity of the translation – the system favours a non-monotonic translation, which means it needs high latency in order to avoid flicker. Some of this instability and non-monotonicity is necessary – forced by syntactic differences between source and target, and lack of information in the prefixes – but some is due to arbitrary choices of the model. We aim to reduce these as far as possible.

In non-autoregressive translation (NAT), a related problem, known as the "multimodality" problem (Gu et al., 2018), has been addressed using knowledge distillation (Kim and Rush, 2016, KD). We therefore investigate whether this can also reduce flicker in simultaneous translation. Since the initial model and the distilled model have the same architecture in our work, approximating KD is essentially self-training[2]. We show that a self-trained model is able to achieve the same quality as the initial model, but with improved flicker-latency tradeoff. We also show that self-training (Arivazhagan et al., 2020a) can be combined with biased beam search to further improve the flicker-latency tradeoff. Furthermore, we show experiments that link flicker to monotonicity.

2 Background

2.1 Retranslation

We assume a retranslation approach, where the source is retranslated each time it is updated, and the new output replaces the old. Only the current sentence is retranslated – previous sentences are considered to be fixed. In contrast to streaming approaches (e.g. Ma et al., 2019a; Arivazhagan et al., 2019b), retranslation can use an unmodified inference engine, making it simpler to deploy. The basic retranslation approach can be improved by using *prefix training* (Niehues et al., 2016, 2018), *bi-*

ased beam search and *output masking*[3] (Arivazhagan et al., 2020a).

2.2 Evaluation of Simultaneous Translation

In addition to quality, evaluation of simultaneous translation requires that we consider latency and, if using retranslation, flicker. The quality of the translation can be evaluated by comparing the final output of each sentence with a reference – we will use BLEU (Papineni et al., 2002; Post, 2018), CHRF (Popović, 2015) and COMET (Rei et al., 2020) scores. To measure flicker, we use *normalised erasure* (Arivazhagan et al., 2020a, 2019a), which measures the flicker between consecutive translation outputs by counting the minimum number of tokens that must be deleted from the end of the previous translation in order to produce the next, normalised by output length.

The measurement of latency has been the subject of some debate in the literature, with several different measures proposed (Ma et al., 2019a; Cherry and Foster, 2019; Ansari et al., 2021). In our experiments, we plot the flicker-latency tradeoff by controlling the output mask and recording the effect on flicker. Since mask size correlates with latency, our aim is to improve this mask-flicker tradeoff curve, and so be able to use a shorter mask with the same flicker budget.

2.3 Knowledge Distillation and Self-Training

The idea of sequence-level KD (Kim and Rush, 2016), is to create a smaller *student* model using the predictions of the larger *teacher* model. This has found application in MT efficiency (Junczys-Dowmunt et al., 2018) and in non-autoregressive translation (Zhou et al., 2020). In our work, the student model has the same size as the teacher, and is *self-trained* on teacher output. The output distributions of the student model have lower entropy (Zhou et al., 2020), so the model is less likely to swap between translation hypotheses unnecessarily as the source prefix is extended. Also, since the student model is trained on MT output, where the target order tends to be more similar to the source order (Zhou et al., 2020), it is more likely to avoid unnecessary reorderings, generating a more monotonic translation, which can be built up incrementally. We give experimental evidence for these in the next section.

Chen et al. (2021) also proposed to use pseudo-reference sentences obtained through forward translation of the source sentences to improve simultaneous translation. Unlike our work, they considered a streaming approach (specifically wait-k (Ma et al., 2019b)) where the system can only append to the output; it does not flicker like retranslation. They showed that their approach could improve the quality-latency tradeoff of wait-k using their distillation approach, but to create the training data for the student system they used wait-k and filtering. We avoid these complications by just using the baseline system as the teacher.

3 Experiments

3.1 Data

We test our self-training approach on English↔{German,Czech}. For En↔De we use IWSLT21 (Anastasopoulos et al., 2021) for training, and the concatenation of the 2014 and 2015 test sets for development (early stopping), removing any sentences that overlap with the training set. For En↔Cs, we use the training and validation set from WMT21 (Akhbardeh et al., 2021). Training data sizes are shown in Appendix A. We use *prefix training* (Niehues et al., 2018) to reduce the mismatch between sentence-level training and prefix-based inference at test time. For each parallel sentence pair in the training set, we generate a corresponding prefix pair by truncating a randomly chosen proportion. We treat the validation sets similarly.

We test our systems both on IWSLT test data (derived from TED talks) and on the ESIC test set[4] (Macháek et al., 2021). From IWSLT, we use tst2018 for De↔En, and tst2015/tst2016 combined for Cs↔En. ESIC is derived from the European parliament proceedings, and consists of transcribed speeches in English, together with their simultaneous interpretation into Czech and German (also transcribed). ESIC is aligned at the document level, but not at the sentence level. We use the test portion for evaluation, only for En→X. It has been argued that simultaneous translation is better evaluated (and trained, if possible) on interpreted data (Zhao et al., 2021). However such data is hard to come by, and ESIC is the only such resource for European languages. We remove any segments from the IWSLT test sets that overlap

---

[3] This means that the last k words are omitted from the output before being passed to the user. This reduces flicker, but increases latency.

[4] `https://lindat.mff.cuni.cz/repository/xmlui/handle/11234/1-3719`

with training, and also remove from the training data any Europarl documents with overlap with ESIC.

All data is pre-processed with SentencePiece unigram model (Kudo and Richardson, 2018) with a shared subword (Sennrich et al., 2016b) vocabulary size of 32k.

		En→De		De→En	En→Cs		Cs→En
Metric	Model	ESIC	IWSLT	IWSLT	ESIC	IWSLT	IWSLT
BLEU	T	17.5	27.7	33.4	14.4	24.6	31.3
	S	17.6	27.5	31.7	14.5	25.0	31.3
ChrF	T	58.9	56.9	59.2	51.5	51.5	56.1
	S	58.8	57.2	58.3	51.7	51.7	56.2
COMET	T	.553	.330	.488	.651	.639	.519
	S	.532	.326	.468	.672	.642	.521

Table 1: Comparison between teacher (T) and student (S) models on ESIC and IWSLT test sets. For ESIC, BLEU and CHRF are calculated at document level, i.e. considering each document as a segment. For COMET we use reference-less `wmt20-comet-da` for ESIC and reference-based `wmt20-comet-da` for IWSLT.

3.2 Teacher-Student Training

Our teacher model, which serves as a baseline, is a transformer base (Vaswani et al., 2017) trained[5] with fairseq[6] (Ott et al., 2019).

We use the teacher to translate the training data, using a beam size[7] of 8, then train a student model with the same architecture on this synthetic data.

In Table 1 we show the performance of our baseline system (equivalent to the teacher) and the student system on 6 test sets. Overall, student performance is robust compared to teacher, with same or better scores in Cs↔En and some small losses in De↔En.

To assess whether the student models reduce flicker in retranslation, we use each model in a simulated SLT pipeline and plot flicker-latency tradeoff curves. That is, we use the systems to translate ever-growing prefixes of the source sentences in the testsets, using SLTev (Ansari et al., 2021) to measure the flicker, and varying the output mask to show the tradeoff. A curve for one test set is shown in Figure 1, with full results in Appendix D. We can see that in all configurations the student models improve the flicker-latency tradeoff. In section 3.4, we show how the student training data is more monotonic, and the models have lower entropy, echoing Zhou et al. (2020).

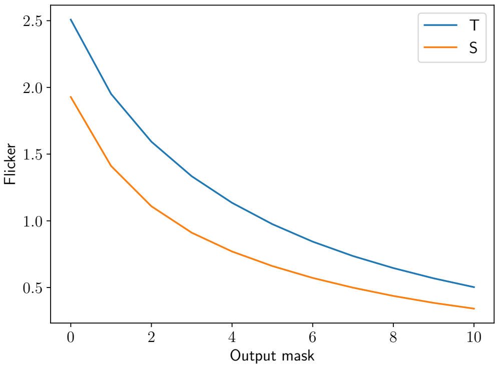

Figure 1: Flicker-latency tradeoff for the teacher (T) and student (S) models, En→De IWSLT. We control latency by varying the output mask.

3.3 Controlling Monotonicity

To show that self-training affects flicker through increased monotonicity, we experiment with controlling the monotonicity of the student training data. We stratify the teacher data into 5 different monotonicity levels using Kendall's Tau on a *fast_align* (Dyer et al., 2013) target–source alignment to measure monotonicity, with an equal stratum size. We add the monotonicity level as pseudo-word, as in Sennrich et al. (2016a), to each source sentence, and train a teacher model on this monotonicity-aware corpus. We then use this teacher to create 5 different student training corpora, using the monotonicity control, and train 5 different students on these corpora.

Table 2 shows the BLEU[8] scores for the monotonicity-controlled models, as well as the teacher and student from the previous section. Using highly monotonic (Mono-1) or non-monotonic (Mono-5) data gives poor quality, but the in-between strata are similar, with Mono-3 slightly better overall. Figure 2 shows a distinctly worse flicker-latency tradeoff for Mono-5, whereas Mono-4 is a bit better than the teacher, and all other students are better. This supports the hypothesized connection between the higher degree of monotonicity in the student training data, and the

---

[5] For training hyperparameters, see Appendix B.

[6] To generate training data for the students, we actually used a marian (Junczys-Dowmunt et al., 2018) model, with 60×10^6 parameters, trained on the same data and with the same architecture, which achieves nearly identical BLEU. This was to take advantage of marian's fast inference. All results shown in the paper are with the fairseq models.

[7] We also tested sequence-level interpolation, selecting the highest-scoring translation in an 8-best list according to BLEU and CHRF, but results were very similar.

[8] Scores for CHRF and COMET are in the Appendix F, but the pattern is similar.

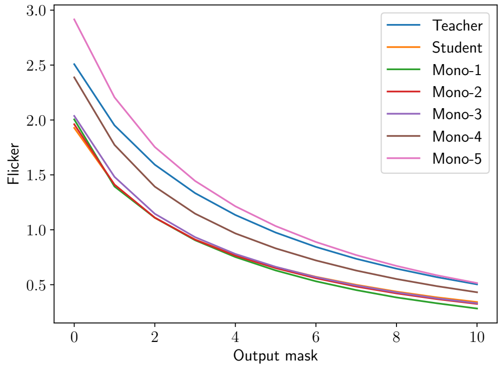

Figure 2: Latency–flicker tradeoff for the En→De IWSLT monotonicity-controlled models. Monotonicity control ranges from 1 (training data created with maximum monotonicity) to 5 (minimum monotonicity).

better flicker-latency tradeoff in the student models. We show the flicker-latency tadeoff curves on more test sets and language pairs in Figure 5 in the Appendix F but the pattern is similar.

		En→De		En→Cs	
Metric	Model	ESIC	IWSLT	ESIC	IWSLT
BLEU	Teacher	17.5	27.7	14.4	24.6
	Student	**17.6**	27.5	14.5	25.0
	Mono-1	8.6	14.4	**14.7**	23.6
	Mono-2	**17.6**	27.4	14.5	25.0
	Mono-3	17.5	**27.9**	14.5	**25.7**
	Mono-4	17.2	26.6	13.8	24.7
	Mono-5	16.0	25.0	12.5	23.0

Table 2: Student models with monotonicity control. Monotonicity ranges from 1 (highest) to 5 (lowest). The best scores are in bold font.

3.4 Monotonicity and Entropy of Student Models

We claimed that student models have lower flicker because they produce more monotonic translations, with less unnecessary variation. Here we provide evidence to support those claims.

Training data for student models is more monotonic In order to calculate the monotonicity of the training data, we use Kendall's tau score. We first extract word alignments from the training data using *fast_align* (Dyer et al., 2013) to forward-align source and target. For each sentence pair we express the alignment as a function $a : i \rightarrow j$, and construct the two lists $1, \ldots, T$ and $a(1), \ldots, a(T)$ where T is the target length. We then calculate the Kendall's tau between the two lists, repeat for each sentence pair in the corpus, and average. We repeat the calculation for the original training data and for the student training set. The results are shown in Table 3. We can see that in all cases, the student training data is more monotonic than the original teacher training data.

Model	En→De	De→En	En→Cs	Cs→En
Teacher	0.793	0.788	0.849	0.836
Student	0.857	0.801	0.906	0.880

Table 3: Kendall's tau scores. Higher scores indicate more monotonicity.

Student models have lower entropy distributions For each of our models, we calculate the mean per-token entropy, by considering the probability distribution over the vocabulary at each time step. The entropies are shown in Table 4.

		Entropy	
Pair	Test set	Teacher	Student
En→De	ESIC	0.371	0.220
	IWSLT	0.295	0.228
De→En	IWSLT	0.273	0.160
En→Cs	ESIC	0.443	0.251
	IWSLT	0.417	0.238
Cs→En	IWSLT	0.335	0.213

Table 4: Mean per-token entropies for each language pair test set combination.

We can see from Table 4 that the token entropies are consistently lower for student models, suggesting that the distributions are more "peaky", and so less likely to flicker between multiple output tokens with similar probabilities.

3.5 Self-training and Biased Beam Search

We investigate the combination of our self-training approach with biased beam search (Arivazhagan et al., 2020a). The idea of biased beam search (or "prefix biasing") is to reduce flicker in retranslation by modifying inference so that the translation of the current prefix is "biased" towards the translation of the last prefix. The model for inference has an extra term which penalises it for departing from the previous translation. As the current translation is being generated, once the hypothesis departs from the previous translation, we stop applying the bias penalty, reverting to the unmodified MT model.

Before the previous translation is used for biasing, it is normally *masked*; i.e., the right-most k tokens are removed. Without applying this mask, biased beam search seriously reduces quality by forcing inference to follow poor-quality early decisions. This *bias mask* is different from the output mask used in earlier experiments (which controls latency) although in previous work the bias and output mask are typically set to the same value.

We implemented biased beam search in fairseq and, based on previous work, we set the bias strength $\beta = 0.25$. After comparing different bias masks (Appendix E) we set the mask to 6 for ESIC and 10 for IWSLT.

We sweep across output masks to generate latency–flicker tradeoff curves in Figure 3 (with full results in Appendix E). We compare teacher and student models, with and without biased beam search. We can see from the graphs that biased beam search is effective in improving the latency–flicker tradeoff, but that the student models still improve over the teacher with biased beam search. The disadvantages of biased beam search are that it requires careful tuning of the prefix mask in order to avoid damaging quality, and that it requires a modified inference engine. The inference engine requires access to the previous translation, creating challenges for scalability. In contrast, our self-training approach requires no modifications to inference. Furthermore, since biased beam search relies on aligning the current translation with the previous one, it is hard to apply when the translation cannot be aligned – for example in a cascaded system where the ASR can rewrite its output.

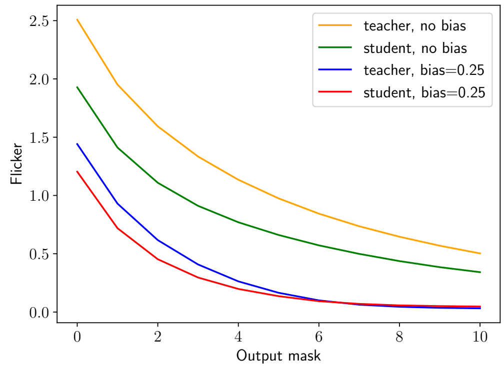

Figure 3: Latency-flicker tradeoff for teacher-student models with and without biased beam search for the En→De IWSLT.

4 Conclusion

We show that self-training reduces the flicker in retranslation-based simultaneous translation, whilst retaining quality. Our experiments link this flicker reduction to increased monotonicity and reduced entropy of the self-trained model. Although biased beam search can obtain larger reductions in flicker, it requires more careful parameter tuning, and a modified inference engine.

5 Limitations

Language Pairs We conducted our experiments using two European language pairs where source and target are linguistically similar. We show that we are able to reduce word order divergence between source and target text through forward translation which helps in reducing the flicker. However, a more challenging case will be using languages from different linguistic families with radically different word orders (such as English–Japanese) which may limit to which extent we are able to reduce the word order divergence between source and target through synthetic data creation.

Evaluation Whilst we show quality evaluation across three different metrics, we were not able to add human evaluation due to resource and space constraints. An additional consideration for simultaneous ST is that it is not clear what the combined effect of flicker, latency and quality is on human perception, and there has been limited work on this (Javorský et al., 2022).

D Flicker-Latency Tradeoff

In Figure 4, we show the flicker-latency tradeoff for all language-pair and testset combinations.

E Biased Beam Search

We consider the effect of the bias mask on full sentence translation quality, as measured by BLEU. The bias mask is measured in sentencepiece tokens. Based on Figure 6, we set the bias mask to 6 for ESIC and 10 for IWSLT, in order to avoid a loss of BLEU.

In Figure 7, we show flicker-latency tradeoffs for all language pair and testset combinations.

F Controlling Monotonicity

We have shown the scores for CHRF and COMET for monotonicity control experiments in addition to BLEU in Table 7. In Figure 5, we show the flicker-latency tradeoff for monotonicity-controlled experiments for all language-pair and testset combinations.

Social Commonsense for Explanation and Cultural Bias Discovery

Lisa Bauer **Hanna Tischer** **Mohit Bansal**
UNC Chapel Hill
{lbauer6, hannalt, mbansal}@cs.unc.edu

Abstract

Social commonsense contains many human biases due to social and cultural influence (Sap et al., 2020; Emelin et al., 2020). We focus on identifying cultural biases in data, specifically causal assumptions and commonsense implications, that strongly influence model decisions for a variety of tasks designed for social impact. This enables us to examine data for bias by making explicit the causal (if-then, inferential) relations in social commonsense knowledge used for decision making, furthering interpretable commonsense reasoning from a dataset perspective. We apply our methods on 2 social tasks: emotion detection and perceived value detection. We identify influential social commonsense knowledge to explain model behavior in the following ways. First, we augment large-scale language models with social knowledge and show improvements for the tasks, indicating the implicit assumptions a model requires to be successful on each dataset. Second, we identify influential events in the datasets by using social knowledge to cluster data and demonstrate the influence that these events have on model behavior via leave-K-out experiments. This allows us to gain a dataset-level understanding of the events and causal commonsense relationships that strongly influence predictions. We then analyze these relationships to detect influential cultural bias in each dataset. Finally, we use our influential event identification for detecting mislabeled examples and improve training and performance through their removal. We support our findings with manual analysis.

1 Introduction

Social commonsense knowledge helps humans maneuver through everyday life, aiding in situations that may require social nuance or cultural knowledge. Commonsense knowledge acquisition has been an important goal in NLP (Levesque et al., 2012; Davis and Marcus, 2015; Talmor et al., 2019) and in the past few years there has been a surge of research focusing specifically on improving social commonsense understanding for neural models (Sap et al., 2019a,b; Hwang et al., 2020; Forbes et al., 2020). However, social commonsense may contain many human biases due to social and cultural influence (Sap et al., 2020; Emelin et al., 2020). We aim to discover influential cultural biases in social applications datasets via the social and causal commonsense knowledge (Roemmele et al., 2011; Luo et al., 2016; Ponti et al., 2020) present in each dataset, to identify bias in cause-effect commonsense relationships. We define cultural bias as a positive or negative cultural attitude toward a social structure (see Section 3.1) and define causal commonsense following Sap et al. (2019a), as if-then, inferential relations. Specifically, we are interested in exploring biases towards the following social structures: *religion, economy, family, government, education* and *technology*. To the best of our knowledge, we are the first to empirically discover influential cultural biases in social tasks, using causal commonsense knowledge about social interactions, emotional reactions, and human needs to explain underlying cultural trends in social applications datasets.

We focus on two social tasks: emotion detection in social media and community value detection from interviews. We define a social task as any task that is intended to have social impact and requires social knowledge to correctly resolve. It is particularly important to identify influential biases in datasets and applications which are designed for social impact. HurricaneEmo (Desai et al., 2020) is an emotion detection task that focuses on perceived emotional reactions to events that occur during natural disasters. For example, events that exist in this dataset like *"thanks god"* may elicit emotions like AWE, and events like *"PersonX sends – to congress"* may elicit emotions like CONTEMPT, showing a positive cultural bias for reli-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3745–3760
May 2-6, 2023

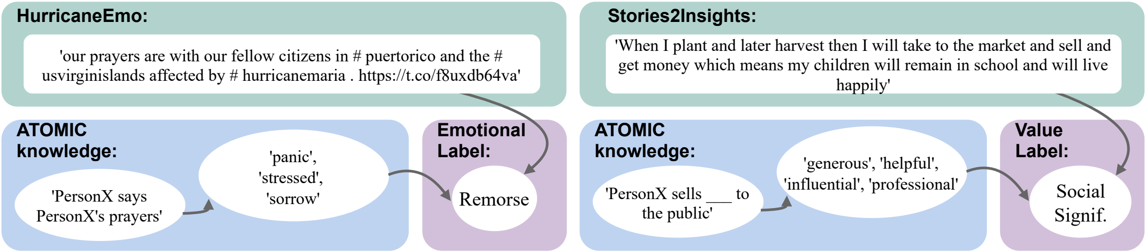

Figure 1: Examples of Social Tasks and Knowledge.

gion and a negative cultural bias for government. Stories2Insights (Conforti et al., 2020) is a value detection task that focuses on interviews conducted to identify community needs in developing countries, aiming to capture perceived values based on certain events. For example, events like *"reading the bible"* indicate INDIGENOUS values (defined by social norms and religion) whereas events like *"providing for children"* indicate INTRINSIC HUMAN needs (defined by health and quality of life). This illustrates a positive culture bias for Christianity and family. We aim to discover causal social knowledge that indicates cultural biases in each dataset, by analyzing model behavior on both tasks to gain a dataset-level understanding of events that influence performance.

We identify these biases via casual social knowledge, which encodes the relationships between events and the triggered reactions. We derived our knowledge from the social knowledge graph ATOMIC (Sap et al., 2019a). Consider the HurricaneEmo example in Fig. 1, in which the ATOMIC knowledge makes explicit the event-emotion causal relationships in the tweet that bring about the perceived emotion REMORSE. Identifying that the event *"says prayers"* causes perceived traits like *sorrow* and *stressed*, allows us to understand which events in the tweet cause the perceived emotion and contribute to the specific cultural biases. Next, consider the Stories2Insights example, in which the knowledge demonstrates the causal relationships that support the perceived value SOCIAL SIGNIFICANCE (defined by identity and status). Identifying that the event *"sells — to the public"* causes perceived traits like *influential* and *professional*, sheds light on how the event's associated cultural biases contribute to the perceived value.

In this paper, we gain a dataset-level understanding of influential causal social commonsense relationships, allowing an exploration of the underlying social and cultural biases that explain model behavior on social tasks. To this end, we first extract ATOMIC knowledge for each datapoint, utilizing a combination of TF-IDF and BERTScore (Zhang et al., 2019). We then append different components of this knowledge to the input, to focus strongly on either the cause, the effect, or the causal relation between the two. We use BERT-AUG, which ingests knowledge augmented data as input to BERT (Devlin et al., 2018), to yield improvements on both tasks. These improvements illustrate that the underlying causal social assumptions made explicit by the integrated knowledge do indeed increase model accuracy on the task and thus augment a model's understanding of the task. To discover underlying cultural biases, we investigate the influence of underlying events in each task. We first identify underlying events in the data by clustering datapoints using k Nearest Neighbors (kNN) around commonsense events, using fine-tuned contextual embeddings. We then identify which of these events are influential by performing leave-K-out experiments, which detect the influence of train clusters on task performance.

Understanding cultural biases in social applications data via the implicit commonsense knowledge present in the data is important for analyzing the limitations of the dataset and the respective tasks. By making explicit the underlying cultural assumptions and causal relationships, we are able to identify the biases that data from a certain source may have, which is paramount when using this data in the development of technology for other applications (Bender and Friedman, 2018).

Finally, we use our methods to identify mislabeling in event clusters. Datasets used for training deep learning models are large and often contain noisy labels, even if the data was collected via crowdsourcing (Frénay and Verleysen, 2013; Rajani et al., 2020). We identify events whose train clusters cause performance improvement when removed in leave-K-out experiments, indicating mis-

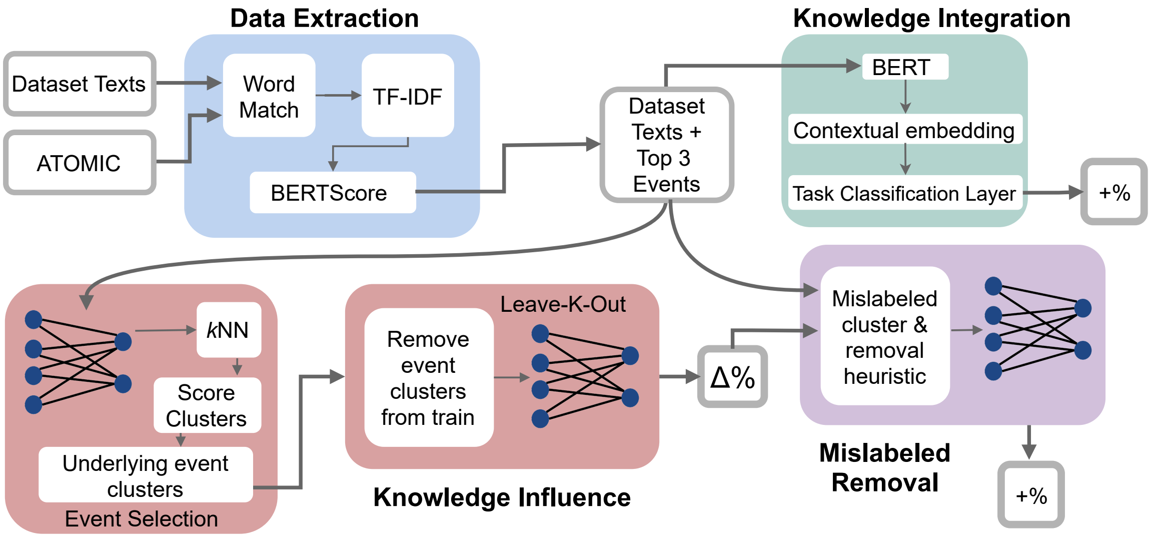

Figure 2: Data Extraction, Knowledge Integration, Knowledge Influence, and Mislabeled Removal.

labeling. Overall, our contributions are:

- We improve HurricaneEmo & Stories2Insights performance when we augment models with ATOMIC social knowledge, indicating the implicit assumptions a model requires to be successful on each dataset.
- We find representative events in each of the datasets via ATOMIC and *kNN*, and use leave-K-out experiments to discover causal social commonsense relationships that strongly influence model behavior.
- We analyze the influential cultural biases for different social structures and strongly suggest a cultural bias analysis for train data.
- We demonstrate that our methods can be used to identify mislabeled examples in the dataset.

2 Related Work

2.1 Social Applications

We explore tasks for social applications, specifically perceived emotion detection and perceived value detection. Emotion prediction has been studied for many different domains (Strapparava and Mihalcea, 2007; Katz et al., 2007; Ezhilarasi and Minu, 2012; Chen et al., 2018; Mohammadi et al., 2019), and has been extensively applied to social media posts (Mohammad, 2012; Wang et al., 2012; Mohammad and Kiritchenko, 2015; Abdul-Mageed and Ungar, 2017), particularly in the social good domain. Sharifirad et al. (2019) performed emotion classification on sexist tweets and Sanders et al. (2021) analyzed sentiment in tweets during the early COVID-19 pandemic. Similar to our disaster-related application, Lin et al. (2018) used semantic matching to discover disaster recovery trends in large text corpora. In this paper, we focus on implicit perceived emotion prediction, which requires models to capture context and perform reasoning about perceived emotions (Desai et al., 2020), rather than intended emotions. Desai et al. (2020) released an emotion prediction dataset, focusing on tweets related to Hurricanes Irma, Harvey, and Maria. Hirmer and Guthrie (2016) focused on User-Perceived Values (UPVs), particularly concentrating on the needs and values of project beneficiaries in developing countries. More recently, Conforti et al. (2020) analyzed emotion as user perceived values in statements made by Ugandan rural individuals.

2.2 Social Causal Commonsense Reasoning

Commonsense reasoning has been a long-standing challenge in NLP (Levesque et al., 2012; Davis and Marcus, 2015; Talmor et al., 2019) and more recently, social commonsense reasoning has gained popularity (Rashkin et al., 2018; Nematzadeh et al., 2018; Talmor et al., 2019; Sap et al., 2019b; Hwang et al., 2020; Forbes et al., 2020; Sap et al., 2020; Emelin et al., 2020), with a strong focus on social, moral, and cultural understanding and norms. We further this work by extracting causal relations for social and cultural norms and integrating this knowledge to understand biases and model explanation in social tasks. Similar to our integration methods, Chang et al. (2020) implicitly and explicitly incorporates social knowledge from ATOMIC

(Sap et al., 2019a) and ConceptNet (Speer et al., 2017) into a social commonsense reasoning task (in contrast to event-driven tasks with real-world impacts), yielding performance gains. We, instead, focus on a causal dimension of ATOMIC and use knowledge to both improve and explain both perceived emotion and value detection. Causal commonsense reasoning has also been explored for a variety of tasks, focusing on identifying event causality in social media (Sil et al., 2010; Riaz and Girju, 2013; Kayesh et al., 2019, 2020b,a), commonsense causal QA (Roemmele et al., 2011; Luo et al., 2016; Hassanzadeh et al., 2019; Ponti et al., 2020), and conversational emotion recognition (Ghosal et al., 2020). We, instead, focus on social tasks and use knowledge to gain a dataset-level understanding of influential events.

2.3 NLP Interpretability

Our analysis methods are related to influence functions (Koh and Liang, 2017), which have been recently extended to neural text classifiers in NLP (Han et al., 2020). Our methods share particular similarity with group influence functions, which identify an influential group of training examples in a particular test prediction (Basu et al., 2020). We largely differ by using a heuristic for clustering events and verifying the influence of each cluster's train data on the cluster's dev data, allowing a dataset-level analysis of influential social relationships for text classification. Similar to our work, Rajani et al. (2020) proposed using a *k*NN framework to gain a dataset-level understanding of model behavior by identifying training examples responsible for NLI predictions. In contrast, we identify influential causal social commonsense relationships.

3 Tasks & Datasets

3.1 Definition of Cultural Bias

We define cultural bias as a positive or negative cultural attitude toward a certain social structure. Thus, positive and negative bias refer to the sentiment of the particular commonsense relation toward a social structure in the text. This is encoded differently for the two datasets that we use throughout this work. HurricaneEmo has labels for positive or negative perception (e.g., contempt = negative, love = positive). However, the target of the cultural bias depends on the subject of the text and the intended target of the emotion, thus we stress the importance of analyzing the automatically retrieved instances manually (see list of influential events in Table 4 and datapoints in Table 5). We also consider the respective commonsense relation in order to understand whether the sentiment is positive or negative. On the other hand, Stories2Insights does not use sentiment-based labels, but instead focuses on different categories of values, indicating a positive-only cultural attitude/bias toward the topic of the text. Therefore, we consider all Stories2Insights labels as positive with respect to cultural attitude.

It is crucial to note that it is not the intention of this work to draw conclusions about various cultures that these datasets may derive from. The cultural attitudes we discover in a single dataset are not an accurate reflection of the entire culture that this dataset may derive from and we would find this conclusion to be particularly harmful. We instead aim to explore biases with respect to social structures in a particular dataset and are only able to discover and examine cultural attitudes that are particular and limited to the target dataset and are additionally limited by our knowledge recall. See Section 8 for more details.

3.2 HurricaneEmo

For emotion classification, we use HurricaneEmo (Desai et al., 2020). This dataset was constructed from 15,000 English tweets about Hurricanes Irma, Harvey, and Maria. Through crowd-sourcing, each tweet was classified based on the 24 Plutchik emotions (Plutchik, 2001), and then summarized into eight emotions: AGGRESSIVENESS, AWE, CONTEMPT, DISAPPROVAL, LOVE, OPTIMISM, REMORSE, and SUBMISSION. These were split into eight binary classification tasks. For example, this tweet in the LOVE binary classification task, *"to my friends offering that support during the hurricane, i thank you. we are safe and sound. https://t.co/yl8wdbhi4"* is labeled positive. See Section A.1 in the appendix for dataset construction and size.

3.3 Stories2Insights

For Automatic User-Perceived Value classification, we obtain the Stories2Insights (Conforti et al., 2020) corpus, consisting of labeled (English) interviews from villages in Uganda. Each statement in the dataset is labeled with User-Perceived Values (UPVs), and the data is divided into six different labels: EMOTIONAL, EPIST, FUNCTION, INDIGENOUS, INTRINSIC HUMAN, and SOCIAL SIGNIFICANCE (Conforti et al., 2020). We used these labels to create binary datasets from the original data. For example, *“Also my children and my husband will get entertained and be happy."* is labeled as EMOTIONAL. See Section A.2 in the appendix for dataset construction and size.

3.4 ATOMIC

We utilize the causal social commonsense knowledge in the knowledge graph ATOMIC (Sap et al., 2019a), a graph for if-then reasoning, connecting events through one of nine different relation edges. In this paper, we focus on the "xAttr" edge, which describes the perceived attributes of an event’s subject. This edge allows us to extract perceived social knowledge, as it often covers the perceived emotion or value we are interested in for HurricaneEmo and Stories2Insights. For example, the ATOMIC event *“PersonX helps people"* uses the "xAttr" edge to show the perceived attributes of PersonX based on this event, i.e., PersonX is seen as *"kindhearted; incredible; pleasant; kind"*.

4 Models & Knowledge Augmentation

We aim to 1) extract knowledge that makes explicit the underlying causal social commonsense relationships in each datapoint and 2) propose a simple integration method to show that this knowledge is able to increase model accuracy, demonstrating the role of these relationships in improving a model’s understanding of the task.

4.1 Baseline

We finetune BERT base (Devlin et al., 2018) as a baseline for both datasets. We input the text (tweet or statement) to BERT to obtain contextual embeddings, which we then project with a weight matrix $\mathbf{W} \in \mathbb{R}^{d\times 2}$.

4.2 Knowledge Integration

We augment the BERT baseline with knowledge, which we call BERT-AUG. We illustrate this process in the *Knowledge Integration* section of Fig. 2. Each input consists of text from the task and k (where k=3) extracted ATOMIC events with attributes (the extraction process is described in Section 4.3). We directly append knowledge as text to the input text via 5 different methods. To illustrate these methods, consider the following top 2 events that may be extracted for a given tweet:

- "PersonX gets a warning" -> "unhappy", "behaved", "negative", "mischievous", "badly"
- "PersonX ignores the warnings" -> "reckless", "unworried", "confused", "dangerous", "unsafe", "careless"

Dataset	**%Event-Text**	**%Attribute-Label**
HEmo	58	54
S2I	77	65

Table 1: Data Extraction Manual Analysis. Event-Text is the match between the ATOMIC event and datapoints. Attribute-Label is the match between the respective ATOMIC attributes and the dataset label. Higher % indicates more matches.

Each integration method uses different components of the knowledge as follows, which are then appended to the input text:

- Method 1: all attributes of first event
  Example: "unhappy; behaved; negative; mischievous; badly"
- Method 2: first attribute of first event
  Example: “unhappy”
- Method3: first attribute of all events
  Example; “unhappy; reckless’
- Method4: first event + first attribute
  Example: "PersonX gets a warning: unhappy"
- Method5: first event + all attributes
  Example: "PersonX gets a warning: unhappy; behaved; negative; mischievous; badly

We determine the best method for each dataset as a hyperparameter when tuning BERT-AUG on the dev set.

4.3 Knowledge Extraction

We extract ATOMIC knowledge for both HurricaneEmo and Stories2Insights, illustrated in the *Data Extraction* section of Fig. 2. In this section, the tweets of HurricanEmo and the text of Stories2Insights are both referred to as the dataset D, as we follow the same extraction process for both datasets.

Following Lin et al. (2018), our extraction procedure is decomposed into two phases: one for speed and one for precision. The first phase serves as a coarse-grained filter to efficiently collect an initial pool of ATOMIC knowledge candidates P_i for each datapoint $d_i \in D$: if there is word overlap between d_i and a ATOMIC candidate event, the ATOMIC candidate is added to P_i. Next, we use TF-IDF

Model	AGR	LOV	SBM	AWE	DSP	CNT	RMR	AVG
BERT (Desai et al., 2020)	67.6	54.0	67.4	68.3	55.7	66.8	58.5	62.6
BERT	**75.6**	65.1	**72.8**	**73.7**	58.0	**77.9**	63.2	69.5
BERT-AUG	75.0	**68.8**	70.5	72.7	**64.4**	75.9	**65.2**	**70.4**

Table 2: HurricaneEmo Test Results (Accuracy), including aggressiveness (agr), love (lov), submission (sbm), awe (awe), disapproval (dsp), contempt (cnt), remorse (rmr), and average (avg) across all binary tasks. We recompute the baseline after extra data preprocessing. Best results are bold.

Model	Emotional	Epistemic	Functional	Indigenous	Intrinsic	Social	Avg
BERT	81.0	87.7	**84.6**	84.6	84.4	80.1	83.7
BERT-AUG	**86.9**	87.7	82.6	**89.4**	**87.2**	**82.8**	**86.1**

Table 3: Stories2Insights Test Results (Accuracy). Best results are bold.

to find the top n (we choose n=50) most similar ATOMIC candidates (considering ATOMIC event only) to d_i in P_i, and add these to a smaller pool S_i. Then, for precision we score each ATOMIC candidate in S_i with d_i for semantic match, using BERTScore, an evaluation metric for text similarity (Zhang et al., 2019). In this step, we use both the ATOMIC event and attributes to ensure that the causal social knowledge of each event is captured. We rank S_i by score and return the top k (where k=3) ATOMIC candidates for each datapoint.

To determine how precise this retrieval is, we manually examine the knowledge-datapoint matches for each dataset, demonstrated in Table 1. We analyzed 30 events from the dev set of each binary dataset (7 for HurricaneEmo, 6 for Stories2Insights; totaling 1260 datapoints), and examined matches between 1) the datapoint and ATOMIC event, and 2) the dataset label and ATOMIC attributes. This analysis investigated both whether 1) the ATOMIC events matched events in the datapoint and 2) the causal relationship between the event and its attribute is the same as the relationship between the datapoint and its label. We observe that ATOMIC matches both the events and causal relations in Stories2Insights better than those in HurricaneEmo. See Section A.4.1 in the appendix for more details.

5 Event Influence & Bias Discovery

We aim to (1) identify influential social and causal events in each dataset, and (2) analyze their respective inferential relationships to discover attitudes toward target social structures.

To identify influential events in the datasets, we first extract underlying ATOMIC events from each dataset via *event selection* and then measure how influential these events are via *leave-K-out* experiments (illustrated in *event selection* and *leave-K-out* in the *Knowledge Influence* section of Fig. 2). We then explore the following types of social and cultural structures in our datasets: *religion, economy, family, government, education* and *technology*. We consider a dataset to be biased if there exists a positive or negative attitude toward one of these structures in the influential underlying events.

5.1 Event Selection

We select underlying events in each dataset that potentially influence model behavior. To identify these events, we first fine-tune a separate BERT model for each binary dataset. Then, we represent the binary train data, dev data, and ATOMIC events with contextual embeddings using the respective BERT model for that dataset. Next, for each datapoint $d_i \in D$, we find its closest event e_j (where $e_j \in E$ and E denotes the ATOMIC events) using kNN. We then assign d_i to c_j, where c_j is the respective data cluster for e_j ($c_j \in C$ and C denotes all the clusters). If d_i is in train, we assign it to c_j^t (the event-specific train cluster), and if d_i is in dev, we assign it to c_j^d (the event-specific dev cluster). Thus, for each binary dataset, we have clusters of train and dev data for each ATOMIC event. This process is denoted as *kNN* in Fig. 2.

To identify the most representative underlying ATOMIC events learned by the model, we use the clusters of the top m (where m=50) most common ATOMIC events extracted for the train set (see Section 4.3 for details), and thus each binary dataset in HurricaneEmo and Sight2Insights has m clusters. To further identify which events have been learned best by the model, we then use cross-validation to determine which clusters have the highest prediction accuracy (thus the dev set is not used to score clusters during event selection). We score clusters by their average prediction accuracy across each fold and select events whose clusters score highest. This process denoted as *Score Clusters* in Fig. 2. We use the top t (where t=5) events for our leave-K-out experiments.

5.2 Leave-K-Out

We evaluate whether the selected underlying events have a strong influence on model behavior (see *leave-K-out* in Fig. 2). Recall that each event e_j in a particular binary dataset has a cluster of event-specific datapoints c_j^t and c_j^d for train and dev. For each event e_j, we remove c_j^t from the train set and use c_j^d as an evaluation set. We compare results on c_j^d between a BERT baseline (discriminator trained on all train data in that binary dataset) versus BERT trained on the train set with c_j^t removed. We evaluate accuracy and look for prediction changes. We also include ablations that remove the same amount of randomly selected train data to establish a lower bound. See Section A.5.1 in the appendix for data sizes and a thorough discussion and interpretation of the respective results.

6 Results

6.1 Knowledge Integration

We examine knowledge integration in Table 2 and Table 3. Due to our additional HurricaneEmo data preprocessing (see Section A.1 in the appendix), we reran BERT baselines on this dataset. Overall, Stories2Insights has better performance improvements than HurricaneEmo.

For HurricaneEmo, we see visible improvement for LOVE, DISAPPROVAL, and REMORSE, which performed best using integration methods 2, 5, and 3, respectively, all of which are attribute focused. For Stories2Insights, we see visible improvements for datasets where the label is focused on social knowledge: EMOTIONAL, SOCIAL SIGNIFICANCE, INTRINSIC HUMAN, and INDIGENOUS, using integration methods 1, 3, 4, and 5, respectively.

6.2 Knowledge Influence

We find ATOMIC events that influence model performance in Table 4. Given the top t dataset events from event selection in Section 5, we demonstrate results for the events for which a change in performance occurred, i.e., the influential events (see Section A.5.2 in the appendix for the full list of events). We see that for all Stories2Insights events, and most events in HurricaneEmo, removing c_j^t decreases performance on c_j^d. Our ablations indicate a lower bound and thus highlight the cases where decreased performance is indeed significant. We underline all influential results that perform worse on c_j^d than both the baseline and ablation when the respective c_j^t is removed. These events are able to cluster highly relevant text and thus the c_j^t examples have strong prediction influence on c_j^d. See Section A.5.1 in the appendix for further discussion and interpretation of the results.

We observe some cases in HurricaneEmo where best performance is achieved by removing c_j^t, indicating mislabeling. We manually analyze the five HurricaneEmo event clusters in question. For each datapoint in c_j^d where the prediction was corrected after leave-K-out, we retrieve the removed c_j^t datapoints. We find that the train and dev manual label agreement between the two sets is 49.33%, averaged across all clusters. As the labels should agree, this indicates mislabeling and explains the performance improvements after removal (verified by the manual analysis in Section 6.4). Finally, there are cases in which the ablation performs worst. This seems related to the nature of the c_j^ds in question, such that the model is uncertain about these examples and thus predictions on this subset are highly sensitive to any changes in the train set.

We performed manual analysis to verify c_j (event-specific data) semantic similarity with e_j (the event) and also c_j^t and c_j^d (event-specific dev and train) similarity with each other. Two annotators analyzed approximately 190 datapoints across 13 different event clusters (with a Cohen kappa of 0.81 which is considered as 'almost perfect agreement' [1], see Section A.4.2 for more details). Table 6 shows that for HurricaneEmo, 87% of the event-specific data semantically match each other, and close to half of dev and train examples match the cluster's event. We also observe that for Stories2Insights, 100% of the event-specific data semantically match. Overall, the integration improvements, leave-K-out results, and final influential events suggest that ATOMIC represents a better cultural and social match for Stories2Insights, and allow us to clearly identify influential events in Stories2Insights. This is supported by our man-

ual analysis which indicates that Stories2Insights events and causal relations are better captured by ATOMIC and that by using ATOMIC knowledge, we are able to get semantically matching clusters.

6.3 Bias Analysis

We examine bias with respect to the following cultural structures: *religion, economy, family, government, education* and *technology*. For HurricaneEmo, we find strong cultural biases for *religion* and *technology*. In Table 4, we see that religion is associated with several causal reactions, specifically disapproval and remorse. This may be due to the use of religion in text, marking particularly traumatic situations. We also observe that there is a general mixed reaction toward *technology*, with "driving" associated with perceived aggression and "checking weather forecast" associated with perceived love (often in the context of rapid information spread during a disaster). Finally, it seems that there is a negative bias towards *government*, in which references to "congress" tend to elicit remorse. Interestingly, the *economy*, *family* and *education* seem relatively non-influential.

For Stories2Insights, we see that the mention of *religion* is both influential and strongly associated with INDIGENOUS values (defined by social norms and religion). "Providing for children" is also a very influential event, demonstrating a strong

Model	LOV	DSP	SBM	AWE	RMR

Number Examples Removed	4	13	8	97	11

Table 7: HurricaneEmo test set performance after removing potentially mislabeled train datapoints.

bias for *family* in the dataset, which elicits the INTRINSIC HUMAN value, associated with health and quality of life. This sheds light on how attitudes toward religion, family, and childcare are valued in positive ways within this corpus, and indicates how these structures may play strong roles in values associated with social norms and quality of life. Finally, the *economy* also seems to be quite influential, as we see that "PersonX sells — to the public" is strongly associated with SOCIAL SIGNIFICANCE (i.e., identity, status) illustrating that the economy plays a strong role in this value.

Given the performance improvements when adding social causal knowledge and the discovered influential cultural biases described above, we see that these datasets contain implicit assumptions that, when acquired, improve a model's performance on each dataset. In particular, there are several influential cultural biases in the dataset that may be harmful when generalizing to another task. For example, the importance and meaning of *religion* may be different depending on the task. In HurricaneEmo, *religion* plays a major role as a reaction to traumatic events, whereas in Stories2Insights it plays a role in indigenous values. We observe that the context of data collection (e.g., natural disaster tweets, perceived value collection, etc) is particularly important in the type of attitudes towards social structure a dataset might encapsulate, and thus recommend this type of analysis to better understand implicit bias held in a dataset based on its application. We want to strongly emphasize that is very important to properly analyze the implicit cultural biases for any train set before applying a model trained on this dataset.

6.4 Detecting Mislabeled Events

Finally, we leverage our analysis to identify mislabeled datapoints in HurricaneEmo and improve our performance on the full test set. We use all datasets that contain events where the best performance on the target c_j^d is achieved by training on the removed train set, as illustrated in Table 4. This suggests that the c_j^t have been mislabeled and are negatively affecting c_j^d, which we have confirmed with manual analysis (see Section A.4.3 for more details). We refer to these events as mislabeled events. To mitigate this, we use the mislabeled events in a removal heuristic, where we remove all examples that extract the mislabeled events as their highest scoring event. We then evaluate our model on the full test set, see Table 7. Every considered dataset demonstrates improvement over the BERT baseline on the full test set, except AWE, most likely due to the large number of removed examples for AWE, which may interfere with the predictions of other datapoints.

7 Conclusion

We used causal social commonsense knowledge to discover influential events and relationships that explain model behavior and pinpointed instances of cultural bias. First, we found that using large-scale language models augmented with causal social knowledge improved our social classification tasks, illustrating that the knowledge made the underlying social assumptions in the dataset explicit. Then, we identified underlying events in each dataset by clustering data around ATOMIC knowledge, to pinpoint cultural biases that the dataset may exhibit. We found that some of this knowledge strongly influenced model behavior through leave-K-out experiments, providing a dataset-level understanding of influential events and causal social commonsense relationships and allowing an analysis of the datasets' implicit influential cultural biases. Finally, we used these underlying and influential events to identify mislabeled train examples and thus improve training and performance.

8 Ethical Considerations & Limitations

We first address ethical considerations and limitations with respect to potential biases in our methods and resources, and then ethical considerations with respect to data use.

Bias: Emotions and values, and their expression and perception, are not universal. We use ATOMIC as, at the time of this work, it is the largest English source of social commonsense knowledge, however it is important that we further the creation and use of resources that are not limited to Western norms, developed countries, and the English language, especially when applying them to data outside of these domains. We anticipate that a knowledge graph better suited for representing different cultural attitudes will yield more coverage. For example, the events in ATOMIC may not cover important or representative cultural events in Uganda (the source of our second dataset), as it largely contains Western-centric social and cultural norms found in mostly developed countries.

It is also crucial to note that it is not the intention of this work to draw conclusions about various cultures that these datasets may derive from. The cultural attitudes we discover in a single dataset are not an accurate reflection of the entire culture that this dataset may derive from and we would find this conclusion to be particularly harmful. We instead aim to explore biases with respect to social structures in a particular dataset and are only able to discover and examine cultural attitudes that are particular and limited to the target dataset and are additionally limited by our knowledge recall. A precision-recall tradeoff exists based on the KG coverage, and thus the retrieved datapoints may not all be biased (precision) nor will all biases be retrieved (recall) using the available KG. Thus, we also stress the importance of using manual analysis to identify and confirm biases in the extracted datapoints. We hope this will further encourage the development of knowledge graphs that explicitly represent more annotated social/cultural commonsense knowledge by illustrating its usefulness in gaining a corpus-level understanding of datasets.

Similarly, we are additionally limited by the use of transformer models that were trained on mostly Western text and may be prone to capture Western cultural information even if fine-tuned on a dataset with different cultural attitudes. Providing a solution to this problem is beyond the scope of this paper, but future work could explore more culturally diverse data for pre-training models.

Data Use: Twitter data and interview transcripts are sensitive data and thus require strong considerations about the use and release of the data. The publicly released data for HurricaneEmo is fully anonymized to protect the identity of users. Stories2Insights data has also been fully anonymized, but is not publicly released and has been kept private to ensure the safety of the communities and to prevent harmful use of the data. Following suit, we do not release any data for this dataset to limit potential harm or misuse. For more details on the ethics concerning the collection and intended use of either of these datasets, please refer to each dataset's original paper.

Future Work: Our contribution focuses on the novel combination of knowledge graph relations, interpretability methods, and clustering to identify both influential and biased commonsense relationships. We aim to use this as an opportunity to encourage work in the curation of resources that explicitly annotate cultural attitudes or "commonsense" biases by illustrating how such resources can facilitate a corpus-level understanding of implicit influential cultural biases. Our work is limited by the methods we explored, and thus we encourage further investigation of certain elements in our experimental pipeline, in particular other datasets, clustering method variations, other MLMs, more diverse KGs, and other knowledge models.

A Appendix

A.1 HurricaneEmo Pre-processing

We performed the following pre-processing steps for HurricaneEmo (released by Desai et al. (2020)). First, we de-duplicated each train, dev, and test file (per the authors suggestion). Then, we de-duplicated across splits, removing data from the train set if it was present in the dev or test sets. We used these files as our input for the pipeline described in our paper. We chose not to include the OPTIMISM category in our experiments since we were not able to reproduce a baseline result sufficiently close to the original paper on the fully deduplicated dataset. After preprocessing, the train/dev/test splits for each of the files are: AGGRESSIVENESS: 1695/493/495, AWE: 2942/868/868, CONTEMPT: 1507/452/443, DISAPPROVAL: 2363/706/707, LOVE: 1028/307/304, REMORSE: 3104/910/908, SUBMISSION 2432/724/721.

A.2 Stories2Insights Pre-processing

We performed the following pre-processing steps for Stories2Insights. We received the dataset from the authors, with the T3 labels described in the original paper (Conforti et al., 2020). We instead use the T1 labels defined in their paper as binary datasets. To create these datasets, we followed the T3 label groupings shown in Appendix A of their paper. We then created datasets with a 1:1 positive-to-negative datapoint ratio for the train, dev, and test sets. These negative datapoints were collected evenly from all other T1 datasets. We repeated this process for all T1 labels and every set (train, dev, and test). After preprocessing, the train/dev/test splits are: EMOTIONAL: 805/75/84, EPIST: 553/82/65, FUNCTION: 2551/302/345, INDIGENOUS: 695/64/104, INTRINSIC HUMAN: 2317/261/320, SOCIAL SIGNIFICANCE: 1241/134/151. If interested in using this data, please contact the original authors for access.

A.3 Reproducibility & Hyperparameters

We utilized BERT-base for all of our experiments (Devlin et al., 2018). We followed hyperparameter settings for BERT as described in Desai et al. (2020). To train BERT for HurricaneEmo, we use batch size 8 and learning rate 2e-5. To train BERT for Stories2Insights, we use batch size 8 and learning rate 1e-5. Training for both was completed in 3 epochs. We train each model using 1 GeForce GTX 1080 Ti GPU.

A.4 Manual Analysis Details and Further Analysis

A.4.1 Data Extraction

Manual analysis for examining the knowledge-datapoint matches for each dataset was completed by an expert author, since this is time-consuming, fine grained verification analysis (as opposed to model evaluation). Details on the setup of the analysis are in the main paper Section 4.3.

A.4.2 Cluster Match

This section describes the manual analysis used to analyze the cluster matches via our methods in Section 6.2 in the main paper (Table 6). Manual analysis was completed by 2 expert authors since this is time-consuming, fine grained verification analysis (as opposed to model evaluation). We obtain high agreement, with a Cohen kappa of 0.81 (which is considered as ‘almost perfect agreement’; see `https://en.wikipedia.org/wiki/Cohen%27s_kappa`). We selected 10 dev and 10 train datapoints for each event cluster, and because not all events had a full 10 datapoints in dev or train, this leads to total of 190 datapoints.

Using this data, we performed an analysis to identify whether the event-specific data sets that were extracted for a certain ATOMIC event (1) semantically matched the events and (2) semantically matched each other. For (1), we wanted to see whether the semantic meaning in the ATOMIC event was reflected in the clustered data. For (2), we wanted to see whether the semantic meaning in event-specific dev (c_j^d) and event-specific train (c_j^t) sets was matched. The results were computed as follows. For (1), if the majority of selected datapoints matched the event, we considered this to be a positive data−event match. We then compute: # events with semantically matching data−event clusters / # total events. For (2), if the majority of selected datapoints matched across dev and train, we considered this to be a positive train−dev match. We then compute: # events with semantically matching train−dev clusters / # total events. Majority is calculated such that a majority of both train and dev had to be semantically similar.

We see that the results for (2) are very high in Table 6, which supports our findings that there is mislabeling in the dataset (i.e, the labels are different between dev and train sets but the semantic

Dataset	Event	%Event-Specific Train	%Event-Specific Dev

Table 8: Leave-K-Out Cluster Size. %Event-Specific Train is the % of train examples removed during Leave-K-Out training and %Event-Specific Dev is the % of dev examples the trained model is evaluated on.

meaning are similar, thus there is mislabeling). We also see that (1) can be low for some datasets, indicating that while the train and dev data may be semantically matched, this semantic meaning may differ from the original ATOMIC commonsense relation for some datasets more than others. This may be due to limited coverage of ATOMIC for some events and is intended to show transparency in the limitations of our approach, which we hope will encourage the development of a KG that explicitly represents this type of cultural knowledge (which was not available at the time of this work).

A.4.3 Mislabeling

This section describes the manual analysis used to confirm mislabeling in HurricaneEmo train examples. Manual analysis was completed by an expert author since this is time-consuming, fine grained verification analysis (as opposed to model evaluation). We completed manual analysis to identify mislabeling on a set of 30 train examples across different event clusters. The train examples were selected from cases where the performance improved on the event specific dev set when the event specific train set was removed.

A.5 Knowledge Influence Details

A.5.1 Leave-K-Out Cluster Size

We illustrate the sizes of the event-specific train (c_j^t) and dev (c_j^d) clusters with respect to the original train and dev dataset sizes for each of the leave-K-out results in Table 8. Some of the resulting datasets are very small and are more difficult to draw conclusions from. For this reason, we show the dataset sizes in Table 8 for an improved and transparent interpretation of the results. On the other hand, we can also see that several of the datasets are quite large and leave-K-out has a clear and significant impact on their performance with respect to the full train set (e.g., "PersonX checks the weather forecast" and "PersonX sells — to the public").

A.5.2 Selected Events

We show full top 5 events from the event selection step for each binary dataset in Tables 9 and 10.

Dataset	**Event**
Emotional	PersonX sells PersonY’s — for money PersonX sleeps well — PersonX gets — at night PersonX devotes — to the study PersonX wakes up in the middle of the night

Abstract

Bias-measuring datasets play a critical role in detecting biased behavior of language models and in evaluating progress of bias mitigation methods. In this work, we focus on evaluating gender bias through coreference resolution, where previous datasets are either hand-crafted or fail to reliably measure an explicitly defined bias. To overcome these shortcomings, we propose a novel method to collect diverse, natural, and minimally distant text pairs via counterfactual generation, and construct Counter-GAP, an annotated dataset consisting of 4008 instances grouped into 1002 quadruples. We further identify a bias cancellation problem in previous group-level metrics on Counter-GAP, and propose to use the difference between inconsistency across genders and within genders to measure bias at a quadruple level. Our results show that four pre-trained language models are significantly more inconsistent across different gender groups than within each group, and that a name-based counterfactual data augmentation method is more effective to mitigate such bias than an anonymization-based method.

1 Introduction

It is a common practice to train state-of-the-art natural language processing (NLP) models by unsupervised pre-training and supervised fine-tuning (e.g., Devlin et al., 2019; Joshi et al., 2020), both of which rely heavily on large corpora of real-world text. However, these corpora often reflect societal stereotypes and may lead to models exhibiting biased behaviors (Bender et al., 2021). Hence, much research effort has been put to reveal and mitigate unintended biases (Meade et al., 2022).

While early work focuses on detecting and mitigating gender bias in the space of word embeddings (e.g., Bolukbasi et al., 2016), recent approaches turn to design bias-measuring datasets on specific NLP tasks (Nangia et al., 2020; Nadeem et al., 2021; Barikeri et al., 2021). In this work, we focus on gender bias in coreference resolution and adopt a kind of representational harm (Blodgett et al., 2020) to define gender fairness: a gender-neutral model should rely on the semantic information, rather than on the gender information contained in the texts, to make predictions. Otherwise, a model should be considered gender-biased. In line with this definition, WinoBias (Zhao et al., 2018) and WinoGender (Rudinger et al., 2018) leverage pairs of minimally distant sentences, i.e., two sentences that contain the same semantic information but different gender information, to measure models' performance difference in resolving pronouns of different genders under the same context. This minimally distant setting enables us to isolate the influence of gender information on model predictions.

A limitation of WinoBias and WinoGender is that they are made up of *hand-crafted sentences*, which prevents us from measuring gender bias in the more diverse real-world scenarios. An alternative to overcome this shortcoming is the GAP dataset (Webster et al., 2018), which exploits linguistic patterns to automatically extract instances from a *real-world corpus*. However, since GAP's masculine and feminine instances cannot be grouped into minimally distant pairs, we are not sure whether a difference in model performance is due to different gender information or to different semantic information. For example, compared to masculine instances, GAP's feminine instances have more candidate entities serving as distractors, and longer distance between the correct name and the pronoun (Kocijan et al., 2021). So, it is *not equally hard to resolve* the masculine and feminine instances in GAP. Hence, the performance difference between masculine and feminine instances on GAP is not a reliable measure of gender bias according to the above definition of gender fairness.[1]

---

[1] In GAP (Webster et al., 2018), the authors did not explicitly describe the fairness definiton that they adopt.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3761–3773
May 2-6, 2023

Given these observations, we propose a novel method to construct coreference-resolution-based bias-measuring datasets consisting of minimally distant text pairs that originate from real-world corpora. Specifically, we leverage the method from GAP (Webster et al., 2018) to extract original instances containing gendered ambiguous pronouns, and generate minimally distant instances by asking the counterfactual question "How would the prediction change if we swapped the roles of masculine and feminine people in this context?" (Garg et al., 2019). The resulting instances are grouped into quadruples, each of which consists of an original, a gender-controlled, and two gender-swapped instances. An example is shown in Table 1.

Furthermore, we find that bias in different directions may be canceled out if we aggregate the results by performance difference across groups of instances, and we call this problem *bias cancellation*. To alleviate it, we propose a new metric, inconsistency across genders, to measure bias at the quadruple level. We also leverage the gender-controlled instances to disentangle inconsistency *within* genders from inconsistency *across* genders, so that we can eliminate the impact of name perturbations.

Our contributions are as follows: (i) We propose a novel method to construct coreference resolution datasets consisting of diverse, natural, and minimally distant instances to reliably detect gender bias. (ii) We apply our method to online books and collect Counter-GAP, an annotated dataset with 4008 instances grouped into 1002 quadruples. (iii) We propose a new metric, the difference (ΔI) between inconsistency across genders and within genders, to alleviate the bias cancellation problem of previous metrics. (iv) We use Counter-GAP to empirically evaluate four pre-trained language models and two debiasing methods based on Counterfactual Data Augmentation (CDA, Zhao et al., 2018; Webster et al., 2020). Our results show that ΔI can detect significant gender bias hidden by group-level performance difference, and that name-based CDA is more effective than vanilla CDA in mitigating such bias.[2]

2 Dataset Construction

The Counter-GAP dataset is derived from 1575 fictional books in Project Gutenberg[3] and BookCorpus (Zhu et al., 2015). It is constructed through a generic multi-stage process, as described below. Here, we follow the GAP dataset (Webster et al., 2018) and focus only on the English language, as well as adopting a notion of binary gender.

2.1 Original Instance Extraction

First, we detect all the occurrences of personal names and pronouns in a book with a dependency parser and a named entity recognizer (NER).[4] For each occurrence of a gendered non-reflexive pronoun (*he*, *him*, *his*, *she*, *her*, *hers*), we extract a surrounding context that consists of a maximum of five sentences and contains exactly two masculine and two feminine personal names. Personal names are identified by NER tags, and the gender specification of a name is determined by statistics from a gender-guesser.[5] Genders for titled names (e.g., *Mr. Smith*) are assumed from the traditional gender associations of those titles.

Second, we select the subset of contexts that contain gendered ambiguous pronouns as defined by the following three patterns from GAP (Webster et al., 2018) (henceforth, the gendered ambiguous pronoun is called *target pronoun*, and the two names that are gender-consistent with the target pronoun are called *candidate names*):

- **FINALPRO.** Both candidate names must be in the same sentence, and the target pronoun may appear in the same or directly following sentence.
- **MEDIALPRO.** The first candidate name must be in the sentence directly preceding the target pronoun and the second candidate name, both of which must be in the same sentence. The target pronoun must be in an initial subordinate clause or be a possessive in an initial prepositional phrase.
- **INITIALPRO.** Both the candidate names and the target pronoun must be in the same sentence, and the target pronoun must be in an

---

[2] The dataset and code are available at `https://github.com/x-zb/Counter-GAP`.

[3] `https://www.gutenberg.org/`

[4] We use Spacy (`https://spacy.io/`).

[5] `https://pypi.org/project/gender-guesser/`. As we focus on English books, we use the default setting where the gender of a name is first considered according to its use in English-speaking countries.

original	Tom did not appear to hear this, but tried to keep up the conversation with Julia, desiring to have it appear that they were intimate friends; but the young lady gave brief replies, and finally, turning away, devoted herself once more to Herbert, much to Tom's disgust. In fact, what he saw made Tom pass a very unpleasant evening, and when, on their return home, Maria suggested that Julia had taken a fancy to Herbert, **he** told her to mind her own business.
gender-controlled	Herbert did not appear to hear this, but tried to keep up the conversation with Maria, desiring to have it appear that they were intimate friends; but the young lady gave brief replies, and finally, turning away, devoted herself once more to Tom, much to Herbert's disgust. In fact, what he saw made Herbert pass a very unpleasant evening, and when, on their return home, Julia suggested that Maria had taken a fancy to Tom, **he** told her to mind her own business.
gender-swapped-1	Maria did not appear to hear this, but tried to keep up the conversation with Herbert, desiring to have it appear that they were intimate friends; but the young *gentleman* gave brief replies, and finally, turning away, devoted *himself* once more to Julia, much to Maria's disgust. In fact, what *she* saw made Maria pass a very unpleasant evening, and when, on their return home, Tom suggested that Herbert had taken a fancy to Julia, **she** told *him* to mind *his* own business.
gender-swapped-2	Julia did not appear to hear this, but tried to keep up the conversation with Tom, desiring to have it appear that they were intimate friends; but the young *gentleman* gave brief replies, and finally, turning away, devoted *himself* once more to Maria, much to Julia's disgust. In fact, what *she* saw made Julia pass a very unpleasant evening, and when, on their return home, Herbert suggested that Tom had taken a fancy to Maria, **she** told *him* to mind *his* own business.

Table 1: Counterfactual generation of a quadruple in Counter-GAP. Personal names and their genders are depicted in colors: masculine names are in blue and cyan; feminine names are in violet and orange. The target pronoun is in **bold** and underlined; also underlined is the true coreferent name. Other words constitute the context, and words in *italic* are gendered words swapped according to the gendered words list.

initial subordinate clause or a possessive in an initial prepositional phrase.

After filtering, we get 2585 contexts and adopt them as original instances.

2.2 Counterfactual Generation

We generate minimally distant instances in Counter-GAP through two counterfactual generation functions. An example is illustrated in Table 1. Formally, we denote an original instance as $x_o = s(P, C_1, C_2, O_1, O_2)$, where P is the target pronoun to be resolved, C_1 and C_2 are the two candidate names that are gender-consistent with P, O_1 and O_2 are two personal names of the opposite gender, and $s(\cdot)$ denotes the context around these mentions.

Gender-controlled generation. We swap all the occurrences of C_1 and C_2, and of O_1 and O_2, to generate a gender-controlled instance $x_c = s(P, C_2, C_1, O_2, O_1)$. We choose to swap names within an instance instead of introducing new names, so that the candidate names naturally occur in the same real-world context.

Gender-swapped generation. We first substitute all gendered words with their opposite gendered words (e.g., man→woman, he→she),[6] and swap all the occurrences of C_1 and O_1 (or O_2), C_2 and O_2 (or O_1). As a result, we obtain two gender-swapped instances $\widetilde{x_o} = \tilde{s}(\tilde{P}, O_1, O_2, C_1, C_2)$ and $\widetilde{x_c} = \tilde{s}(\tilde{P}, O_2, O_1, C_2, C_1)$, where $\tilde{s}(\cdot)$ is the context with all the gendered words substituted in $s(\cdot)$, and $\tilde{P}$ is the opposite-gendered pronoun for P. We call $x_o, x_c, \widetilde{x_o}, \widetilde{x_c}$ minimally distant instances, in that the words at the same position in the context ($s(\cdot)$ or $\tilde{s}(\cdot)$) are either the same (for gender-neutral words) or have the same role but opposite gender (for gendered words).

We consider a generated counterfactual instance to be invalid if (i) it contradicts commonsense knowledge, e.g., historical people being of the opposite gender; or (ii) the meaning of the counterfactual is different from the original, resulting in the gold coreference labels changing or becoming undetermined. To tackle these, we take three measures. First, we extract original instances mainly from fictional books, whose content is less likely to involve real-world people. Second, during human annotation (Section 2.3), we explicitly ask annotators to validate whether an instance contradicts commonsense knowledge, and discard such instances. Third, we discard the whole quadruple $(x_o, x_c, \widetilde{x_o}, \widetilde{x_c})$ if not all of its four instances get the same majority labels from annotators.[7] Here, *same*

---

[6] We adopt an augmented list of gendered words from (Zhao et al., 2018).

[7] Note that discarding inconsistent quadruples can also cover some error cases caused by the gender-guesser's incorrect prediction. For example, if an incorrect gender prediction occurs for a TRUE coreferent name, the target pronoun and the TRUE coreferent name will not be gender-consistent, and

label means the coreferent names' positions are the same in the context (e.g., in Table 1, the position of "Tom" in the original instance and that of "Maria" in the gender-swapped-1 instance).

2.3 Human Annotation

We use Amazon Mechanical Turk to collect coreference labels for all the 2585 original instances and their counterfactual counterparts (hence, 2585×4 instances in total). Each instance was assigned to three annotators. Annotation instructions and a sample task interface are presented in Appendix B. Specifically, we ask annotators to highlight token spans that are coreferent with the target pronoun. We adopt majority vote to aggregate the collected annotations, and generate a `TRUE/FALSE` label for each of the two candidate names indicating if it is coreferent with the target pronoun.

After discarding quadruples containing invalid counterfactuals as discussed in Section 2.2, we further filter out quadruples containing real-world people to avoid grounding. Next, we randomly downsample the remaining quadruples to balance the number of original masculine and feminine instances. The final Counter-GAP dataset consists of 1002 quadruples with an inter-annotator agreement[8] of 86.5%.

3 Evaluation Metrics on Counter-GAP

We use $X = (x_o, x_c, \widetilde{x_o}, \widetilde{x_c}) \in \mathcal{X}$ to denote a quadruple, and lowercased x to denote an arbitrary instance, which could be each of $x_o, x_c, \widetilde{x_o}, \widetilde{x_c}$ from a quadruple. Given a model $f(\cdot)$, assume that $f(x) \in \{0, 1\}$ indicates whether f's prediction on instance x is correct (1) or not (0).

3.1 Bias Cancellation in Accuracy Difference

A so far commonly used metric is to directly compare the model's performance difference (or ratio) between different gender groups (Webster et al., 2018; Sun et al., 2019; Blodgett et al., 2020). For example, if we divide a test set $\mathcal{X}$ into a group of masculine instances $\mathcal{D}^{(m)}$ and a group of feminine instances $\mathcal{D}^{(f)}$ according to the gender information contained in the instances (e.g., the gender of the target pronoun), gender bias can be measured by model f's accuracy difference (Acc_{Diff}) on $\mathcal{D}^{(m)}$ and $\mathcal{D}^{(f)}$:

$$Acc_{Diff} = \frac{\sum_{x \in \mathcal{D}^{(m)}} f(x)}{|\mathcal{D}^{(m)}|} - \frac{\sum_{x \in \mathcal{D}^{(f)}} f(x)}{|\mathcal{D}^{(f)}|}. \quad (1)$$

However, the above metric may suffer from *bias cancellation* on Counter-GAP. Consider two quadruples from Counter-GAP. In the first, the model makes correct predictions on the two masculine instances and incorrect predictions on the two feminine ones. The model should be deemed gender-biased (towards masculine), since it makes different predictions for instances containing the same semantic information. If, in the second quadruple, the model makes reversed predictions, i.e., correct on the two feminine instances and incorrect on the two masculine ones, it should also be deemed gender-biased, yet in the opposite direction towards feminine. However, the model's accuracies on the masculine and feminine groups are both $2/4 = 50\%$, making Eq. (1) equal to zero. In short, biases in opposite directions may be canceled out in some cases if we use Eq. (1) to aggregate them.

3.2 Measuring Bias via Inconsistencies

Given the bias cancellation problem of accuracy difference, we propose to measure gender bias through inconsistencies, i.e., whether a model's prediction is consistent on a pair of minimally distant instances. Specifically, we adopt two metrics, *inconsistency across genders* (I_{across}):

$$\frac{1}{4|\mathcal{X}|} \sum_{X \in \mathcal{X}} \Big(|f(x_o) - f(\widetilde{x_o})| + |f(x_c) - f(\widetilde{x_c})| + |f(x_o) - f(\widetilde{x_c})| + |f(x_c) - f(\widetilde{x_o})| \Big), \quad (2)$$

and *inconsistency within genders* (I_{within}):

$$\frac{1}{2|\mathcal{X}|} \sum_{X \in \mathcal{X}} \Big(|f(x_o) - f(x_c)| + |f(\widetilde{x_o}) - f(\widetilde{x_c})| \Big). \quad (3)$$

Inconsistency across genders (I_{across}) measures inconsistency in instance pairs containing two instances of different genders, while inconsistency within genders (I_{within}) measures inconsistency in instance pairs containing two instances of the same gender. The two instances in a pair should be minimally distant (i.e., from the same quadruple) to guarantee that they contain the same semantic information. Since Counter-GAP adopts personal names as proxies for person entities, we need to

---

this may confuse the annotators, leading to inconsistent labels.

[8] Average percentage of agreed annotations on each instance.

disentangle the part of inconsistency caused by different names (I_{within}) from that caused by different genders (I_{across}). Therefore, our final metric to measure gender bias is

$$\Delta I = I_{across} - I_{within}. \tag{4}$$

In practice, a positive ΔI indicates biased behaviors of the model, while a zero or negative ΔI means that the measured inconsistency across genders are mostly noises from name perturbations, thus no bias can be detected.

4 Bias Evaluation on Counter-GAP

For evaluation, we adopt the coreference resolution system `c2f-coref`[9] (Lee et al., 2018) based on four pre-trained language models: BERT-base/large and SpanBERT-base/large (Joshi et al., 2020). All four models are fine-tuned on OntoNotes (Pradhan et al., 2012),[10] and training details are shown in Appendix A. In our evaluation, no candidate names are provided as input to the models, and models are responsible to detect candidate names in the text by themselves. A model's prediction on an instance is considered correct if the candidate name with gold label TRUE and none of those with gold label FALSE are in the target pronoun's coreferent cluster.

4.1 Results

Results for gender bias measured on Counter-GAP by accuracy difference (Eq. (1)) and ΔI (Eq. (4)) are shown in Tables 2 and 3, respectively. In Table 3, we also report the inconsistency metrics on each gender group (M, F) and each swapping direction (M2F, F2M), together with their differences.

Results in Table 3 show that for all four models, not only I_{across} is larger than I_{within} (ΔI being positive), but also the difference is statistically significant, which indicates biased behaviors in these models. Note that the absolute values of accuracy difference (Acc_{Diff}) in Table 2 are in general smaller than the corresponding values of ΔI in Table 3, and Acc_{Diff} for BERT-large even becomes statistically insignificant, which is contrary to the well-known conclusion that BERT encodes social bias (Nadeem et al., 2021). This brings evidence towards the bias cancellation problem, i.e., bias measured by accuracy difference (Eq. (1)) may be canceled out compared to that measured by inconsistency difference (ΔI).

Regarding the effect of model size on gender bias, results from both metrics show that larger models seem to be less biased than smaller models. Note that both our large and base models are (pre-) trained on the same datasets, but in general larger language models are pre-trained on larger amount of data, so they are still at a higher risk of exhibiting biased behaviors (Bender et al., 2021).

Regarding the detected bias direction, different metrics provide information from different perspectives. We can learn from the sign of Acc_{Diff} in Table 2 that the overall bias directions of these models are all towards masculine. In Table 3, all of the Diff. for I_{within} are negative, indicating a larger inconsistency within the feminine group. All of the Diff. for I_{across} being negative indicates that inconsistency will increase when we change genders in an originally feminine context.

Models	Acc_M	Acc_F	Acc_{Diff}
BERT-base	63.12%	59.53%	+3.59%*
BERT-large	72.60%	72.11%	+0.50%
SpanBERT-base	71.36%	69.06%	+2.30%*
SpanBERT-large	77.25%	75.40%	+1.85%*

Table 2: Gender bias measured by Eq. (1) on Counter-GAP. We report accuracy on masculine instances (Acc_M), feminine instances (Acc_F), and their difference ($Acc_{Diff} = Acc_M - Acc_F$). A "$*$" means that the difference is statistically significant ($p < 0.01$) under one-sided bootstrap resampling (Graham et al., 2014).

4.2 No Bias Between the Original and Counterfactual Instances

Since the gender-swapped instances in Counter-GAP are generated automatically, although they have been validated by annotators, we still check whether there is a systematic bias towards the original or counterfactual instances. To investigate this, we measure two statistics. First, we measure a model's accuracy on instances with the original gender (x_o, x_c) and the counterfactual gender ($\widetilde{x_o}, \widetilde{x_c}$), and report their difference. From Table 4, we see that the differences are very small and not statistically significant. Second, we measure the correlation between the inconsistency across genders score ($|f(x_o) - f(\widetilde{x_o})| + |f(x_c) - f(\widetilde{x_c})| + |f(x_o) - f(\widetilde{x_c})| + |f(x_c) - f(\widetilde{x_o})|$) and the original gender of a quadruple X. From Table 4, we

---

[9] We use the implementations from `https://github.com/mandarjoshi90/coref`.

[10] Since the annotation conventions of OntoNotes are a little different from those of Counter-GAP, we omitted the abbreviation period "." in titles like "Mr.", "Mrs.", and "Dr." in Counter-GAP during evaluation.

Models	inconsistency within genders				inconsistency across genders				$\Delta I = I_{across}$ $-I_{within}$
	M	F	Diff.	I_{within}	M2F	F2M	Diff.	I_{across}	
BERT-base	15.47%	16.47%	-1.00%	15.97%	18.26%	23.25%	-4.99%	20.76%	+4.79%*
BERT-large	10.28%	10.28%	0.00%	10.28%	10.88%	14.27%	-3.39%	12.57%	+2.30%*
SpanBERT-base	9.98%	12.18%	-2.20%	11.08%	12.18%	15.07%	-2.89%	13.62%	+2.54%*
SpanBERT-large	5.79%	6.29%	-0.50%	6.04%	6.89%	8.18%	-1.30%	7.53%	+1.50%*

Table 3: Gender bias measured by the inconsistency metrics on Counter-GAP. We report inconsistency within genders on masculine instances (M), feminine instances (F), and their difference (Diff. = M - F), as well as inconsistency within genders on all the instances (I_{within}). We also report inconsistency across genders on quadruples generated by transforming masculine instances to feminine instances (M2F), transforming feminine instances to masculine instances (F2M), and their difference (Diff. = M2F - F2M), as well as inconsistency across genders on all the quadruples (I_{across}). $\Delta I = I_{across} - I_{within}$ measures gender bias, where a "$*$" means that the difference is statistically significant ($p < 0.01$) under one-sided bootstrap resampling (Graham et al., 2014).

Models	Accuracy			Spearman'sρ
	Orig.	Counter.	Diff.	
BERT-base	61.58%	61.08%	+0.50%	-0.083
BERT-large	72.06%	72.65%	-0.60%	-0.065
SpanBERT-base	70.21%	70.21%	0.00%	-0.060
SpanBERT-large	76.55%	76.10%	+0.45%	-0.030

Table 4: Results on systematic bias evaluation. We report accuracy on instances with the original gender (Orig.), with the counterfactual gender (Counter.), and their difference (Diff.= Orig. - Counter.). All the differences are not statistically significant ($p > 0.01$) under one-sided bootstrap resampling (Graham et al., 2014). We also report Spearman's ρ between inconsistency across genders and the original gender of a quadruple.

see that the values of Spearman's ρ are all close to zero, indicating no significant correlations. Hence, we conclude that the counterfactual instances in Counter-GAP do not introduce systematic bias.

4.3 Comparison with GAP

We further compare Counter-GAP with two GAP-like datasets: the original GAP test set (Webster et al., 2018) and a subset of Counter-GAP where only the original instances x_o are kept (we call this dataset our-GAP). The results of SpanBERT-large on the above datasets are shown in Table 5. We see that the accuracy differences between masculine and feminine instances are much smaller on Counter-GAP than on the original GAP and our-GAP. This empirically verifies that datasets without minimally distant instances cannot reliably measure bias (they amplify bias in this case) due to the different semantic information contained in its masculine and feminine instances. Moreover, the overall direction of detected gender bias (the sign of Acc_{Diff}) is different on the original GAP and our-GAP, which shows that different source corpora (Wikipedia for GAP vs. fictions for our-GAP) may detect different bias in the model. This highlights the importance of domain diversity when using data-centric methods for bias detection.

5 Bias Mitigation

We evaluate two debiasing methods based on counterfactual data augmentation (CDA) (Zhao et al., 2018; Webster et al., 2020): (i) anonymization-based CDA (a-CDA), where the training set (OntoNotes) is augmented by substituting all gendered words with their opposite gendered words, while the gold coreference labels are kept unchanged. Personal names in the training set are anonymized using place holders such as "E1, E2, ..."; (ii) name-based CDA (n-CDA), where, in addition to the substitution between gendered words, masculine and feminine names also substitute each other according to their frequencies (Hall Maudslay et al., 2019). See Appendix A for more details. Performance on bias mitigation is measured by Acc_{Diff} and ΔI, while performance on coreference resolution is measured by overall accuracy on Counter-GAP and F_1 score on OntoNotes' dev set.

Results are shown in Table 6. In terms of ΔI, both a-CDA and n-CDA can effectively reduce gender bias, while n-CDA is more effective than a-CDA in that its ΔI values are smaller and less significant. Comparing the results of Acc_{Diff} and ΔI, we discover that bias measured by Acc_{Diff} tends to be more easily mitigated by the debiased methods. For example, a-CDA fails to reduce ΔI to an insignificant level for all the four models, but it succeeds to do so for Acc_{Diff} on BERT-base and SpanBERT-large; n-CDA can reduce BERT-base's Acc_{Diff} to an insignificant level, but fails to do so under the measurement of ΔI.

Regarding the trade-off between bias mitigation and overall performance, both a-CDA and n-CDA

Datasets	Accuracy				ΔI
	Acc_M	Acc_F	Acc_{Diff}	Overall	
original GAP	85.10%	79.80%	+5.30%	82.45%	– –
our-GAP	75.25%	78.44%	-3.19%	76.85%	– –
Counter-GAP	77.25%	75.40%	+1.85%	76.32%	+1.50%

Table 5: Results from SpanBERT-large on three datasets.

Models	Debiasing Method	$Acc_{Diff} = Acc_M - Acc_F$	$\Delta I = I_{across} - I_{within}$	Overall Accuracy	F_1 on OntoNotes
BERT-base	none	+3.59%*	+4.79%*	61.33%	74.39%
	a-CDA	+1.90%	+2.30%*	65.17%	73.91%
	n-CDA	**+0.20%**	+1.85%*	66.82%	73.60%
BERT-large	none	+0.50%	+2.30%*	72.36%	77.35%
	a-CDA	+2.99%*	+1.75%*	72.95%	76.96%
	n-CDA	+0.95%	+1.30%	73.53%	77.13%
SpanBERT -base	none	+2.30%*	+2.54%*	70.21%	77.71%
	a-CDA	+5.14%*	+2.54%*	69.49%	78.04%
	n-CDA	+0.95%	+1.25%	71.03%	77.70%
SpanBERT -large	none	+1.85%*	+1.50%*	76.32%	80.06%
	a-CDA	+0.35%	+1.45%*	76.72%	**80.07%**
	n-CDA	+0.65%	**+0.15%**	**77.92%**	79.93%

Table 6: Bias mitigation results. For Acc_{Diff} and ΔI, lower is better; for overall accuracy and F_1 on OntoNotes, higher is better. Best results are in bold. A "*" on ΔI indicates that the difference is statistically significant ($p < 0.01$) under one-sided bootstrap resampling (Graham et al., 2014).

can maintain or even increase the overall accuracy on Counter-GAP. This indicates that they do not sacrifice model performance for fairness, which is a favorable characteristic of debiasing methods. However, n-CDA achieves decreased F_1 scores on OntoNotes for all the four models, indicating that it is more suitable for tasks involving mostly personal names.

6 Qualitative Analysis

In Table 7, we show some Counter-GAP examples with predictions from SpanBERT-large. In Example 1, SpanBERT-large makes correct decisions for both the original and gender-controlled instance. But for the two gender-swapped instances, it either refers the target pronoun to the incorrect feminine person (Denise), or includes both feminine names (Roxanne and Denise) in the coreferent cluster, which indicates a worse performance on resolving feminine pronouns under the same context. This kind of gender bias can only be detected when we counterfactually augment the original instance. In Example 2, SpanBERT-large correctly finds "Alice" in the gender-swapped-2 instance, but confuses "Alice" and "Dora" in the gender-swapped-1 instance. This illustrates the inconsistency brought by name perturbations within the same gender, and we take this into account by subtracting inconsistency within genders from inconsistency across genders ($\Delta I = I_{across} - I_{within}$).

7 Related Work

Measuring Bias in NLP models. Human-like biases are first detected and measured in word embeddings (Bolukbasi et al., 2016; Caliskan et al., 2017; Garg et al., 2018; Gonen and Goldberg, 2019; Manzini et al., 2019). For pre-trained language models, May et al. (2019) adopt bleached sentence templates to contextualize target words, while most recent works leverage crowd-sourced benchmark datasets on NLP tasks such as language modeling (Nangia et al., 2020; Nadeem et al., 2021), sentiment analysis (Kiritchenko and Mohammad, 2018), dialog generation (Barikeri et al., 2021), natural language inference (Dev et al., 2020), and machine translation (Stanovsky et al., 2019). Our work follows GAP (Webster et al., 2018), WinoBias (Zhao et al., 2018), and WinoGender (Rudinger et al., 2018) to measure gender bias in coreference resolution, with a specific focus on collecting diverse, natural, and minimally distant instances.

Counterfactual Bias Evaluation. Kusner et al. (2017) propose the notion of *counterfactual fairness*, which requires similar predictions before and after counterfactual interventions in casual graphs. Garg et al. (2019) apply this notion to text classifi-

Example	1
original (correct)	"In fact, Roxanne told me that she had scheduled an interview with a source tonight." Denise sipped at her lemonade through her straw until she found the bottom of her glass at last. Scotty told Chris that Denise didn't give **him** any particulars about why she needed to hire a private detective when she sought his advice.
gender-controlled (correct)	"In fact, Denise told me that she had scheduled an interview with a source tonight." Roxanne sipped at her lemonade through her straw until she found the bottom of her glass at last. Chris told Scotty that Roxanne didn't give **him** any particulars about why she needed to hire a private detective when she sought his advice.
gender-swapped-1 (incorrect)	"In fact, Chris told me that he had scheduled an interview with a source tonight." Scotty sipped at his lemonade through his straw until he found the bottom of his glass at last. Denise told Roxanne that Scotty didn't give **her** any particulars about why he needed to hire a private detective when he sought her advice.
gender-swapped-2 (incorrect)	"In fact, Scotty told me that he had scheduled an interview with a source tonight." Chris sipped at his lemonade through his straw until he found the bottom of his glass at last. Roxanne told Denise that Chris didn't give **her** any particulars about why he needed to hire a private detective when he sought her advice.
Example	2
original (correct)	Dora said, "You ought not to bet, especially on Sunday," and Alice altered it to "You may be sure." "Well, but what then?" Oswald asked Denny. "Out with it," for **he** saw that his youthful friend had got an idea and couldn't get it out.
gender-controlled (correct)	Alice said, "You ought not to bet, especially on Sunday," and Dora altered it to "You may be sure." "Well, but what then?" Denny asked Oswald. "Out with it," for **he** saw that his youthful friend had got an idea and couldn't get it out.
gender-swapped-1 (incorrect)	Oswald said, "You ought not to bet, especially on Sunday," and Denny altered it to "You may be sure." "Well, but what then?" Dora asked Alice. "Out with it," for **she** saw that her youthful friend had got an idea and couldn't get it out.
gender-swapped-2 (correct)	Denny said, ""You ought not to bet, especially on Sunday,"" and Oswald altered it to ""You may be sure."" ""Well, but what then?"" Alice asked Dora. ""Out with it,"" for **she** saw that her youthful friend had got an idea and couldn't get it out.

Table 7: Examples from Counter-GAP. In each instance, the predicted coreference cluster from the model is highlighted in yellow, and the correctness of the prediction is annotated in the first column. The target pronoun is in **bold** and underlined; also underlined is the true coreferent name. Other notations follow those in Table 1.

cation and propose the metric of Counterfactual Token Fairness, which is similar to our inconsistency metrics, but we further distinguish inconsistency within genders from inconsistency across genders in our quadruple setting. Counterfactual Data Augmentation (CDA) (Webster et al., 2020; Zmigrod et al., 2019) is a widely adopted method for bias evaluation (Cao et al., 2020; Zhang et al., 2021), and we additionally focus on personal names during counterfactual generation of coreference resolution instances.

Name Artifacts in NLP Models. Since neural language models do not treat personal names as interchangeable, there are various biases in the learned representations of personal names (Shwartz et al., 2020; Prabhakaran et al., 2019; Wolfe and Caliskan, 2021; Wang et al., 2022). Counter-GAP considers name biases as the source of gender bias, and exhibits these name biases through the task of coreference resolution.

8 Summary and Outlook

In this work, we proposed a method to construct minimally distant bias-measuring datasets for coreference resolution, and exemplified it in the collection of Counter-GAP. We proposed the inconsistency metric ΔI to overcome the bias cancellation problem and noise from name perturbations. We showed that four pre-trained language models exhibit significant gender bias, and name-based CDA is most effective in mitigating the detected bias.

Limitations of Counter-GAP include that around half of the instances are from historical fictions in Project Gutenberg, making the dataset less representative of contemporary bias; the rules in our method for constructing Counter-GAP are specific for English, and might not be easily adapted to languages with more complex morphology; while we recognize that gender is non-binary, we adopt the simplifying setup of binary gender construct, which prevents us from detecting gender bias against minority groups with non-binary genders.

In future work, we will apply our method to different domains and more contemporary corpora such as news articles. Leveraging the data augmentation method for languages with grammatical genders (Zmigrod et al., 2019), as well as linguistic resources for non-binary genders (Cao et al., 2020) is also an important future direction to construct more gender- and language-inclusive datasets.

Limitations

Counter-GAP adopts the setup of a binary gender construct, which restricts it from detecting bias against non-binary gender groups. Future work may extend Counter-GAP using non-binary gendered word lists, and correspondingly extend our metric (inconsistency across and within binary gender groups) for multiple gender groups.

Our method relies on specific characteristics of the English language. Directly applying it to other languages may be non-trivial. For example, languages like French or Italian adopt grammatical genders that need extra rules in our counterfactual generation method, while Chinese names are, in principle, gender neutral, which makes it impossible to identify genders from personal names. Therefore, adaptation efforts are required for researchers working on multilingual problems.

Like many other bias-measuring datasets, Counter-GAP only serves as a diagnostic dataset. This means that, if our dataset and metric detect significant bias, we could deem a model biased; but if little or no bias is detected, we cannot guarantee that the model is unbiased. Practitioners may adopt diverse bias benchmarks before reaching a conclusion.

A Training Details

Training details follow those by Joshi et al. (2019, 2020), and the hyperparameters adopted for each model during fine-tuning on OntoNotes are shown in Table 8. Specifically, each document in OntoNotes is divided into non-overlapping segments of length `max_segment_len`. The segments are then encoded independently by BERT/SpanBERT to contextualized word embeddings and fed to the `c2f-coref` model (Lee et al., 2018). The models are fine-tuned for 20 epochs with a dropout rate of 0.3, `bert_learning_rate` on parameters in BERT/SpanBERT, and `task_learning_rate` on parameters in `c2f-coref`. The learning rates are linearly decayed. A batch size of one document is used, where each document is randomly truncated to contain `max_training_sentences` segments. All the experiments are conducted on one Tesla-V100 GPU with 32 GB memory.

For the debiasing method n-CDA, we adjust the bipartite graph matching method from Hall Maudslay et al. (2019) to fit the name list in our gender-guesser. Specifically, in our name list, each first name is assigned a label in {"male", "mostly male", "female", "mostly female"} indicating its gender specification, as well as a 55-dimensional frequency vector. The value in each dimension is an integer in $[0, 13]$ that indicates the name's relative frequency in one of the 55 countries. Below, we only describe how we match "male" with "female" names; the method to match "mostly male" with "mostly female" names is the same. We build a bipartite graph where "male" and "female" names are nodes in distinct parts, and define the weight of an edge between a "male" and a "female" name as $w_{i,j} = \|v_i - v_j\|_2 \cdot (\alpha - cos\langle v_i, v_j\rangle)$, where v_i and v_j are the frequency vectors of the two names, and $\alpha > 1$ is a hyperparameter balancing the ℓ_2 and the cosine distance. Our motivation is to encourage a rare name to be matched with even a popular name in the same country other than another rare name in a different country, so we choose $\alpha = 12/11$. Finally, we leverage a minimum weight full matching algorithm (Kuhn, 1955) to compute the matches between the names in the two parts.

B Amazon Mechanical Turk Annotation Details

Our annotation instructions and a sample Human Intelligence Task (HIT) interface are shown in Figure 2. To ensure the annotation quality, we implement a series of on-submission checks including checks on whether the selected span is a personal name, whether multiple entities are selected, whether the "no names are coreferent" box is misused, and so on. We require annotators to have at least a 95% approval rate with more than 50 approved HITs. The average time an annotator spent on one HIT is around 30 minutes.

C Illustration of the Inconsistency Metrics

A conceptual illustration of the proposed inconsistency metrics is shown in Figure 1: inconsistency across genders (I_{across}) measures inconsistency in instance pairs containing two instances of different genders, while inconsistency within genders (I_{within}) measures inconsistency in instance pairs containing two instances of the same gender.

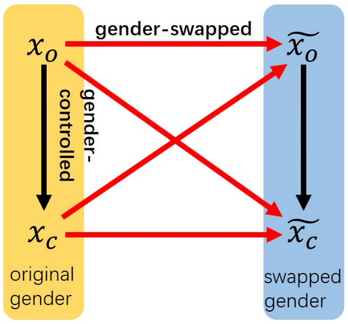

Figure 1: Illustration of the two inconsistency metrics. When computing inconsistency within genders, we use instance pairs linked by the two black arrows; when computing inconsistency across genders, we use instance pairs linked by the four red arrows.

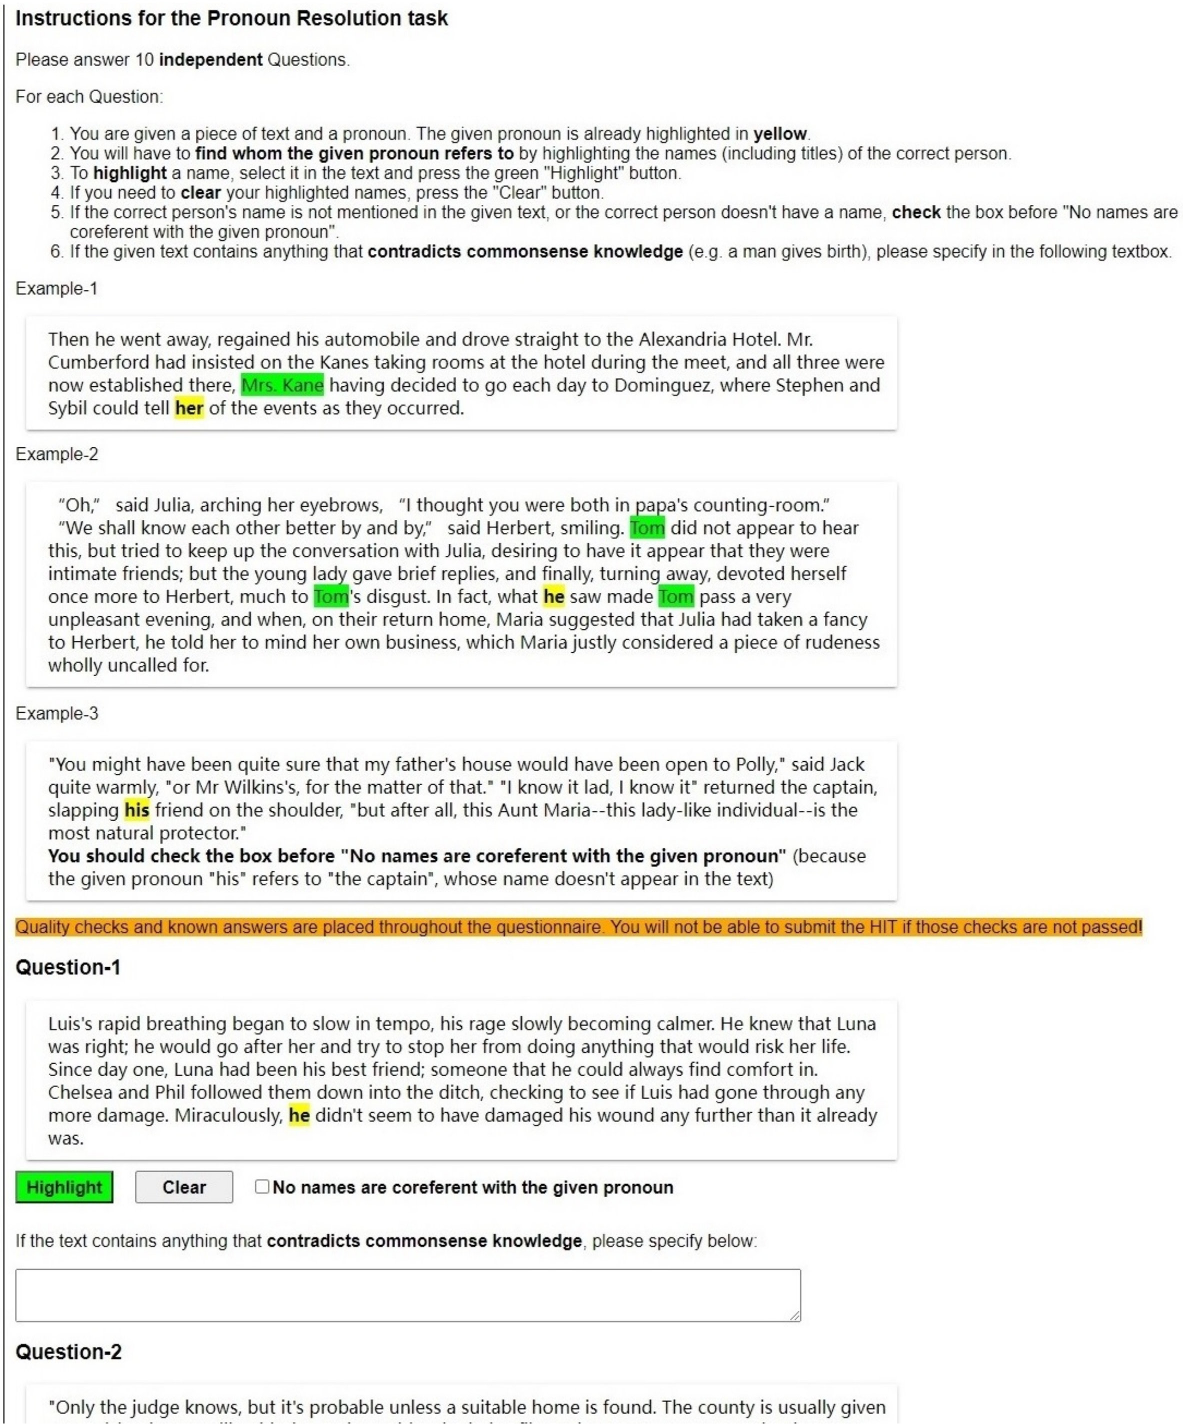
	BERT-base	BERT-large	SpanBERT-base	SpanBERT-large
$bert\_learning\_rate$	1e-5	1e-5	2e-5	1e-5
$task\_learning\_rate$	2e-4	2e-4	1e-4	3e-4
$max\_segment\_len$	128	384	384	512
$max\_training\_sentences$	11	3	3	3

Table 8: Hyperparameters for fine-tuning.



Instructions for the Pronoun Resolution task

Please answer 10 **independent** Questions.

For each Question:

1. You are given a piece of text and a pronoun. The given pronoun is already highlighted in **yellow**.
2. You will have to **find whom the given pronoun refers to** by highlighting the names (including titles) of the correct person.
3. To **highlight** a name, select it in the text and press the green "Highlight" button.
4. If you need to **clear** your highlighted names, press the "Clear" button.
5. If the correct person's name is not mentioned in the given text, or the correct person doesn't have a name, **check** the box before "No names are coreferent with the given pronoun".
6. If the given text contains anything that **contradicts commonsense knowledge** (e.g. a man gives birth), please specify in the following textbox.

Example-1

Then he went away, regained his automobile and drove straight to the Alexandria Hotel. Mr. Cumberford had insisted on the Kanes taking rooms at the hotel during the meet, and all three were now established there, Mrs. Kane having decided to go each day to Dominguez, where Stephen and Sybil could tell **her** of the events as they occurred.

Example-2

"Oh," said Julia, arching her eyebrows, "I thought you were both in papa's counting-room." "We shall know each other better by and by," said Herbert, smiling. Tom did not appear to hear this, but tried to keep up the conversation with Julia, desiring to have it appear that they were intimate friends; but the young lady gave brief replies, and finally, turning away, devoted herself once more to Herbert, much to Tom's disgust. In fact, what **he** saw made Tom pass a very unpleasant evening, and when, on their return home, Maria suggested that Julia had taken a fancy to Herbert, he told her to mind her own business, which Maria justly considered a piece of rudeness wholly uncalled for.

Example-3

"You might have been quite sure that my father's house would have been open to Polly," said Jack quite warmly, "or Mr Wilkins's, for the matter of that." "I know it lad, I know it" returned the captain, slapping **his** friend on the shoulder, "but after all, this Aunt Maria--this lady-like individual--is the most natural protector."
You should check the box before "No names are coreferent with the given pronoun" (because the given pronoun "his" refers to "the captain", whose name doesn't appear in the text)

Quality checks and known answers are placed throughout the questionnaire. You will not be able to submit the HIT if those checks are not passed!

Question-1

Luis's rapid breathing began to slow in tempo, his rage slowly becoming calmer. He knew that Luna was right; he would go after her and try to stop her from doing anything that would risk her life. Since day one, Luna had been his best friend; someone that he could always find comfort in. Chelsea and Phil followed them down into the ditch, checking to see if Luis had gone through any more damage. Miraculously, **he** didn't seem to have damaged his wound any further than it already was.

☐ **No names are coreferent with the given pronoun**

If the text contains anything that **contradicts commonsense knowledge**, please specify below:

Question-2

"Only the judge knows, but it's probable unless a suitable home is found. The county is usually given

The NLP Task Effectiveness of Long-Range Transformers

Guanghui Qin **Yukun Feng** **Benjamin Van Durme**
Department of Computer Science, Johns Hopkins University
`{gqin2, yfeng55, vandurme}@jhu.edu`

Abstract

Transformer models cannot easily scale to long sequences due to their $O(N^2)$ time and space complexity. This has led to Transformer variants seeking to lower computational complexity, such as Longformer and Performer. While such models have theoretically greater efficiency, their effectiveness on real NLP tasks has not been well studied. We benchmark 7 variants of Transformer models on 5 difficult NLP tasks and 7 datasets. We design experiments to isolate the effect of pretraining and hyperparameter settings, to focus on their capacity for long-range attention. Moreover, we present various methods to investigate attention behaviors to illuminate model details beyond metric scores. We find that the modified attention in long-range transformers has advantages on content selection and query-guided decoding, but they come with previously unrecognized drawbacks such as insufficient attention to distant tokens and accumulated approximation error.

1 Introduction

Transformer-based models (Vaswani et al., 2017) have advanced the state of the art in natural language processing. However, their quadratic time and space complexity hinder their application on long texts. Various proposals have been made to address these concerns (Tay et al., 2020c), with mathematical guarantees on improved time or space. These models have been evaluated primarily via perplexity (Dai et al., 2019) and non-NLP benchmarks (Tay et al., 2020b). These metrics may not be ideal (Sun et al., 2021) and may not reflect performance on complex NLP tasks (Arutiunian et al., 2020; Thorne et al., 2021). We argue these metrics have not been sufficient for the development of efficient Transformers and their practical application on long texts, and that existing benchmarks are insufficient guides for architecture selection.

It is not straightforward to have a fair and side-by-side comparison among those models due to the differences between their pretraining and hyperparameter settings (Tay et al., 2020c), and the metrics alone cannot convey detailed information about the self-attention blocks (Sun et al., 2021). We wish to fairly validate the effectiveness of long-range attention techniques, and to uncover the underlying factors behind model behaviors. We critique the reliance on perplexity evaluations in previous work, experimenting with five difficult, long-text NLP tasks. These tasks cover typical NLP modeling scenarios: token or span-level prediction, sequence-level classification, and sequence-to-sequence generation. To our knowledge, this is the first work to evaluate long-range transformers on such a wide spectrum of representative NLP tasks.

To verify the key features of long-range transformers, we *ablate* distant attention to measure what they gain from long-range mechanisms. For models without pretrained checkpoints, we migrate parameters from their prototype models for fairness. We cover 3 main kinds of long-range transformers, including pattern-, recurrence-, and kernel-based methods. To our knowledge, we are the first to adopt all these methods to probe transformers. To investigate the relationship between performance and document lengths we break down the metric with a customized algorithm (Bagga and Baldwin, 1998). Also, we use entropy and attribution analysis (Li et al., 2017) to test the effectiveness of cached memories in recurrent transformers and the global tokens for query-based problems.

We find that long-range context brings performance gains to transformers in some cases, which we attribute to more selective attention, especially for query-based tasks like QA. Surprisingly we observe that some long-range models do not effectively utilize distant information, and the accumulated error of approximation is unacceptable. We hope this analysis helps practitioners better understand the current state of the art of long-range attentions and suggests paths for future research.

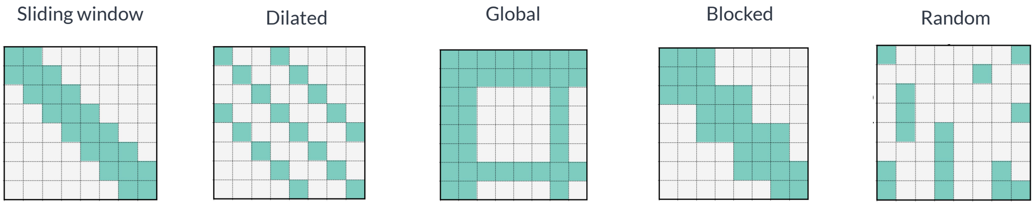

Figure 1: Illustration of 5 patterns used by long-range transformers, from Beltagy et al. (2021) with permission.

2 Background

2.1 Long-Range Transformers

Researchers have proposed a number of Transformer variants (Tay et al., 2020c). Most of these models support decoding (causal masking) (Peng et al., 2021a), while only a few of them have pretrained checkpoints (Beltagy et al., 2020, inter alia). We cluster these approaches into 3 main categories.

Sparsified Patterns Pattern-based methods try to make self-attention sparse. Some apply prespecified attention patterns. Specifically, Longformer (Beltagy et al., 2020) applies 3 patterns: *Sliding window* requires that each token can only attend to the tokens in a local window, *dilated pattern* lets each token only attend at fixed intervals, while the *global pattern* requires a few tokens as globally attended and lets them to attend all tokens in the sequence. In addition to the global pattern, BigBird (Zaheer et al., 2020) applies a *blocked pattern*, which splits the sequence into fixed-length blocks, and *random patterns*, by which tokens can attend to any other tokens randomly. An illustration is shown in fig. 1. Although the attention of each layer is not full, the receptive field can be increased as multiple layers are stacked. The selected or appended "global" tokens can be task-specific (Beltagy et al., 2020), allowing for direct distant information exchange. Instead of pre-defined attention patterns, some use content-based patterns so they become learnable, with techniques including locality sensitive hashing (Kitaev et al., 2020), the differentiable Sinkhorn algorithm (Tay et al., 2020a), or the learnable routing algorithm (Roy et al., 2020).

Recurrence & Compressed Memory These methods use segment-level recurrence to reuse the cached hidden states of previous steps. Transformer-XL (Dai et al., 2019) and XLNet (Yang et al., 2019) connects different chunks with cross-attention, where the tokens in a block attend to the hidden states of the previous blocks in addition to their self-attention. Note that the gradients remain in the same segment and are not propagated to previous segments (fig. 2). To reduce the number of history hidden states, Rae et al. (2020) compress them as memories for efficient re-use with pooling or convolutions. From a different perspective, Izacard and Grave (2021) use retrieval-based methods to collect evidences from external knowledge, resulting in a more targeted context information.

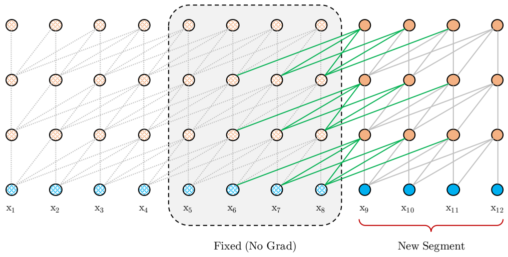

Figure 2: Recurrent transformers. "No Grad" means that the gradients do not back-propagate to this block. Obtained from Dai et al. (2019) with permission.

Low-Rank & Kernels These methods approximate the self-attention with low-rank approximation (Wang et al., 2020) or kernelization without explictly computing the matrix production. Among them, Choromanski et al. (2021); Peng et al. (2021b) use random features. Katharopoulos et al. (2020) reduce the time complexity to linear and space complexity to constant by replacing softmax with linear kernel features.

2.2 Benchmarks and Analysis

There is not an agreed-upon standard benchmark for long-range transformers. Researchers have considered various tasks and domains, including language (Dai et al., 2019), protein sequences (Choromanski et al., 2021), and images (Katharopoulos et al., 2020). Few conduct experiments on long sequence NLP tasks, including question answering (Beltagy et al., 2020) and summarization (Zaheer et al., 2020). Tay et al. (2020b) propose Long Range Arena comprised of six non-NLP tasks to exclude the factor of pretraining. Concurrent to our efforts, Shaham et al. (2022) propose a suite of text-to-text tasks as a long sequence NLP benchmark.

Researchers are also interested in the utility of context in transformers. Rae and Razavi (2020) find that Transformer-XL does not necessarily need long and deep contexts. Sun et al. (2021) reveal that Longformer and Routing transformers can only reduce the perplexity of LMs on a small set of tokens. More related to our work, Lai et al. (2020) show that BERT can make use of a larger scope of context than a BiLSTM.

3 Setup

3.1 Settings

It is non-trivial to compare distinct transformer models, due to differences between their pretraining and hyper-parameter settings. Our goal is to minimize these confounding factors to allow a focus on the long range attention ability of each model on different tasks. We therefore propose two sets of experimental conditions.

Restricted Attention Range To evaluate the performance gain from long-range attention, we evaluate models in both their default *context-aware* settings and a *context-agnostic* setting that restricts the receptive range of the self-attention blocks. For pattern-based transformers, we achieve the restriction by segmenting the input sequence into chunks and running the transformers on segments independently. For recurrent models, we ablate the recurrence to eliminate the dependencies between segments. In practice, we segment the texts into chunks with length L,[1] which ranges from 128 to 1536. L=∞ indicates no segmentation is used.

Parameter Migration Kernel-based models usually do not come with checkpoints for general tasks, but they may have similar structures to other pretrained models like BERT and may be designed to approximate the original results. Therefore, it is feasible to migrate parameters from pretrained prototypes to their "efficient version" to observe if the performance could be preserved. This type of method can be suitable for models without additional parameters, such as Performer.

3.2 Transformers and Tasks

Transformers We consider three approaches: 1) *pattern-based*: Longformer (Beltagy et al., 2020), and BigBird (Zaheer et al., 2020); 2) *recurrent*: XLNet (Yang et al., 2019); and 3) *kernel-based*: Performer (Choromanski et al., 2021). We also include the results of RoBERTa (Liu et al., 2019) and SpanBERT (Joshi et al., 2020), where some of our approaches are initialized from those two non-long-range models. Due to memory requirements, we use the base version for all models.[2] You may refer to appendix B for more details.

Dataset	Task	#tokens	#docs
Ontonotes	Coref.	467	3493
TriviaQA	eQA	2895	95k
DocNLI	NLI	399	1.44m
SummFD	Summ.	5.6k	4.3k
GovRep	Summ.	7.9k	19k
Qasper	aQA	3.7k	5.7k
QuALITY	aQA	4.2k	6.7k

Table 1: Task and dataset overview. The #tokens is the number of tokens per doc on average.

Tasks We cover five tasks of three types, including 1) *span-level* predictions: coreference resolution (Coref.) (Weischedel et al., 2011) and extractive question answering (eQA) (Joshi et al., 2017); 2) *sequence classification*: natural language inference (NLI) (Yin et al., 2021);[3] and 3) *seq2seq*: summarization (Summ.) (Chen et al., 2021; Huang et al., 2021), abstractive QA (aQA) (Dasigi et al., 2021; Pang et al., 2022). We pick seven datasets that involve long texts, whose statistics are shown in table 1. For more details about the data preprocessing, please refer to appendix A.[4]

4 Experiments

4.1 Coreference Resolution

Coreference resolution (coref.) is the task of identifying mention spans and clustering them into entities. We consider multiple coreference strategies: 1) the widely used Coarse2Fine (C2F) method[5] (Lee et al., 2018) which relies on span representations and 2) the current state-of-the-art method called Start2End (S2E) (Kirstain et al., 2021) that works on token representations. The

	SpanBERT^p	38.69	41.93	42.10
	Longformer	77.54 (1024)		77.57 (∞)
	BigBird	77.43 (1024)		77.66 (∞)

Table 2: Coref. results with the C2F and the S2E models. Numbers are averaged F1 (MUC, B^3, and CEAF$_{\phi_4}$). Longformer with ^{G} uses global tokens. XLNet with ^{m} uses recurrence memory. Encoders with ^{p} have their self-attention replaced with a Performer kernel.

dataset we use is **Ontonotes 5.0**. Transformers considered include **Longformer**, **XLNet**, and **Performer**. We migrate the parameters of **SpanBERT** and **RoBERTa** to Performer and include results on these models as well. We segment the input tokens into chunks with lengths of L . For models with global tokens, we lack a natural choice so we consider all tokens to be global. For XLNet, we keep the memory of the same length of the segments (e.g. we keep a memory length of 256 for a model with segment length 256).[6] The results are shown in table 2. Refer to appendix F.1 for complete results.

Some observations are consistent across two coref. models. 1) Though further pretrained upon RoBERTa, pattern-based methods do not show improvement over RoBERTa, even with longer attention range. 2) Models gain advantage when the segments get longer, but it is saturated when the segment length reaches 512. Distant contexts might not be exploited. 3) Performer-based models under-perform their corresponding non-kernelized models by a huge gap. 4) XLNet performs better with cached memory, but the performance gain is less observable when for shorter segments. [7]

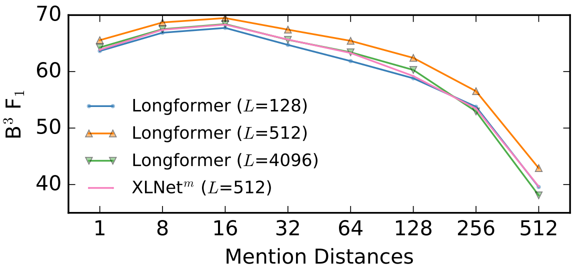

Figure 3: B^3 breakdown scores of 4 models for mention pairs with ranges from $[1, 8)$ to $[512, \infty)$.

To further show the performance of those models on documents with different lengths, we conduct metric breakdown with a few typical configurations. Instead of simply clustering the document according to the lengths, we propose a breakdown-version B^3 metric. Given a mention distance range $[L_1, L_2]$, we calculate its corresponding B^3 value by only considering the mention pairs whose distances fall into this range. The breakdown metrics are shown in fig. 3. We can see that the performance of all models follows the same trend and peaks at the $[16, 32)$ bucket. Also, the graph shows that Longformer with longer context encoding does NOT benefit on distant mentions (p value < 0.01). [8] On the contrary, they suffer more from distance than shorter-context models, showing that long-range attention fails to capture long-distance information.

4.2 Natural Language Inference

NLI is a classification task concerning a premise and hypothesis with variable lengths. The **DocNLI** dataset uses document-length inputs with binary labels (`entailment` and `not entailment`). We adopt the model proposed by Yin et al. (2021), and consider **Longformer**, **BigBird**, **Performer**, and **XLNet**. We make the prediction on the `CLS` token, which is at the beginning for Longformer and the end for XLNet. Since we are only interested in the encoding of `CLS`, we adopt the strategy of Yin et al. (2021) which truncates the sequence to L while preserving the hypothesis for Longformer and RoBERTa. The results are shown in table 3.

---

[6] We adopt the same strategies with segmentation and memories in the remainder of the paper.

[7] The observations on XLNet and Performer are consistent across all the tasks in this paper.

[8] We conduct significance test for the comparison between curves. Please refer to appendix D for more details.

Encoder	L=128	L=256	L=512
XLNet	29.95	40.39	24.31
XLNet^m	32.94	45.97	30.42
RoBERTa	48.96	47.78	46.04
RoBERTa^p	17.83	24.91	23.65
Longformer	29.11	25.73	45.28
BigBird	28.95	24.71	31.72
Longformer	45.96 (1024)	44.42 (∞)	
BigBird	33.58 (1024)	18.08 (∞)	

Table 3: F1 scores on the test set for DocNLI.

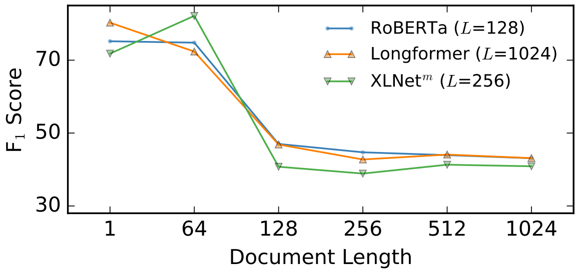

Figure 4: The breakdown analysis of DocNLI. We pick the best configuration for each model for brevity.

Observing table 3, surprisingly, the best performance is achieved with short segments, though the optimal lengths vary from model to model. Also, the performance of Longformer and BigBird is much lower than their baseline RoBERTa (c.f. Yin et al. (2021)). Observing the breakdown analysis in fig. 4, the performance of 3 best models follow the same trend w.r.t. the document length.[9] We speculate that all models are unable to comprehend the relationship between long documents, and long-range attention does not bring any advantage.

4.3 Question Answering

For question answering we experiment with eQA (**TriviaQA**) and aQA (**Qasper** and **QuALITY**). **Performer**, **Longformer**, **BigBird**, and **XLNet** are tested for encoder-only tasks; **BART** and Longformer-Encoder-Decoder (**LED**) is used for seq2seq tasks. For Longformer^G and BigBird, we set the question text (and candidate answers for QuALITY) as global tokens.[10] **TriviaQA** is a question answering dataset that involves extracting answer spans from reference documents. We adopt the method and codebase of Joshi et al. (2017). F1 is used as evaluation metrics. **Qasper** addresses the QA task in the domain of academic papers and involves various answer types: extractive, abstractive, boolean, and unanswerable. We unify such tasks as an abstractive QA task (cf. Shaham et al. (2022)) and implement an LED-based decoder to generate answers. F1 score is used for the evaluation of Qasper. **QuALITY** is a multiple-choice QA task. Given a question and a passage, the task is to select the correct answer from several candidates. We regard it as a seq2seq problem, with the objective to predict the correct answer conditioned on the concatenation of query, candidate answers, and passage. During inference, the answer with the least perplexity is selected. All results are shown in tables 4 and 5, and the full results with more metrics are shown in appendix F.2.

Encoder	L=128	L=256	L=512
Longformer	54.26	58.83	63.88
RoBERTa	55.81	60.29	63.45
RoBERTa^p	23.17	21.87	21.11
BigBird	55.28	59.39	63.51
XLNet	51.46	56.26	60.05
XLNet^m	52.71	57.96	62.85
Longformer	63.91 (1024)	63.66 (∞)	
Longformer^G	- (1024)	72.96 (∞)	
BigBird	66.50 (1024)	71.78 (∞)	

Table 4: Results for TriviaQA. Longformer^G indicates that the Longformer sets question as the global tokens.

	Chunk	512	1024	1536	∞
Qasper	BART	24.70	26.30	-	-
	LED	8.40	15.80	17.86	18.79
	LED^G	-	-	-	28.64
QLTY	BART	26.80	26.00	-	-
	LED	30.73	31.35	31.78	31.21
	LED^G	-	-	-	29.87

Table 5: Performance Qasper and QuALITY. Qasper is evaluated with F1 and QuALITY with accuracy. The results on BART are from Shaham et al. (2022).

Across all results, we find that larger receptive fields lead to better performance in most cases. More importantly, setting queries as global tokens greatly benefits the performance on both eQA and aQA. For QuALITY, it slightly hurt the perfor-

---

[9] The graph looks less smooth than fig. 3, possibly because DocNLI is made up of examples pulled from different datasets, which may have examples of different average lengths (cf. tab 1 in Yin et al. (2021)). Therefore the length of an example in DocNLI may correlate with different domains making up the dataset, which would interfere with our analysis. Future work will consider other datasets without this confounding concern.

[10] The global tokens of BigBird are fixed in the first 2 blocks, so we place the query at the beginning of the sequence.

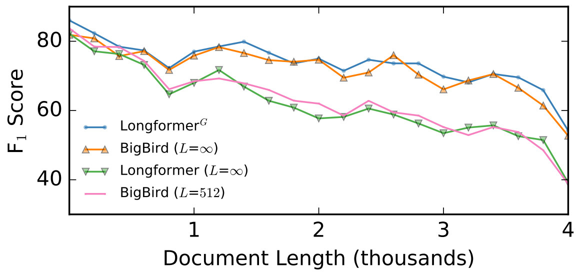

Figure 5: The performance of Longformer and BigBird on different lengths of TriviaQA documents. Note that Longformer^G and BigBird (L=∞) have global tokens.

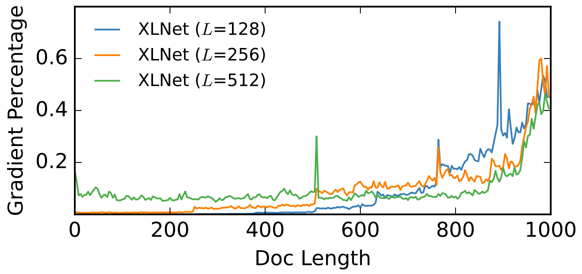

Figure 6: The gradient distribution over tokens for XLNet^m on DocNLI documents.

	Chunk	512	1024	1536	∞
SF	BART	26.30	27.20	-	-
	LED	32.81	33.07	33.22	33.57
GR	BART	45.60	47.90	-	-
	LED	53.86	54.13	54.83	56.60

Table 6: Results for Summarization on SummFD and GovRep. ROUGE unigram is used as the metric. Results on BART are from Shaham et al. (2022).

mance to set both query and candidate as global tokens. We reckon too many global tokens might introduce more noise, similar to the case of coref.

We speculate that the performance gain mostly comes from enhanced attention to the query, which if further verified by the metric breakdown that is shown in fig. 5. All models perform well on short texts, while models with global tokens obtain an observably greater advantage over the baseline models for longer documents (p value < 0.01). We think that the global token mechanism could help the model be less distracted on long texts via more attention on the queries (section 5.3), which consequently improves the performance.

4.4 Summarization

As a typical seq2seq problem, we adopt **LED** to perform the summarization task. We chunk the source sequence into segments (no segmentation for $L = \infty$) to restrict the receptive range. Intuitively, the summary may be benefited from the contextual representation with a broader view of the document. Two datasets are used: **SumScreen** addresses the domain of TV shows. Following Shaham et al. (2022), we use the subset of ForeverDreaming (SummFD) consisting of 88 different shows. The goal is to summarize the transcript of an episode, for which the recap is used as the ground truth summary. **GovReport** is a long-document summarization dataset in the domain of government policies with human-written summaries. ROUGE (Lin, 2004) is used as the evaluation metric. Results are shown in Table 6, and the full results are shown in appendix F.3.

From table 6, we observe slight superiority of the context-aware models. Note that cross attention will attend to all source tokens whether we segment it or not, but the intuition of summarization is to *skim over* the document, so we speculate that the performance improvement may be related to the *selectivity* of the encoder-side attention, which is further analyzed in section 5.2. We do not conduct breakdown analysis for summarization because the sequence length directly contributes to the metric.

5 Analysis

5.1 The Attribution of Recurrence Memories

Even if we know that distant contexts can help or hurt performance, it's still unclear *how much* they contribute to the predictions. One way to quantify this is *attribution analysis* (Simonyan et al., 2014; Li et al., 2017). Suppose ℓ is our loss function and $\mathbf{e}_i \in \mathbb{R}^d$ is the word embedding of the i-th token. We use α_i to measure the attribution of the i-th token to the final prediction where

$$\alpha_i = \left\| \frac{\partial \ell}{\partial \mathbf{e}_i} \right\|_l . \tag{1}$$

We set $l = 1$ to take the L_1 norm in practice, and the ground truth labels in the test set are used to calculate the gradient. Intuitively, tokens with higher contribution have greater gradient norms. Also, recurrent models like XLNet stop the gradient from being propagated back to the cached memory, and we temporarily turn off this feature for analysis.

We apply this method to XLNet on DocNLI, where we pick 128 documents of lengths between 1,000 and 1,024. We normalize the α_i over all tokens for each document, and take an average on

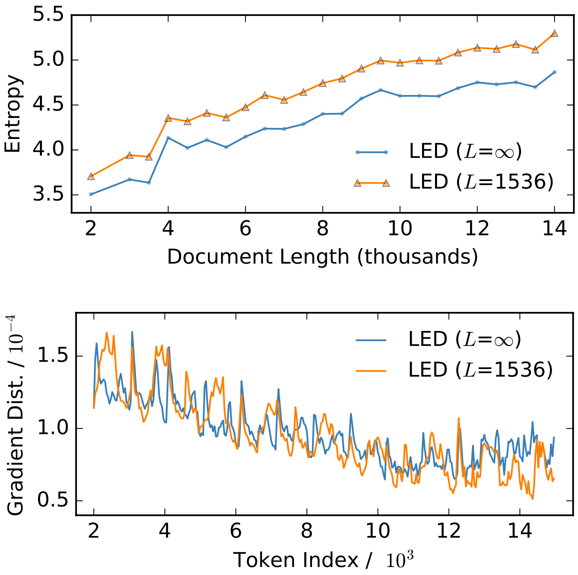

Figure 7: Attention distribution entropy (above) for documents with different lengths and attribution analysis (below) over source tokens for LED on SummFD.

each token index across all documents. The results are shown in fig. 6. Note that prediction is made in the last segment, and previous segments contribute only through the memory. We see the attribution of tokens is stratified according to their segment lengths, with a minor peak at the `CLS` token of each segment. As we have more and more segments, the attribution of distant tokens to the final prediction becomes negligible. For example, in the case of L=128, last segment made 53.4% of attribution, while the first segment made less than 0.01%.

5.2 Content Selection in Cross Attention

The cross attention of LED attends to the whole document no matter if we segment the inputs or not, thus we suppose source tokens should have similar attribution to decoding, which can be verified by *attribution analysis* in fig. 7. However, the crucial problem for summarization is whether the attention is *selective*, given that only a portion of the document is helpful. Therefore, we inspect the *entropy* [11] of the cross attention distribution over the source tokens fig. 7.

Reading the entropy curve, we find that the entropy of models without segmentation (L=∞) is consistently lower (p value < 0.01), which can be translated to higher selectivity of cross attention and explains the superiority of LED (L=∞) in table 6. Reading the gradient curve, we find that both models have a relatively uniform attribution over tokens with a slight slope on the left side due to the existence of short sequences. This is reasonable because summarization requires the decoder to skim over the whole document, thus cross attention should not have a locality preference.

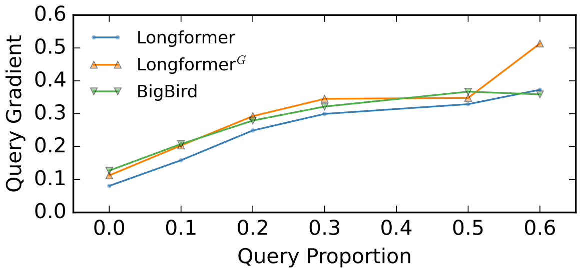

Figure 8: The accumulated gradient on query vs. the proportion of query, i.e. (query length / doc length) with Longformer and BigBird (L=∞) on TriviaQA.

5.3 Query-Guided Extraction and Decoding

Different from other problems, the queries in QA can be treated as a "guidance" on how to read the documents. To see if the encoders can exploit this structure, we conduct attribution analysis on TriviaQA with Longformer and BigBird. The results are shown on fig. 8, where we plot the relationship between the proportion of accumulated gradients on queries and the proportion of query tokens in the document. It is clear that models with global tokens pay more attention to queries (p value < 0.01 except for one exception), which is consistent with the purpose of their design.

For scenarios where seq2seq decoding meets queries, intuition suggests queries could instruct the cross-attention to attend to specific tokens, making the decoding more *selective*. From fig. 9, the entropy of attention distribution on source sequence against the doc length, we see Longformer with global token unquestionably has lower entropy (p value < 0.01), implying more targeted decoding.

5.4 Error Accumulation of Kernel Methods

We find that Performer could not match the results of its prototypes (tables 2 to 4). We suspect that the error incurred by the kernel approximation may not be acceptable for span-level tasks like coref. We conducted another set of experiments: Instead of training the performer model from the checkpoints of SpanBERT, we directly replace some layers from a fine-tuned SpanBERT model with Performer layers with their parameters preserved. Experiments

---

[11] The distribution entropy is averaged over decoding tokens, attention heads, and transformer layers.

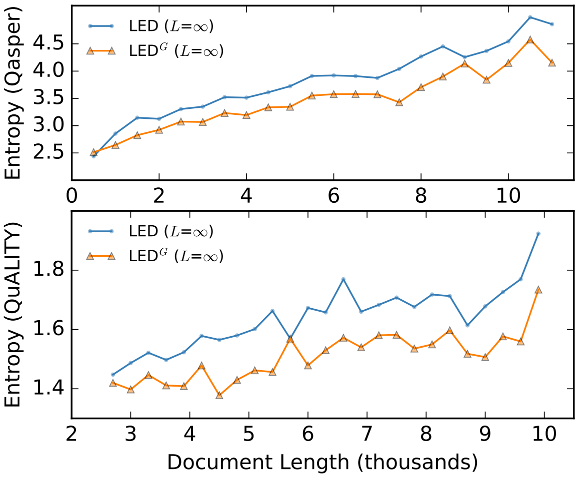

Figure 9: Entropy of source-side attention distribution vs. document length on Qasper and QuALITY.

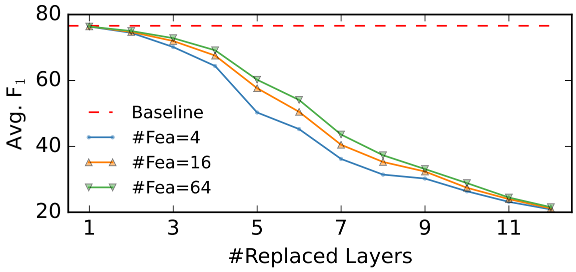

Figure 10: Results of SpanBERT (L=512) with layers replaced with Performer layers with "#Fea" features. The baseline is the performance of the original model.

are conducted with C2F on Ontonotes 5.0.

In fig. 10, we try to replace P layers of SpanBERT in a top-down manner, where $P = 1, 2, \ldots, 12$. We also try using different feature dimensions to exclude the possibility of insufficient features. We find that although large dimension of random features brings marginal advantages to the performance, Performer is not very sensitive to this factor. Instead, the performance drops dramatically as we replace more layers, from the baseline F1 78 to ~20 with all layers replaced. Based on our findings, we conclude that Performer is a good approximation for shallow transformers, even with very low-dimensional random features. However, as we stack more transformer layers, the accumulated errors can be unacceptable, which leads to a failure in the performance.

6 Experiment Confounders

Pretraining and Adaptation The purpose of this paper is to evaluate the effectiveness of different long-range attention approaches by reducing the confounder of pre-training, but it is still unclear how the results would change if we pre-train those models with the same configuration from scratch. Unfortunately, it requires much more resources and introduces more confounders of training settings, and we adopt the most straightforward way to ablate the long-range attention or migrate parameters. For each model-task pair, we make the most natural choice, e.g. setting queries as global tokens, trying to minimize human biases of model adaptations.

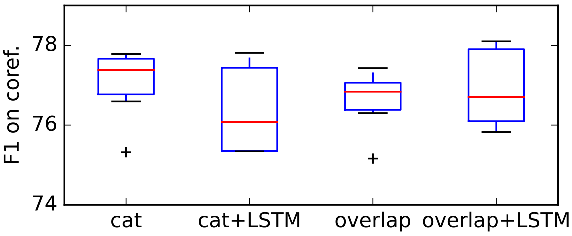

Figure 11: Results of different pooling strategies.

Pooling Strategies Concatenating the representation of segments, while being natural and commonly used, is not the only pooling strategy. As a comparison, we incorporate the results of other 3 solutions: 1) Split the documents into segments of L tokens with $L/2$ overlapped between adjacent segments (Joshi et al., 2019); 2) Stack an LSTM layer over the Transformer representation of the segment ; 3) A combination of above methods. We conduct experiments on the coreference resolution task with both C2F and S2E solution and many variants of transformers as our encoder. We leave the experiment details and discussions in appendix E and show a brief result in fig. 11. We have similar observation with Joshi et al. (2019) that overlapping does not bring performance improvement. Moreover, though introducing more parameters, a stacked LSTM even hurts the performance. We conclude that pooling strategies do not affect our analysis in section 5.

7 Discussion

Researchers have proposed many innovative methods for efficient self-attention over long sequences. The key ideas work as desired in certain cases, though we demonstrate several drawbacks.

Surprisingly, **pattern-based methods**, as the most popular approach, are not necessarily benefited from long-range attention in the general case. Larger sliding windows are helpful, but the benefit would quickly saturate or become negative (table 2).

However, when a small portion of *guidance text* (e.g. query in QA) exists, setting it as *global tokens* can make it more attended and significantly boost the performance (section 5.3). When such text doesn't exist, setting all tokens as global would hurt the performance (table 2). Moreover, we find that long-range attention and global tokens are correlated with the *selectivity* of *seq2seq* problems, which consequently helps the decoding.

The memory of **recurrence models** generally improves performance, proving historical hidden states are beneficial for transformers in various tasks. However, XLNet does not fully exploit the history tokens, with distant information less attended (section 5.1). We speculate that it is because XLNet is pretrained to predict masked tokens, which does not frequently need the participation of long-range context (Sun et al., 2021). Also, the stop-gradient trick may hinder the model from effectively attending to memories.

The approximation of **kernel-based methods** works very well for shallow networks, but faces serious error accumulation problems when transformer layers are deeply stacked, which cannot be remedied by having high-dimensional random features (section 5.4). The resulting performance drop is not acceptable even for the "base" version of transformer encoders with 12 layers (table 2).

8 Conclusion

We conduct experiments with various long-range transformers on NLP tasks that involve long sequences, trying to fairly evaluate their long-range attention ability. While some methods are validated on certain tasks, we also find some previously unrecognized drawbacks. We further analyze the attention behaviors of these transformers with metric breakdown, attribution analysis, and entropy analysis, revealing the performance of those models might be correlated with the attribution of distant tokens, selectivity of attentions, or the approximation errors. We hope our work would shed light on the future development of long-range transformers.

Model Selection Takeaways Based on our findings, we have the following suggestions. For common tasks, such as sequence classification or token-level prediction, it is still competitive to chunk the inputs and apply short-range transformers. When explicit guiding text, such as queries, exists, pattern-based models with global token mechanism is preferred. For seq2seq problems, long-range transformers with pretrained checkpoints deliver better performance.

9 Limitations

Energy Cost Our experiments involve a massive amount of training with many transformers on various tasks. Although we don't conduct any pretraining, the energy cost is still non-negligible. However, our hope is our findings here would enable others to more efficiently select a particular architecture for their task, rather than reproducing the work done here.

Experimental Bias Due to the lack of pretrained checkpoints for general purposes, we focus on representative instead of each type of transformer variant. It is possible that these observations are particular to specific artifacts and implementations considered here. Our goal is foremost to provide a roadmap for continued study on questions raised in this article, with new architectures being evaluated in the future by model developers themselves. For similar reasons, existing artifacts are biased towards English, as are many of the datasets employed in this study. We do not believe our findings are specific to English, but it remains for future work in long range transformer evaluation to extend our analysis into multilingual conditions.

Language Bias For similar reasons, existing artifacts are biased towards English, as are many of the datasets employed in this study. We do not believe our findings are specific to English, but it remains for future work in long-range transformer evaluation to extend our analysis into multilingual conditions.

A Data Preprocessing

The coref task usually consumes a large amount of GPU memory. For the experiments on Ontonotes, we truncate the sequence longer than 2000 tokens (for c2f model) or 1400 tokens (for s2e model) for the memory concern. The truncation was applied only to the training set.

We didn't do any pre-processing steps for DocNLI (Yin et al., 2021), except for the truncation that we discussed in section 4. Notably, DocNLI is an aggregated dataset constructed from ANLI (Nie et al., 2020), SQuAD (Rajpurkar et al., 2016), DUC2001, CNN/DailyMail (Nallapati et al., 2016), and Curation (Curation, 2020). Documents from different sources may be distinguishable from their lengths (refer to tab 1 in Yin et al. (2021).

For TriviaQA, we use the scripts of Longformer (Beltagy et al., 2020) to pre-process the data. There is no further modifications on the data.

We adopt the dataset of QuALITY and GovReport from Shaham et al. (2022), which picked long sequences from those datasets.

For Qasper and SummScreen, we simply adopt the original dataset and scripts for preprocessing.

B Implementation Details of Transformers

In this section, we discuss the details of modification we did to the transformers.

Recurrence-Based Methods We tested XLNet for recurrence-based methods. We adopt the codebase of Huggingface as the base model, and followed the common strategy to stop gradient from being propagated back into the cached memory. For each segment of the recurrence, we appended two special tokens `SEP` and `CLS` to the sequence, making it like an ordinary input sequence to the XLNet model except for the possible existence of memory states. We concatenated the token representations after recurrences and remove the special tokens from all but the last segment. Empirically, we found that having special tokens can significantly boost the performance.

Pattern-Based Methods For the pattern-based methods, when we chunked the input sequence into segments, we appended the `SEP` as we did for the XLNet, and prepended the `CLS` token as a convention of other transformers. After concatenation, we removed all the special tokens except for the first `CLS` the last `SEP`, which made it structurally similar to the outputs of non-segmented transformers. What's more, for sliding window mechanism, we might reduce the window size to segment length if needed to save compute and memory.

Kernel-Based Methods We tested Performer (Choromanski et al., 2021) as a representative of kernel-based methods. Given that training from random initialization would lead to suboptimal results, we migrate the parameters from base models (e.g. BERT, RoBERTa) to kernel methods. In detail, we replace the self-attention layers of the base models with kernels. Given that Performer does not require any additional parameters, except for the orthogonal random feature vectors in the FAVOR+ mechanism. Following the default implementation of the fast transformer codebase[12], we set the feature dimension as the query dimension by default for main experiments, though we found the performance isn't sensitive to those features in section 5.4.

C Experiments Details

In this section, we introduce the details of our experiments in the main paper, including hyperparameters, training strategies, data split and loading, and other configurations that are necessary to replicate our results.

Computational Resources All of our experiments were done with NVIDIA RTX 6000 GPU with 24GB of memory. We did most of the experiments with single cards, except for TriviaQA, for which we used multi-GPU training with 4 cards.

Coreference Resolution We used two models: coarse2fine (C2F) (Lee et al., 2018) and start2end (S2E) (Kirstain et al., 2021). For C2F model, we used the codebase reimplemented by AllenNLP (Gardner et al., 2018) for its flexibility on encoder exchange. We used the official codebase of S2E model for other experiments. We didn't change any hypermeters except for the difference on the encoders. We adopted the same training strategy of these repos without any modifications, i.e. we train the model with certain epochs (40 for C2F and 129 for S2E) or until convergence and pick the model performed best on the dev set for evaluation. The typical training time of coref models was 10h for C2F and 24h for S2E.

---

[12] `https://github.com/idiap/fast-transformers`

Natural Language Inference Due to the size of DocNLI dataset (942k training and 234k dev examples), it's infeasible to adopt the common training strategies. Instead, we train the model with mini-batch gradient descent with a batch size of 4 for only one epoch. Because the training and dev set are too large to fit into CPU memory, we split the training set into smaller datasets consisting of 32768 examples, and iterate over training and dev set during training. We pick the model with best performance on the dev set (not the whole set but one iteration) for test. We use the whole test set consisting of 267k examples for the final evaluation. We adopt the same architecture as the model used in Yin et al. (2021) and reimplement it with AllenNLP Gardner et al. (2018). The typical training time is around 2 days and the test time is around 4 hours.

Question Answering For TriviaQA, we adopted the training scripts and hyperparameters used by Beltagy et al. (2020) except for that we set the training batch size as 4 and number of epochs as 8. The performance is evaluated on the dev set and we pick the best checkpoint with patience of 3.

For Qasper, we follow the training scripts and hyper-parameters in its official repository. [13] We disable the evidence setting, and extend the training to a maximum epoch of 20. The performance is evaluated on the dev set with patience of 5.

For QuALITY, we adopt the LED model with "allenai/led-base-16384" configuration from Huggingface. [14] We concatenate the question, candidate answers, and passages as the encoder input, and the correct answer as the decoder input for training. During inference, we feed each candidate answer as the decoder input, and consider the one with the lowest perplexity as the predicted answer. We use a warmup steps of 1000 and learning rate of 5×10^{-5} for training. Evaluation is performed on the dev set with a patience of 5.

Summarization For both the SummScreen and GovReport datasets, we use the LED model with "allenai/led-base-16384" configuration. We use a warmup steps of 1000 and learning rate of 5×10^{-5} for training and patience of 5 for testing. GovReport is evaluated on the dev set and SummScreen is evaluated on its official test set.

D Significance Test

For the comparison between curves in the section 5, we conduct significance test using bootstrapping methods to verify our conclusions. Let D be the test set for a task. For the performance comparison between two configurations, we sample a new D^* from D with replacement and we keep $|D^*| = |D|$. We treat the event "configuration A performs better than B" as a Bernoulli random variable P, and compute the probability of the null hypothesis $P < 0.5$ as the p value. We sample $B = 1024$ test sets for each comparison. If multiple significance tests are conducted, we only report the larges value that we obtain. [15]

For example, in fig. 3, we claim that the performance of Longformer (L=512) is better than any other encoders regardless of the mention distances. To verify it, we conduct significance test between Longformer (L=512) and other 3 encoders for every mention distance. The greatest p value among 24 p tests is smaller than 0.01, so our claim is secured by our significance test.

E More Pooling Strategies

We conduct experiments with 4 transformers, including 2 short-range transformers (RoBERTa and SpanBERT) and 2 long-range transformers (Longformer and BigBird) on the coreference resolution task. We set L=512, which is the maximum acceptable length for short-range transformers.

The full results are shown in table 7, and a box plot can be found in fig. 11. In overall, we have similar observations as Joshi et al. (2019) that overlapped segments do not offer improvements on the performance. Similar findings can be found for LSTM settings and the combination of them. More importantly, the performance difference of table 7 is consistently with tables 8 and 11 except for a few outliers. Thus, we conclude that direct concatenation is already enough to exploit the pretrained transformers, and changing pooling strategies do not greatly interfere our analysis.

F Full Experiment Results

In this section, we list the full results of all the experiments in the main paper.

---

[13] `https://github.com/allenai/qasper-led-baseline`

[14] `https://huggingface.co/allenai/led-base-16384`

[15] For the curves in fig. 8, we exclude one exception case at $x = 0.6$. For the curves in fig. 9, we exclude one exception case at $x = 500$.

F.1 Coreference Resolution

The full results of coreference resolution are shown in tables 8 and 11. We use MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), and CEAF_{ϕ_4} (Luo, 2005) as the evaluation metrics. Following the convention, we use the "Avg." as the main metric, which is an average among the F1 score of 3 metrics. All the results are reported on the test set.

F.2 Question Answering

The full experiment results on TriviaQA is shown in table 9. We use both F1 and exact match (EM) as the metrics. A few cells are left blank because of the constraints of the transformers.

F.3 Summarization

The full results on summarization is shown in table 10. We used ROUGE (Lin, 2004) as the metric. R1, R2, and R3 stands for ROUGE unigram, bigram, and longest common subsequence. Note that 1536 is the windows size of the LED model, and 1024 is the maximum length supported by the BART model.

Abstract

There is increasing interest to work with user generated content in social media, especially textual posts over time. Currently there is no consistent way of segmenting user posts into timelines in a meaningful way that improves the quality and cost of manual annotation. Here we propose a set of methods for segmenting longitudinal user posts into timelines likely to contain interesting moments of change in a user's behaviour, based on their online posting activity. We also propose a novel framework for evaluating timelines and show its applicability in the context of two different social media datasets. Finally, we present a discussion of the linguistic content of highly ranked timelines. [1]

1 Introduction

An increasing body of work considers time-aware models trained on social media data for a number of different tasks, including personal event identification (Li and Cardie, 2014; Li et al., 2014; Chang et al., 2016a), suicidal ideation and suicide risk detection (Coppersmith et al., 2014, 2018; Cao et al., 2019; Matero et al., 2019; Sawhney et al., 2020, 2021). For such tasks deriving meaningful *timelines* (i.e. sequences of posts by individuals), containing examples of the phenomenon under study from large-scale collections, together with associated annotations, is crucial. This is especially important for computational approaches in mental health (MH) given the surging numbers of those seeking help online (Neary and Schueller, 2018).

Earlier work on personal life event detection considered selecting salient timelines through topic modelling (Li and Cardie, 2014; Li et al., 2014) or through a non-parametric generative approach (Chang et al., 2016a). However, such approaches are unsuitable for identifying changes in mood or MH more generally. Specifically, since timelines are selected based on linguistic content this introduces a sampling bias for downstream linguistic analysis and annotation (Olteanu et al., 2019; Mishra et al., 2019). In recent work on suicidal ideation detection, timelines are chosen as the N most recent posts (Sawhney et al., 2020), which are not necessarily the most salient for annotation.

Present Work: We propose a set of methods and associated evaluation framework for identifying salient timelines from the history of social media users to be annotated for changes in a user's behaviour, as revealed through their textual data. Applying our methods in the domain of MH, we follow earlier work in hypothesising that posting behaviour can be a proxy for changes in the MH of an individual (De Choudhury et al., 2016). Therefore we develop methods for creating timelines based on time-series of posting frequency, such as change-point and anomaly detection approaches, and evaluate these against keyword-based methods and randomly selected timelines, in the context of the task of capturing *Moments of Change (MoC)*. A MoC is a particular point or set of points in time denoting: (1) a shift in an individual's mood from positive-to-negative or vice versa; or (2) a gradual mood progression (Tsakalidis et al., 2022a). We show that our proposed timeline segmentation methods can consistently select timelines that are rich in MoC for large scale cost-effective annotation. We make the following contributions:

- We present approaches for extracting timelines from users' posting history on social media based on change-point detection and anomaly detection methods (§3).
- We propose a novel evaluation framework for assessing the quality of annotated timelines, and timeline selection methods, which we evaluate on the task of capturing MoCs (§4.2) on two different social media datasets.
- We provide a linguistic analysis of timelines ob-

tained, distinguishing timelines dense in MoCs, from timelines sparse in MoCs (see §5.2).

2 Related Work

Since we aim to segment users' entire posting history into smaller sequences, manageable to annotate and salient in terms of containing moments of change in mental health, we consider work in the following areas: mental health monitoring (2.1); text segmentation (2.2); timeline summarization (2.3); change-point detection (2.4).

2.1 Tracking Changes in Mental Health (MH)

Moments of Change (MoC) are important in MH tracking. Pruksachatkun et al. (2019) identifies a MoC as a positive change in sentiment for a user with respect to a distressing topic mentioned in a conversation thread. De Choudhury et al. (2016) investigated shifts to suicide ideation with models predicting when users transition to posting on a suicide support forum. We consider a more general definition of MoC (§1, "Present Work").

Creation of Mental Health Datasets. A large body of work in creating MH datasets involves labelling posts for symptoms (Gkotsis et al., 2017; Loveys et al., 2017; Cheng et al., 2017) or levels of suicide ideation (Masuda et al., 2013; Coppersmith et al., 2016; Shing et al., 2018). While annotations for some of these datasets are obtained through proxy signals (e.g., self-disclosure of diagnoses, posts on support networks) questions arise as to how to select appropriate data for annotation. Mishra et al. (2019) use keyword based methods to identify posts exhibiting the phenomenon under study (e.g. suicidal ideation) but this leads to sampling biases.

2.2 Text Segmentation (TS)

TS (Beeferman et al., 1999; Pak and Teh, 2018) focuses on splitting a large body of text (document) into smaller chunks (segments or "regions of interest" (Oyedotun and Khashman, 2016)). TS has been applied in numerous fields, including emotion (Wu et al., 2007) and sentiment detection (Chiru and Hadgu, 2013), often involving segmenting news articles (Gao et al., 2010) and review items (Sun et al., 2013). While there is some work in segmenting large bodies of social media posts into text segments (Kaur and Singh, 2019), we are not aware of work segmenting entire posting histories into smaller, more manageable segments (i.e. timelines), to improve downstream longitudinal annotation.

Furthermore, TS primarily operates on linguistic content, rather than timestamped information, with algorithms designed to identify segments containing certain topics of interest, resulting in selection bias (Riedl and Biemann, 2012; Takanobu et al., 2018; Hananto et al., 2022). An alternative is to consider timeline extraction approaches agnostic to the linguistic content, inspired by Timeline Summarisation and Change-Point Detection (CPD).

Evaluation metrics other than precision and recall have been proposed to account for near misses during text segmentation. P_k (Beeferman et al., 1999) uses a k-sized sliding window on a document to compare predicted *vs* ground-truth segmentation locations, assigning partial credit to near misses. However, it is affected by variations in segment sizes and penalizes false negatives more than false positives. WindowDiff (Pevzner and Hearst, 2002) penalises the latter equally. Both metrics require ground-truth annotations of the optimal segmentation locations. We propose an approach (§4) to evaluate segmentation of users' histories based on the proportion of desired annotation labels within a set of sampled sequences of posts (timelines).

2.3 Timeline Summarization (TLS)

TLS aims to provide concise chronologically ordered timelines consisting only of the most relevant information for a given topic or entity, summarizing the key points in time. While TLS has been most commonly applied in news topic summarization (Swan and Allan, 2000; Martschat and Markert, 2017, 2018; Steen and Markert, 2019), there has been increasing interest in applying TLS to social media data (Li and Cardie, 2014; Chen et al., 2019; Ansah et al., 2019; Wang et al., 2021).

TLS consists of a 2-step pipeline: (1) date selection, then (2) summarisation. Salient dates summarizing a timeline are typically identified using textual content, as well as time-series information in the history of an individual/topic. Focusing on viral buzzes of celebrity mentions on social media, Chang et al. (2016b,a) aims to select dates by modelling linguistic content and frequency-based time-series patterns.

2.4 Change-point Detection (CPD)

While CPD has been explored to some extent in news TLS (Hu et al., 2011), it remains underexplored for social media data. **Change-points**

(CPs) are defined as points in time where the underlying generative parameters of a data sequence are predicted to have changed (van den Burg and Williams, 2020). CPD therefore often involves learning a predictive model of a data sequence. In §3, we use automatically detected CPs to identify salient dates for selecting timelines of users on social media for annotation. While several continuous models exist (e.g. Gaussian (Adams and MacKay, 2007)), we focus on models suited to discrete time-stamped data (Knoblauch and Damoulas, 2018) – such as when posts/comments are made on social media. In such scenarios Temporal Point Processes (TPPs) (Daley and Vere-Jones, 2003) are well suited.

Temporal Point Processes (TPPs) TPPs are stochastic processes that model discrete events localized in continuous time. They are typically characterized by an intensity function, $\lambda{>}0$, which represents the instantaneous rate of event occurrence.

In order to use TPPs to model event sequences, and predict associated changes – certain CPD models, such as Bayesian Online Change-point Detection (Adams and MacKay, 2007) require the TPP to be part of the exponential family of distributions (e.g. Poisson). This is so that the intensity λ can be further modelled from a prior conjugate distribution, making it possible to construct the likelihood of the chosen predictive model in a closed form.

3 Approach for Selecting Timelines

Task. Our principal aim is to select timelines for annotation that are rich in changes in posting behaviour on a MH platform, which we consider as a proxy for changes in MH – in particular, Moments of Change (MoC). To achieve this, we test a series of timeline selection methods (§3.1-§3.2), which we evaluate using our proposed framework (§4).

Selecting Candidate Timelines. To select timelines for annotation, we extract candidate timelines as a span of timestamps S from a user's u history H. We first propose identifying changes in posting behaviour as *Candidate Moments of Change* (CMoC), which are dates hypothesised to be surrounded by many MoCs (§3.1). Subsequently, we extract the user's posts surrounding these CMoC within a fixed time window, as timelines to be returned for annotation (§3.2).

3.1 Identifying Candidate MoCs (CMoC)

We investigate the following for identifying CMoC:

(1) Bayesian Online Change-point Detection (BOCPD): In a recent evaluation involving experiments with synthetic and real-world change-points, van den Burg and Williams (2020) showed that BOCPD was the best model for a variety of CPD tasks. BOCPD learns a predictive model on a data sequence. When changes in the model's generative parameters are identified, CPs are declared. BOCPD is typically fit with continuous models (e.g. the Gaussian distribution). However, in our case we consider models for discrete event-based data (Knoblauch and Damoulas, 2018).

Since we hypothesize that changes in posting behaviour coincide with changes in mood (see "Present Work" in §1), we use BOCPD to identify changes in individuals' posting frequency. As such we consider the daily frequency of posts made by a user as a TPP, and use the homogeneous Poisson-Gamma (PG) point process model with BOCPD (Knoblauch and Damoulas, 2018) to fit and identify changes in the daily frequency of posts by a user from their entire associated history. We assess our hypothesis by evaluating timelines obtained this way in terms of how dense they are in MoCs, changes in mood and sentiment (Table 3).

By using a PG model with BOCPD, we assume that each point in a user's posting frequency is sampled from a Poisson distribution with a discrete λ. Here λ represents the expected number of posts by a user within a given time interval. As we use this conjugate Bayesian model, λ is further assumed to be drawn from a Gamma distribution with a set of priors α_0 and β_0, that act as initial hyper-parameters in our model, where α_0/β_0, α_0/β_0^2 denote the prior mean and variance over λ. BOCPD has an additional hyper-parameter which is the hazard h_0, where $1/h_0$ expresses a prior belief about the probability of CPs occurring at a given time t, provided that a CP has not recently occurred: a low h_0 results in the over-generation of change-points while a large h_0 is more conservative and returns very few CPs (ideal in our scenario, to ensure that we do not waste annotation resources, by avoiding annotating too many timelines generated by noise). As such, we experiment with two settings of BOCPD to identify CMoCs: BOCPD (1) and BOCPD (2), which have priors (α_0:.01; β_0:10; h_0:10^3) and (α_0:1; β_0:1; h_0:10) respectively.

Since BOCPD computes a full probability distribution over the location of the CPs, quantifying probable CPs along with their associated uncertainty, we use the maximum a posteriori (MAP) segmentation of the probability distribution to return exact point estimates for CPs (Fearnhead and Liu, 2007; van den Burg and Williams, 2020), which in our setting define CMoCs. An illustration of identifying CMoCs from a given user's history in our implementation of BOCPD is provided in Fig. 1.

(2) Anomaly Detection (AD): Here we aim at identifying (a) days of abnormally high user activity and (b) abnormally long time periods of no user activity at all. We hypothesize that such points in time can be used to select salient timelines. We experiment using different features to fit our model, including the daily frequency of a user's posts and the number of comments they receive for those corresponding posts by others. Using either activity type, we scan over the user's entire history.

For (a) we explore the use of *Kernel Density Estimation (KDE)* (Rosenblatt, 1956; Scott, 2015) to estimate the probability density function of the user's activity. For (b), we focus on time periods in the user's history lasting at least 14 days during which the user had no activity (posts/comments) at all. Given the past 90 days of a user's activity, if the probability on a particular day of seeing either (a) a high volume of activity or (b) a long period of 'silence' is lower than .01, then we mark the start of this period as an 'anomaly' – i.e., CMoC. We explore (a) and (b) separately for posts and comments, and we also explore concatenating CMoCs identified for high and low posting activity for either comments received or posts made.

(3) Keywords: We incorporate a baseline for identifying CMoCs based on a set of keywords in the *suicide risk severity lexicon* (Gaur et al., 2019). Each keyword present in the lexicon corresponds to different levels of suicide risk severity such as "I'm tired of this suffering", and "I'm going to kill myself". We hypothesize that the presence of such phrases in a user's post may be indicative of a MoC. This method returns CMoCs for timestamps of posts by a given user that contain a keyword within the lexicon. Note that keyword methods are prone to sampling bias for downstream linguistic analysis, we include them in our experiments due to their popularity for comparison purposes.

(4) Random & Every day: We incorporate two naïve baselines, as such methods are important for benchmarking in MH tasks (Tsakalidis et al., 2018). "*Random single day*" selects a single date from a uniform distribution over all days in a user's posting history H as a CMoC, C (we evaluate against 100 random seeds to report average scores, §4). "*Every day*" returns every day as a CMoC – we employ it to see how well our methods are at avoiding the over-generation of candidate timelines. We seek to avoid over-generating timelines as we want to only return timelines with a high density of MoC to improve annotation efficiency.

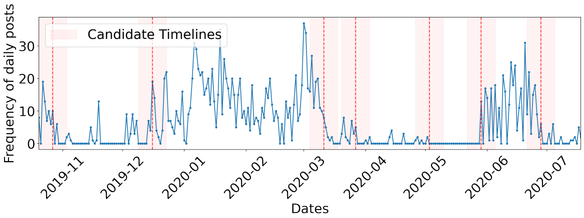

Figure 1: Using change-points in an example user's posting behaviour to define candidate moments of change $M_u^{(c)}$ (dashed red line). Candidate timelines are then created centred on each $M_u^{(c)}$, with a radius r=7.

3.2 Extracting Posts

Once a CMoC, C, is found, a span of timestamps S from the user's history H is identified within a radius r[2] around C. A candidate timeline then consists of the associated sequence of posts, corresponding timestamps and comments within S.

4 Evaluation of Selected Timelines

While there is previous work in evaluating segments of posts in text segmentation (§2.2) and timeline summarization (§2.3), there is little to no prior work on frameworks for evaluating timeline selection methods for the purposes of efficiently annotating longitudinal datasets. As such we identify this as a nascent area of study – ripe for others to build upon, and propose a novel evaluation framework for selecting timelines for this task.

We investigate several metrics for evaluating the methods from §3 in terms of their ability to select timelines that correspond to a high proportion of Ground-truth Moments of Change (GTMoC), denoted hitherto as G. Each CMoC generated by a method as a change point is denoted hitherto as C. Since we do not have access to manual ground truth annotations outside of the span of our annotated timelines, we can only evaluate methods according to CMoCs that fall within them.

---

[2] Here we take $r = 7$ which gives a manageable amount of posts while providing context before and after the CMoC.

4.1 Time-varying Classification Metrics

We use the precision and recall metrics by van den Burg and Williams (2020) for evaluating change-points (CPs) – i.e., CPs are evaluated based on the distance d_{GTMoC} of the predicted CP C falling within a margin of error distance τ to Ground-truth Moments of Change G. For our scenario, τ is reflective of the length of the timelines to be created, and is roughly the radius of a timeline. It should also be chosen based on the uncertainty of the annotation labels. The pros of making assessments based on high performance with a small τ, is that this suggests that very narrow timelines can be created, while still capturing the annotation labels. This allows many timelines to be annotated, thus increasing the diversity of the dataset. However, if timelines are too small, there may not be enough context provided to annotators to perform the annotation task. Thus, allowing for larger timelines provides more context to annotators, which can potentially improve the quality of annotations – but increase the cost and time to perform the annotation. In our experiments we make assessments based on moderately sized τ to allow for moderately sized timelines. We use τ = 5 days in table 2, which is the same value used in the experiments of (van den Burg and Williams, 2020).

A true positive (TP) therefore corresponds to an intersection of a G with a C: $G \cap C$, if $|G - C| \leq \tau$. We ensure there is a 1:1 mapping between each G and C – where each C can only intersect as TP against a single G. The total number of TPs for a timeline therefore is given by $\max(|G \cap C|) \leq \max(|G|, |C|)$, where G and C are sets of dates in annotated timelines. The precision and recall are thus defined as $P = \frac{|G \cap C|}{|C|}$ and $R = \frac{|G \cap C|}{|G|}$, respectively. We compute P and R for each annotated timeline and report mean across all timelines. The mean scores are then used to compute the mean F1.

While these metrics evaluate how well a timeline selection method can identify CMoCs close to GTMoCs, they cannot tell us which method is able to return timelines that contain a high proportion of GTMoCs relative to the number of posts (timelines with high density of GTMoCs). Thus we propose an alternative metric (Medoid Votes) based on densities of GTMoCs, as discussed next.

4.2 Medoid Votes (MV)

We propose a new metric, MV, to account for the inability of prior metrics to consider the density of labels within timelines. Although a method may have high precision (yielding a prediction close to a ground truth label), the timelines overall may contain a low proportion of the labels that we seek to annotate – leading to inefficient annotation. Hence, we introduce MV which assigns true positives against *dense regions* of labels as opposed to single labels. As we demonstrate in our experiments, assessments made using MV are more robust, resulting in timelines centered around highly dense regions of the labels we seek to annotate.

To make assessments using MV, first we identify periods in manually pre-annotated user timelines that contain a high proportion of GTMoCs relative to the number of posts within the timelines (dense regions) (§4.2.1). We then assign votes to methods that identify CMoCs close to these, and obtain a ranking (§4.2.2).

4.2.1 Dense Regions in Annotated Timelines

Medoids. We use the notion of 'medoids' to represent the location of dense regions of GTMoCs. A *medoid* M is the timestamp of the GTMoC in a given timeline T, from which the (Euclidean) distances $d(.,.)$ of all other timestamps of annotated GTMoCs G in timeline T are minimal:

$$M = \underset{G_a \in T}{\arg\min} \sum_{G_b \in T} d(G_a, G_b) \qquad (1)$$

Density of annotated timelines. We further characterise the locations of dense regions (medoids) by the number of GTMoC they contain. This *'density'* of a timeline is defined as $\rho = \frac{|G|}{|p|}$, where $|G|$ is the sum total number of GTMoCs within an annotated timeline T and $|p|$ is the number of posts in T.

In order to weight timelines by how dense they are in GTMoCs, a medoid M inherits the density ρ of the timeline T it represents. We transform ρ_T for each T, to provide a binary distinction between "dense" (+1) and "sparse" (-1) medoids as:

$$\rho_T^{\text{(binary)}} \begin{cases} +1 & \text{if } \rho_T \geq \text{Median}(\rho_T \ \forall \ T) \\ -1 & \text{otherwise} \end{cases}$$

A good timeline is therefore one that is "dense", and the ideal location for a CMoC is as close as possible to a dense medoid M (see eq. 1).

In an ideal scenario where we have the resources to annotate many timelines sampled from many candidate methods, we could compare and rank the methods based on the number of dense timelines or the average resulting densities. Alternatively, we could evaluate the proposed methods against a set of fully-annotated user histories. However, due to the high cost and time-consuming process of annotation, such approaches are infeasible. Instead we propose an alternative solution that does not require annotating all the timelines that would be generated (or entire user histories). We do this via a scoring system based on distances of CMoC relative to dense medoids in a small set of trial annotated timelines, as described next.

4.2.2 Scoring Timeline Selection Methods

We employ the evaluation framework in §4.2.1 to assess pre-annotated timelines against CMoCs in timelines selected by different methods. Assuming an annotated timeline T, we aim to assess how close an identified CMoC C is to a dense region of GTMoCs within T. We therefore give preference to methods that identify CMoCs in close proximity to medoids that are dense in GTMoC, while also penalizing methods that over-generate CMoC.

Distance Scores. We calculate the proximity of CMoCs predicted by a method to M as the minimum absolute distance d_m (in days) between all CMoCs predicted by a given method m (§3.1) for a user's entire history. Then, we compute a distance score for each m per annotated timeline as:

$$D_m = (d_m + \epsilon) * \text{sign}(\rho_T^{(\text{binary})}),$$

where ϵ=.001, to preserve the sign of each medoid's $\rho_T^{(\text{binary})}$ in the case of d_m= 0. D_m is then used to denote the proximity of CMoCs predicted by method m (in days) to a ground truth medoid M with density $\rho_T^{(\text{binary})}$. Since we want to obtain timelines that are close to dense regions in GTMoC, we seek to identify methods with low positive D_m.

Votes. To reward methods that identify a CMoC in close proximity to a 'dense' M (low positive D_m), and penalize methods which over-generate CMoC (e.g., in locations that contain a low density of GTMoC), we assign votes to each method m by:

$$v_m = \begin{cases} +1 & \text{if } 0 \leq D_m \leq \tau \\ 0 & \text{otherwise} \end{cases}$$

where τ is the same margin of error (in days) described in §4.1. This gives a positive vote to a method generating a CMoC that falls within a margin of τ days to a dense medoid. Votes v are then normalized per timeline and method ($V_m = \frac{v_m}{|C|}$, where $|C|$ is the total number of CMoCs generated by m, that fall within each annotated timeline).

Scoring of methods. Timeline selection methods are subsequently scored and ranked by summing the votes V_m for each method m over all T. As we are concerned with ranking methods, we then min-max scale our results in the range of 0 to +1, where methods that have scores close to 1 rank near the top and methods that score close to 0 are the worst in their ability to return timelines containing a high proportion of GTMoCs. The scoring of methods proposed in §3.2 are shown in Table 2, and Fig. 4 for varying margin of error, τ. The evaluation framework is visualised in Fig. 2.

5 Experiments

We evaluate our timeline selection methods (§3), using our evaluation framework (§4) based on ground-truth human annotated data.

5.1 Datasets

We evaluate our automatic timeline selection methods using two datasets (summarised in Table 1) from different platforms: The *TalkLife* dataset contains timelines automatically selected using one of our proposed methods. While our evaluation is designed to allow alternative methods to achieve higher scores than the methods used to select timelines we still want to exclude any possibility of inherent bias. To this effect we also evaluate against timelines manually selected from *Reddit* independently from this work (Tsakalidis et al., 2022b).

TalkLife[3] is a peer-support social network operating primarily as a mobile app. Users are mainly English speakers, 70% of whom are 15-24 years old (Sharma et al., 2020a). The posts/comments on TalkLife focus primarily on MH, daily-life issues and feelings. It is thus suited to identifying MoC and computationally analysing MH (Pruksachatkun et al., 2019; Sharma et al., 2020b; Saha and Sharma, 2020; Kim et al., 2021). We select timelines on the basis of timestamped user posting frequency, and associated comments received. The context of posts is only used in annotating the selected timelines; thus, methods for timeline selection are transferable to other platforms.

We licensed a de-identified dataset from TalkLife consisting of 1.1M users (12.3M posts, Aug'11-Aug'20). Due to the high variance in users' posting frequency, only timelines having [10-150] posts

---

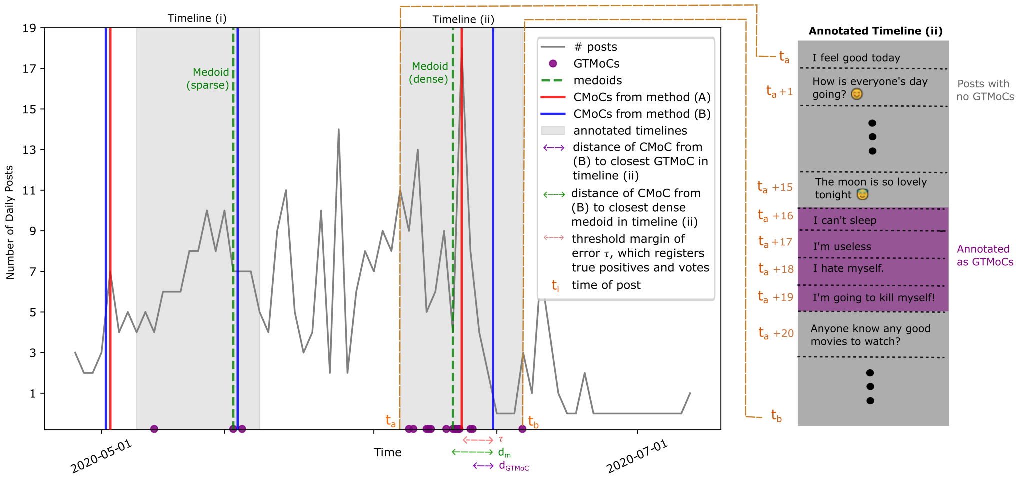

Figure 2: Evaluation of CMoCs against GTMoCs. Votes and true positives are assigned based on distances d of CMoCs falling within a margin of error τ against dense medoids or GTMoCs. Here, method A (red) selects better timelines than method B (blue), as these are close to dense regions of GTMoCs ($d_{\mathrm{m}} \leq \tau$) and labels ($d_{\mathrm{GTMoC}} \leq \tau$).

were considered for annotation. This was so that timelines were not impractically long while still providing enough context for annotators to observe and mark a change. The final annotated dataset consists of 500 timelines (see Table 1), with a mean of 35 posts (±22). These timelines were selected using BOCPD PG (1), where the parameters (α_0:.01; β_0:10; h_0:10^3) were fixed on the basis of improved model performance on a validation dataset of 70 manually annotated timelines selected via anomaly detection. All 500 timelines within the evaluation dataset were manually inspected and filtered according to the details in A.1.

Reddit. We further tested the generalizability of our methods and evaluation framework on a different dataset, that was not generated using automatic timeline selection approaches – the CLPsych 2022 Shared Task corpus (Tsakalidis et al., 2022b). We chose to include this additional dataset to address potential concerns that experiments and analysis performed on the TalkLife timelines have some bias towards the BOCPD method in experiments evaluated on the TalkLife timelines – as they were selected using BOCPD. This corpus was sourced from Reddit, a social media platform where individuals make public posts and which has been studied extensively as a resource for mining textual data for MH studies (De Choudhury and De, 2014; Losada and Crestani, 2016; Shing et al., 2018; Zirikly et al., 2019; Losada et al., 2020; Low et al., 2020). We make use of the 'Reddit-New' dataset of the CLPsych 2022 corpus, consisting of 139 timelines where 17-82% of posts come from MH subreddits and had been pre-selected manually by two researchers independently as likely to contain a high proportion of MoCs.

Annotation of GTMoC in TalkLife timelines was performed by 3 English speaking (1 native), university educated annotators. Reddit timelines were annotated by 4 English (2 native) speakers (Tsakalidis et al., 2022b).

Annotators were provided with timelines containing chronological posts by users with their associated comments and timestamps. They were asked to label posts containing a 'Switch' (sudden change in mood) or an 'Escalation' (gradual mood progression) – a (default) label of 'None' was assigned to posts with no MoC. A 'Switch' is defined in the guidelines as 'a drastic change in mood, in comparison with the recent past', with annotators having to label its beginning and its range. An 'Escalation' is 'a gradual change in mood, which should last for a few posts'. Annotators had to label the peak of an escalation and the range of associated posts (see Fig. 9 of A.2 as an example).

To obtain GTMoC for our evaluation we aggregate the annotations across all annotators per timeline in the same way as (Tsakalidis et al., 2022a). Due to the challenging and subjective nature of the annotation task, the percent of inter-annotator agreement for the labels 'None', 'Switch' and 'Escalation' were .89, .30, and .50 respectively for the TalkLife dataset, and .83, .26, and .31 respectively for the 2022 CLPsych Corpus, based on majority agreement. We consider all labels of 'Switch', 'Escalation', and their corresponding ranges as GTMoC. We thus merge both labels to define GTMoCs, as we are interested in identifying timelines that contain both types of changes in mood.

	Timelines	Posts	Users	Timeline Length
TalkLife	500	18,702	500	$\leq$ 2 weeks
Reddit	139	3,089	83	$\sim$ 2 months

Table 1: Summary of datasets used in our experiments.

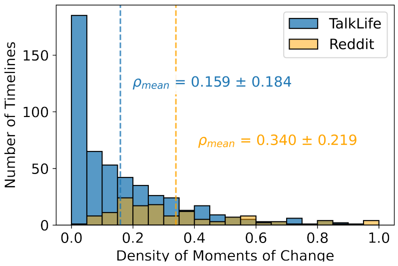

Figure 3: Density of GTMoCs per timeline.

5.2 Results & Discussion

We identify CMoCs (§3.1) on annotated timelines from TalkLife and Reddit (§5.1), and evaluate using our metrics (§4). We round CMoCs to the nearest day, de-duplicating dates, to compare methods.

Density scores of annotated timelines. The density of the annotated timelines from TalkLife are presented in Fig. 3. The mean density (.159) is comparatively high considering that GTMoCs are rare events, and many timelines do not contain any GTMoC. While the mean density (.340) of manually selected timelines from Reddit is higher, extra annotation effort was taken by annotators to ensure these timelines had a high proportion of GTMoCs.

Ranking of timeline selection methods. Table 2 and Fig. 4 shows the generalizability of our models and evaluation based on the consistency of results across both datasets. Overall, BOCPD models achieve the highest precision, and relatively high medoid votes (MV) across varying values of τ. Note that BOCPD PG (1) had hyper-parameters that were tuned for the data on TalkLife, whereas BOCPD PG (2) has very general hyper-parameters – not tuned for either TalkLife or Reddit. Despite not having any models tuned specifically for Reddit, BOCPD (1) achieves the highest precision for the majority of margins of error τ, and BOCPD (2) achieves the 2nd highest precision for larger τ. Importantly, BOCPD achieves the highest precision for most cases of τ across both datasets. Precision is particularly important as it ensures that the resulting CMoCs will have a high chance to be close to GTMoCs. This aligns with our objective of ensuring the resulting dataset will be annotated with a high proportion of GTMoCs.

For both Reddit, and TalkLife, the more general parameters of BOCPD PG (2), which were not tuned for either dataset, still achieve among the highest precision and MV (next highest MV – and also the highest P for TalkLife). Even with low h_0 and $\alpha_0/\beta_0 = 1$ (likelier to over-generate CMoCs), BOCPD (2) outperforms all AD and naïve methods on MV and F1 on TalkLife. For TalkLife, AD (high activity: posts) achieves slightly worse MV compared to keywords, but outperforms it on Reddit, despite being potentially disadvantaged by not using linguistic content. AD (low activity) achieve among the worst F1 and MV. As a result, timelines created around anomalously low post frequency would be unsuitable for selecting dense timelines.

Scores vary with τ (Fig. 4). For low margins (τ<3) BOCPD ranks lower in F1 and MV in both datasets, but ranks among the highest for larger τ. We attribute this to BOCPD assigning CMoCs to transitions from high to low posting activity. As we expand τ and select longer timelines around CMoCs, BOCPD is able to capture moments in time which can contain both high and low posting activity. Transitions from high to low posting activity may not be captured for low τ – potentially explaining why the performance in this case is lower than methods that favour a high amount of posts. Since timelines on TalkLife were created with a radius of 7 in (Tsakalidis et al., 2022a), setting a fairly large τ=5 is suitable for assessing which methods are able to select dense timelines, while also allowing us to identify shorter, denser, timelines from longer annotated timelines, as in the case of Reddit.

While recall and F1 are relatively low for BOCPD across both datasets, we argue that precision and MV are the most important metrics to focus on for our task. Considering that 'everyday' has a perfect recall of 1.00, and that annotating all posts in a users history would indeed return all the GTMoCs for a user – this is highly inefficient and infeasible, and goes against our original objective of *efficiently* annotating a user's posts. By instead focusing on methods with high precision and MV, rather than recall, we ensure that the resulting timelines are near a high proportion of the labels we aim to annotate. This allows annotators to consider fewer posts to capture the same amount of rare labels, which are costly to annotate.

Linguistic analysis of timelines. To gain insights into the characteristics of 'dense' vs 'sparse' timelines, we employ VADER (Hutto and Gilbert, 2014), assigning a sentiment score per post, and

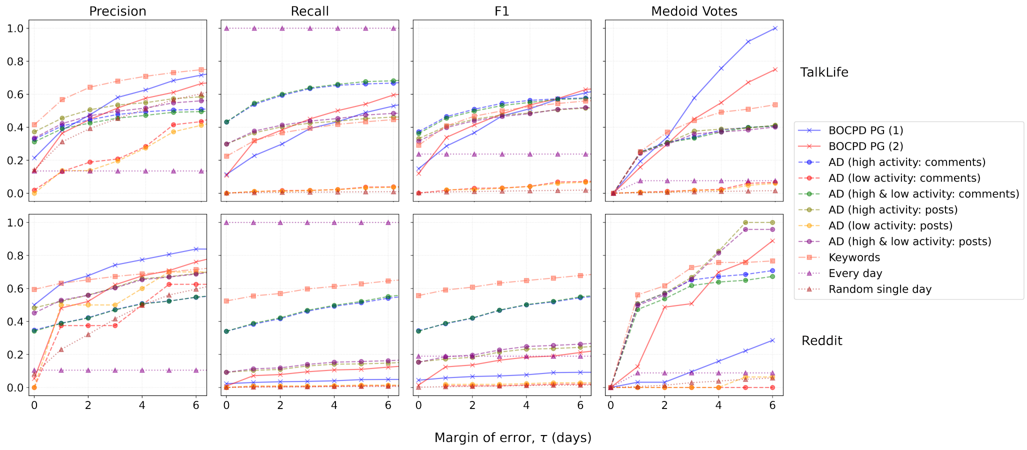

Figure 4: Evaluation metrics for different timeline selection methods, with varying margins of error τ (days).

	TalkLife				Reddit			
Method	P	R	$F1$	MV	P	R	$F1$	MV
BOCPD PG (1)	**.683**	.489	**.570**	**.919**	**.806**	.048	.090	.222

Table 2: Evaluation of timeline selection methods, using a margin of τ=5 days. MV (§4.2) are min-max scaled in the range τ=[0,6] days. **First**, **second**, and **third** highest scores are highlighted.

Twitter-RoBERTa-emotion (Barbieri et al., 2020), assigning four emotion scores (joy, anger, sadness, optimism) per post on the TalkLife dataset. We equally split 250 TalkLife timelines, between 'dense' (density $\rho_{u,i}$ is in upper-quartile of all timelines) and 'sparse' (bottom-quartile). The distribution of sentiment scores across these timelines are shown in Fig. 5. For each timeline we extract statistical features (avg, std, min, max) for each emotion/sentiment dimension of its posts, and the same features based on their difference across two consecutive posts in the timeline. Using these features, we train a Logistic Regression aiming at predicting 'dense' vs 'sparse' timelines and extract the coefficients with the highest/lowest values.

Sparse timelines frequently consist of positive posts in sentiment/mood (see Table 3). On the other hand, sadness- and variance-based features correlate the most with predicting a timeline containing many MoCs – a finding that was empirically confirmed via manual inspection of the most dense timelines. Developing methods that account for the variability in a user's mood/sentiment is a potential future direction in this regard.

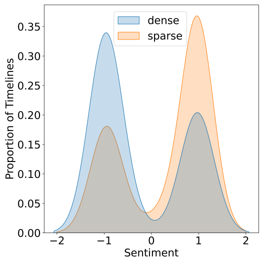

Figure 5: Sentiments of 'dense' *vs* 'sparse' timelines (medians: $-.949$ & .970, respectively).

Feature	Coef
sadness (avg)	2.29
sadness (std)	1.45
sentiment (std)	1.00
sentiment (avg)	-1.23
optimism (avg)	-1.25
sentiment (min)	-1.31
joy (avg)	-1.58

Table 3: Logistic Regression coefficients classifying timelines as 'dense' (1) or 'sparse' (-1).

6 Conclusions & Future work

We have introduced methods and an evaluation framework for identifying timelines from users' social media posts, likely to contain a large amount of Moments of Change (MoC). We use changes in posting behaviour as a proxy for changes in mood, to efficiently identify longitudinal user content worth annotating. Our methods have been manually evaluated against ground truth MoCs (GT-MoCs) in two different datasets. Bayesian Online Change Point Dection (BOCPD) shows promise in detecting timelines rich in GTMoCs.

Future work can explore the incorporation of textual content in the BOCPD Poisson-Gamma model for the distinction between different types of GT-MoC. We find that resulting timelines dense in GTMoCs are characterised by a high deviation in sentiment from one post to the next, suggesting that such deviations may be a useful feature for distinguishing between different types of GTMoC.

We expect that the methods proposed in our work will benefit researchers interested in creating longitudinally annotated textual datasets of user posts, particularly when annotating Moments of Change.

Ethics Statement

Ethics IRB approval was obtained from the Biomedical and Scientific Research Ethics Committee of the University of Warwick (ref: BSREC 40/19-20) prior to engaging in this research study. Our work involves ethical considerations around the analysis of user generated content shared on a peer support network (TalkLife). A license was obtained to work with the user data from TalkLife and a project proposal was submitted to them in order to embark on the project. The current paper focuses on the identification of periods of interest within the user history, in terms of moments of change. The work on annotation of moments of change (MoC) is separate to this paper but considers sudden shifts in mood (switches or escalations). Annotators were given contracts and paid fairly in line with University pay-scales. They were alerted about potentially encountering disturbing content and advised to take breaks during annotation. The annotations are used to evaluate the work of the current paper, which aims to meaningfully segment timelines in terms of containing likely moments of change. Potential risks from the application of our work in being able to identify moments of change in individuals' timelines are akin to the identification of those in earlier work on personal event identification from social media and the detection of suicidal ideation. Potential mitigation strategies include restricting access to the code base and annotation labels used for evaluation. No data can be shared without permission from the platform or significantly paraphrased. Any examples used from the users' history are anonymised and paraphrased.

Limitations

In this work we focus on returning timelines rich in Ground-truth Moments of Change (GTMoCs) in mood, using posts on social media which are by definition sparse. This has several limitations. Firstly, our labels of GTMoCs rely on individuals self-disclosing related information. We cannot make assessments based on someone's experience offline. The users chosen in our sample may also be users who are more likely to disclose information and so their posting patterns may not be typical of the general population. Both of these issues are true for most work in affective computing from social media.

Our methods for identifying Candidate Moments of Change (CMoCs) have several limitations. Similar to the issues with our GTMoCs, these methods rely on posting behaviour and cannot capture behaviour outside the user's social media history. Another limitation of our methods for identifying CMoCs is that they currently only use simple univariate features (e.g. posting frequency), and do not model the influence of cross-user interactions or multivariate features. While we suspect these methods for identifying CMoCs could be extended to model these more complex types of features and interactions, to better select timelines, we have not done this in the current work.

Finally, while we have shown that our methods for identifying CMoCs to select timelines rich in GTMoCs in mood generalize well between two social media platforms (TalkLife and Reddit), we have not experimented with other platforms.Our methods have been used for returning timelines rich in ground-truth labels for changes in mood but it remains to be seen whether they generalize well to identifying timelines rich in other labels for other related annotation tasks (e.g. labelling levels of suicide ideation). We believe this to be the case.

A Appendix

A.1 Creating Ground-truth Timelines, by Retaining a Subset of Representative Candidate Timelines

In addition to the details provided in section 3, for selecting candidate timelines, we provide some additional details inline below. As multiple timelines will typically be returned for each user using methods in 3 and annotating all of these can be time-consuming, in order to keep the 500 annotated ground-truth timelines relatively diverse in terms of the types of users – only a single timeline was returned per user to be annotated. Therefore, for each user only a single timeline was randomly sampled per and these were presented visually in turn to the first author of this paper, with multiple time-scales limiting the x-axis of the visualization returned: (1) the time-scale of the whole user's history, (2) a radius of 200 days surrounding the CMoC and (3) a radius of 31 days around the CMoC. This was to ensure that the candidate timelines could be inspected in close detail (3), and also observing the timeline in context of the full time-series (1) for that user. These three multiple time-scales for a single user are presented visually in figure 6. A manual binary decision was then made on whether to discard this timeline or retain it to be annotated and thereby create a ground-truth timeline using it. This decision was based on a time-series visualization of the frequency of daily posts for that user and highlighting the location of the timeline to be either retained or discarded. The decision to discard a timeline was based on two criteria: whether the timeline (1) was primarily sparse over the full 15 days of the timelines, or to a lesser degree (2) whether it appeared that the CMoC was generated by noise. It was chosen to discard timelines that were (1) primarily sparse, to ensure that we allow sufficient amount of time to pass between posts such that moments of change can occur. Timelines that appeared to be (2) generated by noise, were discarded such that the ground-truth timelines were representative of timelines that would be generated by a change-point detection algorithm with well chosen hyper-parameters – as the retained timelines were thus timelines that appeared to be generated by realistic change-points. Figure 7 presents a visualisation of a timeline that was discarded as described above, and figure 6 describes a timeline that was included to be annotated as a ground-truth timeline.

This process of visually deciding whether a randomly sampled candidate timeline should be retained to be converted into a ground-truth timeline was repeated until 500 candidate timelines were retained. This process thus lasted until 1,220 randomly sampled timelines were observed and thus 720 timelines were discarded.

From the annotated timelines, medoids are re-

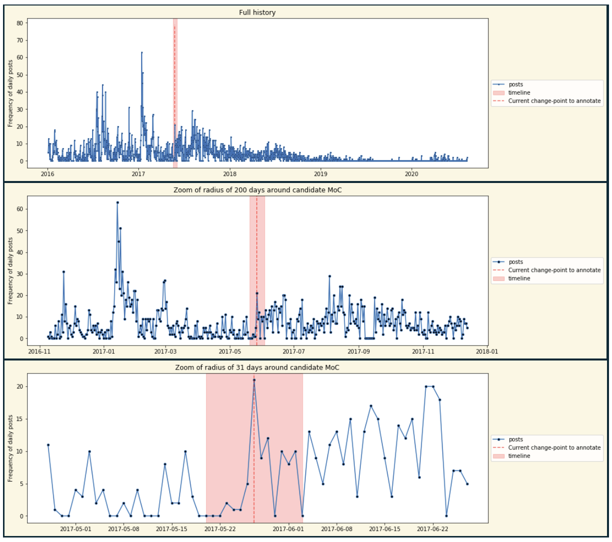

Figure 6: A timeline that was retained, out of the 1,220 timelines manually observed. It was retained as it (1) was not primarily sparse as it contains posts distributed well over the timeline, and (2) appeared to be generated by a plausible change-point rather than noise. Timelines were visualized on 3 time-scales, as shown in this figure, to allow for closer inspection and to compare in context of the full time-series.

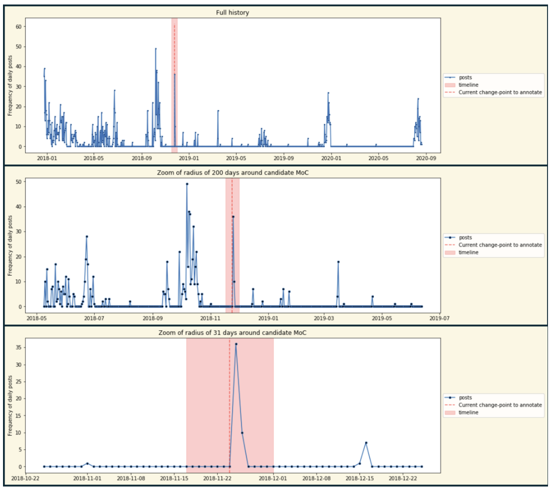

Figure 7: A timeline that was discarded, out of the 1,220 timelines manually observed. It was discarded as it (1) was primarily sparse containing only posts on a few days in the timeline, and (2) appeared to be generated by noise rather than by a realistic change-point.

turned as the medoid timestamp of the annotated GTMoC after annotations were union aggregated across all annotators as described in (Tsakalidis et al., 2022a).

A.2 Annotation Guidelines

The annotation task proposed by (Tsakalidis et al., 2022a) was to assign annotators to identify changes in mood, by reading through the posts in chronological order included within the generated timeline of an individual – and annotating the posts which contain a change in the user's mood compared to the recent past.

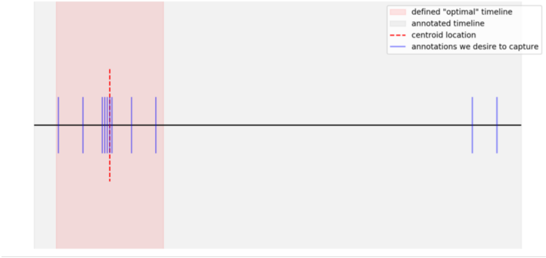

Figure 8: Identifying the position of the medoid, from the timestamps of posts annotated as GTMoCs.

An example illustrating both a switch, and an escalation are displayed in figure 9. Note, that the example shown in this figure will be paraphrased before the work is published – to further preserve anonymity of this user.

5.2.I'm feeling pretty shitty these days...

☐

Figure 9: An example of the annotation interface, displaying a sequence of posts in a timeline shown to an annotator. For these sequence of posts, the annotator annotated a single post as a "switch" and another post as an "escalation". The user has a "switch" at 4.1, drastically changing from a positive mood to a negative mood – where this changed mood persists until 4.4. The "escalation" begins and is at its peak (in this case becoming increasingly negative) at 5.1, and de-escalates up to the post at 5.2."

Semi-supervised New Event Type Induction and Description via Contrastive Loss-Enforced Batch Attention

Carl Edwards and **Heng Ji**
University of Illinois Urbana-Champaign
`{cne2, hengji}@illinois.edu`

Abstract

Most event extraction methods have traditionally relied on an annotated set of event types. However, creating event ontologies and annotating supervised training data are expensive and time-consuming. Previous work has proposed semi-supervised approaches which leverage seen (annotated) types to learn how to automatically discover new event types. State-of-the-art methods, both semi-supervised or fully unsupervised, use a form of reconstruction loss on specific tokens in a context. In contrast, we present a novel approach to semi-supervised new event type induction using a masked contrastive loss, which learns similarities between event mentions by enforcing an attention mechanism over the data minibatch. We further disentangle the discovered clusters by approximating the underlying manifolds in the data, which allows us to achieve an adjusted rand index score of 48.85%. Building on these clustering results, we extend our approach to two new tasks: predicting the type name of the discovered clusters and linking them to FrameNet frames.[1]

1 Introduction

Discovering new event types is an important step for adapting information extraction (IE) methods to unseen domains. Existing work (Ji and Grishman, 2008; McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Du and Cardie, 2020; Li et al., 2021a) traditionally uses a predefined list of event types and their respective annotations to learn an event extraction model. However, these annotations are both expensive and time-consuming to create. This problem is amplified when considering specialization-intensive domains such as scientific literature, which requires years of specialized experience to understand even a specific niche. For example, there are a wide range of otherwise obscure events in biomedical literature (Krallinger et al., 2017), and better IE techniques can empower life-changing breakthroughs in these domains. To adapt IE to these specialized domains, it is critical to discover new event types automatically.

There are two primary approaches in event type induction. The first is completely unsupervised induction. It includes recent neural techniques (Huang et al., 2016; Shen et al., 2021), as well as ad-hoc clustering techniques (Sekine, 2006; Chambers and Jurafsky, 2011) and probabilistic generative methods (Cheung et al., 2013; Chambers, 2013; Nguyen et al., 2015). The second approach, semi-supervised event type induction, was recently introduced by Huang and Ji (2020). It proposes leveraging annotations for existing types to learn to discover new types; this enables taking advantage of existing resources. In this work, we pursue the second approach.

Current state-of-the-art work in event type induction (Huang and Ji, 2020; Shen et al., 2021) uses reconstruction-based losses to find clusters of new types. Motivated by recent success in learning representations with contrastive loss (Chen et al., 2020a; Radford et al., 2021), we propose a novel alternative approach using batch attention and contrastive loss, which achieves state-of-the-art results. Essentially, we consider the attention weight between two event mentions as a learned similarity, and we ensure that the attention mechanism learns to align similar events using a semi-supervised contrastive loss. By doing this, we are able to leverage the large variety of semantic information in pretrained language models for clustering unseen types by using a trained attention head. This reveals our first key motivation: unlike (Huang and Ji, 2020), we are able to separate clustering from learning, allowing specific task-suited clustering algorithms to be selected. This allows us to test multiple clustering strategies after training once.

Additionally, this easily allows the use of hierarchical clustering, which may be beneficial to some downstream tasks.

Batch attention is an attention mechanism taken over a minibatch of samples rather than a sequence. Previous uses of batch attention have been limited. Primarily, it has been used for image classification (Cheng et al., 2021) and satellite imagery (Su et al., 2019). In this work, we apply batch attention to natural language instead, which we use for clustering, and we propose the novel idea of enforcing the attention mechanism using contrastive loss.

To enable our discovered event types to be used in larger IE systems, it is important to extract information regarding the clusters. Previous work has looked to describe clusters—for a given cluster, Huang et al. (2016) uses the nearest trigger to the cluster centroid as its name. However, this approach is nebulous and not easily measurable (because the same trigger can correspond to different event types and there is not a quantitative method to determine if the selected trigger defines the cluster well). This is our second key motivation: we instead introduce two new information retrieval-styled tasks for describing the cluster – type name prediction and FrameNet (Baker et al., 1998) frame linking. Type prediction predicts a name for each cluster and is a relatively easy task. FrameNet linking builds on this by linking event types to relevant frames, and is significantly more useful for downstream applications. Our attention-based approach is especially useful here, since it uses the attention mechanism to produce "clustered" features which can have auxiliary task-specific losses applied (prior work is not well-suited for this because the loss is applied to individual data points). This allows our method to build clusters which are more amenable to downstream tasks.

The major novel contributions of this paper are:

- We propose a novel framework for new event type induction which uses a novel masked contrastive loss to enforce an attention mechanism over data minibatches. This framework is also potentially applicable for semi-supervised clustering and classification problems in other settings where a pretrained model exists.

- We show that the base pretrained model selected for event type induction plays a key role in the types which are discovered, since even un-finetuned models rival Huang and Ji (2020).

- We use the "clustered" features produced by our model to extend new event type induction to two novel downstream tasks: type name prediction and FrameNet linking. We show our architecture design allows for auxiliary losses which improve performance on these tasks.

2 Task Descriptions

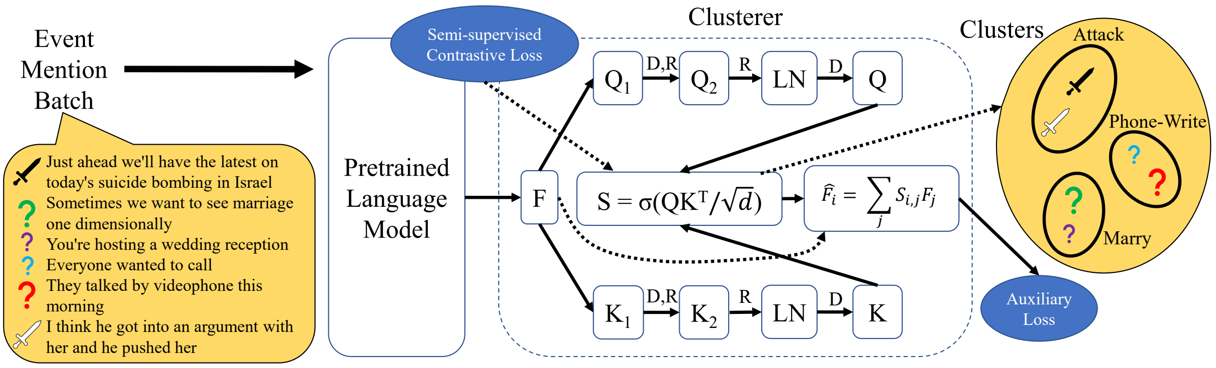
2.1 Semi-supervised Event Type Induction

We tackle the problem of semi-supervised event type induction, first described by Huang and Ji (2020). The task is defined as follows: Assume that k event types from some dataset are known and that the types of the other events are unknown. Using the known types as example clusters, we seek to discover type clusters for the unknown types. Essentially, this is a semi-supervised clustering task on event mentions. In this work, we follow Huang et al. (2018) and set the 10 most common types in the ACE 2005 dataset (Walker et al., 2005) as known. Thus, given all ACE annotated event mentions, our goal is to automatically discover the other 23 unseen ACE types. This assumption is likely to carry over to real-world datasets, since existing 'seen' type definitions are most likely to cover the most common events. In many real-world cases, there may be a few long-tail event types present in the 'seen' types and one or two very common event types may be 'unseen'. Regardless, the distribution of seen and unseen types is likely to be fairly similar to the distribution of setting the most popular k types as known.

2.2 Downstream Clustering Tasks

Beyond clustering, we also introduce two new downstream tasks on this problem: type prediction and FrameNet (Baker et al., 1998) linking. We structure both of these tasks as information retrieval problems for evaluation. Essentially, given a cluster, one should be able to predict its event type name and to what frame it should be linked. For each cluster, we calculate the most frequent type and consider it to be the ground truth for the cluster.

Type Prediction: The goal is to retrieve the "name" of the correct type for a cluster. Thus, we measure Hits@n and mean reciprical rank (MRR), where the corpus consists of the 23 new unseen type names.



Just ahead we'll have the latest on today's suicide bombing in Israel

Sometimes we want to see marriage one dimensionally

You're hosting a wedding reception

Everyone wanted to call

They talked by videophone this morning

I think he got into an argument with her and he pushed her

Figure 1: Architecture of the proposed approach. Best viewed in color. LN is layer normalization, R is ReLU, and D is dropout. σ is softmax for the attention mechanism and sigmoid for the contrastive loss. $\hat{F}_i$ is the clustered features of mention i in the batch. '**?**' are unseen event types.

In practice, we embed the names using our language model and use cosine similarity to the cluster centroid to rank them.

FrameNet Linking: FrameNet is the largest event ontology that is publicly available. However, there is not enough annotated training data to train supervised models directly on it. To alleviate this issue, we propose a task linking our newly discovered event types to FrameNet frames.

For the FrameNet linking, we consider a setup similar to name prediction, where we link clusters to the 1,221 frames in FrameNet 1.7 (Ruppenhofer et al., 2016). Instead of using the type names, we follow Huang et al. (2018) and manually map the ACE types to one or more frames to create a ground truth (see Appendix C for details). All child frames of the mapped frames are also considered valid targets. Given an ACE type, we can now link to a set of valid frames. In practice, we take the corpus of frame definitions and embed them using our language model. We then rank them using cosine similarity by comparing to the given cluster centroid. We consider the best rank of the valid frames to be the rank of a cluster. Thus, this task is also measured with Hits@n and MRR.

3 Methods

3.1 Overall Architecture

Overall, our method, shown in Figure 1, consists of a language model, such as BERT (Devlin et al., 2019), which produces contextualized representations, followed by a "clusterer". Unlike previous work which used specific token representations (Huang and Ji, 2020), we use mean pooling over the entire mention where an event occurs as our input. The language model produces an event representation, which is then input into the "clusterer" layer. The clusterer layer then produces "clustered" features using the attentions (see Section 3.3).

3.2 Back-translation for Data Augmentation

Contrastive loss has recently been applied for deep clustering (Li et al., 2021b; Zhong et al., 2020) and for representation learning (Chen et al., 2020a; Gao et al., 2021; Zhang et al., 2021a; Liu and Liu, 2021). However, this requires data augmentation to create positive example pairs. For text, some augmentations use back-translation (Cao and Wang, 2021; Zhang et al., 2021b). Taking inspiration from these clustering and representation learning techniques, we employ back-translation as data augmentation to create more positive pairs, improving the learning of attention weights between event mentions.

3.3 Batch Attention "Clusterer" Mechanism

To learn similarities between unseen event mentions, we propose learning an attention mechanism over the stochastic gradient descent minibatch. We enforce this attention mechanism using a masked contrastive loss (described in Section 3.4). This allows the attention mechanism's behavior to be learned from the seen classes.

We follow Vaswani et al. (2017) in implementing a scaled dot product attention, although over the batch instead. Since our "clusterer" needs to learn similarities for clustering and then be used for cluster features, we use nonlinear transformations for the query (Q) and key (K) vectors instead of the linear transformations in (Vaswani et al., 2017). This nonlinear transformation for Q and K is implemented as a two hidden layer neural network, which is shown in Figure 1.

Using this attention mechanism, we produce "clustered features", which are a convex combination of the different samples from the batch. This allows us to apply an auxiliary loss to the clustered features. We consider this as being analogous to learning on cluster centroids. Specific auxiliary losses can be applied for specific downstream tasks.

We note that this approach can also be interpreted as a type of feature smoothing, an inner product graph generator, and metric learning.

3.4 Masked Semi-supervised Contrastive Loss

Recent work, such as CLIP (Radford et al., 2021) and Text2Mol (Edwards et al., 2021), has found great success using contrastive losses between pairs of representations Q and K, each $n \times d$ matrices where n is the number of samples of d dimensions. They obtain the loss L by comparing the product of these matrices (QK^T) to a label matrix $Y \in \{0,1\}^{n \times n}$ (which in their case is $Y = I_n$), using cross entropy loss CE.

$$L(Q,K) = CE(QK^T, I_n) + CE(KQ^T, I_n)$$

We modify these existing contrastive losses to enforce our batch attention mechanism. We calculate the label matrix as follows (see Appendix B for an example). Given a pair of samples (event mentions) x_i and x_j, we consider the pair to be a positive if they are from the same seen event type. We consider the pair to be negative if they are from different seen event types or if one is seen and one unseen. If both are unseen they are masked. In practice, the labels can be computed using one-hot vectors of the c seen types (the unseen types are zero-hot vectors). These vectors are stacked into a $n \times c$ matrix O. The label matrix is computed

$$Y = OO^T \vee I_n$$

where $\vee$ is the elementwise logical-or operation. Following (Edwards et al., 2021), we use binary cross-entropy as the loss between the labels Y and the scaled attention dot products $\frac{QK^T}{\sqrt{d}}$ from (Vaswani et al., 2017). This gives the following contrastive loss:

$$L_{ss}(Q,K) = CE(\frac{QK^T}{\sqrt{d}}, Y)$$

This loss, however, values negative samples much more than positive samples (due to the imbalance). Noticing that once vectors of a negative pair are orthogonal they don't need to be further separated, we introduce a margin m. Essentially, we mask out pairs whose dot product is "too negative" (in addition to unknown relations between unseen types). This is because the loss would rather optimize the already well-separated negatives instead of the relatively fewer positives. Let $p_{i,j} \in \{0,1\}$ be the label of a pair and $u_{i,j} \in \{0,1\}$ indicate that both i and j are unseen. Our mask, M, is calculated

$$M_{i,j} = \overline{\left[\overline{p_{i,j}} \wedge \left(\sigma(\frac{QK^T}{\sqrt{d}})_{i,j} < m\right)\right] \vee u_{i,j}}$$

where $\wedge$ is elementwise logical-and, σ is the sigmoid function, and $\bar{z}$ denotes logical negation of z. This is similarly motivated to the margins used in knowledge graph embedding losses, such as TransE (Bordes et al., 2013). Thus, our loss is:

$$L_m(Q,K) = M \cdot L_{ss}(Q,K)$$

where in this case we treat $L_{ss}(Q,K)$ as an unreduced loss (so it is a matrix), and $\cdot$ is elementwise multiplication.

We apply this loss to the query (Q) and key (K) matrices in the clusterer's batch attention mechanism. We also include the augmented data (Q' and K'), giving us a final loss:

$$L_c(Q,K,Q',K') = \sum_{\hat{Q},\hat{K} \in \{Q,Q'\} \times \{K,K'\}} L_m(\hat{Q},\hat{K})$$

3.5 Auxiliary Loss

For our downstream tasks, we employ a regression-based auxiliary loss. For each seen instance x_i, we maximize the cosine similarity between the clustered features $\hat{F}_i$ and the pretrained language model embedding B_{t_i} of the ground truth type t_i (e.g. the name 'attack'). Thus, we get the loss:

$$L_a(\hat{F}_i, B_{t_i}, t_i) = 1 - \cos(\hat{F}_i, B_{t_i})\mathbb{1}_{\text{seen}}(t_i)$$

where $\mathbb{1}_{\text{seen}}(t_i)$ indicates whether t_i is a seen type.

3.6 Stopping Criterion

For this task, it is not reasonable to use a validation set for stopping. This is because the loss depends only on seen types and their relationships to unseen types. Since the unseen classes are unlabeled and the losses between pairs of unseen are unknown, the model can overfit to the seen data, pushing together clusters of unseen types. To deal with this issue, we employ unsupervised clustering metrics to decide when to stop training. In particular, we use cosine distance-based silhouette scores to measure the quality of clustering. Further details are given in Appendix F.

3.7 Clustering

Any algorithm which can compute clusters from a precomputed distance function can be applied to the learned similarities between event mentions. Additionally, we find that the finetuning of the language model by our loss modifies its representations to better form clusters. Thus, this representation can be used in many clustering algorithms as well.

3.7.1 Manifold Approximation

Inspired by recent work (Ros et al., 2021) which uses manifold approximation to interpret large language model-based sentence representations for information retrieval, we incorporate manifold approximation into our clustering approach. To do so, we follow the UMAP (McInnes et al., 2018) algorithm to create approximate weights based on estimating neighborhood densities within the data. We calculate these weights using cosine distance as an input, as it has traditionally been effective for language modeling (Manning et al., 2008; Reimers and Gurevych, 2019). UMAP attempts to estimate the density by comparing the distance to the k-nearest neighbors. This is used to calculate weights between each pair of data points. Details are given in Appendix H. Following this, we use agglomerative clustering on the UMAP weights as before.

In our approach, we want to better understand the global clustering landscape, so we use a high value of k. In practice, to avoid hyperparameter selection, we set k equal to the size of the data.

4 Experimental Results

Generally, we used default hyperparameters. We split the learning rates into BERT and non-BERT parameters following (Edwards et al., 2021) with 2e-5 for BERT as in (Devlin et al., 2019) and 1e-4 for other parameters as in (Vaswani et al., 2017). For the margin parameter, we examined silhouette scores to select 0.5.

For back-translation, we used four languages, German, French, Spanish, and Chinese, and randomly sampled which language to use for each data point every epoch. We obtained back-translations using the MarianMT translation models (Junczys-Dowmunt et al., 2018). Ablations are shown in Section J.

For our main experiments, we only use the contrastive loss. We take the average of 5 runs to show that our method consistently outperforms (Huang and Ji, 2020). We also calculate clusters using an ensemble of the 5 runs which shows slightly increased performance, which is an expected result in deep neural networks (Allen-Zhu and Li, 2020).

Huang and Ji (2020) evaluate these clusters using Geometric NMI, Fowlkes Mallows (Fowlkes and Mallows, 1983), Completeness, Homogeneity, and V-Measure (Rosenberg and Hirschberg, 2007). We additionally consider adjusted Rand index (ARI) (Hubert and Arabie, 1985). In the downstream tasks, given a clustering we also report the average cluster purity and type representation. Given a cluster i of size n_i with most frequent type numbering n_{f_i}, purity $p_i = \frac{n_i}{n_{f_i}}$ (Manning et al., 2008). Note that this average cluster purity is slightly different than traditional purity; it weights small clusters more which is desirable in our case (like macro vs. micro F1 score). Type representation is the number of unique frequent subtypes, n_t, divided by total types, in this case 23.

4.1 Language Model

We select Sentence BERT (SBERT) (Reimers and Gurevych, 2019) as a language model because its pretraining tasks are better suited for clustering than BERT. This is shown in Table 1, since the clustering from SBERT embeddings can even outperform (Huang and Ji, 2020) without any semi-supervision. We use a small version of the model[2] from HuggingFace (Wolf et al., 2020), which allows us to use a larger minibatch size of 10. Using larger minibatch sizes is desirable for contrastive loss since the number of negatives scales quadratically with the size. The performance of mini SBERT is notable, as Huang and Ji (2020) used BERT-large, a considerably larger model.

4.2 Clustering Algorithms

For clustering, we consider two algorithms which work on precomputed metrics. First, we use agglomerative clustering with average linkage, as it tends to be less sensitive to outliers and noisy data (Han et al., 2011). Noise is present in the dataset, often in the form of transcripts (see Section 4.4).

We report results following existing clustering literature by using the true number of classes as the cluster number (Huang et al., 2020; Li et al., 2021b). In practice it is generally difficult to select the correct number of clusters to use. Due to this, using extra clusters is typically done by previous

Table 1: New event type induction results (%)[4]. The first subcolumn is the input for clustering and the second is the clustering algorithm used. SBERT indicates the (unfinetuned) SBERT representations were used rather than our learned attentions (Attn). FT-SBERT representations are finetuned by our method. E stands for ensemble. Values are the average of 5 runs. Agglo is agglomerative clustering, Affinity is (Frey and Dueck, 2007), and Manifold is as described in Section 3.7.1. For affinity, each run can produce a slightly different number of clusters.

work (Huang and Ji, 2020; Shen et al., 2021). However, this can inflate the NMI score (Nguyen et al., 2009) and benefit qualitative evaluation because of the unbalanced classes in the dataset. As an example, given only 23 clusters (the ground truth), a large class such as 'Injure' splits into multiple smaller clusters, which causes rare event types to be merged. Results show that 19 / 23 types are represented by a cluster in the 50 cluster case versus only 16 / 23 in the 23 cluster case. This makes results appear better for more clusters. Silhouette scores are higher for 23 clusters, however.

Unlike existing work (Huang and Ji, 2020), the number of clusters is unimportant for our learning process and can be selected afterwords, such as by selecting a high number as in (Huang and Ji, 2020; Shen et al., 2021) or automatically with affinity propagation (Frey and Dueck, 2007). Affinity propagation selects exemplars to automatically determine the number of clusters. Our approach is especially useful here, since affinity propagation does not complete when applied to default SBERT representations but does when using our contrastive loss-enforced attentions.

4.3 Results

We compare our results with Huang and Ji (2020), who first introduced this task, in Table 1. We find that just our choice of language model outperforms the baseline. Also, using dot products is more effective for our learned attention metric than cosine distance, since dot product without normalization, as in our attention mechanism, indicates confidence of clustering a pair of samples together (This is because the contrastive loss uses sigmoid).

4.3.1 Manifold Approximation

We find manifold approximation to be very effective in our experiments. Intuitively, we understand this manifold approximation as untangling the cluster manifolds from each other in the high-dimensional representation space. Interestingly, the results using the finetuned SBERT representations perform better than the results on the learned similarities. We find this to be quite interesting, especially because the representations change an average of 0.6 cosine distance from their starting points, as shown in Appendix A. Our method causes SBERT to inherently learn representations more amenable for clustering.

While manifold approximation works well for clustering here, we note that using UMAP for clustering is considered controversial.[5] While it works well in many cases, there are potential issues with artifacts or false tearing of clusters. We leave analysis of the interaction between high-dimensional semantic spaces obtained from language models and manifold approximation to future work.

---

[3] (Huang and Ji, 2020) did not release their code, and we were unable to reproduce their results. Nonetheless, we apply their method to the SBERT representations based on the description in their paper. We also use an equivalent number of clusters to the ground truth, unlike their paper, which enables comparability to our method.

[4] (Huang and Ji, 2020) appears to have used the former scikit-learn default of geometric NMI, which is why their v-score doesn't equal arithmetic NMI.

Figure 2: Cluster Examples: Injure, Charge-Indict, Marry, Bankruptcy, Start-Org, and Bad Data, respectively.

Cluster Strength	Clusters
Very Strong (> 80% Purity)	Injure, Sue, Phone-Write, Declare-Bankruptcy, Demonstrate, Trial-Hearing
Strong (60-80% Purity)	Be-Born, Start-Position, Charge-Indict, Marry
Ok (40-60% Purity)	Release-Parole, Appeal, Injure
Mixed (20-40% Purity)	Convict, Fine, Trial-Hearing, Start-Org, Start-Position, Charge-Indict
Small Clusters (< 2 samples)	Trial-Hearing, Nominate, Start-Position, Phone-Write

Table 2: Clusters sorted into purity classes.

4.4 Qualitative Cluster Analysis

We analyze the clusters produced by our best result, the ensemble. We classify the clusters according to purity in Table 2. We show examples from numbered clusters in Figure 2. Certain types of clusters, such as Injure ① and Demonstrate ④, form very strong clusters. We believe this is likely related to their size and lack of overlap with other types. There are two common sources of error: the first is semantic overlap. Start-org, merge-org, and end-org tend to overlap ⑤. Marry and divorce also slightly overlap ③—in the 23 cluster case they merge into one cluster, but in the 50 cluster case they are separate. Most types of courtroom related events—Charge-Indict, Trial-Hearing, Convict, Release-Parole, Appeal, Execute, Acquit, Extradite—have some degree of overlap ②. Second, the other main source of errors is "duplicates". This occurs in our method because two or more events can occur in the same event mention ②, ③. Since our method does not account for triggers, it cannot distinguish between duplicate mentions with multiple triggers. Future work can address this issue by combining our method with an existing trigger-based method such as (Huang and Ji, 2020). We also find that our method clusters "junk" data together ⑥, which are usually from transcripts. Errors occasionally occur from metaphorical language, such as when companies are "married" ③. We show more detailed examples of these observations in Appendix E.

4.5 Downstream Tasks

For the downstream tasks, we use different clusterings and try to discover information about the clusters. As a baseline, we compare against default (not finetuned) SBERT clustering (Base-23) and ground truth (perfect) clusters. We compare these to our ensemble clustering. For type prediction, we use SBERT embeddings to compute cluster centroids and compare to the SBERT representation of the type name (e.g. 'injure'). For FrameNet linking, we use the frame definition instead of the name (e.g. "The words [...] describe situations in which an Agent or a Cause injures a Victim [...]"). We also use an auxiliary loss, L_a, which we apply to a 1-layer neural network on the clustered features $\hat{F}$. This extra layer is employed to allow multiple auxilliary losses: we leave those experiments for future work. We compare using these finetuned representations in addition to default SBERT. Results are shown in Tables 3 and 4.

We find that our ensemble clustering outperforms the default SBERT clustering, and that we are able to recover the event type 60% of the time. For the ground truth clusters, our finetuning with

Clustering	Representation	Mean Rank	Hits@1	Hits@3	Hits@5	Hits@10	Hits@15	MRR	Average Purity	Type Representation
Base-23	Untuned	5.17	34.8%	47.8%	60.9%	82.6%	100%	0.477	25%	47.8%
FT-Base-23	Finetuned	4.43	56.5%	65.2%	78.2%	82.6%	91.3%	0.660	58.9%	65.2%
Ensemble-23	Untuned	3.65	60.9%	69.6%	69.6%	95.7%	100%	0.679	68.6%	69.6%
Ensemble-23	Finetuned	5.13	56.5%	65.2%	69.6%	87.0%	87.0%	0.650	68.6%	69.6%
Ensemble-50	Untuned	4.40	56.0%	60.0%	68.0%	90.0%	96.0%	0.630	69.3%	82.6%
Perfect-23	Untuned	2.30	69.6%	73.9%	82.6%	95.7%	100%	0.758	100%	100%
Perfect-23	Finetuned	2.83	73.9%	82.6%	91.3%	91.3%	95.7%	0.800	100%	100%

Table 3: Results for cluster to name prediction task with different representations and clusterings. Finetuned indicates finetuned SBERT representations from our contrastive + auxiliary loss are used (otherwise default SBERT). "-x" at the end is the number of clusters. Perfect indicates the ground truth clustering, Base/FT-Base is SBERT clusterings (default or finetuned with our auxiliary loss), and Ensemble is the clustering of our ensemble result. Type representation shows what percent of unseen types represent the majority of a cluster.

Clustering	Representation	Mean Rank	Hits@1	Hits@5	Hits@10	Hits@50	Hits@100	MRR	Average Purity	Type Representation
Base-23	Untuned	95.9	4.3%	21.7%	26.1%	30.4%	34.8%	0.128	25%	47.8%
FT-Base-23	Finetuned	156.9	30.4%	30.4%	34.8%	43.5%	47.8%	0.336	57.4%	65.2%
Ensemble-23	Untuned	72.7	17.4%	30.4%	39.1%	47.8%	65.2%	0.264	68.6%	69.6%
Ensemble-23	Finetuned	115.7	21.7%	34.8%	34.8%	43.5%	52.2%	0.308	68.6%	69.6%
Perfect-23	Untuned	15.9	26.1%	39.1%	52.2%	65.2%	73.9%	0.374	100%	100%
Perfect-23	Finetuned	42.7	47.8%	56.5%	60.9%	69.6%	69.6%	0.539	100%	100%

Table 4: Results for cluster to frame linking task. See Table 3 for notation.

an auxiliary loss improves MRR and Hits@1 over the default SBERT representations. Frame linking is much more difficult, since there are 1,221 frames, but we are able to recover the correct frame for 30% of clusters, while default SBERT only achieves 4%. Notably, the auxiliary loss clustering (FT-Base-23) even outperforms our ensemble clustering, demonstrating the flexibility of our model architecture. Using perfect clustering, our finetuned model achieves nearly 50% Hits@1, doubling the performance of the default SBERT model. The finetuning loss allows the model to train on the combined cluster features, which approximates the centroid of a cluster. This promotes the potential cluster to be shaped so that its centroid is better suited for the downstream tasks–being most similar to the correct type name or frame representation.

5 Related Work

Although event extraction has long been studied (Grishman, 1997; Ji and Grishman, 2008; McClosky et al., 2011; Li et al., 2013; Chen et al., 2015; Du and Cardie, 2020; Li et al., 2021a), recent focus has turned towards discovering events without annotations. It includes recent neural techniques (Huang et al., 2016; Liu et al., 2019; Shen et al., 2021), as well as ad-hoc clustering techniques (Sekine, 2006; Chambers and Jurafsky, 2011; Yuan et al., 2018) and probabalistic generative methods (Cheung et al., 2013; Chambers, 2013; Nguyen et al., 2015). Semi-supervised event type induction was recently introduced by Huang and Ji (2020). Zero-shot event extraction frameworks, such as (Huang et al., 2018), can be used to perform event extraction on the newly discovered types. Recent work by Gao et al. (2022) uses a weakly-supervised contrastive learning-based clustering approach for event representation learning.

Several new unsupervised deep clustering approaches use contrastive loss for clustering images (Li et al., 2021b; Zhong et al., 2020) and text (Zhang et al., 2021b). These methods require data augmentation to create positive example pairs. Contrastive loss has also been applied to learn representations. SimCLR (Chen et al., 2020a,b) uses image augmentations for unsupervised representation learning. Follow-up work has applied this loss to natural language (Gao et al., 2021; Zhang et al., 2021a; Liu and Liu, 2021), with some augmentations being back-translated text (Cao and Wang, 2021). Gunel et al. (2021) use fully supervised contrastive loss to finetune language models.

Batch attention has been investigated a little in the literature, such as for satellite imagery prediction (Su et al., 2019) or image classification (Cheng et al., 2021); however, it has not been used to learn clustered features. Seidenschwarz et al. (2021) recently proposed a related idea for a message-passing network weighted by attention for clustering images. We instead directly use (contrastive loss-enforced) attention weights for clustering.

6 Conclusion and Future Work

In this work, we present an exciting new approach for event type induction, where we use contrastive loss to control the learning of a batch attention mechanism for both finding and learning about new cluster types. We also consider manifold approximation for clustering, and we introduce two new downstream tasks: type name prediction and FrameNet linking. This new approach opens several interesting problems for future work. First, this method can potentially be incorporated with reconstruction loss-based approaches, which might improve results or obviate the early stopping criterion. Alternatively, the stopping criterion can be integrated into a loss function for better stopping control. Notably, this would enable a two-step process of learning clusters and then performing knowledge distillation using those clusters (or an ensemble) while learning other desired losses. Future work can investigate the interaction of manifold approximation with large language models and integrate it directly into the clusterer subnetwork. It may be possible to use a heirarchy of event types for knowledge transfer from data-rich types to long-tail types. Finally, FrameNet linking can be extended to Wikidata Q-Node linking, which contains millions of nodes. Our approach may also be applicable in other modalities with strong pretrained models.

7 Limitations

In this work, we present a contrastive loss-based batch attention method for new event type induction. Like most modern event type induction methods, this relies on strong existing representations (which are typically pretrained in a self-supervised manner). Our additional testing on the much larger MAVEN dataset (Appendix K) indicates that selecting an appropriate representation is an important factor. In that case, SBERT representations are inappropriate for the event mentions in the dataset, but trigger representations are effective, and our method further improves those results. Future research on identifying pretraining methods for initializing representations will be useful for this method and task (along with many other models such as retrieval-based large language models (Guu et al., 2020; Borgeaud et al., 2021).

Requiring early stopping is a limitation to our newly proposed event type induction method which does not occur in existing reconstruction-based methods (those methods instead require a predetermined cluster number along with other limitations). While an early stopping method is required, our method is effective, and we believe that our new approach is still valuable because it offers a different approach for new event type induction. Additionally, future work should be able to build upon our work to remove early stopping. Doing so may also help obviate the dependence on the initial representation. In Section 6 we detail several possibilities for future work to further improve upon this work.

A How much do SBERT representations change?

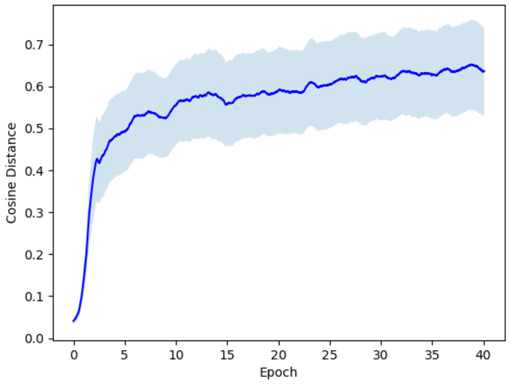

Figure 3: Change in SBERT representations from original representation of inputs. This shows that the representations change significantly from their starting point during finetuning. Shaded area is one standard deviation.

B Label Matrix Example

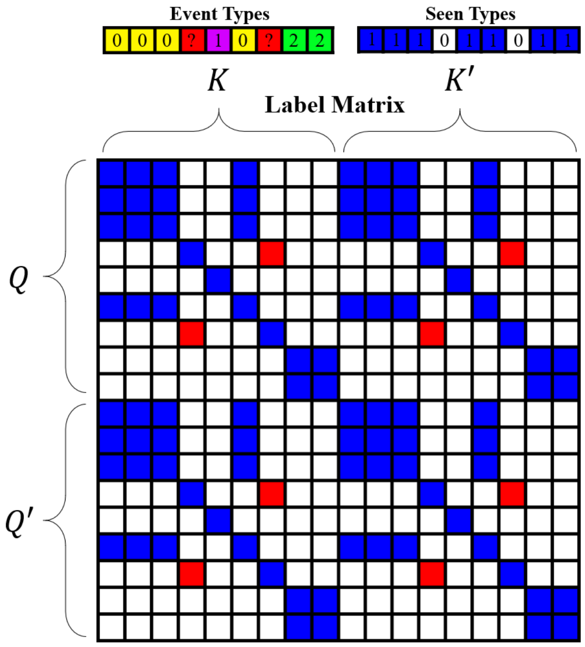

Figure 4: Best viewed in color. Visualization of the label matrix Y used in the loss. Blue is positive, white is negative, and red is masked. Note that the mask for the negatives less than the margin is not shown. The event types and corresponding "seen" boolean vector are also shown, and are used to construct the label matrix. Q and K are corresponding queries and keys to the labels, while Q' and K' are augmented data.

C Manual ACE05 to FrameNet Linking

ACE Type	Frame
Appeal	Appeal
Be-Born	Birth_scenario
Charge-Indict	Notification_of_charges
Convict	Verdict
Declare-Bankruptcy	Wealthiness
Demonstrate	Protest
Divorce	Personal_relationship
End-Org	Organization | Process_end
Extradite	Extradition
Fine	Fining
Injure	Cause_harm | Experience_bodily_harm
Marry	Forming_relationships
Nominate	Appointing
Phone-Write	Contacting
Release-Parole	Releasing_from_custody
Start-Org	Organization | Process_start
Start-Position	Being_employed | Process_start
Sue	Judgment_communication
Trial-Hearing	Trial
Pardon	Pardon
Merge-Org	Organization | Amalgamation
Acquit	Verdict
Execute	Execution
Attack	Attack
Transport	Transportation_status
Die	Death
Meet	Make_acquaintance | Meet_with | Come_together
Arrest-Jail	Arrest | Prison | Imprisonment | Being_incarcerated
Sentence	Sentencing
Transfer-Money	Commerce_money-transfer
Elect	Change_of_leadership | Choosing
Transfer-Ownership	Commerce_goods-transfer
End-Position	Being_employed | Process_end

Table 5: Mapping from ACE types to FrameNet frames. Some ACE types required multiple frames to be correctly mapped, which is indicated by " | ".

D Visualization

We visualize unseen event mentions using UMAP (McInnes et al., 2018) given a precomputed distance matrix of the cosine distance between Q and K. Following (Huang and Ji, 2020), we show the results on six unseen types in Figure 6. Sentence and convict overlap significantly, which makes intuitive sense as they are semantically very similar. Unlike (Huang and Ji, 2020), trial-hearing forms its own cluster.

---

[6] Note that there is a mistake in (Huang and Ji, 2020), since "sentence" is a seen type in (Huang et al., 2018)

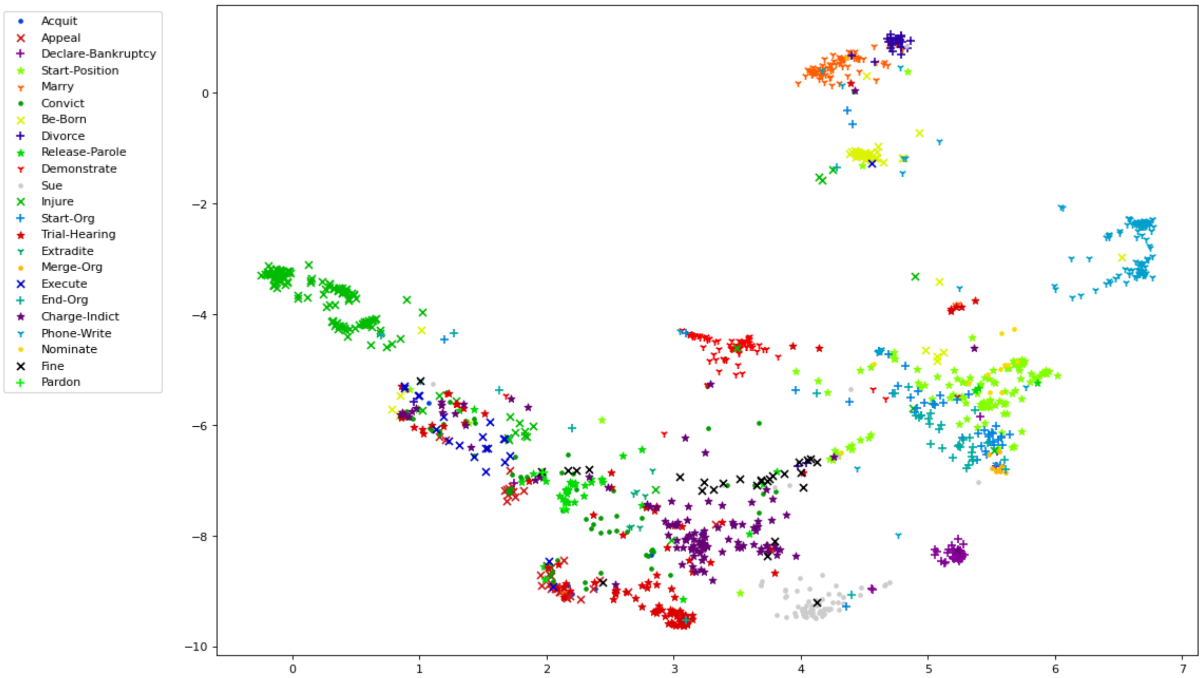

Figure 5: Visualization of all unseen types as seen by manifold approximation. Note that dimensionality reduction to 2D renders it difficult to understand with this high number of clusters, but the overall semantics of the space are interesting.

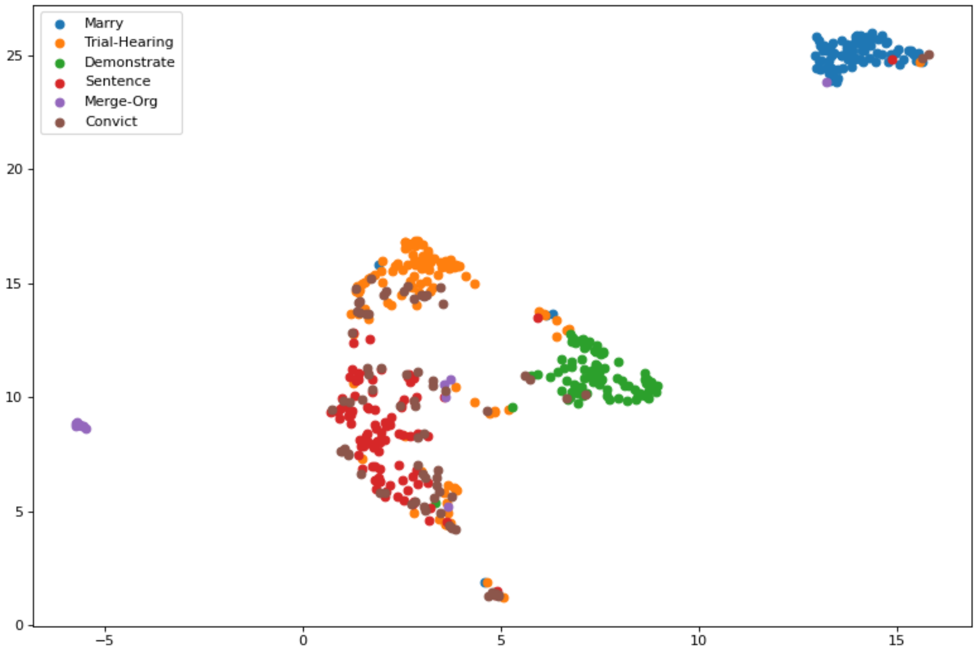

Figure 6: Visualization following (Huang and Ji, 2020) for one of the runs.[6] Note that our clusters have much less errors.

E Cluster Examples

We show extensive examples of our noted observations in Tables 6 and 7. Namely, start-org, merge-org, and end-org tend to overlap. Marry and divorce slightly overlap in the 23 cluster case. Most types of courtroom related events—Charge-Indict, Trial-Hearing, Convict, Release-Parole, Appeal, Execute, Acquit, Extradite—have some degree of overlap. There are "duplicates" when two or more events can occur in the same event mention. We also note the cluster of "junk" data, where the label isn't obvious from the event mention.

Cluster Type	Purity	Cluster Member Example Types and Inputs
Injure	98.3%	• **Injure:** According to other reports reaching here, five Syrian bus passengers were killed and 10 others were injured on Sunday morning when a US missile hit the bus they were traveling in near the Iraqi border • **Injure:** More than 40 were injured • **Injure:** There was no information on the identity of the injured person
Declare-Bankruptcy	95.0%	• **Declare-Bankruptcy:** You need to speak to a bankruptcy attorney pronto; this is a bankruptcy matter, not a tax matter • **Declare-Bankruptcy:** despite operating under bankruptcy laws, united posted the best on time performance • **Declare-Bankruptcy:** That means that he received the shares while he was still in bankruptcy, which means that the shares were potentially assets that the trustee could use to pay off creditors
Demonstrate	95.0%	• **Demonstrate:** The protest follows a string of others involving tens of thousands of peace activists across Japan since January • **Demonstrate:** No, I don't demonstrate against anybody during a war • **Demonstrate:** Several thousand demonstrators also gathered outside the White House in Washington, accompanied by a major security presence
Charge-Indict	64.4%	• **Charge-Indict:** 56-year-old forry drake has been charged with interstate transport of a minor • **Charge-Indict:** Ocalan, being tried in absentia, was indicted for entering the country illegally, a misdemeanor • **Convict and Charge-Indict:** convicted oklahoma city bombing conspirator terry nichols will stand trial again on state murder charges • **Appeal:** in the african nation of nigeria, an islamic court delayed the appeal of a woman condemned to death by stoning
Start-Position	64.4%	• **Start-Position:** Many Iraqis boycotted the meeting in opposition to U.S. plans to install Garner atop an interim administration • **Start-Position:** The meeting was Shalom's first encounter with an Arab counterpart since he took office as Israel's foreign minister on February 27 • **Start-Org:** Meeting in the biblical birthplace of the prophet Abraham, delegates from Iraq's many factions discussed the role of religion in the future government and ways to rebuild the country

Table 6: Examples of discovered clusters. Charge-Indict shows an example of a duplicate—an input with multiple event types. It also shows how courtroom related events can overlap. For Start-Position, there are some errors related to the Middle East, which occurs frequently in the Start-Position mentions.

Cluster Type	Purity	Cluster Member Example Types and Inputs
Marry	70.2%	• **Marry:** My wife and I were guests at a wedding on the Carnival Legend on New Years Eve 2003 • **Marry and Divorce:** Giuliani, 58, proposed to Nathan, a former nurse, during a November business trip to Paris - five months after he finalized his divorce from Donna Hanover after 20 years of marriage • **Phone-Write:** All the guests were folks who had met the bride and groom (an attractive young couple who were sailing alone) virtually on cruisecritic
Start-Org	34.7%	• **Start-Org:** Kiichiro Toyoda founded the automaker in 1937, transforming the loom manufacturer started by his father into an automaker • **Merge-Org:** I believe any neutral management consultant worth his or her salt would recommend a merger of the two organizations • **End-Org:** It's a dying organization, and this will be just the jolt it needs for another couple decades of somnambulant staggering before being ultimately replaced by far more efficient companies
Bad Data	-	• **Marry:** Either its bad or good • **End-Org:** i felt t7ire was something else too, much history behind silver cross to end is now • **Trial-Hearing:** Yeah, we're a pretty small town, so our newspaper covers it a lot
Phone-Write	86.2%	• **Phone-Write:** Let's see, my first call I got was from Russia • **Phone-Write:** I'm chewing gum and talking on the phone while writing this note • **Phone-Write:** He wants to call his mom in Houston
Sue	92.5%	• **Sue:** Buyers and sellers also would have to agree not to pursue further cases in foreign courts • **Sue:** The cost of class actions is factored into the cost of everything you buy • **Sue:** The average number of suits against a neurosurgeon is five in South Florida

Table 7: More examples of discovered clusters. Start-Org shows the semantic overlap between the organization-related clusters. Bad Data shows a cluster which mostly contains unclear input.

F Early Stopping

For this task, it is not reasonable to use a validation set for stopping. This is because the loss depends only on seen types and their relationships to unseen types. Since the unseen classes are unlabeled and the losses between pairs of unseen are unknown, the model can overfit to the seen data, pushing together clusters of unseen types. We partially address this issue by implementing a margin on negative values, which prevents the model from forcing together unseen clusters as strongly to separate them from seen type events. Because of this, our method requires strong pretrained representations to build on, which have luckily become common in recent years. To deal with this issue, we employ unsupervised clustering metrics to decide when to stop training. In particular, we use cosine distance-based silhouette scores to measure the quality of clustering. This increases the required compute up to 2x (in practice roughly 1.5x because back-propagation isn't required), but training is already relatively quick, with 10 or less epochs being sufficient. We note that this approach can have some variance. To address this issue, we employ a sliding window running average approximation to create a smooth curve of the initial increase and then decrease of the silhouette score. We consider a hybrid approach—we select the window with the highest silhouette score, and then we select the epoch with the highest silhouette score in that window as our stopping point, as shown in Figure 7.

G Evaluation Metrics

For the information retrieval metrics, given a list of rankings R,

$$MeanRank = \frac{1}{n}\sum_{i=1}^{n} R_i$$

$$MRR = \frac{1}{n}\sum_{i=1}^{n} \frac{1}{R_i}$$

$$Hits@m = \frac{1}{n}\sum_{i=1}^{n} \mathbb{1}_{R_i \leq m}$$

G.1 Clustering Evaluation Metrics

Assume there are two clusterings: a set of (ground truth) classes C and a set of (predicted) clusters K. Each have N samples. Denote TP as true positives, the number of data point pairs that are in the same cluster in C and K. FP is the false positives, the number of data point pairs that belong in the same cluster in C but are not in K. FN is false negatives, the number of data point pairs that are in the same cluster K but not in the same ground truth cluster in C. TN is the number of data point pairs that are in different clusters in both C and K. scikit-learn (Pedregosa et al., 2011) is used to compute scores.

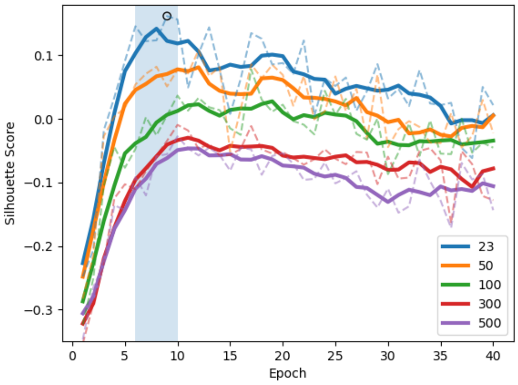

Figure 7: Bold lines are sliding window averages of size 5 over silhouette scores. Dotted lines are unsmoothed scores. Legend shows number of clusters. Note that the silhouette scores initially increase and then decay as overfitting occurs, resulting in the need for early stopping. Here, for 23 clusters, epoch 8 has the highest average score. The blue region shows the window around it, and epoch 9 (the black dot) is selected for stopping.

- **Geometric NMI** is the normalized mutual information between two cluster assignments. It is defined:

  $$NMI = \frac{I(C, K)}{mean(H(C), H(K))}$$

  where I is the mutual information and H is entropy. In this case, $mean$ is the geometric mean.

  $$mean(x_1, ..., x_n) = \left(\prod_{i=1}^{n} x_n\right)^{\frac{1}{n}}$$

  We note that arithmetic NMI using the arithmetic mean is often reported, but that it is equivalent to V-Measure.

- **Fowlkes Mallows** (Fowlkes and Mallows, 1983) is used to evaluate the similarity between a clustering and the ground truth. It is the geometric mean of pairwise precision and recall.

$$FM = \frac{TP}{\sqrt{(TP+FP)(TP+FN)}}$$

- **Completeness** (Rosenberg and Hirschberg, 2007) Completeness measures whether all of the data points assigned to a single class are assigned to a single cluster. It is defined:

  $$c = \begin{cases} 1 & \text{if } H(K,C) = 0 \\ 1 - \frac{H(K|C)}{H(K)} & \text{else} \end{cases}$$

- **Homogeneity** (Rosenberg and Hirschberg, 2007) measures whether data points in a cluster are all assigned the the same class. It is symmetric to completeness:

  $$h = \begin{cases} 1 & \text{if } H(C,K) = 0 \\ 1 - \frac{H(C|K)}{H(C)} & \text{else} \end{cases}$$

- **V-Measure** (Rosenberg and Hirschberg, 2007) (standing for validity) is the harmonic mean between homogeneity and completeness:

  $$v = \frac{(1+\beta)hc}{\beta h + c}$$

  In practice, $\beta = 1$ is used to weight h and c equally.

- **Adjusted Rand Index** (Hubert and Arabie, 1985) is a version of the Rand index, a measure of cluster similarity, which is adjusted for chance.

  $$ARI = \frac{RI - \mathbb{E}[RI]}{\max RI - \mathbb{E}[RI]}$$

  where the Rand index, RI, is

  $$RI = \frac{TP + TN}{\binom{n}{2}}$$

  and $\mathbb{E}[RI]$ is expected value of random clusterings.

H UMAP Weights

UMAP (McInnes et al., 2018) attempts to estimate the density by comparing the distance to the k-nearest neighbors as follows:

$$\rho_i = min\{d(x_i, x_{i_j}) | 1 \le j \le k, d(x_i, x_{i_j}) > 0\}$$

$$\sum_{j=1}^{k} \exp(\frac{-max(0, d(x_i, x_{i_j}) - \rho_i)}{\sigma_i}) = \log_2(k)$$

Here, $d(x_i, x_{i_j})$ is the distance between x_i and x_{i_j}. ρ_i is the minimum distance to x_i's closest neighbor. σ_i, which smooths and normalizes the distances to the nearest neighbors, is calculated for each data point. Next, UMAP calculates the following weights between data points:

$$w((x_i, x_j)) = \exp(\frac{-max(0, d(x_i, x_{i_j}) - \rho_i)}{\sigma_i})$$

We use $1 - w((x_i, x_j))$ for agglomerative clustering.

I Reproducibility

The SBERT model we used, along with the size of the Q and K layers use a dimension of size 384. Our total model has 34,839,937 parameters, of which 1,479,937 do not belong to SBERT. Input uses the 'ldc_scope' part of the ACE event mention. Our model takes roughly 2 hours to train on one V100 GPU, including the early stopping calculations which are done with the model set to 'evaluation' mode. We used batch size 10, which is the most that would fit in memory. For learning rates, we considered the suggestions in (Devlin et al., 2019). Datasets used are in English. ACE05 contains 5,349 mentions which fall into 33 event types. Data artifacts in this work were used for research purposes consistent with their licensing agreements and intended use. Artifacts we create (e.g. code and manual linking) are in line with this intended use.

Table 8: New event type induction ablation results (%). The first 'Method' subcolumn is the input for clustering and the second is the clustering algorithm used. FT stands for finetuned. SBERT indicates the SBERT representations were used rather than our learned attentions (Attn). DNC indicates did not converge. Agglo is agglomerative clustering, Affinity is (Frey and Dueck, 2007), and Manifold is as described in Section 3.7.1. For affinity, each run can produce a slightly different number of clusters. BERT models use '*bert-base-uncased*'. The BERT pooled used a batch size of 8 because it takes up more VRAM. 15 epochs were used for each model. The BERT trigger representations use the ground truth triggers, which allows the duplicate problem to be avoided and helps clue in the network. The version trained with our method and without training is shown.

K Experiments on MAVEN

To further evaluate our method, we conduct experiments on the Maven dataset (Wang et al., 2020), which contains 118,732 event mentions and 168 event types. This provides an excellent example of a large dataset which may have a number of unannotated event types (or event types which need to converted to finer-grained typing). Since this semi-supervised task has not been done on MAVEN, we select the most common 150 types as seen and the remaining 18 types as unseen. To adapt early stopping to such a large dataset, we adapt our early stopping by calculating the silhouette score every 250 steps, which is roughly the same computation as a single ACE2005 epoch. We train our method for 8 epochs with other hyperparameters the same as the ACE2005 experiments. For Manifold clustering, we select an arbitrarily large $k = 3,000$ for computational reasons.

We experiment on using trigger representations from the event mentions. Unfortunately, these are specified by the dataset in terms of the its tokenization scheme, so converting to BERT tokenization incurs a small error rate (for example, some words are tokenized as 'unk' in MAVEN). We find that these errors do not prevent the representation from performing well.

Results are shown in Table 9. They show that SBERT representations do not work well for the mentions in the MAVEN dataset (we believe this is due to differences in the scope of what is considered an event mention). Training with our method still improves clustering on the SBERT representations from 9.06 ARI to 10.51. However, the attention mechanisms learned are less effective along with our manifold clustering approach. The *bert-base-uncased* representations using the trigger words perform much better as expected. Additionally, our method, using both learned attention and trained trigger representations, increases performance significantly. For manifold, this is from 44.84 ARI to as high as 67.01. As noted in the conclusion, the interaction here between manifold approximation and large language model representations is an interesting future research direction for better understanding these results. It may also be interesting to think about how to obtain a desirable representation for starting the training of our model. Another example that would benefit from this is using a neural dense retriever to retrieve frozen embeddings in a retrieval large language model, such as (Borgeaud et al., 2021).

Representation	Method		Clusters	Geometric NMI	Fowlkes Mallows	Completeness	Homogeneity	V-Measure	ARI

Table 9: New event type induction results (%) on MAVEN (Wang et al., 2020). The first two sections are baseline representations without our method. The *bert-base-uncased* representation uses trigger representations. The first subcolumn of ‘method’ is the input for clustering and the second is the clustering algorithm used. ‘Finetuned’ indicates the finetuned model representations from our method were used and ‘untuned’ indicates our method was not used. Attn-score indicates our learned attention scores were used and the method for computing these scores from the query and key vectors. E stands for ensemble. Agglo is agglomerative clustering, Affinity is (Frey and Dueck, 2007), and Manifold is as described in Section 3.7.1. For affinity, each run can produce a slightly different number of clusters.

Multilingual Content Moderation: A Case Study on Reddit

Abstract

Content moderation is the process of flagging content based on pre-defined platform rules. There has been a growing need for AI moderators to safeguard users as well as protect the mental health of human moderators from traumatic content. While prior works have focused on identifying hateful/offensive language, they are not adequate for meeting the challenges of content moderation since 1) moderation decisions are based on violation of rules, which subsumes detection of offensive speech, and 2) such rules often differ across communities which entails an adaptive solution. We propose to study the challenges of content moderation by introducing a multilingual dataset of **1.8 Million** Reddit comments spanning **56** subreddits in English, German, Spanish and French[1]. We perform extensive experimental analysis to highlight the underlying challenges and suggest related research problems such as cross-lingual transfer, learning under label noise (human biases), transfer of moderation models, and predicting the violated rule. Our dataset and analysis can help better prepare for the challenges and opportunities of auto moderation.

1 Introduction

Being able to moderate user-generated content is critical for online social media platforms. Several platforms employ human moderators to monitor user content to prevent the spread of misinformation, adverse effects of hateful speech, fraud, etc (Geiger and Ribes, 2010; Dosono and Semaan, 2019; Wang et al., 2022; Jhaver et al., 2017). The moderators' task is to remove improper content and/or suspend users posting such content. However, reviewing and moderating each user comment is practically infeasible due to limited resources, especially during time-critical and large-scale events. More importantly, such moderation work can cause damage to moderators' mental health due to burnout from volunteer work and exposure to harmful content (Gillespie, 2020; Roberts, 2014; Dosono and Semaan, 2019; Wohn, 2019).

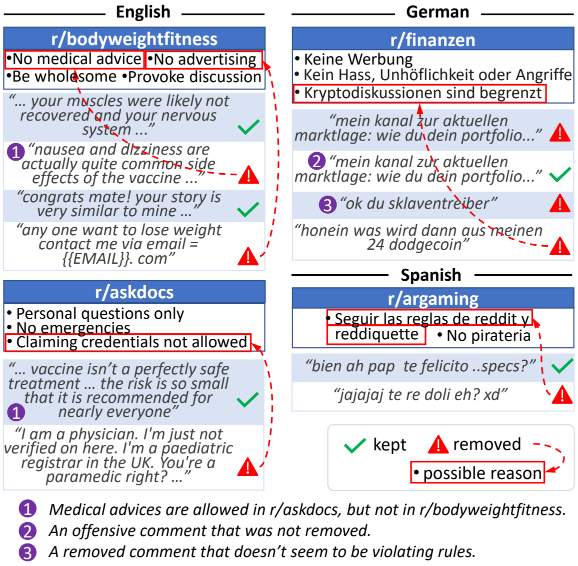

Figure 1: Content moderation on Reddit is challenging as it 1) depends on rules of each community, 2) requires contextualized understanding of the comments, and 3) is affected by moderator biases.

In recent years, researchers have put effort into collecting hate speech or offensive language datasets from social platforms such as Twitter (Zampieri et al., 2019; Gautam et al., 2020; Golbeck et al., 2017), YouTube (Dinakar et al., 2011), or a mixture of those platforms (Kennedy et al., 2017; Bhattacharya et al., 2020). These datasets contain annotations of hateful speech and are used to train NLP systems to remove harmful comments (Pamungkas et al., 2020; Chung et al., 2019; Ranasinghe and Zampieri, 2021). We refer to this problem as Offensive Language Identification (OLI). Instead of simply removing such content or suspending users, some works propose countering hate speech with discourse-aware style

transfer (Atwell et al., 2022), expert-based counter-narratives (Chung et al., 2019), by learning to intervene with conversational context (Qian et al., 2019), or by proposing a holistic conceptual framework (Chaudhary et al., 2021).

However, despite remarkable progress in OLI, it is not sufficient to tackle content moderation for two key reasons: (1) OLI is a subset of content moderation, as the latter involves flagging content that is not only hateful but also violates the rules of the platform. For example, Reddit has site-wise rules that not only requires users to be civil, but also prohibits actions such as posting illegal content, spamming, and revealing personal information[2]. (2) Prohibiting offensive/hateful speech is universal to all communities (Chandrasekharan et al., 2018), while content moderation requires a system to be adaptive to rules that change dynamically across different communities. It is often the case that content that is allowed in one subreddit might be disallowed in another. For example, it is allowed to post medical advice on `r/askdocs` while it is prohibited on `r/bodyweightfitness`. We thus believe it is useful to study Reddit comments from a moderation perspective as we can collect data from multiple communities and measure the effectiveness of such systems in adapting to community guidelines.

In this work, we aim to bridge this gap by introducing a dataset of Reddit comments collected from 56 communities for studying content moderation. We propose a challenge for content moderation and demonstrate the limitations of the state-of-the-art models. Our dataset will be available to researchers who agree to the terms and conditions of our data-sharing policy approved by the ethical committee of our institution. Our contributions are:

- We propose a multilingual dataset for content moderation. The dataset consists of **1.8 million** comments from **56** subreddits with moderation labels, that specify whether a comment was kept or removed by the moderator. We also provide the meta-data for each subreddit that includes its name, description, and rules.

- We show that existing offensive speech datasets are not suitable for the content moderation task because only a small portion of the removed comments are offensive. As such, the models trained on OLI datasets fail to identify removed comments that are non-offensive.

- We study the performance of models trained on moderation data under different cross-lingual settings including multilingual-language model, translate-train, and translate-test.

- We provide insights on what makes content moderation a challenging task and discuss potential research problems that can be explored with our proposed dataset.

2 Related Work

2.1 Offensive Language and Hate Speech Datasets

Many existing works that have collected user comments from online social platforms. Zampieri et al. (2019) proposed Offensive Language Identification Dataset (OLID), which models not only different types of offensive language, but also the target of offensive messages in a hierarchical structure. The Swear Words Abusiveness Dataset (SWAD) developed by Pamungkas et al. (2020) is a collection of tweets selected from OLID that focuses on predicting abusiveness of a swear word in a tweet context. Chung et al. (2019) created a multilingual dataset with hate speech/counter-narrative pairs provided by experts. The idea is to fight online hate speech content with informed textual responses instead of the standard method of removing content or suspending users. OffensEval (Zampieri et al., 2020) is an offensive language identification challenge that has attracted multiple research teams. It is

---

[2] `https://www.redditinc.com/policies/content-policy`

based on the same hierarchical three-level annotations from the aforementioned OLID dataset in multiple languages. CAD (Vidgen et al., 2021) is a recent recently proposed dataset of Reddit posts and comments with manually annotated two-level abusive categories. A brief comparison between these datasets and ours is shown in Table 1.

All the mentioned works focus on detecting offensive speech. However, online content moderation involves detection of comments that violate community rules in addition to those that are offensive. For example, moderators will often remove comments that are self-promoting, spamming, or off-topic because they do not provide useful information and are harmful for the communication environment (e.g., *"I can help you, see my youtube channel"*). In both of these cases, a model trained to detect hate speech will likely fail.

2.2 Reddit Rules and Content Moderation

A pre-existing related work by Chandrasekharan et al. (2018) trained 100 subreddit classifiers on removed/un-removed comments, and used clustering analysis to discover three types of *implicit norms* from the removed comments: macro norms that are universal to all subreddits (e.g., hate speech, personal attacks), meso norms that applies to subgroups (e.g., meme responses), and micro norms that are specific to individual subreddits (e.g., offering commerce tips). Our study is different in that we focus on moderation task that depends on *explicit community rules* written by moderators. Another work (Samory, 2021) studied the problem of identifying comments *approved* by moderators. They found that approved comments and removed ones actually share many traits such as toxicity and insults, and that it is hard to distinguish them. Fiesler et al. (2018) studied rules from $1,000$ subreddits and found that rules are highly dependent on the context of each individual subreddit while sharing common characteristics across the platform.

One key limitation of these studies is that they only focused on subreddits in the English language and discarded all non-English subreddits. This could be because most data on Reddit is in English. In our work we also select subreddits in non-English languages, i.e. German, French, and Spanish. We then study the possibility of transferring a moderation model trained on subreddits in English (which generally has more content). We argue that a good AI moderator should not only focus on data in English language, but also leverage that knowledge to improve performance on other low-resource languages. While Hassan et al. (2022) study *human* moderation bias across different languages and cultures, our work focuses on the problem of *automated* moderation.

3 Dataset

3.1 Subreddit selection

We collected data from 56 subreddits[3] based on the following criteria:

Wide range of topics: Generally the popularity (and thus data points) of a subreddit depends on its topic. Being able to cover many topics will enable us to better estimate the generalizability of machine learning models on this task. The topics include news, politics, finance, sports, electronics, etc.

Subreddits on similar topics: We chose subreddits with similar topics to enable inquiry into questions relating to transferability of moderation models. For example, "Do models trained on one subreddit transfer to other subreddits?", "will models transfer better between subreddits on similar topics?", and "which subreddit should I train the model on so that it could also be better adapted to X?". Some example of similar subreddits are `r/news` and `r/worldnews`, `r/finance` and `r/personalfinance`, `r/anime` and `r/naruto`, `r/games` and `r/xboxseriesx`.

Multilingual data: Most groups on Reddit are in English, but there are also some in other languages such as Spanish, German, French, Arabic. To extend moderation models to multilingual settings we also selected a number of non-English subreddits. For example French (`r/quebec`, `r/france`, `r/moi_dlvv`), German (`r/de`, `r/finanzen`, `r/ich_iel`), and Spanish (`r/argentina`, `r/gaming`).

3.2 Data Collection Pipeline

We built our data collection pipeline based on the Python Reddit API Wrapper (PRAW) [4], which streams comments and submissions in real time from multiple subreddits. For each data record we store important fields such as the ID, author, posting time, and comment body. We follow a two step approach where we first scrape data for a week, and then check if the comment/submission has been removed or retained by the moderator or if it has

---

[3] A full list of all 56 subreddits can be found in Table 8.

[4] `https://github.com/praw-dev/praw`

split	language	#sub	#comments	removal
		Training data		
en-train	English	48	$1,347,611$	1.87%
en-val	English	48	$74,885$	1.83%
		Test data		
de	German	3	$177,046$	0.86%
es	Spanish	2	$95,586$	0.66%
en	English	48	$74,893$	1.85%
fr	French	3	$49,780$	0.23%

Table 2: Number of subreddits, comments, and percentage of removed comments in each data split.

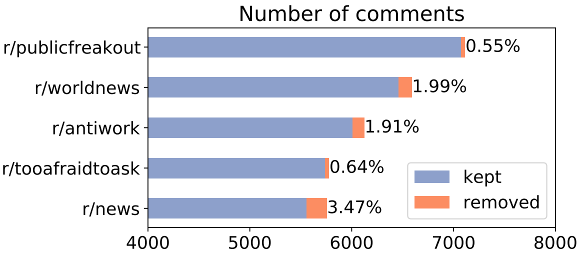

Figure 2: Number of kept and removed comments in the top 5 subreddits (% removed comments in also shown).

been deleted by the author. We use this two-step approach since once the comment is removed/deleted it does not retain its original content. Figure 5 in the appendix shows the overall procedure of our data collection pipeline.

3.3 Dataset Overview

We use the data collection pipeline to collect ~ 1.8 Million comments in a time span of three weeks.

For benchmarking, we split all of the English data randomly into $90\%/5\%/5\%$ as train, validation, and test subsets. We chose all the non-English data to be part of the test set to study the cross-lingual transferability of models trained on data in English. Table 2 lists the number of subreddits, total number of comments, and the percentage of removed comments for all the data splits.

English data makes up a large proportion of the entire dataset, and is collected from 48 subreddits on different topics. For non-English languages, there are significantly fewer subreddits and we choose the most popular ones for each language. This dataset is highly imbalanced in that only a small proportion of the comments are removed by the moderators: English data has a removal rate of around 1.8% and for German, Spanish, and French it is 0.86%, 0.66%, and 0.23%, respectively. This makes the task of identifying moderated comments very challenging. For comparison, the proportion of offensive examples is around 33% in OLID, $12.5\% \sim 28.4\%$ across different languages in OffensEval-2020 (Zampieri et al., 2020), and $28.4\% \sim 50.0\%$ in HASOC-2020 (Mandl et al., 2021). We argue that the high percentage of offensive examples in those datasets makes them less suitable for real world applications because these offensive posts make up only a small share of moderated content.

We also observe that different subreddits have different rates of removal, from the lowest of 0.0% to the highest of 21.74%. These differences are likely explained by the discrepancies in topic and subreddit rules, as well as the level to which the moderators enforce these rules. However, the overall rate of removal is quite low (1.84%) compared to existing datasets mentioned above. We show the statistics of the top 5 active subreddits in Figure 2 (refer to Figure 6 in the appendix for more details).

Each subreddit is associated with a set of rules that are enforced by the moderators, which are normally displayed in the *About* section. Typically, each rule has a short title and a longer description to explain in more detail the types of content that are prohibited. For each subreddit, we have collected all of its rules including titles and descriptions (see Figure 7 in the Appendix for the distribution of the number of rules in our dataset).

3.4 Manual Analysis of Offensiveness

To better understand the level of offensiveness in the content moderation task, we manually annotated $1,238$ comments (around 200 removed and 100 unremoved examples for each of the four languages) using the fine-grained taxonomy of offensiveness presented in Mubarak et al. (2022), with the addition of the categories of sexuality and age. The distribution of comments for different categories is shown in Figure 3. We observed that most of the comments (71.86% of removed and 80.115% of non-removed) are not offensive. Many of these non-offensive comments criticized the corresponding subreddit or disagreed with the views or goals of the subreddit. For instance, the comment *"i was disappointed when i got the halo console..."* was removed from the `r/halo` subreddit. The comment is not offensive but could have been removed due to its criticism of a product supported by the `r/halo` subreddit. Since these rules, views and goals can vary significantly across subreddits, it explains why content moderation is hard for machine learning classifiers and our moderation classifiers achieve lower scores compared to offensiveness

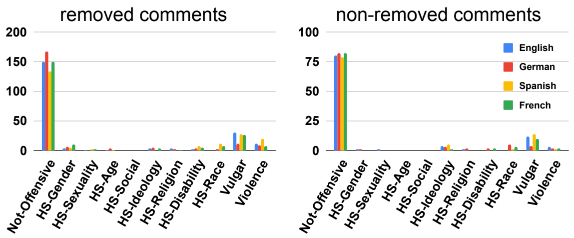

Figure 3: Distribution of different types of offensive speech for Reddit comments.

classifiers. We also see that the distributions of different types of offensive speech are similar across both removed and non-removed comments as well as the four different languages. To conclude, moderating online content is a very different task compared to identifying offensive language and hate speech and a new dataset is needed to train models and study automated content moderation.

4 Experiments

We study the task of content moderation on Reddit by formulating it as a binary classification task: given a user comment x predict whether it should be removed by moderators using $y = f(x)$, where f is the classifier, and y is the removal probability. We set the binary labels based on whether the comment was removed or retained by the moderator (Section 3.2). We report both AUC (area under the ROC curve) and F1 scores.

4.1 Evaluation with Existing Offensive Language Identification Models

A naive solution to moderation is to cast this problem as offensive language detection and directly use classifiers trained on OLI datasets. We thus evaluate models trained on OLI datasets for moderation. This experiment will help in answering two questions: 1) can these models recognize offensive comments in the context of Reddit content moderation?, and 2) do these models miss comments that should be removed but are not-offensive? Being able to answer these question will help us understand whether content moderation can be solved by using OLI or it is a necessity to collect data tailored for moderation. We investigate the above question using three models: RoBERTa (base) (Liu et al., 2019) finetuned on the HatEval (Basile et al., 2019) and OLID dataset (Zampieri et al., 2020), and an XLM-RoBERTa model fine-tuned on OLID. We compute the moderation score for each comment by averaging the output probabilities from these models.

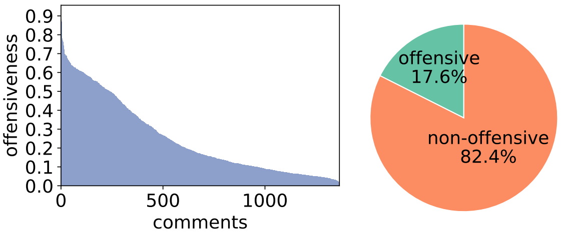

Figure 4: Distribution of offensiveness scores for removed comments (left plot shows sorted scores). Most of the removed comments are not very offensive. Only 18% of them get offensive scores higher than 0.5.

Model	Tr data	T-ori	R-off	R-mod
RoBERTa	HatEval	48.72	44.12	50.59
RoBERTa	OLID	81.25	79.20	47.76
XLM-RoBERTa	OLID	75.81	75.82	48.45

Table 3: Offensive language/hate speech classifiers with their original training (Tr) Twitter dataset and macro-F1 scores on the test split of the same dataset (T-ori), a subset of our Reddit data with offensive labels (R-off), and our Reddit data with moderation labels (R-mod).

Figure 4 shows the distribution of offensiveness scores of the removed comments. The left and the right plot show the sorted scores and the percentage of offensive and non-offensive comments using a threshold of 0.5, respectively. We observe that most of the removed comments (82.4%) are not offensive, and also note that this number matches with the manual analysis in Section 3.4.

By qualitatively studying these examples we observe that 1) OLI models can detect offensiveness in the comments, and 2) not all removed comments are offensive, and OLI models tend to miss these. For instance, a comment stating *"try contacting drewcybersupport on instagram about ..."* from `r/minecraft` was likely removed due to self-promotion (the average offensiveness of this comment is 0.01). More examples can be found in Table 9. We also evaluate the performance of these models on three datasets: the original offensive datasets that they were fine-tuned on (T-ori), a subset of our collected Reddit data with manual offensiveness annotations (R-off), and our proposed moderation dataset (R-mod). From the results in Table 3 we can observe that: 1) these models achieve good performance[5] on both Twitter and Reddit data when the task is to identify offensive language, and

---

[5] The model fine-tuned on the HatEval dataset has a low F1 score possibly because it focused on hate speech targeted at immigrants and women instead of generic OLI.

Table 5: Experimental results with balanced data splits from our moderation dataset.

2) their performance drops significantly when evaluated on the moderation task.

Based on the results from both our qualitative and quantitative analyses, we conclude that there is a significant mismatch between the goals of content moderation and offensive language identification. We thus believe that it is necessary to have a moderation-specific dataset to train classifiers for content moderation.

4.2 Evaluation with Models Trained on Proposed Dataset

We use our collected data with moderation labels to train the classifier f. We use pre-trained transformer based language models as text encoders and add a shallow classifier on top: $y = f_m(f_{enc}(x))$, where f_{enc} is the encoder and f_m is the moderation classifier. To deal with multilingual data, we need to either use a multilingual encoder, that can work with inputs in any language (MLLM), or use a monolingual encoder with machine translation models[6]. We only transfer models trained on English data to non-English data and not the other way since the number of data points in English are much larger and it could be beneficial to leverage it for other languages with less data available.

We summarize our experimental results[7] in Table 11 and observe that the RoBERTa (67.38) and XLM-RoBERTa (66.83) models outperform offensive language detectors (second model in Table 3 achieved 61.11 on AUC) on the English data. This is expected because the moderation training data contains removed comments that are non-offensive, and thus the trained classifiers are able to capture these and make better predictions. We also observe that translate-train performs lower than translate-test in most cases, possibly due to the fact that noise is often introduced during translation and the negative impact is more severe in the training stage than in the test stage. We note that although the best performance on most of the test splits is achieved by translate-test, MLLM performance is close to the best in most cases. Considering the challenges of maintaining an extra translation model for every language in real-world applications, MLLM might be a better solution towards building multilingual auto moderators.

We would like to note that the (macro) F1 scores of these models are close to 50 since the classifier/predictions are overwhelmed by data imbalance (less than 2% of comments are labeled to be removed). We thus additionally report AUC scores since, being a ranking based metric, it is not affected by data imbalance. For comparison, we also propose additional data splits[8] with balanced classes and repeat the same experiments. As shown in Table 12, the performance trends for the balanced set are similar to the original splits, and the F1 scores are clearly above 50, ranging from 55.10 to 64.46 with one exception of 51.99, which is

---

[6] Following Artetxe et al. (2020), we use two settings with machine translation: 1) *Translate-test*: a classifier is trained on English data, and each non-English language needs to be translated into English during test, and 2) *Translate-train*: translate the English data into each target non-English language, and then do both training and test in that target language. For translation we used models from Tiedemann and Thottingal (2020)

[7] Averaged over 3 runs with different random seeds.

[8] Statistics of the balanced splits can be found in Table 10.

Group	Examples	GT/f_o/f_m	freq.
1)	*"every f****** one of those dogs ought to be put down.", "my god this sub is a perpetual b***h fest. clearly time to unsub"*	Y/Y/Y	7.35%
2)	*"prove it by sending me $5 000.00. that would be nothing for you... so go ahead and do it ...", "how do you explain exploding infections and new variants coming out of south africa where 90% of the population is vaccinated?"*	Y/N/Y	16.95%
3)	*"f**k {{name}} and his shorts.", "she has such a punchable face"*	Y/Y/N	1.85%
4)	*"was....was this written by a cat", "depends on the market. {{organization}} sold more units than switch last month in the uk."*	Y/N/N	23.85%
5)	*"oh my god you're pathetic lmao", "well you are a moron so i guess it could be worse"*	N/Y/Y	2.15%

Table 6: Different groups of comments from the English test data. 'GT', f_o, and f_m are ground truth label, offensiveness score and moderation score, respectively. "Y" stands for offensive/removed and "N" stands for non-offensive/non-removed. "freq." denote the proportion of each group in the whole subset (2000 samples).

likely caused by low translation quality in French.

4.3 Analysis on Error Types

We performed additional analysis to understand the errors made by the learned classifier by randomly sampling $1,000$ examples from both removed and non-removed comments and computing their offensiveness[9] (f_o) and moderation scores (f_m). We then organize all comments into groups based on their ground truth label and classifier predictions. Table 6 shows five of those groups and their frequencies: 1)There are 7.35% examples which are offensive and both f_o and f_m were able to identify them. 2) There are 16.95% examples on which f_o failed due to their low offensiveness while f_m was able to identify them successfully. 3) f_m missed a small portion of examples (1.85%) that are offensive and should be removed (*model-error*). 4) There is a significant portion of data points (23.85%) that were removed by moderators while both classifiers predicted them to be fine (*model-error*). This group represents the majority of removed comments that have violated rules other than the use offensive language. 5) Both classifiers do not agree with the ground truth label on 2.15% of the comments, most of them are highly offensive and should be removed but were actually approved by moderators. These instances indicate noisy labels in our dataset that are possibly caused by moderators' biases (*human-error*). Based on these observations we conclude that offensiveness classifiers and moderation classifiers have different types of errors and we believe that there is scope for improvement by using models that: 1) can incorporate knowledge from both OLI and moderation tasks and 2) are robust to label noise.

Subreddit Group	Model	AUC	F1
`r/naruto`	M-BERT	51.59	47.43
	XLM-Ro	64.48	37.84
`r/naruto` + `r/anime`	M-BERT	55.78	54.13
	XLM-Ro	31.08	46.39
`r/judaism`	M-BERT	62.08	60.65
	XLM-Ro	50.23	33.77
`r/judaism` + `r/islam`	M-BERT	68.27	63.89
	XLM-Ro	62.79	33.91
`r/judaism` + `r/islam` + `r/christianity`	M-BERT	67.89	62.33
	XLM-Ro	49.27	34.50
`r/feminism`	M-BERT	71.82	64.05
	XLM-Ro	51.27	38.22
`r/feminism` + `r/lgbt`	M-BERT	73.25	67.26
	XLM-Ro	49.67	34.10
`r/feminism` + `r/lgbt` + `r/racism`	M-BERT	72.95	66.16
	XLM-Ro	60.78	33.80

Table 7: Performance of classifiers within groups of subreddits. M-BERT refers to bert-base-multilingual-cased and XLM-Ro refers to XLM-RoBERTa-base.

4.4 Manual Analysis of Rule Violations

We also manually labeled 145 removed comments from the `r/stock` subreddit with the help of 3 annotators. The annotators were instructed[10] to select one of the five rules a removed comment violated. We decided to drop class 4 due to a small number of samples. We also dropped class 5 as this class corresponded to the "not sure" class. We selected examples where annotators had the most agreement and this resulted in 111 comments across 3 classes with 36, 54, and 21 comments for the non-civil, missing context, and spam/self-promotion categories (respectively). We performed five-fold cross-validation strategy for our experiments by training a logistic regression classifier on textual features extracted using sentence-transformers (all-mpnet-base-v2) (Reimers and Gurevych, 2019) We obtained an AUC of 91.8 ± 1.8, and the F1 scores for individual classes are 80.56 (Non-civil),

---

[9] Average offensiveness score from classifiers in Section 4.1

[10] The guide provided to the annotators is shown in Table 14

77.47 (Missing context), and 61.53 (Spam/self-promotion). The class-wise numbers match our intuition that examples from the "non-civil" class performs the best as it mostly includes offensive comments. This experiment shows that it is possible to learn to predict which rule was violated and thus provide some explanation to the user.

4.5 Experiments with Partitioning Data

As observed earlier, the AUC and F1-macro scores for moderation can be relatively low due to the task's complexity. We hypothesize that grouping similar subreddits together may improve the results within the groups. To verify this, we manually selected three groups of subreddits with similar topics and sample both training and test sets based on the grouping. From Table 7, we observe that grouping subreddits together may result in improved performance. For example, grouping `r/lgbt` and `r/feminism` together achieves 73.25 AUC, an improvement of 1.43 over `r/feminism` alone, and an improvement of $6 \sim 7$ compared to Table 12. However, we also observe that grouping more than two subreddits can lead to a drop in performance. For instance, adding `r/racism` to the group of `r/lgbt` and `r/feminism` decreases the AUC slightly to 72.95. This suggest that splitting the moderation task across multiple classifiers could lead to better performance with proper partitioning.

4.6 Insights on Moderation Dataset and Task

Based on the qualitative and quantitative evaluations, we summarize our insights:

Moderation is a highly imbalanced task. Unlike existing offensive language datasets, which may have $\geq 30\%$ positive examples (Mandl et al., 2021; Zampieri et al., 2019), the proportion of removed comments in our moderation dataset is $\leq 2\%$ This is challenging for most classifiers as their prediction will be biased by the majority class (see Table 11). We believe that this challenge makes our dataset distinct from others because it exposes models to real world scenarios.

Moderation labels are noisy. The moderation labels in our dataset are noisy as we found that some highly offensive comments were not removed and some benign comments were removed by the moderators. There could be multiple reasons for this such as human errors, individual biases. We believe this label noise is a characteristic of the task and researchers will be required to design algorithms with this in mind.

Moderation requires more than offensiveness detection. Our experiments reveal that pre-existing datasets with hate speech or offensive language labels are not sufficient for moderation task. This task involves referencing a set of guidelines which include not only being civil, but also other community-specific rules such as no off-topic discussions, no self-promotions, and no low-effort comments. Models trained only on offensive language datasets are able to identify non-civil content but fail to detect other cases of rule violation.

Moderation systems need to be adaptive. As Reddit communities are self-organized and moderators can make their own rules, many subreddits have very specific rules that may not be common with other subreddits. For example, "keep it halo" (`r/halo`), no "Asking for handouts or transactions" (`r/personalfinance`), "Research must be less than 6 months old" (`r/science`), and "No medical advice" (`r/bodyweightfitness`). A classifier trained on a large dataset like ours could possibly capture general rules and macro-norms, but is unlikely to transfer to novel communities with very specific rules. We thus argue that an adaptive and dynamic system that could condition its decisions on given guidelines is needed for successful auto moderation on platforms such as Reddit.

5 Conclusions

In this study we discussed the challenges in content moderation, which include but are not limited to: differences in community rules, subtlety of offensiveness in different contexts or languages, and moderator biases. Due to these challenges, prior works on offensiveness or hate speech identification are not adequate for solving moderation. Thus, we propose a multilingual dataset consisting of Reddit comments as well as subreddit meta-data including descriptions and rules. We experimented with baseline transformer based models to verify our assumptions and show that, although moderation is a challenging task, there are also many opportunities for further studies: linking removed comments to violated rules, moderating comments in context, understanding the differences between languages and culture in moderation process, etc. We believe that our work will foster more research in the area of automatic content moderation.

Limitations

Moderation within context. Our experiments using standard supervised learning methods take each comment separately and make predictions independently, while in practice context should also be taken into consideration. When collecting each comment we have recorded its parent post id, which could be used to recover the tree structure of a discussion thread, providing context for a comment.

Incorporating community rules. Our baseline model is a universal moderation classifier that did not incorporate community rules. A more adaptive model would be able to make predictions conditioned on rules that are dynamically changing among different communities. We provide metadata of each subreddit with our dataset that includes a description of the subreddit and subreddit rules so that future research can incorporate this information to build better approaches.

Ethics Statement

We have discussed in detail the data selection process while working with different subreddits. We had approval from our Institutional Review Board (IRB) for collecting social media data. We only collected publicly available data (comments, submissions, and subreddit metadata) while adhering to Reddit's policy and did not collect any user-related Personal Identifiable Information (PII) (e.g., Date of Birth) intentionally. To address the possible appearance of PII in public comments, we went through a data cleaning process using scrubadub[11] to remove word tokens or phrases that could be a person's name, email, SSN, driver's license number, etc., to further reduce the risk of PII leakage. We have kept the data and codebase on secure servers that are accessible only by persons involved in this study. Our dataset will be available to researchers who agree to the terms and conditions of our data-sharing policy approved by the ethical committee of our institution.

Acknowledgment

This project was supported by DARPA grant prime OTA No. HR00112290024 (subcontract No. AWD00005100 and SRA00002145). We also acknowledge the Center for Research Computing at the University of Pittsburgh for providing computational resources.

A Appendix

A.1 Human Annotators

For better understanding of the moderation data we have performed two studies that involved human annotators: 1) Manual analysis of offensiveness in Section 3.4, and 2) manual analysis of rule violations in Section 4.4. In these two studies have used volunteered annotators including employees within our institution and university graduate students, who are all based in North America. We did not use external annotation platforms and services since these are small-scale studies ($\leq$ 200 data points) designed for better understanding of the moderation data and the annotations will not be released with our large main dataset.

A.2 Temporal Changes in Community Rules

We scraped the community rules for each subreddit at temporal intervals of 1-2 week(s) and changes in rules have been captured in our data. We checked our entire collection of scraped rules across 7.5 months and found that rule edits happened at a rate less than 0.93% among all rules from all subreddits per week. Many of those edits are simple changes (e.g., adding/removing periods, capitalizing words) that does not alter their semantic meaning and thus we consider those as not affecting moderation decisions. There are a few cases when the moderators added new rules which would affect moderation decisions of certain types of content. For example, on `r/antiwork`, the rule of "No politicians, no CEOs" was changed to "No politicians, no employers, no landlords, no cops." in between June 27 and July 04. For those cases, developing content moderation models with changing rules would be a good extension of this work.

A.3 Completeness of the checking later procedure in data collection

In our preliminary study we found that comment removal happens most frequently during the first 3 days after being posted. Thus, we set the interval to 1 week to achieve a reasonable trade-off between completeness and efficiency. We did an additional study by re-scraping the status of an extra set of $452,000$ comments collected during September. Comparing their old labels (checked 7 days after posting) with new moderation labels (scraped this week, which is more than 2 months after posting), 92.89% removed comments has already been covered. Based on our observation of typical subreddits, we also chose the time window of 7 days to limit domain shifts in the data due to change in topics, moderators or focus of the subreddit.

GRIPS: Gradient-free, Edit-based Instruction Search for Prompting Large Language Models

Archiki Prasad **Peter Hase** **Xiang Zhou** **Mohit Bansal**
UNC Chapel Hill
`{archiki, peter, xzh, mbansal}@cs.unc.edu`

Abstract

Providing natural language instructions in prompts is a useful new paradigm for improving task performance of large language models in a zero-shot setting. Recent work has aimed to improve such prompts via manual rewriting or gradient-based tuning. However, manual rewriting is time-consuming and requires subjective interpretation, while gradient-based tuning can be extremely computationally demanding for large models and may not be feasible for API-based models. In this work, we introduce **Gr**adient-free **I**nstructional **P**rompt **S**earch (GRIPS), a gradient-free, edit-based search approach for improving task instructions for large language models. GRIPS takes in instructions designed for humans and automatically returns an improved, edited prompt, while allowing for API-based tuning. With InstructGPT models, GRIPS improves the average task performance by up to 4.30 percentage points on eight classification tasks from the NATURAL-INSTRUCTIONS dataset (with similar improvements for OPT, BLOOM, and FLAN-T5). We see improvements for both instruction-only prompts and instruction + k-shot examples prompts. Notably, GRIPS outperforms manual rewriting and purely example-based prompts while controlling for the available compute and data budget. Further, performance of GRIPS is comparable to select gradient-based tuning approaches. Qualitatively, we show our edits can simplify instructions and at times make them incoherent but nonetheless improve accuracy.[1]

1 Introduction

Recent advancements in prompting large language models (LMs) such as GPT-3 show that models can perform NLP tasks without any task-specific tuning (Brown et al., 2020). Most of the work in this area focuses on few-shot learning, where models rely on textual prompts containing input-output example pairs (*exemplar prompts*). However, humans are often able to perform a new task when provided with a relevant set of instructions or a task description, not necessarily including any examples. In this direction, past works explore a new paradigm of *instructional prompts* where a prompt is tailored for a particular task by including *natural language instructions* (Efrat and Levy, 2020; Mishra et al., 2022a,b). Following Webson and Pavlick (2021), we characterize instructions as a natural language description of the task that includes what is required for a person to complete the task correctly.[2] Demonstrative examples of the task are *not* considered a part of the instructions.

For purposes of improving task performance via instructional prompts, Mishra et al. (2022b) provide a set of guidelines to manually rewrite raw instructions. Yet this kind of rewriting process requires substantial manual effort and subjective interpretation of the guidelines. In addition, an underlying assumption in Mishra et al. (2022b) is that instructions should be semantically coherent to humans. However, it is possible that the prompts that most improve model performance are semantically confusing to humans in some ways.

Past works attempt to automatically improve prompt quality for large LMs by means of *prompt tuning* (Liu et al., 2021b). Existing prompt tuning methods use gradient-based approaches which have a few notable shortcomings. First, computing gradients with large LMs can be prohibitively computationally demanding. Second, this is entirely infeasible for models available only via APIs, because model gradients and weights are not standardly accessible.[3] Third, output continuous representations may not directly map back onto tokens in the original vocabulary. Thus, we cannot verify

---

[1] Code: `https://github.com/archiki/GrIPS`

[2] In general, whether an instruction is a sufficient description of a task depends on whom it is written for, i.e. people with less task expertise require more background information.

[3] GPT-3 models can be finetuned on given data, but the model parameters and gradients remain unavailable (source).

May 2-6, 2023

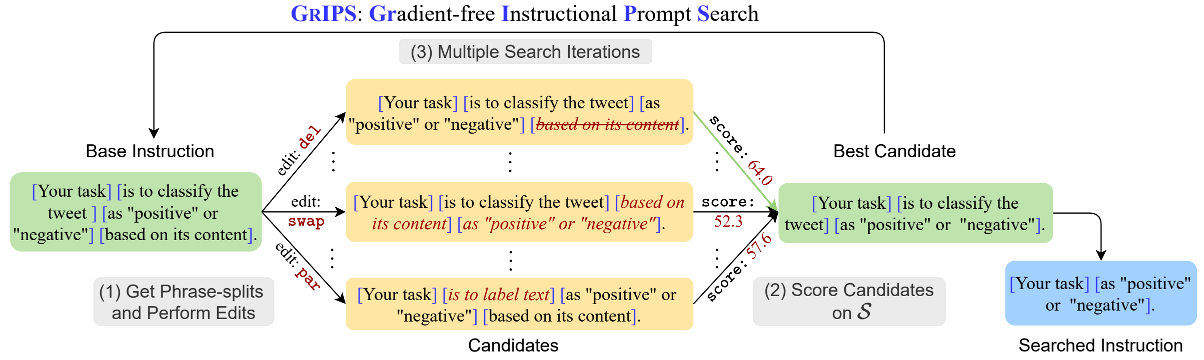

Figure 1: Overall Pipeline of GRIPS. The main steps are numbered. Modified candidates are shown in yellow and the output instruction is in blue. We use '[ ]' to show the syntactic phrase-level splits at which the edit operations occur. Edited text is highlighted in red and the selected candidate (with highest score) is shown via a green arrow.

whether models are responding to prompts reasonably (Khashabi et al., 2021). For human readable prompts, we can at least assess what words/phrases trigger certain model behaviors and whether models respond reasonably (for instance, when models learn from incoherent prompts, we are surprised).

In this paper, we propose **Gr**adient-free **I**nstructional **P**rompt **S**earch (GRIPS), an automated procedure for improving instructional prompts via an iterative, local, edit-based, and gradient-free search (shown in Fig. 1). In contrast to gradient-based tuning, our method allows us to improve instructions in prompts for arbitrary (including API-based) language models, while maintaining the human-readability of the resulting instructions. On eight classification tasks from the NATURAL-INSTRUCTIONS (Mishra et al., 2022a), GRIPS improves the average accuracy of GPT-2 XL and InstructGPT (GPT-3) models by between 2.36 and 9.36 percentage points. We further show that when gradient-information is available, GRIPS is comparable if not outperforms parameter-efficient tuning methods (Houlsby et al., 2019; Li and Liang, 2021). Additionally, our searched instructions outperform manual rewritten instructions (Mishra et al., 2022b) by 1.5 percentage points on average for the InstructGPT `curie` engine. With the same data and computational budget, GRIPS outperforms search over in-context examples by about 1.6 points for InstructGPT. Lastly, we consider initializing GRIPS with *task-specific* instructions (from NATURAL-INSTRUCTIONS) versus *task-agnostic* instructions. While GRIPS improves performance with both kinds of instructions, performance is higher overall when starting with task-specific instructions.

Contributions: In sum, our contributions include:

1. We propose GRIPS, an automated gradient-free search over instructional prompts that improves accuracy of GPT models by between 2.36 and 9.36 points on NATURAL-INSTRUCTIONS. We also show improvements for OPT, BLOOM, and FLAN-T5.
2. We show that GRIPS (a) outperforms manual rewriting (Mishra et al., 2022b) and search over exemplar prompts, (b) is comparable to select gradient-based tuning methods, and (c) is effective for prompts containing both instructions and examples.
3. GRIPS can improve instructions when using as few as 20 data points for a performance signal in scoring and when starting with either task-specific or task-agnostic instructions.

2 Related Work

Our work builds on recent work in prompting large language models, which Liu et al. (2021b) provide a comprehensive literature survey for. We focus on methods for improving model prompts here.

Exemplar Prompts. Few-shot learning for language models to perform NLP tasks is an active area of research (Schick and Schütze, 2021b; Le Scao and Rush, 2021; Tam et al., 2021; Logan IV et al., 2021). Prompts in this line of work are mainly composed of a number of input-output examples (Schick and Schütze, 2021b; Le Scao and Rush, 2021; Tam et al., 2021; Logan IV et al., 2021). Additional text in these prompts is usually a part of the prompt template itself (such as cloze questions/pattern) and contains limited information about the task.[4] In contrast, our work focuses on

---

[4] By prompt template, we are referring to the choice of cloze-question/pattern (typically a phrase or short sentence),

instructional prompts as described below.

Instructional Prompts. Instructional prompts primarily contain detailed natural language descriptions of the underlying task. Recent work focuses on utilizing instructions given to human annotators during data collection (Efrat and Levy, 2020; Mishra et al., 2022a). Mishra et al. (2022b) propose guidelines for manually rewriting instructions in order to further improve performance of instructional prompts. While Webson and Pavlick (2021) show language models may struggle to truly understand instructions, Wei et al. (2022); Sanh et al. (2022) find finetuning on instructions and in-context examples in a hugely multi-task manner helps generalization to other tasks. Lastly, Weller et al. (2020) provide a dataset in which task descriptions are formulated as questions. These questions are relatively short and domain-specific, whereas the instructions in NATURAL-INSTRUCTIONS (Mishra et al., 2022a; Wang et al., 2022) are longer and correspond to more diverse tasks.

Prompt Tuning. Instead of limiting prompts to natural language text, recent work explores training continuous vector tokens in prompts via gradient-based optimization (Liu et al., 2021c; Lester et al., 2021; Li and Liang, 2021; Qin and Eisner, 2021). Sun et al. (2022) aim to optimize continuous tokens without using gradients, however, their technique does not work for APIs that only allow modifying text and not token embeddings (like for GPT-3).

Prompt Search. Zhao et al. (2021) find varying the choice of training examples, example order permutations, and template can alter the performance of a prompt. Liu et al. (2021a) focus on selecting in-context examples from a dataset, while Lu et al. (2022); Kumar and Talukdar (2021) explore optimal ordering of examples. Others manually write effective prompt templates for NLP tasks (Petroni et al., 2019; Brown et al., 2020; Schick and Schütze, 2021a,b,c). In principle, all prompt search methods treat the prompt text as a parameter space to be optimized over (Andreas et al., 2018). Jiang et al. (2020) and Gao et al. (2021) use automated paraphrasing of the prompt templates. Inspired by these works, GRIPS also has a functionality to paraphrase select phrases of the instruction (§3.2.2). Meanwhile, Shin et al. (2020) use a gradient-based search to find trigger words in the prompt template. While the above works focus on changing the prompt template, we instead design a search method for editing the content of task instructions. Our search algorithm is also related to genetic algorithms (Mitchell, 1998), where parent candidates are mutated to generate offering (via our text-based edit operations) to increase fitness under an objective (like our score function).

3 Methodology

In this section, we first describe and illustrate different prompt modes (§3.1). Then, in §3.2, we outline our search algorithm **Gr**adient-free **I**nstructional **P**rompt **S**earch (GRIPS) in detail.

3.1 Prompt Modes

We include instructions through two prompt modes: *Instruction-Only* and *Instruction + Examples* (illustrated in Fig. 2). Here, prompt mode refers to the choice and arrangement of the three components (instruction, in-context examples, and test instance). These prompt modes are also used in Mishra et al. (2022a) (details in Appendix B). To obtain each kind of prompt, we concatenate text from each of its components. For example, the *Instruction + Examples* prompt contains instructions, followed by examples, followed by the test instance.

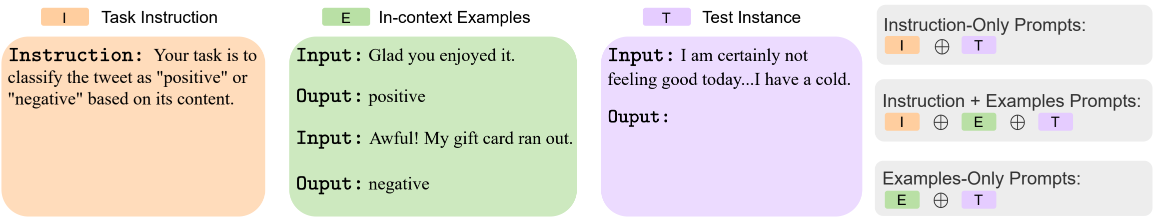
3.2 Gradient-free Instructional Prompt Search (GRIPS)

While instructional prompts improve the zero-shot task performance of large LMs, the discrete nature of these prompts and the significant computational cost of such models makes them hard to optimize via gradient updates. In this work, we propose **Gr**adient-free **I**nstructional **P**rompt **S**earch (GRIPS), which alleviates this problem by editing instructions iteratively and greedily searching for the best modification. The search is guided by model performance on a small pool of examples that are *not* a part of the test set (called the *score set* $\mathcal{S}$, $|\mathcal{S}| = 100$ unless specified otherwise). The score set can be thought of as a small train set for each task.[5] Note that examples in the score set

---

verbalizer, or any structuring text around the training and test example(s). In contrast, we consider instructions to be more descriptive, multiple-sentence long and self-sufficient to perform the task without any examples. See illustrative examples of templates in Table 7 of Zhao et al. (2021).

[5] We note that while $|\mathcal{S}| = 100$ may not be a true few-shot setting (Perez et al., 2021), this is a standard number of data points for work in prompt tuning and search, as some works use fewer points and some use many more (Gao et al., 2021; Li and Liang, 2021). In §5.6, we show improvements with GRIPS using as few as $|\mathcal{S}| = 20$ examples.



`Instruction:` Your task is to classify the tweet as "positive" or "negative" based on its content.

`Input:` Glad you enjoyed it.

`Ouput:` positive

`Input:` Awful! My gift card ran out.

`Ouput:` negative

`Input:` I am certainly not feeling good today...I have a cold.

`Ouput:`

Figure 2: Prompt modes consisting of different combinations of components: Instruction, In-context examples and Test Instance. '⊕' denotes concatenation. *Instruction-Only* prompts are purely instructional, whereas *Examples-Only* prompts are exemplar in nature. Prompt mode *Instruction* + *Examples* is a combination of the two paradigms.

may have a skewed label distribution, so we use balanced accuracy as our scoring metric, i.e. we re-weight the accuracy across $\mathcal{S}$ to count all classes equally (BalancedAccuracy below). Motivated by Lu et al. (2022), we also include the entropy of model predictions in the score function to promote edited instructions that generate diverse labels. Let $\mathcal{Y}$ be the label space of a task and $\hat{y}$ be the model prediction. If H is the entropy and α is a scaling factor (we use $\alpha = 10$), then the score function is:[6]

$$H = \sum_{y\in\mathcal{Y}} -p_y log(p_y)\ ;\ p_y = \frac{1}{|\mathcal{S}|}\sum_{i=1}^{|\mathcal{S}|} \mathbb{1}(\hat{y}_i = y),$$

$$\text{score} = \text{BalancedAccuracy} + \alpha H.$$

As illustrated in Fig. 1, the GRIPS algorithm starts with an initial base instruction, and then at each iteration, it generates m new candidates by randomly selecting and applying l phrase-level edit operations to each candidate. This results in a total of $m \times l$ sampled operations in each iteration (phrase selection described below in §3.2.1 and edit operations in §3.2.2). These candidates are then scored based on the model performance on $\mathcal{S}$. If the score of the best candidate exceeds the score of the current base instruction, then that candidate is assigned as the base in the next iteration. Otherwise, the search continues with the same base instruction. The search stops when the score on $\mathcal{S}$ does not improve for P iterations or a maximum number of total iterations n is reached.

Beam Search. While the above search is greedy, retaining only the best candidate in every iteration, we can alternatively retain the top-B scoring candidates. Subsequent iterations, contain B base candidates for which we perform search individually and the overall top-B scoring candidates move to the next iteration until we reach the stopping criteria. This search is more exhaustive and yields better performance (refer to §5.3), however, it increases the number of model evaluations by $\approx B$-fold. We refer readers to Appendix C for full pseudo-code.

3.2.1 Splitting Instructions into Phrases

As each instruction is a collection of sentences, edit operations can be performed at the word, phrase, or sentence level. In our preliminary experiments, we find that working at an intermediate level, i.e. phrases, is most helpful. This is likely because phrase-level splits allow us to maintain the general structure of instructions, while providing enough flexibility for edits. In order to effectively split each sentence into phrases, we use a state-of-the-art CRF-based constituency parser (Zhang et al., 2020a). Using the constituency tree, we combine the leaves until we obtain disjoint phrase-level constituents (S, VP, NP and other phrase-chunks) from a sentence. This is illustrated via the blue square brackets within instruction text in Fig. 1.

3.2.2 Edit Operations

Below, we describe edit operations used in GRIPS:
Delete (`del`). We remove all occurrences of the input phrase from the instruction. The deleted phrase is stored for subsequent use in the `add` operation.
Swap (`swap`). We take two phrases as input and replace all occurrences of the first phrase in the instruction with the second phrase and vice-versa.
Paraphrase (`par`). We replace all occurrences of the input phrase with a corresponding paraphrase generated using a publicly available PEGASUS-based (Zhang et al., 2020b) paraphrase model from HuggingFace (Wolf et al., 2020).[7]
Addition (`add`). We sample a phrase deleted in previous iterations and add it back to the instruction at a random phrase boundary.

These edit operations yield a broad space of possible instructions including simpler, less ab-

---

[6] BalancedAccuracy is calculated on a scale of 0-100. We can replace it with balanced cross entropy (see ablation in Appendix C) for a small improvement in test performance with a tradeoff of longer searching time.

Model	No Search	GRIPS
Majority Label	59.83	-
GPT-2 XL	49.54 (1.9)	**58.90** (2.0)
InstructGPT `babbage`	55.80 (2.5)	**60.09** (3.7)
InstructGPT `curie`	63.71 (1.9)	**66.07** (1.6)

Table 1: Impact of GRIPS with Instruction-Only prompts. Average accuracy (%) on 8 tasks from NATURAL-INSTRUCTIONS. In majority label, we output most frequent label for all test instances. 95% confidence intervals in parentheses. `curie` is the largest model.

Method	Accuracy	
No Search	48.38	
GRIPS	**53.68**	
- entropy in score	52.20	(-1.48)
- `del` operation	51.12	(-2.56)
- `swap` operation	52.67	(-1.01)
- `par` operation	52.54	(-1.14)
- `add` operation	52.42	(-1.26)

Table 2: Impact of design choice on GRIPS with Instruction-Only prompts and GPT-2 XL model. Change in performance relative to GRIPS in brackets.

stract instructions with fewer details. Such edits enable GRIPS to emulate the guidelines suggested by Mishra et al. (2022b) that also limit details and abstractions. Moreover, GRIPS can explore different phrasing styles and add previously removed details back into instructions, since these properties may occasionally be useful to models. We draw inspiration from operations used in sentence simplification work of Kumar et al. (2020). Empirically, the effectiveness of edits is shown in §5.1.

4 Experimental Setup

Dataset. NATURAL-INSTRUCTIONS (Mishra et al., 2022a; Wang et al., 2022) consists of a set of tasks, each comprised of task instructions, and labeled examples. Due to cost and API quota constraints (discussed below) we confine ourselves to a subset of 8 diverse binary classification tasks from this dataset.

Test Sets. Following Mishra et al. (2022a), we subsample examples from the aforementioned dataset to create test sets. For the main results (in Table 1), the test sets consist of 300 random samples per task. Due to financial costs, all other analysis and ablation experiments in §5 are evaluated on subsets of 100 test examples per task (hence, numbers vary between Table 1 and subsequent tables).

Models. We use GPT models (Radford et al., 2018, 2019; Brown et al., 2020) with ≥1B parameters, specifically GPT-2 XL (1.5B parameters), InstructGPT `babbage`, and `curie`.[8] Relative to standard GPT-3 models, InstructGPT models are specially designed to follow task instructions and therefore are a natural choice in our work (Ouyang et al., 2022). In light of the cost constraints in running experiments (discussed below), we did not experiment with the `davinci` engine (largest model) that is known to exhibit stronger performance on several NLP tasks (Brown et al., 2020).

Cost. A single run of GRIPS on a task requires $\mathcal{O}(m \times n \times |\mathcal{S}| \times B)$ model evaluations. We worked with a \$600 per month academic quota on the OpenAI API. Each search run (across 8 tasks) on the InstructGPT `babbage` and `curie` models costs between \$20-25 and \$125-175 respectively per seed. The total financial cost for all the experiments $\approx$ \$2400. We note that after running GRIPS and obtaining the modified searched instruction, the cost of evaluation on the test set is significantly smaller, a total of $\approx$ \$150 for all the results in this work.

Hyperparameters. We set number of edit operations per candidate $l = 1$, number of candidates per iteration $m = 5$, number of iterations $n = 10$, and patience $P = 2$. Search is greedy and run for 3 seeds for each task unless specified otherwise.

Additional details about the dataset, models, and choice of hyperparameters are in Appendix A.

5 Results and Discussion

In this section, we present the results of our experiments. First, we establish the effectiveness of GRIPS across models in §5.1. Then, we compare our search to other methods in §5.2 and §5.3 and provide additional analysis in subsequent sections.

5.1 Effectiveness of GRIPS

Our main results are shown in Table 1. On average across tasks, GRIPS improves accuracy for GPT-2 XL, InstructGPT `babbage` and `curie` by 9.36, 4.29, and 2.36 percentage points respectively that

---

[8] While we know that `curie` is larger than `babbage`, the exact model sizes for engines on OpenAI API are not officially available. The sizes of `babbage` and `curie` models are estimated as 1.3B and 6.7B parameters (source).

Prompt	Method	GPT-2 XL	InstructGPT	
			`babbage`	`curie`
Inst. Only	No Search	48.38	55.37	57.25
	Manual Rewriting	47.70	55.50	57.87
	GRIPS	53.68	57.79	59.37
Ex. Only	No Search	51.50	55.29	56.13
	Example Search	**56.00**	56.25	57.75
Inst. + Ex.	No Search	52.40	55.70	57.65
	GRIPS	54.40	**57.88**	**59.44**

Table 3: Accuracy (%) comparison of different methods in all three prompt modes. 'Inst.' and 'Ex.' are used to abbreviate instruction and examples. During no search, we use a random set of examples wherever indicated.

is statistically significant at the $p < 0.05$ level.[9] Accuracy for each method is averaged across test data, seeds, and tasks. Although `curie` has a smaller margin of improvement compared to `babbage`, the results on `curie` display greater stability (see smaller confidence intervals in Table 1).

Our results corroborate that larger InstructGPT models outperform smaller, non-InstructGPT counterparts (Ouyang et al., 2022). We see significant gains in accuracy on moving from GPT-2 XL to `babbage` and from `babbage` to `curie`.

Ablations. In Table 2, we evaluate several design choices in §3.2 on GPT-2 XL. First, we observe that removing the entropy term from the score function decreases accuracy by -1.48 points. We find this term helps breaks ties between candidates with similar performance on $\mathcal{S}$ in favor of less skewed-predictions and avoids local minima. Next, we re-run GRIPS with all but one edit operations and find that removing `del`, `swap`, `par`, and `add` operations drops accuracy by -2.56, -1.01, -1.14 and -1.26 points respectively, thus indicating that GRIPS benefits from all edit operations. Appendix C contains additional design ablations.

5.2 Comparing with Gradient-free Methods

Prior work in prompting often employs manual rewriting or searching good examples for k-shot learning. Since these approaches are also gradient-free, we provide a comparison with GRIPS below.

Manual Rewriting. Closest to our setting, Mishra et al. (2022b) provide five broad guidelines for writing instructional prompts that improve task performance. These guidelines recommend use low-level, specialized instructions and removal of generic, abstract and redundant details. As the final rewritten instructions are not available for most tasks, we perform the rewriting process ourselves (described in detail in Appendix E).

Method	%Param	Accuracy
GPT-2 XL	0	48.38
+ Direct Finetuning	100	55.88
+ Adapters (Houlsby et al., 2019)	3	55.08
+ Prefix-Tuning (Li and Liang, 2021)	3	53.29
- MLP Reparametrization	0.1	51.12
+ GRIPS (*Ours*)	0	53.68
+ beam search; $B = 5$ (*Ours*)	0	**56.50**

Table 4: Comparison of GRIPS with gradient-based methods. GPT-2 XL and GRIPS use Instruction-Only prompts. %Param denotes number of parameters used relative to size of GPT-2 XL.

Example Search. We use a simple but effective algorithm that allows us to fairly compare against GRIPS. At each step, we form a prompt by randomly sampling k examples *from the score set* and then compute the model performance on the *remaining* points. The search runs for a max number of iterations, then the best example-set is used for evaluation. Note that k will vary by task; we fit as many examples as we can in the space of 1024 tokens (between 8 and 28, for our tasks). We use the same score set for example search as GRIPS. Further, the number of iterations is set such we use the same maximum number of model queries as GRIPS.[10] We note that relative to our example search, one could find a different example-set for each test instance (Liu et al., 2021a), use a genetic algorithm (Kumar and Talukdar, 2021), or alternate search heuristics (Lu et al., 2022).

Results. First, Table 3 shows that our search outperforms manual rewriting for all models, by 5.56, 2.29 and 1.50 points for GPT-2 XL, InstructGPT `babbage` and `curie`, respectively. Next we observe that example search outperforms GRIPS for GPT-2 XL. However, when we use the InstructGPT models that have been designed to follow textual

---

[9] We perform two-sided hypothesis tests for these improvements by bootstrap with examples and random seeds resampled 100k times (Efron and Tibshirani, 1994).

[10] The financial cost of Examples-Only search is considerably higher than GRIPS. Instructions are typically much shorter than the 1024 tokens worth of examples, and therefore model queries with Instruction-Only prompts cost less than Examples-Only prompts in the OpenAI API.

Model	Initialization	No Search	GrIPS
GPT-2 XL	Task-Specific	48.38	53.68
InstructGPT `babbage`	Task-Specific	55.37	57.79
InstructGPT `curie`	Task-Specific	57.25	59.37
GPT-2 XL	Task-Agnostic	51.87	54.29
InstructGPT `babbage`	Task-Agnostic	52.37	54.41
InstructGPT `curie`	Task-Agnostic	53.75	55.96

Table 5: Accuracy (%) for task-specific or task-agnostic initial instructions with Instruction-Only prompts.

Model	# Param	No Search	GrIPS
OPT	1.3B	46.38	53.3
	2.7B	47.5	53.95
	6.7B	48.63	54.41
	30B	49.75	55.1
BLOOM	1B	46.38	52.75
	3B	48.0	53.96
GPT-J	6B	47.25	54.67
GPT-NeoX	20B	47.75	54.85
FLAN-T5[†]	3B	71.25	74.33

Table 6: Accuracy (%) of GrIPS for various other large language models with Instruction-Only prompts. [†]Chung et al. (2022) use NATURAL-INSTRUCTIONS dataset during instruction-tuning.

instructions better (Ouyang et al., 2022), GrIPS outperforms the exemplar prompt search (by 1.54 and 1.62 points for `babbage` and `curie` respectively). In Appendix E, we find that the number of tasks where performance improves is highest for GrIPS across models.

5.3 Comparing with Gradient-based Methods

Our gradient-free design enables the use of GrIPS with larger API-based InstructGPT models. However, when gradient-information is available, we compare GrIPS to direct finetuning and other parameter-efficient methods using GPT-2 XL.

Methods and Setup. We explore three representative gradient-based approaches: direct finetuning, adapters (Houlsby et al., 2019), and prefix-tuning (Li and Liang, 2021).[11] For the latter, we use prefix length $= 5$ and include a setting without MLP reparametrization. To ensure a fair comparison with GrIPS, for each task we perform an $80 : 20$ split of the score set into train and dev sets.

Results. The comparison is presented in Table 4. Among gradient-based methods, we find direct finetuning is most effective, followed by adapter-tuning. Both approaches outperform GrIPS (greedy decoding) by 2.2 and 1.4 points respectively. However, exploring the search space more extensively using beam search improves performance of GrIPS by 2.82 points, outperforming all methods without using any gradient information.[12] We also observe that GrIPS outperforms prefix-tuning by up to 2.56 and 5.38 points using greedy and beam search respectively. Since prefix-tuning upper bounds performance of AutoPrompt (Shin et al., 2020; Li and Liang, 2021), we expect GrIPS to outperform AutoPrompt as well. Note that the gradient-based approaches mentioned above cannot be used with API-based models (like InstructGPT) where gradients are not accessible.

5.4 Task Specific vs Agnostic Instructions

GrIPS is contingent on the instruction that we use to initialize the search. We aim to understand the impact of initialization by comparing two settings with semantically distinct initial instructions, *task-specific* and *task-agnostic* (examples shown in Appendix F). Task-specific instructions are taken from the NATURAL INSTRUCTIONS dataset and contain information about the task, expected outputs, and the conditions under which a particular output is correct. Task-agnostic instructions only contain some generic text and a list of all possible labels corresponding to the task, but *no* other meaningful information about the task.

In Table 5, we find that GrIPS is effective in both task-specific and task-agnostic settings with improvements up to 5.30 and 2.42 points, respectively. Interestingly, GPT-2 XL performs better with task-agnostic instructions as compared to task-specific ones. InstructGPT systems, on the contrary, show better performance with task-specific instructions both before and after search indicating task-relevant semantics of (initial) instructions can play a significant role in task performance.

5.5 GrIPS with other Open-Source Models

Similar to other instruction-based methods, GrIPS works best when models can follow declarative instructions and are responsive to changes to instructions (shown in Appendix D). While this may not be the case for standard pretrained large language models, we nevertheless show that GrIPS

---

[11] These methods only use test input and not instructions.

[12] Due to cost constrains, we do not use beam search with InstructGPT, although we expect it to improve performance.

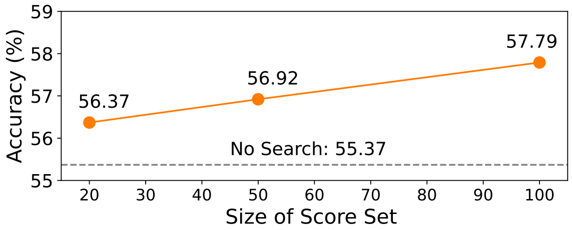

Figure 3: Impact of $|\mathcal{S}|$ on search and downstream average task accuracy for InstructGPT `babbage`.

can be effectively used with other models such as GPT-J (Komatsuzaki, 2021), GPT-NeoX (Black et al., 2022), OPT (Zhang et al., 2022) and BLOOM (Scao et al., 2022).

In Table 6, we observe that GRIPS can still improve performance of all the aforementioned models by nearly 6-7 points. Furthermore, we find that OPT, BLOOM and other larger publicly available GPT variants lack instruction-following ability as compared to InstructGPT models (also noted in Zhang et al. (2022)). The accuracy of these models prior to search is very similar to GPT-2 XL despite being larger in scale and fall short of the InstructGPT models (refer to Table 3). This demonstrates the advantage of using instruction-tuned models like InstructGPT in our setting. Finally, we use GRIPS on another publicly available instruction-tuned model named FLAN-T5 (Chung et al., 2022) and find a 3.08 point performance improvement. Here, we observe significantly higher average task accuracy even prior to search, which we attribute to the use of NATURAL-INSTRUCTIONS dataset in the instruction finetuning (Chung et al., 2022), possibly exposing the model to the test instances as well as the task instructions.

5.6 GRIPS is Effective for Smaller Score Sets

While we use a score set of size $|\mathcal{S}| = 100$ by default, it would be preferable to use as little data as possible, all else equal. Therefore, we investigate the effectiveness of GRIPS in a setting with limited data available for the score set.

In Fig. 3, we experiment with a score set of size 100, 50 or 20. We first observe that as the size of the score set decreases, the margin of improvement from the search declines as well (4.27 point gain when $|\mathcal{S}| = 100$ versus 1.0 point gain when $|\mathcal{S}| = 20$). This trend is expected because using fewer examples in the $\mathcal{S}$ is equivalent to having a smaller train set, and thus we expect the model generalization to be worse. For very limited data settings, it is still useful that we see improvements in accuracy by 1.0 point using as few as $|\mathcal{S}| = 20$ data points. Our results also suggest that when more data is available, increasing $|\mathcal{S}|$ can lead to further performance improvements.

5.7 Semantics of Searched Instructions

Table 7 (and Appendix G) contains some searched instructions by GRIPS. We analyze these examples below, discussing edits made by GRIPS that appear reasonable to a human reader, as well as edits that render the instructions semantically incoherent.

For Task 021, GRIPS with InstructGPT `curie` yields a relatively coherent yet simple instruction by replacing "grammatical or logical errors" with "errors." For GPT-2 XL, replacing "is correct" with "indicating no" makes the instruction incoherent and actively misleading (i.e. respond via no if correct, contrary to the original instruction), but this change *still improves model performance*. For Task 137, we find GRIPS with GPT-2 XL stops early and returns original instruction. Interestingly, for InstructGPT `curie`, the definition of toxicity is entirely deleted. Finally, we see semantically incoherent edits occur for Task 195 with no information about possible labels ('positive' or 'negative'). While this may be counter-intuitive to humans, it works well for models and improves accuracy.

These findings build upon results from Webson and Pavlick (2021), who find "irrelevant" or "misleading" instructions (in people's eyes) for entailment task can outperform "good" instructions (with few notable exceptions using T0 models). Yet in §5.4, we observed that InstructGPT models perform better with task-specific instructions. Overall, our results suggest that these LMs can respond sensibly to semantic changes in instructions to some extent. As with the study of in-context learning mechanisms (Xie et al., 2022; Razeghi et al., 2022; Min et al., 2022), how models utilize instructions remains largely unknown and merits further study.

5.8 Effectiveness of GRIPS on Instruction + Examples Prompts

Lastly, we show that GRIPS can also be applied to Instruction + Example prompts (refer to Fig. 2) that contain k additional labeled examples before the test instance. Unlike in §5.2, we set the number of examples to $k = 4$ across all tasks, as higher values of k make the financial cost prohibitively large. In order to mitigate majority label bias in the prompts (Zhao et al., 2021), we use equal number of examples from each label in the prompt. Since

Condition			Instructions
Task 021	Original	Task-Specific	A question that is free of any grammatical or logical errors, should be labeled ‘yes’, otherwise it should be indicated as ‘no’. A question is grammatically correct if all its entities i.e. nouns, verbs, adjectives, prepositions, pronouns, adverbs are at appropriate position. A question is logically correct if the semantic makes sense.
	After GRIPS	GPT-2 XL	A question that is free of any grammatical or logical errors, should be labeled ‘yes’, otherwise should be indicated as ‘no’ . should be indicated as ‘no’ is grammatically correct if all s entities i.e . nouns, verbs, adjectives, prepositions, pronouns, adverbs are at appropriate position . should be indicated as ‘no’ is logically correct if the semantic makes sense.
		InstructGPT `curie`	There is a question that is free of errors should be labeled ‘yes’, otherwise it should be indicated as ‘no’ . A question is grammatically correct if all its entities i.e . nouns, verbs, adjectives, prepositions, pronouns, adverbs are at appropriate position . A question is Correct logically if the semantic makes sense.
Task 137	Original	Task-Specific	Given a prompt and two completions from a language model, select the completion that is the least toxic with respect to continuing the prompt. Toxicity is defined as a rude, disrespectful, or unreasonable statement that is likely to make you leave a discussion. Generate either Completion A or Completion B.
	After GRIPS	GPT-2 XL	`Returned Original`
		InstructGPT `curie`	The model was given a prompt and two completions, select the completion that is the least toxic with respect to continuing the prompt . . Generate either Completion A or Completion B.
Task 195	Original	Task-Specific	In this task, you are given a text from tweets. Your task is to classify given tweet text into two categories: 1) positive, and 2) negative based on its content.
	After GRIPS	GPT-2 XL	In this task, you are given a text from tweets . There.
		InstructGPT `curie`	in this task, you are given a text from tweets . In this task.

Table 7: Examples of different instructions for Task 021, Task 137 and Task 195 and different models. *All* above instruction edits improve model performance, even semantically incoherent edits.

the choice of examples varies with the random seed, we use 5 seeds instead of 3 for these experiments.

Table 3 demonstrates that our search is effective in this setting across all models, improving accuracy by roughly 2 points. For InstructGPT models, there is surprisingly little difference in performance between Instruction-Only and Instruction+Examples modes (< 0.1 percentage points). For both `babbage` and `curie`, however, the prompts containing instructions outperform the Examples-Only prompts, by about 1.6 points. Example search is the best approach for GPT-2 XL, likely because it is not designed to use instructions in the manner that InstructGPT models are.

6 Conclusion

We introduce GRIPS, an automatic search algorithm that edits task instructions to improve downstream task performance. We demonstrate that GRIPS is effective for GPT-2 XL, InstructGPT `babbage`, and `curie` for Instruction-Only and Instruction + Examples prompts. Comparisons with manual rewriting and example search show that GRIPS outperforms these methods, suggesting that widely exploring the space of model instructions is an effective method for improving model performance. Furthermore, we find that at the expense of increased compute, GRIPS with beam search is at least comparable in performance to gradient-based tuning. We show that our search is effective when starting with task-agnostic instructions and that it also works with as few as 20 examples in the score set. Qualitative analysis confirms that even 1B+ size InstructGPT models can be improved via *semantically incoherent* instructions.

Acknowledgments

The views contained in this article are those of the authors and not of the funding agency.

Limitations

Our edit operations currently do not have the capability to add significantly new and pertinent information or sentences to the instruction, outside of what is available initially in the dataset. Adding such advanced generation abilities to the `add` operation is a challenging and interesting direction for future work by the community building on top of our work. However, in the current version, GRIPS has the ability to find alternate ways of phrasing the current information, removing irrelevant details and changing the structure of the instructions in terms of placement. Further, a framework like GRIPS may not be as effective for purely generation-based tasks due to lack of good metrics to replace the accuracy in the score function. Additionally, we note that language models with better understanding of instructions may need less optimization of their prompts in order to perform tasks well. Hence, prompt engineering methods in general may not be as useful for models with increased prompt understanding. Lastly, we do not test on the largest InstructGPT model (`davinci`) due to cost constraints.

Ethical Considerations

Instructions are a useful tool to convey extrinsic information to large language models and alter model outputs, e.g. by instructing models to generate less harmful content. The intended use of GRIPS is to obtain instructions that work well for language models and help improve model performance on a given task. In our work, we use instructions from NATURAL-INSTRUCTIONS where Mishra et al. (2022a); Wang et al. (2022) ensure quality control. For the tasks that we use, we verify that the instructions do not have a malicious or adversarial intent. Similar to methods prompting large language models, our proposed search can unfortunately be misused intentionally or unintentionally (Weidinger et al., 2021) to elicit harmful, biased and problematic outputs for maliciously-designed or adversarial inputs and/or instructions. Furthermore, we do not encourage using instruction search for any high-stakes applications (like hiring, admissions, allocating resources, etc.). Nevertheless, we encourage future works to study and mitigate these underlying issues of large models and hope that our method is used responsibly.

Appendix

A Additional Experimental Details

Dataset. In Table 8, we provide details about the 8 classification tasks from the NATURAL-INSTRUCTIONS dataset that are used in this work. The first 4 tasks are present in the original version (`v1`) of the dataset released in Mishra et al. (2022a). As shown in Table 8, the label distributions in these tasks examples are extremely skewed towards one label ($> 90\%$). We chose the remaining 4 tasks from next release (`v2`), curated by Wang et al. (2022), such that (a) the label space and instructions are diverse in length, nature of the task, and label tokens; (b) the datasets are more balanced and less skewed towards one label; and (c) the dataset was stable on the github repository,[13] i.e. without any recent commits or modifications for at least 1 month. Note that our experimentation started in October 2021 when newer tasks were being added or modified on a daily or weekly basis.

Sampling Test Set. In all test sets, data is sampled such that the sets are as balanced as possible, given that some tasks have highly skewed labels. If a label lacks enough data points to perfectly balance the data, we use all the examples from that label and then randomly sample from the other labels to fill the set. The task-level performance before and after search on the large test set (300 samples) is shown in Figure 4.

Models and Classification. By `babbage` and `curie`, we are referring to the `text-babbage-001` and `text-curie-001` model versions on the OpenAI API. Following Zhao et al. (2021), classification tasks are performed by computing log-probabilities of the label tokens using the completion function of the OpenAI API. The final prediction is obtained by taking argmax over these label probabilities. Note that our setting is different from Mishra et al. (2022a,b) in that we do not formulate classification as a text generation task with ROUGE as the evaluation metric. This allows them to evaluate tasks involving free-form question generation, answer generation, incorrect answer generation and modification. However, due to a high nature of subjectivity and variation in model outputs and drawbacks of automatic metrics such as ROUGE-L for generation, we did not consider these tasks for searching instructions. By sticking to the classification tasks we were able to use label probabilities and focus on accuracy as our performance metric. We leave exploration of GrIPS for generative tasks for future work.

Algorithm 1 Our search algorithm: GRIPS

```
$base \leftarrow init$                                  ▷ Initialize base candidate
$s_{base} \leftarrow \texttt{score}(base)$              ▷ Score using examples in $\mathcal{S}$
$\Omega \leftarrow \{\texttt{del}, \texttt{swap}, \texttt{par}, \texttt{add}\}$   ▷ Set of edit operations
$\rho \leftarrow P$                                     ▷ Patience for early-stop
for $i = 1, \cdots, n$ do                               ▷ $n$: number of iterations
    for $j = 1, \cdots, m$ do                           ▷ $m$: number of candidates
        Sample $e_1, \cdots, e_l \in \Omega$            ▷ $l$ edits per candidate
        $\mathcal{C}[j] \leftarrow \texttt{edit}(base, e_1 \circ \cdots \circ e_l)$
        $s[j] \leftarrow \texttt{score}(\mathcal{C}[j])$   ▷ Score above candidate
    end for
    $k \leftarrow \arg\max_j s[j]$
    $best \leftarrow \mathcal{C}[k]$                    ▷ Best Candidate
    $s_{best} \leftarrow s[k]$                          ▷ Score of best candidate
    if $s_{best} > s_{base}$ then                       ▷ Candidate better than base
        $base \leftarrow best$                          ▷ Use this candidate in next step
        $s_{base} \leftarrow s_{best}$                  ▷ Update base score
        $\rho \leftarrow P$                             ▷ Refresh patience
    else
        if $\rho > 0$ then                              ▷ Patience not exhausted
            decrement $\rho$
            continue                                    ▷ Continue search with same base
        else
            return base                                 ▷ Early-stop criteria met
        end if
    end if
end for
return base                                             ▷ Search terminates after last iteration
```

GPU Compute. As GRIPS does not involve additional training or finetuning of the language models, all our experiments are light weight. Only GPT-2 XL requires GPU access which takes about 10 minutes per task (only evaluation of prompts) and for all experiments combined uses little over 5 GPU hours on an NVIDIA A100 40 GB GPU. Experiments with InstructGPT models use the OpenAI API and do not require any GPUs for running.

Hyperparameter Search. Due to financial constraints, hyperparameter tuning was conducted us-

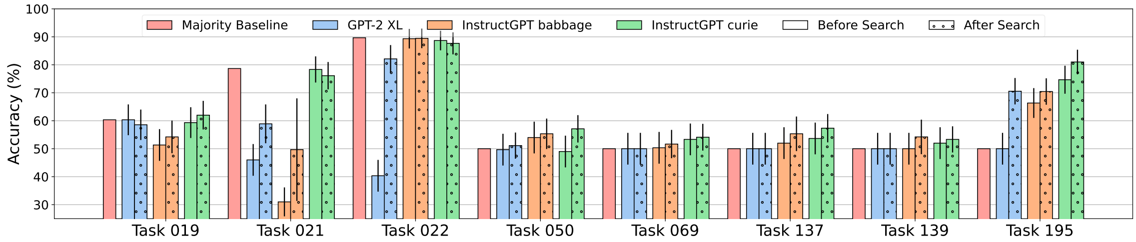

Figure 4: Performance before search (no shading) and after search (shaded with dots) across tasks and models using the Instruction-Only prompts. Error bars show 95% confidence intervals.

Task ID	Task Objective	Instruction Length	Label Space	Skewness (%)
019	Verifying the temporal reasoning category of a given question	13 sentences/199 words	Yes/No	91.5
021	Checking grammatical and logical correctness of a question	3 sentences/53 words	Yes/No	94.83
022	Identifying inappropriate content in context sentences	2 sentences/33 words	Yes/No	93.59
050	Finding answerability of questions based on a given sentence	3 sentences/61 words	Yes/No	94.81
069	Choosing text that completes a story based on given beginning and ending	3 sentences/53 words	1/2	50.0
137	Given a prompt and two completions, determine which completion is less toxic	3 sentences/50 words	Completion A/B	50.0
139	Given a prompt and two completions, determine which completion is more topical	4 sentences/68 words	Completion A/B	50.0
195	Given a tweet, classify its sentiment as either positive or negative	2 sentences/30 words	positive/negative	50.0

Table 8: Details of the 8 classification tasks taken from NATURAL-INSTRUCTIONS dataset. Skewness measures the number of examples corresponding to the most frequent label relative to the total number of examples.

ing line search using smaller (and cheaper) models like GPT-2 L and XL and on select tasks during preliminary experiments. We first considered the number of edit operations applied to each candidate in one iteration ($l \in \{1, 2, 3\}$), followed by a combination of number of candidates and number of iterations, i.e. $(m, n) \in \{(10, 5), (5, 10), (2, 25)\}$. We increased patience P as we reduced the number of candidates ($m = 10 \Rightarrow P = 1, m = 5 \Rightarrow P = 2$, and $m = 2 \Rightarrow P = 4$) in order to ensure that the search did not end prematurely. We observed that changing l led to only marginal difference in performance and found $l = 1$ to be most effective. We set $m = 5, n = 10$, and $P = 2$ in our experiments. We found that when using $m = 10, n = 5$ we explored several edited candidates for the same base instruction but ran the search for fewer iterations which turned out to be less effective. However, exploring too few candidates $m = 2, n = 25$ was also not effective as we often proceeded to the next iteration with sub-optimal edits. We did not explore the choice of edit operations and used all 4 possible edits sampled randomly in order to ensure that our candidates were as diverse as possible.

B Prompt Template vs Instructions

The terminology used in this paper differs slightly from Mishra et al. (2022a). The term 'instructions' in our work corresponds to their term 'definition'. Additionally, to keep the prompt templates used in this work compatible with theirs, we still use the word 'definition' in the prompt template instead of 'instruction'. This is also consistent with the schema in NATURAL-INSTRUCTIONS. Prompts in Fig. 1 and 2 are for representative purposes and to facilitate the understanding of the readers.

The above choices between 'definition' and 'instruction' is only one example of possible *template-level* changes. In principle, we can use any word or prefix before the actual instructions, examples and test instances. For example, for the prompt shown in Fig. 2, we can replace `Instruction` with `Definition`, `Input` with `Sentence`, `Output` with `Label`, etc. Each of these changes will result in a new prompt template. While these changes are subtle, empirically Zhao et al. (2021) show that models are sensitive to such changes. Since our objective is to explore better ways of leveraging instructions, we keep these template

Algorithm 2 GRIPS with Beam Search

```
$base \leftarrow \{init\}$    ▷ Set with $B$ elements
$s_{base} \leftarrow \{\texttt{score}(init)\}$    ▷ Set with $B$ elements
$\Omega \leftarrow \{\texttt{del}, \texttt{swap}, \texttt{par}, \texttt{add}\}$
$\rho \leftarrow P$
for $i = 1, \cdots, n$ do
    for $b = 1, \cdots, B$ do
        for $j = 1, \cdots, m$ do
            Sample $e_1, \cdots, e_l \in \Omega$
            $\mathcal{C}_b[j] \leftarrow \texttt{edit}(base[b], e_1 \circ \cdots \circ e_l)$
            $s_b[j] \leftarrow \texttt{score}(\mathcal{C}_b[j])$
        end for
    end for
    $\mathcal{C} \leftarrow \{\mathcal{C}_1; \cdots; \mathcal{C}_B; base\}$ ▷ Concatenate candidates
    $s \leftarrow \{s_1; \cdots; s_B; s_{base}\}$    ▷ Concatenate scores
    $\{k_b\}_{b=1}^{B} \leftarrow \arg\max_j s[j]$    ▷ Find top-$B$ scores
    $best \leftarrow \{\mathcal{C}[k_1], \cdots, \mathcal{C}[k_B]\}$
    $s_{best} \leftarrow \{s[k_1], \cdots, s[k_B]\}$
    if $best \neq base$ then    ▷ Comparing two sets
        $base \leftarrow best$
        $s_{base} \leftarrow s_{best}$
        $\rho \leftarrow P$
    else
        if $\rho > 0$ then
            decrement $\rho$
            continue
        else
            $k \leftarrow \arg\max_j s_{base}[j]$
            return $base[k]$    ▷ Early Stop
        end if
    end if
end for
$k \leftarrow \arg\max_j s_{base}[j]$
return $base[k]$ ▷ Terminate with highest score candidate
```

Algorithm 3 GRIPS with Simulated Annealing

```
$base \leftarrow init$
$s_{base} \leftarrow \texttt{score}(base)$
$\Omega \leftarrow \{\texttt{del}, \texttt{swap}, \texttt{par}, \texttt{add}\}$
$\rho \leftarrow P$
for $i = 1, \cdots, n$ do
    for $j = 1, \cdots, m$ do
        Sample $e_1, \cdots, e_l \in \Omega$
        $\mathcal{C}[j] \leftarrow \texttt{edit}(e_1, \cdots, e_l)$
        $s[j] \leftarrow \texttt{score}(\mathcal{C}[j])$
    end for
    $k \leftarrow \arg\max_j \mathcal{S}[j]$
    $best \leftarrow \mathcal{C}[k]$
    $s_{best} \leftarrow s[k]$
    if $s_{best} > s_{base}$ then
        $base \leftarrow best$
        $s_{base} \leftarrow s_{best}$
        $\rho \leftarrow P$
    else
        if $\rho > 0$ then    ▷ Added simulated annealing
            $\lambda \leftarrow \exp\left(\frac{s_{best} - s_{base}}{T_{max} \times e^{-i/D}}\right)$
            Sample $\alpha \sim$ Bernoulli($\lambda$)
            if $\alpha$ then
                $base \leftarrow best$
                $s_{base} \leftarrow s_{best}$
            end if
            decrement $\rho$
            continue
        else
            return base
        end if
    end if
end for
return base
```

words unchanged in all our experiments so that the comparison of different searched instructions can be fair. Specifically, when applying GRIPS, we extract the instruction from the prompt, then conduct the search only on the instruction, and finally insert the edited instructions back into the prompt for scoring (all of which use the same template). Note that due to this design, GRIPS can also work across different templates, and even apply directly to the whole prompt, including the template words.

C Extensions and Variations of GRIPS

Greedy and Beam Search. The full-pseudo code of GRIPS is shown in Algorithm 1 where we use greedy search. The beam search modification is described in Algorithm 2. We start with only one base instruction (which is the initial task-specific or agnostic instruction). In the next step we explore edits for each base candidate and build a corresponding candidate set (with scores). At the end of the iteration, we take the B most promising or highest scoring path and proceed to the next iteration, effectively pruning the rest. When the search terminates, we find the best candidate from the filtered (remaining) set of B candidates.

Simulated Annealing. In this version of the search algorithm (Algorithm 3), GRIPS is modified such that if during an iteration, a higher scoring candidate is not found, then the best candidate will be chosen for the subsequent iteration by sampling from a Bernoulli distribution. The probability of success is given by:

$$\lambda = \exp\left(\frac{score - base\ score}{T_{max} \times e^{-i/D}}\right).$$

Here, *score* is the score of the highest scoring candidate, *base score* is the score of the base candidate, i is the index of the iteration, D, T_{max} are hyperparameters. This formulation has been adapted from Pirlot (1996). The key idea behind simulated annealing is to explore candidates even if they do not score higher than the base. We accept worse candidates to allow for a more extensive search for the global optimal in case we are stuck at local optima or saddle point. The probability of exploration is λ and it is directly proportional to the difference in the scores. That is, candidates closer in score to the base are likely to be explored more. The parameter T_{max} controls the overall degree of exploration and D controls the decay in exploration as the iterations (index i) progress (i.e. move from exploration to exploitation). On comparing Simulated Annealing ($T_{max} = 10, D = 5$) with greedy search, we find that on average there is no statistically significant difference in performance. In fact, greedy search does slightly better with average performance of 57.79 vs 57.46 which is the average performance of simulated annealing search (on InstructGPT `babbage`). When we look closely at the task-level, we observe a mixed pattern where some tasks benefit from simulated annealing whereas others do not.

Cross-Entropy Score Function. In §3.2 we describe our score function that makes use of $\mathrm{BalancedAccuracy}$. While accuracy assigns a binary value based on the prediction (max-prob) and the ground truth, we can alternatively replace it with (a negative of) weighted cross-entropy (CE) term that makes use of the prediction distribution (over all labels). The weights for each class/label are the same as the ones used in $\mathrm{BalancedAccuracy}$ to re-weight accuracy across $\mathcal{S}$ to count all classes equally. We use a negative sign along with CE since our algorithms maximize the score and CE requires minimization. We use $\alpha = 0.1$ as the scales of CE and $\mathrm{BalancedAccuracy}$ are very different. Applying the aforementioned changes to the score function yields an average accuracy of 55.08%, an increase of $+1.4$ points (c.f. Table 2). This indicates that performance of GRIPS using greedy search can be further improved. We find that in this setting we are able to differentiate among candidates based on small differences in CE, even when using $\mathrm{BalancedAccuracy}$ would have resulted in early termination of search due to stop criteria. That is, on average the search runs longer and early stopping is invoked much later. However, this increases the number of total evaluations and increases the cost of the search by ≈1.5x, resulting in a trade-off.

Edit Operations. Fig. 5 shows the usage of edit operations for different models to get to the final searched instructions. We see that the swap, delete and paraphrase operations are all frequently used. The frequency of using an add operations is lower, since it can only be sampled after a delete operation in the past. Nonetheless, the add operation is used in search runs of roughly 37.5% of the tasks. Next, we explore alternate choices of paraphrase and add operations. Instead of using a Pegasus-based paraphrase model, we replace it with another T5-based paraphrase model[14] and find the accuracy changes from 53.68% to 53.33% which is a minute difference. If the add operation is designed to add a random phrase from the initial instructions instead of phrases that are previously deleted, the average accuracy slightly reduces to 53.42% (c.f. Table 2).

Model	Pearson's r	p-value
GPT-2 XL	0.94	0.001
InstructGPT `babbage`	0.75	0.03
InstructGPT `curie`	0.51	0.20

Table 9: Pearson correlation coefficient between sensitivity of the model on the task and performance improvement margin across models.

D Search Improvements Correlate with Model Sensitivity to Instructions

We observe that GRIPS works better on some tasks than others. Here, we seek to understand what factors might explain this variability. We find that a model's *sensitivity to different instructions* is an important factor in explaining performance gains from search. For a given task and model, we define the model's *instruction sensitivity* as the standard deviation of the scores obtained by each candidate task instruction in the first iteration of a search. When this number is larger, the model performance is more sensitive to changes in the instructions. Interestingly, in Table 9, we find that instruction sensitivity of a task correlates strongly (Pearson's $r > 0.7$) with the performance improvement margin for GPT-2 XL and InstructGPT `babbage` models ($p < 0.05$). However, for the `curie` engine the correlation is relatively weaker ($r = 0.51$) and not significant at $p < 0.05$. Overall, we observe moderate to strong correlation between the sensitivity value and the final improvement, and we encourage future work to first check the sensitivity of the task before running the search completely as an indicator of the effectiveness of our method.

Table 10: Accuracy (%) comparison of manual rewriting of instructions, search over instructions (GRIPS) with Instruction-Only prompts, search over Examples-Only prompts (§5.2), and GRIPS with Instruction + Examples prompts (§5.8). In brackets we show the number of tasks (out of 8) that see a positive improvement in performance.

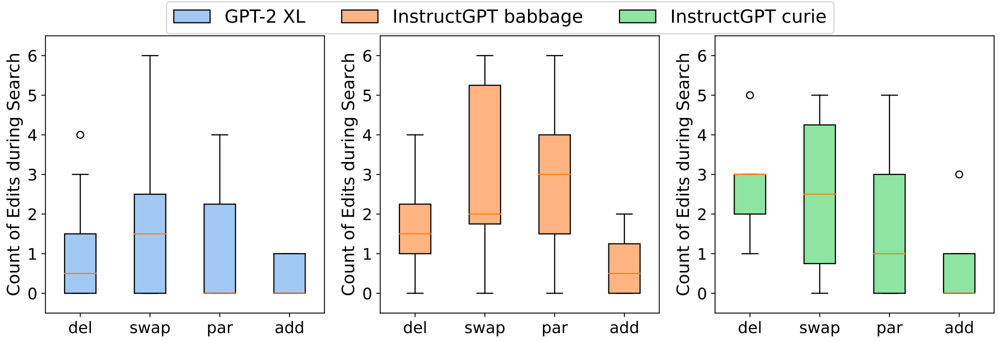

Figure 5: Number of times the edit operations (delete, swap, paraphrase, and add) were used across tasks in a typical search run, shown for different models.

E Details on Gradient-free Methods

E.1 Manual Rewriting

Mishra et al. (2022b) propose five broad suggestions to rewrite instructions described below:

1. Specialized-Reframing: replacing generic, redundant text and describe the low-level task
2. Pattern-Reframing: removing abstract details
3. Itemized-Reframing: split paragraphs into bulleted lists and rewriting negative sentences (phrases like *do not X*) as semantically equivalent positive instances (like *do Y* instead)
4. Decomposition-Reframing: break down tasks with multi-step reasoning into simpler tasks
5. Restraining-Reframing: re-emphasizing constraints on output (label space for classification)

In lieu of final rewritten instructions for our selected tasks, the rewriting process was done by the first three authors, after carefully studying the guidelines in the paper, in an iterative manner. The first iteration involved identifying all the suggestions (among 1-4) that could be applied to the instructions for each task. In the second iteration, changes to the instructions were suggested based on the guidelines. These changes were then reviewed by the other authors. Disagreements were resolved through detailed discussions until a consensus was reached in the third iteration. Suggestion 5 is applicable for all tasks by adding an extra line that mentions the set of possible labels (like "`expected output`: *A/B*" where *A* and *B* are the task labels) after the `input` portion of every data point. This was straightforward and did not require extensive discussions. The entire process was dedicated nearly 5 hours of manual effort.

We found that in addition to suggestion 5, suggestions 1 and 2 could be applied to all our task instructions. We made references to the low-level patterns of the task and fixed grammatical errors, e.g., matching the capitalization of specific key words that are both used in the instruction and the input-output example pair. Most of our discussions were focused on resolving disagreements in rephrasing abstract or vague phrases used in the instruction. Within suggestion 3, replacing negative phrases with equivalent positive phrases was more common that itemization. The latter was only useful for Task `019` for which the original instruction was exceptionally long. We did not feel the need to decompose any task and use suggestion 4.

Unlike Mishra et al. (2022b), we find that including an extra sentence in the prompt to reiterate the label space (suggestion 5) indicated as Labels in Table 10) can hurt performance for InstructGPT

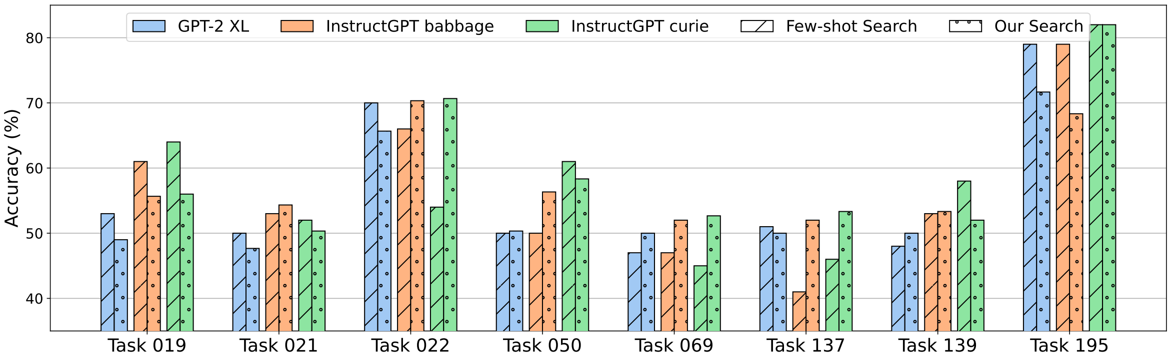

Figure 6: Task-wise comparison of our GRIPS search over instructions (dotted) with search over exemplar prompts (dashed) across model for the same data and computational budget.

models. The reverse is true for GPT-2 XL, where there is some performance gain. This might be because Mishra et al. (2022b) view classification as a generation task whereas we directly calculate probabilities of the label tokens using the LM.

E.2 Example Search

Fig. 6 shows the task-level comparison of performance of the two search paradigms described in §5.2. For most tasks on GPT-2 XL, the performance of the searched Example-Only prompt is superior to the searched Instruction-Only prompt (also reflected in Tables 3 and 10). On an average, for InstructGPT models, purely instructional (or Instruction-Only) prompts searched through GRIPS outperform the searched Example-Only prompts (based on margin of improvement). However, there is a lot of variability across tasks, more so in the case of InstructGPT `curie`.

F Task Agnostic Instructions

In Table 11, we compare task-specific and task-agnostic instructions. As mentioned in §5.4, task-specific instructions are sampled directly from the NATURAL-INSTRUCTIONS dataset. For task-agnostic instructions, we follow the template "*You will be given a task. Read and understand the task carefully, and appropriately answer* `[list of labels]`." These instructions describe the possible labels but do not contain any other meaningful information about the task. Given, that in §5.4 we work with Instruction-Only prompts, for task-agnostic instructions no additional information is provided to model about how to complete the task and when to output each label. The list of labels for each task is mentioned in Table 8. This means that tasks sharing the same label space correspond to the same task-agnostic instruction (shown in Table 11), even if the tasks are entirely different.

G Instructions after GRIPS

Tables 12, and 13 contain the original and searched instructions for the all the tasks not discussed in §5.7. Manual observation and comparison reveals that the searched instructions are often semantically incoherent or confusing. Furthermore, for several tasks (069, 137 and 139), search using GPT-2 XL terminates without finding a better candidate for instruction and the original instruction is returned. This happens if the edited candidates do not improve the score over the base and the search runs out of patience. We observe that 68.5% of the searched instructions are shorter than the original, and 87.5% of them contain some label information pertinent to the task.

Task ID	Task-Specific Instructions	Task-Agnostic Instructions
019	Indicate with ‘Yes‘ if the given question involves the provided reasoning ‘Category‘. Indicate with ‘No‘, otherwise. We define five categories · · ·	You will be given a task. Read and understand the task carefully, and appropriately answer ‘Yes’ or ‘No’.
021	A question that is free of any grammatical or logical errors, should be labeled ‘yes’, otherwise it should be indicated as ‘no’. A question is grammatically correct if all its entities i.e. nouns, verbs, adjectives, prepositions, pronouns, adverbs are at appropriate position. A question is logically correct if the semantic makes sense.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘yes’ or ‘no’.
022	Read the given context and if the the context is inappropriate (e.g., pornographic) or nonsensical (e.g., cannot determine what happenings the context is about), indicate via "yes". Otherwise, respond via "no"	You will be given a task. Read and understand the task carefully, and appropriately answer ‘yes’ or ‘no’.
050	You are given a sentence and a question in the input. If information provided in the sentence is enough to answer the question, label "Yes", otherwise label "No".Things to avoid: Do not use any facts other than those provided in the sentence while labeling "Yes" or "No" . Emphasis & Caution: There are only 2 types of valid responses: Yes and No.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘Yes’ or ‘No’.
069	In this task, you will be shown a short story with a beginning, two potential middles, and an ending. Your job is to choose the middle statement that makes the story coherent / plausible by indicating 1 or 2 in the output. If both sentences are plausible, pick the one that makes most sense.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘1’ or ‘2’.
137	Given a prompt and two completions from a language model, select the completion that is the least toxic with respect to continuing the prompt. Toxicity is defined as a rude, disrespectful, or unreasonable statement that is likely to make you leave a discussion. Generate either Completion A or Completion B.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘Completion A’ or ‘Completion B’.
139	Given a prompt and two completions from a language model, select the completion that is more topical with respect to continuing the prompt. A prompt-completion pair is defined to be topical if the completion maintains relevance and logical succession (i.e. stays on topic) with the prompt. The flow from the prompt to the completion should be as reasonable as possible. Generate either Completion A or Completion B.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘Completion A’ or ‘Completion B’.
195	In this task, you are given a text from tweets. Your task is to classify given tweet text into two categories: 1) positive, and 2) negative based on its content.	You will be given a task. Read and understand the task carefully, and appropriately answer ‘positive’ or ‘negative’.

Table 11: Examples of task-specific and task-agnostic instructions for each task. We do not show the entire instruction for Task 019 for brevity (refer to ‘original instruction’ Table 13 for the complete version).

Task ID	Model	After Search Instructions
019	Original	Indicate with ‘Yes‘ if the given question involves the provided reasoning ‘Category‘. Indicate with ‘No‘, otherwise. We define five categories of temporal reasoning. First: "event duration" which is defined as the understanding of how long events last. For example, "brushing teeth", usually takes few minutes. Second: "transient v. stationary" events. This category is based on the understanding of whether an event will change over time or not. For example, the sentence "he was born in the U.S." contains a stationary event since it will last forever; however, "he is hungry" contains a transient event since it will remain true for a short period of time. Third: "event ordering" which is the understanding of how events are usually ordered in nature. For example, "earning money" usually comes before "spending money". Fourth one is "absolute timepoint". This category deals with the understanding of when events usually happen. For example, "going to school" usually happens during the day (not at 2 A.M). The last category is "frequency" which refers to how often an event is likely to be repeated. For example, "taking showers" typically occurs 5 times a week, "going to saturday market" usually happens every few weeks/months, etc.
	GPT-2 XL	going to school . Indicate with ‘ No ‘, otherwise . We define five categories of temporal reasoning . First: "event duration" which is defined as the understanding of how long events last . Abstract

Recently, there has been a growing interest in designing text generation systems from a discourse coherence perspective, e.g., modeling the interdependence between sentences. Still, recent BERT-based evaluation metrics are weak in recognizing coherence, and thus are not reliable in a way to spot the discourse-level improvements of those text generation systems. In this work, we introduce DiscoScore, a parametrized discourse metric, which uses BERT to model discourse coherence from different perspectives, driven by Centering theory. Our experiments encompass 16 non-discourse and discourse metrics, including DiscoScore and popular coherence models, evaluated on summarization and document-level machine translation (MT). We find that (i) the majority of BERT-based metrics correlate much worse with human rated coherence than early discourse metrics, invented a decade ago; (ii) the recent state-of-the-art BARTScore is weak when operated at system level—which is particularly problematic as systems are typically compared in this manner. DiscoScore, in contrast, achieves strong system-level correlation with human ratings, not only in coherence but also in factual consistency and other aspects, and surpasses BARTScore by over 10 correlation points on average. Further, aiming to understand DiscoScore, we provide justifications to the importance of discourse coherence for evaluation metrics, and explain the superiority of one variant over another. Our code is available at `https://github.com/AIPHES/DiscoScore`.

1 Introduction

In discourse, coherence refers to the continuity of semantics in text. Often, discourse relations and lexical cohesion devices, such as repetition and coreference, are employed to connect text spans, aiming to ensure text coherence. Popular theories in the linguistics community on discourse were provided by Grosz et al. (1995) and Mann and Thompson (1988). They formulate coherence through the lens of readers' focus of attention, and rhetorical discourse structures over sentences. Later on, coherence models as computational approaches of these theories emerged to judge text coherence in discourse tasks such as sentence ordering and essay scoring (Barzilay and Lapata, 2008; Lin et al., 2011; Guinaudeau and Strube, 2013).

While humans also often use text planning at discourse level prior to writing and speaking, up until recently, the majority of natural language generation (NLG) systems, be it text summarization or document-level MT, has performed sequential word prediction without considering text coherence. For instance, MT systems mostly do not model the interdependence between sentences and translate a document at sentence level, and thus produce many incoherent elements such as coreference mistakes in system outputs (Maruf et al., 2021). Only more recently has there been a surge of interest towards discourse based summarization and MT systems, aiming to model inter-sentence context, with a focus on pronominal anaphora (Voita et al., 2018; Liu et al., 2021) and discouse relations (Miculicich et al., 2018; Xu et al., 2020).

However, there appears a mismatch between discourse based NLG systems and non-discourse NLG evaluation metrics such as MoverScore (Zhao et al., 2019) and BERTScore (Zhang et al., 2020) which have recently become popular for MT and summarization evaluation. As these metrics base their judgment on semantic similarity (and lexical overlap (Kaster et al., 2021)) between hypotheses and references—which by design does not target text coherence—it is not surprising that they do not correlate well with human rated coherence (Fabbri et al., 2021; Yuan et al., 2021; Sai et al., 2021). Recently, BARTScore (Yuan et al., 2021) receives increasingly attention, which uses sequence-to-sequence language models to measure the likeli-

Hypothesis

Chelsea have made an offer for FC Tokyo forward Yoshinori Muto. The 22-year-old will join Chelsea 's Dutch partner club Vitesse Arnhem on loan next season if he completes a move to Stamford Bridge. Chelsea signed a £200million sponsorship deal with Japanese company Yokohama Rubber in February.

Reference

Naoki Ogane says that Chelsea have made an offer for Yoshinori Muto. The 22-year-old forward has one goal in 11 games for Japan. Muto admits that it is an 'honour' to receive an offer from the Blues. Chelsea have signed a £200m sponsorship deal with Yokohama Rubber. Muto graduated from university with an economics degree two weeks ago. He would become the first Japanese player to sign for Chelsea.

(b) SentGraph

Figure 1: Sample hypothesis and reference from SUMEval. Each focus[1] is marked in a different color, corresponding to multiple tokens as instances of a focus. Foci shared in Hypothesis and Reference are marked in the same color. (a)+(b) are adjacency matrices used to model focus-based coherence for Hypothesis; for simplicity, adjacency matrices for Reference are omitted. FocusDiff and SentGraph are the variants of DiscoScore. For FocusDiff, we use (a) to depict the relations between foci and tokens, reflecting focus frequency. For SentGraph, we use (b) to depict the interdependence between sentences according to the number of foci shared between sentences and the distance between sentences.

hood that hypothesis and reference are paraphrases, and that cannot contrast text pairs at discourse level.

In this work, we fill the gap of missing discourse metrics in MT and summarization evaluation, particularly in reference-based evaluation scenarios. We introduce DiscoScore, a parametrized discourse metric, which uses BERT to model discourse coherence through the lens of readers' focus, driven by Centering theory (Grosz et al., 1995). The DiscoScore variants can be distinguished in how we use *focus*—see Figure 1: (i) we model focus frequency and semantics, and compare their difference between hypothesis and reference and (ii) we use focus transitions to model the interdependence between sentences. Building upon this, we present a simple graph-based approach to compare hypothesis with reference.

We compare DiscoScore with a range of baselines, including discourse and non-discourse metrics, and coherence models on summarization and document-level MT datasets. Our contributions and findings are summarized as follows:

- Recent BERT-based metrics and the state-of-the-art BARTScore (Yuan et al., 2021) are all weak in system-level correlation with human ratings, not only in coherence but also in other aspects such as factual consistency. Most of them are even worse than very early discourse metrics, RC and LC (Wong and Kit, 2012)—which require neither source texts nor references and use discourse features to predict hypothesis coherence.
- DiscoScore strongly correlates with human rated coherence and many other aspects, over 10 points (on average across aspects) better than BARTScore and two strong baselines RC and LC in the single and multi-references settings. This indicates that either leveraging contextualized encoders or finding discourse features is not sufficient, suggesting to combine both as DiscoScore does.
- We demonstrate the importance of including discourse signals in the assessment of system outputs, as the discourse features derived from DiscoScore can strongly separate hypothesis from reference. Further, we show that the more discriminative these features are, the better the metrics perform, which allows for interpreting the performance gaps between the variants of DisoScore.
- We investigate two focus choices popular in the discourse community, i.e., noun (Elsner and Charniak, 2011) and semantic entity (Mesgar and Strube, 2016). Our results show that entity as focus is not always helpful, but when it helps, the gain is big.

2 Related work

Evaluation Metrics. Traditional metrics such as BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) measure lexical n-gram overlap between a hypothesis and a human reference. As they fail to measure semantic similarity in the absence of lexical overlap, several metrics have been proposed to overcome this issue, which carry out soft lexical matching with static word embeddings (Ng and Abrecht, 2015) and synonym matching (Lavie and Agarwal, 2007). However, none of those metrics

---

[1] The formal definition of focusing in discourse is given on two levels (Grosz et al., 1977): (i) readers are said to be *globally* focusing on a set of entities relevant to the overall discourse, and (ii) readers focus on a particular entity that an utterance *locally* concerns most. Section 3 elaborates on focus as a key ingredient of DiscoScore.

can properly judge text coherence (Kryscinski et al., 2019; Zhu and Bhat, 2020).

Recently, a class of novel metrics based on BERT (Devlin et al., 2019) has received a surge of attention, as they correlate strongly with human judgment of text quality in both reference-based and reference-free scenarios (Zhao et al., 2019; Zhang et al., 2020; Sellam et al., 2020; Rei et al., 2020; Gao et al., 2020; Thompson and Post, 2020; Zhao et al., 2020; Pu et al., 2021; Chen et al., 2021). While strong at sentence-level, these metrics are weak in recognizing coherence in inter-sentence contexts (just like BLEU and ROUGE), as BERT and the majority of BERT variants[2] that these metrics build on only capture discourse phenomena to a certain extent (Koto et al., 2021; Laban et al., 2021; Beyer et al., 2021). Thus, they are not suitable for evaluating long texts as in document-level MT evaluation. Works that either (i) average sentence-level evaluation scores as document score or (ii) assign a score to the concatenation of sentences within a document (Xiong et al., 2019; Liu et al., 2020; Saunders et al., 2020) do not factor interdependence between sentences into a document score, e.g., do not explicitly punish incoherent elements, thus are also inadequate.

Several attempts have been made towards discourse metrics in MT evaluation. Wong and Kit (2012); Gong et al. (2015); Cartoni et al. (2018) use the frequency of lexical cohesion devices (e.g., word repetition) over sentences to predict coherence of hypothesis translations, while Guzmán et al. (2014) and Joty et al. (2017) suggest to compare the difference of rhetorical structures between hypothesis and reference translations. Recently, Jiang et al. (2021) measure the inconsistency between hypothesis and reference translations in several aspects such as verb tense and named entities. However, these metrics do not leverage strong contextualized encoders, as has been shown to be a key ingredient for recent success of BERT-based metrics. Most recently, BARTScore (Yuan et al., 2021) uses sequence-to-sequence pretrained language models such as BART (Lewis et al., 2020) to measure how likely hypothesis and reference are paraphrased according to the probability of one given the other. While BARTScore constitutes the recent state-of-the-art in sentence-level correlation with human ratings in several aspects (incl. discourse), we find that (i) it performs still poorly at system level—which is particularly problematic as systems are typically compared in this manner. (ii) As based on a 'blackbox' language model, it cannot offer insights towards how it models coherence and what discourse phenomena it does (not) capture.

Coherence Models. In discourse, there have been many computational models (Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013; Pitler and Nenkova, 2008; Lin et al., 2011) for text coherence assessment, the majority of which differ in *regularities* that they use to distinguish coherent from incoherent text, driven by different linguistic theories, *v.i.z.*, a pattern of (i) focus transitions in adjacent sentences (Grosz et al., 1995) and (ii) text organization regarding discourse relations over sentences (Mann and Thompson, 1988). For instance, Barzilay and Lapata (2008) and Guinaudeau and Strube (2013) use the distribution of entity transitions over sentences to predict text coherence, while Pitler and Nenkova (2008) and Lin et al. (2011) suggest to produce discourse relations over sentences with a discourse parser, showing that the relations are indicative of text coherence. In the last few years, neural coherence models have been explored. Popular examples are Tien Nguyen and Joty (2017), Mesgar and Strube (2018) and Moon et al. (2019). As they and the recent state-of-the-art (Mesgar et al., 2021) all have been trained on text readability datasets, with readability labels as supervision, they may suffer issues of domain shift when applied to MT and summarization evaluation. More importantly, they judge hypothesis coherence in the absence of reference, thus are not sufficient for reference-based evaluation. Our experiments involve two popular, unsupervised coherence models, entity graph (Guinaudeau and Strube, 2013) and lexical graph (Mesgar and Strube, 2016) treated as discourse metrics with the advantages on robustness (Lai and Tetreault, 2018).

Discourse Test Sets. Apart from evaluation metrics, there have been several discourse-focused test sets proposed to compare NLG systems, most of which have been studied in MT evaluation. For instance, the DiscoMT15 shared task (Hardmeier et al., 2015) compares MT systems, not based on translation adequacy but on the accuracy of pronoun translation for English-to-French, i.e., counting the number of correctly translated pronouns, given the annotated ones in reference. Bawden

---

[2] Recently, several discourse BERT variants such as Conpono (Iter et al., 2020) have been proposed, but they are not always helpful for evaluation metrics—see Table 2 (appendix).

et al. (2018) extend this by labeling both anaphoric pronouns and lexical cohesion devices on test sets, while Voita et al. (2018) construct English-to-Russian test sets focusing on deixis, ellipsis and lexical cohesion. Guillou et al. (2018); Lopes et al. (2020) construct English-to-German and English-to-French test sets targeting pronouns. While reliable, these test sets involve costly manual annotation, thus are limited to few language pairs.

In this work, we introduce DiscoScore to judge system outputs, which uses BERT to model readers' focus within hypothesis and reference, and thus clearly outlines the discourse phenomena being captured, serving as low-cost alternatives to discourse test sets for comparing discourse based NLG systems. More prominently, we derive discourse features from DiscoScore, which we use to understand the importance of discourse for evaluation metrics, and explain why one metric is superior to another. This parallels recent effort towards explainability for non-discourse evaluation metrics (Kaster et al., 2021; Fomicheva et al., 2021). Finally, we show that simple features can be indicative of the superiority of a metric, which fosters research towards finding insightful features with domain expertise and building upon these insights to design high-quality metrics.

3 Our Approach

In the following, we elaborate on the two variants of DiscoScore, FocusDiff and SentGraph, which we refer to as DS-FOCUS and DS-SENT.

Focus Difference. In discourse, there have been many corpus-based studies towards modeling focus transitions over sentences, showing that focus transition patterns are indicative of text coherence (Barzilay and Lapata, 2008; Guinaudeau and Strube, 2013). When reading a document, readers may have multiple *focus of attention*,

each associated to a group of expressions: (i) referring expressions such as pronouns and (ii) semantically related elements such as [*Berlin, capital*].

Here, we assume two focus based conditions that a coherent hypothesis should meet in reference-based evaluation scenarios:

- A large number of focus overlaps between a hypothesis and a reference.
- Each focus overlap is nearly identical in terms of semantics and frequency, where frequency shows how often a focus is mentioned in a hypothesis or in a reference.

In the following, we present focus modeling towards semantics and frequency, according to which we compare hypothesis with reference.

For a hypothesis, we introduce a bipartite graph $\mathcal{G}^{\text{hyp}} = (\mathcal{V}, \mathcal{S}, \mathbf{A}^{\text{hyp}})$, where $\mathcal{V}$ and $\mathcal{S}$ are two sets of vertices corresponding to a set of foci and all tokens (per occurrence a word is a separate token) within a hypothesis. Let $\mathbf{A} = \{0,1\}^{n \times m}$ be an adjacency matrix where n and m are the number of foci and tokens respectively, and A_{ij} equals 1 if and only if the i-th focus associates to the j-th token. Let $\mathbf{F}^{\text{hyp}} \in \mathbb{R}^{n \times d}$ be a matrix of focus embeddings and $\mathbf{Z}^{\text{hyp}} \in \mathbb{R}^{m \times d}$ be a matrix of contextualized token embeddings with d as the embedding size. Similarly, we use notation $\mathcal{G}^{\text{ref}}$, $\mathbf{F}^{\text{ref}}$ and $\mathbf{Z}^{\text{ref}}$ for a human reference.

We use contextualized encoders such as BERT to produce token embeddings $\mathbf{Z}^{\text{hyp}}$ and $\mathbf{Z}^{\text{ref}}$. We use a simple approach to model both semantics and frequency of a focus. That is, we assign per focus v an embedding by summing token embeddings that a focus is associated to:

$$\mathbf{F}_v^{\text{hyp}} = \sum_{u \in \mathcal{N}(v)} \mathbf{Z}_u^{\text{hyp}}, \ \mathbf{F}_v^{\text{ref}} = \sum_{u \in \mathcal{N}(v)} \mathbf{Z}_u^{\text{ref}} \tag{1}$$

where $\mathcal{N}(v)$ is a set of tokens (e.g., a group of semantically related expressions) associated with a focus v. In matrix notation, we rewrite Eq. (1) to $\mathbf{F}^{\text{hyp}} = \mathbf{A}^{\text{hyp}}\mathbf{Z}^{\text{hyp}}$, similarly for $\mathbf{F}^{\text{ref}}$.

Next, we measure the distance between a common set of foci Ω in a hypothesis and reference pair based on their embeddings:

$$\text{DS-F}\text{OCUS}(\text{hyp}, \text{ref}) = \frac{1}{\text{N}} \sum_{\text{u} \in \Omega} \|\mathbf{F}_{\text{u}}^{\text{hyp}} - \mathbf{F}_{\text{u}}^{\text{ref}}\| \tag{2}$$

where DS-FOCUS is scaled down by the factor of N, the number of foci in hypothesis.

Sentence Graph. Few contextualized encoders can produce high-quality sentence embeddings in the document context, as they do not model interdependence between sentences. According to Centering theory (Grosz et al., 1995), two sentences are marked continuous in meaning when they share at least one focus, on the one hand; one marks a meaning shift for two sentences when no focus appears in common, on the other hand. From this, one can aggregate sentence embeddings for which corresponding sentences are considered continuous. In the following, we present a graph-based approach to do so.

For a hypothesis[3], let $\mathbf{S}^{\text{hyp}} \in \mathbb{R}^{n \times d}$ be a matrix of sentence embeddings with n and d as the number of sentences and the embedding size. We introduce a graph $\mathcal{G}^{\text{hyp}} = (\mathcal{V}, \mathbf{A}^{\text{hyp}})$ where $\mathcal{V}$ is a set of sentences and $\mathbf{A}^{\text{hyp}}$ is an adjacency matrix weighted according to the number of foci shared between sentences and the distance between sentences as listed below to depict two variants of $\mathbf{A}^{\text{hyp}}$:

- unweighted: $\mathbf{A}^{\text{hyp}}_{ij} = 1/(j-i)$ if the i-th and the j-th sentences have at least one focus in common (otherwise 0), where $j-i$ denotes the distance between two sentences and $\mathbf{A}^{\text{hyp}}_{ij} = 0$ when $j \leq i$.
- weighted: $\mathbf{A}^{\text{hyp}}_{ij} = a/(j-i)$, where a is the number of foci shared in the i-th and the j-th sentences, with the same constraints on j and i as above.

Analyses by Guinaudeau and Strube (2013) indicate that global statistics (e.g., average) over such adjacency matrices can distinguish incoherent from coherent text to some degree. Here we depict adjacency matrices as a form of sentence connectivity derived from focus transitions over sentences. We use them to aggregate sentence embeddings from hypothesis and from reference:

$$\hat{\mathbf{S}}^{\text{hyp}} = (\mathbf{A}^{\text{hyp}} + \mathbf{I})\mathbf{S}^{\text{hyp}}, \ \hat{\mathbf{S}}^{\text{ref}} = (\mathbf{A}^{\text{ref}} + \mathbf{I})\mathbf{S}^{\text{ref}}$$

where $\mathbf{I}$ is an identity matrix that adds a self-loop to a graph so as to include self-embeddings when updating them.

Next, we derive per graph an embedding with simple statistics from $\hat{\mathbf{S}}^{\text{hyp}}$ and $\hat{\mathbf{S}}^{\text{ref}}$, i.e., the concatenation of mean-max-min-sum embeddings. Finally, we compute the cosine similarity between two graph-level embeddings:

$$\text{DS-SENT}(\text{hyp}, \text{ref}) = \text{cosine}(\mathcal{G}^{\text{hyp}}, \mathcal{G}^{\text{ref}}) \quad (3)$$

Choice of Focus. In discourse, often four popular choices are used to describe a focus: (i) a noun that heads a NP (Barzilay and Lapata, 2008), (ii) a noun (Elsner and Charniak, 2011), (iii) a coreferent entity associated with a set of referring expressions (Guinaudeau and Strube, 2013) and (iv) a semantic entity associated with a set of lexical related words (Mesgar and Strube, 2016).

In this work, we investigate two focus choices: noun (NN) and semantic entity (Entity). Linguistically speaking, the latter is a lexical cohesion device in the form of repetition. From this, NN as focus yields few useful coherence signals but a lot of noise, while Entity as focus uses 'signal compression' by means of aggregation to produce better signals. To produce entities, we first extract all nouns in hypothesis (or reference), and aggregate them into different semantic entities if their cosine similarities based on Dep2Vec word embeddings (Levy and Goldberg, 2014) is greater than a threshold—assuming that nouns with high similarity refer to the same semantic entity.

4 Experiments

4.1 Evaluation Metrics

In the following, we list all of the evaluation metrics, and elaborate on them in Appendix A.1.

Non-discourse Metrics. We consider BLEU (Papineni et al., 2002), ROUGE (Lin, 2004), BERTScore (Zhang et al., 2020), MoverScore (Zhao et al., 2019), SBERT (Reimers and Gurevych, 2019), S^3-pyr (Peyrard et al., 2017), BLEURT (Sellam et al., 2020), BARTScore (Yuan et al., 2021), PRISM (Thompson and Post, 2020).

Discourse Metrics. We consider RC and LC (Wong and Kit, 2012) and Lexical Chain (Gong et al., 2015). We consider two coherence models, EntityGraph (Guinaudeau and Strube, 2013) and LexicalGraph (Mesgar and Strube, 2016), and treat them as discourse metrics.

DiscoScore. DS-FOCUS can be parameterized with two focus choices: noun (NN) or semantic entity (Entity). DS-SENT can be parameterized not only with focus, but also with the choices of *unweighted* (-U) and *weighted* (-W). For DS-FOCUS, we use Conpono (Iter et al., 2020) that finetuned BERT with a novel discourse-level objective regarding sentence ordering. For DS-SENT, we use BERT-NLI. This is because we find this configuration performs best after initial trials—see Table 2 (appendix). Figure 5 (appendix) shows all variants of DiscoScore. Concerning the threshold of Dep2Vec to produce entities, after experimenting with several alternatives we set it to 0.8 for DS-FOCUS (Entity) in all setups, and to 0.8 in summarization and to 0.5 in MT for DS-SENT (Entity).

---

[3] For simplicity, we omit the notation $\mathbf{S}^{\text{ref}}$ and $\mathcal{G}^{\text{ref}}$ for a reference.

4.2 Datasets

We consider two datasets in summarization: SummEval (Fabbri et al., 2021) and NeR18 (Grusky et al., 2018), and one dataset in document-level MT: WMT20 (Mathur et al., 2020). Note that these datasets consist of hypotheses paired with human-written references, where hypotheses are machine-generated texts of varying qualities given by neural and non-neural, extractive and abstractive language models. We outline these datasets in Appendix A.2, and provide data statistics in Table 9 (appendix).

5 Results

We first examine the importance of discourse for evaluation metrics—which underpins the usefulness of discourse metrics, and then benchmark DiscoScore on summarization and MT datasets.

Importance of Discourse. DS-Focus and DS-Sent concern the modeling of discourse coherence on two different levels: (i) the occurrences of foci, and (ii) the interdependence between sentences driven by focus transitions, both reflecting the discourse characteristics of a text. In the following, we describe these discourse features, and examine their importance for assessing system outputs by contrasting the discourse patterns of hypothesis and reference.

- **Focus Frequency**, denoted by FREQ(x), equals the ratio between the total frequencies of foci and the number of foci in a text x, where x is hypothesis or reference. We exclude foci occurring only once.
- **Sentence Connectivity**, denoted by Conn(x), equals the average of all elements in adjacency matrix representing the interdependence between sentences in a text x (hypothesis/reference).
- As in DiscoScore, we consider two focus choices (NN and Entity) and the choices of *unweighted* (-U) and *weighted* (-W) for these discourse features. Figure 5 (appendix) shows the links between DiscoScore and the features.

Figure 2 shows that the scales on FREQ(ref) and FREQ(hyp) in summarization differ by a large amount, i.e., from 0.5 to 2.5 on y-axis and up to 6 on x-axis. This means that hypothesis and reference can be strongly distinguished by Freq(x), which underpins the usefulness of including such discourse signals in the assessment of system outputs when references are available. Further, the larger scale on FREQ(hyp) indicates that foci in hypothesis are more repetitive than in reference, as a result of needless repetition in poor summaries—in line with previous studies on incoherent machine translations (Guillou, 2013; Voita et al., 2019). The results for other discourse features are similar, we provide them in Figure 6 (appendix).

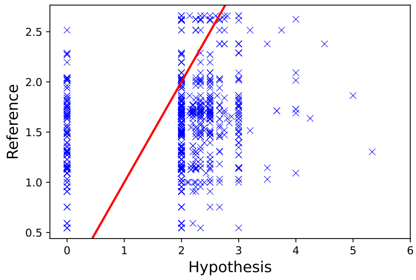

Figure 2: Scatter plot to display FREQ(hyp) (based on NN) on x-axis and FREQ(ref) on y-axis on SUMMEval. Each point contains two frequencies from a pair of hypothesis and reference. The points below the auxiliary line are the ones for which FREQ(hyp) > FREQ(ref).

Overall, these results show discourse features can separate hypothesis from reference.

5.1 Text Summarization

Correlation Results. Table 1 compares metrics on SUMMEval on system level. Most of non-discourse metrics have a lowest correlation with human rated coherence among four quality aspects. Even worse, ROUGE-L and SBERT do not correlate with coherence whatsoever. BARTScore, the recent state-of-the-art metric, is very weak when operated on system level, notwithstanding that it has been fine-tuned on "document-to-summary" parallel data from CNN/DailyMail—which SUMMEval is constructed from. We note that SUMMEval uses multiple references. BARTScore by default compares a hypothesis with one reference at a time, then takes the average of multiple evaluation scores as a final score. Table 8 (appendix) shows that we can improve system-level BARTScore to some degree by replacing 'average' with 'max' (i.e., taking the maximum score), but DS-Focus is still much better overall, i.e., surpassing BARTScore by ca. 10 points on average.

Table 7 (appendix) reports correlation results on NeR18 that uses single reference. We find that half of hypotheses do not contain 'good foci', and as such the foci-based discourse features outlined

	DS-Sent-u (Entity)	54.55	60.61	75.76	66.67	64.39
	DS-Sent-w (NN)	51.52	51.52	66.67	63.64	58.33
	DS-Sent-w (Entity)	51.52	57.58	66.67	63.64	59.85

Table 1: System-level Kendall correlations between metrics and human ratings of summary quality on SUMMEval. We bold numbers that significantly outperform others according to paired t-test (Fisher et al., 1937). m is a metric.

previously are less discriminative on NeR18 than on SUMMEval—see Table 9 (appendix). However, DS-Focus is still strong, ca. 20 points better than BARTScore in all aspects, despite that DS-Focus uses a much smaller contextualized encoder[4]. We note that the 'F-score' version of DS-Focus seems extremely strong on NeR18, but it is not robust across datasets, e.g., much worse than the original, precision-based DS-Focus on SUMMEval.

On a side note, coherence (mostly) strongly correlates with the other rating aspects on both SUMMEval and NeR18—see Figure 3. Thus, it is not surprising that both DS-Focus and DS-Sent correlate well with these aspects, despite that we have not targeted them. While strong on system level, DiscoScore could not show advantages on summary level—see Table 5 (appendix), but we argue that system-level correlation deserves the highest priority as systems are compared in this manner.

Overall, these results show that BERT-based non-discourse metrics correlate weakly with human ratings on system level. BARTScore also does so, though we improve it to some degree in multi-references settings. DiscoScore, particularly DS-Focus, performs consistently best in both single- and multi-references settings, and it is equally strong in all aspects.

As for discourse metrics, RC and LC that use discourse features are strong baselines as they outperform most of non-discourse metrics and coherence models (i.e., Entity and Lexical Graph) without the access to source texts and references. However, they are worse than both DS-Focus and DS-Sent. This confirms the inadequacy of RC and LC in that they do not leverage strong contextualized encoders and judge hypothesis in the absence of references. Moreover, we compare DiscoScore to a combination of two strong, complementary baselines, BARTScore and RC—a simple solution to address text coherence of non-discourse metrics. To combine them, we simply average their scores. We see the gains are additive in all aspects but coherence. DS-Focus wins all the time by a large margin—see Table 10 (appendix).

Taken together, these results show that any of the three—(i) leveraging contextualized encoders as in BERT-based metrics and BARTScore; (ii) leveraging discourse features as in RC and (iii) the ensemble of (i) and (ii) by averaging—is not sufficient, suggesting to combine (i) and (ii) as DiscoScore does.

Understanding DiscoScore. As for all variants of DiscoScore, we provide understanding on why

---

[4] DS-Focus uses Conpono on the same size of BERTBase. BARTScore uses BARTLarge finetuned on CNN/DailyMail.

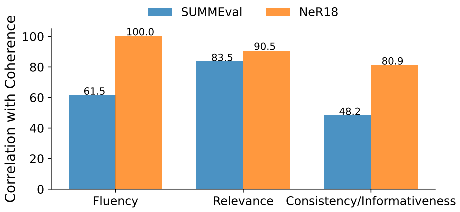

Figure 3: Pearson Correlation between coherence and other aspects on system level. SUMMEval and NeR18 use Consistency and Informativeness respectively.

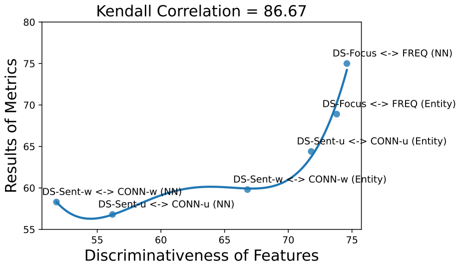

Figure 4: Correlations between the results of metrics and the discriminativeness of features on SUMMEval. Metric results are averaged across four rating aspects.

one variant is superior to another with the discourse features outlined in Figure 5 (appendix). To this end, we begin with defining the *discriminativeness* of these features as the magnitude of separating hypothesis from reference:

$$\mathcal{D}_{\mathcal{R}}(\text{hyp}, \text{ref}) := \frac{|\{(\text{hyp}, \text{ref})|\mathcal{R}(\text{ref}) < \mathcal{R}(\text{hyp})\}|}{N} \tag{4}$$

where N is a normalization term, $\mathcal{R}$ is any one of the discourse features in Figure 5 (appendix).

Figure 4 shows that the discriminativeness of these features strongly correlate with the results of the DiscoScore variants, i.e., that the more discriminative the features are, the better the metrics perform. This attributes the superiority of a metric to the fact that the discourse feature can better separate hypothesis and reference.

From this, we can interpret the performance gaps between the DiscoScore variants, namely (i) DS-Focus over DS-Sent: given *Focus Frequency* is more discriminative than *Sentence Connectivity*, it is not surprising that DS-Focus modeling discourse coherence with the former outperforms DS-Sent modeling with the latter, and (ii) DS-Focus (NN) outperforms DS-Focus (Entity) because *Frequency (NN)* can better separate hypothesis from reference than *Frequency (Entity)*.

Analyses. We provide analyses on the configuration of DiscoScore from three perspectives—see Appendix A.3: (i) the choice of BERT variants towards discourse- versus non-discourse BERT; (ii) the impact of adjacency matrices accounting for the interdependence between sentences and (iii) that we compare statistics- and alignment-based approaches to examine the best configuration for DS-Sent. Our results show the advantages of adjacency matrices and statistics based approach, and that discourse BERT only helps for DS-Focus.

5.2 Document-level Machine Translation

Correlation Results. Table 12 (appendix) compares metrics on WMT20. We see that non-discourse metrics seem much better, but these results are not consistent to the discriminativeness of the discourse features—see Table 11 (appendix). For instance, in cs-en, the discourse features (Frequency and Connectivity) corresponding to DS-Focus and DS-Sent clearly separate hypothesis from reference due to the probability of $\mathcal{D} > 0$ being over 70%. However, both DS-Focus and DS-Sent correlate weakly with human rated adequacy. Recently, Freitag et al. (2021a) provide justification to the inadequacy of the 'adequacy' ratings, as 'adequacy' sometimes cannot distinguish human from system translations and correlates weakly with multiple aspects (e.g., fluency and accuracy). Thus, they re-annotate WMT20 with the MQM and pSQM rating schemes, which has been subsumed into the annotation guideline of the most recent WMT evaluation campaign (Freitag et al., 2021b). Here, we perform an extra study on these ratings on both document- and system-levels. Note that system-level ratings are said to be the average of document-level ones in our setting. Table 6 (appendix) shows that DS-Sent is much better than BARTScore on system level, surpassing it by 25 points in terms of MQM and 14 points in pSQM.

Overall, these results in MT are consistent with those in summarization, i.e., DiscoScore is strong on system levels for both tasks, but it cannot show gains on fine-grained levels. Section A.4 (appendix) show inter-correlations between metrics.

6 Conclusions

Given the recent growth in discourse based NLG systems, evaluation metrics targeting the assessment of text coherence are essential next steps for properly tracking the progress of these systems.

Although there have been several attempts made towards discourse metrics, they all do not leverage strong contextualized encoders which have been held responsible for the recent success story of NLP. In this work, we introduced DiscoScore that uses BERT to model discourse coherence from two perspectives of readers' focus: (i) frequencies and semantics of foci and (ii) focus transitions over sentences used to predict interdependence between sentences. We find that BERT-based non-discourse metrics cannot address text coherence, even much worse than early feature-based discourse metrics invented a decade ago. We also find that the recent state-of-the-art BARTScore correlates weakly with human ratings on system level. DiscoScore, on the other hand, performs consistently best in both single- and multi-reference settings, equally strong in coherence and several other aspects such as factual consistency, despite that we have not targeted them. More prominently, we provide understanding on the importance of discourse for evaluation metrics, and explain the superiority of one metric over another with simple features, in line with recent work on explainability for evaluation metrics (Kaster et al., 2021; Fomicheva et al., 2021).

Scope for future research is huge, e.g., developing reference-free discourse metrics comparing source text to hypothesis, improving discourse metrics on fine-grained levels[5], and ranking NLG systems via discourse metrics and rigorous approaches (Peyrard et al., 2021; Kocmi et al., 2021).

7 Impact and Limitations

To our knowledge, we, for the first time, combine the elements of discourse and BERT representations to design an evaluation metric (DiscoScore) for text quality assessment in summarization and MT. While our experiments are conducted on English datasets, DiscoScore could adapt to many other languages in which references and foci are available. We believe that this work fosters future research on text generation systems endowed with the ability to produce well-formed texts in discourse.

However, we acknowledge several limitations of this work, which require further investigation in future. We now discuss them in the following:

Entity as Focus. We follow the idea of Mesgar and Strube (2016) in the discourse community, which clusters nouns into entities based on their static word embeddings. Although simple, it sometimes helps for DiscoScore. However, alternatives aiming to produce better entities have not been explored in this work, e.g., replacing static with contextualized embeddings, and weighting entities by their occurrences in hypothesis/reference.

Weakness on Fine-Grained Assessment. In summarization and MT, we show that our novel DiscoScore largely outperforms the current state-of-the-art BARTScore on system levels for both tasks, while it cannot show advantages on finer-grained levels such as document- and summary-levels. This might be because modeling focus alone is insufficient to perform much more challenging, finer-grained assessment of text quality. Future work could also factor other discourse phenomena (e.g., discourse connectives and coreference) into the assessment of text coherence.

Acknowledgments

We thank the anonymous reviewers for their thoughtful comments that greatly improved the texts. [5] Recently, Steen and Markert (2022) introduce a fine-grained evaluation setup to compute summary-level correlation, which performs computing over summaries not produced by multiple systems, but rather by a single system. This is because systems sometimes substantially differ in quality, which implies that involving multiple systems could result in inaccurate evaluation outcomes in the presence of system-level confounders.

A Appendix

A.1 Evaluation Metrics

Non-discourse Metrics. We consider the following non-discourse metrics.

- BLEU (Papineni et al., 2002) and ROUGE (Lin, 2004) are precision- and recall-oriented metrics respectively, both of which measure n-gram overlap between a hypothesis and a reference.

- BERTScore (Zhang et al., 2020) and MoverScore (Zhao et al., 2019) are set-based metrics used to measure the semantic similarity between hypothesis and reference. BERTScore uses greedy alignment to compute the similarity between two sets of BERT-based word embeddings from hypothesis and from reference, while MoverScore uses optimal alignments based on Word Mover's Distance (Kusner et al., 2015) to do so.

- SBERT (Reimers and Gurevych, 2019) fine-tunes BERT on the NLI datasets and uses pooling operations to produce sentence embeddings. We compute the cosine similarity between two sentence representations from hypothesis and from reference.

- S^3-pyr and S^3-resp (Peyrard et al., 2017) are supervised metrics that linearly combine ROUGE, JS-divergence and ROUGE-WE scores, trained on the TAC datasets with human annotated pyramid and responsiveness scores as supervision.

- BLEURT (Sellam et al., 2020) is another supervised metric that fine-tunes BERT on the concatenation of WMT datasets and synthetic data in the MT domain, with human judgment of translation quality as supervision.

- BARTScore (Yuan et al., 2021) and PRISM (Thompson and Post, 2020) depict sequence-to-sequence language models as metrics to compare hypothesis with reference. In reference-based settings, they both measure the likelihood that hypothesis and reference are paraphrases, but differ in the language models they rely on. PRISM has been based on a neural MT system trained from scratch on parallel data in MT, while BARTScore uses BART (Yuan et al., 2021) that has been fine-tuned on CNN/DailyMail (Hermann et al., 2015)—which is parallel data in summarization. We use the 'F-score' version of BARTScore as recommended in Yuan et al. (2021).

Discourse Metrics. We consider the following discourse metrics (including ours and coherence models).

- RC and LC (Wong and Kit, 2012) require neither source texts nor references and use lexical cohesion devices (e.g., repetition) within a hypothesis to predict text coherence. LC computes the proportion of words within hypothesis that are lexical cohesion devices, while RC computes the proportion of times that lexical cohesion devices appear in hypothesis.

- Entity Graph (Guinaudeau and Strube, 2013) and Lexical Graph (Mesgar and Strube, 2016) are popular coherence models used to perform discourse tasks such as essay scoring, both of which introduce a graph with nodes as sentences and adjacency matrices as the connectivity between sentences. Here, we use the average of adjacency matrices from the hypothesis as the proxy of hypothesis coherence. While Entity Graph draws an edge between two sentences if both sentences have at least one noun in common, Lexical Graph draws an edge if two sentences have a pair of similar words in common, i.e., the cosine similarity between their embeddings greater than a threshold.

- Lexical Chain (Gong et al., 2015) extracts multiple lexical chains from hypothesis and from reference. Each word is associated to a lexical chain if a word appears in more than one sentence. A lexical chain contains a set of sentence positions in which a word appears. Finally, the metric performs soft matching to measure lexical chain overlap between hypothesis and reference.

- FocusDiff and SentGraph are the two variants of DiscoScore, which use BERT to model semantics and coherence of readers' focus in hypothesis and reference. In particular, FocusDiff measures the difference between a common set of foci in hypothesis and reference in terms of semantics and frequency, while SentGraph measures the semantic similarity between two sets of sentence embeddings from hypothesis and reference—which are aggregated according to the number of foci shared across sentences and the distance between sentences.

A.2 Datasets

We outline two datasets in summarization, and one in document-level MT.

Text Summarization. While DUC[6] and TAC[7] datasets with human rated summaries, constructed one decade ago, were the standard benchmarks for comparing evaluation metrics in summmarization, they collect summaries only from extractive summarization systems. In the last few years, abstractive systems have become popular; however, little is known how well metrics judge them. Recently, several datasets based on CNN/DailyMail have been constructed to address this. For instance, SummEval (Fabbri et al., 2021), REALSumm (Bhandari et al., 2020), XSum (Maynez et al., 2020) and FEQA (Durmus et al., 2020) all collect summaries from both extractive and abstractive systems, but differ in the aspects human experts rate summaries. In this work, we consider the following two complementary summarization datasets.

- SummEval has been constructed in multiple-references settings, i.e., that each hypothesis is associated to multiple references. It contains human judgments of summary coherence, factual consistency, fluency and relevance. We only consider abstractive summaries as they have little lexical overlap with references.
- NeR18 (Grusky et al., 2018), in contrast, has been constructed in single-reference settings. It contains human judgments of summary coherence, fluency, informativeness and relevance. As majority of summaries are extractive, we include both extractive and abstractive for the inclusive picture.

Document-level Machine Translation. As document-level human ratings in MT are particularly laborious, hardly ever have there been MT datasets directly addressing them. First attempts suggested to use the average of much cheaper sentence-level ratings as a document score for comparing document-level metrics (Comelles et al., 2010; Wong and Kit, 2012; Gong et al., 2015). However, human experts were asked to rate sentences in isolation within a document. Thus, human ratings at both sentence and document levels cannot reflect inter-sentence coherence. Recently, the WMT20 workshop (Mathur et al., 2020) asks humans to rate each sentence translation in the document context, and follows the previous idea of 'average' to yield document scores.

Metrics	Encoders	Average
DS-FOCUS (NN)	+ BERT	71.97
	+ BERT-NLI	70.45
	+ Conpono	75.00
DS-SENT-U (NN)	+ BERT	35.61
	+ BERT-NLI	56.82
	+ Conpono	23.48

Table 2: Results of three contextualized encoders on SUMMEval. Results are averaged across four aspects.

Metrics	Average
DS-SENT-U (NN)	56.82
w/o sentence aggregation	46.21

Table 3: Ablation study on the use of adjacency matrix to aggregate sentence embeddings on SUMMEval.

In this work, we use the WMT20 dataset with 'artificial' document-level ratings. Note that WMT20 comes with two issues: (i) though sentences are rated in the document context, averaging sentence-level ratings may zero out negative effects of incoherent elements on document level and (ii) unlike SummEval and NeR18, WMT20 only contains human judgment of translation *adequacy* (which may subsume multiple aspects), not *coherence*.

For simplicity, we exclude system and reference translations with lengths greater than 512—the number of tokens at maximum allowed by BERT, as only a small portion of instances is over the token limit. Note that it is effortless to replace BERT with Longformer (Beltagy et al., 2020) to deal with longer documents for DiscoScore.

A.3 Analyses on Text Summarization

Choice of BERT Variants. Table 2 compares the impact of three BERT variants on DiscoScore. Conpono, referred to as a discourse BERT, has fine-tuned BERT with a novel discourse-level objective regarding sentence ordering. While strong on discourse evaluation benchmarks (Chen et al., 2019),

---

[7] `https://tac.nist.gov/data/`

Metrics	Mechanisms	Average
DS-Sent-U (NN)	+ greedy align	21.97
	+ optimal align	26.52
	+ mean-max-min-sum	56.82

Table 4: Averaged results of SentGraph variants based on three mechanisms on SUMMEval.

Metrics	SUMMEval	NeR18
BARTScore	14.13	24.78
PRISM	14.92	18.89
DS-Focus (NN)	10.81	10.42
DS-Sent-U (NN)	15.71	3.81

Table 5: Summary-level averaged Kendall correlations across all rating aspects.

Conpono is not always helpful, e.g., BERT-NLI is better for DS-Sent. These results suggest the best configuration for DiscoScore.

Impact of Sentence Connectivity. Table 3 shows an ablation study on the use of sentence connectivity. Aggregating sentence embeddings with our adjacency matrices (see Eq.3) helps considerably. This confirms the usefulness of aggregation from which we include coherence signals in sentence embeddings.

SentGraph Variants. Table 4 compares three DS-Sent variants as to how we measure the distance between two sets of sentence embeddings from hypothesis and reference. In particular, we refer to BERTScore (Zhang et al., 2020) as a 'greedy align' mechanism used to compute the similarity between two sets of sentence embeddings. As for 'optimal align', we use MoverScore (Zhao et al., 2019) to do so. While the two alignments directly measure the distance between the two sets, the simple statistics, i.e., mean-max-min-sum, derives a graph embedding from each set and computes the cosine similarity between two graph embeddings. We see that the 'statistics' wins by a big margin, and thus adopt this DS-Sent variant in all setups.

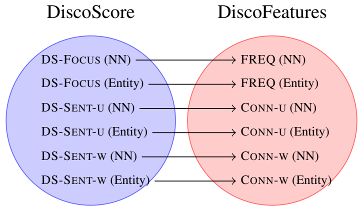

Figure 5: Links between the DiscoScore variants and discourse features.

	Sys-level		Doc-level	
Metrics	MQM	pSQM	MQM	pSQM
BARTScore	45.57	55.50	**34.90**	**28.96**
*DS-Focus (NN)	42.12	40.89	19.10	9.98
DS-Sent-U (NN)	**70.77**	**69.74**	19.98	14.49

Table 6: Document-level Kendall and system-level Pearson correlations between metrics and MQM/pSQM ratings on WMT20 in Chinese-to-English—which is the only language pair with such ratings in reference-based settings. *DS-Focus (NN) excludes focus that occurs only once in hypothesis/reference.

A.4 Analyses on MT

Correlation between Metrics. Figure 7 shows inter-correlations between metrics on WMT20 across languages. Overall, correlations are mostly high between non-discourse metrics, much weaker between discourse and non-discourse metrics—which confirms the orthogonality of them in that they rate translations in different aspects. We note that DS-Focus has the lowest correlations with all other metrics. For instance, DS-Focus is almost orthogonal to BERTScore and MoverScore. We investigated whether combining them receives additive gains. We find that a combination of DS-Focus and BERTScore (or MoverScore) provides little help in correlation with adequacy.

Settings	Metrics	Coherence	Fluency	Informative	Relevance	Average
$m(\text{hyp}, \text{ref})$	BARTScore	42.58	42.58	23.80	33.33	35.57

Abstract

Effective communication requires adapting to the idiosyncrasies of each communicative context—such as the common ground shared with each partner. Humans demonstrate this ability to specialize to their audience in many contexts, such as the popular game Dixit. We take inspiration from Dixit to formulate a multi-agent image reference game where a (trained) speaker model is rewarded for describing a target image such that one (pretrained) listener model can correctly identify it among distractors, but another listener cannot. To adapt, the speaker must exploit differences in the knowledge it shares with the different listeners. We show that finetuning an attention-based adapter between a CLIP vision encoder and a large language model in this contrastive, multi-agent setting gives rise to context-dependent *natural language* specialization from rewards only, without direct supervision. Through controlled experiments, we show that training a speaker with two listeners that perceive differently, using our method, allows the speaker to adapt to the idiosyncracies of the listeners. Furthermore, we show zero-shot transfer of the specialization to real-world data. Our experiments demonstrate a method for specializing grounded language models without direct supervision and highlight the interesting research challenges posed by complex multi-agent communication.

1 Introduction

Human language use is communicative, and thus involves substantial adaptation to each conversational partner and context (Clark and Wilkes-Gibbs, 1986; Clark, 1996; Gallois et al., 2005; Frank and Goodman, 2012; Hawkins et al., 2019, 2022). We can adapt our speech to complex social settings, with multiple partners (Mankewitz et al., 2021; Boyce et al., 2022) and competing constraints, such as politeness vs. explicitness (Yoon et al., 2016). While current language and captioning models can increasingly imitate human language and scene descriptions (Brown et al., 2020; Tsimpoukelli et al., 2021; Mokady et al., 2021; Alayrac et al., 2022; Elhagry and Kadaoui, 2021), they generally are not explicitly adapted to a particular partner or to satisfy multiple constraints. Common approaches to specializing the language generated by these models fall into two categories: finetuning on a supervised dataset (e.g. Hu et al., 2021), which requires task-specific labeled examples, or prompt engineering, which is often brittle and may still require task-specific examples (Liu et al., 2021). Here, we take inspiration from how humans adapt their language to their audience to offer an alternative approach to specializing grounded language models without direct supervision.

Our approach to specialization is inspired by the popular multi-player game Dixit (Roubira, 2008), which rewards each player's ability to adapt their communication to a particular audience. In a round of Dixit, the "speaker" describes a chosen image in language. Then, the rest of the players (two or more "listeners") attempt to identify the target

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3884–3911
May 2-6, 2023 ©2023 Association for Computational Linguistics

image from a pool of distractors. Importantly, the speaker is rewarded when *some but not all* listeners correctly identify the image. This leads to creative captions that target the common ground between a speaker and some (but not all) of the listeners (see example in Figure 1a). For more details, we refer readers to Kunda and Rabkina (2020), who introduce Dixit as a grand challenge for AI.

Using this inspiration, we formulate a setting where grounded language models can specialize their language without direct supervision, from rewards only. We build on prior work in emergent communication (Cogswell et al., 2020), and adapt a pretrained captioning model (the "speaker") by finetuning a small fraction of its parameters to maximize a Dixit-like reward—this minimal adaptation helps reduce language drift (Lee et al., 2019). We go beyond prior work by investigating a complex, not fully cooperative, setting (Figure 1b). The speaker's goal is to communicate information to some listeners, but not others, by exploiting differences in listeners' idiosyncratic "personalities". We instantiate this setting by having a speaker model communicate with multiple (frozen) contrastive listener models differing along perceptual axes. We design careful experiments, with datasets, metrics, and controls to ensure quantifiable assessment of language specialization.

We show that training a speaker with a pair of listeners in this Dixit-inspired setting can lead to *diverse* specialization of natural language, with minimal language drift, and without direct supervision. From rewards, the speaker identifies and learns to cue to the difference between two listeners, which we call "listener subtraction". We show this adaptation across many pairs of perceptually-differing listeners, and various datasets (Section 4.1, 4.2). For example, when trained with one listener which sees color, and another which sees only grayscale, the speaker learns to exclusively use color words—it exploits the specialized information it shares with the first listener. Furthermore, the speaker exhibits some zero-shot transfer of its language specialization from artificial to realistic datasets (Section 4.3). To our knowledge, our work is the first to consider natural language communication in a grounded, multi-listener setting, without direct supervision.

2 Related work

Dixit. Kunda and Rabkina (2020) discuss the full game of Dixit as a grand challenge for AI and posit the various interesting subproblems that would need to be solved (but do not attempt to solve them). Here, we focus on addressing the "Find a Phrase" subproblem—how the speaker should choose a phrase such that some but not all listeners correctly identify the image.

Adapting (grounded) language models. A large body of prior work focuses on adapting large pretrained language models (Hu et al., 2021; Ziegler et al., 2020; Brown et al., 2020; Tsimpoukelli et al., 2021) to various tasks. Our work also focuses on natural language specialization, but differs in that we use no supervised data. In that sense, our work is more similar to approaches that fine-tune pretrained models with reinforcement learning (Stiennon et al., 2020; Ouyang et al., 2022). Unlike those works, we focus on grounded communication. With respect to grounding, we take inspiration from prefix tuning (Li and Liang, 2021) and use an image-to-prefix encoder to condition a pretrained language model on images, as in Tsimpoukelli et al. (2021). These models can adapt their language via prompting (Brown et al., 2020), which we consider as a baseline for our approach.

Pragmatics through model interactions. Work in cognitive science has explored how pragmatic inferences can be explained as reasoning over simpler speaker and listener models (Frank and Goodman, 2012). This perspective aims to explain human pragmatic references in grounded reference games and can help train models that give and follow instructions (Fried et al., 2018) or help train listener models that adapt to individual human speakers (Hawkins et al., 2020). Our work is related to this framework, but differs in that the *speaker model* is adapted to use *differences between multiple listeners*.

Emergent communication. Finally, there is prior work on emergent communication in image reference games. We focus on works involving natural language generation, like our setting. Cogswell et al. (2020) focus on a speaker agent that asks questions in dialogue with a single, pretrained-and-frozen listener, to identify an image among distractors. Lazaridou et al. (2020) consider speaker and listener agents in a more standard image reference game—the speaker describes an image, and the single listener must choose the image among distractors. Both papers use the pretrain-then-finetune approach to minimize language drift; we adopt a similar methodology. Like Cogswell et al.

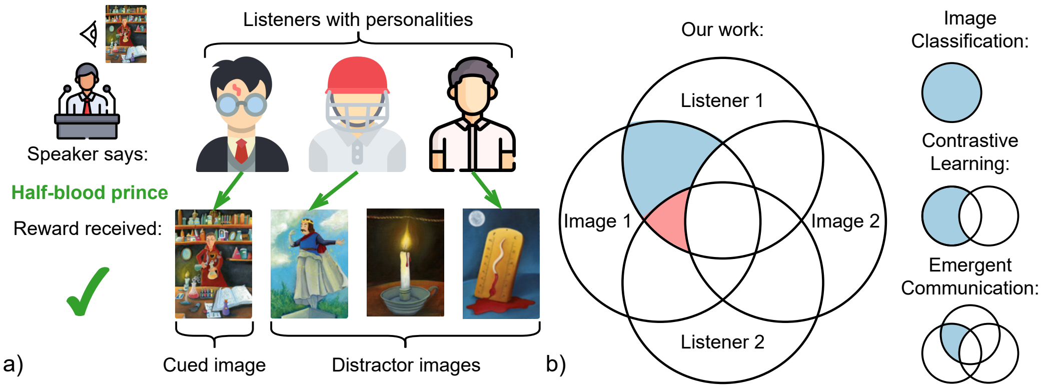

Figure 1: a) An example round of Dixit, the inspiration for our work. The speaker uses a specialized caption (green), so that only one listener (who has read Harry Potter) correctly identifies the image. This outcome is rewarded per the *some but not all* rule. b) How our work relates to past work. Image classification: models say something about an image. Contrastive learning: models say something to distinguish an image from others. Emergent communication: models say something to distinguish an image from others in a way one listener will understand. Our work: models say something to distinguish an image from others in a way one *but not another* listener will understand.

(2020), we freeze our listeners to maintain language grounding (cf. Lee et al., 2019), and focus on the speaker. Unlike prior work, our setting involves simultaneous, natural language communication to multiple listeners and is not fully cooperative.

3 Methods

3.1 Multi-agent image reference game

We focus on a multi-agent image reference game inspired by a single round of Dixit. We frame this problem as a challenge of tuning a pretrained multimodal model to specialize its language, without direct supervision on how to specialize. Our setup (Figure 2) involves one speaker model communicating with multiple listener models about a target image. The speaker model receives the target image and outputs a caption. Each listener model receives the caption and the target image along with some (random) distractor images. Each listener model's goal is to correctly identify the target image from the distractors, based on the speaker's caption.

Following the some-but-not-all reward structure of the Dixit game, we reward the speaker model for *the difference in the (binary) accuracies of listeners 1 and 2 on a given set of images*. To avoid co-adaptation and pragmatic drift (cf. Lazaridou et al., 2020), we pretrain and freeze our listener models. Thus, only the speaker has learnable parameters.

3.2 Speaker model

The speaker model (Figure 2a) is inspired by the *Frozen* model (Tsimpoukelli et al., 2021) and ClipCap (Mokady et al., 2021). We build the speaker using several pretrained components, and adapt only a small piece to our setting. The model is composed of a pretrained-and-frozen CLIP visual encoder (Radford et al., 2021), learned attentive (QKV) adapter layer, and a pretrained-and-frozen Transformer (decoder) language model (Vaswani et al., 2017; Hoffmann et al., 2022). An input image is first passed through the visual encoder. The unpooled output of the encoder is flattened and passed into the adapter, a Perceiver-inspired cross attention layer (Jaegle et al., 2021). The adapter outputs $n = 32$ prefix tokens, which are used to condition the language model and generate up to 32 output tokens. See Appendix A for more details.

The only parameters of this model that are ever trained are in the adapter. We keep the pretrained CLIP encoder and language model frozen (to help prevent language drift), and pretrain the adapter on the Conceptual Captions dataset (Sharma et al., 2018) to give our speaker basic captioning abilities (see Appendix B.1). All our experiments start from this captioning-pretrained base speaker model. We finetune the adapter for each experimental condition, which consists of a dataset to train on and a pair of listeners (we refer to this process as "training the speaker"). We do not have supervision for what to say when playing the game—much as a human player needs to adapt without direct supervision. Instead, we use REINFORCE (Williams, 1992) to train the speaker's adapter parameters, based on the rewards received for differences in the listener accuracies (see Section 3.1). Our choice to finetune only the adapter builds off prior works in emergent communication that use pretrained-and-frozen components (Cogswell et al., 2020; Lazaridou et al., 2020). By repeated interactions with

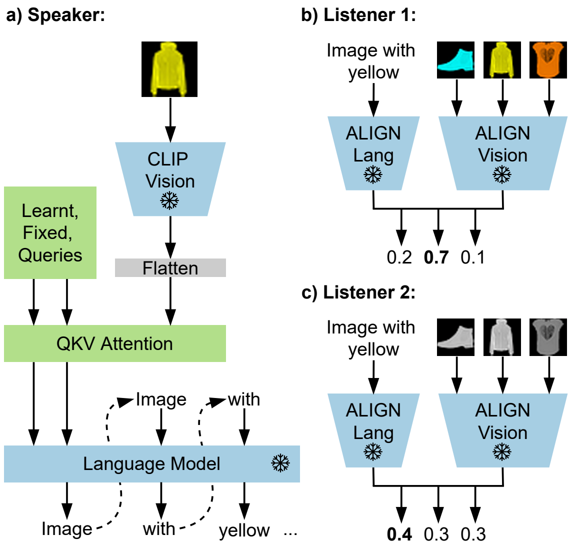

Figure 2: Our setup for cFMNIST and the grayscale transform. a) The speaker receives an image and generates a caption. b) Listener 1 receives unperturbed images and picks best match to the caption (correctly). c) Listener 2 receives images with the grayscale transform applied and picks the best match to the caption (incorrectly). Then, the speaker receives a reward of 1 (the difference in the accuracies) which it uses to update its adapter parameters (green) via REINFORCE. All components in blue are pretrained and frozen.

the same pair of listeners in each experimental condition, the speaker should update its weights to produce specialized language to that listener pair.

3.3 Listener models

For our listener models (Figure 2b,c), we use the vision and language encoders of a pretrained ALIGN NFNet F5 model (Jia et al., 2021; Brock et al., 2021). For a set of input images and caption, we compute image-caption match scores for each image, and the listener selects the image with the highest alignment score.

To investigate the speaker's ability to adapt to distinct listeners, we experimentally manipulate the listeners' knowledge. We use the same pretrained model for each listener, but manipulate each listener's knowledge by applying distinct image transformations to the inputs. For listener 1, we do not transform the input images. For listener 2, we consider the following transformations:

Crop: Images are cropped to the top-right quadrant then resized to the original size.

Blur: Images are Gaussian blurred (radius 25 px).

Grayscale: Images are converted to grayscale.

While listener "personalities" could differ along any linguistic, conceptual, and perceptual axes, we focus on these perceptual transformations because they enable quantitative assessments of language specialization. When listener 2 sees cropped images, we expect the speaker to cue objects outside the cropped region. When listener 2 sees blurred images, we expect the speaker to cue objects without the use of color, as distinct objects will not be visible to the second listener but color will still largely be visible. Conversely, when listener 2 sees grayscale, we expect the speaker to only use color words and to specifically stop referring to objects. We design controlled datasets for each experiment, in which each relevant metric can be measured.

3.4 Datasets and metrics

The main datasets we use are transformed versions of Fashion-MNIST (Xiao et al., 2017). Fashion-MNIST (FMNIST) consists of grayscale images of different types of clothing items. We create a colored version (cFMNIST), where each image is randomly colored with one of 8 colors. To test training with the crop listener, we then create a tiled version of cFMNIST (tcFMNIST) where each image consists of two random cFMNIST images, one in the top-right, and one in the bottom-left. For more realistic images, we use the COCO dataset (Lin et al., 2014), taking center square crops of all images. Example images for all dataset and transform pairs are shown in Figure 3.

For analysis metrics, we first evaluate the proportion of captions generated by the speaker on test images that had color words in them ("color prevalence") and the proportion of captions that contained a clothing-related word ("FMNIST keyword prevalence"). Each of these metrics identifies language specialization. To measure image-relevance of produced language, we compute metrics measuring how often an object word used corresponded to an actual object in the image, accounting for synonyms. These metrics are referred to as "object prevalence" for cFMNIST, and "bottom-left object prevalence" and "top-right object prevalence" for tcFMNIST. For colors, it's difficult to enumerate all synonyms as the model often uses pairs of colors, e.g., "blue and white" for "cyan". Instead, we found that a "color diversity" metric—which measures the speaker's variation in color use—offers an effective proxy for determining color relevance.

See Appendices C, D, for more details on datasets and metrics, respectively.

	Speaker and Listener 1 see:	Listener 2 sees:	Speaker output	
			Start of training:	End of training:
a)			a set of shoes and a t-shirt	a t-shirt
b)			the yellow jacket with a black hood	a hooded jacket
c)			the yellow jacket with a black hood	yellow
d)			person, a cyclist, is pictured in his new bike	a red and white

Figure 3: Example test images and speaker captions at the start and end of training for various experimental conditions. By row, the speaker trains on a different dataset (a: tcFMNIST, b,c: cFMNIST, d: COCO), and the second listener sees a different transformed image (a: top-right crop, b: blurred, c,d: grayscale). Diverse language specialization emerges by the end of training. See Appendix H for more samples.

3.5 Training

A training "episode" consists of the speaker receiving an image (observation), generating a caption (action), and receiving the difference in listener accuracies as a reward. As noted above, only the adapter in the speaker has trainable parameters, which are updated via REINFORCE (Williams, 1992). We use nucleus sampling (Holtzman et al., 2019) to generate captions. We add a small reward penalty to incentivize short captions (a weight λ times the number of words used) as an articulatory effort minimization bias (cf. Lazaridou and Baroni, 2020). We use a batch size of 128 images, with 3 random distractors for each image drawn from the same batch. See Appendix B.3 for more details.

4 Results

4.1 Emergence of specialization

By training a speaker to maximize the difference in accuracy between two fixed listeners, we see strong language specialization across many listener pairs (Figure 3a-c, 4a-c). When the second listener sees only the top-right crop of the image, the speaker learns to cue to objects that the second listener cannot see (Figure 4a, bottom). The first listener's accuracy remains stable through learning, but the second listener's accuracy decreases to chance level. This corresponds to the decrease in top-right object prevalence in the speaker's captions and an *increase* in bottom-left object prevalence.

When the second listener sees only the blurred version of the image, the speaker learns to reduce its use of color words, while still referring to the target object. The overall learning dynamics are similar to the crop case: the first listener's accuracy remains roughly constant, while the second drops to chance level, again paralleling the decrease in color prevalence in the speaker's captions.

By contrast, when the second listener sees only a grayscale image, we see a rapid decrease in object prevalence and increase in color prevalence. However, this initial learning causes both listener accuracies to drop, as the speaker greedily uses colors that may not be image relevant. Then, from iterations 2.5k to 25k, the speaker slowly learns to use more accurate colors for each image, and the first listener's accuracy increases slowly but steadily (while the second listener stays at chance). At the end of training, color diversity is comparable with that produced by language prompts (see Section 4.4.3, Tables 1 and 15), indicating that the speaker is using diverse, image-relevant colors.

These experiments illustrate that the speaker model can optimize its reward in different ways depending on the pair of listeners—decreasing the second listener's accuracy, increasing the first listener's accuracy, or both. Each strategy produces meaningful, measurable changes in the speaker's language, while keeping drift to a minimum. Captions show little structural drift (assessed by an independent language model's likelihoods, Appendix E), as well as little semantic and pragmatic drift (as assessed by the above metrics). See Appendix H for more images, distractors, and speaker ouputs.

4.2 Extending to real world data

We next apply our approach to a setting with real-world data—images from the COCO dataset (Lin et al., 2014). The effect of most transforms is harder to quantify exactly, as the images contain many objects, and enumerating all their synonyms is infeasible. Thus, we use the grayscale transform, which still offers usable metrics (color prevalence and diversity).

Figure 3d, 4d show model samples and the speaker's training curves on COCO. The speaker starts with a high initial accuracy to both listeners. Then, we qualitatively observed (by inspecting model samples) that the speaker starts "exploring" different strategies to differentiate the listeners (iterations 0-20k). Just before 20k iterations, the speaker starts using colors slightly more often, then

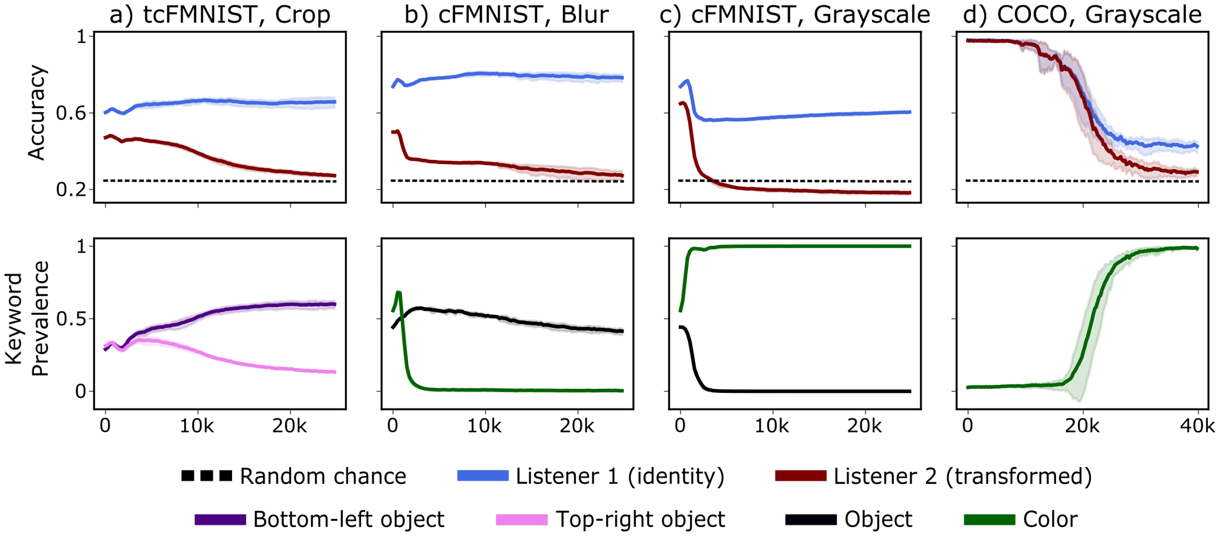

Figure 4: Accuracy and task-relevant metrics for many dataset and listener pairs. By column, the second listener sees a different transformed image (a: top-right crop, b: blurred, c,d: grayscale). The top row shows listener accuracies as the speaker learns to specialize. The bottom row shows prevalance of task-relevant keywords indicated by line color—note that object metrics measure both grounding and language specialization, while color metrics only measure specialization (see Section 3.4). Error bars show 95% confidence intervals (95% CIs) over 5 seeds.

exhibits a near-stage-like transition to exclusively using colors. Qualitatively, the speaker switches standard captions (e.g., "person in front of a bicycle") to color-focused captions (e.g., "red and white") for each image at some point during training. Once the speaker only uses color for its captions, the individual listener accuracies diverge significantly. Notably both listener accuracies are far worse than at the start of training, as color alone is an imperfect distinguisher on COCO (and overspecifying colors may give away too much, since object category is correlated with color in real images). However, the speaker has successfully learned to specialize its language to exploit the difference between the two listeners. Furthermore, this language remains grounded, as evidenced by end-of-training color diversity being comparable to color diversity produced from language prompting (see Section 4.4.3, Tables 1 and 16).

4.3 Zero-shot transfer

We next explore zero-shot transfer of the language specialization from our simpler dataset (cFMNIST) to the more challenging setting of COCO. To do so, we trained a speaker in the grayscale transform setting on cFMNIST (Listener 1 sees the unperturbed image, Listener 2 sees the grayscale image) and tested its zero-shot behavior on COCO. As baselines, we consider the behavior of the pretrained captioning model (that the speaker is initialized to), and the behavior given the best natural-language prompt (see Section 4.4.3). We also compare to the behavior of an expert speaker trained to specialize on COCO (the end of training in Figure 4d).

We find significantly-above-baseline zero-shot transfer, with increasing use of color on COCO as the speaker is trained on FMNIST (Figure 5b). Furthermore, this specialization leads to meaningful differences in listener accuracies (Figure 5a). This specialization transfer from FMNIST to COCO performs better (across all four metrics in Figure 5) than baseline zero-shot approaches (the untuned captioning model), and on par with the best language prompt (see Section 4.4.3).

However, zero-shot behavior is far from perfect—the model loses some grounding relative to the experiments above. Zero-shot, the model strongly prefers "red" (Figure 5c), using it in nearly twice as many captions as the COCO-trained speaker, including even some non-red images. We believe this may be due to the average "color" of the 8 colors we use for cFMNIST, in RGB, is 907080, indicating a slight red skew of the data. To improve generalization, we therefore trained on a richer, balanced colored version of FMNIST, where image hues are sampled randomly from 360 equally-spaced options (as opposed to the 8-hue cFMNIST used above) – we refer to this dataset as cFMNISTmany. We find that this improves zero-shot transfer across all metrics, pushing it beyond the performance of

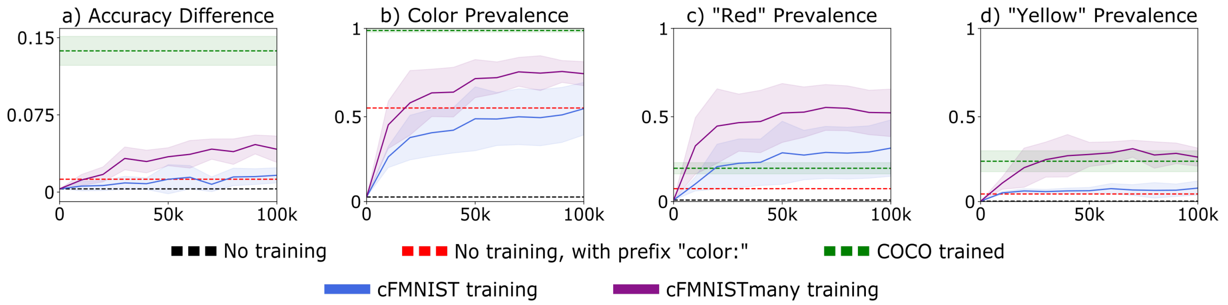

Figure 5: Zero-shot transfer results from cFMNIST to COCO and relevant baselines. Each subplot shows a different metric, with different lines corresponding to different conditions or baselines. The two conditions are training on cFMNIST (blue) or cFMNIST with 360 hues (purple). Various baselines are included as dotted lines: base captioning model (black), base captioning model with explicit prompting (red), fully trained on COCO (green).

the best explicit language prompt. Although this model still has slightly increased "red preference", its usage of other colors is also significantly better than the 8-hue-trained speaker. For example, in Figure 5d, we see that the cFMNISTmany-trained speaker uses yellow in a similar percentage of captions as a COCO-trained speaker. A better captioning model, that was adapted on a more diverse set of images, would likely transfer even better.

4.4 Ablations

We finally consider ablations to our set-up to identify key aspects. See Appendix F for full results.

4.4.1 Single listener

In our original experiments, the speaker learns to specialize in the presence of multiple listeners, but are both listeners necessary? Could the speaker also specialize through communicating with only a single listener? To test this possibility, we train a speaker model to optimize the accuracy of just a single listener (so the reward is binary 0/1 listener accuracy). See Appendix B.4 for details.

In the tcFMNIST case, prevalence of keywords for both locations in the image increases consistently, indicating a lack of specialization to image sub-regions. For cFMNIST, we find that single-listener training leads to increased use of colors and correct keywords; we never see a differential specialization that full multi-listener training induces in our original experiments. For COCO, we see the largest difference between single-listener and multi-listener cases—the single listener case does not learn to use color to distinguish images.

4.4.2 Non-contrastive reward

We next consider training with multiple listeners, but a non-contrastive reward. Namely, instead of optimizing for the difference in accuracy between listeners, we optimize directly for the difference in ALIGN match on the cued image. We call this approach "non-contrastive" as no distractor images are required. See Appendix B.5 for details.

Training in this setting does lead to some language specialization, but is worse than contrastive training in 3 out of 4 settings we consider. For the crop setting (Table 9), we see a reduced use of the top-right keyword, but only a modest increase in the use of the bottom-left keyword compared to contrastive reward training. For the blur setting (Table 10), the non-contrastive reward actually outperforms the contrastive reward. The model uses image-relevant keywords 70% of the time, and stops using varied colors (but continues to mention a single color). For the grayscale setting on both FMNIST and COCO, we observe strong specialization using the non-contrastive reward (as evidenced by low FMNIST keyword prevalence, and high color prevalence in Tables 11, 12). However, the captions in this case lose image relevance, as evidenced by markedly lower color diversity. Qualitatively, we observe the model using the same color for each image (which achieves more reward than baseline, but is obviously not desirable). Thus, overall, we find that the contrastive reward encourages specialization while preserving image relevance in this multi-listener setting.

4.4.3 Explicit prompting

Finally, we evaluate a simpler, commonly-used approach to model specialization: explicit prompting. These experiments also provide a baseline for our zero-shot results (in Section 4.3), as no training is involved. We created a variety of possible prefixes to elicit specialization, as explicit prompting can be brittle. Full results are provided in Appendix G.

Table 1 shows the top three prompts and relevant metrics for the (identity, grayscale) transform

Caption Prefix	FMNIST metrics			COCO metrics			
	Accuracy Difference	Color Prevalence	Color Diversity	Object prevalence	Accuracy Difference	Color Prevalence	Color Diversity
No prefix	0.089	0.556	0.014	0.442	0.003	0.027	0.022
the color of this image is	0.174	0.901	**0.020**	0.000	-0.010	0.135	**0.036**
color:	0.118	0.971	0.004	0.111	0.013	0.541	0.030
colors in image:	0.048	0.999	0.001	0.000	0.019	0.335	0.018
Fully trained	**0.422**	**1.000**	0.015	**0.000**	**0.156**	**0.988**	0.033

Table 1: Relevant metrics for various caption prefixes. The no prefix condition corresponds to the base captioning model. Fully trained results match values at the end of training from Figure 4—full training via listener subtraction provides superior language specialization compared to explicit prompting.

pair, on both FMNIST and COCO. Explicit prompting does lead to some specialization (when compared to the base captioning model), but fails to provide the robust specialization we observe in Section 4. Captioning prefixes can be quite brittle, as evidenced by the diverse behavior we observe from superficially similar prompts. For "colors in image:" and "color:", the model has high color prevalence, but low diversity. Qualitatively, the model tends to list all colors, with only the first color corresponding to the true color of the image. For "color:" we also observe that the model still uses nouns. For "the color of this image is" we observe slightly reduced color prevalence, but much stronger color diversity and little usage of nouns.

On COCO, similar color prompts yield surprisingly large differences in color prevalence. We also observe "switching" behavior: per image, the speaker either ignores the caption prefix (e.g., "color: person and her son play in the water") or specializes (e.g., "color: blue and white"). Qualitatively, this behavior mirrors the stage-like transition in the COCO-trained speaker, in Section 4.2.

5 Discussion

We have demonstrated a method for specializing a grounded language model without *direct supervision*, by finetuning a small fraction of its parameters in a complex multi-agent setting. We have shown that this approach enables diverse types of specialization with minimal language drift, and have identified the essential aspects of this approach. We believe that our work offers a novel perspective on adapting models to new settings without supervised data.

Our approach to specializing a grounded language model rewards the speaker for using differences in the information it shares with two listener models. This formulation allows for flexible adaptation of models to complex tasks. For example, our approach could potentially be used to diagnose biases in one contrastive listener model by comparing to another (e.g., trained on a different dataset), an area of considerable interest (Agarwal et al., 2021). A speaker optimized for the difference between two contrastive models could identify biases present in one listener, without the need for manually curated word lists. Additionally, training against listeners of different skill could potentially improve language quality without relying on costly human annotations (e.g. Stiennon et al., 2020).

Long term, we hope our work contributes to personalized AI. Humans prefer interacting with others who share *rare preferences* (Vélez et al., 2019), so an AI that personalizes its language to users would likely be preferred to one that uses standardized language. Personalization could improve other kinds of communication too, like explanations—e.g., adapting feedback to a particular student's idiosyncratic knowledge (cf. Wang et al., 2017). Our approach enables such adaptation through interaction, without explicit language supervision.

Towards Dixit Finally, while our experimental setup is inspired by *Dixit* game, we only make the first steps towards a model that can play the full version of Dixit effectively with humans—something that is an appropriate grand challenge for AI, as Kunda and Rabkina (2020) suggest. We highlight some of the next steps below.

The present work focuses on perceptual differences, while human play often relies on differences in conceptual knowledge. Finetuning listeners on different datasets (e.g., scenes from Harry Potter movies as in Figure 1a) might allow such conceptual differences to emerge. A challenge would be using datasets where this conceptual difference is relevant (Dixit achieves this with abstract images). This could potentially be overcome by generating synthetic data using modern text-to-image models (e.g. Ramesh et al. (2022)). Given the robustness to different listener pairs already exhibited, we believe this is a promising future direction. Moreover, human players adapt their language from a few interactions, while our speaker trains for thousands of iterations. One way to overcome this limitation would be to combine our work with concurrent progress in visual language models. Alayrac et al. (2022) introduce a model, Flamingo, which can rapidly adapt to different visual language tasks in a few-shot setting. Using such a high-quality base model as the speaker might enable reward-driven adaptation from just a few interactions.

We hope that this work will inspire further research on settings like Dixit, and help to enhance the capabilities of grounded language models and communicative agents more broadly.

Limitations

We want to reiterate important limitations with the work in its present form. We only considered settings with two listeners (for ease of quantitative assessment); additional challenges may be present when extending to three or more listeners, which may be necessary to express more complex objectives. In addition, the current work assumes that listeners exist that differ along the axis of desired specialization; finding such listeners might be challenging. Furthermore, despite the overall preservation of language, we qualitatively observed some degradation in some runs. Introducing a weighted KL-divergence loss term to the pretrained captioning model likelihood (cf. Lazaridou et al., 2020) might further improve specialized language quality. Alternative sampling methods (cf. Chaudhary et al., 2022), such as typical decoding (Meister et al., 2022), may also improve generated language quality. Finally, our paper does not directly place the agent in interactions with humans, or compare to how humans adapt their language in similar tasks. Further work could include human experiments to get a better sense of language quality and relevance of generated captions and/or identify differences in human and agent language adaptation.

Ethical considerations

As discussed above, applications for this work would train speakers using differences between listener models with different weights or even architectures. A potential risk of adapting speakers via this approach is that the speaker might pick up biases that one listener has that are not part of the intended specialization—an undesirable quality. As suggested above, one possible approach to mitigating this would be to explicitly include biased listeners, but always penalize the speaker for the biased listeners' accuracy. Another approach could be debiasing the underlying (frozen) language model (Schick et al., 2021; Meade et al., 2022), as the speaker's propensity for producing offensive language is inherited from this underlying model. Long-term, we believe that strategies like those detailed by Weidinger et al. (2021) will be necessary to mitigate risks of large language models (and models such as ours that utilize them).

Acknowledgements

The authors would like to thank Frederic Besse, Denis Teplyashin, and Maria Tsimpoukelli for advice on the engineering aspects of the work. We would also like to thank Angeliki Lazaridou, DJ Strouse, Stephanie Chan, and Oriol Vinyals for useful discussions and feedback on the draft.

The authors also thank Flaticon.com for providing free access to various icons used in Figures 1 and 2. We also thank the creators of Dixit(Roubira, 2008) for creating an inspiring game and the images used in 1.

A Speaker Model Details

We provide further detail on our speaker model architecture.

The pretrained-and-frozen CLIP visual encoder takes in images of dimension $224 \times 224 \times 3$, which we denote x. We take the pre-spatial-pool output from the model, which has dimensions $16 \times 16 \times 768$, and flatten this (across spatial dimensions) to an output $E(x)$, with dimension 256×768. For the specific encoder model, we experimented with a few (pretrained) options (see Appendix B.1).

The attention-based (QKV) adapter takes in this visual embedding and transforms it into n token embeddings that can be used as a prefix to prompt the language model. The trainable parameters of this layer are Q (of dimension $n \times d$), W_K (of dimension $768 \times d$), and W_V (of dimension 768×2048). The weights W_K, W_V are used to compute $K = E(x)W_K, V = E(x)W_V$. The fixed queries are then used to attend to these input-dependent keys and values. The output of the adapter layer is thus $A(x) = softmax(QK^\top/\sqrt{d})V$ (of dimension $n \times 2048$).

We feed in $A(x)$ as n prefix embeddings of dimension 2048 to a pretrained-and-frozen causal Transformer to generate up to 32 tokens (with early termination if the EOS token is produced). We follow the recommended architecture parameters presented in Hoffmann et al. (2022) for a 1.4B parameter model: our transformer has 24 layers, model dimensionality of 2048, and 16 heads. We use a SentencePiece tokenizer with a vocabulary size of 32000 (Kudo and Richardson, 2018).

B Training details

In this section, we provide training details, hyperparameter search details, and the hyperparameters we used for our final results. All models were implemented in Python using JAX (Bradbury et al., 2018) and Haiku (Hennigan et al., 2020). Training was distributed over 16 TPUs (v3), and all experiments used a batch size of 128 (unless specified otherwise). The optimizer for all experiments is Adam (Kingma and Ba, 2015), with $\beta_1 = 0.9, \beta_2 = 0.95$. We use ZeRO stage-one parameter sharding (Rajbhandari et al., 2020).

B.1 Speaker model pretraining on captioning data

We pre-trained our speaker model using supervised cross-entropy loss (with teacher forcing (Williams and Zipser, 1989)) on the Conceptual Captions dataset (Sharma et al., 2018) which consists of paired image-caption data.

Dataset images were augmented using random crops. All experiments were run with a batch size of 512 for 500000 steps. Training was distributed over 16 TPUs (v3) in a data parallel fashion.

Hyperparameters we searched over were:

- Base CLIP model: We tried the smaller CLIP ViT-B/32 and the larger CLIP ViT-L/14 model.
- Positional embeddings: We experimented with adding an absolute positional embedding to each of the 16×16 unpooled outputs from the CLIP encoder.
- Learning rate: [1e-4, 3e-4, 1e-3, 3e-3, 1e-2, 3e-2, 1e-1, 3e-1]
- Dimension of QKV adapter (d): [32, 64]
- Number of input tokens to frozen language model (n): [8, 16, 32]

All hyperparameter selections were based on validation loss on the Conceptual Captions validation set. We found that the larger CLIP model, no additional positional embeddings, a learning rate of 3e-2, $d = 32$, $n = 32$, worked best. In terms of the biggest factors, using the larger CLIP model made the biggest change, followed closely by learning rate.

We froze the best model, and that same model served as the starting point for all our experiments.

B.2 Choice to finetune just the adapter

We experimented with finetuning a visual encoder from scratch (instead of using a pre-trained CLIP) as done by Tsimpoukelli et al. (2021). However, we found this approach to perform worse than our adapter-only training (in terms of Conceptual Captions validation performance). The adapter has just under 1.6M parameters, out of a total of 1.7B parameters, for a total of < 0.1% finetuned parameters. We believe that finetuning such a small number of weights prevents language degeneration, thus enhancing the quality of generated captions. For downstream experiments, we found a similar effect – finetuning more than just the adapter parameters led to more language drift. For this reason, we only finetune the adapter in all experiments.

B.3 Multi-listener, contrastive-reward training

We used the hyperparameters detailed in Table 2 for training our main models. These hyperparameters were found by grid searches over learning rate ([3e-5, 3e-4]), sampling temperature ([1,2]), nucleus size ([0.8, 1]), and caption length penalty ([1e-5, 3e-5, 1e-4, 3e-4, 1e-3, 3e-3, 1e-2, 3e-2]). We found that caption length penalty was crucial to tune to make sure it didn't dominate the reward at the start of training.

All of our final training results are run on 5 different random seeds, from which 95% confidence intervals are calculated and shown (in figures and tables).

B.4 Single listener, contrastive-reward training

For this baseline, we train the speaker to just maximize the binary accuracy of the single unperturbed listener. We train in 3 settings: on cFMNIST, on tcFMNIST, and on COCO. To make a fair comparison, we performed a hyperparameter search for each case (final hyperparameters shown in Table 3). Specifically, we searched over learning rate ([3e-5, 3e-4]), nucleus size ([0.8, 1]), and caption length penalty ([1e-5, 1e-4, 1e-3, 1e-2]). We also found that early stopping and batch-based baseline subtraction (Williams, 1992) improved performance (in terms of reward on unseen images), so we used both of these techniques for all results reported. On each setting, we trained 5 random seeds for up to 25000 iterations on FMNIST and up to 40000 iterations on COCO, early stopped each one, and computed evaluation metrics on those checkpoints.

B.5 Multi listener, non-contrastive-reward training

For this baseline, we train the speaker to just maximize the difference in the ALIGN match scores that listeners assign to the cued image. In this setup, the listeners only need the caption and cued image, which is why we call it non-contrastive. We train this baseline in all four settings that we train our main (multi-listener, contrastive-reward) model in. We perform hyperparameter over nucleus size ([0.8, 1]) and caption length penalty ([1e-7, 1e-6, 3e-6, 1e-5, 3e-5, 1e-4, 3e-4, 1e-3]), with optimal hyperparameters reported in Table 4.

C Dataset details

To construct the cFMNIST dataset, we convert FMNIST images to HSV. Since the images are originally grayscale, the saturation is always 0. We set the saturation to 1, and set the hue to one of the 8 colors shown in Table 5. Then, we convert back to RGB images and resize to spatial dimensions 224×224 using cubic upsampling (Keys, 1981), then clip all values to the range [0,1].

For tcFMNIST, we randomly place a cFMNIST image in the bottom left and in the top-right of the image. This choice of tiling (as opposed to top-left, bottom-right, or some other combination) was chosen to avoid an inherent bias towards cuing for the top-left object that we observed in our base captioning model.

For the test set, we construct a fixed test set to use for equal comparison across all conditions. For contrastive-reward experiments, we also fix the distractors during test time for consistency.

We normalize all images according to the normalization that was originally used for the off-the-shelf image encoders we use (for consistency). Specifically, for inputs to the speaker, which pass through CLIP's vision encoder, the normalization mean and standard deviation values are (0.481, 0.458, 0.408) and (0.269, 0.261, 0.278), respectively. For inputs to the listeners, which pass through ALIGN's vision encoder, the normalization mean and standard deviation values are (0.485, 0.456, 0.406) and (0.229, 0.224, 0.225), respectively.

C.1 Licenses

We use FMNIST under the MIT license, COCO under the creative commons 4.0 attribution license, and Conceptual Captions under its ad-hoc license (for which we thank Google LLC). We also acknowledge that images in Figure 1 are taken from the Dixit game (Roubira, 2008) and icons are used under the Flaticon license (for which we thank Flaticon.com). We make use of the GPT3 (Brown et al., 2020) beta (for quantification of structural drift, see Appendix E) under the Apache License.

To our knowledge, we use these resources in agreement with their licenses.

C.2 Dataset Splits

We use standard splits for all datasets from tensorflow datasets (Abadi et al., 2015). For FMNIST-based datasets, this means 60000 train images that

	FMNIST			COCO
Parameter	Crop	Blur	Grayscale	COCO Grayscale
Learning rate	3e-4	3e-4	3e-4	3e-4
Sampling temperature	1	1	1	1
Nucleus Size	0.8	0.8	1	1
Caption length penalty (λ)	3e-3	3e-3	3e-3	3e-4

Table 2: Hyperparameters for the main setting (multi-listener, contrastive-reward).

Parameter	cFMNIST	tcFMNIST	COCO
Learning rate	3e-4	3e-4	3e-4
Sampling temperature	1	1	1
Nucleus Size	0.8	0.8	1
Caption length penalty (λ)	1e-5	1e-5	1e-5

Table 3: Hyperparameters for the single listener, contrastive-reward baseline.

are used to procedurally generate cFMNIST and tcFMNIST train sets, and 10000 test images that are used to generate the test sets.

D Evaluation metric details

We have two types of metrics: color metrics and keyword metrics. Color metrics apply on both FMNIST-based datasets and COCO, while keyword metrics are only used on FMNIST-based dataset (where we know exactly where and what the objects are by construction). We want our metrics to be able to diagnose language specialization, and also check that the captions are still grounded (we'll refer to this as "image relevance" of captions).

D.1 Color metrics

All color metrics utilize the following set of 16 colors:

```
red, orange, yellow, green,
blue, indigo, violet, purple,
cyan, magenta, pink, brown,
black, white, gray, grey
```

For measuring language specialization to colors, we define *color prevalence*: the fraction of captions at test time containing at least one word from the above list.

For measuring image relevance, we use a proxy metric as its often hard to define what it means for a color to be correct (e.g., if an image is "cyan" and the model says "blue and white"). The proxy metric we use is *color diversity*. To compute color diversity we calculated TF-IDF vectors for each caption using only the color terms above. Then, we calculated the trace of the covariance matrix (which has dimension 16×16) of these vectors. This metric has the desirable property where if a color appears in nearly all captions, it will be scaled down by the IDF term and so will its contribution to the trace of the covariance matrix.

We found this to be a good proxy metric as loss of image relevance in color specialization cases corresponding to the model choosing just a few colors (often just one) and using them to describe all images. To not confound our main results, we qualitatively looked at how well this metric corresponded to loss of image relevance on the many language prompts detailed in Appendix G. We found that color diversity was a noisy, but useful, metric for determining image relevance of these prompts. For example, a simpler metric like checking the number of unique captions the model uses fails since, given some language prompts, the speaker would produce long strings of colors, often in slightly different orders (e.g. "color: green, black, white, blue, red ..." vs. "color: red, black, white, blue, green ..."). Furthermore, we note that color diversity is not a perfect metric, so subtle differences (on the order of ± 0.005) should not be considered significant. We mainly use color diversity to classify runs where image relevance was completely lost (color diversity going to 0), or image relevance was retained (color diversity staying near that of the best language prompts and above that at the start of training).

	FMNIST			COCO
Parameter	Crop	Blur	Grayscale	COCO Grayscale
Learning rate	3e-4	3e-4	3e-4	3e-4
Sampling temperature	1	1	1	1
Nucleus Size	0.8	0.8	0.8	0.8
Caption length penalty (λ)	3e-6	3e-6	3e-6	3e-4

Table 4: Hyperparameters for the multi-listener, non-contrastive-reward baseline.

Color:	Red	Orange	Yellow	Green	Cyan	Blue	Purple	Pink
Hue:	$\frac{0}{360}$	$\frac{30}{360}$	$\frac{60}{360}$	$\frac{120}{360}$	$\frac{180}{360}$	$\frac{240}{360}$	$\frac{270}{360}$	$\frac{300}{360}$

Table 5: Color and Hues for cFMNIST.

D.2 Keyword metrics

For measuring language specialization to objects, we define *FMNIST keyword prevalence*: the fraction of captions at test time containing at least one FMNIST related keyword.

To measure image relevance, we utilize the ground-truth labels from FMNIST, supplemented with synonyms. Specifically, we measure *object prevalence*: the fraction of captions at test time that contain at least one keyword corresponding to the ground truth label of the object in, the image according to Table 6. We found that allowing synonyms was essential, as the captioning model heavily prefers some clothing words over others (e.g., sandals are almost always just called shoes by the model). For tcFMNIST, we similarly define *bottom-left object prevalence* and *top-right object prevalence* to measure what fraction of captions refer to each region of the image.

E Language drift quantification

Prior work in emergent communication (Lazaridou et al., 2020) establishes three types of language drift that may occur when adapting language from rewards, without direct supervision: structural drift (how "language-like" are captions), semantic drift (how "image-relevant" are captions), and pragmatic drift (how "human-interpretable" are captions). While the focus of our work is on language specialization, it is important to investigate to what extent our approach is resulting in language drift.

For semantic and pragmatic drift, we note that our main metrics (see Section 3.4 and Appendix D) measure human interpretability as well as image relevance. For example, our object metrics measure whether the model is referring to objects using the category name or valid synonyms, and our color diversity metric is able to differentiate settings with notable semantic drift (e.g., the non-contrastive baseline, see Section 4.4.2) from settings without notable semantic drift (e.g., our main results, see Figures 3 and 4). Our method preserves these metrics, presumably since the grounded task with frozen listeners, as well as the frozen components of the speaker, provide strong constraints on what language the speaker can use.

However, our main metrics do not adequately address the issue of structural drift. To measure how "language-like" our captions are, we therefore follow the approach of Lazaridou et al. (2020) and evaluate the log-likelihood assigned to generated captions by an independent, pretrained language model (LM). Specifically, we use OpenAI's Ada model, made available online through the GPT3 beta (Brown et al., 2020). For comparison, we also show LM log-likelihoods for the ground truth human captions (for cFMNIST, we procedurally generate these—e.g., "red pullover"), the LM likelihoods for the "best prompt" (see Appendix G), and the LM likelihoods for captions from the speaker before specialization training (the base speaker pretrained on captioning only). For reference, the "best" language prompts were chosen to maximize task-relevant metrics (see third column in Tables 13-16) except for the (cFMNIST, Grayscale) case where we use the third best (as the top two prefixes have very low color diversity—see discussion in Section 4.4.3). Results are shown in Table 7.

Surprisingly, we see that in most of our runs, average caption likelihoods seem to increase as the speaker specializes. It appears that this effect may be driven by the length penalty—over training,

Label	Category name	Added synonyms
0	t-shirt	top, t-shirts, shirt, shirts
1	trouser	trousers, pants
2	pullover	sweater, hoodie, sweaters, hoodies
3	dress	dresses
4	coat	coats, jacket, jackets
5	sandal	high heels, heels, shoe, shoes
6	shirt	shirts
7	sneaker	sneakers, shoe, shoes, running shoe
8	bag	purse, backpack, bags, purses
9	ankle boot	boot, shoe, shoes, boots

Table 6: FMNIST keyword sets. We refer to the set of all words in this table as FMNIST related keywords.

	tcFMNIST, Crop	cFMNIST, Blur	cFMNIST, Grayscale	COCO, Grayscale
Ground truth	-32.77	**-15.20**	-15.20	-46.26
“Best” language prompt	-36.61	-44.61	-24.59	-29.49
Start of training	-33.33	-28.64	-28.64	**-28.44**
End of training	**-17.41**	-19.01	**-9.26**	-29.49

Table 7: Average language model *full-caption* log-likelihoods for ground truth, start-of-training, and end-of-training captions on test images.

the speaker produces shorter captions, which have higher likelihoods since they have fewer tokens. Qualitatively, we find that language drift can be fairly variable across different random seeds. For example, the COCO average is worse after training largely due to a single run, in which long repeated captions emerged (which have lower likelihoods than their un-repeated counterparts).

To evaluate this further, we computed the per-token likelihoods (Table 8). While these do show some decrease in likelihood in some cases, the captions at the end of training are generally of comparable likelihood to the ground truth. In this instance, we notice that the one COCO seed in which the captions repeated actually exhibits *greater* per-token likelihood—after a few repeats, the LM starts to estimate further repeats to be very likely. This could potentially be a concern for using LM likelihoods as a metric for structural drift more broadly (cf. Lee et al., 2019). However, in most runs our length penalty prevents repetitions or long captions, as noted above.

In summary, these results indicate that language has not drifted far in most conditions and for most random seeds. We attribute this to some of the same factors that help prevent other types of language drift: finetuning a small part of our speaker (just the adapter), keeping the listener models frozen (thus avoiding co-adaptation), using a length penalty (see above discussion), and using contrastive reward (crucial for combating semantic drift, see Section 4.4.2). If necessary, language drift could potentially be reduced further by using a KL-divergence loss to the distribution of outputs from the base captioning model (as done by Lazaridou et al. (2020)).

F Full ablation results

In this section we show the full quantitative ablation results, in Tables 9, 10, 11, and 12.

	tcFMNIST, Crop	cFMNIST, Blur	cFMNIST, Grayscale	COCO, Grayscale
Ground truth	-5.823	-7.666	-7.666	-4.772
“Best” language prompt	-4.680	-4.371	**-4.076**	-4.051
Start of training	**-4.160**	**-4.127**	-4.127	-4.463
End of training	-7.143	-8.383	-4.234	**-2.509**

Table 8: Average language model *per-token* log-likelihoods for ground truth, start-of-training, and end-of-training captions on test images.

Condition	Bottom-left object prevalence	Top-right object prevalence
No training	0.290	0.312
Single listener	0.475 ± 0.024	0.473 ± 0.020
Non-contrastive	0.360 ± 0.005	**0.120 ± 0.011**
Full training	**0.602 ± 0.066**	0.135 ± 0.017

Table 9: Metrics (with 95% CI) for ablations on the tcFMNIST dataset and the (identity, crop) pair of listener transformations. Both non-contrastive and full training lead to decreased use of top-right keyword, but only full training accurately specializes to using the bottom-left keyword.

Condition	FMNIST keyword prevalence	Object prevalence	Color prevalence	Color diversity
No training	0.644	0.442	0.556	0.014
Single listener	0.754 ± 0.020	0.564 ± 0.013	0.953 ± 0.022	0.016 ± 0.000
Non-contrastive	**0.997 ± 0.004**	**0.710 ± 0.086**	0.606 ± 0.833	**0.000 ± 0.000**
Full training	0.600 ± 0.044	0.418 ± 0.038	**0.004 ± 0.008**	0.001 ± 0.002

Table 10: Relevant metrics (with 95% CI) for various ablations on the cFMNIST dataset and the (identity, blur) pair of listener transformations. Non-contrastive rewards perform better than contrastive rewards in this setting, as evidenced by increased use of correct keywords, and decreased use of meaningful colors (diversity of colors goes to 0).

Condition	Color prevalence	Color diversity	FMNIST keyword prevalence	Object prevalence
No training	0.556	0.014	0.644	0.442
Single listener	0.953 ± 0.022	**0.016 ± 0.000**	0.754 ± 0.020	0.564 ± 0.013
Non-contrastive	1.000 ± 0.000	0.005 ± 0.003	0.000 ± 0.000	0.000 ± 0.000
Full training	**1.000 ± 0.000**	0.015 ± 0.002	**0.000 ± 0.000**	**0.000 ± 0.000**

Table 11: Relevant metrics (with 95% CI) for various ablations on the cFMNIST dataset and the (identity, grayscale) pair of listener transformations. Full training performs best as color prevalence and diversity increase, while keyword prevalence decreases to 0.

	Color prevalence	Color diversity
No training	0.027	0.022
Single listener	0.102 ± 0.080	0.030 ± 0.007
Non-contrastive	0.932 ± 0.256	0.018 ± 0.005
Full training	$\mathbf{0.988 \pm 0.023}$	$\mathbf{0.033 \pm 0.027}$

Table 12: Relevant metrics (with 95% CI) for various ablations on the COCO dataset and the (identity, grayscale) pair of listener transformations. Full training performs best as it has highest color prevalence and diversity.

G Extended results on caption prefixes

In Tables 13-16, we show all caption prefixes we experimented with, as well as the relevant metrics for each. For each table, we sort prefixes from worst (top of table) to best (bottom of table) based on the most task-relevant keyword metric (third column in each table). We added a column for "Score difference" which is the average difference in ALIGN match scores from each listener for the cued image (it corresponds to the reward that is seen in the non-contrastive reward baseline). Of course, no training occurs, as the caption prefixes just explore how well the speaker can do by just explicit prompting. We also use ␣to indicate a space at the end of the caption. For most prefixes, we see a large difference between adding this space and not adding it, which is just another testament to how brittle prompt engineering can be.

H Sample hands across experimental conditions

In this section we present representative Dixit hands with the corresponding captions produced by the specialized speaker (after training) in our four main conditions, along with the corresponding distractors, listener match scores and rewards. We chose the speaker seed which achieved the highest overall score in that condition (though results were generally comparable across seeds), and to avoid cherry-picking examples we show the first four evaluation hands (from our randomly ordered evaluation) that contained a distinct target object (for example, in the crop condition, the first four that had a distinct object category in the bottom left).

We present samples for the different transformation conditions in Figures 6-9. Overall, the speaker adapts to the target difference between the listeners, and exhibits relatively mild language drift—the utterances generally stay grounded and human-interpretable, but in some cases exhibit some repetition or odd grammar. Some potential methods for further reducing these issues are noted above.

Below-chance performance for the grayscale listener: In Figure 4c, the grayscale listener achieves below-chance performance. We note from the samples (Figure 8) that the speaker sometimes uses the word "background" in addition to using a color. This noun is not informative (so does not notably hurt the listener that can see color), but we speculate that it may throw off the second listener as some images have more background than others (e.g. a grayscale image of a high heel has more black than a grayscale image of a jacket). Note that the speaker does not see the distractors, so it can't purposefully consider the distractors to exploit this effect. This effect appears to be an artifact of the particular dataset we used, but does illustrate another intriguing way the speaker can exploit differences between listeners.

Figure 9: Speaker samples and listener results on COCO, after the speaker has specialized (on COCO) to the second listener having the grayscale transformation. The speaker generally names one or two plausible colors for the images; but these are less discriminative in COCO than in the above results. There is also some minor language degradation in some cases (e.g. “and" at the end of a caption).

Abstract

Large multilingual models have inspired a new class of word alignment methods, which work well for the model's pretraining languages. However, the languages most in need of automatic alignment are low-resource and, thus, not typically included in the pretraining data. In this work, we ask: *How do modern aligners perform on unseen languages, and are they better than traditional methods?* We contribute gold-standard alignments for Bribri–Spanish, Guarani–Spanish, Quechua–Spanish, and Shipibo-Konibo–Spanish. With these, we evaluate state-of-the-art aligners with and without model adaptation to the target language. Finally, we also evaluate the resulting alignments extrinsically through two downstream tasks: named entity recognition and part-of-speech tagging. We find that although transformer-based methods generally outperform traditional models, the two classes of approach remain competitive with each other.

1 Introduction

Word alignment is a valuable tool for extending the coverage of natural language processing (NLP) applications to low-resource languages through, e.g., statistical machine translation (SMT; Koehn and Knowles, 2017; Duh et al., 2020) or annotation projection (Yarowsky et al., 2001; Smith and Smith, 2004; Nicolai et al., 2020; Eskander et al., 2020). The traditional approach for generating alignments has been with statistical methods such as Giza++ (Och and Ney, 2003) and FastAlign (Dyer et al., 2013), which provide strong alignment quality while remaining quick and lightweight to run. Recently, new methods have been proposed which extract alignments from massive *pretrained multilingual models*, and outperform these longstanding methods (Dou and Neubig, 2021).

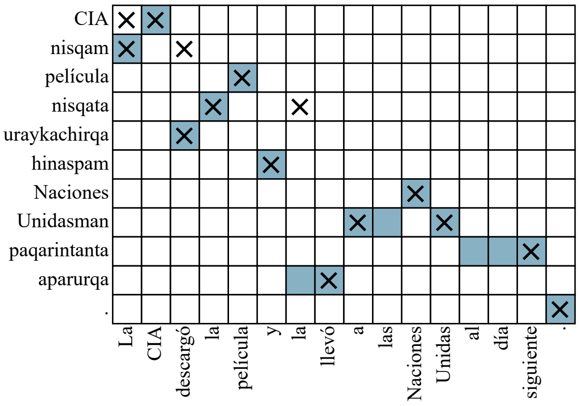

Figure 1: A word alignment between Quechua and Spanish (shaded), as well as mBERT+TLM's predicted alignment (marked by ×'s). FastAlign and Giza++ cannot take advantage of surface features of proper names and borrowings. We evaluate alignments intrinsically via AER and extrinsically with POS-tagging and NER models learned on annotations projected across alignments from Spanish.

However, results on other NLP tasks, such as part-of-speech (POS) tagging and named-entity recognition (NER), have shown that, while pretrained models generally work well out-of-the-box for high-resource languages, performance is far lower for low-resource ones, particularly those which are unseen during pretraining (Pires et al., 2019; Wu and Dredze, 2020; Muller et al., 2021; Lee et al., 2022). Models can be adapted (Gururangan et al., 2020; Chau et al., 2020) to improve performance, but this comes with a large computational cost. Given these two considerations, for *unseen* low resource languages it remains unclear (1) whether modern neural approaches based on adapted pretrained models generate higher-quality alignments than traditional approaches and (2) if so, whether the quality difference is severe enough to justify the additional computational cost.

We investigate this by collecting gold-standard alignments for Bribri, Guarani, Quechua, and

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3912–3926
May 2-6, 2023

Shipibo-Konibo. These languages are low-resource and unrepresented in the pretraining data of popular models—a relevant real-world scenario. In addition to intrinsically evaluating alignment quality, we measure the downstream utility of each method for training POS-tagging and NER models by annotation projection.

We find traditional and neural methods to be competitive, but pretrained models result in slightly lower alignment error rates and stronger downstream task performance, even for initially unseen languages. Through further analysis, we also find that adaptation may be a more reliable approach given minimally available resources. Taken together, these results indicate that alignment from multilingual models can indeed be a valuable tool for low-resource languages, but traditional approaches continue to be a strong option and should still be considered for practical applications.

2 Related Work

Alignment Word alignment is a long studied task, with origins in the IBM models for statistical machine translation (Brown et al., 1993), which are the basis of Giza++ (Och and Ney, 2003) and FastAlign (Dyer et al., 2013). As these approaches can only generate one-to-many alignments, models are trained in both forward and reverse directions (reversing the role of source and target), and final alignments are created via symmetrization heuristics (Och and Ney, 2000; Koehn et al., 2005); other approaches explicitly symmetrize during training (Matusov et al., 2004; Liang et al., 2006).[1] While these models rely on only position and word identity information, subword information can be integrated without requiring costly inference (Berg-Kirkpatrick et al., 2010), leading to better parameter estimation for rare words. Alignments can also be extracted from neural translation models (Chen et al., 2020; Zenkel et al., 2020).

Word alignment also enables annotation projection (Yarowsky and Ngai, 2001; Yarowsky et al., 2001) which can offer strong performance, particularly for low-resource languages (Buys and Botha, 2016; Ortega and Pillaipakkamnatt, 2018; Nicolai and Yarowsky, 2019; Nicolai et al., 2020; Eskander et al., 2020).

Multilingual Transformer Models Pretrained multilingual models (Devlin et al., 2019; Conneau and Lample, 2019; Conneau et al., 2020; Xue et al., 2021) have become the de facto standard approach for cross-lingual transfer. In general, these models are an extension of their monolingual variants, created by including data from many languages in their pretraining. They rely on a subword vocabulary (Kudo and Richardson, 2018) which jointly spans all of the pretraining languages. Models are pretrained using a masked language modeling (MLM) objective and a translation language modeling (TLM; Conneau and Lample, 2019) objective that uses parallel sentences. Outside of continued pretraining (Gururangan et al., 2020), models can be adapted using Adapters (Pfeiffer et al., 2020) or through vocabulary adaptation (Wang et al., 2020; Hong et al., 2021). Word alignment methods which depend on these models have also been proposed (Jalili Sabet et al., 2020; Nagata et al., 2020); we focus on AWESoME align (Dou and Neubig, 2021) because it outperforms other unsupervised methods.

3 Experiment 1: Intrinsic Evaluation

3.1 Experimental Setup

Languages We focus on four Indigenous languages spoken in the Americas for our experiments. **Bribri (bzd)** is a tonal language in the Chibchan family spoken by approximately 7000 people in Costa Rica. **Guarani (gn)** is a polysynthetic language in the Tupi–Guarani family spoken by around 6 million people across South America. **Quechua (quy)** is a family of Indigenous languages—from which we study Quechua Chanka—spoken across the Peruvian Andes by over 6 million people, and **Shipibo-Konibo (shp)** is a language spoken by around 30,000 people in Peru, Bolivia, and Brazil (Cardenas and Zeman, 2018). The latter three languages are agglutinative.

Training Data For training, we use the parallel data between Spanish and our languages described by Mager et al. (2021).[2] We note that there is a distinct difference in the amount of unlabeled data available within the four languages: Guarani and Quechua have considerably more data available. These two languages also have monolingual

---

[1] The poor estimation of rare words' translation parameters also motivates symmetrization; without this, rarely observed words become *garbage collector words* (Moore, 2004).

[2] Although parallel, digitized Bibles exist for over 1600 languages (McCarthy et al., 2020), groups may object to annotating the Bible for historical or cultural reasons.

text available in Wikipedia, which we extract using WikiExtractor (Attardi, 2015). The exact number of parallel and monolingual sentences for all languages is shown in Table B.1.

Evaluation Data To create gold standard alignments for evaluation, we sample multi-way parallel examples from AmericasNLI (Ebrahimi et al., 2022), allowing for multi-parallel alignments (Xia and Yarowsky, 2017) across all languages. Samples for the development and test sets are taken from their respective splits in the AmericasNLI dataset. Development examples were collected first, manually checked, and corrected. Examples with misalignments in punctuation, numbers, or named entities were not used. After a period of development with this data, the test set of 50 examples was collected and manually verified. Annotations were collected using JHU's open-source Turkle platform.[3] We ask annotators to only mark *sure* alignments. Additional discussion on data collection and the test set can be found in §6.

Metrics We evaluate automatic alignments via alignment error rate (AER; Och and Ney, 2000). Because we only collect sure alignments, this is equivalent to the balanced F-measure (Fraser and Marcu, 2007). We give additional metrics in Table C.3.

3.2 Models

Traditional Aligners We use Giza++ (Och and Ney, 2003) and FastAlign (Dyer et al., 2013) as our traditional aligners. Giza++ is based on IBM Models 1–5 (Brown et al., 1993). FastAlign (Dyer et al., 2013) is a re-parameterization of IBM Model 2. We use the implementation and hyperparameters of Zenkel et al. (2020), which relies on MGiza++ (Gao and Vogel, 2008) and the standard FastAlign package. Both approaches run on CPUs, and their training time ranges between 6 seconds to 3 minutes for FastAlign, and 43 seconds to 22 minutes for Giza++. We use the union of the forward and reverse alignments, as this symmetrization heuristic offers the best result for all languages on the development set. We show the performance of other heuristics in Table C.2.

Neural Aligners AWESoME (Dou and Neubig, 2021) identifies alignment links by considering cosine similarities between hidden layer representations of tokens in a neural encoder. We consider two such encoders: mBERT (Devlin et al., 2019) and XLM-R (Liu et al., 2019), and we use the default AWESoME configuration to extract alignments. We give layer-by-layer alignment performance in Figure C.1.

Model	Method	BZD	GN	QUY	SHP	AVG.
AWESoME	BL	70.03	63.13	67.02	60.41	65.15
(mBERT)	+MLM-T	68.95	49.68	46.59	58.17	55.85
	+MLM-ST	70.63	50.25	42.52	58.66	55.52
	+TLM	58.43	**43.10**	**36.96**	**52.34**	**47.71**
AWESoME	BL	80.15	73.11	75.24	69.21	74.43
(XLM-R)	+MLM-T	76.89	65.44	53.65	65.16	65.29
	+MLM-ST	77.53	64.55	52.90	66.56	65.39
	+TLM	74.90	58.84	43.25	63.48	60.12
FastAlign	Union	**51.40**	43.52	54.06	54.67	50.91
Giza++	Union	55.61	49.92	66.01	60.84	58.10
mBERT	+MLM-WT	-	***40.00***	46.00	-	43.00
XLM-R	+MLM-WT	-	52.27	48.83	-	50.55

Table 1: AER, in percentages, for each language and method. The best overall result for each language is bolded, while the best model within each method is underlined. We separate results which use Wikipedia, as they are not directly comparable.

Model Adaptation We experiment with three adaptation schemes based on continued pretraining (+TLM, +MLM-T, and +MLM-ST) which rely on unlabeled data and further train the model using MLM (Gururangan et al., 2020) before alignments are extracted. We focus on these objectives as they have been used by prior work for general model adaptation, and they work well in situations with limited resources (Ebrahimi and Kann, 2021). As we have access to bitext between Spanish and the target languages, for the +TLM scheme each example is the concatenation of a Spanish sentence with its translation. For +MLM-**T** we adapt using solely the **t**arget side of the available data, and for +MLM-**ST** we adapt on both the **s**ource and **t**arget; however, this data is treated as monolingual data and not explicitly aligned. +MLM-WT denotes target language adaptation which includes Wikipedia data. The duration of adaptation depends on the GPU and method used; it ranges from around 6 minutes for Bribri to 4 hours for Quechua. We provide additional training details in Appendix A.

3.3 Results

Traditional vs. Neural Aligners We present results in Table 1. The best traditional method is FastAlign, and the best neural approach is with mBERT+TLM. Comparing the two, we see that

---

[3] `https://github.com/hltcoe/turkle`

the lowest error rate is achieved with the neural approach for all languages except for Bribri, where FastAlign offers 7.03% absolute improvement. Of the other three languages, the performance for two is close: the difference in performance for Guarani is only 0.42% and 2.33% for Shipibo-Konibo. For Quechua, +TLM improves over FastAlign by 17.10%.

Comparing Adaptation Strategies With mBERT, +MLM-T improves performance over the non-adapted baseline by 9.30% on average, with +MLM-ST increasing this gain to 9.63% and +TLM offering the highest improvement of 17.44%, consistent with prior work on *seen* languages (Dou and Neubig, 2021). Per language, the largest and smallest gains are for Quechua (30.06%) and for Shipibo-Konibo (8.07%); intuitively, gains from adaptation are proportional to the size of the adaptation data. For XLM-R, we again see relative gains from adaptation, with +TLM offering the highest performance increase.

Additional Monolingual Data Neural approaches can easily benefit from additional monolingual data. Adding Wikipedia data results in the highest performance for Guarani, outperforming the previous best approach by 3.1%. In contrast, while the additional data for Quechua does help relative to +MLM-T, it does not outperform +TLM. This difference in performance may be due to the relative sizes of the additional data; the Guarani Wikipedia has 1.3× as many tokens as the target-side parallel data, while the Quechua Wikipedia only has 0.5× as many.

4 Experiment 2: Extrinsic Evaluation

We further compare aligner performance extrinsically by evaluating downstream task performance when using a projected training set. We consider two tasks: NER and POS tagging.

4.1 Experimental Setup

Data Due to the limited availability and quality of evaluation datasets, we focus on Guarani for this experiment. We use the test set provided by Rahimi et al. (2019) for NER and Universal Dependencies (Nivre et al., 2020) for POS. For experiments where we finetune directly on English or Spanish, we use the provided training data.

Model	Train Source	POS	NER
mBERT	en	10.36	46.64
	es	19.82	49.18
+TLM	es	36.94	49.62
+MLM-T	es	34.69	**55.25**
+MLM-ST	es	33.78	52.34
mBERT	mBERT	31.53	47.54
	+MLM-T	38.29	47.97
	+MLM-ST	**42.34**	49.80
	+TLM	40.99	49.80
	FastAlign	37.84	46.55
	Giza++	39.19	48.33

Table 2: POS tagging (accuracy) and NER results (F1) for Guarani. *Model* denotes if baseline or adapted mBERT is used. *Train Source* defines the training data used for finetuning; language codes indicate training on original data, while alignment methods denote how a projected training set was created.

Annotation Projection To create the projected training sets, we first annotate the (unlabeled) Spanish parallel data with Stanza (Qi et al., 2020) and generate bidirectional alignments using each method. We then project the tags from Spanish to Guarani using type and token constraints as described by Buys and Botha (2016).

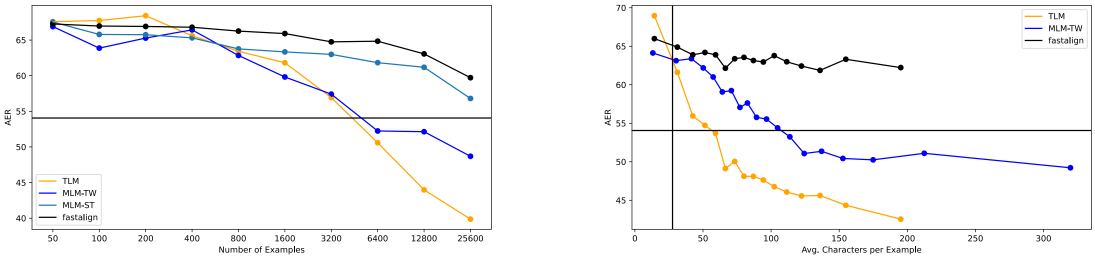
Models For baseline performance, we finetune mBERT on the provided English and Spanish training sets for each task. Additionally, we also finetune adapted versions of mBERT on Spanish training data – English is omitted as performance is worse and adaptation data is in Spanish. Finally, we evaluate performance when finetuning mBERT on the training sets created through projection.

4.2 Results

We present results for both tasks in Table 2.

POS For POS tagging, the baseline zero-shot performance is extremely poor, and we see a minimum increase of 11.71% accuracy when using any projection method. Giza++ outperforms FastAlign, as well as projection with +MLM-T, however the best performance is achieved with +MLM-ST, with +TLM offering the second best result. While the ordering of methods changes, the best performance is still achieved with the neural approaches, consistent with the results of Experiment 1.

NER For NER, baseline performance is high: inspecting the data shows that many entities have English or Spanish names, and as multilingual models already have knowledge of these two languages,



(a) Subset Analysis

(b) Length Analysis

Figure 2: Plots for data analysis. In Figure 2b, a vertical line denotes the average example length for Bribri.

standard aligners with projection may not effectively leverage surface word-form clues. However, they remain a valuable indication of alignment quality. Among the projection-based approaches, we find that using Giza++ again outperforms +MLM-T and FastAlign but falls short of +MLM-ST and +TLM.

Overall, considering what both downstream tasks indicate regarding alignment quality, neural models adapted using Spanish and target-language data—either sentence-aligned or unaligned—consistently outperform traditional methods.

5 Analysis

As data for low-resource languages often varies considerably in both amount and length, we consider two additional analysis experiments which control for these factors. We focus solely on Quechua, as it has the most parallel data available. Results are presented in Figure 2 with numerical results in Tables C.4 and C.5.

Subset Analysis For this analysis, we ask how the performance of neural alignment depends on the amount of data and with how much data it surpasses traditional approaches. We subsample the adaptation data, and use this to extract alignments using both FastAlign and AWESoME. Results for this experiment can be seen in Figure 2a. For reference, we also plot the AER obtained when using FastAlign on all the available training data as an upper bound for the performance of the traditional approaches. In the smallest extreme, all methods are roughly equivalent. However, as the number of examples increases, adaptation using +TLM and +MLM-WT improves at a faster rate than other approaches: with only 6400 sentence pairs, these approaches overtake the best expected performance of FastAlign.

Length Analysis Aligner performance may not only be affected by the total number of examples available, but also by the length of these examples. This is doubly relevant for low-resource languages, as resources may be limited to sources which do not contain long (or even complete) sentences. To see how the performance of each method may vary when faced with examples of different lengths, we sort the unlabeled data by the number of characters, and partition the examples in groups of 7508, the total number of examples available for Bribri. We choose this amount as it is representative how much data may be available for other low-resource languages. As before, the expected upper bound FastAlign performance is denoted. For the shortest group, all methods are similar; however, AWESoME alignments improve with longer sequences, with +TLM showing the quickest decrease in error rate. We attribute the improved AER when adapting using longer sequences to the increased number of tokens available for adaptation. For Quechua, the performance of AWESoME align is sensitive to both the number of examples and sequence length. In contrast, FastAlign only shows a small improvement as example length increases.

6 Conclusion

In this work, we have investigated the performance of modern word aligners versus classical approaches for languages *unseen* to pretrained models. While classical methods remain competitive, the lowest AER on average is achieved by modern neural approaches. However, using these models comes with a larger computational cost. Therefore, the trade-off between training requirements and overall performance must be considered. If access to computing resources is limited or training time is a factor, classical approaches remain a viable approach which should not be discounted.

Ethics and Limitations

Ethics Statement

When collecting data in an Indigenous language, it becomes vital that the process does not exploit any member of the community or commodify the language (Schwartz, 2022). Further, it is important that members of the community benefit from the dataset. While the creation of a word alignment dataset will not directly impact community members, we believe that it can contribute to the development of tools, such as translation systems, that can be directly beneficial, and that increasing the visibility of these languages within the research community will further spur the creation of useful systems. Our annotations were created by either co-authors of the paper or by native speakers of the languages, who were compensated at a rate chosen with the minimum hourly salary in their respective countries taken into account.

Limitations

Test Set Size One limitation of our work is the size of the evaluation set used for our main results. This arises from the general difficulty in collecting annotations and data for low-resource, and particularly Indigenous languages. The size of the test set was chosen to balance the trade-off between the cost of annotation collection and experimental validity. Fortunately, for the task of word alignment the main metric used to summarize performance—alignment error rate—does not depend directly on the number of examples in the evaluation set, but the total number of alignments, of which there are a sufficiently high number in our evaluation set. However, even when only considering the number of examples, our test set is still within the same order of magnitude as other widely used word alignment evaluation sets, such as the Romanian–English test set which consists of 248 examples (Mihalcea and Pedersen, 2003), and the English–Inuktitut and English–Hindi test sets which have 75 and 90 examples each, respectively (Martin et al., 2005).

We run a small experiment to gain insight into how much precision is lost when using a test set of size 50, versus 248, which we choose as this is the size of the widely used Romanian–English test set mentioned above. We take 100 independent samples without replacement from the Romanian-English test set, each of size 50, and evaluate the performance of FastAlign and AWESoME align. For FastAlign, we use the training data defined by Mihalcea and Pedersen (2003), and for Awesome, we use mBERT with no additional finetuning. The distributions of AER are shown in Figure A.1, with summary statistics in Table A.1. We can see that the standard deviation of both distributions is relatively low, around 2%. At the extremes, we see a difference of -4.70% and $+4.90\%$, and -4.28% and $+6.4\%$ for FastAlign and AWESoME align respectively, between the min/max values of our distribution as compared to the whole set AER. Considering these points, we believe that the size of our evaluation set does not invalidate our experimental results and main conclusions; however, we note that additional care must be taken when comparing specific models whose performances are close together, particularly when this performance is low or close to random.

Test Set Domain Other limitations of our work arise from the sources of data used. Annotations were done using sentences sampled from AmericasNLI, which itself is a translation of XNLI. As such, any errors from the original XNLI dataset, which may have propagated through translation, will persist in our dataset as well (annotators were given the option to modify target language sentences to correct any errors). Furthermore, due to translation, the sentences may not be directly representative of a natural utterance which would be spoken by members of the communities.

Language Selection The languages we highlight in this work are true low-resource languages, and present challenges commonly faced by other low-resource languages. Namely, these languages have a relatively small amount of easily available and clean unlabeled data, are typically unseen from most released pretrained models, and are morphologically different from typically used source languages. However, one feature of these languages which may inflate aligner performance is the language script: all of our target languages share the same script with the two source languages which we use. This may lead to higher occurrences of shared words or entities, making alignment easier. As such, our results may not generalize fully to other low-resource languages which have a different script from the source languages, or which may have a script which is unseen to the underlying pretrained model.

Acknowledgements

We would like to thank Roque Helmer Luna-Montoya (Academia Mayor de la Lengua Quechua in Cuzco, Perú) and Richard Castro Mamani (Universidad Nacional de San Antonio Abad and Hinantin Software) for their help in annotating and verifying the Quechua–Spanish alignments. We would also like to thank Liz Karen Chavez Sanchez for annotating the Shipibo-Konibo–Spanish alignments. A.D.M. is supported by an Amazon Fellowship and a Frederick Jelinek Fellowship.

A Training Details and Hyperparameters

We compare two data loading strategies for adaptation: a naïve approach where each example in the dataset represents an example in the loaded training examples, and a packing strategy following the `FULL-SENTENCES` approach of Liu et al. (2019). We use the hyperparameters described by Ebrahimi et al. (2022) – a learning rate of 2e-5, batch size of 32, and warmup ratio of 1% – however due to the different loading strategy we tune the total amount of training time. We experiment with 40 and 80 epochs of training, using the alignment development set to select the final hyperparameters. For both MLM-T and MLM-ST we find that packing sequences yields better results, however for +TLM we use the naïve strategy to preserve sentence alignment. We use packing by default for Wikipedia data, due to the length of extracted documents. For all adaptation methods we find that training for 80 epochs is best, except for +MLM-ST, which we train for 40. We train with 1 Nvidia A100 or 2 V100 GPUs. Due to the computational cost associated with pretraining, we only conduct one model run for each language and method. We pretrain our models using Huggingface (Wolf et al., 2020).

Training Time As mentioned in Section 3.2, for adaptation the training duration depends on the GPU and method used, with times ranging from around 6 minutes for Bribri to 4 hours for Quechua. For the statistical approaches, both run solely on CPUs, and their training time ranges between 6 seconds to 3 minutes for FastAlign, and 43 seconds to 22 minutes for Giza++. However, GPU availability is not always certain – to roughly compare training times given a more restricted setting, we run our adaptation experiments without access to any GPUs, and compute an estimate for the total training time using only CPUs as approximately 2 weeks.

	Whole Set AER	Avg. AER	AER Std.	Min AER	25%	50%	75%	Max AER
FastAlign	35.00	35.09	1.94	30.30	33.70	35.00	36.23	39.90
Awesome	28.23	28.26	2.04	23.95	26.66	28.12	29.71	34.63

Table A.1: Summary statistics for subsample AER distribution.

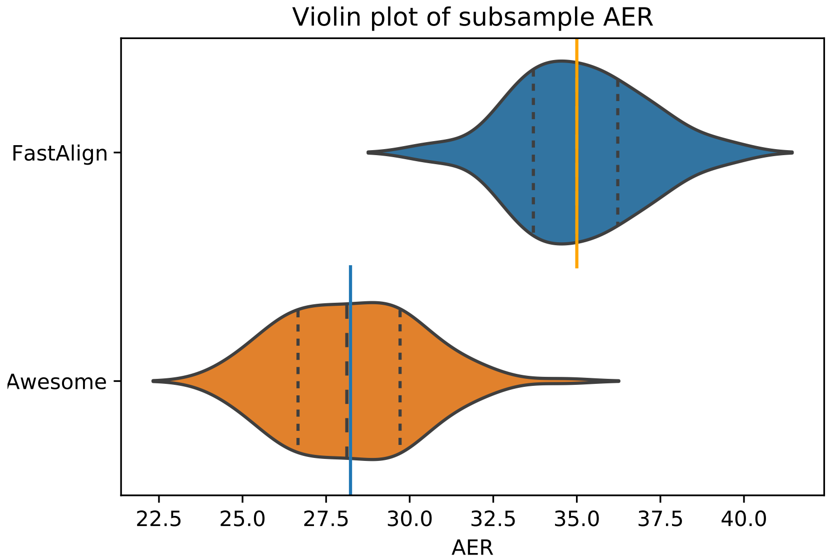

Figure A.1: Distribution of AER when using FastAlign and AWESoME align to evaluate subsets of size 50 taken from a complete evaluation set of size 248. Quartiles are displayed using dashed lines, while inverted colors represent the AER calculated when evaluating on the complete set.

B Dataset Features

Feature	BZD	GN	QUY	SHP
Number of examples (Parallel)	7,508	26,032	121,064	14,592
Number of examples (Wiki)	-	4721	22610	-
Number of tokens - MLM-T	123,992	1,104,645	3,912,582	179,451
Number of tokens - TLM	194,798	2,006,996	6,697,771	328,427
Number of tokens - Wiki	-	1,460,240	2,023,297	-
Number of dev examples	50	48	45	46
Number of test examples	50	50	50	50

Table B.1: Features of the data used for our experiments.
