outperforms TANDA by around 1, 3, and 1 absolute percent points on WikiQA, TREC-QA, and WQA, respectively. On MRR, it outperforms TANDA by around 2, 3, and nearly 2 absolute percent points on WikiQA, TREC-QA, and WQA, respectively.

B Nodes Modeled as Sentence Pairs

In the context of QA, we decide if an answer is correct or not for a question by training QA classifiers. This means that most information is captured by the pair, which is seen as the whole object. In general, we aim at modeling the similarity between pairs in the graph as we want to learn the patterns that make a pair correct. A graph having nodes as pairs directly enable this kind of learning, with also the great advantage that cross encoding two pieces of text in a transformer always produces a much higher accuracy than separated encoding of question and answer.

Evaluating and Improving the Coreference Capabilities of Machine Translation Models

Abstract

Machine translation (MT) requires a wide range of linguistic capabilities, which current end-to-end models are expected to learn implicitly by observing aligned sentences in bilingual corpora. In this work, we ask: *How well do MT models learn coreference resolution from implicit signal?* To answer this question, we develop an evaluation methodology that derives coreference clusters from MT output and evaluates them without requiring annotations in the target language. We further evaluate several prominent open-source and commercial MT systems, translating from English to six target languages, and compare them to state-of-the-art coreference resolvers on three challenging benchmarks. Our results show that the monolingual resolvers greatly outperform MT models. Motivated by this result, we experiment with different methods for incorporating the output of coreference resolution models in MT, showing improvement over strong baselines.[1]

1 Introduction

Machine translation (MT) may require coreference resolution to translate cases where the source and target language differ in their grammatical properties. For example, consider translating *"The trophy didn't fit in the suitcase because it was too small"* from English to French: *"Le trophée ne rentrait pas dans la valise car elle était trop petite"* (Sakaguchi et al., 2020). In French, suitcase (*"valise"*) is grammatically feminine, and trophy (*"trophée"*) is masculine, while the source-side English does not encode grammatical noun gender. This requires an MT model to infer that *"it"* refers to the suitcase (and not the trophy) to correctly produce the feminine inflection for the phrase *"it was too small"* (*"elle était trop petite"*), whereas an incorrect coreference resolution may produce the masculine inflection (*"il était trop petit"*) corresponding to the trophy.

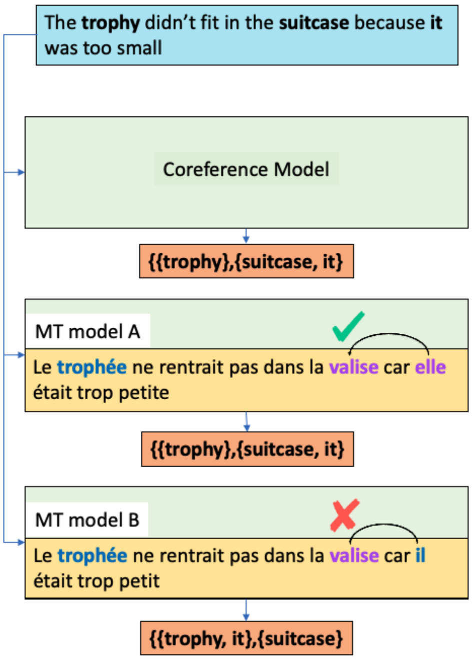

Figure 1: MT models can be compared to source-side coreference resolvers. An example translation from English (turquoise) to French (yellow). Our method first identifies the grammatical gender of the mentions in the target language marked in purple (female) and blue (male), followed by inferring the source side clusters (orange), through gender agreement.

Such texts evade lexical one-to-one translation, and instead demand source-side coreference resolution as a prerequisite for a correct translation. The prominent end-to-end approach to MT assumes that translation models implicitly learn source-side coreference resolution by observing aligned source-target pairs, without intermediate coreference supervision. While the importance of addressing such semantic phenomenon has been stated in various works (Le Nagard and Koehn, 2010; Stojanovski and Fraser, 2018), it was also observed that the ubiquitous BLEU metric (Papineni et al., 2002) does not adequately quantify it (Hardmeier and Federico, 2010; Freitag et al., 2022).

This work addresses the following research question: *How well does MT learn coreference when compared against explicit coreference supervision?* Answering this question can improve our understanding of the way MT models operate and also has practical implications: if implicit supervision lags behind monolingual training, it would motivate integration between end-to-end MT approaches and explicitly-supervised monolingual components.

In Section 3 we devise an evaluation paradigm that reduces MT output to source-side coreference resolution predictions by inferring coreference clusters from source inputs and predicted target translations. E.g., in the previous example, a feminine inflection for the pronoun "it" in French can infer linking "it" with "suitcase", while a masculine French inflection links "it" with "trophy", as shown in Figure 1. This approach allows us to distill the coreference resolution abilities of MT models and compare them against state-of-the-art coreference resolution models, trained explicitly on the task.

We use this approach to evaluate the coreference capabilities of several commercial and open source MT systems, translating from English to six target languages. We conduct our experiments in both synthetic (WinoMT and Wino-X; Stanovsky et al., 2019; Emelin and Sennrich, 2021) and naturalistic settings (BUG; Levy et al., 2021). Our results show that state-of-the-art coreference resolvers vastly outperform MT models on several benchmarks, indicating that explicit supervision may lead to better coreference performance.

Following this finding, in Section 4, we develop methods for improving coreference in MT, both implicitly and explicitly. Our implicit approach consists of fine-tuning MT models on texts that specifically require many coreference decisions, thus exposing the model to more implicit coreference signal. Our explicit approach further enriches source sentences with predicted coreference markers. We show that these approaches improve coreference over the end-to-end MT approach, achieving comparable or better results than much larger MT models, both commercial systems and open-source.

More broadly, our approach can be applied to improve the translation of other semantic phenomena that diverge in realization between source and target languages, such as plurality in second-person pronouns (Stanovsky and Tamari, 2019) or tense marking (Wolfram, 1985).

2 Background: Gender Bias in MT

We start our work by extending the methodology developed in (Stanovsky et al., 2019), which relies on target-side morphology to infer the translated gender of certain professions.

In particular, assuming a dataset of English sentences D, where each instance includes gold coreference annotation between a human entity and its pronoun (e.g., *"The* ***doctor*** *asked the nurse to help* ***her*** *with the procedure."*), they evaluate gender bias from English to language T with morphological gender in the following manner:

1. Predict word alignment between D and $M(D)$, i.e., the output translations of an MT model M. This finds the translations for pronouns (e.g., *"her"*) and possible entities (e.g *"doctor"*, *"nurse"*) in the target language T.
2. Automatically extract the gender of the possible entities and the pronouns in the target language based on morphological features.
3. Check whether the gender of the co-referred entity (e.g., *"doctor"*) in T corresponds to the gender of the English pronoun (e.g., *"her"*).

The gender bias of M is then defined as the difference in performance between stereotypical and anti-stereotypical gender role assignments.

We use a similar setup to address a different question: rather than evaluating the gender bias of the model, we evaluate its coreference abilities, which may be hindered by bias, but also by the inherent difficulty to infer coreference in the absence of an explicit training signal.

3 MT Models Fare Poorly Against Coreference Resolvers

The approach taken in WinoMT is limited as it restricts the evaluation to sentences with a known gender in English, indicated by a gendered pronoun of a human entity (e.g., *her*). Consider the sentence in Figure 1: *"The trophy didn't fit in the suitcase because it was too small"* with the coreference cluster $\{$suitcase, it$\}$. Step 3 in Stanovsky et al.'s method will fail to assign a coreference label to the translation, because *"it"* does not have a gender in English. In this section, we extend the WinoMT approach in order to estimate more general coreference abilities of MT models.

To achieve this, we note that many languages have gender agreement between pronouns and the noun that they refer to. Therefore, correct target-side gender agreement requires (implicitly) resolving the source-side coreference of the relevant entities. As exemplified in Figure 1, a reader of the French translation would infer from the gender inflection of "it" whether it refers to "suitcase" or the "trophy". I.e., a feminine pronoun ("elle") would agree with the feminine noun suitcase ("valise"), while a masculine pronoun ("il") would agree with the masculine noun trophy ("trophée'). We therefore formulate a new metric quantifying the ability of the MT model to implicitly resolve source-side coreference (henceforth, *Target-side Consistency*), defined as the proportion of instances in which the morphological gender of an entity (e.g., "suitcase") matches that of its referring pronoun (e.g., "it") in the target language T.

This metric examines whether an MT model is consistent in its coreference decisions, regardless of whether it correctly inferred the coreference relations in the input text. Indeed, some texts may keep the English ambiguity in the translation, and hence absolve the MT model from resolving coreference. For example, in the sentence *"The battery didn't fit in the suitcase because it was too small"*, both *battery* and *suitcase* are feminine in French. Our proposed metric will correctly indicate that the MT model was successful in such cases (albeit trivially). The metric thus serves as an upper bound on the MT model's coreference abilities.

We note that while this framing uses the morphological gender inflection of common nouns, it is different in motivation from measures of gender bias. In our example above, gender inflection allows us to determine whether an MT model correctly employs common sense rather than examining whether it tends to prefer stereotypical gender norms. While a model's gender bias may explain some loss in coreference abilities, the model's ability to resolve coreference need not be aligned with the degree of its bias (e.g., a random gender assignment would result in unbiased performance, but very poor coreference ability).

Most importantly, by considering the gender of the entity and the pronoun, we obtain mention clusters which can be compared against those produced by coreference resolution models. In our example figure, both the first MT model and the coreference model produce the correct clustering: {{trophy}, {suitcase, it}}, while the second MT model errs by producing: {{trophy, it}, {suitcase}}.

Another aspect of our evaluation methodology is its generality. Our method does not require a reference translation or make any particular assumptions about the generated output. As there are generally many correct translations, this flexibility allows us to accurately assess the model's coreference abilities. For instance, our methodology does not assume the gender of the entity's translation as can be seen in the first example in Table 7 where the two systems translate the entity "jar" differently. Further, some languages might not always translate an English pronoun into a pronoun but still express its gender in a different word. Consider the second example in Table 7 where the alignment model (step 2 in §2) finds that the English word "it" is aligned with both "l" and "trouvée" in French. Here, the feminine suffix of the past participle "trouv**ée**" indicates that the ellipsis "l" corresponds to a feminine entity.

3.1 Evaluation Setup

Evaluation datasets. The first dataset we use is Wino-X (Emelin and Sennrich, 2021), a filtered subset of WinoGrande (Sakaguchi et al., 2020) built to test commonsense reasoning and coreference resolution of MT models and multilingual encoders. The dataset contains sentences similar to the one in Figure 1. All sentences have two entities and a pronoun, "it", coreferring to one of them. The dataset consists of three parts, each part constructed for a different target language (German, French, and Russian), where each part only contains sentences where the two entities have different morphological gender in the target language (e.g., in French *"trophy"* is masculine whereas *"suitcase"* is feminine). Hence, applying our target-side consistency metric on these filtered sentences avoids trivial instances where both candidate entities have the same gender in the target language, and provides a clearer picture of the coreference capabilities of the model.

Second, we use WinoMT (Stanovsky et al., 2019),[2] a dataset built following the Winograd schema (Levesque et al., 2011), designed to test gender bias and coreference resolution of MT models. The sentences in this dataset contain two human entities and one gendered pronoun, e.g., *"The doctor asked the nurse to help her in the proce-*

[2] WinoMT is a combination of Winogender (Rudinger et al., 2018) and WinoBias (Zhao et al., 2018).

Dataset	#sentences
Wino-X (en → de)	3,774
Wino-X (en → fr)	2,988
Wino-X (en → ru)	2,238
WinoMT	3,888
BUG	1,717

Table 1: Statistics of our evaluation datasets. Note that in all datasets we use the corresponding English source-side sentences as our input.

dure". The gendered pronoun reveals the gender of the entity and adds gender attributes to the source cluster. In our example, *"her"* refers to the *"doctor"*, revealing the doctor's gender.

Our third dataset is BUG (Levy et al., 2021), a semi-automatic collection of naturalistic English sentences that are challenging with respect to societal gender-role assignments. Similar to WinoMT, each sentence contains a human entity, identified by their profession and a gendered pronoun. To reduce noise, we use the GOLD portion of this dataset which was validated by human annotators. All datasets statistics are presented in Table 1.

Machine translation models. We apply our evaluation methodology to four Transformer-based machine translation models from EasyNMT:[3] mBART50 (Tang et al., 2020; Liu et al., 2020), M2M_418M, M2M_1.2B (Fan et al., 2021), and the bilingual Opus-MT (Tiedemann and Thottingal, 2020), representing the state-of-the-art for publicly available neural machine translations models. In addition, we measure coreference consistency on the output of two commercial systems: Google Translate[4] and Microsoft Translator.[5]

Target languages. For WinoMT and BUG, we translate from English to six different languages: Arabic, German, Spanish, Hebrew, Russian and French. These languages form a diverse set with respect to how they encode grammatical gender (e.g., number of grammatical genders), as well as to their orthography, word order and other linguistic traits, while still allowing for highly accurate automatic morphological analysis. These languages belong to four families: (1) Romance languages: Spanish and French, which have gendered noun-determiner agreement with two grammatical genders; Spanish is also a *pro-drop* language, i.e., pronouns can be omitted in certain cases, which in our setting may keep the coreference ambiguity of the source-side English sentence (Webster and Pitler, 2020). (2) Slavic languages (with Cyrillic alphabets): Russian with 3 grammatical genders. (3) Semitic languages: Hebrew and Arabic, each with a unique alphabet; both are partial pro-drop languages and have two grammatical genders. (4) Germanic languages: German with 3 grammatical genders.

	Wino-X	WinoMT	BUG
SpanBERT	51.2	76.6	72.0
s2e	**60.8**	81.7	72.2
LINGMESS	58.7	**83.7**	**74.6**

Table 2: Accuracy of SpanBERT, *s2e* and LINGMESS model on our evaluation datasets. For simplicity, we report the accuracy on Wino-X sentences from the three languages as a single corpus, because there is a small difference between the languages (up to 0.3).

	en → de	en → fr	en → ru
mBART50	37.4	**56.6**	44.6
M2M_418M	31.4	48.5	**44.9**
Google	**41.3**	36.3	40.7
Microsoft	40.5	36.7	43.5
Opus-MT	37.4	35.3	43.6

Table 3: Target-side consistency results of commercial and open-source MT systems on Wino-X when translating into German, French, and Russian.

3.2 Target-side Consistency Results

We first evaluate the accuracy of existing coreference resolvers on our three evaluation datasets, where accuracy is defined as the percentage of instances in which the model identifies that the pronoun is coreferring with the correct entity. We select state-of-the-art models trained on CoNLL-2012 (Pradhan et al., 2012): SpanBERT (Joshi et al., 2020),[6] the s2e model (Kirstain et al., 2021) and LINGMESS (Otmazgin et al., 2022). Results in Table 2 show that coreference models perform quite well on WinoMT and BUG but poorly on Wino-X (60.8 for *s2e*), indicating weak commonsense capabilities.

Table 3 shows the target-side coreference consistency scores for all MT models on Wino-X, which, as mentioned above (§3.1), includes only sentences

Table 4: Target-side consistency results of commercial and open-source MT systems on WinoMT and BUG when translating into different languages. These numbers are an upper bound for the source-side coreference accuracy.

where the entity and pronoun should be translated using different genders in the target language. We observe that all MT models perform poorly on Wino-X with the highest average score of 46.2 for mBART50, which vastly underperforms English coreference resolvers by 14.6 points. Interestingly, many instances are inconsistent because models tend to generate *neutral* pronoun whereas a gendered pronoun is expected, for example, *cela*, *c'était* in French (31% of translations) and это,они in Russian (17% of translations), meaning "this" or "they" in English. Likewise, 68% of German translations include neutral pronouns (e.g., "es"), while only 22% of the entities are neutral. The reported percentages were calculated on Opus-MT. Similar trends were observed in all models.

Table 4 shows the target-side consistency results for WinoMT and BUG. Following common practices on those datasets (Stanovsky et al., 2019; Levy et al., 2021), we omit sentences where the candidate pronoun does not provide information about the entity's gender. For example, in French, possessive pronouns agree with the gender of the possessed object, rather than the possessor as in English. Another example is in Spanish, which is a pro-drop language, where a valid translation can drop the pronoun and use a generic verb, leaving the only gender signal in the translation to be marked on the profession noun. See App. §C for more examples.

Similarly to Wino-X, target-side consistency results on WinoMT are consistently lower than coreference resolvers. Further, we observe that consistency is affected by two factors: the MT model and the target language. Regarding models, Opus-MT achieves lowest performance, with average consistency of 59.3, while mBART50 achieves high results with average consistency of 70.5, sometimes surpassing the second-best MT model by about 9 points. This might be due to the extensive pretraining of mBART50, as previously demonstrated for monolingual LMs (Huang et al., 2019; Sakaguchi et al., 2020; Bhagavatula et al., 2020). With respect to target languages, Russian consistency results are systematically lower than the results in other languages, to the extent that the best model in Russian provides lower results than the worst model in most other languages. In contrast, all models in German achieve a consistency score of about 70 or more, which can be due to its similarity with English and the research focus on improving English-German translations.

Consistency results on BUG are higher than on WinoMT for most models, while sometimes surpassing English coreference resolvers, notably in Hebrew and Arabic (e.g., 91.8 for Google vs. 74.6 for LingMess). To understand this gap, we analyze the translation of 50 BUG sentences to Hebrew and French and find that most instances (45 in Hebrew and 33 in French) do not include a distracting entity which should be translated to a different gender in the target language. As mentioned above (§3), our metric trivially indicates those examples as consistent.

Overall, target-side consistency results across all datasets demonstrate that both open-source and commercial MT systems exhibit rather poor coreference capabilities compared to English coreference models.

3.3 Human Validation

The use of automatic tools in the proposed methodology inevitably implies the introduction of noise into the process. To assess the quality of our measurements, we randomly sampled 50 translations of the Opus-MT model from all evaluation datasets and in all target languages (for a total of 750 annotations), annotating each sample in-house by a native speaker of the target language. The human annotators were asked to identify if the candidate pronoun is indeed the target pronoun and to verify that the gender prediction is correct. This way, we can account for both types of possible errors, i.e., alignment and gender extraction.

We compare the human annotations to the output of our automatic method and find that the average agreement over all languages and datasets is above 90% (see full results in App. §A). These results are comparable to the ones reported by Stanovsky et al. (2019), who conducted human validation and reported that their alignment and gender prediction of the entity in question were reliable for 85% of translations across all languages.

Some errors can be caused by idiosyncrasies that affect the morphological analysis, as Stanovsky et al. (2019) noted. For example, gender for certain words in Hebrew cannot be determined without diacritics, and some pronouns in German are used in both masculine and neutral forms (e.g., sein), or feminine and third-person plural forms (e.g., ihr). In addition, we notice that sentences from BUG, specifically in partial pro-drop languages, were found to be more challenging for the alignment model, and account for most mistakes in Hebrew and Arabic.

4 Improving MT Coreference Consistency

In the previous section we showed that the coreference performance of MT systems, obtained through an implicit signal, seems inferior to that of coreference resolution learned from an explicit signal. This result raises the question of whether we can leverage dedicated conference resolvers to improve the consistency of MT coreference.

To address this question, we propose two data augmentation techniques that leverage a source-side English coreference model, and show that fine-tuning on them indeed improves coreference resolution in MT.

Augmented fine-tuning with instances which require coreference resolution. First, we run a coreference resolution model on the source-side sentences. We then consider two approaches for constructing the augmented fine-tuning data: (1) *Coref data* with all sentences that have non-singleton clusters and (2) *Gender data*, a subset of *Coref data* where there is at least one non-singleton cluster with a gendered pronoun (he, she, her, him, hers, his). The motivation for this augmented fine-tuning strategy is that further fine-tuning on such instances would expose the MT model to examples that may bear a coreference signal.

	de	es	fr	ru	he	ar
Coref data	500K	744K	761K	149K	1.1M	1.4M
Gender data	38K	50K	51K	19K	265K	268K

Table 5: Number of fine-tuning instances in *Coref Data* (requiring some sort of coreference resolution) and *Gender data* (requiring coreference resolution with some gendered pronoun) for each target language.

Adding explicit source-side coreference markers. Second, we use the non-singleton clusters from the coreference model to add inline coreference markers in the source sentences. For our example sentence, this process produces the following source-side sequence: *"The trophy didn't fit in the **<ENT1>** suitcase **</ENT1>** because **<ENT1>** it **</ENT1>** was too small"*, indicating that "suitcase" and "it" are coreferring.

4.1 Experimental Setup

MT models. In our fine-tuning experiments, we opt for the Opus-MT model, since its size (68M parameters) and efficiency (Junczys-Dowmunt et al., 2018) enables us to run extensive experiments across many languages.

Training datasets. For fine-tuning data of Spanish, French, and German, we use Europarl (Koehn, 2005), and for Russian, Hebrew, and Arabic, we use CCMatrix (Schwenk et al., 2021), randomly sub-sampled to 5M sentences for computational reasons. In each dataset, we find instances that require coreference resolution and add appropriate markup using the *s2e* coreference resolver. We use *s2e* as it performed well in the previous experiments. Table 5 shows the size of *Coref data* and *Gender data* for all training datasets. Note that invariably *Gender data* is an order of magnitude smaller than *Coref data*.

Fine-tuning and inference. For each language, we fine-tune the Opus-MT model using four different finetuning datasets: (1) *Coref data* (2) *Coref data* with explicit coreference markers, (3) *Gender data* and (4) *Gender data* with explicit coreference markers. The inference on our three evaluation datasets (Wino-X, WinoMT, BUG) conforms with the fine-tuning procedure of each model. Namely, we run the models (1) and (3) on raw English sentences. For the models (2) and (4), we first add explicit coreference markers according to the output of the *s2e* model (a) or the gold annotation (b), then translate those augmented sentences to the different languages.

4.2 Results

Table 6 shows the target-side coreference consistency scores of all our fine-tuned models on Wino-X and WinoMT (see App. §B for the performance on BUG, which follow similar trends). For both datasets, our fine-tuned models surpass the Opus-MT baseline model, while preserving the overall translation quality, as indicated by automatic measures such as BERTScore (Zhang et al., 2020) ($+0.08\%$) and COMET-20 (Rei et al., 2020) ($+0.0025$).

Effect of augmented fine-tuning data. The models fine-tuned on *Coref data* (1) and *Gender data* (3) outperform the Opus-MT baseline for all languages, both in Wino-X and WinoMT. This demonstrates that MT models learn implicitly linguistic phenomena from instances involving those phenomena. Furthermore, we point out that consistency scores on Wino-X are generally higher when fine-tuning on *Coref data* (1, 2a, 2b) while WinoMT results are better when fine-tuning on *Gender data* (3, 4a, 4b). This performance gap likely stems from the similarity between WinoMT and *Gender data* (as both include gendered pronouns), while Wino-X's like sentences with the pronoun "it" appear only in *Coref data*. This further confirms the important role of fine-tuning data, which is in line with the observation of Saunders and Byrne (2020), that smaller, more goal-oriented data is better for fine-tuning, compared to much larger but less focused data.

Effect of explicit coreference markers. In the majority of our experiments (13/18), the explicit fine-tuning models (2a and 4a) outperform the implicit data augmentation approach when using the same augmented data (1 and 3) (see examples in Table 7). These results suggest that an explicit monolingual signal can improve results more than an implicit signal. Results also show that the improvement is more pronounced when incorporating gold coreference markers (2b and 4b) instead of predicted markers (2a and 2b). Hence, applying more accurate coreference resolution models than the *s2e* model will result in higher target-side consistency results.

4.3 Analysis

We turn to observing the empirical effect of the suggested fine-tuning strategies, using additional metrics. For each sentence in Wino-X, we have the gold target pronoun that should appear in its translation. We use it to compute pronoun translation accuracy by comparing the candidate pronoun with the gold target pronoun. Table 8 presents the results. We can see that our method provides a large improvement over the baseline. Comparing these results against those of prominent open-source and commercial MT (see App. §D) shows that our approach outperforms other MT models in German and Russian, and is only second in French.

In WinoMT, Stanovsky et al. (2019) computed *gender accuracy* as the percentage of instances in which the translation preserved the gender of the entity from the original English sentence (§2). Table 9 shows that our approach improved gender accuracy results across all languages except Arabic.

Other metrics that Stanovsky et al. (2019) used, are ΔS and ΔG. ΔS measures the difference in gender accuracy between stereotypical and non-stereotypical gender role assignments (as defined by Zhao et al., 2017), and ΔG measures the difference in performance (F1 score) between source sentences with male and female entities. Our method decreases biases in both ΔS and ΔG by 5-6 points on average, indicating that the explicit signal helps the model in associating the pronoun with the coreferring entity, even in the presence of social and gender biases.

5 Related Work

The study of coreference has a long tradition in machine translation. A long line of work uses pronoun translation as a way of measuring coreference, since BLEU-based evaluation was shown to be insufficient for measuring improvement in coreference (Hardmeier and Federico, 2010).

An alternative evaluation methodology is using automatic reference-based methods that produce a score based on word alignment between the source, reference translation, and translation output, and identification of pronouns in them, such as AutoPRF (Hardmeier and Federico, 2010) and APT (Miculicich Werlen and Popescu-Belis, 2017). Nevertheless, a later human meta-evaluation showed

substantial disagreement between these metrics and human annotators, especially because of the existence of valid alternative translations and pronouns than the ones used in the reference (Guillou and Hardmeier, 2018). Based on these conclusions, Sennrich (2017) developed a scoring-based evaluation approach that compares model scores of a predefined set of correct and incorrect translations and evaluates how often the model selects the correct option.

Our method extends (Stanovsky et al., 2019), which used a reference-free approach by aligning the source and candidate translation, but focused on entity translation accuracy to evaluate gender bias in MT models. The availability of references was assumed by most previous work (Guillou and Hardmeier, 2016; Bawden et al., 2018; Müller et al., 2018; Stojanovski et al., 2020; Emelin and Sennrich, 2021), where most of them are limited to a single language pair. The flexibility afforded by a reference-free approach allows us to evaluate any target language for which an alignment model and morphological analyzer are available. Moreover, our approach is not restricted by a predefined set of translations and can also correctly detect valid translations that are different from the reference.

Several previous methods aimed to improve the coreference abilities of MT models and reduce undesirable biases, by modifying the training data in ways that share some similarities with our method. Vanmassenhove et al. (2018) incorporate a "speaker gender" tag into training data, allowing gender to be conveyed at the sentence level. Similarly, Moryossef et al. (2019) added a prefix to disambiguate the coreference in the sentence. Stojanovski and Fraser (2018) used oracle-based approach to inject new tokens indicating the pronoun translation and its gender into the source sentence. Our method is novel in the way it enriches the data with coreference signal using only the source-side signal, and thus requires only an English coreference resolution model without the need for coreference annotation in the target language.

6 Conclusion

Our work is the first to present an automatic methodology for assessing the coreference capabilities of MT models, that can be applied in any target language and does not require any target side annotations. Furthermore, to the best of our knowledge, we are the first to conduct a large-scale multilingual coreference evaluation study on prominent open-source and commercial MT models, and compare them against state-of-the-art coreference resolvers on three challenging benchmarks. Finally, based on the superior results of coreference resolvers, we propose a novel approach to improve the coreference capabilities of MT models, that outperforms or achieves comparable results to strong and larger MT models. Despite this substantial gain, there is still a performance gap between our model and state-of-the-art coreference resolvers. We hope that our work, and specifically our automatic evaluation methodology, will encourage future research to improve the coreference capabilities of MT models.

Future work can expand our approach to account for number and person agreement phenomena, investigate how to extend our approach to more coreference clusters and more mentions per cluster in intra-sentential as well as inter-sentential settings. Moreover, we intend to investigate how different morphological attributes affect MT models' coreference abilities.

Limitations

Even though our study presents the first large-scale multilingual coreference evaluation study in MT, it still has some limitations that could be addressed in future work. First, our methodology provides an upper bound to the coreference capabilities based on detecting gender valuations. While this could allow for a controlled evaluation experiment, this upper bound can become non-indicative in cases where gender assignment is not a discriminative factor. This can be addressed by accounting for more semantic and syntactic constraints that the translation needs to follow (e.g., singular/plural agreement).

Second, our setting addresses one entity and a single co-referring pronoun in the naturalistic sentences experiment. Our methodology could in principle be augmented to deal with more coreference clusters and mentions per cluster. Another possible extension is to include event coreference in addition to entity coreference. For example, in this work, we focus only on the anaphoric function of the pronoun "it" but further research can also examine the event function of "it" (Loáiciga et al., 2017).

Third, MT models should generally produce translations with accurate gender inflection for all words. However, in this work, we focus on the *coreference* capabilities of MT models by evaluating gender agreement between coreferring *entity* mentions. Future research can extend our evaluation methodology to assess the gender inflection of verb and adjective translation (e.g., the gender of "big" and "small" in Figure 1), using additional tools and resources such as a semantic role labeling model and a dependency parser.

Finally, although in Section 4 we show big gains from the fine-tuning approach, it is clear that there is much room for improving the coreference capabilities of MT models, especially with regard to the performance of state-of-the-art coreference resolvers. We hope this work will help others develop MT models with better coreference capabilities.

	he	ar	es	ru	fr	de
alignment error	14	19	4	4	4	0
gender prediction error	7	7	0	7	2	2
correct annotation	79	74	96	139	144	148
Total # of annotation	100	100	100	150	150	150

Table 10: Human validation results on our three evaluation datasets and six target languages.

A Human Validation Results

Table 10 shows the complete human annotations results. The results indicate that alignment and gender prediction are accurate in most languages. In Arabic and Hebrew, the alignment error occurs more. A possible explanation for that can be the fact that both those languages are partial pro-drop languages. To verify that those results will not affect our measurement, we verified that the error has similar consistency distributions as the rest of our results.

B BUG Consistency Results

Table 11 presents the target-side consistency results of the Opus-MT baseline model and all our fine tuning approach on BUG. Similarly to Wino-X and WinoMT, our fine-tuned models outperform the baseline.

C Omitted Cases

Table 12 shows translation examples from English to French and Spanish that demonstrate unique features in each language. The first example shows a French translation that contains a possessive pronoun, which does not indicate the gender of the possessor. The second example shows a Spanish translation where the pronoun is omitted. In both cases, we can obtain a correct translation without information concerning the aligned pronoun gender, we therefore exclude them from the evaluation.

D Pronoun Translation Accuracy

Table 13 shows pronoun accuracy results of our baselines on Wino-X. We can notice those results are similar to our consistency results although our methodology does not use any annotated target data. Moreover, those results clearly show that MT models struggle with translating sentences that demand solving the source side coreference resolution.

	en→de	en→es	en→fr	en→ru	en→he	en→ar
Opus-MT	79.8	85.1	86.2	67.3	88.8	88.0
gender data	84.1	**87.4**	88.7	69.9	**90.2**	91.3
+coref markers	**84.2**	**87.4**	**88.8**	**70.1**	89.8	**91.8**

Table 11: Target-side consistency results of our implicit and explicit fine tuning approaches on BUG.

Source	[Target lang.] Predicted translation	Phenomenon
The developer argued with the designer because his idea cannot be implemented.	[FR.] Le développeur a argumenté avec le concepteur parce que son idée ne peut pas être mis en œuvre.	"son" is male because the possessed noun ("idée") is male.
The doctor asked the nurse to help her in the procedure	[ES.] El doctor le pidio a la enfermera que le ayudara con el procedimiento	In Spanish, the pronoun "her" is dropped in the translation.

Abstract

Most existing work on text simplification is limited to sentence-level inputs, with attempts to iteratively apply these approaches to document-level simplification failing to coherently preserve the discourse structure of the document. We hypothesise that by providing a high-level view of the target document, a simplification plan might help to guide generation. Building upon previous work on controlled, sentence-level simplification, we view a plan as a sequence of labels, each describing one of four sentence-level simplification operations (copy, rephrase, split, or delete). We propose a planning model that labels each sentence in the input document while considering both its context (a window of surrounding sentences) and its internal structure (a token-level representation). Experiments on two simplification benchmarks (Newsela-auto and Wiki-auto) show that our model outperforms strong baselines both on the planning task and when used to guide document-level simplification models.

1 Introduction

Text simplification aims to transform a given text into a simpler version of itself that preserves the core meaning such that it can be better understood by a wider audience (Gooding, 2022). Simplification has also been shown to be a useful preprocessing step for downstream NLP tasks such as relation extraction (Miwa et al., 2010; Niklaus et al., 2016) and machine translation (Chandrasekar et al., 1996; Mishra et al., 2014; Li and Nenkova, 2015; Štajner and Popovic, 2016).

Previous research has mostly considered the simplification of isolated sentences. Much work has focused on training a statistical or a neural model on pairs of complex and simplified sentences assuming that such models will learn to perform simplification operations (e.g. sentence splitting, lexical simplification or syntactic rephrasing) implicitly from the inductive bias present in the training data (Zhang and Lapata, 2017; Nisioi et al., 2017; Jiang et al., 2020). However, because the training data is obtained using distant supervision techniques and is often imbalanced in terms of simplification operations (many of which occur infrequently (Jiang et al., 2020)), system outputs have been found to be overly conservative, often making no changes or being limited to the paraphrasing of short word sequences (Alva-Manchego et al., 2017; Maddela et al., 2021). In addition, these systems provide limited capacity for controllability and are unable to express alternative variants of the simplified text (Alva-Manchego et al., 2017; Cripwell et al., 2021).

In response, controllable simplification systems have been proposed which either constrain attributes of the output (length, amount of paraphrasing, lexical and syntactic complexity) (Martin et al., 2020) or explicitly specify which simplification operation to perform (Alva-Manchego et al., 2017; Dong et al., 2019; Malmi et al., 2019; Scarton et al., 2020; Maddela et al., 2021; Cripwell et al., 2022).

To guide the simplification of full documents, we combine the power of data-driven neural generative models with strategies from controllable simplification. Our hypothesis is that document-level simplification can be facilitated by a plan specifying how each complex input sentence should be transformed to yield a simplified version of that document - should it be copied, deleted, split or rewritten?

We make the following contributions: We present a model for predicting document simplification plans which leverages both the context of sentences and their internal structure (the words they consists of). We create the data necessary to train this model by labelling complex sentences in simplification corpora with the simplification operation that relates it to the corresponding simplified sentence. We compare our planning model with several alternative neural architectures and we briefly examine the impact of planning on document simplification.

Experiments on two simplification benchmarks (Newsela-auto and Wiki-auto) show that our model outperforms strong baselines both on the planning task and when used to guide document-level simplification models. [1]

2 Related Work

Document-Level Simplification. There is limited existing work on document-level text simplification. Early attempts largely applied sentence-level techniques iteratively over a document (Woodsend and Lapata, 2011a; Alva-Manchego et al., 2019b). However, this is generally viewed as insufficient for certain operations and maintaining the discourse coherence of the document (Siddharthan, 2003; Alva-Manchego et al., 2019b).

There are several works that address subproblems of simplification that only consider a limited set of operations, like paraphrasing and sentence re-ordering (Lin et al., 2021), insertion (Srikanth and Li, 2021) or deletion (Zhong et al., 2020; Zhang et al., 2022). Others fully address simplification but only extend inputs to the level of paragraphs without clearly differentiating the problem from the sentence-level (Laban et al., 2021; Devaraj et al., 2021).

Recently, Sun et al. (2020) proposed a sentence-level model (SUC) that uses an encoding of surrounding sentences as context information to influence the simplification. They use two extra encoders to build a representation of the two preceding and two following sentences, which are attended over in their encoder-decoder generative model. However, when applied to the document-level task, their system was unable to outperform any baseline systems (Sun et al., 2021).

Operation Prediction. Revision-based simplification models learn to predict edit operations to apply at the token-level rather than generating the entire simplification from scratch (Alva-Manchego et al., 2017; Dong et al., 2019; Kumar et al., 2020; Omelianchuk et al., 2021; Dehghan et al., 2022). This has the benefit of providing more control and interpretability over generative approaches, often at the cost of the ability to perform major structural changes. It also allows some systems to leverage non-autoregressive generation strategies, resulting in faster inference times (Malmi et al., 2019; Omelianchuk et al., 2021).

Some works have attempted to predict rewrite operations at the sentence-level. Applying a binary classifier to predict whether simplification should be performed has been found to improve SARI results, reducing conservatism and spurious transformations (Scarton et al., 2020; Garbacea et al., 2021). Others have proposed multi-class systems to predict sentence-level operations that are then used to condition a generative model (Scarton and Specia, 2018; Scarton et al., 2020; Cripwell et al., 2022). These show some capacity for general improvement over end-to-end systems, while also significantly improving performance for specific operations (e.g. splitting in the case of Cripwell et al. (2022)).

At the document-level, there has been limited interest to date. However, there are recent works specifically looking at predicting sentence deletions (Zhong et al., 2020; Zhang et al., 2022). Both of these use features of the discourse structure from surrounding sentences to identify likely deletion candidates.

We bring all of these methods together by proposing a system that uses both sentence and document-level information to predict a multi-class, sentence-level operation plan over an entire document.

3 Problem Formulation

Let C denote an English language document. The aim of document-level simplification is to produce a text S that simplifies the input document C.

As a plan can provide a high-level view of a document, we hypothesize that a document-level simplification model that is based on a plan specifying a simplification operation for each input sentence should fare better than a simplification model that directly simplifies an entire document.

We therefore decompose simplification into a two-stage generation process:

$$p(S \mid C) = p(S \mid C, P)p(P \mid C)$$

where input document $C = c_1 \dots c_n$ is a sequence of complex sentences, $S = s_1 \dots s_k$ is a sequence of simplified sentences and $P = o_1 \dots o_n$ is a sequence of sentence-level simplification operations for C.

---

[1] Pretrained models, code, and data are available at `https://github.com/liamcripwell/plan_simp`.

We consider three simplification operations proposed in previous work on sentence simplification (*copy*, *rephrase*, and *split*) to which we add *delete*, an operation that is needed to account for the fact that, contrary to sentence simplification, document-level simplification can require for a sentence present in the input document to be excluded from the resulting simplified document.

Given the input document C, the first-stage model aims to predict the sequence of simplification operations P that should be applied to each individual sentence in that document. The second-stage model generates the output simplified document S conditioned on the input document C and its accompanying simplification plan P.

In this work, we focus on the planning stage, comparing different architectures and demonstrating the impact of planning on three possible document-level simplification models. We leave the exploration of alternative, more complex architectures for the simplification stage to future work.

4 Data

In this section we introduce the datasets used, explain how annotation is performed for each complex sentence and describe other preprocessing steps.

Dataset. For all experiments, we utilise Wiki-auto and Newsela-auto (Jiang et al., 2020), two datasets of English documents paired with their simplification. These datasets were derived from WikiLarge (Zhang and Lapata, 2017) and Newsela (Xu et al., 2015) by aligning the input document with the output simplification at both the sentence and the paragraph level.

WikiLarge gathers three simplification datasets which were automatically-collated from English Wikipedia and Wikipedia simple (Zhu et al., 2010; Woodsend and Lapata, 2011b; Kauchak, 2013).

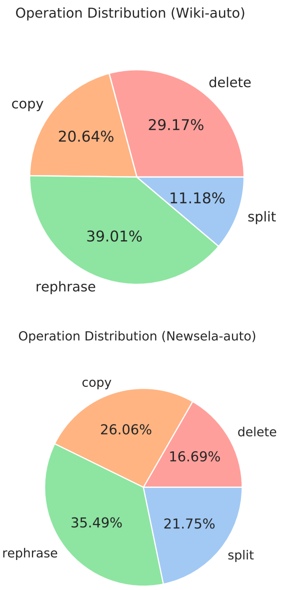

Figure 1: Operation class distributions for Wiki-auto (top) and Newsela-auto (bottom) datasets.

Newsela consists of news articles, each manually rewritten at five different levels of simplification, corresponding to discrete reading levels (0-4) of increasingly simplicity. Aligned pairs are created by pairing every article version with each other version corresponding to a higher reading level. Because of this, there can be up to four aligned document pairs that contain the same document as either the input or the output.

The types of operations present in different reading level pairings differs significantly, with adjacent level transitions being extremely conservative (no instances of deletion throughout entire dataset). To mitigate any issues arising from this, all models we train with Newsela-auto receive a control-token at the start of the input which specifies the target reading level.

We do not use the D-Wikipedia dataset from Sun et al. (2021) as it does not contain sentence/paragraph alignments and is poorly formatted. In particular, all text is lower-cased and pretokenized in a way that makes it difficult to accurately parse sentences. There are also regular formatting issues at points where references exist in the source article.

Annotating Complex Sentences. Using the pairs (c_i, s_j) of complex and simplified sentences available in Wiki-auto and Newsela-auto, we heuristically assign a silver simplification operation label to each complex sentence c_i in these two datasets as follows:

Delete: c_i is not aligned to any s_j.

Copy: c_i is aligned to a single s_j with a Levenshtein similarity above 0.92.

Rephrase: c_i is aligned to a single s_j with a Levenshtein similarity below 0.92.

Split: c_i is aligned to multiple s_js.

Preprocessing. Wiki-auto contains many document pairs with wildly different sizes. We therefore clip all complex documents after the last aligned paragraph. Many simple articles resemble a summarization, rather than a simplification of the complex article (lots of deletion, often consisting of about one sentence from each paragraph in C). Because of this, we also remove documents where more than 50% of aligned sentences are labelled as *delete*. Finally, we remove all articles that exceed 1024 tokens (so that we can fit them into a BART baseline generative model).

For Newsela-auto, article pairs are much more even in length as they are manually created to be gradual, direct simplifications of each other. We perform the same length-based filtering to exclude documents that will not fit into a baseline generative model.

Train/Dev/Test Split. For both datasets we use a train/validation/test split of 92.5/2.5/5. This is applied at the document-level so that sentences from the same document will not exist across different sets. For Newsela, this means that all reading level versions of a single article will exist within the same set.

Table 1 and Figure 1 give some statistics and a graphical description of the two datasets after pre-processing.

5 Planning

We present our model and four alternative models we explored for comparison. Training details are given in Appendix A.

5.1 Model (Contextual Classifier)

Given some input document $C = c_1 \dots c_n$ consisting of n complex sentences c_i, the task of the planner is to predict a sequence $\hat{P} = \hat{o}_1 \dots \hat{o}_n$ of n simplification operations with $\hat{o}_i \in \{$*copy, rephrase, split, delete*$\}$.

One challenge with this is that the operations have different, sometimes conflicting requirements.

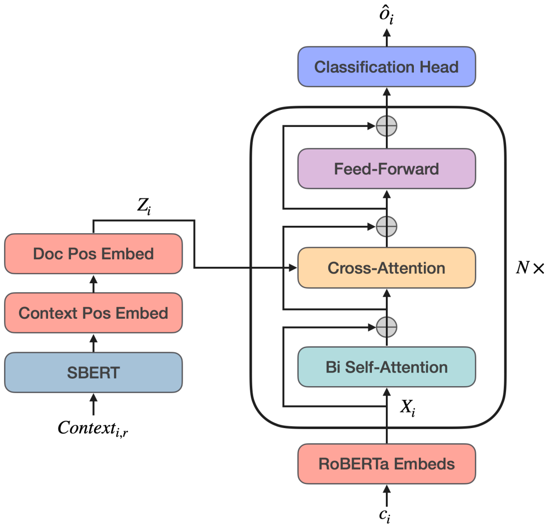

Figure 2: Contextual classifier model architecture.

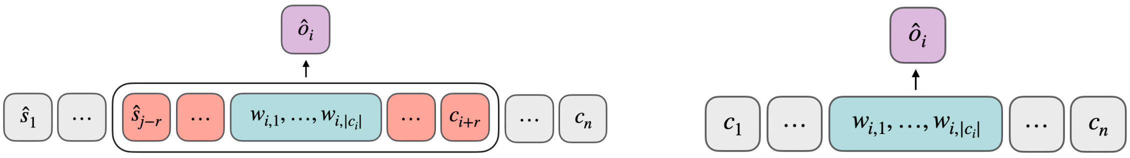
By construction, splitting is mostly context independent as it is mainly determined by the input sentence's internal structure: a sentence will be split only if it has the appropriate syntactic (e.g., The man who sleeps snores → The man sleeps. He snores.) or discourse (e.g., John went shopping after he left work → John left work. Afterwards he went shopping.) structure. For sentence splitting, context (the other sentences in the input document) has little impact.

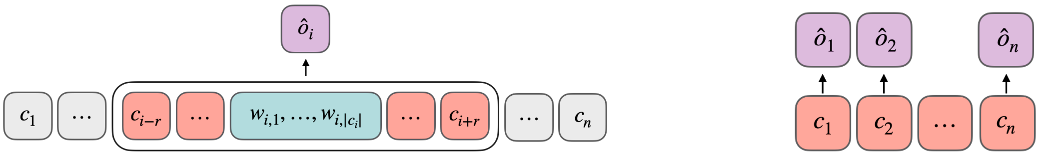
In contrast, deletion and to a lesser extent, copy and rephrase are mostly context dependent. Intuitively, a sentence can only be omitted in the simplified text in cases where it is either redundant with, or of minor semantic import relative to, other sentences in the document. That is, while for splitting, internal sentence structure is the key factor, for deletion, it is the semantics of the input sentence and how it relates to that of the other sentences which matters most.

We model these different requirements by using a token level encoder for the target document sentence c_i (the input sentence to be labelled with a simplification operation) and a sentence level representation of the context where each $c_p \in c_1 \dots c_{i-1}, c_{i+1} \dots c_n$ is represented by a sentence level embedding using SBERT. In this way both the internal structural information needed to capture splitting operations and the contextual information required by the other operations are provided. Specifically, we propose a model for planning that combines a classifier with cross-attention over the (dynamic or static) context and two types of positional embeddings. Figure 2 illustrates our model



(a) Dynamic Contextual Classifier

(b) Classifier



(c) Contextual Classifier

(d) Tagger

(e) Tagger+Dec

(f) EncDec$_{\text{full}}$

Figure 3: Visualisation of the inputs/outputs of the various models, where $w_{i,t}$ is the tth token in c_i, n is the no. sentences in C and m is the no. tokens in C. Sentence-level representations are shown in red, token-level representations in teal, operation labels in pink, and unused parts of C in grey.

architecture.

Classifier with Cross-attention over the Context. We build upon a RoBERTa classifier architecture to enable conditioning upon the surrounding sentences in the document. We do this by inserting an additional cross-attention layer between the self-attention and the feed-forward layer of each transformer block, allowing the model to attend to a latent representation of the surrounding sentences, Z_i.

Context Representation. To obtain Z_i, we take a fixed window of radius r, extract the r sentences on either side of the target sentence to be simplified and concatenate the representation of each of these sentences. Each context sentence is encoded with the pretrained Sentence-BERT (SBERT) model[2] (Reimers and Gurevych, 2019) and combined with custom learnt positional embeddings.[3]

To better simulate autoregressive inference, we consider a strategy where the left context consists of previously simplified sentences, rather than complex ones. We refer to this as *dynamic context*. At training time, we use the ground truth simplifications

$$Context_{i,r} = Concat(s_{j-r..j-1}, c_{i..i+r}) \quad (1)$$

where $j \in \{1,\dots,|S|\}$ is the index of the first sentence aligned to c_i in the simple document S. During inference, the simplifications generated at preceding timesteps $\hat{s}_{j-r..j-1}$ are used.

Positional Embeddings. We use custom positional embeddings to encode both information about document, and relative context-window positions. These are each handled by a dedicated embedding layer and added to the representations of the corresponding context sentence.

Document positional embedding indices are simply the document quintile (1-5) that a given sentence falls into. We use quintiles as this will ensure that all indices are encountered within the input document. The context positional embedding indices are the relative distance of a given sentence from the input sentence c_i, adjusted to be within $\mathbb{N}_0$: $ContextPosIdxs = \{p - i + r \mid p \in \{i - r, \dots, i + r\}\}$.

Initialisation. Given that the cross-attention layers must be trained from scratch, the start of training can see a lot of instability in the model, potentially making it more difficult to model context-independent features of the input sentence. To account for this, we initialise the RoBERTa layers with weights from a context-independent classifier.

5.2 Alternative Models

We compare our model with four alternative models. The different inputs/outputs of the models are illustrated in Figure 3.

Classifier. We fine-tune pretrained `RoBERTa-base` (Liu et al., 2019), which has 12 hidden layers and a hidden size of 768, and

---

[2] Specifically, all-mpnet-base-v2.

[3] At training time, we backpropogate to the positional embedding layers but keep the SBERT weights frozen.

Table 2: Planning Accuracy. **Dyn. Context** is the contextual classifier described in Section 5.1 with $r = 13$, dynamic context and weights initialised using the classifier weights (C: Copy, R: Rephrase, S: Split, D: Delete).

add a pooled classification head which takes the final layer [CLS] representation as input. Given an input sentence c_i, the model simply takes the tokenized sentence as input and outputs a prediction score for each operation class. The model is applied from left-to-right on the input document classifying each sentence in turn. Thus, in this approach, while the model has access to the tokens of the sentence to be classified, there is no notion of context which, intuitively, should be detrimental in particular for deletions.

Tagger. We consider a model that frames the problem as a sequence tagging task over the full document, predicting the entirety of $\hat{P}$ at once. Each c_i is encoded using the same SBERT model as the contextual classifier, with the input document C therefore being represented as a sequence of sentence embeddings. In contrast to the classifier, the tagger makes predictions based both on the input sentence to be classified and on the context. However, because the input representation at each index is for an entire sentence we lose some resolution with respect to token-level content. The approach is thus less adapted for splitting.

Tagger+Dec. We also consider an autoregressive variant of the tagger that better models the dependencies between predicted tags. Here, we include a 1-layer decoder and condition each prediction both on the input document and on the previously predicted operation tags for the earlier sentences. This approach is somewhat similar to Dong et al. (2019); Malmi et al. (2019), except we abstract to the document-level and do not require explicit realisation, as this will be handled downstream by the simplication model.

$\text{EncDec}_{\text{full}}$. Finally, we experiment with an encoder-decoder variant that conditions on a token-level representation of the input, thereby combining a global view and a token-level representation of the input document. We use sentence separator tokens to delimit each sentence in the input document.

5.3 Evaluation Metrics

To evaluate the performance of the various planners we use F1-score, considering each individual prediction at the sentence-level. We report the F1 for each operation class as well as both the micro and macro averages. The micro F1 weights all examples equally, whereas the macro re-weights examples such that each class is represented equally in the final score. Given the class imbalances in the data, we regard macro F1 as our primary metric.

5.4 Results

Table 2 summarizes the results.

Compared to the various baselines, our model consistently shows best results on both datasets. The improvement over the context-free classifier is slightly less on Newsela-auto however. We conjecture that the much larger dataset and additional guidance provided by the reading levels allows the classifier to achieve rather high accuracy without document-level context. We also note that the context-free classifier is markedly outperformed by other models with respect to *delete*, which confirms the intuition that context modeling particularly matters for this operation.

Of the four baselines, $\text{EncDec}_{\text{full}}$ performs worst presumably because the very long input (the whole context is modelled at the token level) challenges the attention mechanism which tends to become blurry as the length of the input increases. This is particularly apparent on the longer Newsela documents.

The tagger models, which both use sentence-level encodings of the complex document, perform

Table 3: Ablations on Newsela-auto TestSet.

worse than the classifier. This highlights the importance of having a token-level modeling of the input sentences.

We observe a strong difference in terms of absolute scores between the two datasets. This is likely a result of Wiki-auto being an inferior simplification corpus (discussed in Section 4).

Next, we examine the impact of our modeling choices using ablation (Table 3) and focusing on the higher-quality, Newsela-auto dataset. Our best model is one with dynamic left-context, a context radius of 13, document position embeddings and weight initialisation. We see (Sub-table **a**) that each of these components help improve performance (document position appears less important with a larger context window). Sub-tables **b-d** show that using a dynamic rather than a static context increases results by up to +6.7 Macro F1, while increasing the context radius from 9 to 13 sentences mostly improves performance when dynamic context is used. Using document positional embeddings also generally improves results (Sub-table **d**).

6 Simplification

To assess whether document plans can help improve simplification models, we experiment with two simple document-level simplification models and compare their performance with and without a preceding planning step.

6.1 Simplification Models

All models use the BART model (Lewis et al., 2020) fine-tuned on aligned text pairs. [4]

We consider two variants for document-level simplification: (i) **Doc-BART**, which is finetuned on full document pairs; and (ii) **Sent-BART** which is finetuned on sentence pairs and iteratively applied to each input sentence at test time.

We compare these to various plan-guided (**PG**) systems whereby one of our planners predicts an $\hat{o}_i$ for each c_i and is given as a control-token to a sentence-level BART simplification model. In the case of the dynamic planner, $\hat{o}_i$ is predicted based on the sequence of previously simplified sentences $\hat{s}_{i-r} \dots \hat{s}_{i-1}$.

Training details are given in Appendix B.

6.2 Evaluation

To measure meaning preservation and fluency, we use BARTScore (Yuan et al., 2021), a state-of-the-

---

Table 4: Results of document simplification systems on Newsela-auto. For BARTScore, s is the source, h is the hypothesis, and r is the reference.

art summarization metric that has proved effective on many other text generation tasks. We also compute SMART (Amplayo et al., 2022), a new metric that considers sentences as the primary unit of comparison. It was shown to be highly effective for document summarization and does not use any neural model, making it very fast to compute (we use the SMARTL+CHRF version). We cannot use other model-based metrics, such as BERTScore or QuestEval, as these do not support texts longer than 512 tokens.

To assess simplicity, we use the Flesch-Kincaid grade level (FKGL), a document-level metric used to measure text readability, which has been found to have the highest correlation with simplicity measures of human-written simplifications (Scialom et al., 2021). We also report the popular SARI (Xu et al., 2016). The EASSE python library (Alva-Manchego et al., 2019a) is used for calculation of FKGL and SARI. We include results for other popular metrics in Appendix D.

At test time we generate sequences using beam search with a beam size of 5 and a maximum length of 1024 tokens. We enforce a minimum length for Doc-BART, which is tuned on the validation set.

We do not conduct a human evaluation as we intend the focus of this work to be on the planning component and include simplification results only to confirm its efficacy. We leave a more in-depth investigation of the interaction between planning and document-level simplification to future work.

6.3 Results

Results can be seen in Table 4.

PG$_{\text{Dyn}}$ achieves the highest results of all systems. Using the silver operation labels (PG$_{\text{Oracle}}$) leads to a substantial further increase in performance across every metric, highlighting the impact of planning and pointing to the possibility of further improvements to be made.

Using either PG$_{\text{Dyn}}$ or PG$_{\text{Clf}}$ yields generally better results than Sent-BART. Both systems achieve better FKGL and SARI, suggesting greater output simplicity. Sent-BART achieves much higher source-oriented BARTScore (faithfulness) than even the references, suggesting some conservativity in its transformations.

PG$_{\text{Clf}}$ achieves slightly higher recall BARTScore than PG$_{\text{Dyn}}$, while also generating the longest outputs, both in terms of tokens and sentences. This suggests it is less effective at identifying sentences for deletion, confirming our hypothesis that context is key for deletion. We can see here that the rank order of SMART matches that of BARTScore, suggesting it is similarly suited for simplification.

Both PG$_{\text{Tag}}$ and PG$_{\text{Tag+Dec}}$ perform quite badly relative to the other PG systems and Sent-BART. However, Doc-BART is by far the worst performing system, presumably a result of it failing to properly handle the long document lengths.

7 Conclusion

In this paper we present an approach to document simplification that decomposes the task into a two-stage process of planning and generation. We propose a planning system that is able to take document context and structure into account to produce a coherent high-level simplification plan. By using this plan to guide a sentence-level simplification model, we are able to outperform end-to-end systems in terms of both meaning preservation and simplicity.

We leave for future work the development of dedicated simplification models that can leverage a document-level plan while also considering contextual information directly during generation.

8 Acknowledgements

We thank the anonymous reviewers for their feedback. We gratefully acknowledge the support of the French National Research Agency (Gardent; award ANR-20-CHIA-0003, XNLG "Multilingual, Multi-Source Text Generation").

Experiments presented in this paper were carried out using the Grid'5000 testbed, supported by a scientific interest group hosted by Inria and including CNRS, RENATER and several Universities as well as other organizations (see `https://www.grid5000.fr`).

9 Limitations

All models we propose are only trained with English datasets and therefore do not extent to other languages. There are also additional high-level simplification operations for which our planning framework does not offer support, such as sentence reordering, insertion, and fusion.

Furthermore, the Newsela dataset which we use in our experiments requires a license to use, meaning that researchers cannot fully reproduce our work without first obtaining said license from Newsela Inc. Due to this constraint and the low-quality alignments observed within the Wiki-auto dataset, we strongly encourage any work towards producing new open-access datasets for the document-level simplification task.

A Training Details for the Planning Models

Each model was trained with a learning rate of $1e^{-5}$, a batch size of 32 and a dropout rate of 0.1. We ran experiments on a computing grid with $2\times$ Nvidia A40 GPUs (45GB memory).

For the contextual classifier, we test with r values of 9 and 13, subject to findings in Appendix C. All layers in common with the standard RoBERTa architecture are initialised with the `RoBERTa-base` pretrained weights. All added positional embedding layers are also initialised with the pretrained weights from the `RoBERTa-base` positional embedding layer. All other layers are randomly initialised.

B Training Details for the Simplification Models

For all generative models, we used a learning rate of $3e^{-5}$, a batch size of 16, and performed dropout with a rate of 0.1 and early stopping. The network has 6 layers in each of the encoder and decoder, with a hidden size of 768. All models were trained on a computing grid using $2\times$ Nvidia A40 GPUs (45GB memory) in under 24 hours.

C Context Window Size

To determine the optimal context window size for the contextual planner we ran a series of experiments with varying values of the radius, r. We used 100,000 random examples from the Newsela-auto (non-adjacent reading levels) training set and trained a model with each of the configurations for 5 epochs. Results can bee seen in Figure 4.

The *deletion* operation is most affected by the inclusion of context, with performance rapidly rising as r grows to 13. The *rephrase* operation appears to slowly degrade in performance as r increases, while the other two operations show no obvious pattern. We also observe that $r = 9$ produces the highest macro F1.

D Extra Evaluation Results

For clarity, we provide scores for a wider range of simplification evaluation metrics that were not included in the main body of the paper in Table 5. These mostly include popular metrics used for sentence simplification that we do not believe adapt as well to the document-level setting, do not provide further insight into system differences, or have not recieved much support in the literature. Specifially, we include BLEU (Papineni et al., 2002), and full operation scores for both SARI and D-SARI (Sun et al., 2021). For D-SARI, we apply the document-level penalties on top of the base EASSE implementation of SARI.

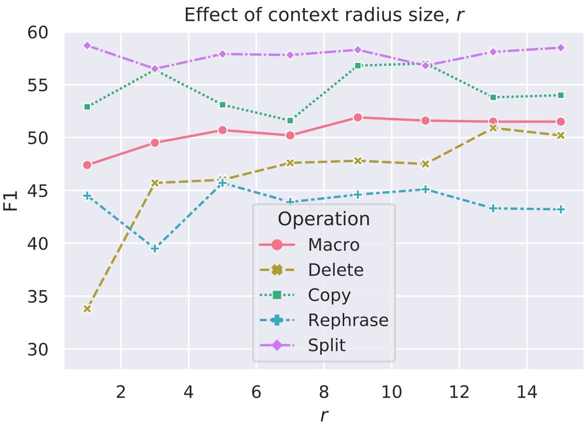

Figure 4: Effect of context window size on F1 scores.

We can see that the main SARI differences between the context-free planner and Sent-BART is that Sent-BART achieves higher keep, while the planner achieves higher add. This suggests that Sent-BART is likely more conservative in edits. Further, as the planner does not have access to contextual content, it is likely failing to consistently copy/delete the correct parts of the text.

E Example Planner Predictions

Figure 5 shows example snippets of planner model outputs. We have selected representative extracts that highlight the strengths and weaknesses of the main models. We do not include outputs from Tagger as they are virtually identical to Tagger+Dec in most cases and therefore do not provide further insight.

F Example Simplification

Figure 6 shows system output examples for the simplification models. We only show texts from Wiki-auto as they are easier to showcase due to their shorter length, as well as their being licensing restrictions for Newsela content.

System	BLEU ↑	**D-SARI** ↑	add	keep	delete	**SARI** ↑	add	keep	delete
Input	46.2	8.76	0.0	26.29	0.0	20.52	0.0	61.56	0.0
Reference	100.0	99.98	99.99	99.97	99.99	99.99	100	99.97	99.99
Doc-BART	31.13	30.60	16.54	25.01	50.24	47.07	20.41	55.40	65.40
Sent-BART	70.74	66.27	53.89	71.95	72.95	73.02	55.91	83.66	79.48
PG$_{\text{Tag}}$	48.08	42.96	31.70	44.01	53.17	56.13	35.61	65.61	67.18
PG$_{\text{Tag+Dec}}$	48.12	43.31	31.57	44.68	53.69	56.06	35.54	65.54	67.11

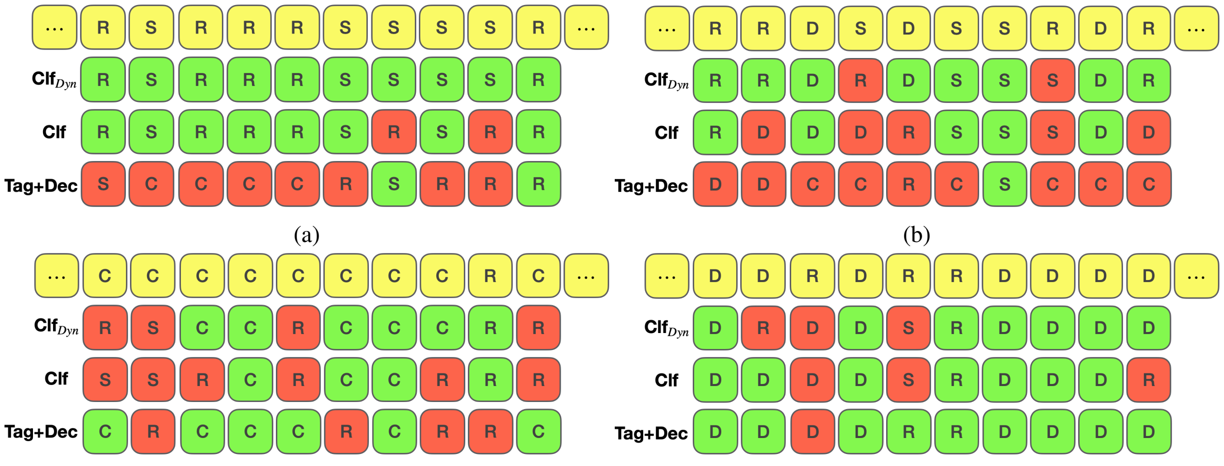
PG$_{\text{Oracle}}$	**78.97**	**77.02**	**63.44**	**83.92**	**83.70**	**80.74**	**65.22**	**89.94**	**87.05**

Table 5: Extra results for document simplification experiments on Newsela-auto.



(a) (b)

(c) (d)

Figure 5: Example planning results for various models. Subfigures show representative snippets from Newsela-auto test-set documents. The silver labels are shown above in yellow, and system outputs are shown on the rows below with correct predictions in green and incorrect predictions in red. Clf$_{Dyn}$ is our best performing model, the contextual classifier with dynamic context. Figure 5a shows a case where there are lots of context-agnostic operations (rephrase, split) resulting in poor performance from Tagger+Dec. Figure 5b shows a varied snippet where Clf$_{Dyn}$ appears to be the best at identifying both rephrase and split, as well as delete. Figures 5c and 5d show that Tagger+Dec is capable of performing well in situations demanding a lot of context-dependent operations (copy, delete).

Abstract

Aspect-based sentiment analysis (ABSA) has attracted broad attention due to its commercial value. Natural Language Generation-based (NLG) approaches dominate the recent advance in ABSA tasks. However, current NLG practices are inefficient because most of them directly employ an autoregressive generation framework that cannot efficiently generate location information and semantic representations of ABSA targets. In this paper, we propose a novel framework, namely Efficient Hybrid Generation (EHG) to revolutionize traditions. Specifically, we leverage an Efficient Hybrid Transformer to generate the location and semantic information of ABSA targets in parallel. Besides, we design a novel global hybrid loss function in combination with bipartite matching to achieve end-to-end model training. Extensive experiments demonstrate that our proposed EHG framework greatly improves the efficiency of NLG-based methods and outperforms the competitive baselines in almost all cases.

1 Introduction

Aspect-based sentiment analysis (ABSA) enjoys broad commercial value, e.g., analyzing customer's opinions through review data to improve products. ABSA consists of four basic sentiment elements, including aspect term, opinion term, aspect category and sentiment polarity. Illustrated in Fig. 1, the aspect terms a_1, a_2 in the sentence belong to the aspect categories c_1, c_2 , respectively, and their corresponding opinion terms are o_1, o_2 , with sentiment polarity s_1, s_2. For simplicity, we name the aspect term and opinion term as **sentiment entities** (SE), and the aspect category and sentiment polarity as **sentiment abstractions** (SA). The majority of ABSA subtasks utilize sentences as input and the combination of SE and SA as output, so we define the output set of all ABSA subtasks as **sentiment tuples** (ST). Fig. 1 shows all the subtasks studied in this work.

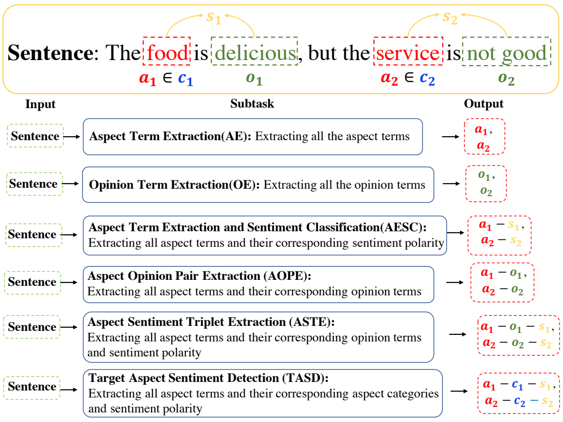

Figure 1: The six ABSA subtasks studied in this work, where a_1=*food*, a_2=*service*, c_1=*food quality*, c_2=*service general*, o_1=*delicious*, o_2=*not good*, s_1=*positive*, s_2=*negative*.

Natural Language Understanding (NLU) based approaches were utilized in early research for modeling ABSA problems. The Two stage pipeline, i.e., using a sequence tagging model to extract SE, then using a classification model to distinguish SA (Li and Lam, 2017; Ma et al., 2017; Xue and Li, 2018; Fan et al., 2019), ignored the semantics of the labels and propagated error in a not end-to-end manner. Besides, unique end-to-end NLU variants were proposed to enhance the information interaction between elements within ST, however, these approaches suffered from complex model design and were not generic for different ABSA subtasks.

Natural Language Generation (NLG) based approaches model the ABSA tasks uniformly as sequence-to-sequence generation tasks (Zhang et al., 2021b; Yan et al., 2021; Zhang et al., 2021a; Mao et al., 2022) and have dominated the recent advance in ABSA tasks. Specifically, the sequence-to-sequence generation framework can adapt to multiple ABSA subtasks simultaneously without additional architectural design, and the autoregressive generation mode (Neal, 1992) can naturally

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1007–1018
May 2-6, 2023

include information interaction of elements within ST. Despite the superior performance of NLG-based approaches, the autoregressive generation also renders NLG-based methods time inefficient in generating multiple sets of STs. Besides, existing NLG-based methods fail to adequately coordinate the semantic representation of STs and the positioning of SEs when generating results.

In this paper, we propose an Efficient Hybrid Generation framework EHG to generate semantic representations of multiple STs in parallel and simultaneously output the location information of SEs corresponding to each ST. EHG is composed of two modules: Efficient Hybrid Transformer (EHT) and Entity Correction Module (ECM). For EHT, inspired by DETR (Carion et al., 2020), we use a fixed number of *object queries* to detect STs in sentences in parallel and locate the corresponding SE. Further, we pass *object queries* that detect ST (obtained by *Filter* or *Matcher*), through the *Semi-Autoregressive Generator* to generate semantic representations of the corresponding ST. In addition we propose a novel global hybrid loss function in combination with bipartite matching named hybrid Hungarian loss, to achieve end-to-end model training. For ECM, we normalize the location information of the corresponding SEs based on the input text and the semantic representation of each ST generated. The contributions of this paper are summarized as below.

- We propose a novel and Efficient Hybrid Generation framework that generates semantic representations of STs and simultaneously locates the SEs within them.
- We introduce a fixed number of *object queries* to detect and decode multiple sentiment tuples in parallel, which greatly improves the efficiency of current generation methods.
- We propose a novel hybrid Hungarian loss function that allows our Efficient Hybrid Transformer to be trained end-to-end.

Experimental results demonstrate that our proposed EHG achieves the state-of-art performance in almost all datasets on the six ABSA subtasks and outperforms existing NLG-based methods in terms of inference efficiency.

2 Related Work

In this section, we summarize the existing NLU-based and NLG-based approaches for aspect-based sentiment analysis.

2.1 NLU-based ABSA

For NLU-based methods, early work was often devoted to solving simple problems. For example, extracting SEs or classifying the sentiment polarity for a given aspect (Tang et al., 2015; Xu et al., 2018; Li et al., 2018; Wang et al., 2016). Among them, the vast majority defined the extraction of SEs as a sequence tagging problem (Huang et al., 2015) and the determination SAs as a classification problem. However, this approach ignores the information interaction of the elements within ST and makes the errors cumulative. Recently, much work has been devoted to solving complex multi-objective problems (ASTE (Zhang et al., 2015; Li et al., 2019; Mitchell et al., 2013), TASD(Wan et al., 2020), AOPE (Zhao et al., 2020; Chen et al., 2020)), such as predicting multiple elements simultaneously. Some of these works use the idea of pipeline to solve the extraction of SEs and the classification of SAs in stages (Peng et al., 2020; Mao et al., 2021). There are also some recent approaches that attempt to introduce interactions between multiple elements in the ST during inference to achieve end-to-end multi-objective modeling (Xu et al., 2021, 2020; Ma et al., 2018). However, this approach usually requires complex model design and is not generic for different ABSA subtasks.

2.2 NLG-based ABSA

Generation frameworks are increasingly used in NLP due to their powerful generality and rich pretrained models (PTMs) (Sutskever et al., 2014; Cho et al., 2014; Radford et al., 2018; Shao et al., 2021). There has been some recent work using NLG-based approaches to solve ABSA problems. Yan et al. (2021) use BART (Lewis et al., 2019) to receive sentence input and generate STs directly autoregressively, where SEs are represented using location indexes. More directly, Zhang et al. (2021b,a); Mao et al. (2022) used T5 to generate semantic representations of STs, and in addition, to locate the location of SEs, Zhang et al. (2021b) additionally proposed an *Annotation* pattern to insert STs to the original sentences. Although the NLG-based approach can model multiple ABSA subtasks in a unified framework, the above two methods share the common problem that the efficiency of the generation will be greatly reduced when there are multiple sets of STs on the input in the autoregressive framework. In addition, for the direct output of the SE index, although it can locate entity locations,

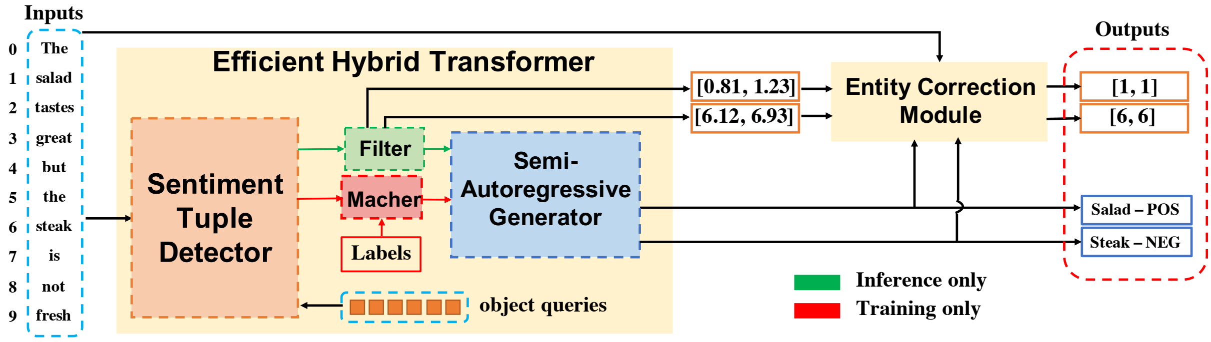

Figure 2: Efficient Hybrid Generation Framework. 1) the input sentence is directly passed through the *Efficient Hybrid Transformer* to generate a set of STs in parallel and locate the corresponding SEs. Specifically, a fixed number of learnable embeddings, called *object queries*, will be fed into the *Sentiment Tuple Detector* along with the input, and each *object queries* will focus on capturing an ST and locating the SE in it. The output of the *Sentiment Tuple Detector* will then be passed through a *Filter* (for training, it's *Matcher*) to remove the part of the ST that is not detected. Finally, the output of the *Filter* will be fed to the *Semi-Autoregressive Generator* to generate multiple STs in parallel. 2) the SE location information will be combined with the input and the corresponding ST to get the corrected SE index by *Entity Correction Module*.

this approach is not intuitive enough compared to directly generating semantic representations, and still requires additional design for scenarios that require the extraction of aspect categories, such as TASD. For the direct generation of semantic representations, it is impossible to locate the location of SEs accurately (the same SE may appear multiple times in the input), and although the *Annotation* pattern is proposed, the operation of inserting sentiment tuples to the input makes the generated results very redundant, which amplifies the problem of autoregressive inefficiency.

3 Methodology

Our proposed Efficient Hybrid Generation Framework is depicted in detail in Fig. 2. Since the output of all six ABSA subtasks contains the part of SEs, they can be described under a unified framework. To facilitate the description, this section expands on AESC as an example, first introducing the task definition, and then Efficient Hybrid Transformer and Entity Correction Module, are described in detail.

3.1 Problem Formulation

As discussed above, the proposed framework contains two parts of output, which are the semantic representation of multiple STs and the location of the corresponding SEs. Specifically, the proposed framework supports a fixed maximum number M of outputs, where M is set to be much larger than the number of STs generally present in the sentence. Here we denote aspect term, opinion term, aspect category, sentiment polarity, sentiment entity, sentiment abstraction and sentiment tuple as a, o, c, s, se, sa and st respectively, and define $X = \{x_i\}_{i=1}^{N}$ to represent an input text of length N, $L_{hybrid}(\cdot)$ represents the proposed hybrid Hungarian loss function. We use hat "$*, \widehat{*}$" to distinguish between model output and ground truth, then the problem is defined as follows,

$$argmin \sum_{j=1}^{M} L_{hybrid}[(d_j^{se}, y_j^{st}), (\widehat{d_j^{se}}, \widehat{y_j^{st}})] \quad (1)$$

where d_j^{se} and y_j^{st} represent the detection result and semantic representation of the j-th ST, respectively. Specifically, $d_j^{se} = (c_j^{st}, idx_j)$ where c_j^{st} is the class label of the ST and there are only two classes representing the presence or absence of the ST respectively. The idx_j is defined as the index range of the SE in the j-th ST normalized in the sentence, and we set $idx_j = [-1, -1]$ when $c_j^{st} = \oslash$ represents the absence of the ST.

Furthermore, since the outputs of different ABSA subtasks may contain different SEs, we describe the idx_j corresponding to the different subtasks as follows:

$$idx_j = \begin{cases} (idx_j^a), & [AE, AESC, TASD], \\ (idx_j^o), & [OE], \\ (idx_j^a, idx_j^o), & [AOPE, ASTE], \end{cases}$$

where $idx_j^a = [0,1]^2$ and $idx_j^o = [0,1]^2$ represent the position indices of a_j and o_j respectively.

3.2 Efficient Hybrid Transformer

Efficient Hybrid Transformer contains two main components, *Sentiment Tuple Detector*, which detects the STs in X, and *Semi-Autoregressive Generator*, which generates a semantic representation for

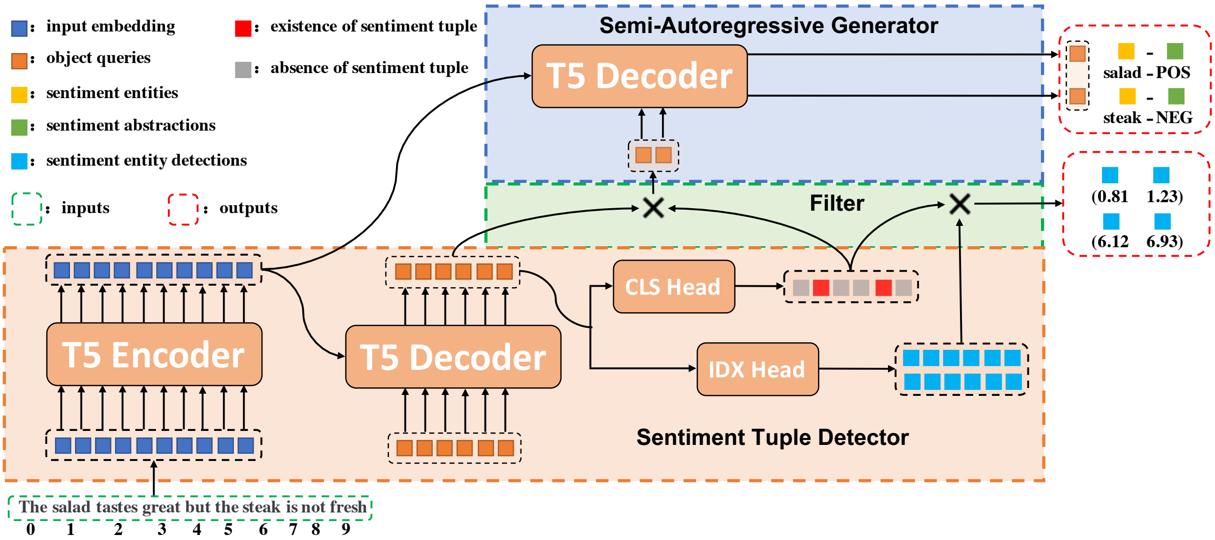

Figure 3: Inference details of Efficient Hybrid Transformer under AESC.

each detected ST, the details are shown in Fig. 3. It is worth mentioning that our EHT uses an asymmetric inference and training process, the difference between the two is that *Filter* is used for inference and *Matcher* is used for training.

3.2.1 Sentiment Tuple Detector

Inspired by DETR, we define mining STs in sentences as an object detection problem. Specifically, we detect the presence of STs and then locate the corresponding SEs in X. The *Sentiment Tuple Detector* utilizes the conventional transformer encoder-decoder architecture (Vaswani et al., 2017) , a setup that is convenient to extend to any similar pre-trained model (Qiu et al., 2020; Peters et al., 2018; Devlin et al., 2018; Raffel et al., 2019; Song et al., 2019), and in this paper we directly use the encoder and decoder of the pre-trained T5 model.

The input text X is vectorized and passed through the encoder to obtain the encoded D-dimensional hidden variable $H \in \mathbb{R}^{N \times D}$. This process can be described in the following form:

$$H = T5Encoder(Embed(X)), \tag{2}$$

where $Embed(X) \in \mathbb{R}^{N \times D}$, represents the vectorized X.

Different from the original autoregressive decoder, the decoder of the *Sentiment Tuple Detector* decodes M objects in parallel. Similar to DETR, we use M learnable embeddings $q^{st}_{in} \in \mathbb{R}^{M \times D}$, called *object queries*, as input to the decoder to generate output embeddings $q^{st}_{out} \in \mathbb{R}^{M \times D}$ through global self-attention and cross-attention with H.

$$q^{st}_{out} = T5Decoder(q^{st}_{in}, H), \tag{3}$$

The output embedding q^{st}_{out} finally outputs the class labels of the STs and the location coordinates of the corresponding SEs independently through the linear projection layer and the feed-forward neural network, respectively.

$$\begin{aligned} \widehat{c}^{st} &= Softmax(MLP(q^{st}_{out})), \\ \widehat{idx}^{a} = FFN_a(q^{st}_{out}), &\ \widehat{idx}^{o} = FFN_o(q^{st}_{out}), \end{aligned} \tag{4}$$

where $\widehat{c}^{st} = \{\widehat{c}^{st}_j\}^M_{j=1}, \in \mathbb{R}^{M \times 2}$ is the class vector of the ST (here only two classes are present and absent). $\widehat{idx}^{a} = \{\widehat{idx}^{a}_j\}^M_{j=1}, \in \mathbb{R}^{M \times 2}$ and $\widehat{idx}^{o} = \{\widehat{idx}^{o}_j\}^M_{j=1}, \in \mathbb{R}^{M \times 2}$ are generated by two 3-layer feed-forward neural networks (FFN) with ReLU activation function and hidden dimension D, representing the normalized position coordinates of a and o, respectively. Since different ABSA subtasks contain different SEs in their outputs, FFN_a and FFN_o are set according to the actual needs, and in the case of ASEC, only FFN_a is used to generate $\widehat{idx}^{a}$.

3.2.2 Filter

The role of the *Filter* in inference is 2-fold, firstly filtering out the output of the *Sentiment Tuple Detector*; secondly the corresponding q^{st}_{out} of detected ST need to be fed into the *Semi-Autoregressive Generator* to decode the semantic representation of STs. The process can be expressed as follows.

$$\widehat{d}^{se}_{\widehat{c}^{st} \neq \varnothing}, q^{st}_{out, \widehat{c}^{st} \neq \varnothing} = Filter(\widehat{D}^{se}, q^{st}_{out}), \tag{5}$$

3.2.3 Semi-Autoregressive Generator

The semi-autoregressive decoder aims to decode the detected STs in parallel. Different from traditional autoregressive decoding, our semi-autoregressive decoder uses $q^{st}_{out,\widehat{c}^{st}\neq\varnothing}$ as the embedding of the starting token for each ST and then performs autoregressive decoding separately. For the s-th ST, we use $q^{st}_{out,s,\widehat{c}^{st}\neq\varnothing}$ as the starting embedding, then the autoregressive decoding process can be expressed as:

$$\begin{aligned} h^d_{s,0} &= q^{st}_{out,s,\widehat{c}^{st}\neq\varnothing} \\ h^d_{s,t} &= T5Decoder(H^e, h^d_{s,t-1}) \\ st_{s,t} &= Softmax(MLP(h^d_{s,t})) \end{aligned} \tag{6}$$

where $h^d_{s,t} \in \mathbb{R}^D$ is the decoder output of step t of the s-th ST, and $st_{s,t}$ is the corresponding token representation, which is generated by a linear projection layer that immediately follows softmax.

Besides Decoder in the *Semi-Autoregressive Generator* shares parameters with the Decoder in the *Sentiment Tuple Detector*, which allows our model to maintain almost the same number of parameters as the original T5.

3.2.4 Matcher

For model training, we need to know the correspondence between a fixed number of M outputs and the ground truth in order to calculate the loss. Thus we use the Hungarian algorithm (Kuhn, 1955) to obtain the optimal bipartite matching between model outputs and the ground truth, and then calculate the loss for the completed matched outputs and the ground truth to train the model, this part focuses on the matching process.

We define $\phi \in \Phi_M$ as all possible mapping connections between the ground truth and the model outputs, and L_{match} as the matching loss function under the given mapping condition, then the objective function for finding the optimal mapping $\phi_{optimal}$ is as follows.

$$\phi_{optimal} = \underset{\phi\in\Phi_M}{argmin} \sum_{j=1}^{M} L_{match}(d^{se}_j, \widehat{d}^{se}_{\phi(j)}) \tag{7}$$

Since we assume that M is greater than the number of STs in the actual input, we use $\varnothing$ to padding each ground truth d^{se} that is less than M. In Eq. 7, the index of $\widehat{d}^{se}$ is mapped by $\phi_{optimal}$ such that L_{match} is minimized. For L_{match}, we consider two components which are class cost L_{cls} and location cost L_{idx}, as follows.

$$L_{match} = \lambda_{cls}L_{cls} + \lambda_{idx}L_{idx} \tag{8}$$

$$L_{cls} = -\sum_{j=1}^{M}(\widehat{p}_{\phi(j)}(c^{st}_j))_{c^{st}_j\neq\varnothing} \tag{9}$$

$$L_{idx} = \sum_{j=1}^{M}(\|idx_j - \widehat{idx}_{\phi(j)}\|_1)_{c^{st}_j\neq\varnothing} \tag{10}$$

where λ_{cls} and λ_{idx} are hyperparameters, $\widehat{p}_{\phi(j)}(c^{st}_j)$ and $idx_{\phi(j)}$ represents the probability of class c_j and normalized index of SEs with index $\phi(i)$, respectively. At this point, we have completed the matching between the model output and the ground truth without any gradient computation, but the accurate matching is very important for the subsequent loss calculation, as discussed later.

3.2.5 Loss

To enable end-to-end training of the EHT, we propose a hybrid Hungarian loss L_{hybrid}, which considers both the detection loss L_{det} and the generation loss L_{gen} under a given optimal matching $\phi_{optimal}$.

$$\begin{aligned} L_{hybrid} &= L_{det} + \mu_{gen}L_{gen} \\ L_{det} &= \mu_{cls}\sum_{j=1}^{M}[-log(\widehat{p}_{\phi_{optimal}(j)}(c^{st}_j)) + \\ &\quad \mu_{idx}(\|idx_j - \widehat{idx}_{\phi_{optimal}(j)}\|_1)_{c^{st}_j\neq\varnothing}] \\ L_{gen} &= \sum_{j=1}^{M}(\sum_{t=1} -log(\widehat{p}_{\phi_{optimal}(j)}(st_{j,t})))_{c^{st}_j\neq\varnothing} \end{aligned}$$

where $\phi_{optimal}$ is obtained in *Matcher*, μ_{cls}, μ_{idx} and μ_{gen} are hyperparameters. For L_{det}, the difference with Eq. 9 is that we use the standard cross-entropy loss and consider the part of $c^{st}_j \neq \varnothing$ into the classification loss as well, which reduces the redundant detections, as will be shown in the experimental section. For L_{gen}, we simply computed the negative log-likelihood loss of the ST generated by the matched $q^{st}_{out,\widehat{c}^{st}\neq\varnothing}$ with the ground truth ST. Thus we jointly optimize L_{det} and L_{gen} for end-to-end training.

3.3 Entity Correction Module

In computer vision, object detection is not required to output the exact pixel coordinates because the images have redundant information, but for ABSA, inaccurate detection of SEs is unacceptable. To solve this problem, we propose an *Entity Correction Module* that corrects the detections of SEs by combining the input text and the output of the *Semi-Autoregressive Generator*.

First, we define SEs in the s-th ST of the model output as $\widehat{se}_s \in \widehat{st}_s$ and the corresponding detection result as $\widehat{idx}_s$, then we have the following

Algorithm 1 Entity Correction Module

```
$N = len(X); res = \widehat{idx}_s$
$Mean_{idx} = Int(mean(\widehat{idx}_s))$
$s, e = \widehat{st}_s[0], \widehat{st}_s[-1]$
$L, R = Mean_{idx}; w = len(\widehat{st}_s))$
while True do
    if $x[L]$==$s$ and $x[L : L$+$w]$==$\widehat{st}_s$ then
        $res \leftarrow (L, L$+$w)$; berak
    else if $x[R]$==$e$ and $x[R$-$w$+1 : $R$+1]==$\widehat{st}_s$ then
        $res \leftarrow (R$-$w$+1$, R)$; berak
    else if $L$==0 and $R$==$N$-1 then
        berak
    else
        $L = max(0, L$-1$)$;
        $R = min(N$-1$, R$+1$)$;
    end if
end while
return $res$
```

algorithm.

In Algorithm 1, $Mean_{idx}$ represents the midpoint of $\widehat{idx}_s$ rounded down. The essence of the whole algorithm is to consider the midpoint $Mean_{idx}$ as a fuzzy detection, and then use $Mean_{idx}$ to initialize two pointers in the input X to search for the nearest SE forward and backward respectively, and finally return the original detection $\widehat{idx}_s$ if there is no match.

4 Experiments

4.1 Datasets

We evaluate our EHG framework on four benchmark datasets Laptop14, Rest14, Rest15, and Rest16 that are publicly available in SemEval 2014, 2015 and 2016 (Pontiki et al., 2014, 2015, 2016). We use multiple publicly available datasets derived from the original dataset to respond to different ABSA subtasks, and these derived datasets are often additionally annotated. Specifically, we used the dataset D_{17} provided by Wang et al. (2017) to evaluate the AE and OE; the dataset D_{19} provided by Peng et al. (2020) to evaluate the AOPE and AESC; the dataset D_{20a} provided by Xu et al. (2020) to evaluate the ASTE task; and the dataset D_{20b} provided by Wan et al. (2020) to evaluate the TASD task.

4.2 Metrics

We use precision(P), recall (R) and F1 scores to evaluate for all experiments, where a correct prediction is considered when and only when the ST is exactly the same as the ground truth.

4.3 Experiment Setup

In order to maintain a similar number of parameters as existing methods, the encoder and decoders in the proposed EHT are derived from the encoder and decoder of T5 base model. Since all T5 decoders in EHT are parameter shared, we have almost the same number of parameters as the original T5[1]. It is worth mentioning that our EHT is based on the T5 model implementation of the huggingface Transformer library[2].

For the different ABSA subtasks, we used a similar experimental setup. We use the AdamW (Loshchilov and Hutter, 2018) optimizer to train the EHT with a learning rate of 3e-4 and a batch size of 2 and a cumulative gradient every two batches, and all Transformers are initialized using a pretrained T5-base. We train all datasets with 16 object queries (M=16), a setting larger than the maximum number of sentiment tuples in all datasets for a single sentence. We set λ_{cls}=2, λ_{idx}=1, μ_{cls}=0.75 and μ_{idx}=1.5 for all ABSA subtasks. In addition, for μ_{gen}, we set 1.5 for AE, OE and AOPE, 1.25 for ASTE, 1 for AESC, and 0.75 TASD. All training processes are performed on an ml.p3.2xlarge instance of Amazon Elastic Compute Cloud, which includes an NVIDIA Tesla V100 (16G) GPU.

4.4 Competitive Baselines

To demonstrate the superiority of our proposed EHG framework, we compare multiple SOTA

---

[1] Compared to T5-base, which has about 222M parameters, our EHT has about 223M parameters.

methods for six ABSA subtasks, including NLG-based methods Gen-idx (Yan et al., 2021), GAS-R (Zhang et al., 2021b) and GAS-Para (Zhang et al., 2021a). In addition, for fairness, all NLG-based methods do not use prediction normalization in GAS-R (Zhang et al., 2021b). For NLU-based methods, IMN-BERT (He et al., 2019), RACL-BERT (Chen and Qian, 2020), SPAN-BERT (Hu et al., 2019), Jet+BERT (Xu et al., 2020), Peng-two-stage (Peng et al., 2020), Li-unified-R (Li et al., 2019), Dual-MRC (Mao et al., 2021), SDRN (Chen et al., 2020), TAS (Wan et al., 2020) and Baseline (Brun and Nikoulina, 2018) are selected for comparison.

The performance: Tables 1, 2, 3, 4 show the main comparison results for AE, OE, ASTE, AOPE, AESC, and TASD, respectively. It is worth mentioning that the proposed method achieves the best F1 score in all cases except for AOPE and ASTE on the Rest14 dataset, and TASD on the Rest15 dataset. In addition, for ASTE and TASD, we also combine EHG with GAS-Para to further improve the performance while maintaining the advantages of the original EHG inference efficiency (EHG-Para), which fully demonstrates that the proposed method can be easily combined with existing NLG-based methods, each taking advantage of the other. Finally, we found that all NLG-based methods achieved stronger performance on ASTE, AOPE, AESC, and TASD tasks compared to NLU-based methods, demonstrating that the semantic interactions within ST tend to be more effective.

Inference efficiency: To demonstrate the speed advantage of the proposed method, we compared the generation speed and generation quality of the ASTE task on the Rest16 dataset for different NLG-based methods. As shown in Fig. 4, where the horizontal coordinate represents the number of STs generated in a single inference, the left vertical coordinate represents the average time to generate different numbers of STs and the right vertical coordinate represents the F1 corresponding to different NLG-based methods for different number of STs in ground truth. It can be clearly found that the inference time of the proposed method is independent of the number of generated STs, but depends only on the longest ST generated in parallel, and that the quality of generation does not decrease for different numbers of STs, but is relatively better among the three methods (highest in 1, 3, and 5).

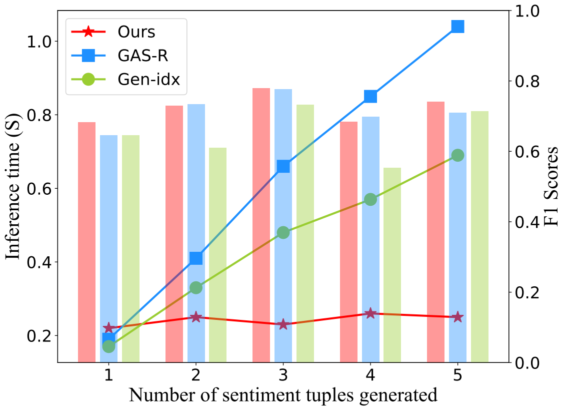

Figure 4: Comparison of the generation speed and generation quality of different NLG-based methods, where the bar chart corresponds to the F1 scores on the right and the line chart corresponds to the inference time on the left.

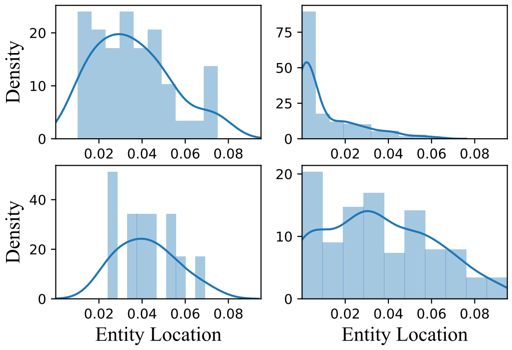

Figure 5: Visualizing the location distribution of sentiment entities detected by the first four object queries on the rest16 test set under the TASD task.

4.5 Analysis and Ablation Studies

To better understand the proposed framework, we visualize the location distribution of SEs (aspect

32	1	63.59	74.64	66.79	66.91

Table 5: Comparing the effects of different μ_{gen} and M for different ABSA subtasks.

To evaluate the impact of different μ_{gen} and M settings on different ABSA subtasks, we trained multiple models for the ablation study. All experiments occurred on the Rest16 dataset, as shown in Table 5. It can be found that the effect of different μ_{gen} is different for different subtasks, where TASD performs best at μ_{gen}=0.75, AESC performs best at μ_{gen}=1, ASTE performs best at μ_{gen}=1 and AOPE performs best at μ_{gen}=1.5. From this we conclude that as the proportion of SA in ST increases, μ_{gen} needs to be smaller to obtain better performance. The reason for this phenomenon we believe is that since SAs are usually composed of a small fixed number of words, it is relatively simple for the model to learn the mapping of different SEs to SAs, while the diversity of SEs is greatly increased, which again makes it relatively difficult to generate SEs. For M, we found that all ABSA subtasks performed best when M was set to 8 or 16, and the performance decreased when M was set to 32. Moreover, through data analysis, we found that the average number of STs per sentence in all datasets is about 1.6, and thus we believe that setting M far beyond the actual number of STs is not conducive to model training.

4.6 Error Analysis

To explore the behavior of EHG more intuitively, we performed an error analysis. Specifically, we verified the actual performance of the ASTE task in the test set of Rest16.

First, we find that the largest percentage of prediction errors is caused by the prediction errors of the opinion term, which accounts for about 50 percent of all errors. As in **Example 2** in Figure 6., in many cases we find that EHG has a mislocalization of the opinion term, which often occurs after "and", which we believe is related to the semi-autoregressive decoding. In **Example 2**, the aspect terms before and after "and" point to a same opinion term, but since the decoding of "server" and

Example 1
Sentence: Portions was just enough for me, but may not be for a big eater.
Gold Lable: (Portions , enough , neutral)
Prediction: (Portions , enough , positive)

Example 2
Sentence: While I could have done without the youth who shared the evening with us, our wonderful server and food made the experience a very positive one.
Gold Lable: (server , wonderful , positive); (food , wonderful , positive)
Prediction: (server , wonderful , positive); (food , positive , positive)

Example 3
Sentence: My friend enjoyed the grilled Alaskan King Salmon with delectable creamed Washington russet potatoes and crisp green beans.
Gold Lable: (grilled Alaskan King Salmon , enjoyed , positive); (creamed Washington russet potatoes , delectable , positive); (green beans , crisp , positive)
Prediction: (grilled Alaskan King Salmon , enjoyed , positive); (creamed Washington russet potatoes , delectable ,positive); (green beans , crisp , positive)

Figure 6: Examples containing the input sentence, gold label and predicted.

"food" by EHG is independent, the relationship between them is difficult to be captured. This is also a part worth optimizing in the future.

Second, we found that EHG is error-prone for neutral sentiment mining, which is of course a common problem of many current ABSA methods. We believe that this is a contradictory point in the ABSA problem, as positive or negative sentiment polarity is often highly correlated with the opinion term, while neutral sentiment polarity often requires the understanding of the whole sentence. However, the model tends to learn the correspondence between opinion term and sentiment polarity while ignoring the semantics of the whole sentence during training, which is also worthy of deeper investigation by researchers.

Finally, since EHG uses different *object queries* to capture different sentiment tuples, it is better at gaining advantages in the extraction of multiple sentiment tuples, as demonstrated by **Example 3** in Figure 6 as well as Figure 4.

5 Conclusion

In this paper, we propose a novel Efficient Hybrid Generation framework to model various ABSA subtasks. Specifically, we propose an Efficient Hybrid Transformer to generate sentiment tuples in parallel and simultaneously locate the corresponding sentiment entities. Moreover, we propose a hybrid Hungarian loss to achieve end-to-end model training. Finally, we propose an entity correction module to normalize the location information of sentiment entities. Extensive experiments demonstrate that our proposed EHG framework achieves competitive results while maintaining efficient inference.

6 Limitations

Although our proposed framework can generate semantic representations of sentiment tuples and the corresponding sentiment entity detection in parallel, there are still some limitations.

First, for the case where the input sentence contains only one set of sentiment tuples, our framework does not have a speed advantage over other NLG-based approaches, due to the fact that the efficiency of the proposed framework is based on the parallel generation of multiple sets of sentiment tuples.

In addition, the convergence speed of the proposed framework is slower than other NLG-based methods, and in all experiments we find that the convergence speed is positively related to the number of *object queries*, specifically, the average number of convergence epochs is 35 when the number of *object queries* is set to 8 and 45 when the number of *object queries* is set to 16.

A Appendix

A.1 Hyperparametric ablation studies

As described in the previous section, the proposed framework has five hyperparameters λ_{cls}, λ_{idx}, μ_{cls}, μ_{idx} and μ_{gen}. Among them, μ_{gen} has been discussed in 4.5, and the ablation experiments of the remaining hyperparameters are released here.

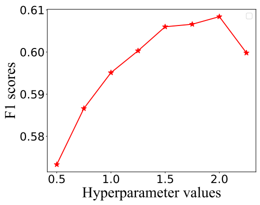

Figure 7: F1 scores under different λ_{cls} settings.

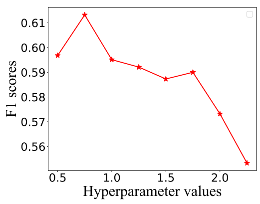

Figure 8: F1 scores under different μ_{cls} settings.

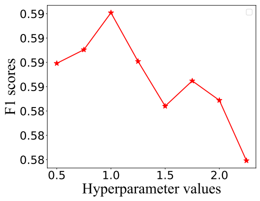

Figure 9: F1 scores under different λ_{idx} settings.

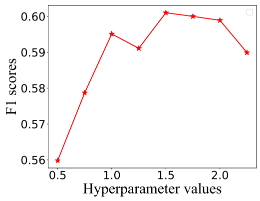

Figure 10: F1 scores under different μ_{idx} settings.

To facilitate the adjustment, we fixed all the remaining hyperparameters to 1 when adjusting a particular hyperparameter, and we set M=8 for all experiments in order to obtain results quickly. All experiments occurred in the ASTE task on the Rest15 dataset. Figures 7, 8, 9, 10 show the curves of F1 variation with λ_{cls}, μ_{cls}, λ_{idx} and μ_{idx}, respectively, from which we use λ_{cls}=2, λ_{idx}=1, μ_{cls}=0.75 and μ_{idx}=1.5 for all experiments.

A.2 Training details

Subtask	Rest14	Rest15	Rest16	Laptop14
AE	40	40	-	40
OE	40	40	-	40
ASTE	50	45	50	40
AOPE	50	55	55	50
AESC	45	45	45	45
TASD	-	40	55	-

Table 6: Training epochs of EHT under different ABSA subtasks and different datasets.

Since our comparison experiments consist of multiple versions of the same dataset, we give the number of training rounds for all ABSA subtasks under different datasets, which can be found in Table 6.

What's New? Summarizing Contributions in Scientific Literature

Abstract

With thousands of academic articles shared on a daily basis, it has become increasingly difficult to keep up with the latest scientific findings. To overcome this problem, we introduce a new task of *disentangled paper summarization*, which seeks to generate separate summaries for the paper contributions and the context of the work, making it easier to identify the key findings shared in articles. For this purpose, we extend the S2ORC corpus of academic articles, which spans a diverse set of domains ranging from economics to psychology, by adding disentangled "contribution" and "context" reference labels. Together with the dataset, we introduce and analyze three baseline approaches: 1) a unified model controlled by input code prefixes, 2) a model with separate generation heads specialized in generating the disentangled outputs, and 3) a training strategy that guides the model using additional supervision coming from inbound and outbound citations. We also propose a comprehensive automatic evaluation protocol which reports the *relevance*, *novelty*, and *disentanglement* of generated outputs. Through a human study involving expert annotators, we show that in 79%, of cases our new task is considered more helpful than traditional scientific paper summarization.

1 Introduction

With the growing popularity of open-access academic article repositories, such as arXiv or bioRxiv, disseminating new research findings has become nearly effortless. Through such services, tens of thousands of scientific papers are shared by the research community every month[1]. At the same time, the unreviewed nature of mentioned repositories and the sheer volume of new publications has made it nearly impossible to identify relevant work and keep up with the latest findings.

Scientific paper summarization, a subtask within automatic text summarization, aims to assist researchers in their work by automatically condensing articles into a short, human-readable form that contains only the most essential information. In recent years, abstractive summarization, an approach where models are trained to generate fluent summaries by paraphrasing the source article, has seen impressive progress. State-of-the-art methods leverage large, pre-trained models (Lewis et al., 2020; Liu et al., 2022), define task-specific pre-training strategies (Zhang et al., 2019), and scale to long input sequences (Zhao et al., 2020; Zaheer et al., 2020). Available large-scale benchmark datasets, such as arXiv and PubMed (Cohan et al., 2018), were automatically collected from online archives and repurpose paper abstracts as reference summaries. However, the current form of scientific paper summarization where models are trained to generate paper abstracts has two caveats: 1) often, abstracts contain information which is not of primary importance, 2) the vast majority of scientific articles come with human-written abstracts, making the generated summaries superfluous.

To address these shortcomings, we introduce the task of disentangled paper summarization. The new task's goal is to generate two summaries simultaneously, one strictly focused on the summarized article's novelties and contributions, the other introducing the context of the work and previous efforts. In this form, the generated summaries can target the needs of diverse audiences: senior researchers and field-experts who can benefit from reading the summarized contributions, and newcomers who can quickly get up to speed with the intricacies of the addressed problems by reading the context summary and get a perspective of the latest findings from the contribution summary.

For this task, we introduce a new large-scale dataset by extending the S2ORC (Lo et al., 2020) corpus of scientific papers, which spans multiple

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1019–1031
May 2-6, 2023

scientific domains and offers rich citation-related metadata. We organize and process the data, and extend it with automatically generated contribution and context reference summaries, to enable supervised model training. We also introduce three abstractive baseline approaches: 1) a unified, controllable model manipulated with descriptive control codes (Fan et al., 2018; Keskar et al., 2019; Liu et al., 2021; He et al., 2022), 2) a one-to-many sequence model with a branched decoder for multihead generation (Luong et al., 2016; Guo et al., 2018), and 3) an information-theoretic training strategy leveraging supervision coming from the citation metadata (Peyrard, 2019). To benchmark our models, we design a comprehensive automatic evaluation protocol that measures performance across three axes: relevance, novelty, and disentanglement. We thoroughly evaluate and analyze the baselines models and investigate the effects of the additional training objective on the model's behavior. To motivate the usefulness of the newly introduced task, we conducted a human study involving human annotators in a hypothetical paper-reviewing setting. The results find disentangled summaries more helpful in 79% of cases in comparison to abstract-oriented outputs. Code and data preparation scripts introduced in this work are available at `https://github.com/salesforce/disentangled-sum`.

2 Related Work

Recent trends in abstractive text summarization show a shift of focus from designing task-specific architectures trained from scratch (See et al., 2017; Paulus et al., 2018) to leveraging large-scale Transformer-based models pre-trained on vast amounts of data (Liu and Lapata, 2019; Lewis et al., 2020), often in multi-task settings (Raffel et al., 2019). A similar shift can be seen in scientific paper summarization, where state-of-the-art approaches utilize custom pre-training strategies (Zhang et al., 2019) and tackle problems of summarizing long documents (Zhao et al., 2020; Zaheer et al., 2020). Other methods, at a smaller scale, seek to utilize the rich metadata associated with scientific articles and combine them with graph-based methods (Yasunaga et al., 2019). In this work, we combine these two lines of work and propose models that benefit from pre-training procedures, but also take advantage of task-specific metadata.

Popular large-scale benchmark datasets in scientific paper summarization (Cohan et al., 2018; Cachola et al., 2020) were automatically collected from open-access paper repositories and considered article abstracts as the reference summaries. Other forms of supervision have also been investigated for the task, including author-written highlights (Collins et al., 2017) and annotations (Meng et al., 2021), citations (Yasunaga et al., 2019), and transcripts from conference presentations of the articles (Lev et al., 2019). In contrast, we introduce a large-scale automatically collected dataset with more fine-grained references than abstracts, which also offers rich citation-related metadata.

Update summarization (Dang and Owczarzak, 2008) defines a setting in a collection of documents with partially overlapping information is summarized, some of which are considered prior knowledge. The goal of the task is to focus the generated summaries on the novel information. Work in this line of research mostly focuses on novelty detection in news articles (Bysani, 2010; Delort and Alfonseca, 2012) and timeline summarization (Martschat and Markert, 2018; Chang et al., 2016) on news and social media domains. Here, we propose a novel task that is analogous to update summarization in that it also requires contrasting the source article with the content of other related articles which are considered pre-existing knowledge.

3 Task

Given a source article D, the goal of disentangled paper summarization is to simultaneously summarize the *contribution* y_{con} and *context* y_{ctx} of the source article. Here, contribution refers to the novelties introduced in the article D, such as new methods, theories, or resources, while context represents the background of the work D, such as a description of the problem or previous work on the topic. The task inherently requires a relative comparison of the article with other related papers to effectively disentangle its novelties from pre-existing knowledge. Therefore, we also consider two sets of citations: inbound citations C_I and outbound citations C_O as potential sources of useful information for contrasting the article D with its broader field. Inbound citations refer to the set of papers that cite D, *i.e.* relevant future papers, while outbound citations are the set of papers that D cites, *i.e.* relevant previous papers. With its unique set of goals, the task of disentangled paper summarization poses a novel set of challenges for automatic summarization systems to overcome: 1) identifying salient

Dataset	#Examples	Avg. #Tokens				
		Paper D	Inbound C_I	Outbound C_O	Contribution y_{con}	Context y_{ctx}

Test	54242	6350	927	892	136	237

Table 1: Token length statistics on the training split of our dataset compared to existing scientific paper summarization datasets. Contribution summaries tend to be shorter than context summaries.

content of D and related papers from C_I and C_O, 2) comparing the content of D with each document from the citations, and 3) summarizing the article along the two axes: contributions and context.

3.1 Dataset

Current benchmark datasets used for the task of scientific paper summarization, such as arXiv and PubMed (Cohan and Goharian, 2015), are limited in size, the number of domains, and lack of citation metadata. Thus, we construct a new dataset based on the S2ORC (Lo et al., 2020) corpus, which offers a large collection of scientific papers spanning multiple domains along with rich citation-related metadata, such as citation links between papers and annotated citation spans. Specifically, we curate the data available in the S2ORC corpus and extend it with new reference labels.

Data Curation Some papers in the S2ORC corpus[2] do not contain a complete set of information required by our summarization task: paper text, abstract, and citation metadata. We remove such instances and construct a paper summarization dataset in which each example a) has an abstract and body text, and b) has at least 5 or more inbound and outbound citations, C_I and C_O respectively. In cases where a paper has more than K incoming or outgoing citations, we first sample K citations for each of incoming and outgoing citations and sort them in descending order by the number of their respective citation from and to the target paper. K is a hyperparameter and we choose $K = 20$ in this work.[3]

Citation Span Extraction Each article in the set of inbound and outbound citations can be represented by its full text, abstract, or the span of text associated with the citation. In this study, we follow Qazvinian and Radev (2008) and Cohan and Goharian (2015) in representing citations with the sentences in which the citation occurs.[4] Thus, an outbound citation is represented by a sentence from the source paper. Usually, such sentences directly refer to the cited paper and place its content in relation to the source paper. Analogously, an inbound citation is represented by sentences from the citing paper and relates its content with the source paper.

Reference Generation Our approach relies on the availability of reference summaries for both contributions and contexts. However, such annotations are not provided or easily extractable from the S2ORC corpus, and collecting expert annotations is infeasible due to the associated costs. Therefore, we apply a data-driven approach to automatically extract contribution and context reference summaries from the available paper abstracts. First, we manually label 400 abstracts sampled from the training set. Annotations are done on a sentence-level with binary labels indicating *contribution*- and *context*-related sentences.[5] This procedure yields 3341 sentences with associated binary labels, which we refer to as golden standard references. Next, we fine-tune an automatic sentence classifier using the golden standard data. As our classifier we use SciBERT (Beltagy et al., 2019), which after fine-tuning achieves 86.3% accuracy and 0.932 for Area under ROC curve in classifying *contribution* and *context* sentences on a held-out test set. Finally, we apply the fine-tuned classifier to generate reference labels for all examples in our dataset, which we refer to as silver standard references. The statistics of the resulting dataset are shown in Table 1.

4 Models

Our goal is to build an abstractive summarization system which has the ability to generate contribu-

---

[2] Release ID: 20190928.

[3] Among other values, we experimented with 20, as the trade-off between computational cost and rich citation contexts.

[4] If a publication is cited multiple times within a source article we concatenate all relevant sentences.

[5] Sentences not labeled as contribution are considered context, we leave finer-grained labels for future work.

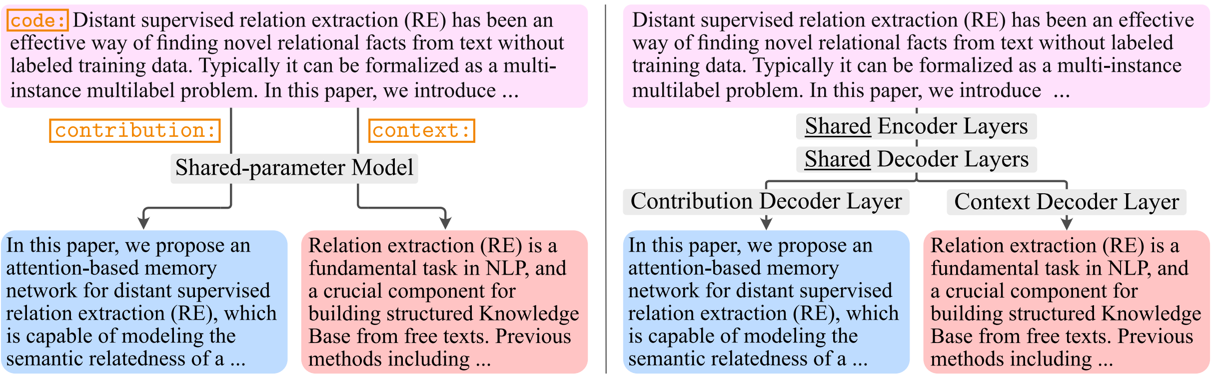

Figure 1: Model diagram. Left: CONTROLCODE model, in which inputs are prefixed with a prompt symbol and passed to a shared model to control the output mode. Right: MULTIHEAD model, which shares all of the model's parameters apart from the last decoder layer for different output modes, and chooses the final decoder layer accordingly to control the output mode.

tion and context summaries based on the source article. To achieve the necessary level of controllability, we propose two independent approaches building on encoder-decoder architectures:

CONTROLCODE (CC) A common approach to controlling model-generated text is by conditioning the generation procedure on a control code associated with the desired output. Previous work on controllable generation (Fan et al., 2018; Keskar et al., 2019; Chan et al., 2021; Luo et al., 2022) showed that prepending a special token or descriptive prompt (Liu et al., 2021) to the model's input during training and inference is sufficient to achieve fine-grained control over the generated content. Following this line of work, we modify our training instances by prepending textual control codes, `contribution:` or `context:`, to the summarized articles. During training, all model parameters are updated for each data instance and the model is expected to learn to associate the provided prompt with the correct output mode. The approach does not require changes in the architecture, making it straightforward to combine with existing large-scale, pre-trained models. The architecture is shown on the left of Figure 1.

MULTIHEAD (MH) An alternative way of controlling generation is by explicitly allocating layers within the model specifically for the desired control aspects. Prior work investigating multi-task models (Luong et al., 2016; Guo et al., 2018) showed the benefits of combining shared and task-specific layers within a single, multi-task architecture. Here, the encoder shares all parameters between the two generation modes, while the decoder shares all parameters, apart from the final layer, which splits into two generation branches. During training, each branch is individually updated with gradients from the associated mode. The model shares the softmax layer weights between the output branches under the assumption that token-level vocabulary distributions are similar in the two generation modes due to the common domain. This approach is presented on the right of Figure 1.

4.1 Informativeness-guided Training

In addition to supervising the models with gold-standard summaries, we consider guiding them to generate summaries with a focus on contributions using *informativeness* (Peyrard, 2019). Specifically, informativeness measures the user's degree of surprise after reading a summary given their background knowledge, and can be formally defined as:

$$Inf(D, K) = -\sum_i P_D(\omega_i) \log P_K(\omega_i), \quad (1)$$

where ω_i is a primitive semantic unit, P_K is the probability over the unit under the user's knowledge, P_D is the probability over the unit with respect to the source document, and i is an index over all semantic units within a summary.

Since paper contributions are novel contents introduced to the community, we argue that contributions cause surprisal given the general knowledge about the state of the field. Quantified such surprisal as informativeness, we explore utilizing this measure as an auxiliary objective that is optimized during training. We define the semantic unit ω_i as the summary itself,[6] which enables a simple interpretation of the corresponding probabil-

---

[6] For simplicity in modeling, we chose the entire summary. However, this goes against the requirement set by Peyrard (2019) that ω_i is a *primitive* semantic unit, because a paragraph's meaning can be decomposed into higher granular units.

ities. We estimate P_D as the likelihood of the summary given the paper content, $P_D(\omega_i) = p(y \,|\, D)$. Since each paper is associated with a unique context and background knowledge, we treat the background knowledge as all relevant papers published before the source paper, *i.e.*, outbound citations C_O. Therefore, P_K is estimated as the likelihood of the summary given the previous work, $P_K(\omega_i) = p(y \,|\, C_O)$. We formulate the informativeness function as:

$$Inf(D, K) = \begin{cases} -p(y_{con} \,|\, D) \log p(y_{con} \,|\, C_O) \\ -p(y_{ctx} \,|\, D) \log p(y_{ctx} \,|\, C_I) \end{cases}, \tag{2}$$

where the conditioning depends on the generation mode of the model, and aim to maximize it during the training procedure. The estimation of each term is done by a forward pass on the model with corresponding input and output pairs: $p(y_{con} \,|\, C_O)$ is computed by estimating the probability of y_{con} when feeding C_O as the encoder input.

Combined with a cross entropy loss L_{CE}, we obtain the final objective which we aim to the minimize during training:

$$L = L_{CE} - \lambda\, Inf(D, K), \tag{3}$$

where λ is a scaling hyperparameter determined through cross-validation. Note that C_I, C_O are only used during training. Models trained with this objective is applicable to papers without citation information at inference time.

5 Experiments and Results

In this section, we describe the experimental environment and report automatic evaluation results. We consider four model variants:

- **CC**, **CC+INF**: CONTROLCODE model without and with the informativeness objective,
- **MH**, **MH+INF**: MULTIHEAD model without and with the informativeness objective.

5.1 Evaluation

We perform automatic evaluation of the system outputs (s_{con}, s_{ctx}) against the silver standard references (y_{con}, y_{ctx}). For this purpose, we have designed a comprehensive evaluation protocol, shown in Figure 2, based on existing metrics that evaluates the performance of models across 3 dimensions:

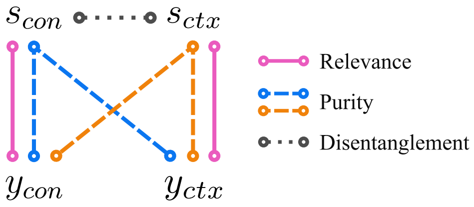

Figure 2: Diagram illustrating the evaluation protocol assessing summaries along 3 axes: relevance, purity, and disentanglement.

Relevance Generated summaries should closely correspond with the available reference summaries. We measure the lexical overlap and semantic similarity between (s_{con}, y_{con}) and (s_{ctx}, y_{ctx}) using ROUGE (R-i) (Lin, 2004) and BERTScore (Zhang et al. 2020; BS), respectively.

Purity Generated contribution summary should closely correspond with its respective reference summary, but should not overlap with the context reference summary. We measure the lexical overlap between s_{con} and $(y_{con},\, y_{ctx})$ using NouveauROUGE $_{con}$ (N$_{con}$-i) (Conroy et al., 2011). The metric reports an aggregate score defined as a linear combination between the two components:

$$\begin{aligned} \text{NouveauROUGE}_{con}\text{-}i = \alpha_0^i \\ + \alpha_1^i \text{ROUGE-}i(s_{con}, y_{con}) \\ + \alpha_2^i \text{ROUGE-}i(s_{con}, y_{ctx}), \end{aligned}$$

where weights α_j^i were set by the original authors to favor outputs with maximal and minimal overlap with related and unrelated references, accordingly. Analogously, we calculate N$_{ctx}$-i in reverse direction between s_{ctx} and $(y_{ctx},\, y_{con})$. Purity P-i is defined as the average novelty in both directions:

$$\text{Purity-}i = (\text{N}_{con}\text{-}i + \text{N}_{ctx}\text{-}i)/2; \quad (\text{P-}i).$$

Disentanglement Generated contribution and context summaries should have minimal overlap. We measure the degree of lexical overlap and semantic similarity between (s_{con}, s_{ctx}) using ROUGE and BERTScore, respectively. To maintain consistency across metrics (higher is better) we report disentanglement scores as complements of the associated metrics:

$$\begin{aligned} \text{DisROUGE-}i = 100 - \text{ROUGE-}i; \quad (\text{D-}i), \\ \text{DisBERTScore} = 100 - \text{BERTScore}; \quad (\text{DBS}). \end{aligned}$$

5.2 Results

In Table 2 we report results from the automatic evaluation protocol described in Subsection 5.1.

Model		Relevance				Purity		Disentanglement			
		R-1	R-2	R-L	BS	P-1	P-2	D-1	D-2	D-L	DBS
CC	Con	39.16	15.96	24.65	63.22	2.77	3.69	52.95	72.18	69.12	33.62
	Ctx	41.84	17.24	24.55	63.78

Table 2: Automatic evaluation results on the test set. For all metrics, higher values indicate better results. Con and Ctx refer to contribution summary and context summary, respectively. Purity and Disentanglement are measaured on the pairs of contribution and context summaries.

Original Abstract: Energy optimization in buildings by controlling the Heating Ventilation and Air Conditioning (HVAC) system is being researched extensively. In this paper, a model-free actor-critic Reinforcement Learning (RL) controller is designed using a variant of artificial recurrent neural networks called Long-Short-Term Memory (LSTM) networks. Optimization of thermal comfort alongside energy consumption is the goal in tuning this RL controller. The test platform, our office space, is designed using SketchUp. Using OpenStudio, the HVAC system is installed in the office. The control schemes (ideal thermal comfort, a traditional control and the RL control) are implemented in MATLAB. Using the Building Control Virtual Test Bed (BCVTB), the control of the thermostat schedule during each sample time is implemented for the office in EnergyPlus alongside local weather data. Results from training and validation indicate that the RL controller impoves thermal comfort by an average of 15% and energy efficiency by an average of 2.5% as compared to other strategies mentioned.

Generated Abstract: Despite the advances in research on HVAC control algorithms, most field equipment is controlled using classical methods that include hysteresis/on/off and Proportional Integral and Derivative (PID) controllers. These classical methods do not perform optimally. The high thermal inertia of buildings induces large time delays in the building dynamics, which cannot be handled efficiently by the simple on/off controllers. However, due to the high non-linearity in building dynamics coupled with uncertainties such as weather, energy pricing, etc., these PID controllers require extensive retuning or auto-tuning capabilities, which increases the difficulty and complexity of the control problem. In this work, we introduce novel control algorithms from a branch of machine learning called reinforcement learning. From a controls perspective, reinforcement learning algorithms can be considered as direct adaptive optimal control. Like optimal control, reinforcement training algorithms minimize the cumulative sum of costs over a time horizon. Unlike traditional optimization algorithms can learn optimal control actions

---

Contribution: In this work, we introduce novel control algorithms from a branch of machine learning called reinforcement learning. In our current approach, the impetus is thermostat control. Instead of traditional on/off heating and cooling control, reinforcement learning is utilized to set this schedule to obtain improved Predicted Mean Vote (PMV)-based thermal comfort at an optimal energy expenditure. Hence, a thermostats schedule is computed using an RL controller. The results show that the Q-learning algorithm can learn to adapt to time-varying and nonlinear system dynamics without explicit identification of the plant model in both systems and controls.

Context: The Heating, Ventilation and Air Conditioning (HVAC) systems can account for up to 50% of total building energy demand. In the hopes of moving toward a greener, more energy-efficient future, a significant improvement in energy efficiency is needed to achieve this goal. Despite the advances in research on HVAC control algorithms, most field equipment is controlled using classical methods that include hysteresis/on/off and Proportional Integral and Derivative controllers. However, due to the high nonlinearity in building dynamics coupled with uncertainties such as weather, energy pricing, etc., these PID controllers require extensive retuning or auto-tuning capabilities, which increases the difficulty and complexity of the control problem. The high thermal inertia of buildings induces large time delays in the building dynamics, which cannot be handled efficiently by the simple on/off controllers.

Table 3: Generated samples compared with the original and generated abstracts of the associated paper. The second rows shows the output decoded from DistilBART fine-tuned on our dataset, the third rows shows the outputs from CONTROLCODE model. Our model successfully generates disentangled content, thus making it easier to follow than the abstract.

Relevance Across most models and metrics, relevance scores for context generation are higher than those for contribution summarization. Manual inspection revealed that in some cases generated context summaries also include article contribution information, while this effect was not observed in the reverse situation. Considering that silver standard annotations may contain noisy examples with incorrectly separated references, we suspect that higher ROUGE scores for context summaries may be caused by noisy predictions coinciding with noisy references. Examples of such summaries are shown in the Appendix C. We also observe that informativeness-guided models (+INF) perform on par with their respective base versions, and the additional training objective does not affect the performance on the relevance metric. This insight corroborates with Peyrard (2019) who defines informativeness and relevance as orthogonal criteria.

Purity While the informativeness objective was designed to improve the novelty of generated summaries, results show an opposite effect, where informativeness-guided models slightly underperform their base counterparts. The true reason for such behavior is unknown, however, it might be an indicator that the outbound citations C_O are not a good approximation of reference context summaries y_{ctx}, or the relationship between the two is weak. This effect is more evident in the Medical and Biology domains, which are the two most frequent domains in the dataset.

Disentanglement Results indicate that CONTROLCODE-based models perform better than MULTIHEAD approaches in terms of generating disentangled outputs. This comes as a surprise given that the CC models share all parameters between the two generation modes, but might indicate that the two tasks contain complementary training signals. We also noticed that, both informativeness-guided models performed better in terms of D-1.

Based on both purity and disentanglement evaluations, we suspect that the informativeness objective does guide the models to output more disentangled summaries (second term in Eq 2), but the signal is not strong enough to focus on generating the appropriate content (first term in Eq 2). It is also clear that the MULTIHEAD model benefits more from the additional training objective.

6 Analysis

6.1 Qualitative Analysis

To better understand the strengths and shortcomings of our models, we performed a qualitative study of model outputs. Table 3 shows an example of generated summaries compared with the original abstract of the summarized article. Our model successfully separates the two generation modes and outputs coherent and easy to follow summaries. The contribution summary clearly lists the novelties of the work, while the context summary introduces the task at hand and explains its importance. In comparison, the original abstract briefly touches on many aspects: the context, methods used, and contributions, but also offers details that are not of primary importance, such as the detailed about the simulation environment.

More generally, the described trends hold across summaries generated by our models. The model outputs are fluent, abstractive, offer good separation between modes, and are on topic. An artifact noticed in a few instances of the inspected outputs was leakage of contribution information into context summaries. Factual correctness of summaries is discussed in Section 6.4. Other examples of generated summaries are included in the Appendix C.

6.2 Per-domain Performance

Taking advantage of the rich metadata associated with the S2ORC corpus, we analyze the performance of models across the 10 most frequent scientific domains. Table 4 shows the results of contribution summarization using the CONTROLCODE[7] model. While ROUGE-1 scores oscillate around 40 points for most academic fields, the results indicate that summarizing documents from the Medical domain is particularly difficult, with models scoring about 7 points below average. Manual inspection of instances with low scores (R-1 < 20), exposed that contribution summaries in the Medical domain are highly quantitative (*e.g.* “Among these treated ... retinopathy was noted in X%”). While other domains such as Biology also suffer from the same phenomenon, low-scoring quantitative summaries were 1.9 times more frequent in Medicine than in Biology. An investigation into the domain distribution in our dataset (Appendix) revealed that Biology and Medicine are the two best represented fields in the corpus, with Biology having over twice as many examples. We hypothesize that the poor performance of models stems from the fact that generating such quantitative summaries requires a deeper, domain-specific understanding of the source document and the available in-domain training data is insufficient to achieve that goal.

Metric	R-1	R-2	R-L	BS
Biology	40.63	17.01	25.59	64.23
Medicine	33.97	13.08	21.73	61.75
Mathematics	40.13	15.56	24.42	61.58
Computer science	43.54	16.41	25.86	63.43
None	40.31	18.14	26.68	64.00
Psychology	39.51	15.56	24.34	62.95
Physics	40.09	15.85	24.89	62.10
Chemistry	40.44	17.77	26.14	63.93
Economics	39.56	14.25	23.41	60.91
Materials science	42.52	18.96	27.57	65.25

Table 4: Relevance evaluation of contribution summaries for the top 10 domains generated using the CONTROLCODE model. Performance on Medicine domain is paricularly low.

Dataset	A1	A2	A3	AVG.
S2ORC	82%	78%	70%	77%
CORD	88%	76%	78%	81%

Table 5: Usefulness of disentangled summaries in percentage, *e.g.*, Annotator 1 (A1) chose the disentangled summaries 82% out of all the samples from S2ORC.

6.3 Human Evaluation of Usefulness

To assess the usefulness of the newly introduced task to the research community, we conducted a human study involving expert annotators. The study aimed to compare disentangled papers summaries with traditional, abstract-based summaries in a hypothetical paper reviewing setting. Judges were shown both types of summaries side by side and asked to pick one which would be more helpful for conducting the paper review.[8] Abstract-based sum-

---

[7] The remaining models exhibit the same pattern.

[8] We include a screen shot of the annotation user interface in Appendix B.

maries were generated by a model with a configuration identical to the models previously introduced in this work, trained to generate full abstracts using the same training corpus. Annotators that participated in this study hold graduate degrees in technical fields and are active in the research community, however, they were not involved or familiar with this work prior to this experiment. The study used 100 examples, out of which 50 were decoded on the test split of the adapted S2ORC dataset, while the other 50 were generated in a zero-shot fashion from articles in the CORD dataset (Wang et al., 2020), a recently introduced collection of papers related to COVID-19. The inter-annotator agreement measured by Fleiss' Kappa were 0.41 and 0.33 for the S2ORC and CORD datasets, respectively. Results in Table 5 show the proportion of all examples where the annotators preferred the disentangled summaries over the generated abstracts. The numbers indicate a strong preference from the judges for disentangled summaries, in the case of both S2ORC and CORD examples. The values on CORD samples are slightly higher than those on S2ORC; we suspect this being due to the fact that the annotators were less familiar with the topics described in Covid-related publications and would require more help to review such articles.

6.4 Factuality of Generated Summaries

In the scientific literature domain, the truthfulness of generated summaries with the input articles is a crucial aspect. Thus, we measured the factual consistency of 10 pairs of summaries sampled from Computer Science domain by assessing the validity of each *sentence* in the generated summaries against the input article and representing truthfulness as the proportion of sentences deemed consistent. We compared summaries from CC+INF (contribution, context) and DistilBART, resulting in 57, 71, 67 sentences to evaluate, respectively. As shown in Table 7, we found that most sentences copy segments from various positions in the input and lightly paraphrased or fused them together, which led to high percentage of factually consistent sentences.

6.5 Evaluation against Gold Annotations

As discussed in Section 3.1, contribution and context labels are assigned automatically using a data-driven classifier, which could introduce errors in the process. Therefore, we created a gold standard evaluation set by manually annotating 100 samples from the test set and report the evaluation results in Table 6. A sharp drop in ROUGE scores for the context summaries is caused by some examples receiving zero scores for generating context summaries when the manual annotators judged that there are not existent. The overall trend of CONTROLCODE model outpeforming MULTIHEAD model is still observed in the evaluation. More importantly, a reverse tendency is noticeable when the two models are trained with the informativeness objective. Specifically, the MULTIHEAD model showed significant improvement in terms of novelty and disentanglement.

7 Conclusions

In this paper, we propose *disentangled paper summarization*, a new task in scientific paper summarizing where models simultaneously generate contribution and context summaries. With the task in mind, we introduced a large-scale dataset with fine-grained reference summaries and rich metadata. Along with the data, we introduced three abstractive baseline approaches to solving the new task and thoroughly assessed them using a comprehensive evaluation protocol design for the task at hand. Through human studies involving expert annotators with motivated the usefulness of the task in comparison to the current scientific paper summarization setting. Together with this paper, we release the code, trained model checkpoints, and data preprocessing scripts to support future work in this direction. We hope this work will positively contribute to creating AI-based tools for assisting scientists in the research process.

Limitations

The importance of factuality in scientific literature summarization is crucial, as the summaries will serve as evidence for scientific discussion and citations. While our human annotation showed over 90% of the summary sentences were truthful to the input documents, the gap needs to be filled towards zero non-truthful sentences. In addition, failing to construct discourse-level coherence is another factor non-truthful summaries, which our models do not take into account explicitly.

Our models are developed upon DistilBART, which can process up to 1024 tokens for input. However, scientific documents (such as an 8-page paper like this submission) tend to exceed 1024 tokens. While there might be tendencies as to

Model		Relevance				Purity		Disentanglement

which sections likely discuss contributions or backgrounds, it is important to consider all the documents whenever possible, not to mention those of cited documents. Efficient incorporation of relevant documents at scale (*e.g.*, efficient attention, retrieval-augmented generation) is an active research area and should be considered for future work.

A Implementation Details

Our models build upon DistilBART[9] (Sanh et al., 2019; Wolf et al., 2019), a Transformer-based (Vaswani et al., 2017), pre-trained sequence-to-sequence architecture distilled from BART (Lewis et al., 2020). Specifically, we used a model with 6 self-attention layers in both the encoder and Decoder. Weights were initialized from a model fine-tuned on a news summarization task that are available at `https://huggingface.co/sshleifer/student_cnn_6_6`. For the MultiHead model, the final layer of the decoder was duplicated and initialized with identical weights. We fine-tuned on the training set for 80000 gradient steps on one NVIDIA V100 GPU with a fixed learning rate of 3.0×10^{-5} and choose the best checkpoints in terms of ROUGE-1 scores on the validation set. The loss scaling hyperparameter λ (Eq. 3) was set to 0.05 and 0.01 for the ControlCode and MultiHead models, accordingly. Input and output lengths were set to 1024 and 200, respectively. At inference time, we decoded using beam search with beam size 5. The evaluation was performed using SummEval toolkit (Fabbri et al., 2020).

B Human Evaluation of Disentanglement

In addition to various automatic evaluation, we perform human evaluation on disentanglement to understand which models human annotators prefer. We use Best-Worst scaling (Kiritchenko and Mohammad, 2017) over the 4-tuples of summaries on 50 random samples from the test set and have 3 annotators pick the best and the worst contribution and context summary pairs in terms of disentanglement. The rating in Table 8 shows the percentage a model is chosen as the best minus the percentage a model is chosen as the worst; the rating ranges from -1 to 1. A similar trend to automatic disentanglement evaluation is observed here as well in that introducing the informativeness objective significantly improves MultiHead model, while it conversely affects ControlCode model.

Table 8: Best-Worst scaling scores for Disentanglement.

Model	Rating
CC	**0.027**
CC+INF	0.020
MH	-0.073
MH+INF	**0.027**

We show the annotation user interface in Fig 3.

C Generated Full Samples from Different Models

We show additional samples generated from ControlCode model in Table 9. A common failure case of all our models is the lack of disentanglement between the two summaries. While samples start generating on-topic, the model for context summary generation starts generating contributions at one point.

Table 9: Generated Sample. In this example, the red highlighted segments describe the contribution.

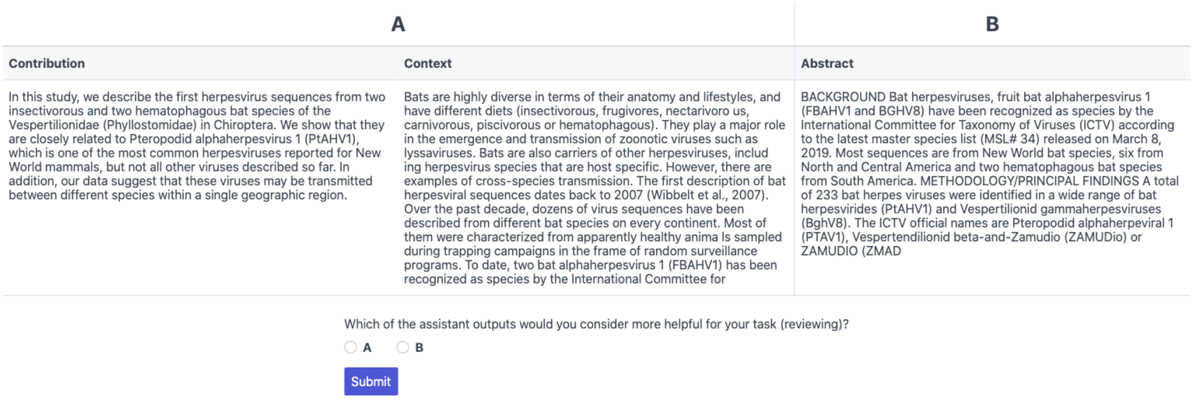
Original Abstract: Domain adaption (DA) allows machine learning methods trained on data sampled from one distribution to be applied to data sampled from another. It is thus of great practical importance to the application of such methods. Despite the fact that tensor representations are widely used in Computer Vision to capture multi-linear relationships that affect the data, most existing DA methods are applicable to vectors only. This renders them incapable of reflecting and preserving important structure in many problems. We thus propose here a learning-based method to adapt the source and target tensor representations directly, without vectorization. . . .

Generated Abstract: The difficulty of securing an appropriate and exhaustive set of training data, and the tendency for the domain of application to drift over time, often lead to variations between the distributions of the training (source) and test (target) data. In Machine Learning this problem is labeled domain mismatch. Failing to model such a distribution shift may cause significant performance degradation. Domain adaptation (DA) techniques capable of addressing this problem of distribution shift have thus received significant attention recently [24]. . . .

Contribution: To address these issues, we propose a novel approach termed Tensor-Aligned Invariant Subspace Learning (TAISL) to learn an invariant tensor subspace that is able to adapt the tensor representations directly. By introducing a set of alignment matrices, the tensors from the source domain are aligned to an underlying tensor space shared by the target domain. Instead of executing a holistic adaptation (where all feature dimensions would be taken into account), our approach performs mode-wise partial adaptation where each mode is adapted separately to avoid the curse of dimensionality. . . .
Context: Deep convolutional neural networks (CNNs) represent the state-of-the-art method for a substantial number of visual tasks. The activations of such CNNs, and the interactions between them, are naturally represented as tensors, meaning that DA should also be applied using this representation. . . . The proposed direct tensor method uses much lower dimensional entities, thus avoiding these estimation problems. To address these issues we propose to learn an invariant tensor subspace that is able to adapt the tensor representations directly. We show in Section 5 that the proposed method outperforms all comparators in DA of the Convolutional Activation of CNNs. Higher-order tensor modeling offers us an opportunity to investigate multiple interactions and couplings that capture the commonality and differences between domains. Following this idea, a novel approach

---

[9] We did not observe a substantial difference in performance between DistilBART and BART.



A		B
Contribution	**Context**	**Abstract**
In this study, we describe the first herpesvirus sequences from two insectivorous and two hematophagous bat species of the Vespertilionidae (Phyllostomidae) in Chiroptera. We show that they are closely related to Pteropodid alphaherpesvirus 1 (PtAHV1), which is one of the most common herpesviruses reported for New World mammals, but not all other viruses described so far. In addition, our data suggest that these viruses may be transmitted between different species within a single geographic region.	Bats are highly diverse in terms of their anatomy and lifestyles, and have different diets (insectivorous, frugivores, nectarivoro us, carnivorous, piscivorous or hematophagous). They play a major role in the emergence and transmission of zoonotic viruses such as lyssaviruses. Bats are also carriers of other herpesviruses, includ ing herpesvirus species that are host specific. However, there are examples of cross-species transmission. The first description of bat herpesviral sequences dates back to 2007 (Wibbelt et al., 2007). Over the past decade, dozens of virus sequences have been described from different bat species on every continent. Most of them were characterized from apparently healthy anima ls sampled during trapping campaigns in the frame of random surveillance programs. To date, two bat alphaherpesvirus 1 (FBAHV1) has been recognized as species by the International Committee for	BACKGROUND Bat herpesviruses, fruit bat alphaherpesvirus 1 (FBAHV1 and BGHV8) have been recognized as species by the International Committee for Taxonomy of Viruses (ICTV) according to the latest master species list (MSL# 34) released on March 8, 2019. Most sequences are from New World bat species, six from North and Central America and two hematophagous bat species from South America. METHODOLOGY/PRINCIPAL FINDINGS A total of 233 bat herpes viruses were identified in a wide range of bat herpesvirides (PtAHV1) and Vespertilionid gammaherpesviruses (BghV8). The ICTV official names are Pteropodid alphaherpeviral 1 (PTAV1), Vespertendilionid beta-and-Zamudio (ZAMUDio) or ZAMUDIO (ZMAD

Figure 3: The annotation interface. Summaries indicated with A and B are disentangled summaries and a generated abstract, respectively.

D Ethical Considerations

While we achieve reasonable automatic evaluation results using the proposed models, we note that these models pose ethical risks in two ways. From readers' perspective, entirely trusting machine-generated summaries would lead to a wrong understanding of the articles, thus potentially harming the progress of the research community. Even though we show that more than 90% of sentences from the annotated summaries were truthful to the input articles, the remaining sentences that were not truthful are impactful enough to misunderstand the contributions.

From writers' perspective, our proposed models could be used maliciously to appear valuable. In a hypothetical situation where our model outputs are regarded trustworthy enough for people to assess articles, "hacking" our summarization model to output over-claming contributions could be possible.

Find Parent then Label Children: A Two-stage Taxonomy Completion Method with Pre-trained Language Model

Abstract

Taxonomies, which organize domain concepts into hierarchical structures, are crucial for building knowledge systems and downstream applications. As domain knowledge evolves, taxonomies need to be continuously updated to include new concepts. Previous approaches have mainly focused on adding concepts to the leaf nodes of the existing hierarchical tree, which does not fully utilize the taxonomy's knowledge and is unable to update the original taxonomy structure (usually involving non-leaf nodes). In this paper, we propose a two-stage method called ATTEMPT for taxonomy completion. Our method inserts new concepts into the correct position by finding a parent node and labeling child nodes. Specifically, by combining local nodes with prompts to generate natural sentences, we take advantage of pre-trained language models for hypernym/hyponymy recognition. Experimental results on two public datasets (including six domains) show that ATTEMPT performs best on both taxonomy completion and extension tasks, surpassing existing methods.

1 Introduction

Taxonomies[1] are an important form of domain knowledge that organize concepts into hierarchical structures, representing "hypernym-hyponym" relationships among concepts in the form of trees or directed acyclic graphs (Shen et al., 2020). Taxonomies are essential components of knowledge systems such as ontologies and knowledge graph (Yu et al., 2020), and are widely used in various downstream applications, including search engineering (Yin and Shah, 2010), recommendation systems (Huang et al., 2019; Zhang et al., 2014), and information filtering (Demeester et al., 2016).

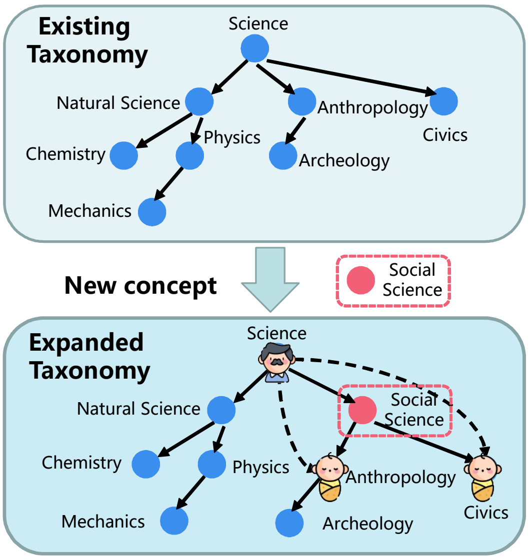

Figure 1: An example of taxonomy completion for a non-leaf node. The new concept "Social Science" needs to be inserted into the correct position in the existing taxonomy.

As domain knowledge continues to evolve, especially with the rapid growth of web content, new concepts are constantly emerging. In order to stay current, original taxonomies must incorporate these new concepts and adapt their hierarchical relationships. For example, as shown in Figure 1, with the advancement of sociology and science, the concept of "Social Science" should be added to the science knowledge system, and the original structure should be adjusted accordingly.

However, existing taxonomies are primarily constructed by human experts (Shen et al., 2018). Manual extraction of domain concepts and detection of hierarchical relationships by domain experts is both time-consuming and labor-intensive, and may result in missing important concepts and relationships.

To extend existing taxonomies automatically, researchers have proposed the tasks of taxonomy

---

[*] These authors contribute this work equally.

[1] In this paper, we mainly focus on the taxonomy represented as tree rather than directed acyclic graph, because trees are the mainstream form at present, such as the online catalog taxonomies of Amazon and Yelp.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1032–1042
May 2-6, 2023 ©2023 Association for Computational Linguistics

expansion (TE) and taxonomy completion (TC). Both tasks aim to append new nodes (concepts) to a given taxonomy . The main difference is that TE focuses on identifying the parent of a given node (usually a leaf node), while TC aims to identify both the parent and child nodes. As illustrated in Figure 1, TE would aim to identify the parent node of "Social Science", while TC would also aim to identify the child nodes of "Social Science".

Recently, researchers have been focusing on using pre-trained language models, such as BERT (Devlin et al., 2018), to improve the performance of taxonomy expansion (Liu et al., 2021; Takeoka et al., 2021). For example, TEMP (Liu et al., 2021) appends new concepts to leaf nodes and generates candidate taxonomy paths, then uses a pre-trained model for ranking and selecting the best path. Musubu (Takeoka et al., 2021) generates candidate "hypernym"-"new concept" pairs using Hearst patterns (Hearst, 1992), and relies on pre-trained knowledge to identify the optimal hypernym node for the new concept. These proposed models have greatly improved the effectiveness of taxonomy updates, thanks to the improved generalization performance of pre-trained language models (Liu et al., 2021).

Although current TE&TC methods have achieved good results, there are several main issues that need to be addressed. Firstly, existing TE methods struggle to extend non-leaf nodes or perform poorly in this task (Zhang et al., 2021). Secondly, while existing TC methods can extend both leaf and non-leaf nodes, they may be less effective in leaf node expansion than specialized TE methods (Liu et al., 2021), potentially due to a lack of sufficient utilization of knowledge. Furthermore, these methods often require large amounts of labeled samples or external resources, which are not always available (Takeoka et al., 2021). Lastly, current TC methods do not typically involve modifying the nodes of the original taxonomy system (all original parent-child relationships are preserved after adding nodes to the taxonomy). However, the insertion of new nodes can modify the relationship of the original nodes. For example, the insertion of "Social Science" in Figure 1 would change the relationship between "Science-Anthropology" from father-son to grandfather-grandson.

To address these issues, we propose **A** **T**wo-stage **T**axonomy compl**E**tion **M**ethod with **P**re-**T**rained Language model (ATTEMPT), which inserts new concepts into the correct position by identifying a parent node and labeling child nodes.

In the first stage of our proposed method, we use the "Taxonomy-path Prompt with Pre-trained model" (PPT) approach to take advantage of the local information of the taxonomy path and convert it into natural language using a prompt method, which helps to better utilize the implicit knowledge of the pre-trained model. Additionally, the pre-trained model's extensive knowledge reserve allows us to avoid the need for external resources and large amounts of labeled data. In the second stage, we propose the "Multiple Nodes Labeling" (MNL) method, which jointly identifies each child node and better utilizes the interdependence between nodes, resulting in more accurate node type prediction (including father-son, sibling and other relationships). Additionally, MNL allows for modification of the original taxonomy nodes and simultaneous annotation of multiple child nodes.

We conduct detailed experiments on two public datasets (including six domains) to evaluate the effectiveness of our proposed method, ATTEMPT, in leaf and non-leaf node expansion. Specifically, for leaf nodes, our parent-finding method (PPT) outperforms the best baseline by 8.2% in accuracy. For non-leaf nodes, our children-finding method (MNL) improves by 21% and 20.3% respectively in accuracy and average F1 score, compared to a pair-wise classification method. On the overall task, our proposed method (ATTEMPT) outperforms other methods by 2.4% in average F1 score.

In summary, the main contributions of this paper include:

- The proposal of a two-stage taxonomy expansion method, ATTEMPT, that inserts new concepts into the correct position by identifying a parent node and labeling child nodes.
- The introduction of a multiple-nodes labeling method, MNL, for the children-finding stage, which allows for the label of zero to multiple children nodes of a given node simultaneously and modification of the original taxonomy nodes.
- The demonstration of the effectiveness of our approach through experiments on two public datasets (including six domains), with the best performance obtained in both non-leaf and leaf node expansion.

2 Related Work

Taxonomy construction aims to build a tree-structured taxonomy with a set of terms from scratch. Existing methods can be roughly divided into two categories. The first is an unsupervised method to construct the taxonomy based on clustering (Alfarone and Davis, 2015; Zhang et al., 2018a; Shang et al., 2020). The terms are grouped into a hierarchy based on hierarchical clustering or topic models (Downey et al., 2015). Each node of this taxonomy is a collection of topic-indicative terms, different from the taxonomy in this paper (each node represented by one individual term). The other approach constructs a taxonomy based on terms, where each node represents a term concept (Cocos et al., 2018; Dash et al., 2020). Hypernymy detection models are often used for this task. For example, pattern-based (Agichtein and Gravano, 2000; Jiang et al., 2017; Roller et al., 2018) or distributional models (Yin and Roth, 2018; Wang et al., 2019; Dash et al., 2020) extract the hypernymy for a given query node and then organize them into a tree structure.

Creating a taxonomy from scratch is labor-intensive. In many scenarios, such as e-commerce, some taxonomies may already be deployed in online systems, which involves the demand of taxonomy extension. QASSIT (Cleuziou and Moreno, 2016) is a semi-supervised vocabulary classification method, mainly based on genetic algorithms. The TAXI (Panchenko et al., 2016) system uses a taxonomy induction method based on lexico-syntactic patterns, substrings, and focused crawling. Later, TaxoGen (Zhang et al., 2018b) uses term embeddings and hierarchical clustering to construct topic taxonomies recursively. TEMP (Liu et al., 2021) is a self-supervised classification extension method that trains models with a new dynamic margin loss margin function.

Taxonomy completion (Zhang et al., 2021) is a recently proposed task that aims to find appropriate hypernyms-hyponyms for new nodes, not just hypernyms. GenTaxo (Zeng et al., 2021) gathers information from complex local structural information and learns to generate full names of concepts from corpora. TMN (Zhang et al., 2021) focuses on channel gating mechanisms and triplet matching networks. CoRel relies on concept learning and relation transferring to build a seed-oriented topic taxonomy.

But the above mentioned methods also have some issues. The addition of new nodes may also lead to changes in the original taxonomy. The taxonomy completion task only finds the hyponyms of a given node, which cannot modify of the original taxonomy. GenTaxo (Zeng et al., 2021) requires a large amount of training data to learn enough information, and CoRel (Huang et al., 2020) focuses more on topic taxonomy than the taxonomy of individual terms. Other works such as CGExpan (Zhang et al., 2020) use the automatically generated class names and the class-guided entity selection module for entity expansion. However, CGExpan (Zhang et al., 2020) is more on the entity set than the tree taxonomy.

In addition, although the above methods can find both hypernyms and hyponyms of a given query node, they do not make sufficient use of the pre-trained model or do not use the pre-trained model at all (Zhang et al., 2021; Zeng et al., 2021). This may lead them to perform poorly on the hypernym recognition task, inferior to the specialized taxonomy extension methods of the pre-trained model (Liu et al., 2021). And most methods of taxonomy extension cannot perform well on the task of taxonomy completion (Zhang et al., 2021). We are dedicated to finding an approach that works in both tasks.

3 Method

Given an existing taxonomy $T = (V, E)$ and a set of new terms V', where V is a set of terms, and E is a set of " hyponym- hypernym" relationships between terms, the task of Taxonomy completion is to insert the new terms $v' \in V'$ into the appropriate position of the existing taxonomy T one by one and extend them into a more complete taxonomy $\tilde{T} = (\tilde{V}, \tilde{E})$.

Figure 2 provided illustrates the overall structure of the ATTEMPT method, which is broken down into two main stages: the parent finding stage and the children finding stage. These two stages work together to identify the relationships between terms in the taxonomy, specifically determining the parent and children of a given term.

3.1 Stage one: Parent Finding

The first stage of the process is to identify the parent node of a given node in the taxonomy. For example, finding the parent node “science" for the node “social science" in Figure 2.

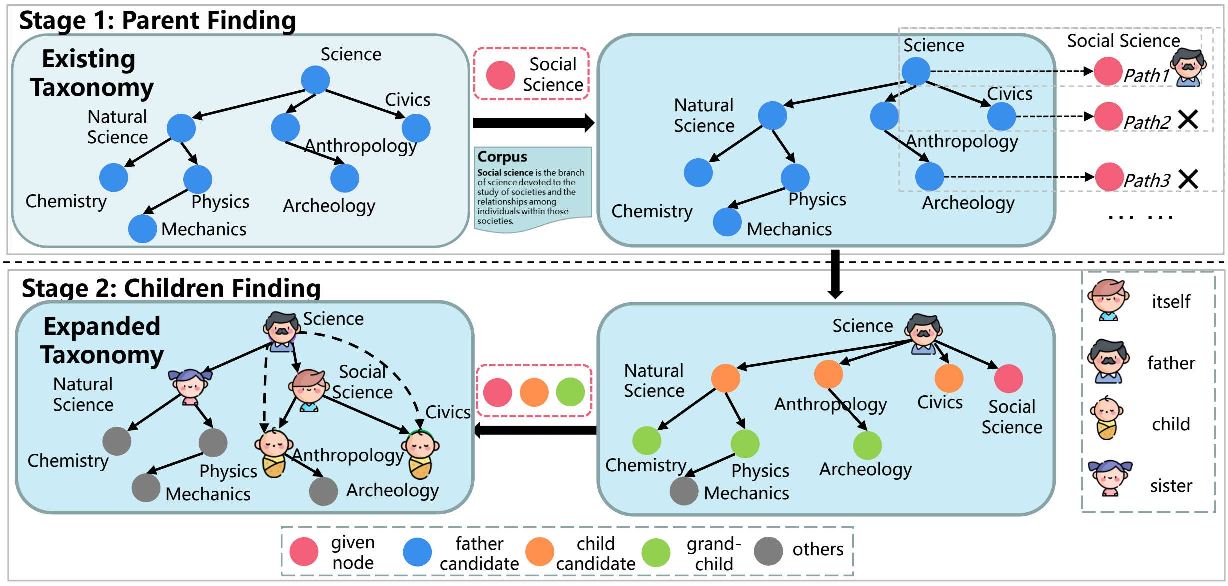

Figure 2: An overview of the proposed method ATTEMPT. ATTEMPT consists of two stages. Given an existing taxonomy and the new concept term ("Social Science"), the first stage is to find the correct parent ("Science") and the second stage is to find all possible children ("Anthropology" and "Civics").

3.1.1 TEMP

The TEMP method (Liu et al., 2021) is the first approach to use pre-trained contextual encoders as the core component for taxonomy extension. The pre-trained contextual embeddings are useful for capturing relationships between terms because they have been trained on a large corpus. TEMP predicts the location of new concepts by ranking the generated taxonomy paths. A taxonomy path of a new term (ND) in the tree-structured taxonomy is the unique path from that term to the root of the taxonomy. The taxonomy path is represented as $P = [ROOT, N_1, N_2, ..., N_D]$, where D is the depth of the ND and $ROOT$ is the root of the taxonomy. In the taxonomy, N_{i-1} is the parent of N_i. TEMP generates taxonomy paths for each term, then adds the new term to be expanded to the end of each path to form new paths. Finally, the new paths are ranked and the highest-scoring path is chosen as the correct parent term.

Equation 1 describes how TEMP uses a contextual encoder to return a sequence of vectors, given a term's definition S and an arbitrary taxonomy path P.

$$\mathrm{Encoder}(S, P) = v_{[\mathrm{CLS}]}, v_1, \ldots, v_{[\mathrm{SEP}]}, v_{p_d}, \ldots, v_{\mathrm{root}} \tag{1}$$

The TEMP method, which uses pre-trained contextual encoders to model taxonomy paths, has been an inspiration for our work. However, TEMP also has some limitations. One of the main limitations is that it can only expand new leaf nodes. Additionally, TEMP has some issues such as:

1) Limited use of local information - although TEMP uses paths to narrow the search range within the taxonomy tree, the problem of too long paths can still arise. In such cases, distant relationships may have a limited impact on the determination of leaf nodes.

2) Inadequate utilization of pre-trained model - TEMP only connects the nodes of the path using special tokens such as $[SEP]$ or $[UNK]$, which does not fully leverage the knowledge encoded by the pre-trained language model.

3.1.2 PPT: Taxonomy-path Prompt with Pre-trained model

To address the limitations of the TEMP method, we proposed PPT (A Taxonomy Expansion Method Based on Taxonomy Path Prompt and Pre-Trained Model). Our approach includes a few improvements:

Utilization of local information - Instead of using the entire taxonomy path, we use the local information nodes l_p closest to the nodes. For example, in Figure 2, for the node "Archeology", the local information nodes would be "Archeology" and "Anthropology". When the depth of the taxonomy path is less than two, we take only one node.

$$l_p = local(P) = \{N_{D-1}, N_D\} \tag{2}$$

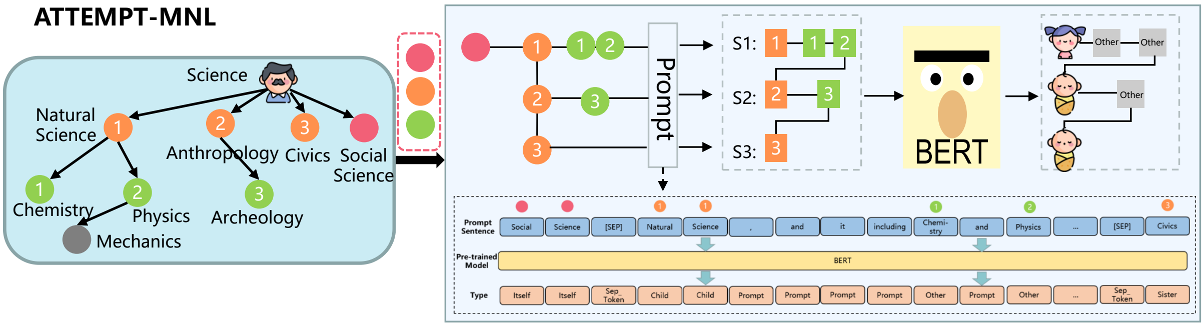

Figure 3: An overview of the MNL (multiple nodes labeling). We concatenate the current node (red), parent node, candidate children nodes (orange) and their children nodes (green) together to form a unified prompt, and then input into BERT. Finally, we realize the prediction of various types of nodes through joint labeling.

Improved pre-trained model utilization - We form a set of taxonomy path points $P_{ScocialScience}$ = (Archeology-Anthropology-Social Science) by combining the local information points of each node and the node Social Science to be extended. We then generate the appropriate natural language S_{Gen} using a prompt function.

$$S_{Gen}(q, l_p) = Prompt(q, l_p) \qquad (3)$$

where q is the node to be expanded and $Prompt$ is a function to generate natural language from prompts. For example, $S_{Gen}(q, l_p)$ = "Social Science including Anthropology, and Anthropology including Archeology". We feed this generated language S_{Gen} into the pre-trained model, rank the results in the same way as TEMP, and use the highest score as the parent node of the given node.

$$\text{Encoder}(S_{Gen}) = v'_{[\text{CLS}]}, v'_1, \ldots, v'_w \qquad (4)$$

The encoder results are as above, where w is the number of output vectors. We trained the model with Margin Ranking Loss (MRL), which is defined as follows:

$$\mathcal{L} = \sum_{P \in \mathcal{P}^+} \sum_{P' \in \mathcal{P}^-} \max\left(0, f\left(P'\right) - f(P) + \gamma\left(P, P'\right)\right) \qquad (5)$$

where $\mathcal{P}^+$ is the set of taxonomy-paths in the taxonomy, $\mathcal{P}^-$ is the set of negative samples, and $\gamma\left(P, P'\right)$ is a function designed for the margin between positive and negative taxonomy-paths. To capture the semantic similarity of different taxonomy-paths, we follow TEMP to set a dynamic margin function based on the semantic similarity as follows:

$$\gamma\left(P, P'\right) = \left(\frac{|P \cup P'|}{|P \cap P'|} - 1\right) * k \qquad (6)$$

where k is a parameter used to adjust margins (usually between 0.1 and 1).

3.2 Stage two: Children Finding

The second stage of ATTEMPT is to identify all the children nodes of a given node in the taxonomy. For example, finding the children nodes "Anthropology" and "Civics" for the node "Social Science", as shown in Figure 2. We propose two methods for this stage: PWC and MNL.

3.2.1 PWC: Pair-wise Classification

In the second stage, we identify all the child nodes of a given term. To do this, we form pairs of possible “hypernym-hyponym" term pairs from the node to be expanded (red node) and each candidate child node (orange node, child of the parent identified in the first stage). These term pairs are connected with the special token $[SEP]$ and fed into a pre-trained language model such as BERT. An example can be seen in Figure 2, where the node to be classified is “Social Science" and the orange candidate child nodes are “natural science," “anthropology" and “civics."

We use the pre-trained model to perform binary classification to determine whether the term pairs have a “hypernym-hyponym" relationship or not. The traditional cross-entropy function is used as the loss function to train the classification model. This method is simple, because the pre-trained model has been trained on a large corpus already and it can identify whether the term pairs have a hierarchical relationship or not. This method is called Pair-wise classification.

Table 1: Baseline comparison on the three datasets in stage one (in %)

3.2.2 MNL: Multiple Nodes Labeling

MNL is a new approach that addresses the problem of identifying multiple children of a given node in the taxonomy. There are two main challenges: determining whether a node has children and how many children it has, and identifying as many children as possible if there are multiple children.

To address these challenges, we first determine whether the given node is a leaf node (has no children) and if so, the second stage ends. If there are multiple children, we treat this as a multiple-choice problem and model it as a sequential labeling task. As shown in Figure 3, we extract the possible siblings, children, and grandchildren (orange and green nodes) of the given node to make use of local information. We then use a prompt function to convert these three types of nodes into natural language (e.g., “Natural Science - Chemistry, Physics" is converted to “Natural Science, and it including Chemistry and Physics").

We concatenate the node to be expanded “Social Science" with all the sentences generated by the prompt, and then feed this into the pre-trained model. Since the model was trained on a large corpus of natural language, the input of natural language is consistent with the pre-training phase, which helps to fully utilize the hidden information of the model and correctly identify the contextual relationships. The addition of local information provides additional context to the model, which allows it to make more accurate predictions about the children of the given term.

4 Experiments

In this section, we first describe the experimental setup and implementation details in Section 4.1 and Section 4.2. We then present the results of our experiments in Section 4.3, including a comparison of our approach to the baseline method. To further understand the contribution of different components of our approach, we conduct ablation experiments in Section 4.4 to investigate the effectiveness of using local information and prompts in ATTEMPT.

4.1 Experimental Setup

Datasets. We conducted experiments on two datasets that include six domains and two types of nodes. The first dataset is the Semeval-2016 task 13 dataset, which was used to evaluate the performance of expanding leaf nodes in stage one. We compared our method to previous approaches such as TEMP (Liu et al., 2021) and STEAM (Yu et al., 2020), which have also been tested on this dataset for leaf node expansion.

To evaluate the expansion of non-leaf nodes, we constructed a new dataset based on Semeval, as there are limited previous datasets that are relevant to this task. This dataset was specifically designed for the purpose of non-leaf node expansion and evaluation.

The following is a description of the two datasets: 1) We used the dataset from Semeval-2016 task 13 [2], which contains three English datasets for the environment, science, and food domains. We followed the setup as in (Yu et al., 2020) and used the randomly-grown taxonomies for self-supervised learning, and sampled 20% of the leaf nodes for testing. We used this dataset to compare our method with other taxonomy extension methods for leaf nodes. 2) As there is limited data available for non-leaf node expansion, we reconstructed the original data. We defined nodes with one parent and no children as leaf nodes and

Table 3: Comparison of the baseline method and ATTEMPT in the overall process(in %)

nodes with one parent and at least one child as non-leaf nodes. More details about the dataset are provided in Appendix A.

Metrics. For the parent finding process in stage 1, we followed the evaluation strategy of (Yu et al., 2020) using Accuracy, Mean reciprocal rank (MRR), and Wu & Palmer similarity (Wu&P) to evaluate our methods. Accuracy (ACC) measures the count of parent or child nodes that are accurately predicted. MRR calculates the average of reciprocal ranks of the true taxonomy path. Wu&P measures the semantic similarity between the predicted taxonomy path and the truth taxonomy-path.

For stage two, we proposed two metrics for evaluating the effectiveness of this phase. One is ACC, which represents whether all children can be found or not. The second one is Avg F1, which can further evaluate how many children are found for a given node. $\text{Avg(F1)} = \frac{1}{n}\sum_{i=1}^{n} \text{F1}$

Compared Methods. We compare with the following methods:

- **BERT+MLP** The method extracts terms embeddings from BERT and then feeds them into a multilayer perceptron (MLP) to predict their relationship.
- **TEMP** (Liu et al., 2021) One state-of-the-art taxonomy expansion framework which predicts new concepts' position by ranking the generated taxonomy paths. The first method that employs pre-trained contextual encoders in taxonomy construction and hypernym detection problems.
- **STEAM** (Yu et al., 2020) A taxonomy expansion framework that leverages natural supervision in the existing taxonomy for expansion.
- **TaxoExpan** (Shen et al., 2020) A self-supervised method for encoding local structures in seed taxonomy using location-enhanced graph neural networks.
- **TMN** (Zhang et al., 2021) A Triplet Matching Network (TMN) that finds suitable hypernym, hyponym word pairs for a given query concept.

4.2 Implementation Details

We present the PPT method for the first stage of leaf node expansion, which is based on TEMP (TEMPs' code link [3]). We use BERT (bert-base-uncased) as the pre-trained language model and split the terms into 10% for validation and 10% for testing. To expand the full type of nodes, both leaf and non-leaf, we use the new data introduced previously and select the same number of leaf and non-leaf nodes as the test set. We use the default optimal hyperparameters of the original TEMP authors and experiment with different learning rates to obtain the best performance. We also use multiple prompts (see Appendix C) according to the settings of Musubu (Takeoka et al., 2021), and take the average result as the experimental result. To reduce the impact of randomness, we repeat the experiment three times.

For the MNL method in stage two, we connect the nodes to be expanded (red), the candidate child nodes (orange), and the child nodes of the candidate nodes (green) and generate natural language by way of prompt. The generated natural language is fed into the pre-training model and labelled. We label the real children of a given node as 1, the sibling nodes as 0, and ignore the computational loss for all the rest of the nodes. In addition, if a term has multiple tokens and one of the tokens is marked as one by the model, we mark all those tokens as child nodes. See Appendix B for more details.

4.3 Experimental Results

As shown in Table 1, our method PPT outperforms the existing TEMP model significantly on both leaf and non-leaf nodes. For leaf nodes, we improved the TEMP model by 8.2%, 6.7%, and 2.8% on Acc, MRR, and Wu&P, respectively. For all types of nodes, the improvement is 11.0%, 9.2%, and 6.4%, respectively.

The comparison results of the two methods tested in the child discovery phase are presented in Table 2. For leaf nodes, the MNL method improves Acc and Avg(F1) by 21% and 20.3%, respectively, compared to the pair-wise classification method over the three benchmark datasets. For all type nodes, the improvement is 11.3% and 11.9%, respectively.

Table 3 presents the comparison results between the baseline method and our ATTEMPT. The baseline method achieves 14.7%, 23.3%, and 30.9% in Avg(F1) metrics for the three datasets of environment, science, and food, respectively. Our ATTEMPT method improved the Avg(F1) by an average of 2.4% over the baseline. The low results in Table 3 are due to the challenging nature of the task. To obtain the correct parent node, all child nodes must be successfully identified. This highlights the potential for further improvement.

4.4 Ablation Studies

To verify local information and prompt effectiveness, we compare and test the changes in experimental results with/without these two types of information on both stages.

Local Information As shown in Table 4, after removing the path nodes, the PPT method in stage 1 decreases on average by 4.3%, 2%, and 2.1% on acc, mrr,wu&p, respectively, on the three datasets. Table 5 also shows that the MNL method decreases by 14.6% and 22.1% on average on accuracy and average F1 score, respectively, after removing the grandchild node information in the child finding stage. We found that local information is essential in both the first and second phases, particularly in the second child lookup phase. Removing local information brings about a significant performance degradation, which may be attributed to our method's modelling of relationships. The individual nodes are closely associated in our MNL method.

Prompt In Table 4, the PPT method with prompt removal decreased in acc, mrr, wu&p by 6.5%, 5.1%, and 2.0% on average, respectively. Meanwhile, in the second stage, the MNL method decreased 8.6% and 15.6% for accuracy and average F1 metrics, respectively, after prompt removal. The scientific data in the second stage showed a slight performance improvement after prompt removal, which we speculate may be due to insufficient data and pre-trained corpus. Overall, the prompt is essential for the parent finding process in the first stage and the child finding process in the second stage.

5 Conclusion

This paper proposes a two-stage taxonomy completion method based on pre-trained Language models (ATTEMPT), which effectively inserts the new concept in the correct position by finding a parent node then labeling children nodes. In addition, we use prompt to generate natural language information suitable for the pre-trained model further to improve the effectiveness of parent node recognition and children labeling for the given node. Our experiments on two types and three domains with six datasets show that our method can enhance the effectiveness of locating the position of a given node in existing taxonomies. Furthermore, the efficacy of local information and prompts in ATTEMPT is also demonstrated by ablation experiments. In conclusion, our proposed ATTEMPT method is an effective approach for taxonomy completion, and it can be further improved with more comprehensive datasets.

Limitations

Since ATTEMPT uses the pre-trained language model to complete the taxonomy, the expansion effect is limited by the model. Generally, pre-trained models with more knowledge scales are better (e.g., BERT-Large V.S. BERT-Base-uncased). However, our paper focuses on how to fully use the knowledge of the pre-trained model rather than verifying whether more knowledge scales better or not. Based on the above, this paper does not conduct more related research (in fact, TEMP (Liu et al., 2021) has been compared and reached similar conclusions). In addition, the selection of prompts will also affect the expansion effect. For the convenience of comparison, we have selected several basic prompts (the same as Musubu (Takeoka et al., 2021)) for experimentation. In future work, we plan to study how to construct or select better prompts for classification expansion. We do not consider the situation of multi-parent nodes according to the TEMP (Liu et al., 2021) settings. And according to our statistics, there are only a few multi-parent nodes in the Semeval-2016(task-13) datasets (1/3843). We will continue investigating how to make better use of the pre-trained model knowledge to solve the taxonomy completion problem.

A Dataset

The original dataset and our reconstructed dataset statistics are in Table 6 and 7.

Dataset	Environment	Science	food
$\|\mathcal{N}\|$	261	429	1486
$\|\mathcal{L}\|$	200	306	1161
$\|\mathcal{D}\|$	6	8	8
$\|\Delta_{leaf}\|$	3.79	5.17	5.37
$\|\Delta_{non}\|$	2.97	4.41	4.78
train(leaf/non)	148/59	226/112	893/284
test(leaf/non)	52/0	85/0	297/0

Table 6: Statistics of the original taxonomy datasets for evaluation. $|\mathcal{N}|$ and $|\mathcal{L}|$ are the number of nodes and leaf nodes in the taxonomy. $|\mathcal{D}|$, $|\Delta_{leaf}|$ and $|\Delta_{non}|$ indicate the depth of the taxonomy and the average depth of leaf nodes and non-leaf nodes respectively.Train(leaf/non) and test(leaf/non) represents the proportion of leaf and non-leaf nodes in train data and test data.

Dataset	Environment	Science	food
$\|\mathcal{N}\|$	261	429	1486
$\|\mathcal{L}\|$	200	306	1161
$\|\mathcal{D}\|$	6	8	8
$\|\Delta_{leaf}\|$	3.79	5.17	5.37
$\|\Delta_{non}\|$	2.96	4.41	4.05
train(leaf/non)	187/46	292/94	1124/214
test(leaf/non)	13/13	21/21	74/74

Table 7: Statistics of the new taxonomy datasets for evaluation.

To prevent the test data from being leaked during training and to thoroughly test the generalization ability of the model when encountering unseen data, we split each original taxonomy tree into two subtrees, one for training and one for testing. For example, the left subtree of the scientific taxonomy in Figure 2, natural science and its children, is used as the test subtree, and the rest is used for training. Specifically, we select the subtree with 20% of the number of nodes of the current taxonomy tree as the subtree for testing and ignore too many leaf nodes to ensure the ratio of leaf nodes to non-leaf nodes is 1:1. Too many leaf nodes will make the child finding stage degenerate into an expansion of leaf nodes, and the model will be easily overfitting. And too few leaf nodes will make the test inadequate, so we use equal leaf and non-leaf node data as the test.

In the training and testing phases, we dig out the node to be expanded in the current taxonomy tree, and if the node has N children, these N children are reassigned to the original parent of the node to be expanded as child nodes. We ignore the case of double parent nodes because their existence is too rare. Only one node in the three datasets containing more than 2000 nodes in our experiments has a dual-parent node. We will consider this case further in our future work.

B Implementation Details

For the fairness of the experiment, we follow the setting of TEMP (Liu et al., 2021). We use 10% terms for validating and 10% for testing. For each benchmark, we try various learning rates and report the best performance. We use multiple prompts to experiment and select the average result as the experimental result. We repeated the experiment three times to reduce the impact of randomness. We train the model using the Pytorch [4] (Paszke et al., 2019) on the NVIDIA RTX3090 GPU. For all methods, the bert-base-uncased [5] model are chosen for feature extraction. The pretrained contextual encoders are of base size with 12 layers. We use the AdamW (Loshchilov and Hutter, 2018) as the optimizer with the warm-up (He et al., 2016), and fine tune the whole model with a learning rate of 2e-5. The dropout (Srivastava et al., 2014) of 0.1 is applied to prevent overfitting.

C Prompt Details

Name	Prompt
Such-as	Y such as X and Z
One-of	X is one of Y, and Z is one of Y
Especiaally	Y, especially X and Z
Is-a	X is a Y, and Z is a Y
Including	Y including X and Z

Meta Self-Refinement for Robust Learning with Weak Supervision

Abstract

Training deep neural networks (DNNs) under weak supervision has attracted increasing research attention as it can significantly reduce the annotation cost. However, labels from weak supervision can be noisy, and the high capacity of DNNs enables them to easily overfit the label noise, resulting in poor generalization. Recent methods leverage self-training to build noise-resistant models, in which a teacher trained under weak supervision is used to provide highly confident labels for teaching the students. Nevertheless, the teacher derived from such frameworks may have fitted a substantial amount of noise and therefore produce incorrect pseudo-labels with high confidence, leading to severe error propagation. In this work, we propose Meta Self-Refinement (MSR), a noise-resistant learning framework, to effectively combat label noise from weak supervision. Instead of relying on a fixed teacher trained with noisy labels, we encourage the teacher to refine its pseudo-labels. At each training step, MSR performs a meta gradient descent on the current mini-batch to maximize the student performance on a clean validation set. Extensive experimentation on eight NLP benchmarks demonstrates that MSR is robust against label noise in all settings and outperforms state-of-the-art methods by up to 11.4% in accuracy and 9.26% in F1 score.

1 Introduction

Fine-tuning pre-trained language models has led to great success across NLP tasks. Nonetheless, it still requires a substantial amount of manual labels to achieve satisfying performance on many tasks. In reality, obtaining large amounts of high-quality labels is costly and labor-intensive (Davis et al., 2013). For certain domains, it is even infeasible due to legal issues and lack of data or domain experts. Weak supervision is a widely-used approach for reudcing such cost by leveraging labels from weak sources, e,g., heuristic rules, knowledge bases or lower-quality inexpensive crowdsourcing (Ratner et al., 2017; Zhou et al., 2020; Lison et al., 2020). It has raised increasing attention in recent years, and efforts have been made to quantify the progress on weakly supervised learning, like the WRENCH benchmark (Zhang et al., 2021).

Although weak labels are inexpensive to obtain, they are often noisy and inherit biases from weak sources. Training neural networks with weak labels is challenging because of their immense capacity, which leads them to heavily overfit to the noise distribution, resulting in inferior generalization performance (Zhang et al., 2017). Various approaches have been proposed to tackle this challenge. Earlier research focused primarily on simulated noise (Bekker and Goldberger, 2016; Hendrycks et al., 2018), required prior knowledge (Ren et al., 2020; Awasthi et al., 2020) or relied on context-free aggregation rules without leveraging modern pre-trained language models (Ratner et al., 2017; Fu et al., 2020).

Recently, Yu et al. (2021) proposed a contrastive regularized self-training framework that achieved state-of-the-art (SOTA) performance in several NLP tasks from the WRENCH benchmark. It trains a teacher network on weak labels, then iteratively applies the teacher to produce pseudo-labels for training a new student model. To prevent error propagation, it filters the pseudo-labels with the model confidence scores and adds contrastive feature regularization to enforce more distinguishable representations. However, we find that this approach is *effective on easy tasks but fragile on challenging ones*, where the initial teacher model already have memorized a substantial amount of biases with high confidence. Consequently, confidence-based filtering is misleading and all future students will be reinforced with these initial wrong biases from the teacher.

To address this weakness, one strategy is learning to reweight the pseudo-labels with meta learning (Ren et al., 2018; Shu et al., 2019; Wang et al.,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1043–1058
May 2-6, 2023

2020). By this means, sample weights are dynamically adjusted to minimize the validation loss instead of prefixed with potentially misleading confidence scores. Nevertheless, if the initial teacher is weak and mostly produces incorrect pseudo-labels, simply reweighting the labels does not suffice to extract enough useful training signals.

In this paper, we propose Meta Self-Refinement (MSR) to go one step further. The teacher is jointly trained with a meta objective such that the student, after one gradient step, can achieve better performance on the validation set. In each training step, a copy of the current student performs one step of gradient descent based on the teacher predictions. The teacher will then update itself towards the gradient direction that minimizes the validation loss of the student. Finally, the actual student is trained by the updated teacher. In MSR, teacher's predictions are iteratively *refined*, instead of only "reweighted", based on the meta objective. This will enable more efficient data utilization since the teacher still has the opportunity to refine itself to provide the proper training signal, even if its initial output label is wrong. To further stabilize the training, we enhance our framework with confidence filtering when teaching the student and apply a linearly scaled learning rate scheduler to the teacher.

In summary, the main contributions are as follows: **1)** We propose a meta-learning based self-refinement framework, MSR, that allows robust learning with label noise induced by weak supervision. **2)** We analyze and quantify how label noise impacts model predictions and representation learning. We find existing methods become less effective in challenging cases when the label noise can be easily fitted. In contrast, MSR is more stable and learns better representation. **3)** Extensive experiments demonstrate that MSR consistently reduces the negative impact of the label noise, matching or outperforming SOTAs on six sequence classification and two sequence labeling tasks.[1]

2 Related Work

Learning with Noisy Labels. Learning in the presence of label noise is a long-standing problem (Angluin and Laird, 1988). Zhang et al. (2017) show that deep neural networks can memorize arbitrary noise during training, resulting in poor generalization. Noise-handling techniques - by modeling (Goldberger and Ben-Reuven, 2017; Patrini et al., 2017; Hendrycks et al., 2018) or filtering (Han et al., 2018; Li et al., 2020) the noisy instances - are proposed to conquer the label noise. While being effective, they typically assume that the noise is feature-independent which may oversimplify the noise generation process in realistic settings (Gu et al., 2021; Zhu et al., 2022). Recently, realistic and feature-dependent noise induced by weak supervision has received significant attention. To handle this type of noise, Awasthi et al. (2020) propose an implication loss that jointly denoises the noisy labels and weak sources. Ren et al. (2020) denoise the weak label by considering the reliability of different weak sources and aggregating them into one cleaned label. Zhang et al. (2021) release a benchmark, WRENCH, including various weakly supervised datasets in both text and image domains.

Self-Training. Self-training (Yarowsky, 1995; Lee et al., 2013) is a simple yet effective framework that is commonly used in semi-supervised learning (SSL). It typically trains a teacher model to provide pseudo-labels for the student model. Different methods have been proposed for better generalization (Xie et al., 2020; Zoph et al., 2020; Mukherjee and Hassan Awadallah, 2020). Recently, self-training has been adopted to tackle weak supervision. Karamanolakis et al. (2021) train a teacher network that aggregates weak labels to form high-quality pseudo-labels for the student. Liang et al. (2020); Yu et al. (2021) initialize the teacher model by training a classifier directly on the weak labels, they apply early stopping to prevent this initial teacher from memorizing the label noise. The student is then trained on the highly confident pseudo-labels provided by the teacher. While the core assumption of self-training - that highly confident pseudo-labels are reliable - is generally valid in SSL, it may not be true for feature-dependent noise induced by weak supervision, especially when the noise is easy to learn. In this case, self-training inevitably suffers more from error propagation and fails to train robust models.

Meta-Learning. Recently, different works leveraged meta-learning techniques to develop noise-robust learning frameworks. The idea is to optimize an outer learner (e.g., sample weights) that guides the inner learner (the classifier) to generalize well. Often, a clean validation dataset is used as a proxy

Figure 1: Sentiment analysis dataset annotated with rule-based weak sources. A weak source is triggered if a specific textual pattern is matched, after which a pre-defined label is then assigned. Otherwise, it abstains. Depending on how many weak sources are triggered, a text may obtain zero, one, or multiple weak labels.

for estimating the generalization performance. Ren et al. (2018) attempt to down weight training samples that increase the validation loss. Shu et al. (2019) employ a neural network to infer such sample weights and show a significant boost on performance under feature-independent noise. Wang et al. (2020) reweight the training samples by their pseudo-labels instead of the original noisy labels. In this work, we aim to leverage meta-learning in a more flexible manner by refining the pseudo-labels instead of reweighting them. Approach-wise, the most related works are (Pham et al., 2021; Zhou et al., 2022) used for semi-supervised learning and model distillation, which also refine the teacher's parameters based on the student feedback. However, they work with samples from clean distributions, while we anticipate the noise memorization effect and enhance our framework with teacher warm-up and confidence filtering to suppress the error propagation.

3 Problem Formulation

Let $\mathcal{X}$ and $\mathcal{Y}$ be the feature and label space, respectively. In standard supervised learning, one is given a clean dataset $\mathcal{D}_c = \{(x_i, y_i)\}_{i=1}^N$, where N is the number of samples. The clean labels y_i are supposed to be annotated by human experts.

In weak supervision, a dataset is labeled by weak sources rather than humans. Weak sources can have diverse forms like lexical rules, knowledge bases, pre-trained models, lower-quality inexpensive crowdsourcing, etc. Figure 1 shows an example of text labeled via weak supervision. Compared to manual annotations, weak labels contain more mistakes. We denote the dataset labeled by weak sources by $\mathcal{D}_w = \{(x_i, \hat{y}_i)\}_{i=1}^N$ where $\hat{y}_i$ is the weak label.[2] Since weak sources might not cover all data, we may have a set of unlabeled data $\mathcal{D}_u$ in addition to $\mathcal{D}_w$. We use $\mathcal{D}_a = \mathcal{D}_w \cup \mathcal{D}_u$ to denote the full set of data. Moreover, as we do not make any assumption on the quality of the weak labels, their distribution can deviate arbitrarily from the distribution of clean labels. Learning with only weak labels can lead to unbounded model errors (Menon et al., 2016; Gu et al., 2021). Hence, following standard practice in weak supervision, we assume the access to a small clean validation set $\mathcal{D}_v = \{(x_i^v, y_i^v)\}_{i=1}^M$ where $M \ll N$. $\mathcal{D}_v$ is used for early stopping, hyper-parameter tuning or meta-learning so that the learned model will not fully overfit the noisy weak labels (Ren et al., 2018; Shu et al., 2019; Zhang et al., 2021).

4 Meta Self-Refinement

We propose a novel meta-learning based framework, named Meta Self-Refinement (MSR), to tackle the label noise induced by weak supervision. In contrast to conventional self-training methods, where the teacher model is fixed after being trained on weakly labeled data, MSR enables the teacher to refine itself based on student performance on the clean validation set, yielding higher-quality labels and more accurate confidence estimates. In this section, we first provide an overview of its training objective (section 4.1), then go into the training details (section 4.2). Figure 2 illustrates the full training process.

4.1 Training Objective

MSR contains a teacher network f and a student network g, both are functions that map $\mathcal{X} \rightarrow \mathcal{Y}$. f is initialized by fine-tuning a pre-trained language model (PLM) on the weakly labeled data $\mathcal{D}_w$:

$$f_1 = \arg\min_f \mathbb{E}_{(x_i, \hat{y}_i) \in \mathcal{D}_w} \mathcal{L}(\hat{y}_i, f(x_i)) \qquad (1)$$

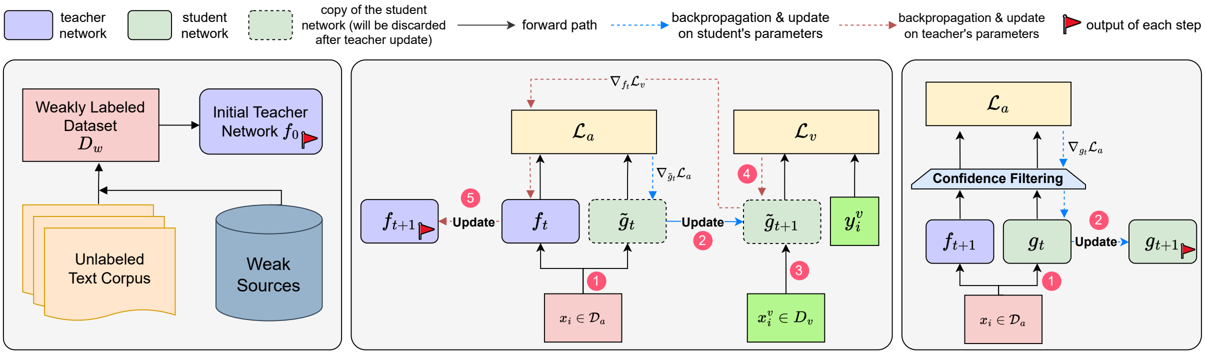
where $\mathcal{L}$ denotes the loss function. We use the cross entropy loss throughout the paper:

$$\mathcal{L}(p, q) = -\mathbb{E}_{y \sim p(y)} \log q(y) \qquad (2)$$

p and q are distributions over the label space $\mathcal{Y}$. The initial student network, g_1, is the PLM without fine-tuning on any data.

---

[2] Multiple weak sources may be triggered simultaneously by a sample. In this case, we can use different aggregation methods like majority voting to determine the final weak label.



(a) Train the initial teacher with weak labels (b) Teacher update (c) Student update

Figure 2: Illustration of our proposed Meta-Self Refinement method (MSR). (a) We start by fine-tuning a PLM on weak labels with early stopping, which yields an initial teacher f_1. (b) At each training step t, f_t gets training signals by performing a "teaching experiment" on $\tilde{g}_t$: a copy of the student network g_t. $\tilde{g}_t$ is updated by fitting f_t with the loss function $\mathcal{L}_a$. f_t is then updated to minimize the validation loss $\mathcal{L}_v$ of $\tilde{g}_{t+1}$. (c): g_t is updated by fitting f_{t+1} with confidence filtering under the loss $\mathcal{L}_a$.

In conventional self-training, f_1 is used to provide pseudo-labels to train the student. By selecting higher-quality pseudo-labels via confidence filtering (Yu et al., 2021) or uncertainty estimation (Mukherjee and Hassan Awadallah, 2020), the student can often outperform its teacher. However, as the teacher is trained solely on the weak labels, it can easily inherit unexpected biases and provide misleading signals to the student. In MSR, instead of using a fixed teacher to provide pseudo-labels, we use student performance on the clean validation set as a feedback signal to dynamically refine the teacher. Specifically, the objective for the teacher f, formulated as in Equation 3, is that *the student network, after fitting the teacher's output labels on $\mathcal{D}_a$, can perform best on the validation set $\mathcal{D}_v$*:

$$\begin{aligned} f^\star &= \arg\min_f \mathbb{E}_{(x_i^v, y_i^v)\in\mathcal{D}_v} \mathcal{L}(y_i^v, g'_f(x_i^v)) \\ g'_f &= \arg\min_g \mathbb{E}_{x_i\in\mathcal{D}_a} \mathcal{L}(f(x_i), g(x_i)) \end{aligned} \tag{3}$$

where g' is the student network after fitting output labels from f on $\mathcal{D}_a$. Intuitively, MSR aims to find the best teacher to help the student achieve the lowest validation loss. After finding the optimal teacher $f^\star$ in Equation 3, the student can then be obtained by learning from the output labels of $f^\star$:

$$g^\star = \arg\min_g \mathbb{E}_{x_i\in\mathcal{D}_a} \mathcal{L}(f^\star(x_i), g(x_i)) \tag{4}$$

end
```

4.2 Training Details

Finding the exact $f^\star$ in Equation 3 involves solving two nested loops of optimization, and each loop can be computationally expensive given the large size of $\mathcal{D}_a$. We resort to an online approximation to merge Equation 3 and 4 into an iterative training pipeline. At each training step t, the teacher f_t is first updated based on the meta-objective of "learning to teach", the student g_t is then trained by the updated teacher.

Teacher Update. To update the teacher in an efficient way, we approximate the inner loop in Equation 3 with a single-step gradient descent of the student network. Namely, the objective of the teacher is changed so that the current student, after *one single gradient descent step* of fitting the teacher, can perform best on the validation set. To do so, the teacher will first conduct a "teaching experiment" on a copy of the current student, denoted as $\tilde{g}_t$. $\tilde{g}_t$ is updated for one gradient descent step to fit the teacher's pseudo labels[3]:

$$\tilde{g}_{t+1} = \tilde{g}_t - \lambda_s \, \mathbb{E}_{x_i \sim \mathcal{D}_a} \, \nabla_{\tilde{g}_t} \mathcal{L}(f_t(x_i), \tilde{g}_t(x_i))$$

where λ_s is the learning rate of the student network. Afterwards, we update the teacher network to minimize the validation loss of $\tilde{g}_{t+1}$:

$$f_{t+1} = f_t - \lambda_t \, \mathbb{E}_{(x_i^v, y_i^v) \sim \mathcal{D}_v} \, \nabla_{f_t} \mathcal{L}(y_i^v, \tilde{g}_{t+1}(x_i^v))$$

where λ_t is the learning rate of the teacher network. It requires calculating second derivatives over f_t. We always use soft labels from the teacher for $\mathcal{L}(f_t(x_i), \tilde{g}_t(x_i))$, so the whole process is fully differentiable. Note that $\tilde{g}_t$ is only used in the "teaching experiment" to help update the teacher. It will be discarded after the teacher is updated.

Student Update. After obtaining f_{t+1}, the real student network is updated with the same objective as in Equation 4, except that we use the updated teacher f_{t+1} instead of $f^{\star}$. As the teacher has performed the "teaching experiment", it will provide more useful signals to guide the student.[4]

Teacher Learning Rate Scheduler. We find the teacher is rather sensitive to its learning rate in practice. If the learning rate is large from the start, the teacher may over-adjust itself due to the large performance gap between the teacher and the student. If the learning rate is small, the teacher will adjust itself too slowly so that more noisy pseudo-labels are passed to the student network. Therefore, we apply a linear learning rate scheduler $R(t) = \frac{t\lambda_t}{T}$ to the teacher network where t denotes the current iteration and λ_t is the targeted learning rate for the teacher. By this means, the teacher's learning rate will gradually increase as it gets better at teaching.

Confidence-Based Label Filtering. Despite having the opportunity to refine itself, the teacher inevitably produces some wrong pseudo labels during training, especially at early iterations of self-refinement. To further reduce error propagation, we only select labels with high confidence to guide the student model. The student is updated as follows:

$$g_{t+1} = g_t - \lambda_s \, \mathbb{E}_{x_i \sim \mathcal{D}_a} \, \nabla_{g_t} \mathcal{L}(f_{t+1}(x_i), g_t(x_i)) \times \mathbb{1}(1 - \frac{H(f_{t+1}(x_i))}{\log(k)} \geq \tau)$$

where $\mathbb{1}$ is the indicator function, $H(f_{t+1}(x_i))$ is the entropy of the distribution $f_{t+1}(x_i)$, k is the number of classes in $\mathcal{Y}$ and τ is a pre-defined confidence threshold. $\log(k)$ is the upper bound of the entropy for k-classification tasks. By this means, only low-entropy (high-confidence) predictions from the teacher are learned. Note that the filtering strategy is only applied to the actual student update step, not during the teaching experiment. Otherwise, the teacher will ignore low-confident samples as they do not contribute to teacher update.

Putting all together, Algorithm 1 summarizes the self-refinement process.

5 Experimental Settings

Datasets. WRENCH (Zhang et al., 2021) is a well-established benchmark for weak supervision and offers weak labels for various datasets. We compare different baselines on six NLP datasets from WRENCH including both sequence classification and Named-Entity Recognition (NER) tasks. For sequence classification, we include AGNews (Zhang et al., 2015), IMDB (Maas et al., 2011), Yelp (Zhang et al., 2015), and TREC (Li and Roth, 2002). For NER tasks, CoNLL-03 (Sang and De Meulder, 2003) and OntoNotes 5.0 (Pradhan et al., 2013) are used. In addition, we further include two sequence classification datasets in low-resource languages, Yorùbá and Hausa (Hedderich et al., 2020), to involve evaluation cases in diverse languages. Table 1 summarizes the basic statistics of the datasets. Majority voting over weak sources is used to determine a single label for each sample.

Dataset	Task	# Class	# Train	# Val	# Test
AGNews	Topic	4	96,000	12,000	12,000
IMDB	Sentiment	2	20,000	2,500	2,500
Yelp	Sentiment	2	30,400	3,800	3,800
TREC	Question	6	4,965	500	500
Yorùbá	Topic	7	1,340	189	379
Hausa	Topic	5	2,045	290	582
CoNLL03	NER	4	14,041	3,250	3,453
OntoNotes5.0	NER	18	115,812	5,000	22,897

Table 1: Dataset statistics. Refer to Appendix A for more details on datasets.

Implementation. RoBERTa-base (Liu et al., 2019) is used as the PLM for English datasets and

---

[3] We use SGD for illustration purposes. The AdamW (Loshchilov and Hutter, 2019) optimizer is used in our experiments.

[4] In theory, if the teacher network is strong enough to generalize among different batches, we can directly update the real student in the "teaching experiment", in the hope that the teacher from the last step can also work in the current batch. However, in practice, we find this mismatch leads to poor performance.

multilingual BERT-base (Devlin et al., 2019) for non-English ones. We utilize the higher[5] library to perform second-order optimization. Refer to Appendix B for detailed hyper-parameter configurations.

Baselines. We compare our method with prior work on learning with noisy labels. 1) **Majority** applies majority vote on the weak labels. Ties are broken by randomly selecting a weak label. 2) **Snorkel** (Ratner et al., 2017) trains a labeling model that aggregates weak labels from different weak sources. 3) **FT-WL** fine-tunes PLMs on the weak labels. 4) **FT-WLST** further applies classic self-training (Lee et al., 2013) on the model obtained by FT-WL. 5) **L2R** (Ren et al., 2018) uses a meta-learning framework to reweight weakly labeled samples. 6) **Meta-Weight-Net** (Shu et al., 2019) also applies meta-learning based sample reweighting. However, the weights are computed through an external reweighting network. 7) **Denoise** (Ren et al., 2020) iteratively corrects wrong annotations in the training set, and the classifier learns with the corrected labels. 8) **UST** (Mukherjee and Hassan Awadallah, 2020) is a self-training based method that assigns higher weights to samples that the teacher is certain about. The uncertainties are measured via MC-dropout on the predictions (Gal and Ghahramani, 2016). 9) **COSINE** (Yu et al., 2021) trains its student network with pseudo-labels which the teacher is highly confident about. In addition, contrastive regularization is introduced to further alleviate error propagation.

For our proposed framework, we report the performances of both **Teacher-Init** (f_1): the initial teacher trained directly on weak labels, and **MSR**: the final student model (g_T). f_1 is obtained by running FT-WL five times and selecting the best one among them according to the validation performance. *For a fair comparison, the same f_1 is used as the initial teacher for all self-training based models.* Finally, we also include the results of fine-tuning PLMs on the clean versions of each dataset, denoted by **FT-CL**, to represent the upper bound performance.

6 Results

Comparison with Baselines. Table 2 shows a comparison among different methods. MSR matches or outperforms SOTAs on all eight datasets. FT-WL outperforms majority voting over the weak labels in all cases except Hausa, which leads to a minor drop. This confirms that PLMs encode useful knowledge in their parameters, enabling them to generalize better than weak rules they are trained on. This phenomenon is particularly noticeable on AGNews, IMDB, and Yelp: direct fine-tuning on the noisy labels (FT-WL) can already achieve decent performance (accuracy above 83%). *We consider them easy tasks since label noise has only a minor impact on performance of PLMs and decent generalization can be attained even without specific noise-handling.* Applying self-training to such simple tasks lead to further performance improvement. COSINE, a SOTA self-training based model, can even perform comparably to the fully supervised model on these three datasets. On the other five datasets, however, FT-WL performs poorly and conventional self-training methods provide little performance boost (even a disservice on OntoNotes). This implies that *self-training relies on a well-performed initial teacher to work effectively.* On challenging datasets where the initial teacher is weak, it struggles to achieve further performance gain. Meta-learning based methods such as L2R performs better than COSINE on these challenging datasets. *MSR can further boost the performance on all the challenging datasets by up to 11.4% in accuracy or 9.26% in F1 score while maintaining comparable results on simpler datasets.*

Error Decomposition. Let $y', \hat{y}, y$ denote the model prediction, the noisy weak label, and the clean label, respectively. To investigate how the label noise influences the model predictions, we decompose model prediction errors into three types: (1) Type-A error: $y' = \hat{y}; \hat{y} \neq y$ (2) Type-B error: $y' \neq \hat{y} \neq y$ and (3) Type-C error: $y' \neq y; y = \hat{y}$. Type-A/B errors correspond to situations in which a model complies with an incorrect weak label $\hat{y}$, or predicts another incorrect class label. If, on the other hand, the weak label $\hat{y}$ is correct, a Type-C error arises if the model predicts a label different than $\hat{y}$. A higher Type-A error rate indicates that a model memorizes more label noise from the weak sources, while a model that underfits fails to learn useful knowledge from the weak sources can have a higher Type-C error rate.

Figure 3 visualizes the three types of errors on three challenging datasets: TREC, Hausa and CoNLL-03. The blue bars represent model robust-

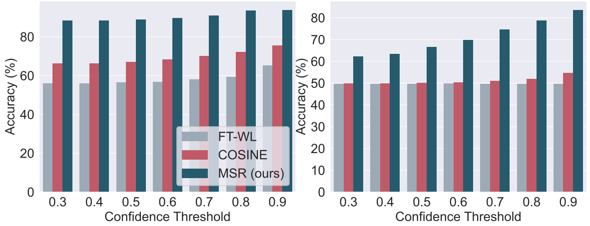
Figure 3: Prediction error decomposition of various weak supervision baselines, evaluated on the test sets. A model is considered robust against label noise if it manages to predict the correct labels despite the wrong weak labels (the robustness is represented by the blue bars). Otherwise, it conforms to the weak label (Type-A error) or predict another incorrect label (Type-B error), which has a negative effect on generalization. The Type-C error rate quantifies the proportion of incorrect model predictions when weak labels are correct. MSR consistently reduces the Type-A error rate and attains a high level of noise robustness.

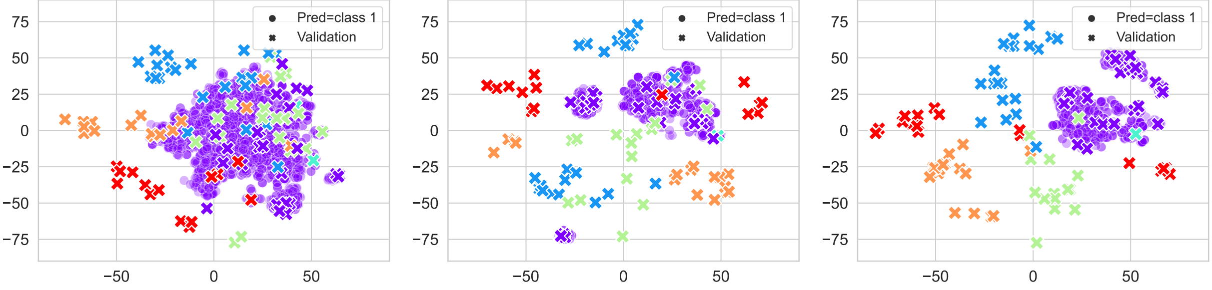


(a) TREC (b) Hausa

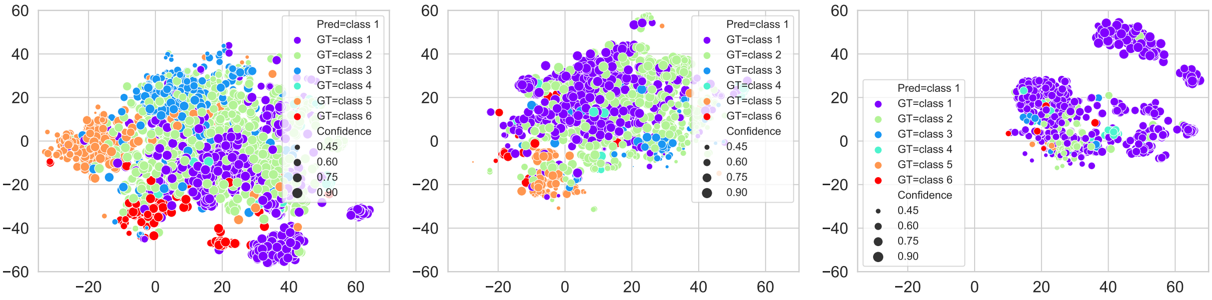
Figure 4: Accuracy *vs.* confidence thresholds.

ness, i.e., how often the model predicts correctly when $\hat{y} \neq y$. It clearly shows that direct fine-tuning on weak labels (FT-WL) has a much higher Type-A error rate compared with the model trained on clean data (FT-CL), suggesting that the model quickly memorizes the label noise. On the other hand, the disparity in type C error rate is much smaller, indicating that all models do not underfit and the knowledge from the weak sources is properly transferred. The Type-B error shows similar trends and does not differ much across models. Overall, Type-A error has the strongest impact on model performance. *All the noisy-handling models mainly help with reducing Type-A errors*. We also observe that while COSINE reduces Type-A errors on TREC, it barely works on the other two datasets. Only MSR manages to consistently reduce Type-A errors by over 20% on all three datasets.

Accuracy vs Confidence. As confidence-based filtering is a key component in both COSINE and MSR, we show the accuracy of model predictions with different confidence thresholds in Figure 4. As can be seen, *even using a high confidence threshold for COSINE, the accuracy is still low*, which is why it struggles to improve on challenging datasets. MSR, on the contrary, consistently attains higher accuracy with higher confidence thresholds, and thereby confidence-based filtering on top of MSR



(a) Teacher-Init (b) MSR student at step 1500 (c) MSR student at step 3000

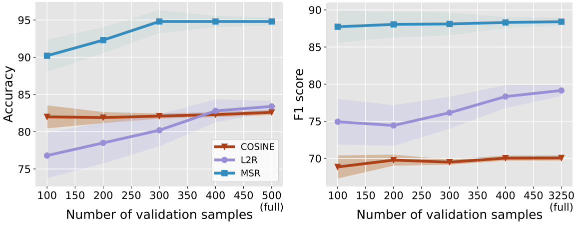


(d) Teacher-Init (e) COSINE (f) MSR

Figure 5: Projected feature space of different models on TREC using t-SNE (Van der Maaten and Hinton, 2008). The circles represent training samples that are predicted as class 1. **a)-c)**: development of MSR during training. Circles are colored by the predicted class (i.e., class 1, in purple). The validation samples are represented by crosses and colored according to the ground truth labels. The MSR student gradually improves its feature space to embed the training and validation samples from the same class in the same area. **d)-f)**: training samples are colored according to their ground truth labels; model confidence is reflected by the size of the circles. Teacher-Init and COSINE misclassify samples with high confidence. MSR attains a cleaner cluster.

help lead to better performance.

Impact of Label Noise on Feature Space. We also analyze how the label noise influences representation learning. Figure 5 illustrates the projected feature space of different models on TREC. For a clear visualization, we present only training samples predicted as class 1 by the models in the form of circles. In figs. 5a to 5c, we further visualize the feature space of validation samples (represented by crosses). As can be seen, initially the feature space of class 1 overlaps with that of other classes from the validation set. As the training proceeds, when the teacher keeps refining itself, the MSR student gradually reduces such overlap and learns a well-split representation space. In figs. 5d to 5f, we compare the feature space between different models. The training samples are colored according to their ground truth classes to highlight the misclassification ratio (the more colorful the clusters, the higher the misclassification ratio). We observe that Teacher-Init makes many wrong predictions with high degree of confidence. In this case, utilizing the confidence score for denoising is fragile. This may explain why COSINE, despite offering a more compact cluster, still has a considerable amount of misclassification. Finally, MSR has a considerably cleaner cluster and is less affected by error propagation than COSINE.



(a) TREC (b) CoNLL-03

Figure 6: Accuracy *vs.* number of validation samples.

Effects of Validation Data Size. The model performance reported in Table 2 is based on the original data splits from the WRENCH benchmark. The size of the validation sets is mostly less than 15% of the training sets. Typically, they are used to perform early stopping and model selection. For meta-learning based methods, they additionally rely on the validation sets for meta-update and might be more sensitive to validation size. Hence, we study how the validation size affects different models. In particular, we randomly sample a subset from the original validation set $\mathcal{D}_v$ and repeat the same training process. Figure 6 presents the results. We find that the validation size indeed has a greater impact on meta-learning approaches. However, *MSR still retains its high generalization performance even with as few as 100 validation samples*, suggesting that MSR is very data efficient in performing the self-refinement.

Configuration	**Seq. Classification (Acc)**	**NER (F1)**
Teacher-Init	73.75	68.99
Student	**83.43**	**81.50**
Teacher	82.38 (↓ 1.05%)	80.26 (↓ 1.24%)
w/o Teacher Scheduler	81.80 (↓ 1.63%)	80.15 (↓ 1.35%)
w/o Confidence Filtering	82.32 (↓ 1.11%)	81.09 (↓ 0.41%)
w/o Both	81.63 (↓ 1.80%)	79.95 (↓ 1.55%)

Table 3: Summary of ablation experiments aggregated across multiple datasets. See Appendix D for results in each dataset.

Ablation Study. Table 3 summarizes the impact of different components of our method. In general, our student model performs slightly better than the teacher. This is as expected because a) the teacher's goal is to guide the student to generalize better, the training loss does not explicitly encourage the teacher to improve its accuracy, and b) the confidence filtering helps the student avoid fitting some wrong pseudo-labels from the teacher. This is also confirmed by the decreased performance when the filter is removed. In addition, applying a learning rate scheduler is better than using a fixed learning rate throughout training.

7 Conclusion

We present MSR, a meta-learning based self-refinement framework that enables robust learning with weak labels. Unlike conventional self-training which relies on a fixed teacher, MSR dynamically refines the teacher based on the student's performance on the validation set. To further suppress error propagation, we introduce a learning rate scheduler to the teacher and add confidence filtering to the student. We demonstrate that our framework performs on par with or better than current SOTAs on both sequence classification and labeling tasks.

Limitations

In this work, Our primary focus is to propose a strong weak supervision method that works reliably under various weak supervision settings. We employ meta-learning techniques to address the issue of unreliable confidence scores under challenging settings (Figure 4). Despite the effectiveness, the main limitation of our method, just like other meta-learning based frameworks, is the computational overhead. The teacher update step (Algorithm 1, Line 4-6) requires computing both the first and second-order derivatives, which incurs additional computation time and higher memory consumption. Consequently, our method requires longer training.[6] Implementation-wise and computation-wise, MSR is as complex as other existing meta-learning based methods, like L2R (Ren et al., 2018) and MW-Net (Shu et al., 2019), but performs substantially better than them in all weak supervision scenarios we evaluated. It is worth noting that MSR has *no overhead at inference time*. In weak supervision, the data annotation cost is considered the most significant bottleneck. A stronger model is often obtained by trading some more computation with the cost and effort of obtaining more human-generated, manual annotations. Hence, the one-off investment of training MSR can be worthwhile for real-world weak supervision applications.

A Dataset Details

We experiment with eight NLP datasets, including six English datasets and two datasets in low-resource languages. All datasets come with their ground truth annotations and as well as the weak labels.

A.1 Datasets Selection Criteria

The WRENCH (Zhang et al., 2021) benchmark contains 23 NLP datasets. We choose representative datasets (like previous research in weak supervision) that **a)** overlap with previous works to enable direct comparisons. **b)** are diverse in terms of weak label quality, languages and tasks to approve the applicability of different baselines.

A.2 English Datasets

We experiment with four popular sequence classification datasets: AGNews, IMDB, Yelp and TREC.

1. **AGNews** (Zhang et al., 2015): originates from AG, which is a large collection of news articles. The news are categorized in four classes: "World", "Sports", "Business" and "Sci/Tech".
2. **IMDB** (Maas et al., 2011): consists of movie reviews with binary labels. It is a commonly used benchmark dataset for sentiment analysis.
3. **Yelp** (Zhang et al., 2015): obtained from the Yelp Dataset Challenge in 2015. Similar to IMDB, it is a sentiment analysis dataset.
4. **TREC** (Li and Roth, 2002): categorizes the questions in TREC-6 datasets into 6 categories: "Abbreviation", "Entity", "Description", "Human", "Location", "Numeric-value".

and with the two sequence labeling datasets: CoNLL-03 and OntoNotes 5.0.

1. **CoNLL-03** (Sang and De Meulder, 2003) NER dataset with four named-entity categories.
2. **OntoNotes 5.0** (Pradhan et al., 2013): NER dataset with 18 named-entity categories.

All weak labels are obtained from the WRENCH benchmark[7] (Zhang et al., 2021).

A.3 Datasets in Low-Resource Languages

Most datasets in the current WRENCH benchmarks are in English. Although weak supervision is desired in low-resource languages, it is understudied as finding annotators for them is more difficult. Hence, we include two low-resource languages, Yorùbá and Hausa, to cover this scenario. Often, learning with weak labels in low-resource languages is more challenging. First, the training set is often much smaller than English datasets. For example, Hausa has only about 2k training samples while AGNews have 96k. Second, the weak labels in low-resource languages can have lower quality as experts for weak source development are harder to find. A set of simple rules is often used for labeling (which is the case in Yorùbá and Hausa). Hence, weak supervision with low-resource languages is a combination of two challenges: training with *small* datasets which have *low-quality* labels.

Yorùbá and Hausa are text classification datasets obtained from (Hedderich et al., 2020).[8]

1. **Yorùbá**: consists of news headlines from BBC Yoruba which are categorized in seven classes: "Nigeria", "Africa", "World", "Entertainment", "Health", "Sport", "Politics".
2. **Hausa**: consists of news headlines from VOA Hausa which have the same seven classes as Yorùbá. However, only five classes are considered in the text classification task. "Entertainment" and "Sport" have been removed due to the lack of samples of these classes.

Hedderich et al. (2020) provided both the clean labels and weak labels on the two datasets. A gazetteer is created for each class for weak supervision. For example, a gazetteer containing names of agencies, organizations, states and cities in Nigeria is used to label the class "Nigeria".

A.4 More Dataset Statistics

We provide more details on the datasets we used in our experiments in Table 4. In general, not all data can be covered by weak sources. No weak source is triggered for some training samples and they remain unlabeled. The coverage of the datasets ranges from 69.08% to 100%. Note that for NER tasks, the coverage is always 100% since if no weak source is triggered for a token, we assign

label "O" (i.e., non-entity) to it. On the other hand, some samples can be covered by two or more weak sources with contradicted weak labels. In this case, we have a conflict. The conflict ratio ranges from 1.86% to 22.76% in the datasets we tested.

B Implementation Details

Models. All baselines in our paper, except the majority vote and the Snokerl model (Ratner et al., 2017) which work with label space only, use the official RoBERTa model[9] (Liu et al., 2019) from Huggingface as the classification backbone for all English datasets, and the multilingual BERT[10] for datasets in African languages. We use the base version of the two models which contain roughly 120M and 110M parameters, respectively.

Fine-Tuning on Classification Task. We fine-tune all layers using AdamW (Loshchilov and Hutter, 2019) as the optimizer. For sequence classification tasks, we pass the final layer of the [CLS] token representation ($\mathbb{R}^{768}$) to a feed-forward layer for prediction. For sequence labeling tasks, the final layers of all tokens ($\mathbb{R}^{768\times L}$, where L is the sentence length) are passed to a shared feed-forward layer to predict the class of each token in the sentence. We report the score where the model performs the best on the validation set during training.

Hyper-Parameters of MSR. We apply grid search on the warm-up steps for the teacher and the confidence threshold for the student network. Table 5 shows our hyperparameter search configuration. We choose the final configurations of the hyperparameters according to the model's performance on the validation set. Table 6 shows the best configurations of parameters we used to produce the results in Table 2.

Evaluation Metrics. For model evaluation, we report accuracy for sequence classification tasks and F1 Score for sequence labeling tasks. In our implementation, we call the function `classification_report()` from the scikit-learn library[11] to compute the accuracy, and use the `Seqeval` class from Huggingface[12] to compute the F1 Score.

C Validation Performance

The average test performance of MSR is reported in Table 2. We further report the corresponding validation performance in Table 7.

Abstract

Although the problem of hallucinations in neural machine translation (NMT) has received some attention, research on this highly pathological phenomenon lacks solid ground. Previous work has been limited in several ways: it often resorts to artificial settings where the problem is amplified, it disregards some (common) types of hallucinations, and it does not validate adequacy of detection heuristics. In this paper, we set foundations for the study of NMT hallucinations. First, we work in a *natural* setting, i.e., in-domain data without artificial noise neither in training nor in inference. Next, we annotate a dataset of over 3.4k sentences indicating different kinds of critical errors and hallucinations. Then, we turn to detection methods and both revisit methods used previously and propose using glass-box uncertainty-based detectors. Overall, we show that for preventive settings, (i) previously used methods are largely inadequate, (ii) sequence log-probability works best and performs on par with reference-based methods. Finally, we propose DeHallucinator, a simple method for alleviating hallucinations at test time which significantly reduces the hallucinatory rate.

1 Introduction

Neural machine translation (NMT) is becoming increasingly accurate (Vaswani et al., 2017; Akhbardeh et al., 2021), particularly in high resource language pairs where parallel data is abundant. However, even the best systems available today may generate *hallucinations*. These are extremely pathological translations that contain content that is unfaithful to the source sequence. Critically, a tiny fraction of these mistakes is all it takes to compromise user trust or safe deployment of NMT models in production.

Unfortunately, although the problem of hallucinations received some attention, research on this highly pathological phenomenon lacks solid ground. First, previous work used multiple and often overlapping definitions and categories of hallucinations which makes it hard to draw connections between observations made in different works (Lee et al., 2018; Raunak et al., 2021; Zhou et al., 2021). Next, since hallucinations are extremely rare, previous work focused on settings in which the phenomenon is amplified, e.g. perturbing data either in training or at inference, or evaluating under domain shift (Lee et al., 2018; Raunak et al., 2021; Müller et al., 2020; Wang and Sennrich, 2020; Voita et al., 2021; Müller and Sennrich, 2021; Zhou et al., 2021). Critically, the analysis on these works mostly relied on the adequacy of the automatic hallucination detection methods they proposed. However, it is not immediate whether these methods translate well to unperturbed settings.

In this work, we set foundations for the study of NMT hallucinations. We take a step back from previous work and, instead of considering perturbed settings for which hallucinations are more frequent, we consider a *natural scenario* and face the actual problem of identifying a small fraction of hallucinations (a “needle”) in a large number of translated sentences (a “haystack”). Then, we provide a rigorous comparison among hallucination detection methods. Apart from analysing those proposed in previous work (e.g., heuristics based on anomalous encoder-decoder attention), we also propose to use simple model uncertainty measures as detectors. For each of these methods, we select examples marked as hallucinations, put them together, and gather human annotations. As a result, we introduce a corpus of 3415 structured annotations for different NMT pathologies and hallucinations. We use this corpus for analysis and show that, in preventive settings where high recall is desirable, previously proposed methods are mostly inadequate, and filtering according to standard sequence log-probability performs the best. In fact, it performs on par with the state-of-the-art COMET (Rei et al.,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1059–1075
May 2-6, 2023

Category	Source Sentence	Reference Translation	Hallucination
Oscillatory	Ist ein Kompromiss aufgrund des zugrundeliegenden Regelsystems unmöglich, so spricht man von Aporie.	The case where, based on the pertinent system of regulations a compromise is not possible, is referred to as Aporia.	Aporia is the name of aporia , which is the name of aporia.
Strongly Detached	Tickets für Busse und die U-Bahn ist zu teuer, vor allem in Stockholm.	Tickets for buses and the subway is too expensive, especially in Stockholm.	The hotel is located in the centre of Stockholm, close to the train station.
Fully Detached	Die Zimmer beziehen, die Fenster mit Aussicht öffnen, tief durchatmen, staunen.	Head up to the rooms, open up the windows and savour the view, breathe deeply, marvel.	The staff were very friendly and helpful.

Table 1: Examples of hallucination types. Hallucinated content is shown shaded.

2020a) which uses reference translation and thus cannot be used in most real-world on-the-fly applications. Surprisingly, its reference-free version COMET-QE (Rei et al., 2020b), which was shown to generally perform on par with COMET (Kocmi et al., 2021; Freitag et al., 2021), substantially fails to penalise the severity of hallucinations. Overall, methods targeting the phenomena are largely unfit, quality estimation systems fail, and sequence log-probability, i.e. a byproduct of generating a translation, turns out to be the best.

Apart from our analysis of detection methods, we propose DeHallucinator, a method for alleviating hallucinations at test time. At a high level, we first apply a lightweight hallucination detector and then, if a translation is flagged, we try to overwrite it with a better version. For this, we generate several MC-dropout hypotheses (Gal and Ghahramani, 2016), score them with some measure, and pick the highest-scoring translation as the final candidate. With this approach, the proportion of correct translations among the ones flagged by the detector increases from 33% to 85%, and the hallucinatory rate decreases threefold.

Overall, we show that (i) in preventive settings, previously proposed hallucination detectors are mostly inadequate; (ii) quality estimation techniques fail to distinguish hallucinations from less severe errors; (iii) sequence log-probability is the best hallucination detector and performs on par with reference-based COMET; and, (iv) our DeHallucinator significantly alleviates hallucinations at test time.

Additionally, we release our annotated dataset along with the model, training data, and code.[1]

2 Taxonomy of Translation Pathologies

Choosing a good taxonomy is a compromise between simplicity (which minimizes annotation effort) and comprehensiveness. Thus, generic quality assessment taxonomies, such as MQM (Lommel et al., 2014), might be unfit or too complex when we focus only on critical errors and hallucinations. For hallucinations, in turn, previous work used multiple, often overlapping, definitions (Lee et al., 2018; Raunak et al., 2021; Zhou et al., 2021; Raunak et al., 2022). The taxonomy we build here is rather general: it covers categories considered previously (Lee et al., 2018; Raunak et al., 2021) and others not reported before. For a broader discussion on the taxonomy of hallucinations in NMT, and how it differs from other natural language generation tasks, refer to Ji et al. (2022).

2.1 Hallucinations

To distinguish hallucinations from other errors, we rely on the idea of detachment from the source sequence. From this perspective, other critical errors such as mistranslation of named entities are not considered as hallucinations. In Section 6 and Appendix D, we show that properties of hallucinations differ a lot from these other errors and thus our taxonomy is very reasonable.

Oscillatory hallucinations. These are inadequate translations that contain erroneous repetitions of words and phrases.

Largely fluent hallucinations. These are largely fluent translations that are unrelated to the content of the source sequence. Previous work assumed they always bear *no relation at all* to the source content (Lee et al., 2018; Raunak et al., 2021). However, we find that a large proportion of fluent hallucinations partially support the source. Therefore, we also consider severity of a hallucination and distinguish translations that are *fully* detached from those that are *strongly* (but not fully) detached.

Note that oscillatory hallucinations can also be either fully or only partially detached, but since these hallucinations are less frequent, in what follows we do not split them by severity. We show examples of these hallucination types in Table 1.

---

[1] All these resources are available at `https://github.com/deep-spin/hallucinations-in-nmt`.

2.2 Translation errors

Undergeneration. These are incomplete translations that do not cover part of the source content. This problem is often studied in isolation (Koehn and Knowles, 2017; Stahlberg and Byrne, 2019; Kumar and Sarawagi, 2019). Undergenerations are sometimes considered as hallucinations (Lee et al., 2018) but we do not consider them so in our work.

Mistranslation of named entities. Appropriately translating named entities (e.g. names, dates, etc.) is also a known difficulty of NMT systems (Ugawa et al., 2018; Li et al., 2021; Hu et al., 2022). Note that for production systems, this error is rather critical. However, we do not consider it as an hallucination as it does not show detachment from the source but rather an incorrect attempt to translate part of its content.

Other errors. These are other incorrect translations that do not fit the categories above. They may include errors related to part of speech, word order, and others. For an extensive analysis on machine translation errors, refer to Vilar et al. (2006).

3 Hallucination Detection Methods

Approaches to hallucination detection generally aim to find low-quality translations that may also satisfy additional constraints. Previous work either relied only on quality filtering (Lee et al., 2018; Raunak et al., 2021; Müller and Sennrich, 2021), or only on heuristics (Berard et al., 2019), or a combination of the two (Raunak et al., 2021). We stick to this general form and consider different quality filters and heuristics.

3.1 Quality Filters

Quality filters come in two forms: reference-free and reference-based filters. The latter rely on reference translations, while the former do not.

Reference-free methods. We use the state-of-the-art COMET-QE (Rei et al., 2020b) for its superior performance compared to other metrics (Mathur et al., 2020; Freitag et al., 2021; Kocmi et al., 2021).

Reference-based methods. Previous work used adjusted BLEU or CHRF2 scores of less than 1% as a standalone criteria (Lee et al., 2018; Raunak et al., 2021; Müller and Sennrich, 2021; Yan et al., 2022). In this work, we analyse CHRF2 because it is more suitable for sentence-level evaluation. In addition to this lexical metric, we also consider neural COMET (Rei et al., 2020a), a state-of-the-art reference-based metric (Kocmi et al., 2021).

Note that in real-world on-the-fly applications, detecting hallucinations is needed when references are not available. Thus, we use reference-based methods to estimate an upper bound for performance of the other methods.

3.2 Hallucination Detection Heuristics

3.2.1 Previously Used Heuristics

Binary-score Heuristics. These heuristics were used by Raunak et al. (2021) to detect oscillatory and fully detached hallucinations. Given a corpus of source-translation pairs, a translation is flagged as an hallucination if it is in the set of 1% lowest-quality translations, and if:

- **Top n-gram count (TNG).** The count of the top repeated n-gram in the translation is greater than the count of the top repeated source n-gram by at least t (in their work, $n = 4$ and $t = 2$);
- **Repeated targets (RT).** The translation is repeated for multiple unique source sentences.

Anomalous decoder-encoder attention. Attention patterns[2] in which most attention mass is concentrated on the source `EOS` token are often associated with a model ignoring the source and generating a hallucinatory translation (Lee et al., 2018; Berard et al., 2019; Raunak et al., 2021). We consider two different criteria targeted to find this pattern:

- **Attn-to-EOS**: the proportion of attention paid to the `EOS` source token;
- **Attn-ign-SRC**: the proportion of source words with a total incoming attention mass lower than 0.2. This was used as a data filtering criterion in Berard et al. (2019).

3.2.2 Uncertainty-Based Heuristics

Now we describe the uncertainty measures we propose to use as hallucination detectors. Previously, these were used to improve quality assessments (Fomicheva et al., 2020; Zerva et al., 2021).

---

[2] These patterns are respective to the average of the cross-attention heads of the decoder's last layer.

Sequence log-probability (Seq-Logprob). For a trained model $P(y|x,\theta)$ and a generated translation y, Seq-Logprob (i.e., model confidence) is the *length-normalised* sequence log-probability:

$$\frac{1}{L}\sum_{k=1}^{L}\log P(y_k \mid y_{<k}, x, \theta). \quad (1)$$

We hypothesise that when hallucinating, a model is not confident.

Dissimilarity of MC hypotheses (MC-DSim). This method measures how the original hypothesis y disagrees with hypotheses $\{h_1, \dots, h_N\}$ generated in stochastic passes. For the same source sentence, we generate these new hypotheses using Monte Carlo (MC) Dropout (Gal and Ghahramani, 2016). Then we evaluate the average similarity:

$$\frac{1}{N}\sum_{i=1}^{N}\textsc{sim}(h_i, y). \quad (2)$$

Different similarity measures can be used in place of SIM (e.g. METEOR (Banerjee and Lavie, 2005), BERTScore (Zhang et al., 2020), etc.). We follow previous work and use METEOR with $N = 10$ (Fomicheva et al., 2020; Zerva et al., 2021).

3.3 Trained Hallucination Detection Model

An exception from the general framework of hallucination detection is the work by Zhou et al. (2021) who *learn* to detect token-level hallucinations. Specifically, the authors create synthetic data where they randomly corrupt some tokens in a translation and reconstruct them with the BART model (Lewis et al., 2020). Then, the authors fine-tune a pretrained language model to identify the replaced tokens.

TokHal-Model. We evaluate the proportion of tokens that are predicted to be hallucinated and use this as a detection score.

3.4 Binary vs Continuous Scores

The methods above fall into two categories: *binary-score* and *continuous-score* heuristics. The former (only TNG and RT) output a value in $\{0, 1\}$, whereas the latter output a value in $\mathbb{R}$ and the prediction is made depending on a chosen threshold.

4 Experimental Setting

Model. We use Transformer base (Vaswani et al., 2017) from `fairseq` (Ott et al., 2019).

Data. We use the WMT2018 DE-EN news translation data excluding Paracrawl (Bojar et al., 2018) – 5.8M sentence pairs. We randomly choose 2/3 of the dataset for training and use the remaining 1/3 as a held-out set for analysis. For validation, we use the *newstest2017* dataset.

Held-out Data Filtering. We are mainly interested in hallucinations produced for clean data. Since our held-out data comes from the WMT2018 training dataset and thus can be noisy, we filter it using Bicleaner, the filtering tool used in official releases of filtered ParaCrawl data (Sánchez-Cartagena et al., 2018; Ramírez-Sánchez et al., 2020; Kreutzer et al., 2022). Following previous work, we exclude examples with a score below 0.5 and end up with about 1.3M examples.

All details on preprocessing, hyperparameters and implementation can be found in Appendix A.

5 Hallucinations Dataset

To analyse the effectiveness of hallucination detection criteria, we pick a subset of examples that are likely to be hallucinations, and obtain fine-grained annotations from professional translators.

5.1 Data for Annotation

Our data selection is motivated by two goals: (i) find as many hallucinatory translations as possible – to analyse hallucinations, (ii) pick some translations from a long tail of hallucination detection predictions – to analyse the behaviour of these detection methods. Thus, we first pick 250 worst-scored samples for each heuristic and quality filter (including binary assignments obtained through TNG and RT). Next, we turn to a broader set of samples and consider translations whose scores fall below a chosen percentile for a given method, i.e. we consider long tails of the scores.[3] For in-domain settings, previous work reported hallucinatory rates of $0.2-2\%$. However, these rates were either obtained on noisy and/or low-resource data or using weaker models. Therefore, in our cleaner in-domain setting with a stronger model, we expect the hallucination rate to lie in the lower end of the indicated range. Thus, we consider approximately 0.4% of the worst scores (which amounts to 5000 flagged translations for each criteria).[4] From

---

[3] From now on, we refer to examples contained in a long tail of a method as “flagged” or “detected” by this method.

[4] The threshold for prediction is consistent with this percentile. For practical details, refer to Appendix G.

these, we sample 250 examples and add them to the dataset. In total, we end up with 3415 examples for annotation.[5]

5.2 Guidelines and Annotation

The annotation guidelines are developed according to the taxonomy defined in Section 2. All details on data collection can be found in Appendix B.

6 High-level Overview of the Dataset

6.1 General Statistics

Figure 1 gives a structured overview of dataset statistics. First, we see that while we picked translations that are likely to be pathological, 60% of the dataset consists of correct translations. This highlights that with the existing methods, finding poor translations reliably is still challenging. Next, note that most of the incorrect translations have translation errors that are not severe enough to be deemed hallucinations. This agrees with the view that hallucinations lie at the extreme end of the spectrum of MT pathologies (Raunak et al., 2021). Finally, the results of the annotation confirm that our data selection is very reasonable. Indeed, while previous work has reported hallucinatory rates of $0.2 - 2\%$ in in-domain settings, we see that, for a reasonably numbered collection of examples, our hallucination rate is substantially higher (9%) – 294 hallucinations among the 3415 translations. In Figure 1, we also show the method-specific statistics of human annotation results for each heuristic and quality filter. Unsurprisingly, the long tails of each method display different characteristics. For example, almost all translations flagged by Attn-to-EOS are correct, whereas the proportion of good translations flagged by COMET-QE or Seq-Logprob is rather small. We will analyse this further in Section 7.

6.2 MT Errors vs Hallucinations

Now let us look separately at the sets of examples with hallucinations and other translation errors. Figure 2 shows the structures of these sets with respect to interactions of the different criteria.

We see that it is reasonable to consider hallucinations separately from other errors: patterns in Figures 2a and 2b are substantially different. For example, for translation errors, COMET-QE performs well, being on par with reference-aware COMET (Figure 2b). However, for hallucinations, it identifies less than half the amount of examples identified not only by COMET, but even by simple uncertainty-based heuristics (Figure 2a). Furthermore, Figure 2 reveals a significant difference between interactions of different criteria for hallucinations and for other translations: hallucinations in our data are most often flagged by multiple criteria simultaneously (e.g. Seq-Logprob flags the majority of hallucinations detected with Attn-ign-SRC and MC-DSim), whereas most MT errors and correct translations are flagged by a single method. This difference in patterns supports our choice of taxonomy: properties of hallucinations are very different from those of other less severe errors.

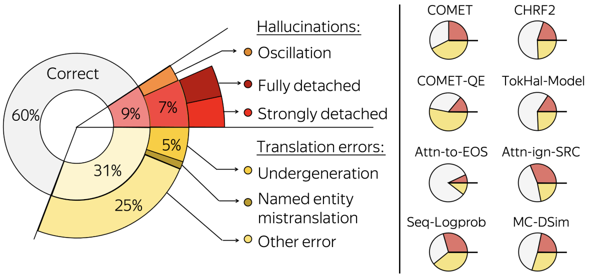

Figure 1: Overall (left) and method-specific (right) statistics of human annotation results. Method-specific statistics show the percentages of correct translations (grey), translation errors (yellow) and hallucinations (red) among the examples flagged by each method.

7 Analysing Detection Criteria

In this section, we provide a comprehensive analysis of the performance of the heuristics and quality filters introduced in Section 3.

7.1 Quality Filters

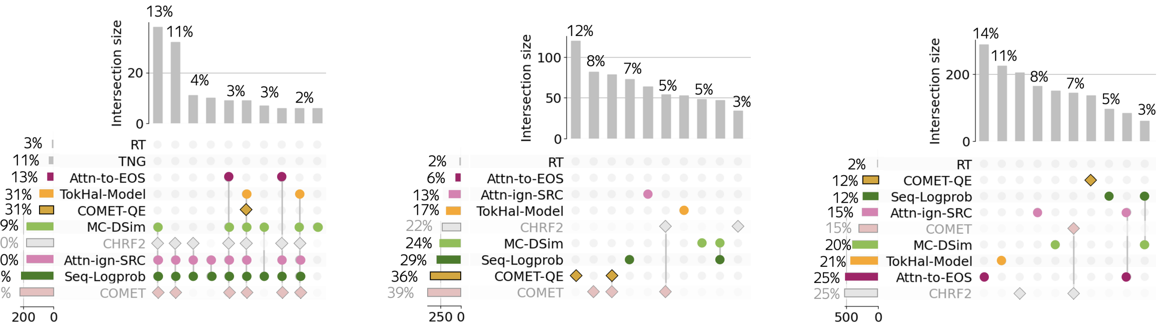
Here we start by analysing reference-based methods, namely COMET and CHRF2, and then turn to the reference-free COMET-QE. Overall, our results show that reference information is helpful, while COMET-QE fails to penalise hallucinations.

Reference information helps detection. Figure 2a shows that leveraging reference information helps detecting hallucinations: COMET detects more hallucinations than any of the other methods. As expected, lexical-based CHRF2 is significantly worse than neural-based COMET. In fact, it lags behind several heuristics (e.g., Seq-Logprob).

We also explore whether previously proposed methods for detecting hallucinations under domain

---

[5] Note that a sample originally obtained from the worst scores or sampled from the long tail of a given method may belong to the long tail of another method.



(a) Hallucinations (b) MT errors (c) Correct translations

Figure 2: Structure of the sets of translations flagged by the considered methods. Horizontal bars show the proportion of examples flagged by each method among all translations of the considered category. Each vertical bar shows the size for the set of translations that are (i) flagged by all the methods marked in the corresponding column and (ii) not flagged by any of the rest; only the top intersections are shown. Quality filters are shown with diamond marks, and detection heuristics – with circles. Methods requiring reference translations are shaded.

Heuristic	**Correct**	**MT Errors**	**Hallucinations**		
			OSC	SD	FD
TNG	0	0	32	0	0
RT	18	19	2	1	7
All dataset	2048	1073	86	90	118

Table 2: Translations flagged by TNG and RT.

shift are appropriate in our cleaner in-domain setting. Specifically, we follow Müller and Sennrich (2021) and consider translations with CHRF2 score lower than 1%. Strikingly, for our clean setting, this approach is inadequate: in the entire held-out set of 1.3M examples, it flagged only 2 translations. This suggests that methods suitable for noisy settings (e.g., domain shift) might not be applicable in settings where models are less likely to hallucinate.

COMET-QE fails to penalise hallucinations. From Figure 1 (right) we see that, as expected, most of the translations flagged by COMET-QE are incorrect. However, the vast majority of them are not hallucinations. Indeed, Figure 2a shows that COMET-QE is one of the worst hallucination detectors, meaning that it fails to rank by the severity of a translation pathology. This supports the hypothesis made in previous work: since quality estimation models are mostly trained on data that lacks negative examples, they may be inadequate for evaluating poor translations (Takahashi et al., 2021; Sudoh et al., 2021).

Overall, among the considered quality filters, only COMET may be used as a hallucination detector. However, it is important to keep in mind that, in on-the-fly applications, detecting hallucinations is needed when references are not available, rendering reference-based methods not applicable.

7.2 Detection Heuristics

The results in Section 7.1 leave a relevant gap: where do we turn to when references are not available? Is there any information, besides quality, that may help detecting hallucinations? Our evidence suggests that in preventive settings, previously proposed heuristics are mostly inadequate, and uncertainty may be the answer for the questions we pose.

Binary-score heuristics perform the worst. Table 2 shows the number of detected translations for Top n-gram count (TNG) and Repeated targets (RT). These heuristics are targeted to identify oscillatory and fully detached hallucinations, respectively. We see that while TNG obtains perfect precision, it fails to identify more than half of the oscillatory translations. RT, in turn, performs poorly across the board: only a few hallucinations are detected, and a significant proportion of flagged translations turn out to be correct. Moreover, Figure 2 shows that even if we join sets of translations detected by TNG and RT (as done in Raunak et al. (2021)), altogether we get *fewer hallucinations than almost any other considered method*. Thus, in preventive settings, these methods are highly inadequate.

Anomalous attention is mostly *not* hallucination. Figures 1 and 2 show that behaviors of Attn-to-EOS and Attn-ign-SRC are significantly different. First, Attn-to-EOS *is not indicative of hallucinations*. Indeed, attention patterns in which most attention mass is concentrated on the EOS token largely correspond to correct translations. On the other hand, Attn-ign-SRC performs well and is second only to uncertainty-based Seq-Logprob. Such a difference in performance is surprising: both methods are motivated by a common belief that if almost all the attention mass is concentrated on the source EOS token, a translation is likely to be a hallucination (Berard et al., 2019; Raunak et al., 2021). In fact, both methods were designed to identify this specific pattern. However, patterns identified with Attn-ign-SRC span from attention mass coming to various uninformative tokens (e.g., punctuation) to examples where attention is mostly diagonal (typically, these correspond to undergenerations). We show examples of such attention maps in Appendix C. Overall, the results highlight a disparity between what is *believed to indicate* hallucinations and what *actually indicates* them.

Note that while Attn-ign-SRC performs relatively well, it should be used with caution: attention-based heuristics rely on the assumption that attention patterns reflect model reasoning. This assumption is not reliable: although there is evidence that attention can play recognizable roles (Voita et al., 2018, 2019), a lot of work questions attention explainability (Wiegreffe and Pinter, 2019; Jain and Wallace, 2019; Serrano and Smith, 2019; Bastings and Filippova, 2020; Pruthi et al., 2020). Since hallucinations identified by Attn-ign-SRC are overwhelmingly contained among the ones identified by Seq-Logprob (Figure 2a), we recommend using the latter instead.

TokHal-Model is unfit for natural hallucinations. Let us recall that the model used for the TokHal-Model scores was trained to identify replaced tokens in corrupted translations that are fluent and do not differ much from the original ones (Zhou et al., 2021). This means that during training, the model was unlikely to observe highly pathological translations that reflect the types of hallucinations produced by actual NMT systems. This raises several concerns when using this model in our setting. For example, it might incorrectly flag adequate tokens such as synonyms or paraphrases. What is more, since severely flawed examples are mostly out of distribution for the model, labels predicted for such translations may be unreasonable.

The results confirm our concerns: Figures 1 and 2a show that (i) the vast majority of translations flagged by TokHal-Model are correct and (ii) it is one of the worst hallucination detectors.

Model confidence may be all you need. Figure 2 shows that Seq-Logprob is *the best heuristic* and performs on par with reference-based COMET. This means that the less confident the model is, the more likely it is to generate an inadequate translation. This agrees with some observations made in previous work on quality estimation (Fomicheva et al., 2020). Interestingly, such performance of the method contrasts with its simplicity: Seq-Logprob scores are easily obtained as a by-product of generating a translation. This distinguishes the method from all the rest that require additional computation (e.g., corpus-level search for RT or generating multiple hypotheses for MC-DSim).

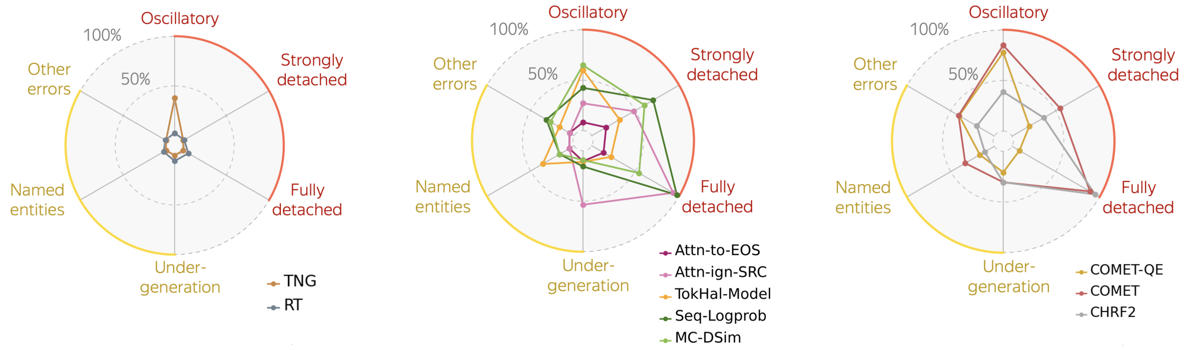
On another note, NMT models have been found to be miscalibrated (Kumar and Sarawagi, 2019). Thus, investigating the impact of recalibration methods – aimed at enhancing prediction reliability – on the detection quality of Seq-Logprob constitutes an interesting avenue for future research.

MC-DSim: hallucinations are mostly unstable. The intuition behind this heuristic is simple: when faced with a source sentence for which a good translation is not immediate, the set of hypotheses the model "keeps at hand" may be very diverse. Indeed, MC-DSim performs relatively well and identifies a good proportion of hallucinations (Figures 1, 2). Thus, most hallucinations are *unstable*: dissimilarity of MC hypotheses helps to identify them.

Note that while MC-DSim is not the best choice for detection, later we will show that the intuition behind this method is very helpful for alleviating hallucinations at test time (Section 9).

7.3 Combining Heuristics and Quality Filters

Intersecting a set of translations obtained via a heuristic with the bottom scored translations according to a quality filter was introduced in Raunak et al. (2021). The motivation for this was to avoid incorrectly flagging good translations as hallucinations (e.g., without this intersection, RT flags good-quality paraphrases). Intuitively, this idea is very reasonable: hallucinations are indeed incorrect translations. However, implementing this in practice requires a good quality estimation model, specifically for ranking poor translations. Unfortunately, we showed in Section 7.1 that for this purpose, even the state-of-the-art COMET-QE is largely inadequate. This means that using such quality estimates may lead to filtering out a lot of hallucinations, which is not desirable in preven-



(a) Binary-score heuristics (b) Continuous-score heuristics (c) Quality filters

Figure 3: Distribution of the translations flagged by each method conditioned on each of the considered pathologies.

tive settings. Our results show that this is exactly the case: e.g., filtering with COMET-QE leads to losing nearly 80% of hallucinations detected by Seq-Logprob. All in all, such an intersection generally does more harm than good.

8 Analysing Hallucination Pathologies

In this section, we look at hallucination pathologies in isolation and show that the behavior of detection methods varies depending on the type of pathology. For example, for a given pathology, some methods may be specialised, whereas others may fail. For a similar analysis on other less severe translation errors, refer to Appendix D.

Fully detached hallucinations. Figure 3 shows that these hallucinations are easily detected by several methods, e.g. Seq-Lobprob, Attn-ign-SRC, COMET, CHRF2. This is not surprising: intuitively, the most severe pathology should be the easiest to detect. However, COMET-QE *fails to identify almost all these hallucinations*. While COMET-based metrics are known to not penalise enough certain types of errors (e.g., discrepancies in numbers and named entities; see Amrhein and Sennrich (2022); Raunak et al. (2022)), such poor performance for completely inadequate translations is highly unexpected. This calls for further research on the behavior of quality estimation models.

On a more general note, previous work suggested that fully detached hallucinations emerge as exact copies of references from training data (Raunak et al., 2021). We validate this hypothesis and find the contrary: out of the 44 unique translations marked as fully detached from the source, only 4 are exact copies of references in the training data. Nevertheless, when looking at these sentences more closely, we see that they do contain large substrings that are seen frequently during training. Therefore, fully detached hallucinations are indeed likely to be traced back to the training data, but they *emerge in non trivial ways and not necessarily as exact copies*. This can be seen as one more evidence that, when dealing with memorisation in language models, it is necessary to consider not just full copies in the training data but also near-duplicates (Lee et al., 2022).

Strongly detached hallucinations. As expected, this pathology is harder to detect than fully detached hallucinations (Figure 3). However, the trends are largely similar: for example, COMET-QE fails again, and Seq-Logprob performs best and outperforms even reference-based COMET.

Oscillatory hallucinations. The method specifically developed to detect this hallucination type (Top n-gram count, TNG) performs worse than most of the other methods. Among the rest, COMET performs best. Interestingly, in contrast to previous observations, COMET-QE performs well, being on par with COMET.

9 DeHallucinator: Overwriting Hallucinations at Test Time

In previous sections, we saw that hallucinations are more unstable than other translations: for them, generated MC-dropout hypotheses tend to vary greatly. This motivates us to look more closely into these hypotheses: are any of these translations *not* hallucinations? Answering this question not only gives insight into the inner workings of hallucinating NMT models, but also leads to an interesting practical application – overwriting hallucinations at inference time. This is of utmost importance for production systems where hallucinations have a deeply compromising effect on user trust.

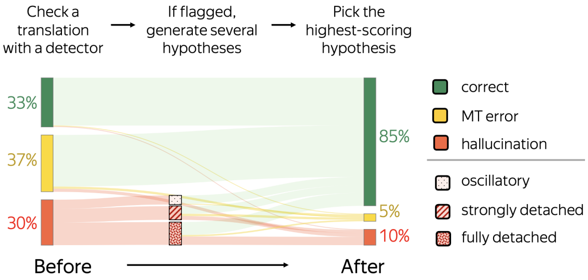


Figure 4: Our pipeline scheme along with results.

Whenever flagged, overwrite with better. Intuitively, our idea is similar to hybrid pipelines when a machine-generated translation is first passed to a quality estimation system and then, if needed, is corrected by human translators. In our case, we first apply a hallucination detector and then, if a translation is flagged, we try to overwrite it with a better translation (Figure 4). For this, we generate several MC-dropout hypotheses, score them with some measure, and pick the highest-scoring translation as a final candidate (in the spirit of reranking approaches (Shen et al., 2004; Lee et al., 2021; Fernandes et al., 2022; Freitag et al., 2022)).

The general pipeline above relies on the choice of a hallucination detector and a scoring measure. For the detector, we use the best of the analysed detectors, i.e. Seq-Logprob.[6] For the scoring measure, a natural choice would be a quality estimation system: by construction, these systems are designed to score translations according to quality. However, as we saw earlier, even the state-of-the-art COMET-QE may fail (Section 7.1). Therefore, we compare two measures: COMET-QE and Seq-Logprob.

In this experiment, we randomly choose 200 translations from our dataset flagged by Seq-Logprob. For each, we generate 10 hypotheses with MC-dropout. Then, for the overwritten translations we gather annotations according to our guidelines (Section 5). The results are summarized in Figure 4. Although we were concerned about COMET-QE because of its low performance when ranking poor translations, we find that for choosing the best hypothesis, it is indeed appropriate and performs better than Seq-Logprob. We thus show results with COMET-QE scores in the main text and with Seq-Logprob in Appendix E.

Most hallucinations and errors become correct. Figure 4 shows that most hallucinations are overwritten with correct translations. This is surprising: in most cases, the model is not stuck in a hallucinatory mode and can generate good translations in a small vicinity of model parameters. In this sense, most hallucinations result from "bad luck" during generation and not profound model defect. Note that fully detached hallucinations are the hardest to improve. This makes sense as these are likely to be traced back to (near-)duplicates in the training data and, therefore, they do highlight model anomalies.

Note that in this pipeline, we overwrite not only hallucinations but also other errors and correct translations that were flagged by the detector. This means that our method needs to appropriately handle such translations. From Figure 4 we see a pleasant side-effect: our approach overwrites most of the errors with correct translations. Just as importantly, almost all originally correct translations remain correct. Overall, the proportion of correct translations among the ones flagged by the detector increases from 33% to 85%, and the hallucinatory rate decreases threefold. In Appendix F, we show several examples of overwritten hallucinations.

10 Conclusions

Dealing with hallucinations is difficult. First, we had to take a step back from previous work and refuse procedures that amplify the problem, as these hinder the behavior of models in their standard settings. After that, we notice that work on detection often relies on assumptions that remained unquestioned (e.g., generic quality measures, targeted heuristics, anomalous attention being suitable detectors). Through extensive experiments, we establish order in detection methods. Surprisingly, despite introduction of several methods specifically targeted for hallucinations, what works best has always been at our disposal: standard sequence log-probability. This suggests that characteristics innate to a model can have a lot of value. In fact, such characteristics are the backbone of our DEHALLUCINATOR, a lightweight approach that significantly alleviates hallucinations at test time. This leaves space for future research on model uncertainty, hallucination prevention, understanding where hallucinations come from, among others. For this, we release our corpus with structured annotations along with the model and its training data. Altogether, this allows us to say that we provide solid ground for future study of hallucinations in NMT.

---

[6] In this experiment, we take the translations from our dataset and consider the percentiles defined in Section 5.

Limitations

We highlight three main limitations in our work. First, although the foundation of our proposed taxonomy for hallucinations rests on the idea of detachment from the source content, we do not evaluate it quantitatively. Indeed, we cannot point whether the model that generated the hallucinations was indeed detached from the source sentence when generating them. Nevertheless, we can guarantee that the hallucinations in our dataset are translations that are detached from the source content according to professional translators. We consider that the quantitative analysis of the detachment to be out of the scope of this paper. Still, it constitutes an interesting line for future research on understanding hallucinations in NMT that may be facilitated with the release of our code, model and annotated dataset.

Second, while this paper comprehensively studies the phenomena of hallucinations in NMT for a high-resource language pair, experiments in more language pairs (including low-resource languages) are necessary to assess the broad validity of our claims. To keep our setup familiar to researchers and practicioners, we opted for a familiar language pair for which data is widely available. Moreover our choice also facilitated the data collection process as there is a large supply of professional translators for this language pair.

Lastly, instead of focusing on more recent NMT models that use large pretrained language models as their backbone, we focused on a Transformer base model. The reason for this choice is that we wanted to keep the setup simple, familiar, easy to reproduce, and computationally economical. Moreover, it was important for our work to have full control on the training and held-out data. Nevertheless, research on hallucinations on more recent and powerful NMT models is an exciting line of future work and we hope our work spurs that research.

A Experimental setup

Data preprocessing. We filter our data using language identification and simple length-heuristics described in Tran et al. (2021). We encode the data with byte-pair encoding (Sennrich et al., 2016) using the SentencePiece framework (Kudo and Richardson, 2018). We set the vocabulary size to 32k and compute joint encodings and vocabulary.

Model parameters. We follow the setup of Transformer base model (Vaswani et al., 2017) (hidden size of 512, feedforward size of 2048, 6 encoder and 6 decoder layers, 8 attention heads). The model has approximately 77M parameters.

Optimizer. Similarly to (Vashishth et al., 2019), we train our model using the Adam optimizer with $\beta_1 = 0.9$ and $\beta_2 = 0.98$ and use an inverse square root learning rate scheduler with initial value 5×10^{-4}, and a linear warm-up in the first 4000 steps.

Training and Inference. Models are trained for 250K updates with a batch size of about 32K tokens. We set dropout to 0.3. At inference time, we produce translations using beam search with a beam of 5. We validate our models during training using SacreBLEU (Post, 2018), and we choose the checkpoint based on best BLEU in validation. We provide BLEU[7] and COMET baselines on WMT evaluation campaigns in Table 3. We train and performance inference on top of the Fairseq framework (Ott et al., 2019).

COMET versions. We use models available in the official repository[8]: `wmt20-comet-da` for COMET and `wmt20-comet-qe-da-v2` for COMET-QE.

TokHal-Model. We follow the official implementation.[9] For the synthetic data generation step, we used BART-large; and, for the token-level hallucination predictor, we used XLM-R (Conneau et al., 2019).

Computing Infrastructure. All our experiments have been ran on a machine with 2 physical Intel(R) Xeon(R) Gold 6348 @ 2.60GHz CPUs (total of 112 threads), and 4 NVIDIA RTX A6000 GPUs. In particular, the NMT model described above was trained in less than 30 hours on a single GPU.

Metric	WMT2014	WMT2017	WMT2018
BLEU	31.1	32.6	38.9
COMET	0.3178	0.3257	0.3340

Table 3: Evaluation metrics for EN → DE for *newstest* sets for the WMT 2014, 2017 and 2018 campaigns.

B Data Collection

We perform a rigorous and comprehensive manual annotation procedure with professional translators, in order to make sure that we are reliably analysing hallucinated translations.[10] First, the translators were asked to be familiar with our task by reading our provided annotation examples, along with detailed annotation instructions. Then they had to pass a test to show they can recognize different pathologies in different translations. We selected the two best translators to gather the annotations. After being hired, we ran three one-hour tutorial sessions to explain the task thoroughly and to clarify any possible questions. During the annotation process, we made sure to be promptly available to answer any question from the translators. We paid a fair wage (25-30 USD per hour) – well above both the US federal minimum and the average EU minimum wage – and inspected their work for quality.

Guidelines. We make available the full guidelines used by the translators along with all other resources in the project repository. In short, the annotators were presented with a source sentence and a model-generated hypothesis and asked to deem that translation as correct (`COR`) or incorrect. If incorrect, they were prompted to answer a series of yes/no questions, regarding the presence of specific hallucinatory pathologies: oscillations (`OSC`), strong detachment (`SD`) and full detachment (`FD`). We also asked annotators to flag critical errors such as named-entity mistranslations (`NE`) and under-generated translations (`UG`).

Inter-annotator agreement. To determine the reliability of our annotations, we asked both our translators to annotate a set of 400 randomly sampled translations. For all hallucinatory categories but `SD`, the annotators achieved – according to Cohen's kappa coefficient (Cohen, 1960) – almost

Fleiss's Kappa Scores					
COR	UG	NE	OSC	SD	FD
0.62	0.73	0.42	0.86	0.45	0.89

Table 4: Fleiss's Kappa inter-annotator agreement scores (↑) for the different categories translators were prompted to identify.

perfect agreement. For all other categories, moderate to substantial agreement was obtained. This confirms that our data conforms very well to our instructions. The agreement scores for each category are displayed in Table 4.

C Patterns of attention maps for translations flagged with attention-based heuristics

The attention maps are shown in Figure 5. While both Attn-to-EOS and Attn-ign-SRC were designed to identify translations for which almost all the attention mass is concentrated on the EOS token, the patterns identified with Attn-ign-SRC are more diverse. They span from attention mass coming to various uninformative tokens (e.g., punctuation and other tokens as in Figure 5b) to examples shown in Figure 5c where attention is mostly diagonal (typically, these correspond to undergenerations; we follow this discussion in the next section).

D Analysing Less Severe Translation Errors

We notice that some of the detection methods are specialised on specific pathologies. For example, Attn-ign-SRC is by far the best for detecting undegenerations. This is expected: an undergeneration does not cover part of the source sentence, thus a significant proportion of source tokens receives little attention mass (see example in Figure 5c). For named entity errors, the best heuristic is TokHal-Model. This mirrors the discussion in Section 7.2: while severe errors (i.e., hallucinations) fall out of distribution for this model, mistranslations of short phrases are more in line with the model's training.

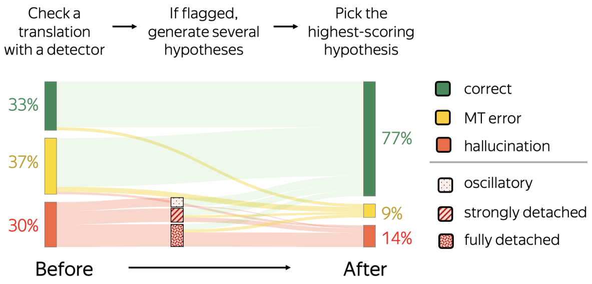

Figure 6: Our pipeline scheme along with results when we use Seq-Logprob as both the detector and the scoring measure.

On a different note, MC-DSim performs much better for hallucinations than for less severe pathologies (Figure 3b). This again points to hallucinations being more unstable than other errors.

E Overwriting Hallucinations with Seq-Logprob as the scoring measure

The results are shown in Figure 6. In order to use Seq-Logprob as the scoring measure, we score all generated hypothesis with the original model. Overall, although the results follow the same trend as those using COMET-QE as the scoring measure, they are slightly worse: the hallucinatory rate is higher and the percentage of correct translations is smaller.

F Examples of overwritten translations

Table 5 shows examples of each hallucination type that have been overwritten with correct translations with the approach described in Section 9.

G Practical Recommendations for Detection

As we have mentioned in Section 3.4, Binary-label heuristics output a value in $\{0; 1\}$, and continuous-score heuristics output a value s in $\mathbb{R}$. These values s can be used to build a binary decision rule: for a given source x, translation $\hat{y}$ and reference y, a translation is flagged by the detector if and only if $s(x, \hat{y}, y) \leq \gamma$. Naturally, s may not need be a function of x, $\hat{y}$ and y (e.g. COMET-QE is only a function of x and $\hat{y}$).

Choosing the thresholds. In our work, we chose the thresholds γ for each detector by assessing the value s correspondent to approximately the 0.4-th percentile to be consistent with the data selection process (see Section 5). We computed these thresholds using the entire filtered held-out data. However, in practice, we obtained very similar results when we obtained these thresholds using a collection of only $10\,000$ examples from that dataset.

We recommend computing these thresholds on in-domain clean data. This will guarantee that the cut-off values were obtained in a scenario where the model performs best. Finally, the definition of the k-th percentile is expected to have an impact on the precision-recall trade-off. Thus, for preventive settings, we recommend sticking to more conservative values of k.

Choosing the detectors. The choice of detector rests upon the application for which it is intended. For high-precision settings, binary-label heuristics such as TNG and variants thereof (Raunak et al., 2022) may be more recommended. For preventive settings, we suggest using Seq-Logprob as the backbone of the hallucination detector. Naturally, we generally obtain higher recall by joining the sets of translations flagged with multiple methods. For example, Figure 3 reveals that joining the set of translations flagged with Seq-Logprob with the set of translations flagged with COMET-QE is very reasonable: COMET-QE performs better for oscillatory hallucinations, while Seq-Logprob is better for the other hallucination types.

Be careful when relying on references. Using reference information is helpful for detecting hallucinations (see Section 7.1), and while it may not be used to detect hallucinatins on-the-fly, it may still prove useful for analysis works. We have found that high-quality parallel data is critical for adequate application of these methods: very low scores might not only be attributed to poor translations, but also to reference mismatches. Indeed, preliminary experiments highlighted this worrying trend, which motivated us to clean the held-out set (Section 4). Thus, if using reference information to detect hallucinations, make sure to thoroughly clean your parallel data.

Investigating UD Treebanks via Dataset Difficulty Measures

Artur Kulmizev Joakim Nivre
Department of Linguistics and Philology
Uppsala University
`{artur.kulmizev,joakim.nivre}@lingfil.uu.se`

Abstract

Treebanks annotated with Universal Dependencies (UD) are currently available for over 100 languages and are widely utilized by the community. However, their inherent quality characteristics are hard to measure and are only partially reflected in parser evaluations via accuracy metrics like LAS. In this study, we analyze a large subset of the UD treebanks using three recently proposed accuracy-free dataset analysis methods: dataset cartography, $\mathcal{V}$-information, and minimum description length. Each method provides insights about UD treebanks that would remain undetected if only LAS was considered. Specifically, we identify a number of treebanks that, despite yielding high LAS, contain very little information that is usable by a parser to surpass what can be achieved by simple heuristics. Furthermore, we make note of several treebanks that score consistently low across numerous metrics, indicating a high degree of noise or annotation inconsistency present therein.

1 Introduction

Datasets have long played a crucial role in dictating the pace of progress in NLP. Their function, for most tasks, is largely two-fold: 1) to collect data points (and their corresponding gold-standard labels) on which statistical models can be trained, and 2) to serve as benchmarks though which various models can be evaluated and compared. In recent years, much research has been devoted towards developing new datasets, tasks, and benchmarks for NLP — so as to articulate the distinguishing aspects of a bevy of new neural models. Syntactic parsing has remained an active area of research in this regard, and Universal Dependencies (UD) (Nivre et al., 2016, 2020; de Marneffe et al., 2021) has emerged as a crucial initiative within NLP, offering a set of cross-lingually consistent annotation principles that have since been adapted to over 100 languages.

Notably, the CoNLL shared tasks of 2017 and 2018 (Zeman et al., 2017, 2018) featured UD at the forefront, inviting researchers to submit systems that could not only parse, but process the entirety of UD across its numerous annotation layers. Beyond parsing, UD has also been utilized for a variety of other ends, including cross-lingual transfer (Ammar et al., 2016; Pires et al., 2019; Wu and Dredze, 2020; Lauscher et al., 2020), domain adaptation (Li et al., 2019, 2020; Stymne, 2020), and linguistic typology (Futrell et al., 2015; Hahn et al., 2020; Levshina, 2019).

Though UD and other initiatives have aided in driving recent advances in NLP, overall progress has typically been measured via aggregate accuracy metrics, which provide little more than a bird's eye view into the data. In the era of deep learning, where popular models are notoriously opaque, it has thus proven vital to study the contents of datasets and identify aspects that may misrepresent model performance. In this vein, numerous studies have shown that the crowd-funded nature of some popular NLP datasets makes them prone to annotation artefacts that are readily exploitable by neural models as heuristics (Kaushik and Lipton, 2018; Gururangan et al., 2018; Poliak et al., 2018; McCoy et al., 2019). With such insights in mind, researchers have shifted their focus towards the *datasets* instead of the models, proposing general methods for exploring the former so as to better understand the performance of the latter. Such approaches have drawn from, e.g., information theory (Perez et al., 2021; Ethayarajh et al., 2022), item response theory (Rodriguez et al., 2021; Vania et al., 2021), and model training dynamics (Swayamdipta et al., 2020). This work, however, has predominately focused on classification tasks and has proven difficult to extend to other classes of problems, such as the structured prediction tasks of UD.

In this paper, we perform an analysis of (a large

subset of) UD v2.9 through the perspective of a popular parsing architecture — namely that of Dozat and Manning (2016). As opposed to much previous work, which prioritizes metrics like LAS in order to build accurate parsers, we aim instead to better understand the underlying data, as well as how our parser interfaces with it. To do so, we extend recently proposed dataset analysis methods based on model training dynamics (Swayamdipta et al., 2020), $\mathcal{V}$-information (Xu et al., 2020; Ethayarajh et al., 2022), and minimum description length (Blier and Ollivier, 2018; Voita and Titov, 2020; Perez et al., 2021) to the dependency parsing scenario. In working with each method, we formalize the following set of research questions:

1. Which treebanks appear *hard* (or *easy*) to parse, given a model's confidence throughout training, and variability therein?
2. Which treebanks contain the most (or least) information that is actually usable by a parser, with respect to a naive baseline?
3. Which treebanks are the most (or least) sample efficient, i.e. most easily fit by a parser, irrespective of training set size?

2 Universal Dependencies

Universal Dependencies (UD) (Nivre et al., 2016, 2020; de Marneffe et al., 2021) is an initiative focused on the development of dependency treebanks. UD is founded upon a *lexicalist* perspective on syntax, which posits that (syntactic) relations are formed directly between words. Although this approach does not take morphological segmentation explicitly into account, UD nonetheless provides such information in the form of lemmas, part-of-speech tags, and morphological features for each word. These design decisions have inspired the widespread adoption of UD as an annotation scheme, which has grown from 10 treebanks across 10 languages in v1.0 to 243 treebanks across 138 languages in v2.11.

2.1 Dependency Parsing

Though UD contains multiple layers, our focus in this paper is on its syntactic layer — the dependency tree annotation upon which parsers are trained and evaluated. As a task, dependency parsing amounts to mapping a sentence $\mathbf{x} = \{x_1, x_2, ..., x_n\}$ to its respective syntactic structure $\mathbf{y}$. This is typically a tree (a rooted, directed, acyclic graph) over $\mathbf{x}$, where each word $x_i \in \mathbf{x}$ (called a dependent) forms an edge with another word $x_j \in \mathbf{x}$ that it syntactically modifies (its head). Though such edges (x_i, x_j) are sometimes considered in isolation, most often they are accompanied by a label describing the relation between x_i and x_j. UD comprises of a base set of 37 such labels, in addition to treebank-specific subtypes that can be introduced by annotators.

Unlike classification or sequence labeling tasks, which entail predicting y given a fixed label set K, parsing is considered a structured prediction task, where the output space is constrained by the sentence length $n+1$ (with a special `root` symbol included). In data-driven parsing, a parser is typically a function f whose parameters θ are fit on some gold-annotated training set X_{train}, e.g. a UD treebank. A trained parser's predictions $\hat{\mathbf{y}} = f_\theta(\mathbf{x})$ can then be evaluated on a held out test set X_{test} by means of various metrics. Commonly, these are *labeled attachment score* (LAS), which is the percentage of all words in X_{test} that are assigned the correct head *and* label by f, and the *unlabeled attachment scores* (UAS), which is the percentage of words that are assigned the correct head, irrespective of label. We will focus primarily on LAS in this study, as it assesses both head attachment and labeling.

2.2 UD Parsing

In conjunction with UD's popularity and transition to v2.0, the CoNLL 2017 and 2018 Shared Tasks on Multilingual Parsing from Raw Text to Universal Dependencies (Zeman et al., 2017, 2018) sought to consolidate trends in parsing research with respect to a wealth of new data, algorithms, and models. Overall, the findings of both shared tasks offered many insights for the future of dependency parsing. Primarily, they helped establish Dozat and Manning (2016)'s parser as the most popular parsing architecture of the neural NLP era. Though many new architectures have been proposed since, the biaffine attention decoder continues to feature prominently in parsing research, where the focus has shifted to the matter of feature representation and fine-tuning, rather than decoding (see, e.g. Kondratyuk and Straka (2019); Üstün et al. (2020)).

3 Beyond Accuracy

In NLP, system performance is typically measured via accuracy, which has the advantage of being intuitive and straightforward to calculate. Moreover, it is often useful in model selection, as well in setting the state-of-the-art for a given dataset or task. Beyond these qualities, however, accuracy leaves much to be desired when investigating models vis-a-vis datasets. For one, it is often reported with respect to a single checkpoint from a model's training regime, which typically consists of numerous epochs and parameter updates. In honing in on one particular checkpoint (usually the best with respect to validation loss or accuracy), one cannot readily assess whether the model was easily fit on the data, or if training was stopped prematurely. Furthermore, in choosing the $\arg\max$ over the output distribution, one inevitably loses information about it: Was the model confident in making its prediction? Or was the distribution highly entropic? Also relevant is the train/test distinction: in evaluating on the latter, one can gauge a model's ability to generalize, but generally cannot assess the goodness-of-fit on the former, nor its sample efficiency. Likewise, accuracy cannot, in principle, adequately assess the *quality* of the training data: can the model learn from all instances therein? Or does the data contain a substantial amount of noise due to, e.g. annotation inconsistencies?

With regard to dependency parsing, accuracy-based metrics like LAS carry a number of additional drawbacks. For example, if working with an arc-factored graph-based dependency parser, one must score all possible n incoming edges for a dependent $x_i \in \mathbf{x}$. If $n = 1$, then x must necessarily be attached to the dummy node and assigned the `root` label. For a treebank consisting of many such sentences (e.g. Russian Taiga), this will lead to artificially inflated accuracies for that particular relation. Another concern is the potential proliferation of functional relations that may arise in some treebanks (e.g. Japanese GSD), where parsers often yield disproportionately high accuracies (Nivre and Fang, 2017). To transcend the limitations of accuracy-based measures in dependency parsing, we consider three recently proposed dataset analysis methods as a means of exploring UD treebanks: dataset cartography (Swayamdipta et al., 2020), $\mathcal{V}$-information (Xu et al., 2020), and minimum description length (Blier and Ollivier, 2018).

3.1 Dataset Cartography

Dataset cartography (Swayamdipta et al., 2020) is a method for analyzing training datasets via the lens of model training dynamics. Put briefly, DC assumes the use of a model f trained to minimize loss on a dataset D of size N. Crucially, for a given instance $D_i = (\mathbf{x}, y^*)$, DC posits that f defines a probability distribution over labels y, such that the probability of the true label $p(y^*|\mathbf{x})$ can be tracked throughout training. Given a gradient descent-based training regime of E epochs, DC defines the notion of *confidence* (CONF) as follows:

$$\textsc{Conf}_i = \frac{1}{E}\sum_{e=1}^{E} p_{\theta_e}(y^*|\mathbf{x})$$

where θ_e are f's parameters following the epoch e update. Intuitively, high CONF values (e.g. ≈ 0.95) for a given training instance D_i indicate that f generally assigns high probability to y^* throughout training — i.e. that D_i is "easy-to-learn". Conversely, low CONF values (e.g. ≈ 0.05) indicate that f generally "fails" to learn from those particular instances.

As a complement to CONF, Swayamdipta et al. (2020) also introduce the *variability* (VAR) metric, which summarizes the tendency of f to waver in its assignment of $p(y^*|\mathbf{x})$ throughout training. VAR is defined as follows:

$$\textsc{Var}_i = \sqrt{\frac{\sum_{e=1}^{E}(p_{\theta_e}(y^*|\mathbf{x}) - \textsc{Conf}_i)^2}{E}}$$

In essence, while CONF is the mean of $p(y^*|\mathbf{x})$ across E, VAR is its standard deviation. Using both of these metrics, Swayamdipta et al. (2020) are able to construct *data maps*, which visualize D through the perspective of f. With VAR and CONF plotted on the x and y axes, respectively, data maps help in identifying select regions of D that are easy or difficult for f to learn — or are otherwise ambiguous.

3.2 $\mathcal{V}$-Information

An alternative approach for quantifying dataset "difficulty" is proposed by Ethayarajh et al. (2022), who leverage the concept of $\mathcal{V}$-Information. Introduced by Xu et al. (2020), $\mathcal{V}$-information (denoted as $I_{\mathcal{V}}(X \rightarrow Y)$) is a framework for estimating the amount of information between random variables X and Y (input and output, respectively) that is *usable* by a model in family $\mathcal{V}$ — e.g., a sentiment classifier or syntactic parser. Here, *usability* is measured with respect to an encrypted form of the input $\varnothing$, from which $\mathcal{V}$ must nonetheless attempt to predict Y — essentially a label-only baseline. Predicting Y from X and $\varnothing$ amounts to measuring $\mathcal{V}$-entropy:

$$H_{\mathcal{V}}(Y) = \inf_{f \in \mathcal{V}} [-\log f'[\varnothing](Y)]$$

and *conditional* $\mathcal{V}$-entropy:

$$H_{\mathcal{V}}(Y|X) = \inf_{f \in \mathcal{V}} [-\log f[X](Y)]$$

where $f \in \mathcal{V}$ is a model that maximizes the log-likelihood of the labels Y with the original input X and f' is the same model trained on the encrypted input $\varnothing$. Given these two quantities, $I_{\mathcal{V}}(X \to Y)$ can be computed as follows:

$$I_{\mathcal{V}}(X \to Y) = H_{\mathcal{V}}(Y) - H_{\mathcal{V}}(Y|X)$$

In essence, $\mathcal{V}$-information is the amount of information between inputs and labels that can be estimated by $\mathcal{V}$ beyond the label distribution itself. Given that $\mathcal{V}$-information is computed with respect to $H_{\mathcal{V}}(Y)$, it is important to note that $I_{\mathcal{V}}(X \to Y) \geq 0$. Also, if X is independent of Y, then $I_{\mathcal{V}}(X \to Y) = 0$.

In addition to functioning as a summary statistic alternative to accuracy, $\mathcal{V}$-information can also be generalized to the instance-case. To do so, Ethayarajh et al. (2022) propose measuring point-wise difficulty, which they deem PVI and calculate as follows:

$$\text{PVI}(x \to y) = -\log_2 p_{f'}(y^*|\varnothing) + \log_2 p_f(y^*|\mathbf{x})$$

where $f_\theta, f'_\theta \in \mathcal{V}$ are models trained on normal and encrypted data, respectively. Recall that, as before, y^* refers to the gold label and not the one with the highest score. Unlike $\mathcal{V}$-information, PVI can return negative values at the instance level (similarly to pointwise mutual information (Shannon, 1948)), which indicates that the model would fare better choosing a class at random.

3.3 Minimum Description Length

Minimum description length (MDL) (Rissanen, 1978) is an information-theoretic concept that concerns the transmission of data through a specified channel — i.e., a probabilistic model. Ideally, a model that is fit well on some data will learn to transmit — or *compress* — it using as few bits as possible (Blier and Ollivier, 2018). Naively, in order to evaluate how well a model, e.g., a neural network, might learn to compress its training data, one might refer to the model's cross-entropy loss after training for a full cycle of E epochs, which amounts to the Shannon-Humman code (Shannon, 1948). However, a model endowed with enough parameters may learn to *fit* the data without necessarily *compressing* it — see, e.g., Zhang et al. (2021), who show that training loss can still be minimized on data that contains no inherent structure (shuffled labels). MDL is thus designed to express not only how well a model might learn to compress some data, but also how efficiently the model itself might be transmitted.

Blier and Ollivier (2018) outline various methods for compressing labels, with or without a model. Among these, they describe online (or prequential) coding (Rissanen, 1984; Dawid, 1984), which transmits the labels and model without explicitly compressing the latters's parameters. Online coding requires D to be partitioned into S blocks where $1 = t_0 < t_1 \cdots < t_S = N$. The model of choice, f, is initialized with parameters θ, learning algorithm $\mathcal{A}$, etc. The first block, t_0, is first evaluated with a uniform prior[1] and then used to train f_s (we omit the parameters θ for brevity). This model is then evaluated on t_{s+1} and reset to its initial state, where it is consequently trained on t_{s+1}, and so on. Formally, the online codelength can be expressed as:

$$L^{\text{online}}(y_{1:n}|x_{1:n}) = \sum_{s=1}^{S-1} \sum_{n=t_s}^{t_{s+1}} -\log_2 p_{f_s}(y_n|x_n)$$

In contrast to the training loss above, which represents the data codelength if the model parameters are known, L^{online} (henceforth MDL) is an implicit way of measuring the same without knowing the model parameters. Effectively, MDL estimates f's ability to generalize with respect to D: models that learn efficiently from limited instances will yield shorter codelengths.

4 Experimental Setup

In this section, we describe our data sampling procedure, the parsing model we employ, and our extension of the aforementioned analysis methods to the context of (graph-based) dependency parsing. More details about how each metric is calculated can be found in Appendix A.

Data In order to compare the analysis obtained with each of the dataset analysis methods, we require a representative sample of UD treebanks.

---

[1] More details on this can be found in Appendix A.

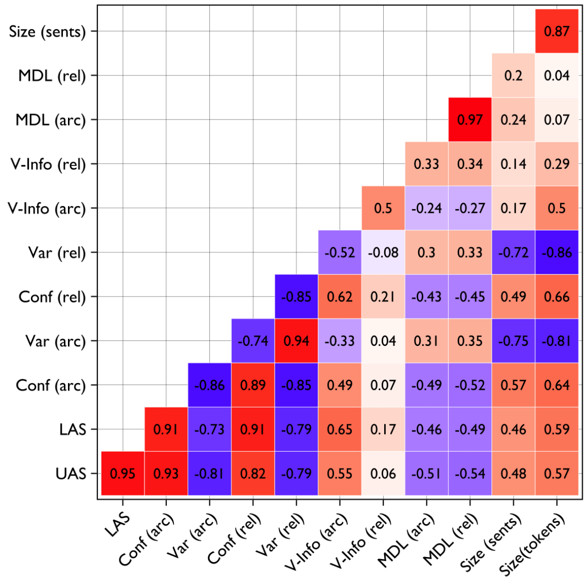

Figure 1: Spearman's ρ across all metrics of interest, including training set size in tokens and sentences.

Since each method requires the training of a parser on some subset of data (as well as a validation set for estimating V-INFO), we consider every UD treebank that contains train, validation, and test splits. To ensure that a) there is sufficient data for training our parsers and b) training is reasonably quick and the models do not overfit, we limit our selection to treebanks whose training sets contain at least 1,000 and at most 20,000 sentences. This gives us 88 treebanks across 58 languages,[2] with Faroese FarPahC having the smallest training partition (1,021 sentences, 23,094 tokens) and Polish PDB the biggest (17,773 sentences, 281,736 tokens). All resuls are reported with respect to UD v2.9, which was the most recent release at the time of experimentation.

Parsing Model We employ a neural parser based on Dozat and Manning (2016)'s biaffine decoder, as implemented in the `SuPar`[3] Python library. For input encoding, we make use of randomly initialized word embeddings ($d \in \mathbb{R}^{100}$) and LSTM-based character embeddings ($d \in \mathbb{R}^{100}$), as well as a stacked three-layer LSTM feature extractor ($d \in \mathbb{R}^{400}$). We choose to forego the use of POS embeddings (contrary to Dozat et al. (2017)), so as to maintain a direct correspondence between the input string and its tree, which is vital for measuring V-INFO. Furthermore, we do not initialize the input embeddings with pretrained representations in order to avoid confounds central to language coverage and overlap (Wu and Dredze, 2020). Each model is trained for 30 epochs with a batch size of 32 and optimized by Adam (Kingma and Ba, 2014) with a starting learning rate of 2e$-$3.

Analysis Methods In order to be able to measure CONF, VAR, and V-INFO, we need to be able to extract the probabilities that parsers assign to gold arcs and labels. Recall that Dozat and Manning (2016)'s parser is effectively a multi-task model, which jointly maximizes the log-likelihood of a given word's correct head, as well as the label for the relation. The arc and label logits are calculated via separate biaffine transformations, which yield a $S_{\text{arcs}} \in \mathbb{R}^{N \times N+1}$ matrix for the former and a $S_{\text{labels}} \in \mathbb{R}^{N \times N+1 \times R}$ tensor for the latter, where N is the sentence length and R is the size of the relation set. To obtain a normalized probability distribution, we apply a softmax to the last dimension of each S_{arcs} and S_{labels}, and index into the correct cell for the gold head and label probabilities.

For MDL, we train parsers on increasingly larger partitions of the training set, starting with a minimum of five sentences and doubling in size up to a maximum of 360 — a total of 995 sentences. We do so in reference to the smallest treebank in our sample (Faroese FarPahC (1,021 sentences)), so as to control for training set size, which varies drastically across treebanks. In accordance with the parser's multi-task design, we compute two separate MDL measures with respect to the separate arc and relation losses, averaged over five trials.

5 Results and Analysis

In this section, we analyze the results of our four metrics: CONF, VAR, V-INFO, MDL. We focus our analysis on arcs (probabilities and loss) and refer to Appendix B for the full set of results. For each metric, we begin with a brief discussion of its pairwise correlation to all other metrics, which is displayed for reference in Figure 1. We continue by framing our analyses with respect to the Top 3 best and worst performing treebanks for each metric.

5.1 Dataset Cartography

Figure 2 (left) depicts the mean CONF and VAR scores calculated across arcs. We observe a strong negative correlation between CONF and VAR. This relationship also appears to be influenced by 1) validation LAS and 2) training set size. This is not surprising, as training set size is a common

---

[2] We filter out four treebanks due to issues with tokenization, etc.

[3] `https://github.com/yzhangcs/parser`

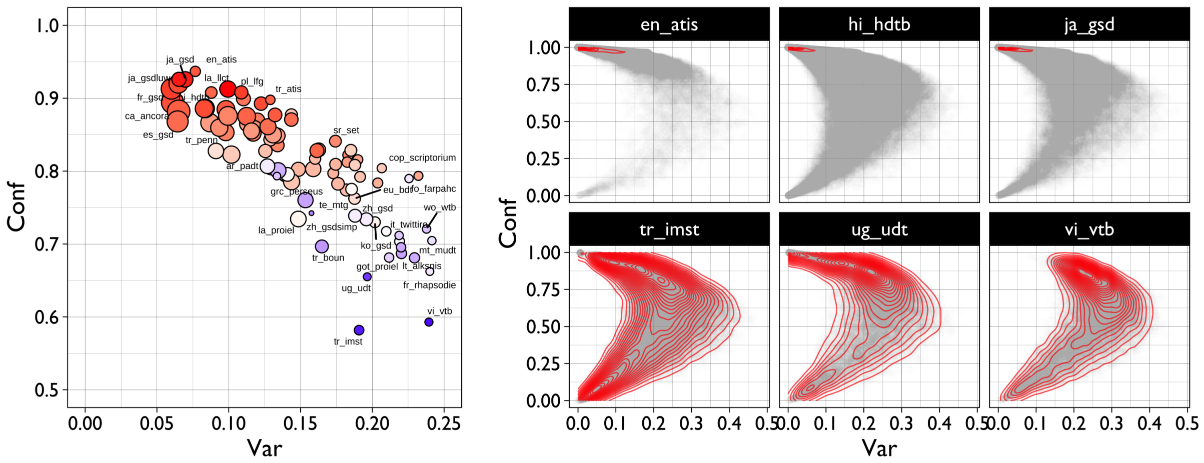

Figure 2: Left: mean CONF and VAR scores for Arcs across all languages; color represents Validation LAS and point size represents the size of the train set in words. Right: Data maps for Arcs for best and worst CONF scoring languages, with 2d densities super-imposed.

predictor of indicates that parser performance can, to a large extent, be reliably estimated simply by observing its confidence throughout training.

In zooming in on individual points, we observe several treebanks in the upper left-hand corner of the arc plot, which corresponds to high average CONF and low VAR. Indeed, many of these points belong to the largest treebanks in the sample, e.g., Hindi HDTB (0.92 CONF, 0.06 VAR, 281,057 tokens), French GSD (0.92, 0.06, 354,505), and Catalan AnCora (0.89, 0.06, 429,141). However, English Atis — a relatively small treebank with 48,655 tokens— tops out with the highest CONF overall at 0.94 (VAR: 0.08). This is unsurprising given the nature of the Atis dataset (Price, 1990), which collects transcriptions of requests sent to automated flight information systems, e.g. *list the nonstop flights early tuesday morning from dallas to atlanta*. The imperative nature of such requests, in combination with a small vocabulary, likely limits the range of structures a parser might encounter during training, thus making the treebank *easy* to fit. Interestingly, the second and third-highest CONF treebanks are both Japanese: GSDLUW (0.93, 0.07, 130,298) and GSD (0.93, 0.07, 168,333). This is likewise expected, as GSD has been observed by, e.g., Nivre and Fang (2017) to possess a large amount of functional relations, which can be parsed with near 100% accuracy.

On the other end of the spectrum, we observe that Turkish IMST (0.58, 0.19, 37,784), Vietnamese VTB (0.59, 0.24, 20,285), and Uyghur UDT (0.67, 0.20, 19,262) yield the three lowest CONF scores overall, as well as generally high VAR. Interestingly, though Turkish IMST does not appear within the top-25 highest VAR treebanks, it nonetheless yields the lowest CONF, indicating the the treebank might be particularly "hard" to parse for reasons other than treebank size (Çöltekin et al., 2017). Conversely, the fact that VTB and UDT are low CONF and high VAR implies that a lack of training data might play a role.

The data maps for the highest and lowest CONF scoring treebanks (depicted in Figure 2 (right)) highlight important disparities between these two groups. Most strikingly, we observe that the overwhelming majority of arcs in the English, Hindi, and Japanese treebanks are concentrated in the upper left high-CONF/low-VAR region, which is characterized as easy-to-learn by Swayamdipta et al. (2020). Indeed, this corresponds to 65.26, 68.02, and 68.32% of all tokens in the English, Hindi, and Japanese treebanks where CONF ≥ 0.95 and VAR ≤ 0.1. Conversely, only 3.04, 7.61, and 0.001% of all arcs in the Turkish, Uyghur, and Vietnamese treebanks are allocated to this region, indicating that this group contains few arcs that might be considered "trivially easy". Likewise, if we define the hard-to-learn region as consisting of points where CONF ≤ 0.25 and VAR ≤ 0.1, we find that 9.5, 5.45, and 5.06% of the latter group's treebanks can be characterized as such, respectively, compared to 0% for any treebank in the former group.

5.2 $\mathcal{V}$-Information

Figure 3 depicts the PVI density for the Top 3 and Bottom 3 treebanks in terms of V-INFO for arcs.

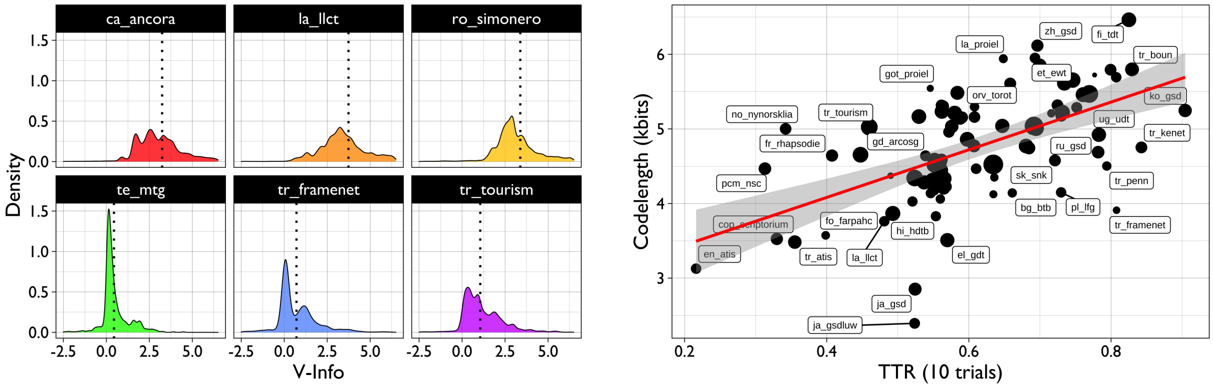

Figure 3: Left: Arc-level PVI density for Top-3 and Bottom-3 V-INFO treebanks, across arcs (labels omitted for space). Right: Block-wise codelength (in bits) for Top-3 and Bottom-3 MDL treebanks, across arcs.

We observe weaker correlations between V-INFO and LAS when measured across all treebanks than we did for CONF or VAR, indicating that V-INFO measures different aspects of parser performance than either of these metrics. Immediately, we can see that the lowest-ranked treebanks — Telugu MTG (0.44 average V-INFO), Turkish FrameNet (0.71), and Turkish Tourism (1.05) — have densities that are skewed towards 0. In particular, Telugu shows a sharp peak around this point, suggesting that it contains many arcs and relations that can be inferred by sentence sizes and label distributions. In contrast, the distributions representing the highest V-INFO treebanks (Latin LLCT (3.74), Romanian SiMoNERo (3.38), and Catalan AnCora (3.24)) are much flatter and more evenly distributed along the space of positive V-INFO values.

Turkish Tourism is composed entirely of hotel and restaurant reviews. Due to the nature of this genre, the treebank's vocabulary is very limited and many of its sentences are exceptionally short — 4.77 tokens on average in the dev set. This limits the space of possible trees that a parser may encounter, potentially biasing it towards certain structures. For example, the adverb "çok" (very) appears in the first position of 128 sentences as modifier of the 2nd word (typically an adjective, e.g., "güzel" (good)). A similar effect can be observed for Telugu MTG, which contains 5.05 words per sentence in its development set, and for Turkish FrameNet, which systematically places the root of the sentence at the penultimate position (91.7% of the time).

Given the observations above, V-INFO can be imagined as a means of simultaneously penalizing regularity and stochasticity in data. We can illustrate this further by returning to the CONF results. Recall that, for arcs, the highest scoring treebank was English Atis. Interestingly, when measuring its arc V-INFO, we find that its rank drops to 77 out of 88 (1.97). Recall that the Atis dataset contains a single genre of data with simple sentences often beginning with *what is*, *show me*, etc. In this case, simply guessing $(1, 0)$ and $(2, 1)$ for the first two arcs yields accuracies of 0.52 and 0.41, respectively, which the label-only baseline employed for calculating V-INFO would likewise capture. By contrast, the lowest scoring CONF treebank — Turkish IMST — retains a low rank of 83 (1.27). Recalling that 9.5% of IMST's tokens are considered hard-to-learn by the cartography metrics, this treebank is likely to contain certain annotation inconsistencies that cannot be systematically captured beyond guessing.[4] Such cases, too, are captured by V-INFO. With this in mind, we might surmise that *high* V-INFO values might represent treebanks with a varied distribution of structures that are likewise consistently annotated, thus requiring strong generalization of the parser.

In addition to arcs, we would also like to note the interesting behavior of V-INFO for relations, which is generally uncorrelated with any other metric (other than arcs). This is due to the fact that the parser must know the identity of both words when deciding upon the relation that binds them. For the vast majority of relations, this cannot be determined from position alone, even if head placement is largely systematic (as in the aforementioned Atis and Tourism treebanks). As a result, aggregate

---

[4] Indeed, this is corroborated by Türk et al. (2019), who discuss the errors resulting from the automatic conversion of IMST to the UD format, among which are 269 cases where a subject bearing a genitive marker was misidentified as an object in the accusative case.

V-INFO for relations (3.89 ± 3.66) is noticeably higher than for arcs (2.40 ± 1.98), albeit with more spread. It is important to note, however, that there are two primary exceptions to this in the form of the `root` and `punct` relations, which can be deterministically assigned to the first (dummy node) and last (end of sentence punctuations) positions.

5.3 MDL

In terms of MDL, we observe only moderate correlations across all other measures, with the strongest between CONF for arcs. Here, we find that MDL for relations (which takes the model's loss into account) is actually more correlated with arc CONF than CONF for relations. Expectably, neither measure is correlated with treebank size, which was controlled across treebanks.

For rankings, we observe that the Top 3 treebanks (for arcs) are largely the same ones as returned by arc CONF: Japanese GSD and GSDLUW, (2.85, 2.39) English Atis (3.12), and Turkish Atis (3.48). This is unsurprising given the reasons outlined in previous sections. Therefore, it seems feasible that MDL — which measures a parser's fit on successively larger, unseen partitions of a dataset — would reflect such qualities as well. MDL's alternative interpretation as a measure of a dataset's sample efficiency is also applicable here: a parser trained on a small number of trees will likely generalize well in these very narrow distributions.

Interestingly, we encounter a handful of new treebanks at the higher end of MDL scores: Finnish TDT (6.46), Chinese GSD (traditional and simplified) (6.11, 6.14), and Latin PROIEL (5.94). Intuitively, a high MDL in the case of parsing might suggest that the model is exposed to a larger diversity of token types during training, which could hinder it in learning various types of dependencies. Following this logic, one might hypothesize that treebanks representing languages with complex morphological systems might yield comparatively higher MDL, due to the higher number of word forms that appear therein. In line with this, we observe that the highest MDL treebanks tend to be morphologically rich, e.g., Finnish, Latin, Turkish, Estonian, Polish, Russian.

In an attempt to quantify the correspondence between a treebank's attested morphological complexity and its MDL, we compute a series of proxy metrics, as featured in Çöltekin and Rama (2018). These include type-token ratio (TTR) (averaged across 10 random samples of 1,000 sentences), number of feature types (in these samples), and feature entropy (calculated across feature types). Indeed, Figure 3 shows a strong correspondence between TTR and MDL, as the two are highly correlated ($\rho = 0.58, p < 0.001$). Significant correlations for feature entropy ($\rho = 0.35, p < 0.001$) and number of feature types ($\rho = 0.28, p < 0.001$) corroborate our hypotheses further. Interestingly, while both Chinese GSD treebanks simultaneously yield the highest MDL and comparatively high morphological scores, the language itself is typically described as having an analytical (impoverished) morphology. We surmise, however, that this fact — combined with Chinese's logographic writing system — contributes to high MDL scores in the same way as morphological richness: a lack of high-frequency function words and a wide range of lexical items lead to large vocabulary sizes. MDL for these treebanks is thus expectably high.

6 Conclusion

In this paper, we investigated 88 UD treebanks through the lens of dataset difficulty measures. We found that CONF and VAR are capable of painting a nuanced picture of how *easy* or *hard* treebanks might be to parse. We also observed that a model's confidence throughout training is an excellent indicator of how well it might generalize to held-out data. Regarding V-INFO, we observed that the measure tends to simultaneously penalize high degrees of predictability and stochasticity, and that treebanks otherwise characterized as *easy* may have low V-INFO due to lack of structural diversity. Finally, treebanks with high MDL seem to be characterized by low sample efficiency, which in turn is related to morphological complexity and vocabulary usage. Given the broad range of insights expressed via these metrics, we hope that our results — however preliminary — will inspire future researchers to pursue a greater understanding of UD as trove of data, so as to push further boundaries in the realms of parsing, typology, etc.

In terms of future work, we make note of several potentially interesting directions. Indeed, one of the main drawbacks of our experimental design is that it only accounts for the perspective of a single parsing architecture — albeit (arguably) the most popular one of the neural era. Dependency parsing, however, has a long research tradition where many different parsing models have been proposed throughout the years — each with their respective advantages and drawbacks (see, e.g. McDonald and Nivre (2007, 2011)). Though we chose to work with an arc-factored graph-based parser due to the need for extracting arc-level probabilities, future studies may consider consider ways of leveraging transition-based parsers (Nivre, 2003) or models that directly maximize full tree probabilities (Koo et al., 2007; Ma and Hovy, 2017). If working with a wide range of parsing models, one could employ item response theory (Rodriguez et al., 2021; Vania et al., 2021), which is a framework that consolidates many predictions per instance in order to identify regions of datasets that may be perceived as difficult, easy, etc. Certainly, this would provide a more broad perspective on UD than what we have offered here.

A different direction that could be explored is data *selection*, which is indeed what Swayamdipta et al. (2020) proposed as the main uses for dataset cartography. Although the CONF and VAR metrics provide valuable insights about UD treebanks in our case, they are nonetheless measured at the *token*-level. This is distinct from their original application, in that each token is crucial for the composition a sentence and cannot be readily removed. Although we experimented with measuring sentence-level CONF and VAR, some preliminary results indicated that a naive application of Koo et al. (2007)'s method is ultimately confounded by sentence length. As such, it would be interesting to experiment with models that directly optimize for tree probability, such as Ma and Hovy (2017). If successful, this would allow us to identify select subsets of treebanks for the purpose of training more accurate parsers with less data, or for choosing the least noisy sentences for typological studies, etc.

Limitations

As already mentioned, the main limitation to our work is that we focus on a single parsing architecture. Indeed, it would be preferable to extend the experiments described here to other parsers in order to evaluate the generalizability of our results. Ideally, we might choose to work with a comparable transition-based parsing algorithm, which have been shown to exhibit different error profiles than their graph-based counterparts (McDonald and Nivre, 2007; Kulmizev et al., 2019). However, the fact that transition-based parsers calculate probabilities over *transitions* instead of *arcs* would render such parsers incompatible with the cartography and V-INFO measures, which reveal interesting insights about our surveyed treebanks. Beyond this, we note that the scope of our current work is quite large, as we compare 10 metrics across 88 treebanks. By this token, we can admittedly only offer a bird's eye view of the UD treebank collection, even if our surveyed metrics offer more nuance than attachment scores.

Ethical Considerations

The research presented in this paper is compatible with the ACL ethics policy. The datasets used come from the Universal Dependencies repository and have appropriate licenses and documentation. The experiments are done with small-scale models that do not have a significant impact in terms of energy consumption.

Acknowledgements

We would like to thank Anders Søgaard for providing useful feedback on an early version of this work, as well as Sasha Berdicevskis for lending insight about computational measures of morphological complexity. We acknowledge the computational resources provided by CSC in Helsinki through NeIC-NLPL (`www.nlpl.eu`).

A Analysis Method Details

Since every surveyed dataset analysis method was proposed with classification tasks in mind, we must make numerous modifications in order to make them applicable to structured prediction problems like dependency parsing.

Dataset Cartography Given that we can index directly into S_{arcs} and S_{labels} throughout the training regime, the process of calculating CONF and VAR for each token is relatively straightforward. As such, we keep track of the probabilities assigned to the gold arcs and labels in the train and development sets after each epoch.

$\mathcal{V}$-information In order to calculate V-INFO, we must be able to estimate $\mathcal{V}$-entropy and conditional $\mathcal{V}$-entropy. Though the latter can be computed by simply fitting a model $f' \in \mathcal{V}$ on a designated training set, the former requires the "encryption" of the input X. To do so, we follow Ethayarajh et al. (2022) in setting every input token string $x \in X$ to _. $\mathcal{V}$-entropy can then be estimated by fitting f' on the same, albeit encrypted, training set, and $I_{\mathcal{V}}(X \to Y)$ subsequently calculated on a held-out (also encrypted) validation set. Though we track V-INFO across all epochs, we report it for $e = 30$, across arcs and labels. Also, it is worth noting that, although we attempted to compute $I_{\mathcal{V}}(X \to Y)$ at the sentence level via unlabeled tree probabilities extracted via Koo et al. (2007)'s method, the model f' trained on encrypted data produced extremely low probabilities, which led to underflow when computing the logarithm. As such, we chose to forego further exploration of this problem for this study.

Minimum Description Length Since our treebanks vary greatly in size, we must set our partitions such that they can span the length of the smallest training set (1,021 sentences). This way, our estimation of MDL remains comparable across treebanks. To do so, we employ partitions $S = \{5, 10, 20, 40, 80, 160, 320, 360\}$ at the sentence level, where the entire training set is shuffled prior to partitioning. For t_0, which does not contain any training data, we follow Voita and Titov (2020) in calculating the codelength over t_0 using a uniform prior. This is computed as follows:

$$L^{\text{unif}}(y_{1:s_1}|x_{1:s_1}) = \sum_{i=1}^{n} \log_2 K_{t_{1_i}} \qquad (1)$$

where K is the number of words (arcs or labels) in a given sentence i in the first partition t_1 (composed of $s = 5$ sentences). Note that this is the extension of uniform coding proposed by Blier and Ollivier (2018) to structured prediction. In a typical classification task with K labels, the same codelength is computed as $L^{\text{unif}}(y_{1:s_1}|x_{1:s_1}) = s_1 \log_2 K$.

For all remaining $t \in S$, we revert a model to its initial state, train it on t_i and compute its codelength over t_{i+1}. Since MDL is particularly sensitive to the ordering of instances within S, we repeat this process for 5 trials, fully re-initializing the model after each one.

B Full Results

The results for all metrics on all treebanks can be found in Table 1.

Abstract

Semantic parsing is a technique aimed at constructing a structured representation of the meaning of a natural-language question. Recent advances in language models trained on code have shown superior performance in generating these representations compared to language models trained solely on natural language text. The existing fine-tuned neural semantic parsers are vulnerable to adversarial attacks on natural-language inputs. While it has been established that the robustness of smaller semantic parsers can be enhanced through adversarial training, this approach is not feasible for large language models in real-world scenarios, as it requires both substantial computational resources and expensive human annotation on in-domain semantic parsing data. This paper presents the first empirical study on the adversarial robustness of a prompt-based semantic parser based on CODEX, a state-of-the-art (SOTA) language model trained on code. Our results demonstrate that the large language model of code is vulnerable to carefully crafted adversarial examples. To overcome this challenge, we propose methods for enhancing robustness without requiring substantial amounts of labelled data or intensive computational resources.

1 Introduction

Semantic parsing is a technique that transforms natural-language utterances (NLs) into machine-readable logical forms (LFs) and has been widely applied in various research fields, such as code generation, question-answering systems, and dialogue systems (Kamath and Das, 2018). Most current state-of-the-art semantic parsers are deep-learning models trained in a supervised manner using in-domain data. However, this approach requires a large amount of in-domain semantic parsing data, which can be costly to obtain (Bapna et al., 2017).

To address this issue, prompt-based semantic parsers based on large pre-trained language models, such as Codex (Chen et al., 2021) and GPT-J (Wang and Komatsuzaki, 2021), have become a new choice for semantic parsing applications. Prompt-based semantic parsers learn to solve a new task by in-context learning, instructing the parsers to generate correct LFs by constructing the prompt with a few demonstration examples. Such a method can significantly lower the cost of annotations by including only a few exemplars in the prompt and achieve comparable results to fully-supervised semantic parsers (Shin and Van Durme, 2022).

Recent studies (Huang et al., 2021; Pi et al., 2022) show that fully-supervised semantic parsers are vulnerable to adversarial attacks, which perturb input sentences into their semantic equivalent adversaries to mislead models to produce attacker-desired outputs. Hence, to mitigate such attacks, various adversarial training methods (Tramer and Boneh, 2019; Shafahi et al., 2019; Ganin et al., 2016; Shafahi et al., 2020) have been proposed to improve the adversarial robustness of the semantic parsers. In light of this, two main questions naturally arise: (1) *Do prompt-based semantic parsers based on large pre-trained language models also suffer from adversarial attacks?* (2) *If so, how can we improve the robustness of the large prompt-based semantic parsers?*

To address the former question, we evaluate the prompt-based semantic parsers on several evaluation sets built by different perturbation approaches mentioned in the AdvGLUE (Wang et al., 2021) dataset. Adopting the adversarial evaluation metrics proposed by Huang et al. (2021), it is found that the prompt-based semantic parsers are vulnerable to various types of adversarial attacks.

According to the experimental results from the first step, we perform a three-fold experiment to answer the latter questions. The first aspect of the study aims to determine if the inclusion of

additional examples within the prompt during in-context learning improves the robustness of prompt-based parsers. This hypothesis is based on prior research that has demonstrated that the increase in the size of the training data results in an enhancement of robustness in fully-supervised models (Pang et al., 2019). The second part of the study aims to determine if the integration of few-shot adversarial examples within prompts can improve the robustness of Codex. This was based on the observation that conventional adversarial training methods often include adversarial examples within the training set (Miyato et al., 2016; Tramer and Boneh, 2019). Finally, the third part of the study aims to evaluate if sampling methods other than random sampling can select more effective examples that improve the robustness of prompt-based parsers.

In this work, we perform a series of experiments to probe CODEX, a large pre-trained model trained on code, on two semantic parsing benchmarks, `GeoQuery` (Zelle and Mooney, 1996) and `Scholar` (Iyer et al., 2017). Our key findings from the above experiments are as follows:

- Prompt-based semantic parsers are vulnerable to adversarial examples, particularly the ones crafted by sentence-level perturbations.
- In-context learning with more demonstration examples in the prompt can improve the in-domain robustness of prompt-based parsers.
- Augmenting the prompt with adversarial examples has limited effect in improving the robustness of prompt-based parsers.
- The few-shot example sampling strategy with higher language complexity can result in stronger robustness for the prompt-based parsers.

2 Related Work

Prompt-based Learning. Prompt-based learning is an alternative approach to supervised learning that aims to reduce the reliance on large human-annotated datasets (Liu et al., 2021). Unlike traditional supervised models, which estimate the probability of an output given an input text, prompt-based learning models estimate the probability of the text directly. This is achieved by applying prompt functions to modify the input text into various prompt templates with unfilled slots. By filling these slots, various Natural Language Processing (NLP) tasks can be completed, such as common-sense reasoning (Kojima et al., 2022), self-rationalization (Marasović et al., 2021), and text style transfer (Suzgun et al., 2022). The development of prompt-based methods has enabled zero-shot and few-shot learning in a variety of artificial intelligence domains (Ramesh et al., 2021; Yang et al., 2022; Sanghi et al., 2022). Recent research has also evaluated the capabilities of few-shot prompt-based learning for semantic parsing (Shin and Van Durme, 2022; Roy et al., 2022a; Drozdov et al., 2022). Our contribution extends the current research by investigating the effect of prompts comprising only a limited number of examples on the robustness of prompt-based semantic parsers.

Adversarial Robustness. Neural networks have achieved impressive performance across various domains. However, as demonstrated by Szegedy et al. (2014), neural models are vulnerable to adversarial examples. Adversarial attacks in NLP normally take on various forms, including character-level manipulations (Hosseini et al., 2017; Ebrahimi et al., 2018; Belinkov and Bisk, 2018; Gao et al., 2018; Eger et al., 2019; Boucher et al., 2022), sentence-level rewriting (Iyyer et al., 2018; Ribeiro et al., 2018; Zhao et al., 2018), and adversarial word substitutions (Alzantot et al., 2018; Liang et al., 2018; Zhang et al., 2019).

There has been an increasing interest in defending against adversarial attacks in large language models via adversarial training (Yi et al., 2021; Ross et al., 2022; Bartolo et al., 2021; Guo et al., 2021). Adversarial training involves incorporating adversarial examples in the training set, thus making the model robust to such attacks. However, adversarial training can sometimes negatively impact the generalization ability of the neural models (Raghunathan et al., 2019; Min et al., 2021).

3 Robustness Evaluation for Prompt-based Semantic Parsing

This section gives an overview of our evaluation framework, including the methods of constructing the evaluation corpora and the evaluation metrics to evaluate the robustness of the prompt-based semantic parser.

Linguistic Phenomenon	Samples (~~Strikethrough~~ = Original Text, **red** = Adversarial Perturbation)
Typo (Word-level)	**NL**: what can you ~~tell~~**te11** me about ~~the~~**th e** population of missouri
Substitution (Word-level)	**NL**: what ~~can~~**will** you tell me about ~~the~~**a** population of missouri
Paraphrase (Sent.-level)	**NL**: ~~what can you tell me about the population of missouri~~ **What information can you provide on Missouri's population?**

Table 1: **Examples from Robustness Evaluation Set**. We show 3 examples from `GeoQuery`. These examples are generated with three different perturbations, and they all can successfully change the predictions of CODEX.

3.1 Construction of the Evaluation Corpus

A robust prompt-based semantic parser should be able to parse both the utterances and their adversarial counterparts into correct LFs. As proposed by Huang et al. (2021), an adversary of an utterance for a semantic parser is defined as i) an utterance with the same semantic meanings as the original one given the human judgment and ii) an utterance on which the semantic parser cannot produce correct LF. Therefore, to evaluate the robustness of prompt-based semantic parsers, we craft the robustness evaluation sets by perturbing the original utterances in existing benchmark datasets with multiple adversarial perturbation methods. Such perturbations should not alter the semantics of the original utterances. Each example in a robustness evaluation set is a perturbed utterance paired with its ground-truth LF. Next, we introduce the details of each perturbation method and how we guarantee the perturbations do not change the semantics. Table 1 illustrates some meaning-preserved utterances after perturbation in the robustness evaluation set of `GeoQuery` based on different perturbation methods. More examples can be found in Appendix B.

3.1.1 Adversarial Perturbations

Following the principles as in Wang et al. (2021) to design adversarial attacks, we perform five word-level perturbations and two sentence-level perturbations to generate seven robustness evaluation sets for the standard evaluation set in each benchmark.

Word-level Perturbations.

- **Typo-based (TB)** uses TextBugger (Li et al., 2018) to replace two words in each utterance with the typos.
- **Random Deletion (RD)** randomly deletes two words in the utterance.
- **Random Swap (RS)** swaps the positions of two random words in each utterance.
- **Context-aware Substitution (CS)** leverages RoBERTa (Liu et al., 2019) to substitute two random words with their synonyms.
- **Context-aware Insertion (CI)** inserts two most probable words selected by RoBERTa at two random positions in each utterance.

Sentence-level Perturbations.

- **Rewriting-based (RB)** chooses Quillbot[1] (Fitria, 2021), a state-of-the-art (SOTA) commercial paraphrasing model, to rewrite the complete utterances. Quillbot has been demonstrated as an effective tool to paraphrase utterances in semantic parsing data (Shiri et al., 2022).
- **Distraction-based (DB)** appends interrogation statements to the end of each NL, inspired by StressTest (Naik et al., 2018). Specifically, we design the following interrogation statements: "who is who; what is what; when is when; which is which; where is where", in which the selected interrogative words are more likely to appear in the utterance.

3.1.2 Data Filtering

In order to ensure that the perturbed examples preserve the meaning of the original NL, we design a two-stage evaluation process:

Step1: We first generate 20 adversarial examples against the original NL for each perturbation method and choose the top 10 candidates ranked based on text similarity scores between the original and the perturbed ones, which are calculated by Sentence-BERT (Reimers and Gurevych, 2019).

---

[1] `https://www.quillbot.com/paraphrasing`

Step2: We engage human experts to select the best one among the 10 adversarial candidates produced in **Step1**.

3.2 Evaluation Metrics

Since the output LFs of the prompt-based language models may not follow the same naming convention (Shin et al., 2021; Shin and Van Durme, 2022) as the ground truth, previous string-based evaluation metrics, including BLEU (Papineni et al., 2002) and Exact Match (Poon and Domingos, 2009), are not suitable for prompt-based semantic parsers. Therefore, we follow Rajkumar et al. (2022) to report the *execution accuracy*, which is based solely on the execution correctness of the LFs on the test sets, for the purpose of robustness evaluation.

Following Huang et al. (2021), we report the experiment results with three variants of execution accuracy, namely *standard accuracy*, *perturbation accuracy* and *robust accuracy*:

- **Standard Accuracy** is measured on the standard (original) test sets.
- **Perturbation Accuracy** tests the performance of the model on perturbed test sets.
- **Robust Accuracy** is defined as $n/|R_{eval}|$. R_{eval} denotes a subset of the perturbed test sets, and n is the number of the utterances in R_{eval} that are parsed correctly. More specifically, R_{eval} consists of the examples whose counterparts before perturbation are parsed correctly. Intuitively, Robust Accuracy estimates the quantity of cases that a parser can successfully parse before perturbation but cannot do so after perturbation, and hence shows the robustness of the parsers against adversarial perturbation.

4 Improving Robustness of Prompt-based Semantic Parsers

Instead of predicting the LF conditioned on the input utterance, large language models such as CODEX could learn to solve a specific task by *in-context learning*. During in-context learning, the parser predicts the LF conditioned on a prompt which consists of a small list of utterance-LF pairs to demonstrate the semantic parsing task and, optionally, a table schema. To defend against adversarial attacks, one seminal approach is adversarial training. One of the most typical adversarial training methods augments the training data with adversarial examples, from which the machine learning model could learn robust features (Allen-Zhu and Li, 2022) by gradient descent. However, directly adapting conventional adversarial training is not suitable for in-context learning. First, the number of demonstration examples is limited due to the restriction on the maximum number of tokens for the pre-trained language model. As a result, we cannot include an arbitrary number of adversarial examples in the prompt, which might not include enough robust features. Second, in-context learning does not update the parameters of the language model. The model would not be optimized towards learning the robust features in the adversarial examples through gradient descent.

Given the difference, it is unclear whether in-context learning could improve the robustness of the parser as the conventional supervised training. In this paper, we conduct the first investigation on in-context learning for model robustness. More specifically, we examine the impact of variants of in-context learning and sampling methods on parser robustness.

4.1 Standard In-context Few-shot Learning

In our setting, given an input utterance $\boldsymbol{x}$, the pre-trained language model $P(\cdot;\theta)$ predicts the LF $\boldsymbol{y}'$ conditioned on the prompt, which consists of a set of demonstration examples $\mathcal{M} = \{(\boldsymbol{x}_i, \boldsymbol{y}_i)\}_{i=1}^{N}$, and a table schema $\mathcal{T}$:

$$\boldsymbol{y}' = \arg\max_{\boldsymbol{y}\in\mathcal{Y}} P(\boldsymbol{y}|\boldsymbol{x}, \mathcal{M}, \mathcal{T}; \theta) \qquad (1)$$

For the *few-shot* setting, the number of demonstration examples N is limited by a budget size.

4.2 Adversarial In-context Few-shot Learning

In adversarial in-context learning, we include the perturbed adversarial examples, $\mathcal{M}_{adv}$, in the demonstration examples:

$$\boldsymbol{y}' = \arg\max_{\boldsymbol{y}\in\mathcal{Y}} P(\boldsymbol{y}|\boldsymbol{x}, \mathcal{M} \cup \mathcal{M}_{adv}, \mathcal{T}; \theta) \qquad (2)$$

4.3 In-context Few-shot Selection

Current in-context learning assumes there is an example pool from where they can select prompting examples. However, most of the works only randomly pick examples from the pools. We argue that the way to select the examples might deeply impact the robustness of the prompt-based semantic parser. Therefore, we examine various strategies to select in-context few-shot examples.

Random Sampling (Random). We randomly sample N utterances from the example pool.

Confidence-based Sampling (Confidence) (Duong et al., 2018). We score each utterance with the confidence of the parser on the predicted LF given the utterance and the table schema. Then we select the ones with the lowest parser confidence scores[2].

Diversity-based Sampling. Following Li et al. (2021), we partition the utterances in the utterance pool into N clusters with the K-means (Wu, 2012) clustering algorithm and select the example closest to the cluster centers. We measure the edit distance (Cluster-ED) (Wagner and Fischer, 1974), and Euclidean distances using utterance features of TF-IDF (Cluster-TF-IDF) (Anand and Jeffrey David, 2011), or Contextual Word Embedding (Cluster-CWE) encoded by Sentence-BERT (Reimers and Gurevych, 2019), between each pair of utterances for K-means.

Perplexity-based Sampling (Sen and Yilmaz, 2020). We score each utterance with the perplexity of GPT-2 on this utterance. Then we select the utterances with the highest (PPL. Asc) and lowest (PPL. Desc) perplexity scores, respectively.

5 Experiments

5.1 Setup

Evaluation Datasets. We evaluate the robustness of the prompt-based semantic parsers via the adversarial robustness sets built on top of the test sets of `GeoQuery` (Finegan-Dollak et al., 2018) and `Scholar` (Finegan-Dollak et al., 2018) with the proposed perturbation methods in Section 3. As in Finegan-Dollak et al. (2018), we choose the *query* splits of both `GeoQuery` and `Scholar`, where there is no LF template overlap among train, test, and dev sets.

Prompt-based Semantic Parser. We choose CODEX (Chen et al., 2021) as the representative prompt-based semantic parser for our evaluation. In recent studies, CODEX has performed comparably via in-context few-shot semantic parsing to the SOTA-supervised trained neural semantic parsers (Shin and Van Durme, 2022; Roy et al., 2022b; Drozdov et al., 2022) in terms of execution accuracy.

To examine the vulnerability of large prompt-based semantic parsers against adversarial examples, we choose the `code-davinci-002` version of CODEX as it is the most powerful variant among all CODEX models, with 175B parameters. In our experiments, we sample a maximum of 200 tokens from CODEX with the temperature set to 0, with the stop token to halt generation.

Prompts. In this work, we adopt the prompt design of `Create Table + Select X` as presented in Rajkumar et al. (2022), which has been shown to be effective for semantic parsing using *static prompting*[3].

The prompt for semantic parsing on CODEX consists of `CREATE TABLE` commands, including specifications for each table's columns, foreign key declarations, and the results of executing a `SELECT * FROM T LIMIT X` query on the tables via the column headers. As described in Section 4.3, we select NL-LF pairs as in-context few-shot examples from the *train* sets.

To guide the prompt-based semantic parser, we also include the textual instruction of "`Using valid SQLite, answer the following questions for the tables provided above.`" as proposed by Rajkumar et al. (2022).

5.2 Research Questions and Discussions

Our experimental results answer the following four research questions (RQs) related to the robustness of CODEX.

RQ1: How vulnerable is the prompt-based semantic parser to adversarial examples?

Settings. To answer RQ1, we evaluate the standard accuracy and perturbation accuracy of CODEX on `GeoQuery` and `Scholar` test sets through *zero-shot* learning.

Results. The zero-shot parsing performances of CODEX are shown in Table 2. Our first observa-

---

[2] The confidence scoring parser is a zero-shot model, meaning that there are no examples present in the prompt. It operates solely based on the input utterance, instructions, and schema provided within the prompt. Please see Section 5.1 for more information on the prompt structure.

[3] In contrast to the approach of Shin et al. (2021) which involves dynamically selecting few-shot examples from an example pool, we refer to static prompting as being performed with a fixed set of examples.

Category	Pert. Strategy	`GeoQuery`			`Scholar`		
		Pert. Acc.	Std. Acc.	Δ	Pert. Acc.	Std. Acc.	Δ
Word-level	TB	53.85	57.14	-3.29	11.35	12.21	-0.86
	RD	50.55		-6.59	10.52		-1.69
	RS	37.36		-19.78	8.31		-3.90
	CS	42.31		-14.83	8.40		-3.81
	CI	38.46		-18.68	8.31		-3.90
Sentence-level	RB	**31.87**		-25.27	**5.22**		-6.99
	DB	35.71		-21.43	7.88		-4.33

Table 2: Results of perturbation accuracy (Pert. Acc.) and standard accuracy (Std. Acc.) of zero-shot performance on `GeoQuery` and `Scholar`. The zero-shot prompt only contain the table information and initial semantic parsing instruction. Perturbation accuracy is calculated based on each perturbation method.

tion is that Codex is more vulnerable to sentence-level perturbations than to word-level perturbations, as indicated by the more significant performance gaps between standard and perturbed accuracies on the sentence-level perturbed test sets. Wang et al. (2021) observed that neural language models are vulnerable to human-crafted adversarial examples where there are complex linguistic phenomenons (e.g., coreference resolution, numerical reasoning, negation). We observe that the rewriting model trained on human paraphrase pairs also introduces such complex linguistic phenomenons.

With respect to the word-level perturbations, Codex is most robust to typo-based perturbations, which is surprising as Wang et al. (2021) shows typo-based perturbation is the most effective attack method for large language models like BERT (Devlin et al., 2019) in the evaluation of natural language understanding tasks. However, utterances with typos drop only 3% of the accuracy of Codex. Random Deletion is also less effective than the other word-level methods, consistent with the observations by Huang et al. (2021) on the fully-supervised semantic parsers. This phenomenon can be attributed to the fact that Random Deletion primarily makes minor modifications to the standard NL utterances, as this method often involves removing non-functional words such as articles, for example, “the” and “a.”

Although Codex is pre-trained on a considerably large dataset, it does not show robustness on the in-domain tasks. We conjecture that the reason is that zero-shot Codex has not yet learned any in-domain knowledge on `GeoQuery` or `Scholar`. So in RQ2, we would address whether in-domain examples would improve the robustness of Codex.

Takeaways. Zero-shot Codex is vulnerable to adversarial examples, especially sentence-level perturbation of utterances, rather than to word-level perturbations.

Table 4: Few-shot performances on `Scholar`. We conduct {3, 5, 10}-shot learning experiments.

RQ2: Does standard in-context few-shot learning improve the robustness?

Settings. We respectively select up to 50 and 10 examples from `GeoQuery` and `Scholar` train sets[4], with the random sampling strategy, to construct prompts for parsers. Then, for each few-shot

---

[4] Due to the larger size of table schema in `Scholar`, we could only include up to 10 examples in the prompt.

learning experiment, we measure standard accuracy, perturbation accuracy and robust accuracy on our various perturbed test sets.

Results. Tables 3 and 4 show the performance of standard in-context few-shot learning on the robustness evaluation sets perturbed by different methods. We observe that more standard examples in the prompt can evidently improve the robust accuracy of CODEX, which demonstrates the effectiveness of standard in-context few-shot learning in improving the robustness of semantic parsing. Although it performs slightly worse on the test sets perturbed by typo-based methods than the one perturbed by the random deletion in `GeoQuery`, we argue that this is due to the performance variance, which does not necessarily hurt the model robustness.

The performance gap between perturbation accuracy with standard accuracy is enlarged when the number of in-context shots increases. However, the robust accuracy grows slowly. This indicates that improving the generalization ability of the parser does not necessarily mean the improvement of the robustness. The trade-off between standard and robust accuracies is a long-standing problem in adversarial training. Raghunathan et al. (2019) shows that increasing the training sample size could eliminate such a trade-off. Our experiments demonstrate that in-context learning follows similar patterns as supervised adversarial training. It can be observed that both objectives can be improved with a limited number of examples when compared to the zero-shot parser. However, the extent of improvement varies.

Takeaways. With more standard in-context examples, few-shot CODEX can be guided to achieve better robustness and standard execution performance.

RQ3: Does adversarial in-context learning improve robustness?

Settings. In this work, we present the experimental results of CODEX on both `GeoQuery` and `Scholar` datasets, using 10 and 5 in-context examples, respectively. In order to assess the robustness of CODEX through adversarial in-context learning, we first augment the standard few-shot examples by incorporating examples whose utterances have been perturbed using various perturbation methods. Subsequently, for each set of augmented examples, we calculate the average robust accuracy of CODEX based on the average of the parser robust accuracies on all robustness evaluation sets.

Adv. L. Strategy	`GeoQuery`		`Scholar`	
	Avg. Robust Acc.	Std. Acc.	Avg. Robust Acc.	Std. Acc.
No Adv.	77.28	74.37	53.10	23.08
No Adv. (× 2)	78.74	79.67	55.97	40.32
TB	77.32	73.62	52.75	34.99
RD	77.40	73.64	53.11	33.65
RS	78.30	74.73	54.88	33.46
CS	78.05	74.47	53.12	34.86
CI	78.14	74.81	54.66	33.65
RB	78.47	75.51	56.58	35.85
DB	78.31	75.08	55.08	35.71

Table 5: The results of the average robust accuracy obtained through Adversarial In-context Learning (Adv. L. Strategy) with different types of perturbed few-shot examples. Additionally, we include results of applying the method with only standard examples (No Adv.), as well as with a doubled number of standard examples (No Adv. (× 2)).

Results. The experimental results of the various perturbation strategies applied to the in-context few-shot examples are presented in Table 5. While the approach of supervised adversarial training has been widely regarded as an effective means of enhancing the robustness of machine learning models, the results indicate that on both `GeoQuery` and `Scholar`, the robust accuracies are only marginally improved through the application of adversarial in-context learning. Previous studies (Raghunathan et al., 2019; Huang et al., 2021) have pointed out that supervised adversarial training can sometimes result in a decrease in standard accuracy, even as it improves robust accuracy. However, the results of adversarial in-context learning diverge from this trend, with significant improvement in standard accuracy, from 23% to more than 33%, observed on `Scholar`, while robust accuracy only experiences marginal improvement. These observations indicate that adversarial in-context learning represents a distinct approach from supervised adversarial training in terms of enhancing the robustness of the model. Furthermore, the results suggest that simply incorporating adversarial examples into the prompt has a limited impact on the robustness of parsers, in contrast to supervised adversarial training.

Of all the perturbation strategies analyzed, the results indicate that CODEX achieves the best performance in terms of both standard and robust accuracy through the application of RB adversarial in-context learning, but experiences the worst performance through TB adversarial in-context learning. The hypothesis is that RB produces utterances

Dataset	Metric	Confidence	Cluster-CWE	Cluster-ED	Cluster-TF-IDF	PPL. Asc	PPL. Desc	Random
GeoQuery	Avg. Robust Acc.	78.77	78.02	82.40	**85.10**	70.36	50.82	73.22

Table 6: The performance of standard few-shot in-context learning using various sampling methods on the `GeoQuery` and `Scholar` datasets. The average robust accuracy, average perturbation accuracy, and standard accuracy are computed for each sampling method to assess their efficiency in this learning scenario.

Dataset	LC. Metric	Confidence	Cluster-CWE	Cluster-ED	Cluster-TF-IDF	PPL. Asc	PPL. Desc	Random
GeoQuery	TTR ↑	7.68	7.24	8.47	**10.26**	5.94	3.22	6.44
	Yule's I ↑	68.55	64.37	69.59	**71.49**	62.94	43.41	58.14
	MTLD ↑	12.44	12.19	13.37	**15.58**	11.32	8.16	10.41
Scholar	TTR ↑	28.18	29.91	31.40	**33.11**	21.15	14.17	25.67
	Yule's I ↑	198.15	207.11	223.76	**262.36**	177.37	102.17	193.31
	MTLD ↑	15.68	15.63	16.34	**19.49**	11.94	13.12	14.36

Table 7: Results of the language complexity of standard NLs sampled by different sampling strategies, measured by three lexical diversity (LC.) metrics. For the ease of readability and comparison, we multiply both TTR scores and Yule's I scores by 100.

with more complex linguistic features, resulting in enhanced standard and robust accuracy during in-context learning. To test this hypothesis, the number of standard examples is doubled (No Adv.×2) to match the size of the examples augmented with the adversarial examples. The results show that the robust and standard accuracies of CODEX are higher than those obtained through adversarial in-context learning, likely due to the greater diversity of linguistic variations in the doubled standard examples.

Takeaways. The robustness of few-shot CODEX can be marginally improved by adversarial in-context learning without significant negative impacts on standard performances.

RQ4: What is the impact of sampling techniques on the robustness of parsers that utilize standard in-context few-shot learning?

Settings. In order to compare the influence of different sampling methods on the robustness of the model, we vary standard in-context examples on `GeoQuery` and `Scholar` with all 7 strategies aforementioned in Section 4.3. We choose the 50-shot setting for `GeoQuery` and 10-shot setting for `Scholar`.

Results and Takeaways. We present standard accuracies in Table 6 when varying the sampling methods for the few-shot example selection. We first observe that different sampling strategies impact the robust and standard performance of the CODEX. Overall, the Cluster methods, which diversify the features of the selected utterances, perform better than the other sampling methods. On the other hand, PPL. Desc sampling method performs consistently poorly than the other sampling methods. In brief, we conclude that CODEX is sensitive to the few-shot example sampling strategies.

RQ4-Ablation: Why does CODEX react differently to various sampling strategies?

Settings. The findings of RQ 1 and RQ 3 indicate that linguistic complexity has an impact on the performance of CODEX. As a result, the results of RQ 4 may also be influenced by linguistic complexity. To further explore this correlation, three lexical diversity metrics, Type-Token Ratio (TTR) (Templin, 1957), Yule's I (Yule, 1944), and Measure of Textual Lexical Diversity (MTLD) (McCarthy, 2005), are adopted to measure the lexical diversity of the selected NLs from `GeoQuery` and `Scholar`. The TTR is defined as the ratio of the number of unique tokens, also known as types, to the total number of tokens. The TTR is used as an indicator of lexical diversity, with a higher TTR indicating higher lexical diversity. Yule's Characteristic Constant (Yule's K) is a measure of text consistency that considers vocabulary repetition. Yule's K and its inverse, Yule's I, are considered more robust to variations in text length than the Type-Token Ratio (TTR). MTLD is computed as the average number of words in a text required to maintain a specified TTR value.

Results and Takeaways. Table 7 presents the lexical diversity of each set of NLs sampled by different approaches. The diversity scores obtained from the three metrics align with the performance of CODEX as presented in Table 6. For instance, the three metrics indicate that the examples selected using the Cluster-TF-IDF method achieve higher lexical diversity compared to those selected through the other methods. Additionally, the Cluster-TF-IDF method also produces the highest results in terms of robust and standard accuracy for CODEX. Thus, it can be inferred that an increase in the lexical diversity of the few-shot examples leads to an improvement in the robust and standard accuracy of CODEX.

6 Conclusion

This study examines the robustness of semantic parsers in the context of prompt-based few-shot learning. To achieve this objective, robustness evaluation sets were curated to evaluate the robustness of the prompt-based semantic parser, CODEX. The research aims to identify methods to improve the robustness of CODEX. The results of our comprehensive experiments demonstrate that even the prompt-based semantic parser based on a large pre-trained language model is susceptible to adversarial attacks. Our findings also indicate that various forms of in-context learning can improve the robustness of the prompt-based semantic parser. It is believed that this research will serve as a catalyst for future studies on the robustness of prompt-based semantic parsing based on large language models.

Limitations

In this study, we examine the robustness of the prompt-based semantic parser, CODEX, by focusing on the impact of prompt design on its execution performance. However, there is a need for future research to investigate more alternative adversarial training strategies for prompt-based semantic parsers in order to advance this field. In addition, our focus is limited to text-to-SQL tasks, and we encourage further investigation into the robustness of semantic parsers across different datasets and LFs. Despite these limitations, we emphasize the importance of exploring more effective prompt design in order to enhance the robustness of prompt-based semantic parsers, including CODEX, which shows non-negotiable vulnerability.

A Experiments

Datasets. The `GeoQuery` dataset contains 877 pairs of NL-LF pairs about U.S. geographical information. On the other hand, `Scholar` contains pairs of NL-SQL regarding information about academic publications. Finegan-Dollak et al. (2018) proposed a dataset split for evaluating the compositional generalization capability of semantic parsers on several datasets, including `GeoQuery` and `Scholar`. The proposed split, referred to as the query-split, presents a more challenging scenario for semantic parsing models. This paper utilizes the query-split, where the two test sets in our experiments include 182 NL-LF pairs from `GeoQuery` and 315 NL-LF pairs from `Scholar`, respectively, during the evaluation of the prompt-based semantic parser.

Hyperparameters. We sample at most 200 tokens from CODEX with temperature 0, with the following strings used as stop tokens to halt generation: “--”, “\n\n”, “;”, “#”.

Model Versioning. The version of the `code-davinci-002` model referred to in this paper is as of the midpoint of the year 2022.

B Adversarial Examples

Table 8 lists the examples generated by all perturbation strategies.

Linguistic Phenomenon	Samples (~~Strikethrough~~ = Original Text, **red** = Adversarial Perturbation)
Typo (Word-level)	**NL**: what can you ~~tell~~**te11** me about ~~the~~**th e** population of missouri
Random Deletion (Word-level)	**NL**: ~~what~~ can you tell me ~~about~~ the population of missouri
Random Swap (Word-level)	**NL**: what can you tell me ~~about~~**missouri** the population of ~~missouri~~**about**
Context-aware Substitution (Word-level)	**NL**: what ~~can~~**will** you tell me about ~~the~~**a** population of missouri
Context-aware Insertion (Word-level)	**NL**: what **what** can you tell me about the **exact** population of missouri
Rewriting (Sent.-level)	**NL**: ~~what can you tell me about the population of missouri~~ **What information can you provide on Missouri’s population?**
Distraction (Sent.-level)	**NL**: what can you tell me about the population of missouri **who is who; what is what; when is when; which is which; where is where**

Table 8: **Examples from Robustness Evaluation Set**. The adversarial utterances in this Table are generated by applying various perturbation strategies to a single utterance “*what can you tell me about the population of missouri*” sampled from the `GeoQuery` dataset. All of the generated utterances can successfully alter Codex’s output.

Leveraging Task Dependency and Contrastive Learning for Case Outcome Classification on European Court of Human Rights Cases

Santosh T.Y.S.S, Marcel Perez San Blas, Phillip Kemper, Matthias Grabmair

Technical University of Munich, Germany
`{santosh.tokala, marcel.perez, phillip.kemper, matthias.grabmair}@tum.de`

Abstract

We report on an experiment in case outcome classification on European Court of Human Rights cases where our model first learns to identify the convention articles allegedly violated by the state from case facts descriptions, and subsequently uses that information to classify whether the court finds a violation of those articles. We assess the dependency between these two tasks at the feature and outcome level. Furthermore, we leverage a hierarchical contrastive loss to pull together article-specific representations of cases at the higher level, leading to distinctive article clusters. The cases in each article cluster are further pulled closer based on their outcome, leading to sub-clusters of cases with similar outcomes. Our experiment results demonstrate that, given a static pre-trained encoder, our models produce a small but consistent improvement in classification performance over single-task and joint models without contrastive loss.

1 Introduction

The NLP task of classifying case outcome information from a textual statement of case facts is generally referred to as Legal Judgement Prediction (LJP)(e.g., Aletras et al. 2016; Chalkidis et al. 2019). It has been studied using corpora from different jurisdictions, such as the European Court of Human Rights (ECtHR) (Chalkidis et al., 2019, 2021, 2022b; Aletras et al., 2016; Medvedeva et al., 2020; Santosh et al., 2022, 2023), Chinese Criminal Courts (Luo et al., 2017; Zhong et al., 2018; Yue et al., 2021; Zhong et al., 2020; Yang et al., 2019), US Supreme Court (Katz et al., 2017; Kaufman et al., 2019), Indian Supreme Court (Malik et al., 2021; Shaikh et al., 2020), the French court of Cassation (Şulea et al., 2017), Brazilian courts (Bertalan and Ruiz, 2020), the Federal Supreme Court of Switzerland (Niklaus et al., 2021), the Turkish Constitutional court (Sert et al., 2021; Mumcuoğlu et al., 2021), UK courts (Strickson and De La Iglesia, 2020), German courts (Waltl et al., 2017), the Philippine Supreme court (Virtucio et al., 2018), and the Thailand Supreme Court (Kowsrihawat et al., 2018).

In this work, we experiment with classifying case outcomes in the ECtHR A and B benchmark tasks introduced by LexGLUE (Chalkidis et al., 2022b). Task B is to identify the set of articles of the European Convention of Human Rights (ECHR) that the claimant alleges to have been violated, while Task A's goal is to classify which of the convention's articles has been deemed violated by the court. The input for both tasks is the case's fact description that has been extracted from the published judgement document. It should be noted that, despite these tasks being typically referred to as instances of 'legal judgement prediction', the fact statements are typically not finalized until the decision outcome is known, making the task effectively one of retrospective classification rather than prediction (Medvedeva et al., 2021). While this does lead to distracting and confounding phenomena (see our prior work in Santosh et al. 2022), the dataset remains a useful resource for the development of NLP models that analyze these fact statements for text patterns that correspond to specific convention articles as drafted by the court. Consequently, we speak of *case outcome classification (COC)*.

Positive instances for Task A are cases in which an article was deemed violated by the court. Negative instances, however, usually encompass not only cases in which that particular article was alleged and considered not violated, but also the cases in which the particular article was not alleged in the first place. Given that the conditional probability of a positive task A label (violation) given its task B label (allegation) can be very high in the LexGLUE dataset, we posit that models can fall into this pitfall of identifying dominant articles

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1103–1111
May 2-6, 2023

with high conditional violation probability, missing information specific to violation classification. Thus, we experiment with multi-task architectures to decouple these reasoning steps involved in Task A . This is similar to work in Chinese criminal cases judgement prediction carried out in Zhong et al. 2018; Yang et al. 2019; Xu et al. 2020; Yue et al. 2021 that coordinated multiple outcome variables (law articles, criminal charges, and penalty terms).

In the ECtHR context, most of the previous works (Chalkidis et al., 2019, 2021, 2022b; Clavié and Alphonsus, 2021; Santosh et al., 2022, 2023) employed independent models for allegation identification and violation classification. Concurrent work by Valvoda et al. 2023 has recently explored multi-task joint models that learn Task A and Task B simultaneously. Their *Claim-Outcome model* decomposes them into two independent classifiers with separate encoders for each allegation and violation classification given allegation information. Our work differs in three ways: (i) We learn the joint representation for both tasks through a shared encoder following our intuition that the shared representation is beneficial as both tasks require similar features at the lower level; (ii) We model dependency from allegation to violation classification at both the allegation outcome and feature levels. Conditioning violation classification on the allegation outcome leads to higher performance, but we find that passing along feature level information yields additional improvement. This way, the violation branch will focus on identifying specific information required for determining violation than falling prey to only allegation level features. (iii) We also model correlations among different articles that tend to be concurrently alleged.

Inspired by recent advances in contrastive learning to learn effective representations (Khosla et al., 2020), we further devise a two-level hierarchical contrastive loss for COC. First, we strive to maximize the latent space distance between different article representations, which assists the model in learning distinct article-specific views of case facts. Second, we apply contrastive learning within each article latent space to form distinct sub-clusters of similar outcome cases. Unlike our two-level hierarchical contrastive learning, a single-level one has been explored for LJP in the concurrent work by Zhang et al. 2023.

Our experiments demonstrate that, given a static pre-trained encoder, our models outperform single-task and joint models without contrastive loss by a small but consistent margin, with larger improvements for sparse classes in classification performance.

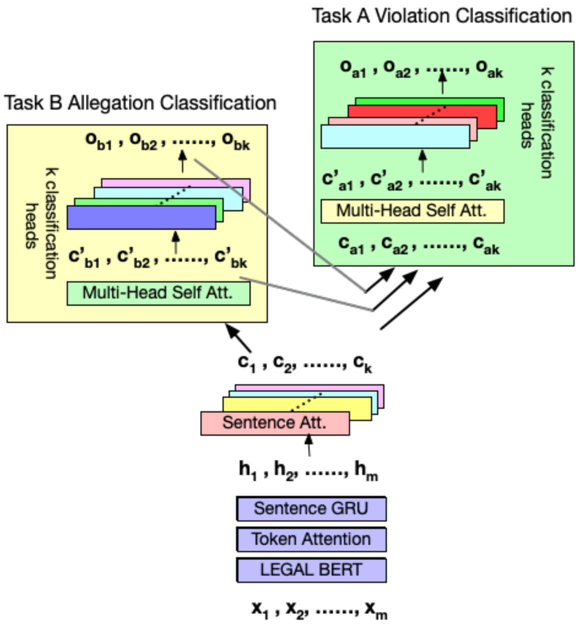

Figure 1: Our architecture capturing task dependency from allegation to violation classification branch.

2 Method

Our model takes as input the case fact description as token encodings $x = \{x_1, x_2, \ldots, x_m\}$ where $x_i = \{x_{i1}, x_{i2}, \ldots, x_{in}\}$ and outputs the set of articles claimed to be alleged by the applicant (Task B) and set of articles deemed to be violated by the court (Task A) as multi-hot vectors. x_i and x_{ip} denote i^{th} sentence and p^{th} token of i^{th} sentence of the case facts respectively. m and n denote the number of sentences and tokens in the i^{th} fact sentence, respectively. Our model is built on top of a hierarchical attention network (Yang et al., 2016), which we chose to be able to process the very long fact description inputs. Our model contains three main components: (1) encoding layer, (2) Article-Specific Case representation and (3) Task Dependency learning. See Fig. 1 for an overview of our model.

Encoding layer: We encode each sentence in the case facts description with LegalBERT (Chalkidis et al., 2020) to obtain the token level representations $\{z_{i1}, z_{i2}, \ldots, z_{in}\}$. Sentence level representations are then computed using a token-level attention mechanism as follows:

$$u_{it} = \tanh(W_w z_{it} + b_w) \;\; \& \;\; \alpha_{it} = \frac{\exp(u_{it} u_w)}{\sum_t \exp(u_{it} u_w)} \;\; \& \;\; f_i = \sum_{t=1}^{n} \alpha_{it} z_{it} \tag{1}$$

where W_w, b_w and u_w are trainable parameters. The sentence level representations $\{f_1, \ldots, f_m\}$ are passed through a GRU encoder to obtain context-aware representations of the case facts $h = \{h_1, h_2, \ldots, h_m\}$.

Article-Specific Case Representation: We disentangle the input case facts into multiple article-view-representations $c = \{c_1, c_2, \ldots, c_k\}$ where k is the total number of modeled convention articles, through aggregating context-aware sentence-level representations h using k sentence-level attention mechanisms similar to eq. 1 for every article individually. Through this article-specific attention mechanism, sentences relevant to a specific article are emphasized and intended to aid in fine-grained reasoning of outcome prediction for every article. This is helpful especially for sparser classes and mitigates the tendency of models to focus on skewed dominant articles. This is distinct from previous works (Chalkidis et al., 2019, 2021, 2022b; Santosh et al., 2022) which use a single vector representation for case facts.

Task Dependency Learning: To capture both the inter-article correlations for allegation, violation classification, and the inter-task dependency, we again use a two-step architecture. First, we apply a multi-head self-attention layer (Vaswani et al., 2017) to the obtained article-specific representations of case c to allow interactions among articles (e.g., some articles are typically alleged together while others usually occur in isolation) and obtain article-interaction-aware allegation feature representations $c'_b = \{c'_{b1}, c'_{b2}, \ldots, c'_{bk}\}$. These c'_b are passed through k article-specific Task B classification layers to obtain the binary outcome o_b corresponding to each article for allegation classification, which are then concatenated into a multi-hot vector.

Then we utilize the task B allegation information to enhance task A violation classification to capture the task dependency. We concatenate the obtained article-interaction-aware allegation representations c'_b and allegation label probability logits o'_b[1] with article-specific case representations c to obtain the enhanced article-specific representation for Task A as $c_{ai} = [c_i, c'_{bi}, o'_{bi}]$. We again employ multi-head self-attention mechanism on these enhanced article-aware representations c_a for violation prediction to capture the correlations that exist between violation of different articles. Finally, the obtained representations are passed through k article-specific Task A classification layers to obtain the binary outcome o_a corresponding to each article's violation output. To be able to evaluate the effectiveness of our interaction architecture in a clean way, we freeze the LegalBERT encoder weights in all our experiments.

2.1 Hierarchical Contrastive Loss

Contrastive learning has recently gained attention as a technique to obtain effective representations. In essence, it involves pulling together an 'anchor point' and its related samples while pushing it away from unrelated samples in the embedding space. Originally developed in self-supervised learning (Chen et al., 2020; Henaff, 2020), it has since been adopted in supervised settings (Khosla et al., 2020) where samples with the same/different labels are deemed related/unrelated with respect to an anchor.

In this work, we use a hierarchical contrastive loss (Liang et al., 2022) alongside the standard binary cross entropy loss on the task outcome probability. On the higher level, this is intended to form distinctive clusters of article-specific case representations. We hypothesize that this distinctiveness maximization constraint in turn helps the article-specific representation component to extract salient information with respect to each article more effectively. At the lower level, inside the latent space for each article, we further perform contrastive learning among cases based on their outcome for tasks A and B, respectively. This allows the positive outcome representations of cases under a specific article to stay closer and separate from the negative outcome cases, leading to formation of sub-clusters. We apply contrastive losses for Task A and Task B separately on the interaction-aware representations. It is calculated as the mean loss computed based on every article based representation as an anchor point. The loss for the interaction-aware representation of the j^{th} case specific to the i^{th} article for Task B $c'_{b_{ij}}$ as an anchor point is calculated as follows:

$$\begin{aligned} l(c'_{b_{ij}}) = &\log\Big(\sum_{f \in Q(i,j)} \frac{\exp(c'_{b_{ij}} \cdot f/\tau_a)}{\sum_{g \in P(i,j)} \exp(c'_{b_{ij}} \cdot g/\tau_a)}\Big) \\ &\times \alpha \sum_{f \in R(i,j)} \frac{\exp(c'_{b_{ij}} \cdot f/\tau_c)}{\sum_{g \in Q(i,j)} \exp(c'_{b_{ij}} \cdot g/\tau_c)}\Big) \end{aligned} \tag{2}$$

where $P(i,j) = \{c'_{b l_m} | l \neq i \;\; \& \;\; m \neq j\}$ (all rep-

---

[1] We use non-binarized response (i.e. probability logits) as it avoids the information loss that can occur in the probability space due to binarization.

resentations except the anchor point), $Q(i,j) = \{c'_{bl_m} | l = i \ \& \ m \neq j\}$ (all representations which share the same article as the anchor point), $R(i,j) = \{c'_{bl_m} | l = i \ \& \ y_{i_j} = y_{l_m} \ \& \ m \neq j\}$, y_{i_j} the denotes binary outcome label of case j with respect to article i (all representations which share the same article and outcome of that article as the anchor point). τ_a and τ_c are scalar temperature parameters that control the penalties on negative samples. The first term in the above equation 2 denotes the contrastive loss among article representations (i.e., for a given anchor point, positive pairs are obtained by article-aware representations of cases in the batch which share the same article with the anchor point; negative pairs are the remaining article representations). The second term contrasts the cases based on their task outcome within specific article representations. Contrastive learning has shown to be more effective with larger batch sizes (Radford et al., 2021; Chen et al., 2020). To account for smaller batch size due to computational constraints incurred with our hierarchical setup, we use a memory bank (Wu et al., 2018) which progressively reuses the representations from previous batches in computing the contrastive loss.

3 Experiments & Discussion

3.1 Dataset & Baseline Models

We experiment on the ECHR task A and B datasets of LexGLUE (Chalkidis et al., 2022b), which consist of 11k case fact descriptions chronologically split into training (2001–2016, 9k cases), validation (2016–2017, 1k cases), and test sets (2017-2019, 1k cases). The label set for both tasks include 10 prominent ECHR articles. Implementation details are given in Appendix A. We compare our models against the following baselines:

Task A/B only: We train single-task models only on task A and B labels, respectively. Their architecture is based on our model with contrastive loss, task dependency and article-specific representation components removed.

Multi-task: Using the same architecture, we also develop a model for both task A and B that is trained in classic multi-task fashion with separate classification heads without article-specific representations and task dependency components.

3.2 Performance Evaluation

Following Chalkidis et al. 2022b, we report micro-F1 (μ-F1) and macro-F1 (m-F1) scores across the 10 ECtHR articles contained in the dataset. We also report hard-macro-F1 (hm-F1) for Task A following Santosh et al. 2022, which is the mean F1-score computed for each article where cases with that article having been violated are considered as positive instances, and cases with that article being alleged but not found to have been violated as negative instances. This forms the most critical measure for violation classification as it conditions on allegation.

Table 1: Results on Task A and B. ‘feat.’, ‘lab,’. ‘Cont.’ indicate feature, label and contrastive, respectively

	Task B		**Task A**		
Model	**μ-F1**	**m-F1**	**μ-F1**	**m-F1**	**hm-F1**
Task B only	76.20	67.15	-	-	-
Task A only	-	-	68.42	56.26	54.14
Multi-task	78.17	69.16	69.29	58.05	55.57
Our Method	79.29	70.97	71.26	65.24	60.90
w/o feat. & lab.	78.93	71.45	70.07	59.14	57.09
w/o feat.	78.59	71.56	70.68	63.93	59.28
w/o label	79.09	71.38	70.32	64.12	61.70
only gold lab.	78.21	70.03	81.46	78.93	66.59
gold lab. + feat.	77.68	70.40	83.19	78.79	67.42
w/o outcome Cont.	78.42	69.48	69.86	60.84	57.62
w/o article Cont.	79.02	71.14	71.16	64.68	59.86
Task A Cont.	-	-	70.16	62.14	58.12
Task B Cont.	78.16	69.42	-	-	-

We compare the performance of our method with the baselines in the first four rows of Table 1. The multi-task method performs better than the individual tasks alone, validating the dependency between them. Our method performs better than the multi-task architecture, highlighting the effectiveness of our feature and label dependency components, as well as of the hierarchical contrastive loss. It scores higher by a small margin in Task B and Task A micro-F1 but achieves a larger benefit (>5%) in task A macro-F1 and hard macro-F1 metrics. This suggests that our model is of particular utility for sparser classes.

3.3 Analysis

3.3.1 Ablation on Task Dependency Learning

We create three ablation conditions by removing one interaction mechanism in each of them: (i) *w/o feature & label* (article-specific representation but with no concatenation with features or labels) (ii) *w/o feature* (article-specific representation concatenated with task B label as classified by the model) and (iii) *w/o label* (article-specific representation concatenated with task B features).

From the second section of Table 1, we observe that even the performance of *w/o feature and label* is better than *multi-task* model indicated by a small but consistent margin, indicating that article-specific case representation is a competitive component. Both *w/o feature*, *w/o label* models perform better than *w/o feature & label* in Task A, demonstrating the benefit of passing on task B model information explicitly. Between them, *w/o label* performs better in m-F1 and hm-F1 scores of Task A than *w/o feature* showing that providing the fine-grained representation of features from the allegation identification model is more useful than the predicted allegation labels only.

Further, to evaluate the impact of allegation identification performance on downstream violation classification, we conduct a control experiment in which we provide the actual gold allegation set of articles as input to the violation component in place of the predicted ones. We create two variants: *only gold labels* and *gold labels + features* (gold labels along with task B features). From the third section of Table 1, we observe that performance on Task A increases substantially in micro-F1 and macro-F1, which is intuitive as the model gets access to perfect allegation information. Interestingly, when adding task allegation feature information, we notice an additional small increase in hard macro-F1, indicating that adding feature information can have beneficial effect even in the presence of gold task B labels. These results form an upper bound of the benefit of using task dependency information from allegation branch to violation branch in our architecture, and the size of the performance gap motivates future work on accurate allegation classification.

3.3.2 Ablation Hierarchical Contrastive Loss

We carry out an ablation experiment for each component of our hierarchical contrastive loss: (i) disable article-level contrastive learning to obtain distinctive article representations ('w/o article contrastive') and (ii) disable outcome-based contrastive learning to separate cases based on outcome within each article cluster ('w/o outcome contrastive'). Intuitively, from the fourth section of Table 1, we observe that removing the outcome contrastive loss has the larger effect on performance, as it directly relates to the predicted label. The smaller but consistent drop in performance when removing article-level contrastive learning supports our hypothesis that maximizing the distinctiveness among article representations encourages the model to learn how to extract article-specific salient information from case facts.

Finally, to study the impact of our contrastive loss component alone, we evaluate single-task models applying our hierarchical contrastive loss referred to as 'Task A/B Contrastive'. From the last section of Table 1, we observe that they outperform their baseline counterparts in both tasks, but still stay behind our model.

4 Conclusion

We improve ECtHR article violation classification from fact statements by leveraging feature and label information from an allegation classification model. We also leveraged hierarchical contrastive loss to contrast between different article representations and case representations based on outcome with respect to a specific article. Given a static pretrained encoder, our models outperform a straightforward multi-task architecture by a small but consistent margin, with larger improvements for sparse classes. These results suggest that the tasks of allegation and violation classification on ECtHR fact statements interrelate in a way that may not be optimally captured using straightforward multi-task architectures, and motivate further research on dependency modeling between related legal classification tasks.

Limitations

In this work, we have demonstrated improvements in violation classification for ECtHR cases by leveraging the dependency from allegation classification at the feature and label level. While our feature transfer and contrastive learning techniques are general, our experimental contributions are contextual to the court. The nature of the fact statements as being influenced by the eventual case outcome and not suitable for prospective prediction has already been addressed in section 1.

While similar tasks (i.e., allegations paired with findings) exist in many other jurisdictions, they will differ in, for example, legal nature, semantic difficulty, and sub-task dependency. In our case, we choose the allegation classification as the auxiliary task which is closely related and also forms a necessary sub-part of deriving the final outcome related to the main task (violation prediction) at hand. We leave an exploration of the relatedness of auxiliary tasks and their impact on LJP/COC for future work.

One major challenge is dealing with long input case facts description, which is currently handled with hierarchical model in this work. These hierarchical models do not allow tokens in one sentence to attend to tokens in other sentence which leads to sub-optimal interaction modelling. This modeling impact on performance is still underexplored except some preliminary empirical work in Dai et al. 2022; Chalkidis et al. 2022a. Additionally, we freeze the weights in the LegalBERT encoder, both to save computational resources and to evaluate the effectiveness of our dependency mechanism in a clean way.

Ethics Statement

We employ pre-trained language models and do not train them from scratch, thus inheriting the biases they may have acquired from their training corpus. Our experiments have been carried out on a dataset of ECtHR decisions which is publicly available as the part of LexGLUE benchmark (Chalkidis et al., 2022b) and has been derived from the public court database HUDOC[2]. Though these decisions are not anonymized and contain the real names of the involved parties, we do not foresee any harm incurred by our experiments beyond making this information available. This collection of decision documents is of course historical data and using it to train model may result in classifiers that exhibit behavior that may be considered biased. For example, Chalkidis et al. 2022c explores disparities in classification performance with regard to an applicant's gender, their age, and the identity of the respondent state. If COC models are deployed as part of a decision support systems, then they of course must be screened for performance/error differences in between groups that are to be treated equally.

The task of LJP/COC in itself raises serious ethical and legal concerns, both in general and specific to the European Court of Human Rights. However, we do not advocate for the practical adoption of LJP/COC systems by courts. Our prior work in Santosh et al. 2022 demonstrates that these systems rely on several shallow surface-level spurious signals that are statistically predictive but legally irrelevant. This highlights the risk of using predictive systems in high stakes domains such as law. In the same work, we argue that models leveraging the case outcome signal for analytical purposes must be developed mindfully and with the goal of aligning their inferences with legal expert reasoning. This further parallels the broader legal NLP community increasingly addressing ethical aspects of developed systems in the context of technical research (e.g., Wang et al. 2021; Medvedeva et al. 2021, 2022; Tsarapatsanis and Aletras 2021; Leins et al. 2020).

In this work, we use COC as a technical benchmarking task that allows the development and study of neural NLP models on legal text. We focus on how to leverage dependencies on two successive tasks (allegation identification and violation classification) based on case facts, as well as on learning effective representations of these facts using contrastive learning. Our results are hence to be understood as technical contributions in pursuit of the overarching goal of developing models capable of deriving insight from data that can be used legally, ethically, and mindfully by experts in solving problems arising in legal research and practice.

All experiments were carried out using Google Colab. We did not track computation hours.

A Implementation Details

Our models compute word embeddings of size 768. Our word level attention context vector size is 300. The sentence level GRU encoder dimension is 200, thus giving a bidirectional embedding of size 400, and a sentence level attention vector dimension of 200. The final dense classifier for all tasks has 100 hidden units. We use a mini batches size of 32 and the model is optimized end-to-end using Adam (Kingma and Ba, 2015). The dropout rate (Srivastava et al., 2014) in all layers is 0.1. We determine the best learning rate using grid search on the development set and use early stopping based on the development set m-F1 score. We finetuned τ_a, τ_c with an additional constraint of $\tau_a < \tau_c$ among the values of $\{0.07, 0.1, 0.14, 0.2, 0.25, 0.3\}$ so that it aids in pulling together the representations belonging to the same article in latent space (leading to distinct article clusters) and also in further slightly pulling together the representations of cases belonging to the same outcome in each separated article-specific embedding latent space compared to the other outcome cases in that same article. We set α to be 0.5. We use a memory bank of size 32 per article and outcome, and store only the most recent examples per article and its corresponding outcome.

Semi-supervised Relation Extraction via Data Augmentation and Consistency-training

Komal K. Teru
The Vanguard Group
`komal_teru@vanguard.com`

Abstract

Due to the semantic complexity of the Relation extraction (RE) task, obtaining high-quality human labelled data is an expensive and noisy process. To improve the sample efficiency of the models, semi-supervised learning (SSL) methods aim to leverage unlabelled data in addition to learning from limited labelled data points. Recently, strong data augmentation combined with consistency-based semi-supervised learning methods have advanced the state of the art in several SSL tasks. However, adapting these methods to the RE task has been challenging due to the difficulty of data augmentation for RE. In this work, we leverage the recent advances in controlled text generation to perform high quality data augmentation for the RE task. We further introduce small but significant changes to model architecture that allows for generation of more training data by interpolating different data points in their latent space. These data augmentations along with consistency training result in very competitive results for semi-supervised relation extraction on four benchmark datasets.

Input sentence: The **battle** led to **panic** on the frontier, and settlers in the surrounding counties fled.

Synonym-replacement: The struggle cause scare on the frontier, and settlers in the surrounding counties fly.

LM-based augmentation: The **battle** reduced **panic** on the frontier, and settlers in the surrounding counties relaxed.

Vanilla BT: The war caused **panic** at the border, and residents of the nearby counties fled.

Our constrained BT: The **battle** sparked **panic** at the border, with residents fleeing in surrounding counties.

Figure 1: Different data augmentation techniques applied to a sample datapoint from SemEval dataset. Existing methods replace the head/tail entities (highlited in red), change the original meaning or do not give very fluent paraphrases.

1 Introduction

Relation extraction is one of the essential components in constructing structured knowledge bases (Luan et al., 2018), performing interpretable question answering (Sun et al., 2021), improving web search, and many other information extraction pipelines. It aims to discover the semantic relation between a given head entity and tail entity based on the context in the input sentence. For example, given a sentence "*The battle led to panic on the frontier, and settlers in the surrounding counties fled.*", the goal is to extract the `Cause-Effect` relation between the head entity '**battle**' and the tail entity '**panic**'. The RE task requires a high level of language understanding and involves a significant level of semantic complexity (Bach and Badaskar, 2007). Due to this semantic complexity it often requires extensive and highly skilled human involvement to obtain good quality labelled data, making data collection an expensive and noisy process. Unsurprisingly, because of the same semantic complexity of the task, models typically require large amounts of labelled data to give production-ready performance.

A common strategy to improve the sample efficiency of machine learning models is semi-supervised learning methods which leverage easily accessible unlabelled data to improve the overall performance. While there are several paradigms of semi-supervised learning methods, consistency training based methods have advanced the state of the art in several SSL tasks (Ghosh and Thiery, 2021). These methods can typically reach performances that are comparable to their fully supervised counterparts while using only a fraction of labelled data points. Recently, strong data augmentation combined with consistency training algorithms have shown great success, even surpassing fully supervised models, in low-data settings of various

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1112–1124
May 2-6, 2023 ©2023 Association for Computational Linguistics

tasks (Xie et al., 2020). Adapting these methods to the task of relation extraction has been challenging due to the difficulty of data augmentation for RE task. This is because, in addition to the input sentence, each data point also consists of a head entity and a tail entity contained in the input sentence. Typical data augmentation techniques used in NLP such as back-translation, synonym-replacement, language-model based augmentation, etc. (Feng et al., 2021) can not be easily applied to such 'structured' input as they do not guarantee the integrity of either a) the entities in the input sentence or, b) the meaning of the input sentence itself. Figure 1 shows that using synonym-replacement and vanilla back-translation (BT) methods (Sugiyama and Yoshinaga, 2019) the entities themselves could be paraphrased or replaced. Matching the new and the old entities is a whole problem in itself. In the Language Model-based augmentation method (Anaby-Tavor et al., 2020), the semantic meaning of the input sentence changes altogether, which makes it difficult to employ consistency training.

Present work. In this work, we leverage the recent advances in controlled text generation to perform high quality data augmentation for the relation extraction task that not only keeps the meaning and the head/tail entities intact but also produces fluent and diverse data points. In particular, we modify back-translation to leverage lexically constrained decoding strategies (Post and Vilar, 2018; Hu et al., 2019) in order to obtain paraphrased sentences while retaining the head and the tail entities. We further propose novel modifications to the widely popular relation extraction model architecture, that allows for generation of more samples by interpolating different data points in their latent space, a trick that has been very successful in other domains and tasks (Berthelot et al., 2019; Chen et al., 2020b,a). Additionally, we leverage the entity types of the head and the tail entities, when available, in a way that effectively exploits the knowledge embedded in pre-trained language models. These data augmentations, when applied to unlabelled data, let us employ consistency training techniques to achieve very competitive results for semi-supervised relation extraction on four benchmark datasets. To the best of our knowledge, this is the first study to apply and show the merit of data augmentation and consistency training for semi-supervised relation extraction task.

2 Related work

Semi-supervised learning for NLP

Semi-supervised learning algorithms can be categorized into two broad classes–1) *self-ensembling* methods and 2) *self-training* methods.

***Self-ensembling* methods** leverage the smoothness and cluster/low-density assumptions of the latent space (Chapelle and Zien, 2005). They train the models to make consistent predictions under various kinds of perturbations to either a) the data (Miyato et al., 2019; Xie et al., 2020), or b) the model parameters themselves (Tarvainen and Valpola, 2017). The former methods are broadly referred to as consistency training methods and have resulted in state-of-the-art performances for several semi-supervised NLP tasks. Sachan et al. (2019) add adversarial noise to both labelled and unlabelled data and train models to make consistent predictions on the original and the corresponding noisy data-point. Many recent methods leverage large pre-trained language models for more advanced data augmentation techniques, like back-translation (Edunov et al., 2018), and further improve performance in the low-data regime (Xie et al., 2020). Recently, Chen et al. (2020b,a) adapted the Mixup algorithm (Zhang et al., 2018) as another form of data augmentation for textual data and show state-of-the-art performance on text classification and NER tasks. Due to the difficulty of data augmentation for relation extraction task (Figure 1), these methods have not been adapted for semi-supervised relation extraction (SSRE) task so far. In this work, we fill that gap and demonstrate the empirical success of consistency training for SSRE.

***Self-training* methods** are the oldest heuristic methods of iteratively expanding the labelled training set by including high-confidence *pseudo-labels* from the unlabelled data. All of the existing works on SSRE fall under this paradigm. These methods famously suffer from the confirmation bias problem where the incorrect predictions of the initially trained model affect the quality of pseudo-labels and eventually cause the label distribution to drift away from the true data distribution, resulting in a *semantic drift*. Lin et al. (2019) was one of the first works to address this by training two different models and augmenting the labelled set with the 'consensus' set, i.e., the data points which are labelled the same by both models. Several works have developed on this idea of improving the pseudo-label quality via various strategies like meta-learning

(Hu et al., 2021a) or reinforcement learning (Hu et al., 2021b). These set of methods constitute our baselines.

Data augmentation for NLP

In this work, we concentrate on two major classes of data augmentation techniques for NLP – sentence-level data augmentation and latent space augmentations. Sentence-level data augmentation techniques include back-translation (Edunov et al., 2018), language-model based augmentations (Anaby-Tavor et al., 2020), and word-replacement strategies (Zhang et al., 2015). We adapt the back-translation techniques to the RE task.

In latent space augmentations one generates more samples by interpolating between pairs of given data points in their latent space. This was originally introduced for image classification (Zhang et al., 2018; Verma et al., 2019; Yun et al., 2019) as a data augmentation and regularization method. Previous works have generalized this idea to the textual domain by proposing to interpolate in embedding space (Cheng et al., 2020) or the general latent space (Chen et al., 2020b,a) of textual data and applied the technique to NLP tasks such as text classification, machine translation, NER task and achieved significant improvements. We show that both these styles of augmentations can be effectively applied to improve performance on SSRE task.

3 Background

Task formulation. In this work, we focus on the sentence-level relation extraction task, i.e., given a *relation statement* $\mathbf{x} : (\mathrm{s}, e_h, e_t)$ consisting of a sentence, s, a head entity, e_h, and a tail entity, e_t (both the entities are mentioned in the given sentence s), the goal is to predict a relation $r \in \mathcal{R} \cup \{\mathrm{NA}\}$ between the head and the tail entity, where $\mathcal{R}$ is a pre-defined set of relations. If the sentence does not express any relation from the set $\mathcal{R}$ between the two entities, then the relation statement $\mathbf{x}$ is accordingly labelled NA.

This is typically done by learning a relation encoder model $\mathcal{F}_\theta : \mathbf{x} \mapsto \mathbf{h}_r$ that maps an input relation statement, $\mathbf{x}$, to a fixed length vector $\mathbf{h}_r$ that represents the relation expressed in s between e_h and e_t. This relation representation, $\mathbf{h}_r$, is then classified to a relation $r \in \mathcal{R} \cup \{\mathrm{NA}\}$ via an MLP classifier.

Base model architecture. Most recent methods for RE use a Transformer-based architecture (Devlin et al., 2019; Vaswani et al., 2017) for the relation encoder model, $\mathcal{F}_\theta$. To represent the head and tail entities in the input to the encoder, the widely accepted strategy is to augment the input sentence s with entity marker tokens–`[E1]`, `[/E1]`, `[E2]`, `[/E2]`–to mark the start and end of both entities. Concretely, an input sentence like "*Lebron James currently plays for LA Lakers team.*" when augmented with entity marker tokens becomes

`[E1]` **Lebron James** `[/E1]` currently plays for `[E2]` **LA Lakers** `[/E2]` team.

This modified text is input to the Transformer-based sequence encoder. Next, the encoder output representations[1] of the tokens `[E1]` and `[E2]` are concatenated to give the fixed length relation representation, $\mathbf{h}_r = [\mathbf{h}_{[E1]} \oplus \mathbf{h}_{[E2]}]$. This fixed length vector is in turn passed through an MLP classifier, $p_\phi(\mathbf{h}_r)$, to give a probability vector, $\mathbf{y}$, over the relation set $\mathcal{R} \cup \{\mathrm{NA}\}$.

4 Proposed approach

In our approach we build on the base model architecture described in §3 and introduce additional model design elements that are necessary to obtain an improved performance in semi-supervised relation extraction (SSRE) task.

We first describe the two data augmentation techniques we perform, and the model architectural changes we introduce that facilitate these augmentations. Then, we describe the training procedure we follow to leverage unlabelled data and achieve state-of-the-art performance on three out of four benchmark datasets for SSRE.

4.1 Constrained back-translation

Back-translation (Edunov et al., 2018) generates diverse and fluent augmentations while retaining the global semantics of the original input. Specifically, one translates a given text into an intermediate language, say, German, and translates it back to the source language, say English. Using different intermediate languages and temperature-based sampling results in a diverse set of paraphrases. Applying this back-translation technique in a vanilla fashion is not possible for RE task because one has little control over the retention of the head and tail entities (Figure 1). Thus, when translating back

---

[1] hidden state from the last layer of the Transformer model

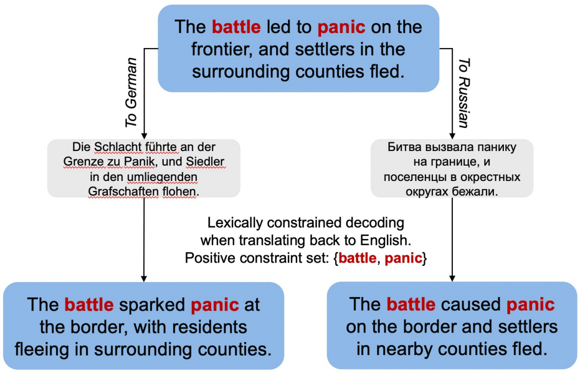

Figure 2: Constrained back-translation process

to the source language from the intermediate language we perform lexically-constrained decoding (Hu et al., 2019), i.e., force the inclusion of pre-specified words and phrases–positive constraint set–in the output. In our case the original head and tail entity words/phrases make up this positive constraints set. We use German and Russian as intermediate languages and use the pre-trained WMT'19 English-German and English-Russian translation models (in both directions) and their implementations provided by Ott et al. (2019). This methodology generates diverse data augmentations for a given sentence. For example, the sentence "*The battle led to panic on the frontier, and settlers in the surrounding counties fled.*" is converted to "*The battle sparked panic at the border, with residents fleeing in surrounding counties*" when back-translated via German, and to "*The battle caused panic on the border and settlers in nearby counties fled.*" when done via Russian. This is illustrated in Figure 2. This strong data-augmentation technique for RE can be applied to both labelled and unlabelled data opening the doors to consistency training (Xie et al., 2020) as we will see in §4.3.

4.2 Latent-space interpolation

Here, we adapt a mixup-based data augmentation technique to the RE task by making necessary modifications to the base model architecture we described in §3. As done in previous works (Chen et al., 2020b,a), we sample two random data points–$(\mathbf{x}, \mathbf{y})$ and $(\mathbf{x}', \mathbf{y}')$, where $\mathbf{x}$ and $\mathbf{y}$ denote the relation statement and the corresponding relation label–from the training data and separately compute the respective latent representations, $\mathbf{h}^m$ and $\mathbf{h}'^m$, upto the layer m of the relation encoder $\mathcal{F}_\theta$ as follows:

$$\mathbf{h}^l = \mathcal{F}_\theta^l(\mathbf{h}^{l-1}); \quad l \in [1, m],$$
$$\mathbf{h}'^l = \mathcal{F}_\theta^l(\mathbf{h}'^{l-1}); \quad l \in [1, m],$$

where $\mathbf{h}^l$ is the latent representation of all tokens in the sentence $\mathbf{x}$ at the l^{th} layer of the encoder. Next, the latent representations of each token in $\mathbf{x}$ at the m^{th} layer are linearly interpolated:

$$\tilde{\mathbf{h}}^m = \lambda \mathbf{h}^m + (1 - \lambda)\mathbf{h}'^m,$$

where λ is the mixing coefficient which is sampled from a Beta distribution, i.e., $\lambda \sim \text{Beta}(\alpha, \beta)$. Then, the interpolated latent representation is passed through the rest of the encoder layers:

$$\tilde{\mathbf{h}}^l = \mathcal{F}_\theta^l(\tilde{\mathbf{h}}^{l-1}); \quad l \in [m + 1, L].$$

This final encoder output representation, $\tilde{\mathbf{h}}^L$, can be interpreted as the encoder output representation of a *virtual* input $\tilde{\mathbf{x}}$, i.e., $\tilde{\mathbf{h}}^L = \mathcal{F}_\theta(\tilde{\mathbf{x}})$. We denote this whole mixup operation[2] as $\tilde{\mathbf{h}}^L := \text{REMix}(\mathbf{x}, \mathbf{x}')$. The label for this augmented *virtual* sample is given by the linear interpolation of the respective labels, $\mathbf{y}$ and $\mathbf{y}'$, with the same mixing coefficient λ i.e., $\tilde{\mathbf{y}} := \text{mix}(\mathbf{y}, \mathbf{y}') = \lambda \mathbf{y} + (1 - \lambda)\mathbf{y}'$. This *virtual* data point, $(\tilde{\mathbf{x}}, \tilde{\mathbf{y}})$, is the augmented data point and can be used as additional training data.

Proposed architecture change. Now, for the RE task we need to extract a fixed-length relation representation from the encoder output representation of the entire input sequence. The traditional way to do this for RE task is by concatenating the encoder output representations of the entity marker tokens `[E1]` and `[E2]`. However, it is challenging to do this for a virtual sample, $\tilde{\mathbf{x}}$, as the entity markers are not clearly defined in this case. We thus modify the relation representation to be the encoder output representation of the `[CLS]` token. However, Baldini Soares et al. (2019) have shown this choice to be sub-optimal compared to concatenation of marker tokens. This is because the marker token representations provide direct access to the contextual information of the respective entities. Although the `[CLS]` token, in theory, has access to the entire context of the sentence, it might be difficult to capture the nuances like the head entity type, tail entity type, and the contextual information around the two entities all in a single vector.

---

[2] REMix entails the model architecture changes discussed below.

On the other hand, entity type information is easily accessible in most RE benchmarks[3]. So, to compensate for the sub-optimal choice of using `[CLS]` token representation as the relation representation, we modify how we represent the entity spans in the input token to more effectively use the easily accessible entity type information. In particular, we note that the entity type labels can trivially be mapped to tokens from any pre-trained language model's vocabulary. For example, entity types like `PERSON` and `STATE_OR_PROVINCE` can be tokenized into a word/phrase like 'person' and 'state or province', respectively. In such cases when entity type information is available, instead of using special marker tokens like `[E1]` and `[E2]` we prepend the entity spans in the input sequence with the word/phrases corresponding to their respective types and enclose these 'type-words' in punctuation marks (Zhou and Chen, 2021). The modified input to the transformer along with the `[CLS]` token looks as follows:

`[CLS]` @ * person * **Lebron James** @ plays
for & * organization * **LA Lakers** & team.

We use different punctuation symbols to distinguish between subject and object entities. Specifically, we use '@' for subject and '&' for object entities. This representation helps leverage the knowledge already contained in the pre-trained large-language model about the type of the entity and offset some of the downside of using a simplified relation representation in the `[CLS]` token. As we will empirically see in §5.4, this use of entity type information is not only effective but is necessary for the optimal functioning of our approach. Zhou and Chen (2021) recently showed the success of this method in the fully supervised setting. Here we use it in conjunction with a simplified relation representation and show its merit in semi-supervised RE setting.

4.3 Consistency training for SSRE

Let the given limited labelled set be $\mathbf{X}_l = \{\mathbf{x}^l_1, ..., \mathbf{x}^l_n\}$, with their relation labels $\mathbf{Y}_l = \{\mathbf{y}^l_1, ..., \mathbf{y}^l_n\}$, where $\mathbf{y}^l_i \in \{0,1\}^{|\mathcal{R} \cup \{\text{NA}\}|}$ is a one-hot vector and $\mathcal{R}$ is the set of pre-defined relations. Let $\mathbf{X}_u = \{\mathbf{x}^u_1, ..., \mathbf{x}^u_m\}$ be a large unlabelled set. The goal is to apply both the data augmentation techniques described above and train a model with consistency loss to effectively leverage unlabelled data along with the limited labelled data.

We largely adapt the semi-supervised training techniques introduced by Chen et al. (2020b). For each $\mathbf{x}^u_i$ in the unlabelled set $\mathbf{X}_u$, we generate K augmentations $\mathbf{x}^a_{i,k}, k \in \{1, 2, ..., K\}$ using the constrained back translation technique with different intermediate languages[4]. These augmentations make up the set $\mathbf{X}_a = \{\mathbf{x}^a_{i,k}\}$. For a given unlabelled data point $\mathbf{x}^u_i$ and its K augmentations $\mathbf{x}^a_{i,k}$ the label is given by the average of current model's predictions on all $K+1$ data points:

$$\mathbf{y}^u_i = \frac{1}{K+1}\left(p_\phi(\mathcal{F}_\theta(\mathbf{x}^u_i)) + \sum_{k=1}^{K} p_\phi(\mathcal{F}_\theta(\mathbf{x}^a_{i,k}))\right),$$

where $\mathbf{y}^u_i$ is a probability vector. This not only enforces the constraint that the model should make consistent predictions for different augmentations but also makes the predictions more robust by ensembling all the predictions. We merge the unlabelled set and the augmented set into $\mathbf{X}_{\text{ua}} = \mathbf{X}_u \cup \mathbf{X}_a$ and the corresponding (pseudo-)labels are given by $\mathbf{Y}_{\text{ua}} = \mathbf{Y}_u \cup \mathbf{Y}_a$, where $\mathbf{Y}_u = \{\mathbf{y}^u_i\}$, $\mathbf{Y}_a = \{\mathbf{y}^a_{i,k}\}$, and $\mathbf{y}^a_{i,k} = \mathbf{y}^u_i \forall k \in \{1, 2, ..., K\}$, i.e., all the augmented data points share the same label as the original unlabelled data point.

Given this cumulative set $\mathbf{X}_{\text{ua}}$ and their generated labels $\mathbf{Y}_{\text{ua}}$ as additional training data, we employ the REMix augmentation technique to generate arbitrary amounts of training data. In particular, we randomly sample two data points $\mathbf{x}^{\text{ua}}_s, \mathbf{x}^{\text{ua}}_t \in \mathbf{X}_{\text{ua}}$, and compute the encoder output representation of a new *virtual* data point with $\text{REMix}(\mathbf{x}^{\text{ua}}_s, \mathbf{x}^{\text{ua}}_t)$ and the corresponding target label with $\text{mix}(\mathbf{y}^{\text{ua}}_s, \mathbf{y}^{\text{ua}}_t)$.

Additionally, while computing the final unsupervised loss in each training iteration we filter out the unlabelled data points with prediction confidence below a certain threshold γ (Xie et al., 2020). Finally, to encourage low-entropy predictions on unlabelled data, we sharpen the predictions with a sharpening coefficient T:

$$\hat{\mathbf{y}}^{\text{ua}}_i = \frac{(\mathbf{y}^{\text{ua}}_i)^{\frac{1}{T}}}{||(\mathbf{y}^{\text{ua}}_i)^{\frac{1}{T}}||_1}.$$

Everything put together, the final unsupervised loss in each training iteration with mini-batch size B is

---

[3] From new datasets/applications viewpoint, when entities are identified in a piece of text it is safe to assume that their types would also be identified.

[4] In our specific implementation K = 2; with German and Russian as intermediate languages.

computed as:

$$\mathcal{L}_{\text{unsp}} = \frac{1}{B}\sum_{\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}}\sim\mathbf{X}_{\text{ua}}}^{B} \mathtt{m}(\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}})\mathcal{L}_{\text{mix}}(\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}}),$$

where

$$\begin{aligned}\mathcal{L}_{\text{mix}}(\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}}) &= \text{CE}(\text{mix}(\hat{\mathbf{y}}_s^{\text{ua}},\hat{\mathbf{y}}_t^{\text{ua}})|| \\ &\qquad p_\phi(\text{REMix}(\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}}))), \\ \mathtt{m}(\mathbf{x}_s^{\text{ua}},\mathbf{x}_t^{\text{ua}}) &= I(\max \mathbf{y}_s^{\text{ua}} > \gamma) I(\max \mathbf{y}_t^{\text{ua}} > \gamma).\end{aligned}$$

Here, $I(.)$ is an indicator function and $\mathtt{m}(.)$ denotes the confidence masking function which filters out the low-confidence datapoints. In our implementation $p_\phi(.)$ is a two-layer MLP classifier on top of the relation encoder model. CE denotes the cross entropy loss function. [5]

This combined with the traditional supervised loss, $\mathcal{L}_{\text{sup}} = \sum_{\mathbf{x}_i\sim\mathbf{X}_l}^{B} \text{CE}(\mathbf{y}_i^l || p_\phi(\mathcal{F}_\theta(\mathbf{x}_i)))$, constitutes the total loss:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{sup}} + \gamma_m \mathcal{L}_{\text{unsp}},$$

where γ_m is a parameter which controls the trade-off between supervised and unsupervised loss.

5 Experiments

We perform experiments on four benchmark datasets for sentence-level RE and compare the proposed model, REMix, against current state-of-the-art SSRE approaches. We further conduct ablation studies and sensitivity analysis to expose the significance of different design choices of REMix.

5.1 Datasets

We use two widely popular relation extraction benchmark datasets: SemEval 2010 Task 8 (SemEval) (Hendrickx et al., 2010), and the TAC Relation Extraction Dataset (TACRED) (Zhang et al., 2017). SemEval is a standard benchmark dataset for evaluating relation extraction models containing 10717 examples in total. Each sentence is annotated with a pair of untyped nominals (concepts; example in Figure 1) that are related via one of 19 semantic relation types (including `no_relation`). TACRED is a large-scale crowd-sourced relation extraction dataset with 106264 examples which is collected from all the prior TAC KBP relation schema. Unlike SemEval, sentences in TACRED are labelled with pairs of typed-entities that are related via one of 42 person- and organization-oriented relation types (including `no_relation`). In addition to these standard benchmark datasets, we also show results on two more datasets: RE-TACRED (Stoica et al., 2021) and KBP37 (Zhang and Wang, 2015). RE-TACRED is a re-annotated version of the original TACRED dataset using an improved annotation strategy to ensure high-quality labels. Zhou and Chen (2021) provide a compelling analysis and recommend using this as the evaluation benchmark for sentence-level RE. KBP37 is another sentence-level RE dataset with 21046 total examples collected from 2010 and 2013 KBP documents as well as July 2013 dump of Wikipedia. In terms of size, this falls between SemEval and TACRED. Similar to SemEval the entity types are not available in this dataset, however the 37 relation types are person- and organization-oriented like in TACRED. This dataset is thus a good segue between the two standard benchmarks. The statistics of these datasets is given in Table 1.

Table 1: Dataset statistics

Dataset	# rel.	examples	# no_relation
TACRED	42	106264	79.51%
RE-TACRED	40	91467	63.17%
KBP37	37	21046	10.33%
SemEval	19	10717	17.39%

5.2 Baselines and implementation details

We compare REMix with three state-of-the-art models that are representative of the existing class of methods for SSRE: MRefG (Li et al., 2021), MetaSRE (Hu et al., 2021a), and GradLRE (Hu et al., 2021b). MRefG leverages the unlabelled data by semantically or lexically connecting them to labelled data by constructing reference graphs, such as entity reference or verb reference. This approach heavily leverages the linguistic structure of the data and is the only existing method that falls outside the *self-training* class of methods. MetaSRE generates pseudo labels on unlabelled data by learning from the mistakes of the classification model as an additional meta-objective. GradLRE on the other hand generates pseudo label data to imitate the gradient

---

[5] Note that we only apply the augmentation techniques on the unlabelled data set. Initial experiments applying these to the labelled data set resulted in only marginal improvements and even performance deterioration in some cases, likely due to introduction of too much noise into an already limited labelled set.

Table 2: F1 score with various amounts of labelled data and 50% unlabelled data. Mean and standard deviation of 5 different runs is reported. Best performance on each configuration is bolded and second best is underlined.

	TACRED			KBP37		
%labelled Data	3%	10%	15%	5%	10%	30%

REMix(ours)	**71.33**± 1.22	**77.94**± 0.59	**79.76**± 0.47	77.58± 0.59	81.13± 0.82	**85.51**± 0.38

descent direction on labelled data and bootstrap its optimization capability through trial and error (Hu et al., 2021b). MetaSRE and GradLRE are two of the strongest methods in the widely adapted *self-training* methods for SSRE.

Implementation details. We follow the established setting to use stratified sampling to divide the training set into various proportions of labelled and unlabelled sets so that the relation label distribution remains the same across all subsets. Following existing work, we sample 5%, 10%, and 30% of the training set as labelled data for the SemEval and KBP37 datasets, and 3%, 10%, and 15% of the training set as labelled data for TACRED and RE-TACRED datasets. For all datasets and experiments, unless otherwise specified, we sample 50% of the training set as the unlabelled set. For TACRED and SemEval datasets we take the performance numbers of all baseline models reported by Hu et al. (2021b). For other datasets, we re-run the models with their best configuration as provided in their respective implementations, when available. To be consistent with all the baselines we initialize the text encoder of REMix with the `bert-base-cased` model architecture and pre-trained weights. Full details of all the hyperparameters can be found in Appendix A.2.

5.3 Main Results

Table 2 shows F1 results of all baseline models and our proposed model, REMix, on the four datasets when leveraging various amounts of labelled data and 50% unlabelled data. We report the mean and standard deviation of 5 different runs (with different seeds) of training and testing. REMix gives state-of-the-art performance on 10 out of 12 different configurations across all four datasets. This reinforces the importance of consistency regularization beyond the currently popular self-training methods for SSRE. Interestingly, the performance gains are significantly higher for TACRED and RE-TACRED datasets–we see an average improvement of as much as 17% when trained on 3% labelled data. This can be attributed to the fact that entity type information is available for these datasets and entity type markers are very effective in exploiting the knowledge embedded in the pre-trained language models. We revisit this observation in our ablation studies (§5.4) where we concretely establish the benefits of using entity type markers.

5.4 Analysis and discussion

We first conduct experiments to empirically demonstrate the effectiveness of three components of our proposed model: i) data augmentation by latent space interpolation (Mix-DA), ii) data augmentation by constrained back-translation (BT-DA), and iii) entity type markers (ET). In Table 3, we report the mean F1 score of five different runs for different variations of our model by removing a certain combination of these components[6]. As can be seen from Table 3, each of these components contributes to the overall success of REMix. For contribution of just the Mix-DA: we compare i) row 1 v/s row

---

[6] We omit standard deviation values for brevity. See the full results and comparisons in Appendix B

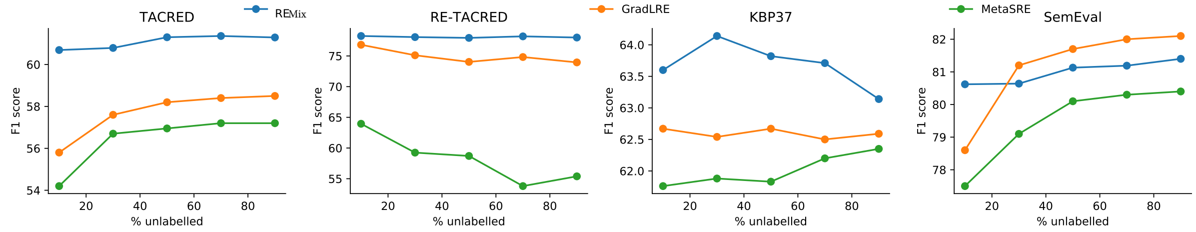

Figure 3: F1 Performance with various unlabelled data and 10% labelled data

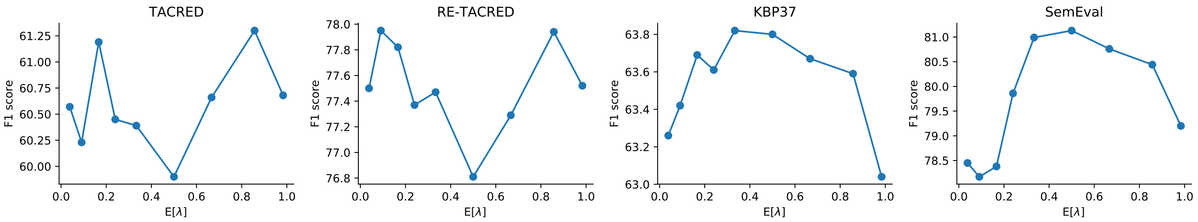

Figure 4: F1 Performance of REMix with 50% unlabelled and 10% labelled data with changing mixing coefficient λ

3, and ii) row 2 v/s row 4. All comparisons show positive improvement. For contribution of just the BT-DA: we compare i) row 1 v/s row 2, and ii) row 3 v/s row 4. We note that BT-DA results only in marginal improvements in most cases. Upon closer inspection we note that the constrained-decoding algorithms we implement for BT-DA are actually not perfect, especially when combined with translation models. It sometimes misses the constraints and sometimes falls into repetitive loops in an attempt to satisfy the constraint. With the ever-improving language generation capabilities, we believe the quality of data augmentation will only improve with time and result in more significant performance improvements. For contribution of both DA techniques together: we compare row 1 v/s row 4. All comparisons show significant improvements with data augmentation. The contribution of entity type markers can be noted in TACRED and RE-TACRED datasets. We see an average drop of 5.4% in F1 score across all 8 comparisons. Although our data augmentation techniques are effective, without the entity type information our method doesn't result in state-of-the-art performance. This reinforces our architectural choice to include entity type markers when using `[CLS]` token for relation representation (§4.2).

Table 3: Ablation results on all datasets using 10% labelled set and 50% unlabelled set.

Mix.	BT-DA	ET	TACRED	RE-T	KBP37*	SemEval*

* these datasets do not have entity type information

Next we examine the effect of using different amounts of unlabelled data. In Figure 3, we report the average F1 score for different models trained with different amounts of unlabelled data and 10% labelled data. REMix outperforms the baselines in all settings except on SemEval dataset, and, interestingly, the performance only marginally changes with the change in the amount of unlabelled data. Note that we train the models until the performance on the validation set stops improving for more than 5 epochs. Hence, REMix generates, in principle, an infinite amount of unlabelled data via the mixup strategy. Coupled with the fact that the label distribution remains the same in all settings, adding more unlabelled data does not seem to add a lot of new information. This explains why the model performance is relatively insensitive to changing amounts of unlabelled data. This also implies that REMix can leverage low amounts of unlabelled data better than the baselines.

Finally, in Figure 4 we show how the performance of REMix changes with a change in the mean of the Beta distribution from which λ is sampled on each iteration. Note that a value near 0 and 1 for λ means the augmented *virtual* data point will be closer to one of the underlying data points. As we get closer to 0.5 the virtual data points get further from the original data manifold and become more 'novel'. On TACRED and RE-TACRED datasets the performance peaks at $\mathrm{E}(\lambda) = 0.15(\text{or } 0.85)$ and drops in the mid-values. This can be interpreted as: adding datapoints far from the original data manifold is detrimental for these datasets. Interestingly, on KBP37 and SemEval the pattern inverts, i.e., the performance increases as $\mathrm{E}(\lambda)$ approaches 0.5, implying that more 'novel' augmentations help for these datasets.

6 Conclusion

In this paper, we propose a consistency-training-based semi-supervised algorithm for relation extraction and empirically show the merit of this class of methods in comparison to the current state-of-the-art *self-training* class of methods. In future work, one could bootstrap the self-training methods with consistency training as done in some previous works on vision tasks (Pham et al., 2021). Additionally, we show how the entity type information, when available, can result in massive performance boosts in the semi-supervised scenario. This is important because in most practical use cases when entities have already been identified, the entity type information is easy available and could be effectively leveraged in the proposed fashion.

7 Limitations

One of the key limitations of our proposed method compared to the baseline methods is the tight dependence on a strong external translation system to get good quality back-translated data augmentations. Secondly, since we use `[CLS]` token embeddings instead of entity-specific embeddings for final classification, it is more challenging to decipher entity-specific context. This is evident from the fact that our method performs relatively the weakest on the SemEval dataset which consists of untyped nominals (concepts) as entities and abstract relations which we believe need more entity-specific context to understand. Hence, our proposed method, REMix, shines bright when the entities in the dataset are typed or named entities whose meaning or type is relatively context-agnostic.

A Reproducibility checklist

A.1 Datasets

The sources of all the datasets are given in Table 4. We use the given train/validation/test splits for TACRED, RE-TACRED and KBP37 datasets. For SemEval dataset, we use the same splits as all the baselines, i.e., we split the original training set into 90% training set and 10% validation set.

A.2 Hyperparameters

We use the BERT tokenizer and set maximum sequence length to 256 to pre-process all datasets. We use the AdamW optimizer (Loshchilov and Hutter, 2019) with 5e-5 learning rate and 0.1 warmup ratio. We sweep over the following hyperparameters: sharpening coefficient T, confidence threshold γ, the Beta-distribution parameters (α, β)[7], and the unsupervised loss weight γ_m. We perform incremental grid search to get the best performing configuration based on the F1 score on validation set. Table 5 shows the set of values we use for each parameter. Table 6 shows the best parameter values on each dataset and configuration. Following Chen et al. (2020b), we use {7, 9, 12} for the mixup layer set; this layer subset contains most of the syntactic and semantic information as suggested by Jawahar et al. (2019).

Table 5: Hyperparameter search values

Parameter	Values
T	{0.4, 0.6, 0.8, 1.0}
γ	{0, 0.15, 0.2, 0.25}
β	{1, 10, 30, 60, 120, 190, 300, 600}*
γ_m	{0.01, 0.1, 1}

* corresponding means of the sampled mixing coefficient, λ, are given by {0.04, 0.09, 0.17, 0.24, 0.33, 0.50, 0.67, 0.86, 0.98}

Table 6: Best hyperparameter values

	TACRED			KBP37		
	3%	10%	15%	5%	10%	30%
T	0.8	0.8	0.8	0.8	0.8	0.8
γ	0.15	0.15	0.90	0.25	0.25	0.70
β	10	10	10	120	120	190
γ_m	0.01	0.1	0.1	0.1	1.0	1.0
	RE-TACRED			**SemEval**		
	3%	10%	15%	5%	10%	30%
T	0.4	0.4	0.4	0.8	0.8	0.8
γ	0.0	0.0	0.9	0.2	0.2	0.7
β	10	10	10	60	60	60
γ_m	0.01	0.1	0.1	0.1	1.0	1.0

A.3 Training details

We train each model on a single NVIDIA Tesla T4 GPU with 16GB memory. We employ mixed precision training and gradient checkpointing techniques for faster and memory-efficient training. Note that we train the models until the performance on the validation set plateaus. The full REMix model roughly takes about 6 hours to train on TACRED, 5 hours in RE-TACRED, 1 hour in KBP37, and about 30 minutes on SemEval. Note that the training time slightly varies (± 30 minutes) depending on the percentage of labelled and unlabelled data we use. The number of parameters in all our models are largely dominated by the `bert-base-cased` that we use as the text encoder. The relatively negligible varying component is the MLP classifier that varies with the varying number of relations in each dataset.

B Full Ablation results

We conduct experiments to empirically demonstrate the effectiveness of three components of our proposed model: i) data augmentation by latent space interpolation, ii) data augmentation by constrained back-translation, and iii) entity type mark-

[7] α is fixed to be 60 and we change the values of β to control the mean of the distribution

Table 7: F1 score with 10% of labelled data and 50% unlabelled data. Mean and standard deviation of 5 different runs is reported.

	Mix.	BT aug.	Ent. type	TACRED	RE-TACRED	KBP37	SemEval
a)	✓	✓	✓	61.30± 0.70	77.94± 0.59	63.82± 0.71	81.13± 0.82
			✗	56.82± 0.64	75.11± 1.16		
b)	✓	✗	✓	60.81± 1.31	77.77± 0.96	63.48± 0.53	79.71± 0.83
			✗	56.35± 0.97	74.67± 1.04		
c)	✗	✓	✓	59.65± 0.92	76.80± 0.98	62.64± 0.69	79.17± 1.64
			✗	55.52± 0.89	73.78± 1.34		
d)	✗	✗	✓	58.96± 1.21	77.25± 0.70	63.14± 0.90	79.20± 0.32
			✗	55.25± 1.53	74.58± 0.91		

ers. In Table 7, we report the performance of different variations of our model by removing a certain combination of these components. As can be seen from Table 7, each of these components contributes to the overall success of REMix. To see the impact of data augmentation by latent space interpolation, we compare the results in row 'a' with the corresponding ones in row 'c', and similarly row 'b' with row 'd'. We see a significant and consistent drop in every comparison with and without that component. Specifically, we see a drop of an average 1.6% in F1 score over all the 12 comparisons. Another interesting pattern that stands out is the significant and consistent drop in performance (average 5.4% in F1 score across all 8 comparisons) when not using entity type markers. When we drop the entity type markers from the input representation, we use the basic entity start and end markers– `[E1]`, `[/E1]`, `[E2]`, `[/E2]`. This only applies to TACRED and RE-TACRED since only these datasets have entity type information readily available. Note that when we do not use any of the data augmentations, consistency training is not possible and we are effectively using only the labelled set for training the model (fourth row in Table 7). Surprisingly, even without any unlabelled data using the entity type markers alone gives better performance than the current state-of-the-art results by GradLRE (Hu et al., 2021b), i.e., an F1 score of 58.96 vs 58.20 on TACRED and 77.25 vs 74.03 on RE-TACRED. This proves the effectiveness of using entity type information in the fashion we use, i.e., by tokenizing the type words to leverage the knowledge embedded in pre-trained language models.

Event Temporal Relation Extraction with Bayesian Translational Model

Abstract

Existing models to extract temporal relations between events lack a principled method to incorporate external knowledge. In this study, we introduce *Bayesian-Trans*, a Bayesian learning-based method that models the temporal relation representations as latent variables and infers their values via Bayesian inference and *translational functions*. Compared to conventional neural approaches, instead of performing point estimation to find the best set parameters, the proposed model infers the parameters' posterior distribution directly, enhancing the model's capability to encode and express uncertainty about the predictions. Experimental results on the three widely used datasets show that Bayesian-Trans outperforms existing approaches for event temporal relation extraction. We additionally present detailed analyses on uncertainty quantification, comparison of priors, and ablation studies, illustrating the benefits of the proposed approach.[1]

1 Introduction

Understanding events and how they evolve in time has been shown beneficial for natural language understanding (NLU) and for a growing number of related tasks (Cheng et al., 2013; Wang et al., 2018; Ning et al., 2020; Geva et al., 2021; Sun et al., 2022). However, events often form complex structures with each other through various temporal relations, which is challenging to track even for humans (Wang et al., 2020a).

One of the main difficulties is the wide variety of linguistic expressions of temporal relations across different contexts. Although many of them share some linguistic similarities, most of the topics in which they occur are characterized by some shared but unspoken knowledge that determines how temporal information is expressed. For example, when it comes to health, prevention is widely practised, with many treatments (e.g., vaccinations) being effective only if administered *before* the onset of a disorder. On the contrary, in the automotive industry, it is common that most people repair their car *after* a problem occurs. However, despite its simplicity, such commonsense knowledge is rarely stated explicitly in text and varies greatly across different domains. For example, in Figure 1, a detection model lacking the commonsense knowledge that *vaccination* can protect people from infection, tends to get confused by the complex linguistic structures in the excerpt and returns the wrong prediction entailing that '*died*' happens `after` '*vaccinated*'. Instead, with the consideration of prior temporal knowledge involving the *vaccination* event from an external knowledge source ATOMIC (Hwang et al., 2021), a model gives the correct prediction that '*died*' occurs `before` '*vaccinated*'.

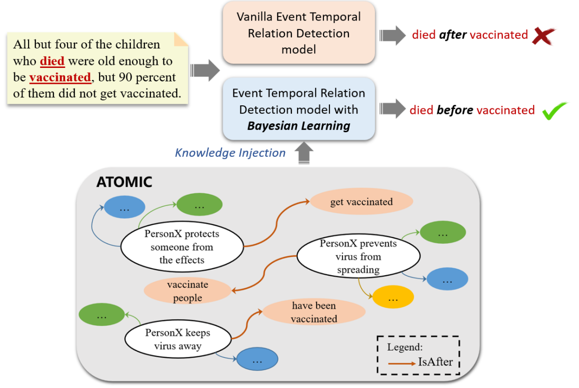

Figure 1: Comparison between with or without external knowledge incorporation on event relation extraction.

Methods proposed in recent studies for event relation extraction are mostly end-to-end neural architectures making rather limited use of such commonsense knowledge (Han et al., 2019a,b). Only a few works have explored the incorporation of external knowledge to mitigate the scarcity of event annotations (Ning et al., 2019; Wang et al., 2020b).

Nevertheless, these approaches typically update the event representations with knowledge features derived from external sources, lacking a principled way of updating models' beliefs in seeing more data in the domains of interests.

In this work, we posit that the Bayesian learning framework combined with translational models can provide a principled methodology to incorporate knowledge and mitigate the lack of annotated data for event temporal relations. Translational models, such as TransE (Bordes et al., 2013), are energy-based models based on the intuition that the relations between entities can be naturally represented by geometric translations in the embedding space. More concretely, a relation between a *head entity* and a *tail entity* holds if there exists a *translational* operation bringing the *head* close to the *tail* vector.

Specifically, we introduce a novel Bayesian Translational model (Bayesian-Trans) for event temporal relation extraction. Compared to conventional neural translational models, which only yield a point estimation of the network parameters, the Bayesian architecture can be seen as an ensemble of an infinite number of neural predictors, drawing samples from the posterior distribution of the translational parameters, refining its belief over the initial prior. As a result, event temporal relations are determined by the stochastic translational parameters drawn from posterior distributions. Additionally, such posteriors are conditioned upon the prior learned on external knowledge graphs, providing the commonsense knowledge required to interpret more accurately the temporal information across different contexts. As shown in the results obtained from the experimental evaluation on three commonly used datasets for event temporal relation extraction, the combination of translational models and Bayesian learning is particularly beneficial when tailored to the detection of event relations. Moreover, a favorable by-product of our Bayesian-Trans model is the inherent capability to express degrees of uncertainty, avoiding the overconfident predictions on out-of-distribution context. Our contributions are summarized in the following:

- We formulate a novel Bayesian translational model for the extraction of event temporal relations, in which event temporal relations are modeled through the stochastic translational parameters, considered as latent variables in Bayesian inference.
- We devise and explore 3 different priors under Bayesian framework to study how to effectively incorporate knowledge about events.
- We conduct thorough experimental evaluations on three benchmarking event temporal datasets and show that Bayesian-Trans achieves state-of-the-art performance on all of them. We also provide comprehensive analyses of multiple aspects of the proposed model.

2 Related Work

This work is related to at least three lines of research: event temporal relation detection, prior knowledge incorporation, and graph embedding.

2.1 Event Temporal Relation

Similar to entity-level relation extraction (Zeng et al., 2014; Peng et al., 2017), the latest event temporal relation extraction models are based on neural networks, but in order to learn from limited labeled data and capture complex event hierarchies, a wide range of optimization or regularization approaches have been explored. Ning et al. (2019) proposed an LSTM-based network and ensured global consistency of all the event relations in the documents by integer linear programming. Wang et al. (2020b) employed RoBERTa (Liu et al., 2019) and converted a set of predefined logic rules into differentiable objective functions to regularize the consistency of the relations inferred and explore multi-task joint training. Tan et al. (2021) proposed using hyperbolic-based methods to encode temporal information in a hyperbolic space, which has been shown to capture and model asymmetric temporal relations better than their Euclidean counterparts. Hwang et al. (2022) adopted instead a probabilistic box embeddings to extract asymmetric relations. Wen and Ji (2021) proposed to add an auxiliary task for relative time prediction of events described over an event timeline. Cao et al. (2021) developed a semi-supervised approach via an uncertainty-aware self-training framework, composing a training set of samples with actual and pseudo labels depending on the estimated uncertainty scores. None of the aforementioned approaches explored Bayesian learning for incorporating prior event temporal knowledge.

2.2 Incorporation of Prior Knowledge

Knowledge plays a key role in understanding event relations because people often skip inessential details and express event relations implicitly which is difficult to understand without relevant knowledge. For example, TEMPROB (Ning et al., 2018b) contains temporal relation probabilistic knowledge which is encoded by Siamese network and incorporated into neural models as additional features (Ning et al., 2019; Wang et al., 2020b; Tan et al., 2021). Unlike previous works, we combine the Bayesian Neural Network with distance-based models, treating the translational parameters as latent variables to be inferred. To this end, we adopt the variational inference (Kingma and Welling, 2014a; Blei et al., 2016; Gui et al., 2019; Pergola et al., 2021a; Zhu et al., 2022), and derive the prior distribution of the temporal relation information from commonsense knowledge bases (Pergola et al., 2021b; Lu et al., 2022). Christopoulou et al. (2021) explored a similar intuition of using knowledge base priors as distant supervision signals, but the approach and the task are different.

2.3 Graph Embedding Learning

Multi-relational data are commonly interpreted in terms of directed graphs with nodes and edges representing entities and their relations, respectively. Several works have recently focused on modelling these multi-relational data with relational embeddings by detecting and encoding local and global connectivity patterns between entities.

TransE (Bordes et al., 2013) has been a seminal work adopting geometric translations of entities to represent relations in the embedding space. If a relation between a head and a tail entity holds, it is encoded via the translational parameters learned at training time. However, TransE cannot model symmetry relation well by simple addition which led to several subsequent studies exploring diverse types of transformation resulting in a family of *translational models* (Wang et al., 2014; Ji et al., 2015; Lin et al., 2015). Among them, Balazevic et al. (2019) proposed to utilize the Poincaré model, mapping the entity embeddings onto a Poincaré ball, and using the Poincaré metric to compute the score function and predict their relations. Chami et al. (2020b) further expanded the idea of embedding learning over manifolds by additionally considering reflections and rotations and redefining the translation over a learned manifold.

Although translational models are shown efficient in modeling graph relation, they provide relatively limited interaction between nodes than neural network-based methods, such as Graph Neural Networks (Estrach et al., 2014; Chami et al., 2020a). Under this framework, nodes in a graph are neural units, which can iteratively propagate information through edges, and whose representations are learnt during the training process. In particular, Relational Graph Convolutional Networks (RGCN) (Schlichtkrull et al., 2018) encode relational data through link prediction and entity classification tasks, while enforcing sparsity via a parameter-sharing technique. Although modeling knowledge graphs has been one of the main focuses of the above-mentioned graph learning approaches, they lack any systematic mechanism to inject prior knowledge and update it during training.

3 Bayesian-Trans Model

In identifying temporal relations between events, we aim at predicting the relation type of two events given in text, commonly denoted as *head* event x_h and *tail* event x_t:

$$\hat{y} = \arg\max_{y \in \mathcal{R}} p(y|x_h, x_t) \tag{1}$$

where $\mathcal{R}$ denotes a set of possible relation types, while x_h and x_t the head and tail event triggers, respectively. Assuming that a set of latent variables $\mathbf{\Lambda}$ denotes the collection of all relation-specific transformation parameters $\mathbf{\Lambda}_r$. For example, in the knowledge embedding learning model such as MuRE (Balazevic et al., 2019), the head entity is first transformed through a relation-specific matrix $\mathbf{W}_r$, followed by a relation-specific translation vector t_r, then $\mathbf{\Lambda}_r = \{\mathbf{W}_r, t_r\}$. By Bayesian learning, the probability of inferring a relation type r can be written as:

$$p(y = r|x_h, x_t) = \int_{\mathbf{\Lambda}} p(y_r|x_h, x_t, \mathbf{\Lambda}) p(\mathbf{\Lambda}|\mathcal{G}) d_{\mathbf{\Lambda}} \tag{2}$$

Here, $p(\mathbf{\Lambda}|\mathcal{G})$ denotes the prior distribution of $\mathbf{\Lambda}$ derived from an existing knowledge graph encoded as $\mathcal{G}$. Directly inferring Eq. (2) is intractable. But we can resort to amortised variational inference to learn model parameters. In what follows, we present our proposed Bayesian learning framework built on translational models for event temporal relation extraction, called **Bayesian-Trans**, with its architecture shown in Figure 2.

In particular, the context S in which the two events occur is the input to our Bayesian-Trans. First, we encode S via a pre-trained language model generating the contextual embeddings e_h and e_t for the triggers of the head and tail events,

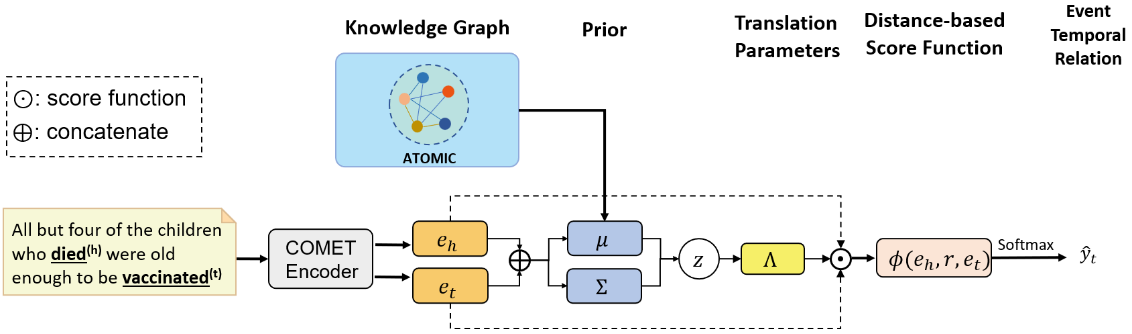

Figure 2: The network structure of Bayesian-Trans. Context sentences are first fed into a COMET encoder to generate event representations. With MLP layers, the event representations are mapped to generate a variational distribution of relation representations which is guided by KG priors. The relation representations are then used in the translational model to generate prediction scores.

respectively. The contextualised event trigger representations, e_h and e_t, are fed as input into a Bayesian translational module. This module, by means of variational inference, determines the parameters of the translational model, encoding the posterior distribution of the temporal relations conditioned upon the input events. Finally, we use a score function on the translated head and tail triggers to predict their temporal relation. We provide a more detailed description in the following.

3.1 Contextual Encoder

The proposed model uses COMET-BART (Hwang et al., 2021) as the context encoder. COMET-BART is a BART pre-trained language model (Lewis et al., 2020) fine-tunned on ATOMIC (Bosselut et al., 2019; Hwang et al., 2021), which is an event-centric knowledge graph encoding inferential knowledge about entities and events, including event temporal relations. The COMET-BART is able to generate consequence events given the antecedent event and a relation with good accuracy thus is regarded encodes knowledge well. Following the approach adopted in previous works (Ning et al., 2019; Wang et al., 2020b; Tan et al., 2021), we use the representation of the first token of an event trigger as the contextual embedding of that event[2], $\mathrm{e}_h, \mathrm{e}_t = \text{COMET-BART}(x_h, x_t)$, where $\mathrm{e}_h, \mathrm{e}_t \in \mathbb{R}^d$. The event representations are then concatenated together and fed through MLPs to generate the parameters of the variational distribution, from which the latent event-pair representation z is sampled. z is then mapped to the parameter space of the translational model as $\mathbf{\Lambda}$.

3.2 Incorporating Knowledge via Bayesian Learning

The proposed model utilizes relation embeddings for classifying event relation in a similar manner as the translational models in knowledge graph embedding, such as TransE (Bordes et al., 2013). If the embedding of the tail event is close enough to the embedding of head event after applying a series of relation-specific transformation, the relation stands, and vice versa. A wide range of translational models typically proposed for learning knowledge graph embeddings can be adopted in the proposed Bayesian-Trans. Additionally, to incorporate prior knowledge, we extend translational models to operate within the Bayesian inference framework. We proceed with introducing a standard translational model in the context of temporal relations, and describe how we extend it to work in the Bayesian framework.

Translational Model Generally speaking, a translational model uses *relation representations* $\mathbf{\Lambda}_r$ to perform "translation" for relation r on the head and tail events. Then, the transformed head and tail event embeddings are compared using a *distance-based score function*, whose score is indicative of the temporal relation between the events. The score function $\phi(\cdot)$ takes the general form:

$$\phi(\mathrm{e}_h, r, \mathrm{e}_t) = -d(\mathcal{T}^h_{\mathbf{\Lambda}_r}(\mathrm{e}_h), \mathcal{T}^t_{\mathbf{\Lambda}_r}(\mathrm{e}_t)) \qquad (3)$$

where r is a relation type, $\mathcal{T}_{\mathbf{\Lambda}_r}(\cdot)$ is a function depending on the parameters $\mathbf{\Lambda}_r$ of relation r to transform the event embeddings e_h and e_t, and $d(\cdot)$ is any distance metrics (e.g., Euclidean distance).

---

[2] We conducted some exploratory experiments adopting the last token or the average representation, but results showed that the first token was still the best option in this context.

We explored several models with different translation functions and distance metrics in the context of temporal relations, including TransE (Bordes et al., 2013), AttH (Chami et al., 2020b), MuRE (Balazevic et al., 2019) and MuRP (Balazevic et al., 2019), and based on our preliminary results[3], we eventually adopted MuRE as it strikes a good balance of training efficiency and accuracy of temporal relation classification. We define the scoring function in the proposed model as follows:

$$\phi(\mathrm{e}_h, r, \mathrm{e}_t) = -\|\mathbf{W}_r \mathrm{e}_h + \mathrm{t}_r - \mathrm{e}_t\|_2^2 \tag{4}$$

where $\mathbf{W}_r \in \mathbb{R}^{d \times d}$ is a diagonal relation matrix and $t_r \in \mathbb{R}^d$ a translation vector of relation r, $\mathbf{\Lambda}_r = \{\mathbf{W}_r, \mathrm{t}_r\}, r \in \mathcal{R}$.

Although the number of parameters to train is rather low, the number of annotated samples is usually small compared to the wide range of linguistic expressions capturing temporal relations. We thus extend the MuRE model into a Bayesian framework to enhance its scalability by treating the translational parameters $\mathbf{\Lambda}$ as latent variables. The proposed framework enhances generalization by defining a variational inference process that optimizes the regularization and leverages the additional information injected via the prior distributions.

Bayesian Inference As shown in the inference equation 2, the prior is derived from an external knowledge graph, such as ATOMIC, as a means to inject prior information about events and temporal relations. In particular, $\mathbf{\Lambda}$ is assumed to follow a Gaussian distribution with unit variance and with mean determined by the relation representations trained on the knowledge graph. The probability function is formulated as a softmax function over a pre-defined scoring function:

$$p(y_r|\mathrm{e}_h, \mathrm{e}_t, \mathbf{\Lambda}) = \frac{\exp\Big(\phi(\mathrm{e}_h, r, \mathrm{e}_t)\Big)}{\sum_{r' \in \mathcal{R}} \exp\Big(\phi(\mathrm{e}_h, r', \mathrm{e}_t)\Big)} \tag{5}$$

with e_h and e_t denoting the embedding for the head and the tail events, respectively.

Yet, Eq. (2) is intractable and cannot be inferred directly. Thus, we resort to amortized variational inference by introducing a variational posterior $q_\theta(\mathbf{\Lambda}|x_h, x_t)$, which follows the isotropic Gaussian distribution and can be modeled as:

$$\begin{gathered} \mu = f_\mu(\mathrm{e}_h; \mathrm{e}_t) \quad \Sigma = \mathrm{diag}\Big(f_\Sigma(\mathrm{e}_h; \mathrm{e}_t)\Big) \\ q_\theta(\mathbf{\Lambda}|\mathrm{e}_h, \mathrm{e}_t) = \mathcal{N}(\mathbf{\Lambda}|\mu, \Sigma), \end{gathered} \tag{6}$$

where f_μ and f_Σ are both fully connected layers that map the event pair representation into the parameters of the variational distribution.

Following the amortized variational inference, we maximize the evidence lower bound (ELBO) $\mathcal{L}_e$, defined in Eq. (7), and approximated by a Monte Carlo estimation with sample size N, as described in Eq. (8):

$$\begin{aligned} \mathcal{L}_e = \mathbb{E}_{q_\theta(\mathbf{\Lambda}|x_h, x_t), \{x_h, x_t\} \in \mathcal{D}} \Big[\log p_\theta(y|x_h, x_t, \mathbf{\Lambda})\Big] - \\ \mathrm{Reg}\Big(q_\theta(\mathbf{\Lambda}|x_h, x_t, \mathcal{G}) || p(\mathbf{\Lambda}|\mathcal{G})\Big) \quad (7) \\ \approx \frac{1}{N} \sum_{n=1}^{N} \sum_{\{x_h, x_t\} \in \mathcal{D}} \Big[\log p_\theta(y|x_h, x_t, \mathbf{\Lambda}^{(n)}) - \\ \mathrm{Reg}\Big(q_\theta(\mathbf{\Lambda}^{(n)}|x_h, x_t, \mathcal{G}) || p(\mathbf{\Lambda}^{(n)}|\mathcal{G})\Big)\Big] \quad (8) \end{aligned}$$

where $\mathrm{Reg}(\cdot)$ is a regularization term which will be discussed in 3.3. To train end-to-end a fully differentiable model, we adopt the reparameterization trick (Kingma and Welling, 2014b).

3.3 Prior Distribution and Regularization

We proceed to discuss how the Bayesian framework enabled the incorporation of prior acquired from an external knowledge source. Then, we provide the details of how we compute the regularization term to induce a more stable training.

Prior Distribution One of the main advantages of the Bayesian inference framework is the possibility to inject commonsense knowledge into the model through the prior distribution of the latent variables, i.e., $p(\mathbf{\Lambda}|\mathcal{G})$ in Eq. (2), where $\mathbf{\Lambda}$ are the translational parameters and $\mathcal{G}$ denotes an external knowledge graph, in our case, the ATOMIC knowledge graph (Hwang et al., 2021). ATOMIC is a commonsense knowledge graph containing inferential knowledge tuples about entities and events encoding social and physical aspects of human everyday experiences. For our task of event temporal relation extraction, we are only interested in the events linked via temporal relations, such as 'ISBEFORE' (23,208 triples) or 'ISAFTER' (22,453 triples). By conducting link prediction on these links, we use relation embeddings learnt using an RGCN (Schlichtkrull et al., 2018) as the mean of the prior distribution for the translational latent variables. For the relations in the experiment

---

[3] Experimental results using different translational models are shown in Table A1.

dataset that do not have applicable counterparts in ATOMIC (e.g., VAGUE), we set their priors to standard Gaussian. The variance of the priors is defined as the identity matrix.

Specifically, we use COMET-BART to encode the event nodes from ATOMIC, then use their context embeddings as the node features in the RGCN. In our preliminary experiment, we also found that RGCN cannot train well on the commonsense graph with only the event-event relation links. The graph is too sparse which makes the information difficult to propagate through the nodes. Thus, we added semantic similarity links based on the cosine similarity of the event context embeddings. During the training of the RGCN, the node embeddings are kept frozen. After the training of the link prediction task, we extract the relation embeddings of the RGCN.

Regularization Term To mitigate the posterior collapse problem (Lucas et al., 2019) and have a stable inference process, we adopt the Maximum Mean Discrepancy (MMD)[4] which is an estimation of Wasserstein distance (Tolstikhin et al., 2018) as the regularization term (Eq. 8).

4 Experimental Setup

Datasets We evaluated the proposed Bayesian-Trans model on three event temporal relation datasets: MATRES (Ning et al., 2018c), Temporal and Causal Reasoning (TCR) (Ning et al., 2018a), and TimeBank-Dense (TBD) (Cassidy et al., 2014). TimeBank-Dense is a densely annotated dataset focusing on the most salient events and providing 6 event temporal relations. MATRES follows a new annotation scheme which focuses on main time axes, with the temporal relations between events determined by their endpoints, resulting in a consistent inter-annotator agreement (IAA) on the event annotations (Ning et al., 2018c). TCR follows the same annotation scheme, yet with a much smaller number of event relation pairs than in MATRES. Table 1 shows the statistics of the datasets.

Class	MATRES	TCR	TBD
BEFORE	6,852	1,780	2,590
AFTER	4,752	862	2,104
EQUAL/SIMULTANEOUS	448	4	215
VAGUE/NONE	1,425	N/A	5,910
INCLUDE	N/A	N/A	836
ISINCLUDED	N/A	N/A	1,060
Total	12,740	2,646	12,715

Table 1: The statistics of MATRES, TCR, and TBD.

Baselines We compare the proposed Bayesian-Trans[5] with the following baselines:

CogCompTime (Ning et al., 2018d) is a multi-step system which detect temporal relation using semantic features and structured inference.

BiLSTM is a basic relation prediction model built by Han et al. (2019b).

LSTM + knowledge (Ning et al., 2019) incorporates knowledge features learnt from an external source and optimize global consistency by ILP.

Deep Structured (Han et al., 2019a) adds a structured support vector machine on top of a BiLSTM.

Joint Constrained Learning (Wang et al., 2020b) constrains the training of a RoBERTa-based event pair classifier using predefined logic rules, while knowledge incorporation and global optimization are also included.

Poincaré Event Embedding (Tan et al., 2021) learns event embeddings based on a Poincaré ball and determines the temporal relation base on the relative position of events.

HGRU + knowledge (Tan et al., 2021) is a neural architecture processing temporal relations via hyperbolic recurrent units which also incorporates knowledge features like LSTM + knowledge.

Relative Event Time (Wen and Ji, 2021) is a neural network classifier combining an auxiliary task for relative time extraction over an event timeline.

UAST (Cao et al., 2021) is an uncertainty-aware self-training model. We show the result of the model which is trained on all the labeled data.

5 Experimental Results

Temporal Relation Classification We first compare Bayesian-Trans with the most recent approaches for temporal event classification in Table 2, including methods with or without commonsense knowledge injection. The results are obtained by training models on the MATRES training set and evaluated on both the MATRES test set and TCR. Table 3 shows results from the TBD dataset which are generated using the provided train, development, and test sets. We report F_1 score on MATRES and TCR following the definition in (Ning et al., 2019), and micro-F_1 on TimeBank-Dense. Compared with existing methods, the proposed

(5) COMET-BART + Vanilla MuRE	81.8	62.6
(6) COMET-BART + Bayesian-Trans	**82.7**	**65.0**

Table 4: Ablation test results on MATRES and TBD.

Bayesian-Trans has generally better performance on all three datasets, with more noticeably improvements on MATRES. Bayesian-Trans has significant performance gains over previous methods with knowledge incorporation, which shows that it can utilize knowledge more extensively. Details of the per-class performance can be found in Table A2 and A3.

Ablation Study We conducted an ablation study to highlight the impact of the different modules composing Bayesian-Trans. The results are shown in Table 4. In particular, we have the following variants: (1) RoBERTa+MLP, using RoBERTa to encode the context and then feeding representations of head and tail events to a multi-layer perceptron (MLP) for temporal relation classification; (2) RoBERTa+ Vanilla MuRE, using MuRE to extract temporal relations without modeling its parameters as latent variables; (3) RoBERTa+Bayesian-Trans, our proposed model by replacing COMERT-BART with RoBERTa as the text encoder; (4) COMET-BART+MLP, using COMET-BART as context encoder and an MLP for temporal relation classification; and (5) COMET-BART+ Vanilla MuRE, the proposed model without Bayesian learning or knowledge incorporation. The results demonstrate that COMET-BART is a better choice as the context encoder. Using MuRE for event temporal knowledge embedding learning does not bring any improvement compared to using a simple MLP layer for event temporal relation prediction (see (1) cf. (2), and (4) cf. (5)). Regardless of the contextual encoder used, the results of (3) and (6) show the benefit of employing Bayesian learning which naturally incorporates prior knowledge of event temporal relations learned from an external knowledge source for event temporal relation detection. With our proposed Bayesian translational model, we observe an improvement of $0.9-1.8\%$ in micro-F$_1$ on MATRES and $0.2-2.5\%$ in micro-F$_1$ on TimeBank-Dense compare to their non-Bayesian counterparts.

Effects of the Priors We further investigate the impact of different priors on the model performance. Inspired by the work on VAEs by Burda et al. (2016) and Truong et al. (2021), we employed

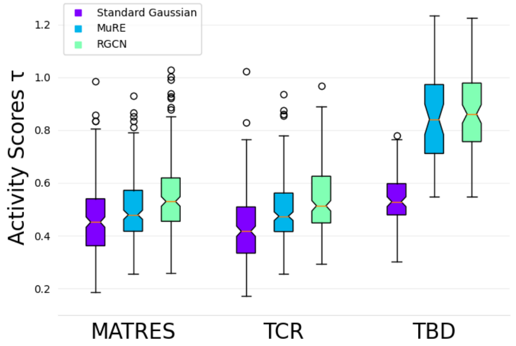

Figure 3: The box chart of the activity scores across all the dimensions of the latent encoding $\mathbf{\Lambda}$ with respect to the priors used in the model.

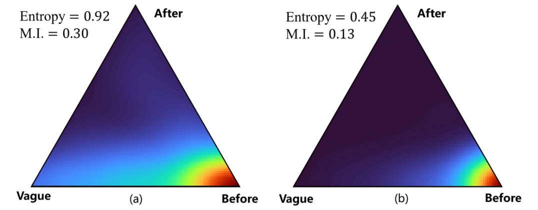
Dataset	Standard Gaussian	MuRE	RGCN
MATRES	81.2	81.8	82.7
TCR	84.3	85.4	86.1
TBD	63.6	64.6	65.0

Table 5: F_1 values based on different priors used in the proposed model.

an *'activity' score*, $\tau = Cov_{e_h,e_t}(\mathbb{E}_{q(\mathbf{\Lambda}|e_h,e_t)}[\mathbf{\Lambda}])$ to evaluate the quality and diversity of the latent encodings. The intuition behind the "activity" score is that if a latent dimension encodes relevant information and is not redundant, its value is expected to vary significantly over different inputs. By computing the score across all the test instances, every dimension of $\mathbf{\Lambda}$ is given an 'activity' value. Latent units with a higher value are considered more active and thus more informative. Figure 3 shows activity scores with respect to different prior distributions, including the standard Gaussian prior and priors learned on ATOMIC using MuRE or RGCN, in which the latent variables are the least active when using standard Gaussian as the prior distribution. The higher activation is obtained using the priors learnt on the external knowledge base. In particular, the prior based on RGCN and MuRE over ATOMIC displays the most active units, with RGCN showing the most active units on average. Table 5 shows the performance of the proposed model based on different priors. Two-sided Welch's t-test ($p < 0.05$) also supports that the RGCN-learned prior improves over standard Gaussian prior.

Uncertainty Quantification We present an analysis of uncertainty quantification of the Bayesian-Trans predictions. We adopted the uncertainty quantification methods as in Malinin and Gales



All but four of the children who died were old enough to be vaccinated , but 90 percent of them did not get vaccinated, CDC officials said

All of the children who died were old enough to be vaccinated, but 90 percent of them did not get vaccinated, CDC officials said

After departing for Jordan on Friday afternoon, Mr. Obama revealed that Mr. Netanyahu and Mr. Erdogan had just spoken by telephone

Figure 4: Examples of temporal relations in text and uncertainty quantification (entropy and mutual information) for the Bayesian-Trans model. Examples (*a*),(*b*) show how simplifying the linguistic structure without altering the temporal relation increases the model confidence. While examples (*c*),(*d*) illustrate the model's detection of temporal linguistic hints and its confidence.

(2018), computing the entropy (*total uncertainty*) and mutual information (*model uncertainty*) to visualize the predictive probabilities on a 2-simplex. Each forward pass on the same test instance is represented as a point on the simplex. For the sake of clarity of the visualization, we removed the EQUAL class, which is hardly ever predicted by the models.

In one of the test cases (Figure 4(a)), the true label is "*die*" BEFORE "*vaccinate*". This example exhibits a rather complex linguistic structure, as such, the model exhibits some uncertainty. Most of the predictions located at the corner are associated with BEFORE, but there also are several predictions scattered around it. We then simplified the sentence structure by removing "*but four*", and fed the modified sentence to the same model. This time, the model predicted the right temporal relation with much lower uncertainty (Figure 4(b)).

In another case study (Figure 4(c)), the true label is "*depart*" AFTER "*reveal*". This test case is rather straightforward, because of the explicit temporal word "before". The model predicted AFTER with high confidence, as shown by the predictive probabilities cluster at the top of the simplex. To show the impact of the temporal description, we swapped it from "*before*" to "*after*" and fed it to the same model. The model recognized the reversed meaning and correctly predicted BEFORE with low uncertainty (Figure 4(d)). The above cases demonstrate that the proposed model reacts to different inputs with reasonable uncertainty, on both the total and model uncertainty scores.

6 Conclusion

We propose a principled approach to incorporate knowledge for event temporal relation extraction named Bayesian-Trans, which models the relation representations in the MuRE translational model, as latent variables. The latent variables are inferred through variational inference, during which commonsense knowledge is incorporated in the form of the prior distribution. The experiments on MATRES, TCR, and TBD show that Bayesian-Trans achieves state-of-the-art performance. Comprehensive analyses of the experimental results also demonstrate the characteristics and benefits of the proposed model.

Limitations

Our approach takes an event pair as input for the prediction of their temporal relation. We observe that if two events reside in different sentences, the error rate increases by 19%. A promising future direction is to construct a global event graph where temporal relations of any two events are refined with the consideration of global consistency constraints, for example, no temporal relation loop is allowed in a set of events. Our current work only deals with even temporal relations, it could be extended to consider other event semantic relations such as causal, hierarchical or entailment relations. The event temporal knowledge in this paper is derived from ATOMIC which can possibly be extended to more sources. Bayesian learning could also be extended to life-long learning. But we need to explore approaches to address the problem of catastrophic forgetting. We didn't exhaustively investigate all the translational models due to the large volume of work in that area. There might be a translational model which can achieve better performance, but the core idea of the proposed framework stays the same.

Ethical Considerations

The goal of the proposed method is to understand the temporal relation between events based on the descriptions in the given text. What the method can achieve in the most optimistic scenario is no more than giving the same text to a human reader and letting him or her explain the event relations. Therefore, the ethical concerns only come from the data collection. In this paper, we only use publicly available datasets which have already been widely used in the research field. As for potential application, as long as the user collects the training data legally, the proposed method does not have the potential to have a direct harmful impact.

A Maximum Mean Discrepancy (MMD)

The Maximum Mean Discrepancy (MMD) can be unbiasedly estimated using the following equation (Nan et al., 2019):

$$\widehat{\mathrm{MMD}} = \frac{1}{N(N-1)} \sum_{n \neq m} f_k\left(z_n\,, z_m\,\right) + \frac{1}{N(N-1)} \sum_{n \neq m} f_k\left(\tilde{z}_n, \tilde{z}_m\right) - \frac{2}{N^2} \sum_{n,m} f_k\left(z_n, \tilde{z}_m\right)$$

where $z_1, ..., z_n$ are sampled from variational distribution q_ϕ and $\tilde{z}_1, ..., \tilde{z}_m$ are sampled from prior distribution p, $f_k(\cdot)$ is inverse multiquadratic knernel $f_k(x, y) = \frac{C}{C+||x-y||_2^2}$ which is often chosen for high-dimensional Gaussians.

Model	**Precision**	**Recall**	**F$_1$**
TransE	**80.0**	84.1	82.0
MuRP	75.4	85.8	80.2
AttH	76.2	**87.4**	81.4
MuRE	79.6	86.0	**82.7**

Table A1: The performance of the proposed Bayesian framework combined with different translational models on MATRES.

B Hyperparameter Settings and Resource Consumption

We conducted a grid-search to determine the optimal hyperparameters and dimensionality of the relation embeddings. The searching range for the dimension of the latent vector the transformation parameters is $[50, 200]$, with a step size of 50. As a result, on the MATRES, the dimension of the latent vector z is 200, the dimension of relation transformation vectors t_r or matrices W_r is 50, the dropout rate is 0.1. On the TBD, the dimension of the latent vector z is 100, and the dimension of relation transformation vectors t_r or matrices W_r is 100, dropout rate is 0. Based on the above settings, the number of parameters of the Bayesian-Trans is 443 thousand (excluding the COMET-BART). The COMET-BART encoder has 204 million parameters. The learning rate α_c for the context encoder is set to $1e-5$, while for other components of the architecture $\alpha = 1e-3$. To calibrate the influence of the regularization term, we set a scaling weight smoothly increasing from $1e-2$ to 2.0 during training. We ran the training for 60 epochs which is enough for the model to converge, and evaluated on the validation set after each training epoch.

All the experiments were conducted on an Nvidia GeForce RTX 3090 GPU. On the TBD dataset, the average training time is 93 seconds per epoch, while the inference time is 4 seconds. On the MATRES dataset, the average training time is 74 seconds per epoch, and the inference time is 7 seconds.

C Comparison of Translational Models

Table A1 shows the performance on MATRES using different translational models in the Bayesian framework. TransE (Bordes et al., 2013) is one of the most commonly used translational models, which only performs the addition transformation on the head event. AttH (Chami et al., 2020b) expands the idea of hyperbolic translational models by making the curvature learnable. It also introduces more types of transformation, reflection and rotation. MuRE (Balazevic et al., 2019) strikes a balance by conducting diagonal matrix transformation and addition transformation. MuRP (Balazevic et al., 2019) is the Poincarè version of MuRE, which projects the head and tail onto a Poincarè ball before performing scaling and addition. The score function of MuRP computes the Poincarè distance instead of the Euclidean distance.

We can observe that TransE performs well, beating the previous state-of-the-art ($F_1 = 81.7$) but gives slightly worse results compared to MuRE. Both translational models in the hyperbolic space, MuRP and AttH, are inferior to the Euclidean-based translational models. As MuRE gives more balanced precision and recall values, it is therefore adopted in our Bayesian learning framework.

Relation	**Precision**	**Recall**	**F$_1$**
BEFORE	82.66	90.40	86.35
AFTER	75.24	88.56	81.36
EQUAL	0.00	0.00	0.00
VAGUE	33.33	15.60	21.25

Table A2: Performance on each relation type class on MATRES.

D Class-Specific Results

In Table A2 and A3, We show the results obtained using Bayesian-Trans under each temporal relation

Relation	**Precision**	**Recall**	**F_1**
BEFORE	77.04	62.98	69.31
AFTER	76.37	62.20	68.56
SIMULTANEOUS	33.33	10.42	15.87
INCLUDES	36.84	10.29	16.09
ISINCLUDED	53.33	10.39	17.39
NONE	59.06	83.80	69.29

Table A3: Performance on each relation type class on TimeBank-Dense.

class on MATRES and TimeBank-Dense, respectively. On MATRES, the performance on BEFORE and AFTER are significantly better than for the other two classes. The model predicts no EQUAL labels, most likely caused by the scarce training data for this class. Previous works in the literature (Han et al., 2019b) have also shown similar class-specific results, with models struggling the most on the prediction of EQUAL and VAGUE relations. Similar conclusions can be drawn from the TimeBank-Dense dataset, that Bayesian-Trans performs relatively well on the BEFORE, AFTER and NONE classes, but performs worse on the other three minority classes.

Persona Expansion with Commonsense Knowledge for Diverse and Consistent Response Generation

Abstract

Generating diverse and consistent responses is the ultimate goal of a persona-based dialogue. Although many studies have been conducted, the generated responses tend to be generic and bland due to the personas' limited descriptiveness. Therefore, it is necessary to expand the given personas for more attractive responses. However, indiscriminate expansion of personas threaten the consistency of responses and therefore reduce the interlocutor's interest in conversation. To alleviate this issue, we propose a consistent persona expansion framework that improves not only the diversity but also the consistency of persona-based responses. To do so, we define consistency criteria to avoid possible contradictions among personas as follows: 1) Intra-Consistency and 2) Inter-Consistency. Then, we construct a silver profile dataset to deliver the ability to conform with the consistency criteria to the expansion model. Finally, we propose a persona expansion model with an encoder-decoder structure, which considers the relatedness and consistency among personas. Our experiments on the Persona-Chat dataset demonstrate the superiority of the proposed framework.

1 Introduction

In the field of open-domain dialogues, maintaining long-term interaction with users by generating human-like responses has been a persistent goal. As efforts along this line of research, persona-based dialogue models aim at generating more engaging and consistent responses based on personal traits (Li et al., 2016b; Qian et al., 2018). As the most widely used benchmark dataset, Persona-Chat (Zhang et al., 2018) consists of personal profiles, which contain 3-5 persona sentences (hereinafter referred to as "personas"), and dialogues conditioned on personas. With the Persona-Chat, many researches have attempted to improve the quality of responses from various perspectives (Song et al., 2020; Liu et al., 2020; Song et al., 2021; Cao et al., 2022). However, since the descriptiveness of personas is limited, they have difficulties in converting what personas imply into attractive responses.

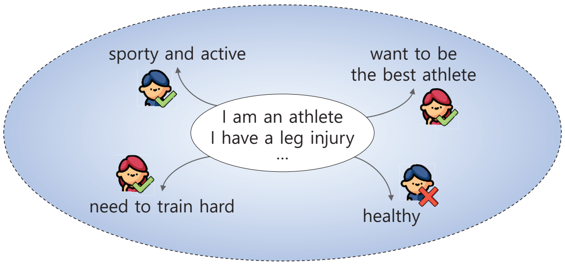

Figure 1: An example of persona expansion with commonsense. The center circle is the predefined profile, and the dashed circle is the valid expandable range.

Unlike dialogue models, humans converse beyond the explicit persona itself through rational reasoning with commonsense knowledge. The commonsense reasoning ability is essential for making an interlocutor engage in conversations with a dialogue agent. Figure 1 illustrates an example of persona expansion through commonsense reasoning. Given the persona '*I am an athlete*', it is possible to infer the characteristic '*sporty and active*' with high probability. The implications of '*want to be the best athlete*' and '*need to train hard*' are also predictable. In order to mimic human reasoning ability, previous works expand original personas (Majumder et al., 2020) or infer new personas from dialogue utterances (Kim et al., 2022). However, the consistency among expanded personas was not explicitly considered. To prolong a conversation, both the engagingness and the consistency of responses are very important. Therefore, we define the two consistencies that must comply with while improving the diversity of responses as follows: 1) **Intra-Consistency** and 2) **Inter-Consistency**. First, the Intra-Consistency means that expanded personas must not contradict the original persona.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1139–1149
May 2-6, 2023 ©2023 Association for Computational Linguistics

If the response conditioned on the expanded persona contradicts the original persona, the interlocutor loses interest in the conversation. Second, the Inter-Consistency means that expanded personas must not contradict other personas in the same profile. For instance, as shown in Figure 1, the attribute of '*healthy*' can be expanded from the original persona of '*I am an athlete*'. However, considering the other persona in the profile, '*I have a leg injury*', this comes to an inappropriate expansion. Therefore, it is necessary to follow the Intra- and Inter-Consistency when expanding personas to improve the persona-based responses.

To achieve the above goals, we propose a novel **P**ersona **E**xpansion framework with **C**ommonsense **K**nowledge (**PECK**). PECK aims to not only improve the diversity of responses but also avoid the problem of contradictions among personas. Both abilities to understand the relatedness and to reason with commonsense knowledge are required to satisfy the consistency criteria. Unfortunately, there are no supervised training datasets for persona expansion. Furthermore, it costs a lot to annotate them to train both abilities. Therefore, we build a silver profile dataset (see Section 4) similar to the gold profile in the Persona-Chat, with simple manipulation of the commonsense knowledge graph ANION (Jiang et al., 2021). In addition, we propose a persona expansion model (see Section 5) consisting of an encoder and a decoder for consistent expansion. The bidirectional encoder learns to understand the relatedness among personas within the same profile. Then, the auto-regressive decoder learns to expand personas consistently with negative log-likelihood (NLL) and unlikelihood (UL) (Welleck et al., 2019a) training objectives. Finally, we conduct extensive experiments on persona expansion and persona-based response generation. Experimental results confirm the superiority of the proposed consistent expansion framework.

The contributions of this work are as follows:

- A novel persona expansion framework that satisfies essential consistency criteria is proposed for attractive chit-chat responses.
- We generate consistent personas with a manipulated silver profile dataset and unlikelihood training objective.
- We show the effectiveness of the proposed expansion framework via experimental results.

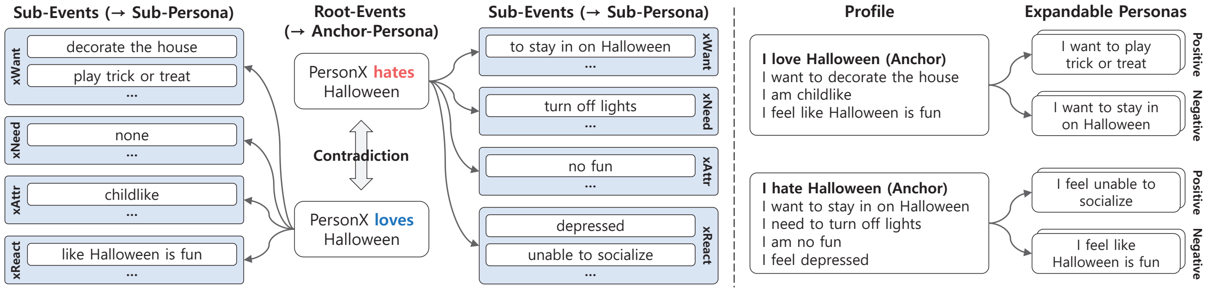
2 Related Work

2.1 Persona Expansion with Commonsense

COMPAC proposed by Majumder et al. (2020) makes a fine-grained choice of a persona to generate more engaging chit-chat responses. They expand the predefined personas leveraging COMET (Bosselut et al., 2019) trained with the commonsense knowledge of ATOMIC (Sap et al., 2019). For instance, COMET deduces expanded personas such as '*I am caring*, *I want to adopt a cat*' from the original persona '*I love animals*' along the nine relations in ATOMIC. Meanwhile, Kim et al. (2022) propose the dual task framework of debiasing persona-based dialogues via a data-driven approach. Similary, they utilize COMET to perform commonsense-based expansion before matching personas with utterances in a dialogue. The commonsense-based expansion in the conventional methods improves the engagingness of persona-based dialogues. However, they did not consider that consistency should be kept in the expansion process. To address this issue, we propose a novel approach of expanding personas and keeping the proposed Intra- and Inter-Consistency among them.

2.2 Commonsense Knowledge Graphs

As the demand for the representation of relations between real-world events, some recent studies on event commonsense knowledge graphs (CSKGs) have been conducted. ATOMIC (Sap et al., 2019) is an event-based CSKG, containing textual descriptions of inferential knowledge on real-world events. ATOMIC provides nine if-then causal relations, in which the reasoning such as causes and effects focuses on the agent (i.e., xAttr, xEffect, xIntent, xNeed, xReact, xWant.) or the other (i.e., oEffect, oReact, oWant). As a follow-up study, Hwang et al. (2021) propose ATOMIC-2020, which contains social and physical relations as well as eventive ones. Further, Jiang et al. (2021) introduce ANION, which focuses on negated and contradictory events contrary to the affirmative ones of ATOMIC. ANION contains 624k if-then rules consisting of negated and contradictory relations. We construct a silver profile dataset by leveraging the inter-event inferential commonsense of ANION via simple manipulation. And then, we compose positive and negative samples of unlikelihood training (Welleck et al., 2019a) for consistent persona expansion by leveraging the oppositions between each profile in the dataset.



(1) Examples of contradictory root-events and their sub-events

(2) Positive and Negative Training Samples

Figure 2: (1) An example of contradictory root-events and their sub-events in ANION. The root-event and its corresponding sub-events are designated anchor-persona and sub-personas, respectively. (2) Training samples for consistent persona expansion. Reasonable expansions are classified as positive samples E^+, and contradictories are classified as negative samples E^-.

3 Problem Statement

In this paper, our goal is to generate expanded personas, which contribute to improving the quality of persona-based responses. To do so, the consistency criteria that expanded personas must comply with are as follows: 1) **Intra-Consistency** and 2) **Inter-Consistency**. Formally, given an original persona $p_i \in P$, where $P = \{p_1, p_2, ..., p_n\}$ is the predefined profile, a persona expansion model aims to generate expanded personas $E_i = \{e_1, e_2, ..., e_m\}$, which do not contradict the original persona p_i and all the remaining personas in profile P. For the model to learn these consistencies, we need original-expandable persona pairs with a positive or negative label, and the profile where the original persona belongs. That is to say, the training dataset should contain {*Original Personas* (*Profile*), *Expandable Personas*, *Label*}. Regrettably, there are no training datasets of this form, and human annotation is expensive. Hence, we construct a new dataset, silver profile, appropriate for our expansion goal through simple manipulation on ANION, the existing commonsense knowledge graph. The detailed construction process will be described in Section 4. Finally, our model trained with the silver profile aims to generate expanded personas consistently from gold profiles within Persona-Chat.

4 Data Construction

Leveraging ANION, we construct a new dataset for training consistent persona expansion. Through exploratory analysis on Persona-Chat, we identified some prominent features of profiles. First, each profile is mostly made up of personas, which are correlated or at least non-contradictory to one another. In the gold profile example in Table 1, three of the five personas (1, 2, 3) are directly correlated, and the others are slightly related. Second, most of all personas indicate the speaker's preferences (i.e., I like –, I love –, I want –) or states (i.e., I am –). Based on these structural and semantical features of profiles, we build a silver profile dataset similar to the gold profile in Persona-Chat to train our expansion model. Statistics of the silver profile dataset are given in Appendix B.

Gold Profile	Silver Profile
1. I play football.	1. I love Halloween.
2. My position is linebacker.	2. I want to decorate the house.
3. I am an athlete.	3. I am childlike.
4. I had 128 tackles last year.	4. I feel like Halloween is fun.
5. My team is the baltimore ravens.	

Table 1: Examples of the gold profile from Persona-Chat and silver profile from ANION.

4.1 Profilizing Commonsense Events

With reference to the aforementioned feature of the profile, the *root-event* existing in ANION and the *sub-events* connected by if-then relations can be defined as the speaker's profile. In this case, the root-event selected for profilizing is the sentence described only for *PersonX*, not including *PersonY*.[1] As shown on the left of Figure 2, the root-event is defined as a dominant *anchor-persona* in the profile, and each sub-event is defined as a *sub-persona* that can be inferred from the anchor-persona. To filter mislinked relations out during ANION deployment, we leverage the RoBERTa (Liu et al., 2019) model fine-tuned with the MNLI

---

[1] In ANION, there are events related to the agent (i.e., *PersonX* –) and events related to the agent and the other people (i.e., *PersonX* – *PersonY* –). In this study, events with *PersonY* are excluded because we only handle personas representing the traits of agent '*I*'.

(Williams et al., 2018) dataset to verify the non-contradiction between a root-event and its sub-events. Also, based on the fact that most personas represent the speaker's preferences or states, we get sub-events from four if-then relations as follows: *xWant*, *xNeed*, *xAttr*, *xReact*. Then, we change the subject of each event to '*I*' and conduct subject-verb matching to convert them into a sentence of a persona type, such as <*PersonX loves Halloween*> → '*I love Halloween*'. An example of silver profile is shown on the right side of Table 1. If '*I love Halloween*' is the anchor-persona, then '*I want to decorate the house*' and '*I feel like Halloween is fun.*' are designated as sub-personas.

4.2 Assigning Expandable Personas to Profile

A silver profile has a maximum of five personas; one is the anchor-persona, and the others are sub-personas from four if-then relations. Since there are one or more sub-personas for each relation, sentences not designated as sub-personas can be assigned as expandable personas. As shown on the right side of Figure 2, '*I want to play trick or treat*' is not designated as a sub-persona, so it is treated as an expandable persona. Through this process, the expandable personas that can be inferred for the four relations are assigned to the profile.

4.3 Aligning Contradictory Profiles

Inspired by Li et al. (2020), we leverage NLL and UL objectives which require both positive and negative samples to endow the model with the consistent expansion ability. Therefore, we align the corresponding contradictory profiles to construct positive and negative samples. In ANION, negated root-events such as <*PersonX hates Halloween*> and <*PersonX does not loves Halloween*> contradict their affirmative <*PersonX loves Halloween*>. Using these opposites as pivots, we construct negative samples by swapping the expandable personas of each other. As shown on the right side of Figure 2, for profiles with '*I love Halloween*' as an anchor-persona, '*I want to play trick or treat*' is a positive expandable persona, and '*I want to stay in on Halloween*' comes to a negative one.

Definition 1 *A silver profile dataset is defined as* $D_{sp} = \{(P_i, E_i^{+/-})\}_{i=1}^{K}$*, where* P_i *is a synthetic profile,* $E_i^{+} = \{E_i^{want}, E_i^{need}, E_i^{attr}, E_i^{react}\}$ *is a set of expandable personas for four relations,* E_i^{-} *is a set of contradictories, and each* $E_i^{rel} = \{e_1^{rel}, e_2^{rel}, ..., e_{m_{rel}}^{rel}\}$ *consists of* m_{rel} *personas.*

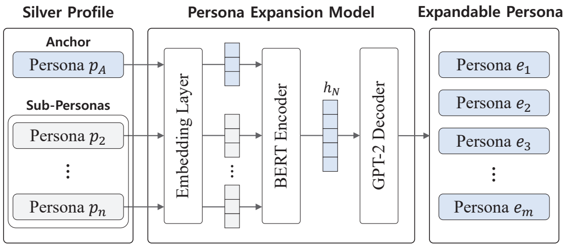


Figure 3: Overview of the proposed expansion model. In the training phase, the model leverages the silver profile dataset to learn consistencies among personas.

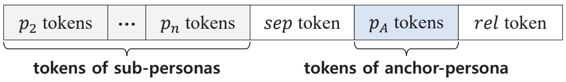

Figure 4: Input token template for training the persona expansion model.

5 Consistent Persona Expansion

5.1 Overview

In this section, we propose a novel consistent persona expansion model. To achieve the consistency criteria mentioned above, we design the model with an encoder-decoder structure as illustrated in Figure 3. The encoder learns to understand the relatedness among personas in the profile, and the decoder learns to consistently reason expandable personas with commonsense knowledge. This separated architecture allows the model to generate expanded personas satisfying the consistencies.

Formally, given a silver profile dataset D_{sp}, the model takes the profile $P = \{p_1, p_2, ..., p_n\}$ as input, where p_1 ($= p_A$) is the anchor-persona, and the others are sub-personas. Then, the target expandable personas are $E^{rel} = \{e_1^{rel}, e_2^{rel}, ..., e_{m_{rel}}^{rel}\}$.

5.2 Encoder

The encoder is initialized by the pre-trained BERT (Devlin et al., 2019) embedding to inherit its bidirectional language understanding ability.

The input consists of unfolded persona profile P to recognize a correlation among personas in the profile. As illustrated in Figure 4, a separate token $[sep]$ is placed between the sequence of sub-personas and the anchor-persona, and a relation token $[rel]$ is placed at the end of the input. The formatted input is as follows:

$$p_2, ..., p_n, [sep], p_A, [rel]. \tag{1}$$

Then, the embedding layer transforms each token of the input into a vector representation. At this time, the sum of the corresponding token and position embedding is used as the vector representation. The resulting vector representation is denoted as $input$. Next, the encoder takes the vector representation and performs multi-head attention (Vaswani et al., 2017) as follows:

$$h_{i+1} = FFN(MultiHead(h_i, h_i, h_i)), \quad (2)$$

where $MultiHead(query, key, value)$ calculates the scaled dot-product attention of query, key, value, $FFN(\cdot)$ is a fully connected feed-forward network, and $h_0 = input$. The encoder outputs the vector representation h_L after L identical layers. The vector representation h_L implies context information for expansion and the correlatedness among all personas in the profile.

5.3 Decoder

The decoder is initialized by the pre-trained GPT-2 (Radford et al., 2019) to leverage its robust autoregressive generation ability.

Unlike the encoder, the decoder adopts the cross-attention and left-to-right mask. First, the cross-attention is performed to reflect the context information among personas. In the cross-attention, the query is the vector representation from previous layer, and the output vector h_L of the encoder is given as the key and value:

$$v_{i+1} = FFN(MultiHead(v_i, h_L, h_L)), \quad (3)$$

where v_0 is initialized from the embeddings of the decoder input $e_j^{rel} (\in E^{rel})$ for given relation rel in Equation 1. Then, the decoder outputs the vector representation v_L after L identical layers. Finally, after the linear and softmax layer, we get the probabilities of each token in the output sequence.

5.4 Training Objectives

For the consistent persona expansion, we exploit negative log-likelihood loss (NLL) and unlikelihood loss (UL). NLL is a conventional objective function for generation tasks that maximizes the probability of the next target token. In contrast, UL is an objective function that minimizes the probability of the next target token, usually used to prevent the model from generating dull and repetitive sequences. In our setting, referred to Li et al. (2020), we use NLL and UL for positive samples (D_{sp}^{+}) and negative samples (D_{sp}^{-}), respectively. The expression for each sample is as follows:

$$D_{sp}^{+} = \{P, E^{+}\}, D_{sp}^{-} = \{P, E^{-}\}, \quad (4)$$

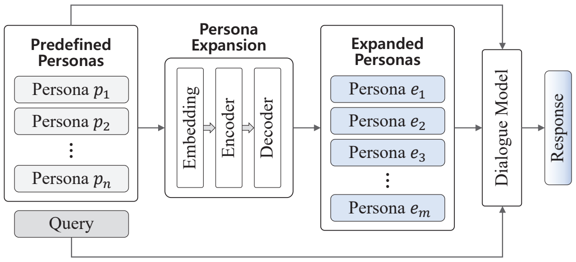

Figure 5: Response generation with persona expansion.

where P is the profile, E^{+} is the expandable personas, and E^{-} is the contradictory personas. For simplicity of expression, we omit the index notation i. See Definition 1 for the exact expression. The NLL and UL losses are calculated as follows:

$$L_{NLL}^{D_{sp}^{+}} = -\sum_{i=1}^{|e|} log(p_\theta(t_i | P, e_{<i})), \quad (5)$$

$$L_{UL}^{D_{sp}^{-}} = -\sum_{i=1}^{|e|} log(1 - p_\theta(t_i | P, e_{<i})), \quad (6)$$

where e is each persona in E^{+}/E^{-}, and t_i is the token of the persona e at time step i. The final objective function of the model computes the weighted sum of NLL and UL losses as follows:

$$Loss = \alpha L_{NLL}^{D_{sp}^{+}} + \beta L_{UL}^{D_{sp}^{-}}, \quad (7)$$

where α and β are hyperparameters. The optimized objective function is obtained with iterative loss back-propagation.

5.5 Persona Expansion

Through the training with silver profile, our model acquires the ability to understand the relatedness among input personas and to generate consistent expanded personas. The model is leveraged to expand the personas of the gold profile in the Persona-Chat. For each persona in the gold profile, we generate five expanded personas per relation (i.e., xWant, xNeed, xAttr, xReact) by beam-search decoding. Then, the number of expanded personas per an original persona comes to 20 (= 5 × 4).

5.6 Response Generation

After persona expansion, we generate diverse and consistent responses utilizing the original and expanded personas, as illustrated in Figure 5. In this paper, we leverage two dialogue models to prove the effectiveness of the proposed framework on response generation.

GPT-2 (Wolf et al., 2019): A GPT-2 model simply concatenates all personas with dialogue history. In our setting, up to five expanded personas with the highest NLI scores on the predefined profile are selected and fed into the dialogue model.

COMPAC (Majumder et al., 2020): A dialogue model that generates fine-grained persona-based responses through expansion and selection. In our setting, the expanded personas generated by PECK framework are selected by COMPAC and used for response generation.

6 Experiments

6.1 Dataset

We conducted experiments on both persona expansion and response generation with Persona-Chat, converted for the ConvAI2 benchmark (Dinan et al., 2020). The Persona-Chat consists of dialogues between two speakers, each utterance conditioned on personas in the speaker's profile. We generated the expanded personas using personas in the predefined profile. And we carried out the response generation using utterances and expanded personas. In our experiments, 16,878 instances were used for training, 1,000 for validation and 1,000 for testing.

6.2 Baselines

To verify the effectiveness of the constructed silver profile dataset and the proposed expansion model, the following three baseline models were adopted and compared.

1. **COMET$_{\textbf{ATOMIC}}$** (Bosselut et al., 2019): As a GPT-2 model fine-tuned on ATOMIC, it expands the original personas along the four relations mentioned above for comparison.
2. **COMET$_{\textbf{SP w/o UL}}$**: We fine-tuned the GPT-2 model with a silver profile dataset as a comparative model, which takes a concatenated sequence of personas as input. UL objective was not used in training.
3. **COMET$_{\textbf{SP w/ UL}}$**: We fine-tuned the GPT-2 using a silver profile dataset and UL with negative samples. The other settings except UL are the same as the above model.

6.3 Evaluation Metrics

6.3.1 Automatic Evaluation

Four metrics were utilized for automatic evaluation. We employed Perplexity (**PPL**), which measures how well a model predicts response tokens, where lower means better. We employed Distinct-1/2 (**Dist-1/2**) (Li et al., 2016a), which measures the diversity of sentences via calculating the ratio of distinct words against total uni/bi-grams. We employed F1 score of BERTScore (**F-BERT**) (Zhang et al., 2019), which measures how semantically relevant the expanded persona is to the original persona or generated response is to the selected persona. We employed Consistency Score (**C.Score**) (Madotto et al., 2019), which measures the consistency of the expanded persona (or response) for the predefined profile P. The scoring process is as follows:

$$NLI(p_i, e) = \begin{cases} 0, & \text{if } e \text{ contradicts } p_i, \\ 1, & \text{otherwise,} \end{cases} \tag{8}$$

$$C.Score(e) = \sum_{i=1}^{n} NLI(p_i, e), \tag{9}$$

where p_i is each persona in the profile P, and e is the expanded persona (or response) to score. RoBERTa was employed for the NLI model, which is fine-tuned with the DNLI (Welleck et al., 2019b) dataset. The Consistency Score is calculated, and scaled to a value between 0 and 1.

6.3.2 Human Evaluation

For qualitative assessment, we conducted evaluations by three annotators. We recruited annotators proficient in the language from an external agency. Annotators had sufficient knowledge of the domain but knew nothing of the proposed model. During the evaluation, there was no interaction among annotators that could affect each other's ratings. Also, annotators were properly compensated for the work they performed.

We randomly selected 100 samples each to evaluate persona expansion and response generation. Human annotators were asked to evaluate samples with the following four metrics: (1) Engagement, (2) Relevance, (3) Diversity, (4) Intra-Consistency, and (5) Inter-Consistency. Ratings range from 1 to 5, with higher scores indicating better. Intra-Consistency measures the consistency between the expanded persona and the original persona. Inter-Consistency is scaled to a value between 1 to 5, after summing up the one-to-one Intra-Consistency score between the expanded persona and each persona in the profile. Further, we conducted human A/B test that provide consensus among annotators for consistency.

Model	Automatic Evaluation				Human Evaluation			
	Dist-1	Dist-2	F-BERT	C.Score	Engagement	Relevance	Intra-Con.	Inter-Con.
$\text{COMET}_{\text{ATOMIC}}$	0.041	0.162	0.806	0.54	2.92	3.01	3.04	2.24
$\text{COMET}_{\text{SP w/o UL}}$	0.044	0.165	0.810	0.66	3.08	3.06	3.12	2.67
$\text{COMET}_{\text{SP w/ UL}}$	0.043	0.164	0.818	0.70	3.05	3.18	3.58	3.52
$\text{PECK}_{\text{w/o UL}}$	**0.052**	**0.183**	0.822	0.74	**3.12**	3.25	3.61	3.73
$\text{PECK}_{\text{w/ UL}}$	0.047	0.179	**0.835**	**0.83**	3.10	**3.70**	**4.11**	**4.05**

Table 2: Automatic and human evaluation results on the persona expansion. The best results are **bolded**, and the second-best are underlined.

6.4 Persona Expansion Results

The automatic and human evaluation results are reported in Table 2. Compared with baselines, PECK outperformed other expansion models in all metrics regarding diversity and consistency. In particular, relevance (i.e., F-BERT, Relevance) and consistency (i.e., C.Score, Intra/Inter-Consistency) were significantly improved compared to diversity (i.e., Dist-1/2, Engagement). This result demonstrated the effectiveness of the proposed framework for consistent persona expansion.

6.4.1 Anlalysis

Through a detailed analysis of the results, we identified the contributions of the following three implements: 1) silver profile dataset, 2) encoder-decoder structure, and 3) UL objective.

First, from the results of $\text{COMET}_{\text{ATOMIC}}$ and $\text{COMET}_{\text{SP w/o UL}}$ in Table 2, the latter model using the silver profile dataset for training showed better performance in all evaluation metrics. Especially, C.Score showed a higher improvement compared to other automatic metrics. In human evaluation, Inter-Consistency increased more significantly than other metrics. This result showed that the presence of the silver profile helped improve the consistency of the expanded personas. In other words, it means that the silver profile sufficiently imbued the expansion model with the characteristics of the profile and correlatedness among personas.

To analyze the impact of the encoder-decoder structure, COMET_{SP} and PECK were trained using the same silver profile dataset. Different from PECK, COMET_{SP} is a model based on GPT-2 with a decoder-only structure. Our experimental results showed that PECK outperformed COMET_{SP} despite being trained on the same dataset. In addition, we found significant increases in C.Score and Inter-Consistency, the metrics representing one-to-many consistency. This means that the encoder has effectively fused personas within the profile so that the decoder could generate expanded personas consistently for the given profile.

PECK vs. $\text{COMET}_{\text{ATOMIC}}$	Intra-Consistency			Inter-Consistency		
	Win	Lose	k	Win	Lose	k
xWant	72.4	11.6	0.62	76.1	9.4	0.71
xNeed	68.3	18.4	0.52	72.7	10.2	0.66
xAttr	74.5	10.8	0.64	79.5	7.8	0.73
xReact	61.8	23.7	0.48	69.4	14.6	0.54

Table 3: Human A/B results for consistency. Ties are not indicated in the table. The values of Fleiss' kappa k (Fleiss, 1971) for all results are in $0.4 < k < 0.8$, indicating moderate and substantial agreements.

In terms of UL objective, both $\text{COMET}_{\text{SP w/ UL}}$ and $\text{PECK}_{\text{w/ UL}}$ models showed higher relevance and consistency than those without UL training. We found that Dist-1/2 and Engagement metrics slightly decreased when using UL training. This result seems to be because the constraint of generation by UL training defected the range of expanded personas. However, despite the decrease in diversity, it can be judged to be a sufficiently attractive expansion. The analysis demonstrated how effective the UL training is in improving consistency while keeping diversity.

6.4.2 Human A/B Test

To compare the consistency of the expansion for each relation, we conducted a human A/B test. Human annotators were asked to choose a more consistent persona between personas expanded by $\text{COMET}_{\text{ATOMIC}}$ and PECK. Table 3 shows that Intra- and Inter-Consistency of the persona expanded by PECK outperformed in all relations. In particular, the performances for Inter-Consistency were better than Intra-Consistency. Through these results, we found that PECK is effective in solving Inter-Consistency contradiction that the existing model cannot control.

Dialogue Model	Expansion Model	Automatic Evaluation				Human Evaluation			
		PPL	Dist-1	Dist-2	C.Score	Engagement	Diversity	Relevance	Consistency
GPT-2	-	22.12	0.054	0.108	0.45	2.08	2.64	2.98	2.25
	COMET$_{\text{ATOMIC}}$	21.43	0.206	0.297	0.39	3.18	2.78	2.71	2.12
	PECK$_{\text{w/ UL}}$	21.18	0.223	0.345	0.67	3.22	3.31	3.05	3.24
COMPAC	-	19.84	0.146	0.253	0.58	2.31	3.02	3.14	2.86
	COMET$_{\text{ATOMIC}}$	16.36	0.836	0.964	0.64	3.35	3.42	3.07	2.97
	PECK$_{\text{w/ UL}}$	**16.21**	**0.851**	**0.986**	**0.76**	**3.43**	**3.67**	**3.22**	**3.53**

Table 4: Automatic and human evaluation results on the response generation. The best results are **bolded**, and the second-best are underlined.

6.5 Response Generation Results

The automatic and human evaluation results on the response generation are reported in Table 4. The dialogue models with expansion showed better performance than those without expansion. Especially, COMPAC with PECK outperformed the others in all evaluation metrics. In the following sections, we further analyze the diversity and consistency of generated responses.

6.5.1 Analysis on Diversity

The results of the response generation showed that persona expansion greatly contributes to improving the diversity of responses. In automatic evaluation, Dist-1/2 metrics significantly outperformed when using expansion models than when not using them. In particular, the values of Dist-1/2 showed greater increases when using the personas expanded by PECK. The impact of expanded personas was noticeable in human evaluation. In Engagement and Diversity, the responses based on expanded personas were rated well by human annotators. This means that PECK framework is helpful in generating attractive responses, which are essential to engage interlocutors and prolong a conversation.

6.5.2 Analysis on Consistency

In terms of consistency, the performance increased significantly when PECK framework was applied. Further, PECK outperformed COMET on both dialogue models. When COMET expansion was utilized for response generation, C.Score, Relevance, and Consistency metrics were, in some cases, lower than without expansion. GPT with PECK achieved better C.Score and Consistency than COMPAC with COMET, despite not performing fine-grained persona selection. This suggests that COMET persona expansion help improve diversity but adversely affects consistency. On the other hand, PECK not only improved the diversity of responses but was also the best in consistency. These results demonstrated that the proposed expansion framework is effective at generating diverse and consistent responses.

Intra-Consistency	
Original Persona	I am primarily a **meat eater**
COMET$_{\text{ATOMIC}}$	I want to **avoid meat** I am **vegetarian** I feel satisfied
PECK$_{\text{w/ UL}}$	I want to **eat meat** I am **carnivore** I feel happy
Inter-Consistency	
Original Profile	I love to rest at home on the weekend (A) I am a **hard worker** My hobby is walking with my dog
COMET$_{\text{ATOMIC}}$	I am **lazy** I want to take a rest
PECK$_{\text{w/ UL}}$	I am **tired** I want to relax

Table 5: Examples of expanded personas. Each sample was picked from all expansions. Red indicates expansion that contradicts the original.

6.6 Case Study on Intra-/Inter-Consistency

Table 5 shows sample cases of persona expansion on Intra-/Inter-Consistency. In Intra-Consistency case, given the original persona '*I am primarily a meat eater*', COMET generated contradictory personas like '*I want to avoid meat*' and '*I am vegetarian*'. On the other hand, PECK generated consistent personas. In Inter-Consistency case, '*I love to rest at home on the weekend*' is an anchor-persona, and '*I am a hard worker*' is a sub-persona to be considered when expanding. COMET generated expanded personas such as '*I am lazy*' and '*I want to take a rest*'. Here, the expanded persona '*I am lazy*' contradicts the contents of the sub-persona. On the contrary, the personas expanded by PECK are consistent with the original profile.

7 Conclusions and Future Work

In this paper, we proposed a novel persona expansion framework to improve the diversity and consistency of the persona-based dialogue. Leveraging the existing commonsense knowledge graphs, we built a silver profile dataset to deliver the ability to conform with the consistency criteria (Intra-/Inter-Consistency) to the expansion model. The expansion model of the encoder-decoder structure was trained using the silver profile dataset with unlikelihood training. After training, the model generated expanded personas that satisfy the consistency criteria. The experimental results proved that the proposed persona expansion is effective at improving the diversity of responses while keeping their consistency with personas. In the future, we plan to extend PECK to leverage more external knowledge, such as ConceptNet (Speer et al., 2017).

Limitations

In this study, the expansion target was limited to personas with a first-person subject. However, if other forms of persona expansion are considered, more diverse and richer responses can be generated. To solve this problem, we plan to research strategies to more effectively utilize various existing commonsense datasets in the persona-based dialogue model.

Ethical Considerations

Through our analysis of the persona expansion, we found that expanded personas highly depend on the commonsense knowledge used in the model training. We built a silver profile dataset utilizing the commonsense knowledge graph ANION and our expansion model trained with the silver profile dataset. As mentioned in ANION, linguistic, social, and cultural biases may exist within the ANION, the source of our silver profile dataset. These biases or stereotypes will affect the meaning of the personas expanded by our framework. This study did not discuss this aspect, but we believe it is an issue worth considering in future works.

A Implementation Details

A.1 Persona Expansion

Our persona expansion model was implemented with HuggingFace Transformers.[2] The encoder and decoder initialize from the publicly available BERT-base-uncased[3] and GPT-2-small[4] model, respectively. Both models are with 12 layers and 768 hidden sizes. In addition, we use an Adam optimizer (Kingma and Ba, 2014), and the learning rate varies from 5e-6 to 5e-5. The α and β, hyperparameters for weighted NLL and UL training, are 0.8 and 0.07, respectively. The training was conducted on an Nvidia RTX3090 24G GPU with a batch size of 16. The best-performing model was found in epochs 11 to 13.

A.2 Response Generation

We utilized the repositories and implementations of GPT-2[5] and COMPAC[6] for response generation. To suit the purpose of our experiment, we adjusted some of the details of these models and trained them in a single-turn dialogue setting.

	Positive	**Negative**	**All**
# of unique anchor personas	4,253	12,540	16,793
# of silver profiles	2,428,926	3,710,299	6,139,225
Average # of profiles per unique anchor persona	571.11	295.88	365.58

Table 6: Statistics of silver profile dataset

Positive Profile				
Relation	xAttr	xNeed	xReact	xWant
Average # of expandable personas	4.48	3.65	2.60	4.55
Negative Profile				
Relation	xAttr	xNeed	xReact	xWant
Average # of expandable personas	3.17	1.24	2.74	3.50

Table 7: Expandable personas per relation

B Statistics of Silver Profile

The statistics of the silver profile dataset are shown in Table 6. We built a total of 6,139,225 synthetic profiles based on 16,793 unique anchor personas. Each profile has expandable personas for four relations. Table 7 shows the average number of expandable personas per relation.

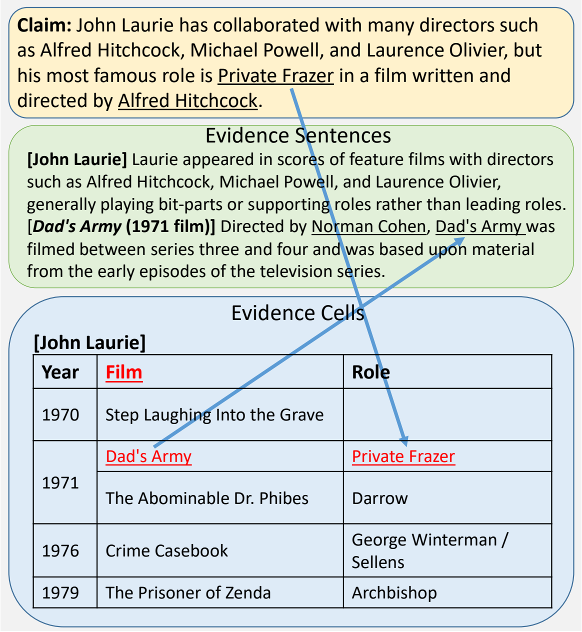
Abstract

FEVEROUS is a fact extraction and verification task that requires systems to extract evidence of both sentences and table cells from a Wikipedia dump, then predict the veracity of the given claim accordingly. Existing works extract evidence in the two formats separately, ignoring potential connections between them. In this paper, we propose a Unified Evidence Extraction model (UniFEE), which uses a mixed evidence graph to extract the evidence in both formats. With the carefully-designed unified evidence graph, UniFEE allows evidence interactions among all candidates in both formats at similar granularity. Experiments show that, with information aggregated from related evidence candidates in the fusion graph, UniFEE can make better decisions about which evidence should be kept, especially for claims requiring multi-hop reasoning or a combination of tables and texts. Thus it outperforms all previous evidence extraction methods and brings significant improvement in the subsequent claim verification step.



Claim: John Laurie has collaborated with many directors such as Alfred Hitchcock, Michael Powell, and Laurence Olivier, but his most famous role is Private Frazer in a film written and directed by Alfred Hitchcock.

Evidence Sentences

[John Laurie] Laurie appeared in scores of feature films with directors such as Alfred Hitchcock, Michael Powell, and Laurence Olivier, generally playing bit-parts or supporting roles rather than leading roles.
[*Dad's Army* (1971 film)] Directed by Norman Cohen, Dad's Army was filmed between series three and four and was based upon material from the early episodes of the television series.

Evidence Cells

[John Laurie]

Year	**Film**	**Role**
1970	Step Laughing Into the Grave	
1971	Dad's Army	Private Frazer
	The Abominable Dr. Phibes	Darrow
1976	Crime Casebook	George Winterman / Sellens
1979	The Prisoner of Zenda	Archbishop

Figure 1: An example in FEVEROUS. The green rectangle shows the gold evidence sentences, while the blue one is the gold evidence table, where the gold evidence cells are underlined.

1 Introduction

FEVEROUS (Aly et al., 2021) is a fact extraction and verification task over structured and unstructured information. Models should extract fine-grained evidence in two formats, namely, sentences and table cells, from a Wikipedia dump and verify the given claim accordingly.

Many previous works focus on the claim verification procedure. They propose various methods to fuse evidence in different formats while leaving the evidence extraction within each format separately (Kotonya et al., 2021; Malon, 2021; Bouziane et al., 2021; Hu et al., 2022). For those efforts on evidence extraction, Saeed et al. (2021) use a neural re-ranker to refine page retrieval. Bouziane et al. (2021) propose a reinforced adaptive retrieval embedding paradigm, but they ignore the possible connections among evidence either in the same format or across different formats. However, there are many gold evidence pieces with fewer lexical or semantic overlaps with the claim, while their necessity is mainly determined by other evidence. Without considering evidence connections during extraction, models may be prone to miss these evidence candidates, thus, propagating errors to subsequent claim verification.

Figure 1 shows an example from FEVEROUS. To refute the given claim, models should find that *Private Frazer* is a role in the film *Dad's Army*, and recognize that its director is *Norman Cohen* instead of *Alfred Hitchcock*. However, the overlap between the claim and the required evidence sentence *Directed by Norman Cohen ...* is only two words:

directed by, without any key entities, which is generally not strong enough to recognize its usefulness. With the evidence cells in the table, one can find that *Private Frazer* is a role in the film *Dad's Army*, which links the evidence sentence and the given claim. Therefore, for the evidence extraction step it is essential to encourage interactions between evidence pieces of different formats.

Meanwhile, evidence in the same format also provides context information to each other, especially for table cells. In Figure 1, the cell *Dad's Army* is not mentioned in the claim, but the column header, *Film*, and the cell in the same row, *Private Frazer*, are strong clues appearing in the given claim, which implies that the cell *Dad's Army* is highly likely to be useful evidence. We argue that models should allow the evidence to accumulate context information from all closely-associated evidence in both formats to extract comprehensive evidence sets for claim verification.

In this paper, we propose a Unified Evidence Extraction model (UNIFEE), which exploits graph attention networks (GAT) to encourage interactions among connected candidates during evidence extraction. We design a novel graph structure, which accommodates all evidence candidates and introduces column nodes to allow evidence candidates of different formats to interact with each other in a similar granularity. This graph also facilitates the interactions among cells in several nested tables with better representation of the table layout. Compared to previous flatten-based methods, our method exploits the structural relationship among cells in complicated tables and enhances the interactions between evidence in both formats.

Experiments on FEVEROUS show that our UNIFEE improves the evidence extraction performances and further boosts the final fact verification scores significantly. The ablation experiments and case study demonstrate the effectiveness of the proposed evidence extraction method and our graph designs. Our code is released to the public for further exploration. [1].

Our contributions can be summarized as follows:

- We propose a novel evidence extraction method, featuring a mixed graph structure with carefully designed column nodes and layout-aware table representations. Our method enables early and thorough evidence interactions within one format or across formats at a similar granularity.

- Experiments show that our method outperforms previous works by a large margin on both the evidence extraction and the final verification results. Thorough analysis shows that our model can recall more multi-hop evidence and also evidence with fewer lexical overlaps with the given claim.

2 Our Model

We take the widely-adopted three-step pipeline for FEVEROUS (Aly et al., 2021), which consists of retrieving pages from Wikipedia dump, extracting sentences and table cells as evidence from the pages, and predicting the veracity label of the given claim based on the evidence set. In this work, we focus on the second step, i.e., evidence extraction. We use the DRQA (Chen et al., 2017) based document retrieval method and the dual-channel verification method proposed by Hu et al. (2022) for the remaining two steps.

Formally, during evidence extraction, n'_s sentences and n_t tables are extracted from n_p retrieved passages by a pair-wise classification model firstly. This pre-processing step narrows the search space of sentences and table cells from thousands to a few dozens, which makes the mixed graph lighter. Then, n_c cells and n_s sentences are extracted by our proposed Unified Evidence Extraction model (UNIFEE). These fine-grained evidence pieces are used for fact verification later.

In UNIFEE, we design a mixed evidence graph (§2.1) to organize evidence of two formats. Then, a graph neural network is applied to the graph to accumulate contextualized information from all evidence candidates with similar granularity, and identify useful evidence from a unified perspective (§2.2).

2.1 Mixed Evidence Graph

There are three kinds of nodes in our mixed evidence graph. Sentence nodes and cell nodes stands for sentences and cells, e.g., *FC Ararat Yerevan* in table 1, evidence candidates. Besides, we further introduce a novel node type representing table columns , e.g., *Senior career* Apps 10 164 8 26* in table 1. The intuition is that textual evidence is mainly at the sentence level but table cells are generally words or phrases. The unbalanced granularities will hinder their interactions. Therefore, we introduce this column node, to act as a mediator for information transmission between the sentence nodes and the cell nodes.

---

[1] `https://github.com/WilliamZR/unifee`

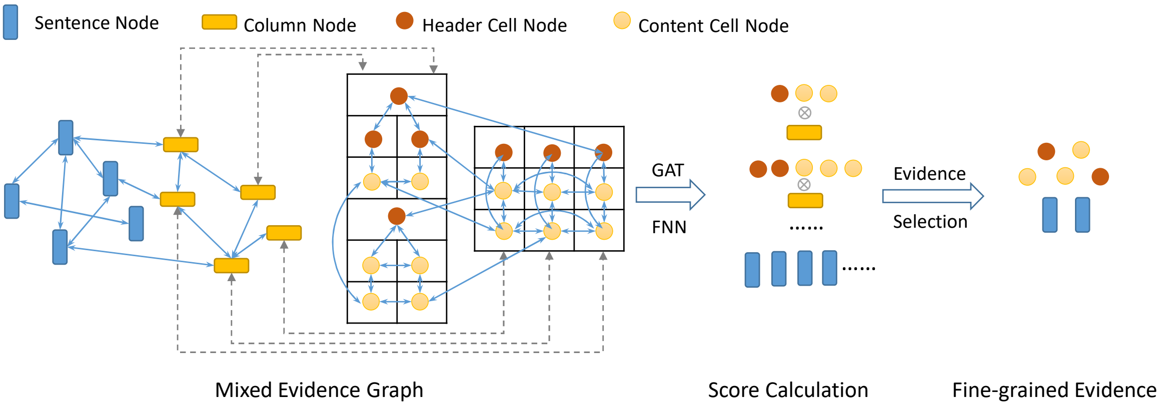

Figure 2: The overview of UNIFEE. The blue lines are edges in the mixed evidence graph, and the gray dash lines indicate which column each column node comes from .

Specifically, the mixed evidence graph G has three types of nodes: sentence nodes, cell nodes (including header cells and content cells), and column nodes, as shown in Figure 2.

The edge connections are elaborated as follows:

Edges among Sentence Nodes and Column Nodes We add bi-directed edges between two nodes v_i and v_j for $v_i, v_j \in V^S \cup V^{Col}$ if and only if the two following conditions:

- v_i and v_j represent evidence in the same Wikipedia page.
- v_i and v_j contain common entities or hyperlinks.

Here the text representation of a column node simply is the concatenation of all cells in that column.

Edges among Cell Nodes Although we expect direct messaging between cells, simply connecting cells in the same rows or the same columns is not enough. The tables in Wikipedia pages are often organized as complicated nested tables. Previous works simply flattening a table or converting cells to strings with human-designed templates will lose delicate structural information layout and cannot reflect the cross-table connections.

Meanwhile, we notice that the tables often have large headers in the middle of themselves in reality, which separates the influenced columns into several parts, and, in this case, cells in the same column could be irrelevant. Disconnecting these cells in the graph will help us remove confusing edges and make the information transmission more reasonable.

Table 1 is a table from the Wikipedia page *Aramais Yepiskoposyan*. We can see that three long headers *Personal Information*, *Senior career* and *National team* cut the table into three parts. The cell organization and contents within each part are consistent while differing a lot across different parts. For example, although the header cell *Personal Information* and the content cell *FC Ararat Yerevan* are in the same column, they do not have a subordinate relationship.

Personal information			
Date of birth	27 September 1968 (age 53)		
Height	1.75 m (5 ft 9 in)		
Position(s)	Midfielder		
Senior career*			
Years	Team	Apps	(Gls)
1986–1991	FC Ararat Yerevan	10	(0)
1992–1997	FC Chernomorets Novorossiysk	164	(8)
1997	FC Kuban Krasnodar	8	(0)

Table 1: A table instance from the Wikipedia.

We believe that a graph deliberately connecting cells in all table candidates can better model the table structures and connections. According to the table layout and lexical features, we connect two cell nodes v_i^C and v_j^C by bi-directional edges:

- If v_i^C and v_j^C are two content cells in the same column and there is no table-header-like cell between them. For example, the header cells *Senior Career** and *Team* separate the content cells *Midfielder* and *FC Ararat Yerevan*.
- If v_i^C and v_j^C are two cells in the same column, v_i^C is a header cell above v_j^C, and no header cell exists between them.
- If v_i^C and v_j^C are two cells in the same row.
- If v_i^C and v_j^C are two cells sharing at least one entity or hyperlink in their contents.

2.2 Evidence Extraction with Mixed Graphs

In this section, we will show how we extract the evidence set with the mixed evidence graph, which encourages evidence to accumulate context information from closely-associated candidates of both formats and make a better decision to form a comprehensive and accurate evidence set for the verification step.

We formulate the task as: given a claim Q and n retrieved Wikipedia pages $P = \{p_i\}_{i=1}^{n}$, the models should extract a sentence evidence set $E = \langle S, C \rangle$, where S are sentences in P and C are cells in P. The evidence set E can be used to support or refute the claim Q.

Node Initialization The column nodes and cell nodes share a common embedding module, which is more efficient and can build an implicit connection between cells and columns apart from the explicit edges in the graph. Specifically, we feed the claim-table pairs into TAPAS (Herzig et al., 2020), a pre-trained table representation model, to get the embedding of cell nodes and column nodes. Each cell node is initialized by averaging the last hidden states of its tokens, $n(v_i^C)$. $\#\text{TOKENS}\,(cell_i)$ means the number of tokens in $cell_i$. T means the table $cell_i$ belongs to.

$$\mathbf{n}(\mathbf{v_i^C}) = \frac{\sum_{t \in \text{TOKENS}(cell_i)} (\text{Tapas}_t(Q, T))}{\#\text{TOKENS}\,(cell_i)}$$

And each column node is initialized as the mean-pooling of the embeddings of all cells in this column $n(v_i^{Col})$. $\#\text{CELLS}\,(col_i)$ is the number of cells in the column i.

$$\mathbf{n}(\mathbf{v_i^{Col}}) = \frac{\sum_{t \in \text{CELLS}(col_i)} (\text{Tapas}_t(Q, T))}{\#\text{CELLS}\,(col_i)}$$

A one-layer GAT is applied to the graph, which updates the node representations by aggregating representations from their neighbors. $h_i^{(l)}$ is the current representation of node i. W^f, $\vec{a}$ and W are training parameters.

$$\begin{aligned} h_i^{(l+1)} &= \sum_{j \in \mathcal{N}(i)} \alpha_{ij}^{(l)} W^f h_j^{(l)} \\ \alpha_{ij}^{(l)} &= \text{softmax}_\text{i}\left(e_{ij}^{(l)}\right) \\ e_{ij}^{(l)} &= \text{LeakyReLU}\left(\vec{a}^T \left[W h_i^{(l)} \| W h_j^{(l)}\right]\right) \end{aligned}$$

With a two-layer feed-forward network and a softmax layer, we obtain the probability of each fine-grained evidence candidate being retrieved. The evidence with a score above a predefined threshold is kept.

The loss is calculated as the weighted sum of the sentence loss L^S, column loss L^{Co}, and the cell loss L^{Ce}. We use cross entropy as the loss function for each part separately.

$$L = L^S + \alpha \cdot L^{Co} + \beta \cdot L^{Ce}$$

$$L^S = -\frac{1}{N^S} \sum_{i=1}^{N^S} \log\left(\text{p}\left(\hat{y}^S = y_i^S | Q, S, C\right)\right)$$

$$L^{Co} = -\frac{1}{N^{Co}} \sum_{i=1}^{N^{Co}} \log\left(\text{p}\left(\hat{y}^{Co} = y_i^{Co} | Q, S, C\right)\right)$$

$$L^{Ce} = -\frac{1}{N^{Ce}} \sum_{i=1}^{N^{Ce}} \log\left(\text{p}\left(\hat{y}^{Ce} = y_i^{Ce} | Q, S, C\right)\right)$$

where N^S, N^{Co}, and N^{Ce} are the total numbers of sentence, column, and cell candidates in the training set, respectively. α and β are the coefficients of L^{Co} and L^{Ce}. If a cell or a sentence is in any of the gold evidence sets, we give it the label as 1, otherwise 0. For the labels of the column nodes, if any of the cells in that column is labeled as 1, this column is labeled as 1, otherwise 0.

The score of a sentence candidate is simply calculated as the softmax result of the label 1. In the training procedure, the cell score is calculated similarly. While in the evidence prediction step, the probability of a cell being retrieved is calculated as the product of the score of the cell node itself and the score of the column node it belongs to.

2.3 Document Retrieval and Claim Verification

For the two remaining steps in the whole pipeline, i.e., document retrieval and claim verification, we follow (Hu et al., 2022). For the document retrieval step, we retrieve evidence pages from the Wikipedia dump with a DrQA retriever (Chen et al., 2017) and re-rank the pages with a combination of BM25 and RoBERTa-base (Liu et al., 2019) re-rankers. For the verification step, we perform bidirectional evidence conversions and dual-channel evidence fusion to predict the final veracity label of the given claim.

3 Experiments

3.1 Evaluation Metrics

There are two main official metrics in the FEVEROUS task, i.e., accuracy and FEVEROUS score. The accuracy calculates the proportion of instances for which the model predicts a correct veracity label. The FEVEROUS score considers not only the correctness of the final veracity label but also the extracted evidence set. It calculates the proportion when the extracted evidence set covers one of the gold evidence sets and the predicted veracity label is consistent with the gold label.

Three additional official metrics are used to evaluate the quality of the extracted evidence sets, i.e., Evidence Precision, Evidence Recall, and Evidence F1. Multiple gold evidence sets are provided in FEVEROUS for each claim. A piece of extracted evidence is correct if and only if it is contained by any gold evidence set. For each instance, the Evidence Precision is the proportion of the correct predicted evidence. The overall Evidence Precision is the average score over all instances. The Evidence Recall is the proportion of instances with a correct extracted evidence set. An extracted evidence set is correct if and only if it covers any of the gold evidence sets. The Evidence F1 is the harmonic mean of the Evidence Precision and Evidence Recall.

3.2 Implementation Details

We retrieve $n_p = 5$ pages from the Wikipedia dump for each claim, and further narrow the evidence searching space to $n'_s = 5$ sentences and $n_t = 3$ tables with RoBERTa-base and DrQA model (same as the official baseline), separately. When we choose the final evidence set according to UNIFEE, the threshold for selecting cells and sentences is both 0.01. At most 25 cells are selected for each claim. As for the results, 12.1 cells and 4.7 sentences are extracted for each instance on average.

We use an Adam optimizer (Kingma and Ba, 2015) with a batch size of 4. The learning rates for pre-trained parameters and the others are 10^{-6} and 10^{-4}, respectively. We train UNIFEE for 3 epochs, which takes 21 hours on a NVIDIA A40 GPU. We use Stanza toolkit[2] to identify entities in the claim and evidence for graph construction. We use base-size RoBERTa[3] and TAPAS[4] for sentence and table embedding in evidence extraction. The sentence encoder in claim verification is RoBERTa-large fine-tuned with NLI and verification tasks[5], same as the official baseline.

Details of the FEVEROUS dataset are shown in Appendix § A.

3.3 Baseline Models

The official baseline (Aly et al., 2021) uses DrQA (Chen et al., 2017) to extract sentences and tables. It uses pre-trained models to retrieve cells from flattened tables. EURECOM (Saeed et al., 2021) proposes a neural re-ranker to improve document retrieval. Both NCU (Gi et al., 2021) and Z team (Kotonya et al., 2021) linearize cells to unify evidence element format with sentences. NCU concatenates the claim and the evidence elements as input into RoBERTa for binary classification. Z team constructs a fully-connected graph of evidence element to extract evidence. A next-hop predictor is introduced by Papelo (Malon, 2021) to extract the required evidence. Sentences and cells are retrieved in multi-hops simply based on word overlap with imagined evidence. FaBULOUS (Bouziane et al., 2021) trains a Multi-Hop Dense Retriever (Xiong et al., 2020) to retrieve sentences and cells separately. DCUF(Hu et al., 2022) strengthens the official evidence extraction method with a multi-turn cell retriever.

3.4 Main Results

Our main results are summarized in Table 2. We obtain remarkable improvements over the best previous model, DCUF, in evidence extraction. In the development/test set, the improvements are 3.98%/3.56%, 11.86%/9.77%, and 5.96%/5.22% in evidence precision, recall, and f1 score, respectively. These results suggest that, with the context information accumulated from other candidates in the mixed evidence graph, our model can extract evidence more accurately. We also find that UNIFEE can easily drop irrelevant evidence and keep crucial evidence even though it has less word-overlapping with the claim. Specifically, compared with the official baseline, UNIFEE extracts 25% more gold evidence, with an average word overlap of 15.8%,

UNIFEE*	**43.48 / 39.36**	**72.35 / 62.41**	**19.04 / 18.35**	**55.08 / 53.87**	**28.30 / 27.37**
DCUF	35.77 / 33.97	72.91 / 63.21	15.06 / 14.79	43.22 / 44.10	22.34 / 22.15
UNIFEE	**44.86 / 41.50**	**73.67 / 65.04**	**19.04 / 18.35**	**55.08 / 53.87**	**28.30 / 27.37**

Table 2: Model performance on the development set and the test set. UNIFEE* means UNIFEE with the verification model of the official baseline instead of DCUF's.

far less than the 28.9% word overlap averagely in the gold evidence extracted by the official baseline.

Our model also achieves better performance on the fact verification metrics of FEVEROUS. Compared to previous state-of-the-art model DCUF, UNIFEE obtains an improvement of 9.09%/7.53% on the FEVEROUS score and 0.76%/1.83% on accuracy at the development/test set. Moreover, we experiment with a simpler verification model taken from the official baseline instead of that from DCUF to see the effectiveness of our evidence extraction step (UNIFEE*). Compared to Bouziane et al. (2021), Kotonya et al. (2021) and Hu et al. (2022) , who use complex verification models with template-based format conversion and(or) dual-channel setting, UNIFEE* still achieves better results. These results suggest that , with a high-quality evidence set, even a simple verification model can achieve good performance.

We also measure the improvement of our model on instances of different challenges in the dev set. Compared to the official baseline, UNIFEE shows an improvement of 65.93% (from 21% to 35%) on instances requiring multi-hop reasoning and 45.32% (from 41% to 59%) on instances requiring the combination of tables and texts, far above the average increase ratio 35.84%. It shows that with information accumulated from connected evidence candidates, UNIFEE can recall more required evidence within a limited evidence size.

Meanwhile, compared to the previous models using multi-turn retriever (Malon, 2021; Bouziane et al., 2021; Hu et al., 2022) for evidence extraction, our method does not require iterative running to retrieve multi-hop evidence and thus is less time-consuming.

3.5 Ablation Study

We evaluate the effectiveness of our Unified Evidence Extraction model with ablation experiments. (1)w/o Fusion Graph: We use the baseline proposed in Aly et al. (2021) to retrieve evidence based on our document retrieval results. (2) w/o Column Nodes: we connect sentences and cells directly if they have common hyperlinks or entities without column nodes as intermediaries. (3) w/o Cross-format Interactions: We deprecate sentence nodes and column nodes, only using cell nodes to retrieve cell evidence. (4)w/o Threshold: We retrieve top 5 sentences and top 25 cells instead of using a threshold.

The results are listed in Table 3. When we apply the evidence extraction model proposed in the official baseline (Aly et al., 2021) on our page retrieval results, the evidence precision, recall, and F1 drop by 3.15%, 14.54%, and 5.47%, respectively. It proves that our UNIFEE extracts the required evidence and removes confusing evidence candidates more confidently with context information accumulated from all evidence candidates of both formats. Meanwhile, the metrics drop a lot when we directly connect sentence candidates and cell candidates, with a decrease of 2.78% on evidence F1. It suggests that with column nodes as intermediaries, UNIFEE allows cross-format evidence interactions at a similar granularity, thus making the information flow over the graph more reasonable and efficient. In the w/o Cross-format Interactions setting, when we remove column nodes and do not add any edges between sentence nodes and cell nodes, the evidence F1 decreases to 25.89%. It shows that context information from evidence of another format is also crucial for the evidence extraction step.

Models	P	R	F1
UNIFEE	**19.04**	55.08	**28.30**
w/o Fusion Graph	15.89	40.54	22.83
w/o Column Nodes	16.74	53.66	25.52
w/o Cross-format Interactions	16.98	54.51	25.89
w/o Threshold	12.48	**56.22**	20.42

Table 3: Ablation study regarding the retrieved evidence on the development set.

We notice that , without cross-format evidence interactions, UNIFEE still outperforms the official baseline by 2.94% and improves the evidence recall by 13.97%, which means that our carefully-designed edges between cells can better represent the layout of complex nested tables, thus improving the cell selection results.

From the w/o Threshold setting, we can see that if we, as many previous works do, directly select the top 25 cells and 5 sentences even whose scores are very low, there will be a slight improvement in the evidence recall, from 55.08% to 56.22%. However, it is at the expense of a 6.56% drop in evidence precision and a 7.88% drop in evidence F1. More irrelevant evidence is selected, which easily confuse the verification model in the final step. With the rough threshold in evidence selection, UNIFEE can dynamically select useful evidence according to their context-aware relevance regardless of the numbers and formats , which helps even simple verification models achieve better performance.

4 Analysis

4.1 Adaptive Evidence Selection

The number of sentences and cells required to verify claims in the FEVEROUS varies a lot. Some claim needs only sentence evidence, some only cell evidence, and many others a combination of both. We find that our UNIFEE can make an adaptive selection of evidence according to the given claim, without being bound to certain formats or a fixed evidence number. With joint evidence extraction in a mixed evidence graph and evidence selection with a threshold, UNIFEE keeps more helpful evidence in the fine-grained evidence retrieval step.

We analyze the relationship between evidence in the gold evidence set and that in the extracted evidence set. The results are shown in Figure 3.

We can see that UNIFEE extracts more cells for claims requiring more cell evidence. For claims that only need sentence evidence, UNIFEE extracts 11 cells on average, and for claims requiring 25 cells, it extracts cells to the maximum limit. We can observe a similar trend for sentence evidence. These results prove that UNIFEE introduces fewer noisy evidence pieces of unwanted formats than the previous works that set a fixed number of each format of evidence, while keeping the required evidence.

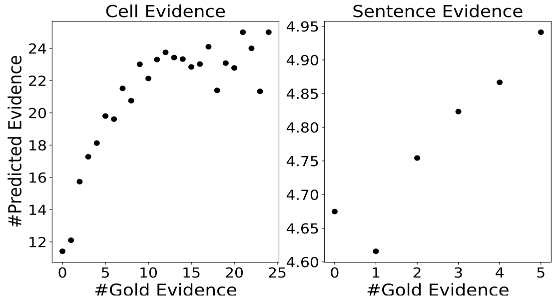

Figure 3: The relationship between the number of gold evidence and the average number of predicted cell/sentence evidence the evidence extraction step.

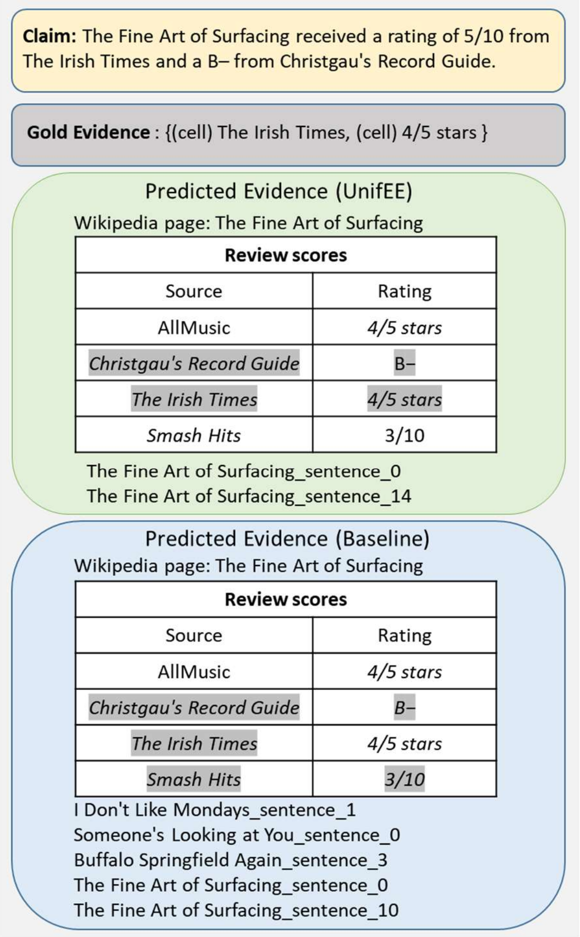
4.2 Positions of Cell Candidates

We find that the baseline cell extraction model is prone to select cells in the first few lines. If the cell evidence is at the bottom of a table, it is likely to be left out. A possible explanation is that when flattening the table into lines and applying a sequence tagging model to extract evidence cells, these cells are too far from their header cells, making it hard to capture the crucial context information. The average row position of the predicted cells in the baseline is 4.37 on average, much smaller than 6.71, the average of the gold ones. By contrast, it is easier for UNIFEE to exclude the interference of the cell positions thanks to its graph structure, where the cells in different lines are almost equivalent. Therefore, it can extract evidence cells at the bottom of the tables, and the average row position of its predicted cells increases to 6.39.

4.3 Case Study

A case is shown in Figure 4. Models are expected to find the cells *The Irish Times* and *4/5 stars* in the same row to refute the given claim *The Fine Art of Surfacing received a rating of 5/10 from The Irish Times*. The baseline model leaves out the cell *4/5 stars* since it has little word coverage with the given claim. Instead, it selects the distracting cell *3/10*. With the carefully-designed graph structure in UNIFEE, our model can obtain context information from the cell *The Irish Times* in the same row and the cell *Rating* in the same column. Meanwhile,



Claim: The Fine Art of Surfacing received a rating of 5/10 from The Irish Times and a B– from Christgau's Record Guide.

Gold Evidence : {(cell) The Irish Times, (cell) 4/5 stars }

the column where *4/5* is situated will be given a high score with the information from the key cell *Rating*, *B-* and even the distracting cell *3/10*. As a result, the cell *4/5* can be easily retrieved.

Figure 4 also shows that UNIFEE introduces less irrelevant evidence, especially when it comes to the unwanted evidence format. The cells *Christgauś Record Guide* and *B-* can support one aspect of the claim, so our model only introduces two more sentences in need. By contrast, the baseline model retrieves two irrelevant cells, and 5 sentences from many different pages, which may confuse the verification model in the next step.

5 Related Works

In this work, we focus on the evidence extraction step of the fact verification based on table and text, i.e. the FEVEROUS dataset (Aly et al., 2021). Other fact verification datasets only concentrate on unstructured data (Thorne et al., 2018) or a single given table (Wang et al., 2021; Chen et al., 2020; Kwiatkowski et al., 2019). These datasets do not require fine-grained evidence extraction or only extract evidence of a single format.

For evidence sentence extraction, most previous works rank claim-sentence pairs with ESIM (Hanselowski et al., 2018; Zhou et al., 2019) or PLM (Liu et al., 2020; Soleimani et al., 2020). There are also works using the multi-turn retrieving method for multi-hop evidence (Stammbach and Ash, 2020) or training the evidence extraction and claim verification model jointly to relieve the error propagation (Yin and Roth, 2018). For cell evidence extraction, SEM-TAB-FACT (Wang et al., 2021) and FEVEROUS (Aly et al., 2021) are the only two verification datasets requiring fine-grained cell selection to our best known. Acharya (2021) propose to parse the claim into logical forms and identify cells with string matching and dependency parsing. Jindal et al. (2021) use an ensemble of BERT fine-tuned on a single-cell NLI task and a cell-wise similarity algorithm to capture the additional relationship. Many previous works on FEVEROUS flatten each table to a sequence and perform binary sequence labeling to select cells (Aly et al., 2021; Hu et al., 2022). However, these models extract evidence according to every single sentence/cell/table, they neglect the connections of evidence candidates. Meanwhile, they are not tailored for evidence extraction of two formats and cross-format evidence interactions, which are the main challenges of our task.

Many efforts aim at fusing evidence of two formats in FEVEROUS. Kotonya et al. (2021) and Gi et al. (2021) convert the extracted table cells to strings with human-designed templates to get a unified evidence set of sentences. Bouziane et al. (2021) convert each evidence sentence to a small table and verify the claim according to a set of evidence tables. Hu et al. (2022) perform bi-directional format conversion and apply dual-channel encoding to the evidence set. However, their format fusion is only performed in the verification step after evidence extraction. Without evidence fusion in the extraction step, much evidence has been left, especially cell evidence and evidence with fewer overlaps with the given claim.

For works fusing evidence in the extraction step, Kotonya et al. (2021) and Malon (2021) convert cells to strings and treat all evidence candidates as sentences for evidence selection. They neglect the delicate structure of nested tables and lose much context information after the format conversion.

Our proposed UNIFEE introduces column nodes and layer-aware table representations, which can gather complex table information and facilitate cross-format interactions in a similar granularity in the evidence extraction step.

6 Conclusion

In this paper, we propose a Unified Evidence Extraction model (UNIFEE) for fact extraction over structured and unstructured data. UNIFEE adopts a mixed evidence graph to encourage evidence interactions among evidence candidates in both formats without manually designed conversion rules. Experiments on the FEVEROUS benchmark demonstrate that, with UNIFEE, a simple claim verification model outperforms previous SOTA results by a large margin. Further analysis shows that UNIFEE enhances the contextualized modeling of cells in complicated nested tables, thus largely improving the evidence extraction performance.

8 Limitations

Although we consider evidence interactions in the evidence extraction step and find out required evidence with less overlapping with the claim, it is hard for our method to recall multi-hop evidence in different pages since these pages are left out in the document retrieval step.

Apart from cell evidence and sentence evidence, there is a small proportion of evidence in the FEVEROUS dataset whose type is *table caption*, *list* or so. We simply ignore evidence of these types in the evidence retrieval step. To further improve the quality of evidence extraction step, we should also take these evidence types into consideration.

Another limitation is that the instances of the three veracity labels is unbalanced. From the details of each split shown in Appendix A, only 3% of the training split is labelled NEI, which makes it hard for models to learn predicting this class accurately. We have not tried solving this problem yet.

A Statistics of the FEVEROUS dataset

FEVEROUS[6] is an open-domain dataset based on English Wikipedia which contains 95.6 million sentences and 11.8 million tables. The dataset has 87,026 claims, with an average length of 25.3. An average of 1.4 sentences and 3.3 cells (0.8 tables) are required to verify each claim. Only text evidence is required in 34,963 instances, only tables in 28,760 instances, and both formats are required in 24,667 instances. 49,115 instances are marked as SUPPORTS, 33,669 as REFUTES, and the remaining 4,242 are marked as NEI. Table 4 displays specific label and evidence distributions in each split.

	Train	**Dev**	**Test**
Supported	41,835(59%)	3,908(50%)	3,372 (43%)
Refuted	27,215(38%)	3,481(44%)	2,973 (38%)
NEI	2,241 (3%)	501 (6%)	1,500 (19%)
Total	71,291	7,890	7,845
Sentences	31,607(41%)	3,745(43%)	3,589 (42%)
Cells	25,020 (32%)	2,738(32%)	2,816 (33%)
Sentence+Cells	20,865 (27%)	2,468 (25%)	2,062 (24%)

Abstract

Pre-trained Language Models (LMs) have become an integral part of Natural Language Processing (NLP) in recent years, due to their superior performance in downstream applications. In spite of this resounding success, the usability of LMs is constrained by computational and time complexity, along with their increasing size; an issue that has been referred to as 'overparameterisation'. Different strategies have been proposed in the literature to alleviate these problems, with the aim to create effective compact models that nearly match the performance of their bloated counterparts with negligible performance losses. One of the most popular techniques in this area of research is model distillation. Another potent but underutilised technique is cross-layer parameter sharing. In this work, we combine these two strategies and present MiniALBERT, a technique for converting the knowledge of fully parameterised LMs (such as BERT) into a compact recursive student. In addition, we investigate the application of bottleneck adapters for layer-wise adaptation of our recursive student, and also explore the efficacy of adapter tuning for fine-tuning of compact models. We test our proposed models on a number of general and biomedical NLP tasks to demonstrate their viability and compare them with the state-of-the-art and other existing compact models. All the codes used in the experiments are available at `https://github.com/nlpie-research/MiniALBERT`. Our pre-trained compact models can be accessed from `https://huggingface.co/nlpie`.

1 Introduction

Following the introduction of BERT (Devlin et al., 2019), generic pre-trained Language Models (LMs) have started to dominate the field of NLP. Virtually all state-of-the-art NLP models are built on top of some large pre-trained transformer as a backbone and are subsequently fine-tuned on their target dataset. While this pre-train and fine-tune approach has resulted in significant improvements across a wide range of NLP tasks, the widespread use of resource-exhaustive and overparameterised transformers has also raised concerns among researchers about their energy consumption, environmental impact, and ethical implications (Strubell et al., 2019; Bender et al., 2021).

As a response to this, different approaches have appeared with the aim to make large LMs more efficient, accessible, and environmentally friendly. Model compression is a line of research that has recently received considerable attention. It involves encoding a larger and slower but more performant model into a smaller and faster one with the aim to retain much of the former's performance capability (Bucilua et al., 2006). Knowledge distillation (Hinton et al., 2015), quantisation (Shen et al., 2020), and pruning (Ganesh et al., 2021) are three examples of such methods.

Adapter modules (Bapna and Firat, 2019; He et al., 2021) are recently introduced as an effective mechanism to address the parameter inefficiency of large pre-trained models. In this approach, several 'bottleneck adapters'(Houlsby et al., 2019a) are embedded inside different locations within the original network. During fine-tuning, the parameters of the

May 2-6, 2023 ©2023 Association for Computational Linguistics

original model are kept fixed, and for each new task only the adapters are fine-tuned. This only adds a small number of parameters to the overall architecture and allows for a much faster and more efficient fine-tuning on different downstream tasks.

Another approach to improve efficiency of LM-based transformers is shared parameterisation, which was popularised by ALBERT (Lan et al., 2019). While the original formulation of transformers (Vaswani et al., 2017) employs full parameterisation wherein each model parameter is independent of other modules and used only once in the forward pass, shared parameterisation allows different modules of the network to share parameters, resulting in a more efficient use of resources given the same parameterisation budget. However, a common downside of this approach is slower inference time and reduced performance. Ge and Wei (2022) posits two different parameterisation methods as an attempt to address the compute and memory challenges of transformer models and explores layer-wise adaptation in an encoder-decoder architecture. These methods exploit cross-layer parameter sharing in a way that would allow for the model to be utilised on mobile devices with strict memory constraints while achieving state-of-the-art results on two seq2seq tasks for English.

In this work, we exploit some of the above approaches to create a number of compact and efficient encoder-only models distilled from much larger language models. The contributions of this work are as follows:

- To the best of our knowledge, we are the first to compress fully parameterised large language models using recursive transformers (i.e. ALBERT-like models that employ full parameter sharing).
- We demonstrate the effectiveness of our pre-trained bottleneck adapters by merely fine-tuning them on downstream tasks while still achieving competitive results.
- We present several light-weight transformers with parameters ranging from 12M for the smallest to 32M for the largest. These models are shown to perform at the same level with their fully parameterised versions.
- Finally, we evaluate our models on a wide range of tasks and datasets on general and biomedial NLP datasets.

2 Background

2.1 LM-based Transformers and Computational Complexity

Ever since the introduction of the transformer architecture (Vaswani et al., 2017), large LM-based transformers such as BERT (Devlin et al., 2019) have become increasingly more popular in NLP and lie at the heart of most state-of-the-art models. A transformer is primarily composed of a number of transformer blocks stacked on top of one another. BERT_{Base} , for instance, consists of 12 of these blocks. The most important component in a block is the multi-head self-attention module. To be useful for language tasks, transformers are pre-trained using a number of self-supervised auxiliary tasks (Xia et al., 2020); these usually include some variation of Language Modelling (LM) and an optional sentence-level prediction task. Examples of the former include Masked Language Modelling (MLM) and Casual Language Modelling (CLM). For the latter, BERT uses Next Sentence Prediction (NSP) and ALBERT (Lan et al., 2019) employs Sentence Order Prediction (SOP).

The standard approach to utilise these pre-trained models is to fine-tune them on a target task. Given N as the sequence length, the computational and time complexity of self-attention is N^2 (Keles et al., 2022). In recent years, different approaches have appeared in the literature to address this bottleneck by modifying the self-attention operation in order to improve the general efficiency of transformers (with different performance trade-offs). Tay et al. (2020) surveys the most common approaches to develop what is referred to as 'efficient transformers'.

The magnitude of the parameters of LM-based transformers is another significant issue that restricts their use. With new releases like GPT-3 and MT-NLG (Smith et al., 2022) that feature hundreds of billions of parameters, these models have become increasingly overparameterised due to the large number of layers and embedding sizes (Rogers et al., 2020).

2.2 Model Distillation

The overparameterisation issue has motivated research into developing methods to compress larger models into smaller and faster versions that perform reasonably close to their larger counterparts. Knowledge distillation (Hinton et al., 2015) is a prominent method that intended to distill a

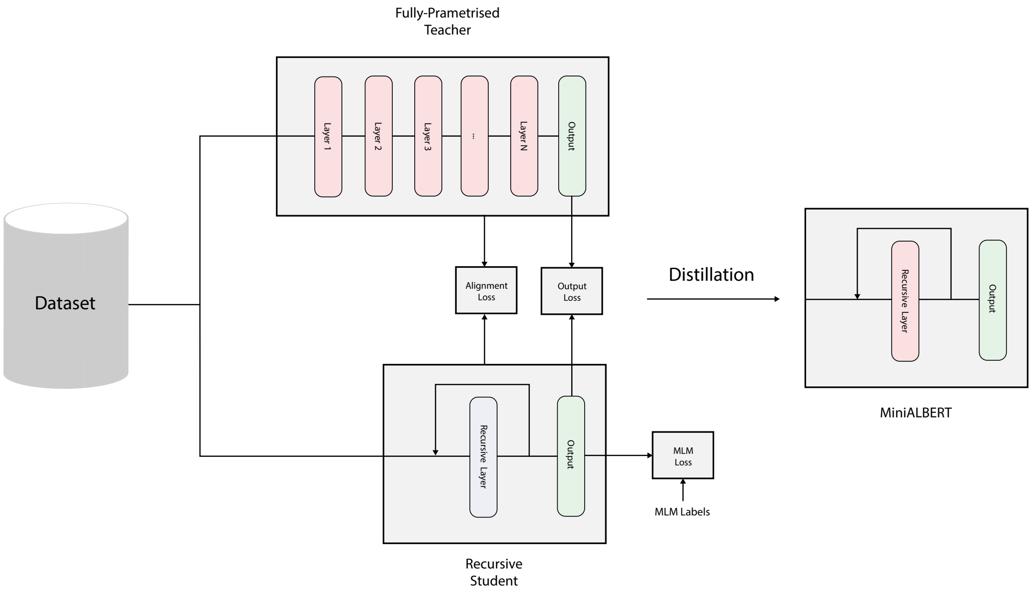

Figure 1: The layer-to-layer distillation procedure proposed for distilling the knowledge of a fully-parameterised teacher into a compact recursive student. While the teacher has fully parameterised layers, the recursive student has only one layer and the output is fed back into the same layer repeatedly. Despite this compact structure, our proposed distillation procedure is designed to align the output of each iteration of the recursive student with a particular layer of the fully-parameterised teacher, as if the student had fully-parameterised layers. Additional losses, namely, Output Loss, and MLM Loss, as shown above, are used for further knowledge distillation.

lightweight 'student' model from a larger 'teacher' network by using the outputs of the teacher netwrok as soft labels. Distillation can either be done task-specifically during fine-tuning, or task-agnostically by mimicking the MLM outputs or the intermediate representations of the teacher prior to the fine-tuning stage. The latter is more flexible and computationally less expensive (Wang et al., 2020). DistilBERT is a well-known example of a distilled model derived from BERT which is claimed to be 40% smaller in terms of parameters and 60% faster while retaining 97% of BERT's performance on a range of language understanding tasks (Sanh et al., 2019).

2.3 Efficient Fine-tuning Approaches

As discussed in Sec 2.1, LM-based transformers involve a large number of parameters and they are often fine-tuned on a target dataset. However, fine-tuning could become time-consuming as the size of the datasets grow. Different techniques exist in the literature to alleviate this bottleneck during fine-tuning. In this section we explore two of these techniques, namely, prompt tuning and bottleneck adapters.

Prompt tuning (Lester et al., 2021) is a technique in which the weights of a language model are kept frozen during the fine-tuning stage and fine-tuning is reformulated as a cloze-style task. Similar to T5, prompt tuning regards all tasks as a variation of text generation and conditions the generation using 'soft prompts'. A typical prompt consists of a text template with a masked token and a set of candidate label words to fill the mask. This turns the target task into another MLM objective in which the right candidates are chosen and soft prompts are learned. This method is especially useful for few-shot learning scenarios where there are not many target labels available for standard fine-tuning.

Bottleneck Adapters (BAs) (Houlsby et al., 2019b; Pfeiffer et al., 2021; Rücklé et al., 2020; Pfeiffer et al., 2020) are another mechanism used during fine-tuning to enhance efficiency of training. Each BA block consists of a linear down-projection, non-linearity, and up-projection along with residual connections. Several of these adapters are placed after the feed-forward or attention modules in a transformer. Similar to prompts, only the BAs are trained during fine-tuning.

2.4 Parameter Sharing via Recursion

Weight sharing is a strategy intended to reduce the overall number of parameters in a model. Lan et al.

(2019) introduced cross-layer parameter sharing in a recurrent-like encoder-only architecture where instead of having several transformer blocks with different parameters, there is only one transformer block whose outputs are recursively fed into itself a number of times. This drastically reduces the number of unique parameters in the model.

Edgeformer (Ge and Wei, 2022) is a recent work towards development of parameter-efficient encoder-decoder models specialised for on-device seq2seq generation. EdgeFormer employs two novel approaches for cost-effective parameterisation which improve on standard cross-layer parameter sharing. In addition to efficient parameterisation, Edgeformer explores the use of layer-wise adaptation in encoder-decoder models. To the best of our knowledge, however, the use of layer-wise adaptation in recursive encoder-only models (Sec 3.2) is yet to be explored.

3 Methods

In this work, we introduce a method to distil the knowledge of a fully parameterised transformer into a lightweight efficient recursive transformer via layer-to-layer distillation. We also experiment with layer-wise adaption of the recursive transformer via bottleneck adapters and factorise the embedding layer for extra parameter saving. In this section, we explain each component of our compact models in detail.

3.1 The Fully Parameterised Transformer

For each layer i, let the multi-head attention and feed-forward blocks be $f^i_{att}(x)$ and $f^i_{mlp}(x)$, respectively. The output of each layer is computed as follows:

$$O_i = f^i_{mlp}(f^i_{att}(O_{i-1})) \tag{1}$$

where O_i is the output of the i^{th} layer of the transformer.

3.2 The Recursive Student

The output of the recursive student is computed as follows:

$$O_i = f_{mlp}(f_{att}(O_{i-1})) \tag{2}$$

where O_i is the output of the i^{th} iteration of the recursive transformer. Note that unlike Equation 1, the multi-head attention and feed-forward blocks in this case are layer-agnostic, i.e. the same layers are used recursively.

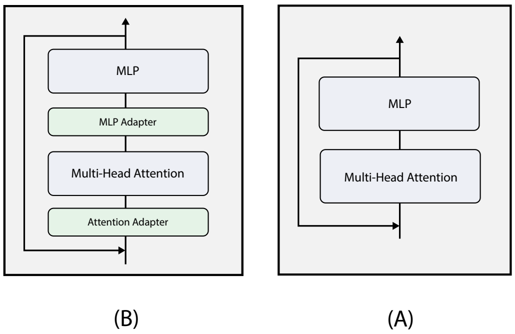

Figure 2: The two recursive students proposed in this work. (A) is a simple recursive student that employs cross-layer parameter sharing, which means that the multi-head attention and MLP blocks are shared across all layers. (B) is a recursive student with cross-layer parameter sharing which additionally uses layer-wise adaption via bottleneck adapters.

3.3 Recursive Student with Layer-wise Adaption

This formulation is identical to the recursive student defined in Section 3.2, except that, in addition to the shared parameters, here we employ a small number of trainable parameters. This will allow the model to capture distinct features in each iteration, similar to how transformer layers behave in a fully parameterised model. To this end, we use Bottleneck Adapters (BAs) which are small bottleneck blocks followed by residual connections, as defined in the following equation:

$$\phi(X) = W_{up}\ \sigma(W_{down}\ X) + X \tag{3}$$

where $\phi(.)$ represents the BA and $\sigma(.)$ is a nonlinearity function such as *RELU* or *GELU*. The recursive student with layer-wise adaption can be formulated as follows:

$$O_i = f_{mlp}(\phi^i_{mlp}(f_{att}(\phi^i_{att}(O_{i-1})))) \tag{4}$$

where $\phi^i_{att}(.)$ and $\phi^i_{mlp}(.)$ are the BAs for the multi-head attention and feed-forward blocks of the i^{th} iteration of the recursive transformer.

3.4 Embedding Factorisation

Following the work of ALBERT (Lan et al., 2019), instead of a full-rank embedding matrix, we use a low-rank matrix with size $|V| \times r$ where V is the vocabulary and r is the rank of the embedding matrix. We additionally use a projection weight with the size of $r \times d$ where d is the hidden dimension of the transformer. This is set to 768 in our experiments. Factorisation can be mathematically expressed as

$$E = E_{low}\, W_e \tag{5}$$

where $E_{low} \in \mathbb{R}^{|V|\times r}$, $W_e \in \mathbb{R}^{r\times d}$ and $E \in \mathbb{R}^{|V|\times d}$. In our experiments, we employ factorisation with ranks 312 and 128, and explore initialising the 312 versions with pre-trained embeddings obtained from the TinyBERT (Jiao et al., 2019) for the general models and TinyBioBERT (Rohanian et al., 2022) for the biomedical models.

In our experiments, we employed factorisation with ranks of 312 and 128 and initialised the 312 versions with pre-trained embeddings from TinyBERT (Jiao et al., 2019) for general models and TinyBioBERT (Rohanian et al., 2022) for biomedical models.

3.5 Distillation Procedure

We use three different loss terms, namely, MLM, alignment, and output. The MLM loss, which is the original loss used in Masked Language Modelling, is defined as follows:

$$L_{MLM}(X,Y) = \sum_{n=1}^{N} CE(f_s(X)^n, Y^n) \tag{6}$$

where X denotes the the model's input, N the number of input tokens, CE the cross-entropy loss function, Y^n the one-hot encoded label for the n^{th} token[1], and $f_s(X)^n$ the output distribution of the student for the n^{th} token. Y^n and $f_s(X)^n$ are both $|V|$-dimensional.

Because the number of layers in the student network is less than that of the teacher, alignment is typically achieved by comparing the student's layers to a subset of the teacher's. However, in our case, the student is recursive and lacks multiple layers. Therefore, in each iteration, we map the output of the student's layer to a specific layer of the teacher, i.e. the first iteration is considered the first layer, the second iteration is the second layer, and so on. The alignment loss is a combination of two terms, namely, attention and hidden losses. Attention loss is used to align the student's attention maps with those of the teacher and is defined as follows:

$$L_{att}(\hat{A}, A) = \frac{1}{HN} \sum_{h=1}^{H} \sum_{n=1}^{N} D_{KL}(\hat{A}_n^h \,||\, A_n^h) \tag{7}$$

$\hat{A}$ and A are the inputs to the loss function, and they correspond to the attention maps of a certain layer of the student and its associated layer of the teacher, respectively. The cosine-based hidden loss is used to align the hidden states of the student and teacher, and is defined as:

$$L_{hidden}(\hat{H}, H) = \frac{1}{N} \sum_{n=1}^{N} 1 - \psi(\hat{H}^n, H^n) \tag{8}$$

where $\hat{H}$ and H are the hidden states of a particular layer in the student and teacher networks. The ψ function denotes cosine similarity[2]. The alignment loss is defined as:

$$\begin{aligned} L_{align}(\hat{A}, A, \hat{H}, H) = \quad & L_{att}(\hat{A}, A) \\ & + L_{hidden}(\hat{H}, H) \end{aligned} \tag{9}$$

The output loss is based on KL divergence and is inteneded to align the output distribution of the student with the teacher on the MLM objective. This loss term is defined as below:

$$L_{out}(X) = \sum_{n=1}^{N} W_n D_{KL}(f_s(X)^n \,||\, f_t(X)^n) \tag{10}$$

where $f_s(X)^n$ and $f_t(X)^n$ are the output distributions of the student and teacher for the n^{th} token, respectively. W_n is 1 if the n^{th} token is masked and 0 otherwise. This ensures that only the masked tokens will contribute to the loss.

The complete layer-to-layer distillation loss used in this study is expressed by the following equation:

$$\begin{aligned} L(X, Y, & A_s, A_t, H_s, H_t) = \\ & \lambda_1\, L_{MLM}(X,Y) \\ & + \lambda_2 \sum_{l=1}^{L} L_{align}(A_s^l, A_t^{g(l)}, H_s^l, H_t^{g(l)}) \\ & + \lambda_3\, L_{out}(X). \end{aligned} \tag{11}$$

A_s and A_t in Equation 11 are collections of attention maps for the student and teacher, respectively. H_s and H_t are sets of hidden states for the student and teacher. L is the number of iterations (layers) of the recursive student. $g(.)$ is a mapping function that connects each iteration of the student to a specific layer of the teacher. Finally, λ_1 to λ_3 are hyperparameters used for controlling the importance of each component of the loss function (we use $\lambda_1 = 1.0$, $\lambda_2 = 3.0$, $\lambda_3 = 5.0$ in our experiments).

---

[1] Y^n is a zero vector if the n^{th} token is not masked.

[2] $\psi(\vec{u}, \vec{v}) = \frac{\vec{u}.\vec{v}}{||\vec{u}||_2 ||\vec{v}||_2}$

Table 1: The DEV set results on the GLUE benchmark. ALBERT$_6$ and ALBERT$_{12}$ denote ALBERT models with 6 and 12 layers respectively, and an embedding size of 128, which are trained on the same data for the same number of training steps as MiniALBERT. DistilBERT$_{base}$ is a DistilBERT model trained with the same distillation setting as Sanh et al. (2019) and for the same number of training steps as MiniALBERT. Adapter denotes layer-wise adaption and EF denotes Embedding Factorisation. The metrics used for reporting the results on each dataset is the same as the official GLUE benchmark. † denotes that the models were trained using adapter tuning in which all weights of the model except bottleneck adapters are kept frozen during fine-tuning. $*$ shows that the bottleneck adapters were initialised randomly since the model has not used bottleneck adapters at the pre-training stage. N/A means that the model did not learn anything from the target dataset. #Params denotes the number of tunable parameters which are used during fine-tuning. Note that for fine-tuning TinyBERT on the downstream tasks, unlike the original paper (Jiao et al., 2019), we do not employ task-specific distillation; this is to ensure the comparison with other models is fair.

4 Experiments and Results

We evaluate our general models on the widely used GLUE benchmark (Wang et al., 2018). All the models were pre-trained on four Tesla V100 32GB GPUs with a total batch size of 192 (48 each) and fine-tuning was done using only one Tesla V100. A random seed of 42 was used consistently throughout training for fair comparison. For all of the datasets, in order to do full fine-tuning, we use a learning rate from the set {5e-5, 3e-5, 1e-5}. For large datasets (MNLI, QQP, QNLI, and SST-2), we train models for a maximum of 5 epochs, and up to ten epochs on other datasets. The hyperparameters used for full-finetuning are listed in Table 7.

For adapter-tuning, the learning rate was selected from the set {5e-5, 5e-4, 1e-3}. Models were trained for a maximum of 10 epochs for large datasets and up to 15 epochs for other datasets. Table 8 details the hyperparameters used during adapter tuning on the GLUE benchmark. The results of the baselines and our general models are available in Table 1.

The biomedical models are evaluated on the task of Named Entity Recognition (NER), which is one of the most prominent tasks in biomedical NLP. We use four well-known datasets, namely, NCBI-disease (Doğan et al., 2014), BC5CDR-disease (Li et al., 2016), BC5CDR-chem (Li et al., 2016), and BC2GM (Smith et al., 2008).

We generally follow the same pre-processing pipeline as Rohanian et al. (2022). For biomedical NER, we use pre-processed datasets from Lee et al. (2020). We fine-tune the models using a learning rate from the set {5e-5, 3e-5, 1e-5} and perform adapter-tuning with a learning rate from {5e-5, 5e-4, 1e-3}. The hyperparameters for the biomedical datasets are presented in Tables 9 and 10. The results of the baselines and our biomedical models are available in Table 2.

5 Discussion

We trained our recursive students both with and without adapters and found that generally having adapters would increase the learning capacity of the model since each iteration provides an extra degree of freedom to the model in order to capture a specific type of feature. As shown in Tables 1

Table 2: The results of biomedical NER for the biomedical baselines and our models distilled from BioBERT-v1.1 on the PubMed dataset. BioALBERT$_6$ and BioALBERT$_{12}$ represent ALBERT models with 6 and 12 layers, respectively, and an embedding size of 128. These models were trained for the same number of steps as BioMiniALBERT using the same data. "Adapter" refers to layer-wise adaptation and "EF" stands for Embedding Factorization. The results are reported using the F1-score as the evaluation metric. The notations here are consistent with Table 1.

Model	Adapter	EF	#Params	NCBI-disease	BC5CDR-disease	BC5CDR-chem	BC2GM	Avg

and 2, in virtually all of the studies, models with adapters outperformed models of comparable size without adapters. In general, both models with and without adapter have outperformed their baseline by a significant margin (as shown in Tables 2 and 1), demonstrating the effectiveness of the proposed layer-to-layer distillation loss for constructing powerful compact recursive models. Comparison between the attention maps of our trained student and teacher models (Figure 3 in appendix) suggests the specific recursive architecture we have introduced in this work is indeed capable of mimicking the components of a larger model.

In addition, our experiments revealed that utilising adapters in the pre-training stage enables the model to effectively use adapter-tuning with only minor performance drops. However, adapter-tuning in models that have not used adapters in the pre-training stage causes major performance drops. We also found that adapter tuning is nearly 30% faster than full fine-tuning. Therefore, with adapter-tuning, the models can be trained for a larger number of epochs given the same training time, which can potentially increase the performance of the model. In general, a higher learning rate was required for adapter-tuning than for full fine-tuning. For both general and biomedical tasks we found that a learning rate of $5e-4$ results in the best performance, however, in some cases, a higher or lower learning rate such as $5e-5$ or $1e-3$ was deemed better.

Another method explored in this work for parameter saving is Embedding Factorisation. In our experiments, we observed that regardless of drastic parameter reduction, models using this approach are still able to perform on par or even in some cases better than models with full-rank embedding.

6 Ablation Studies

6.1 The Effect of The Alignment Loss

One of the main losses explored in this work for knowledge distillation is the alignment loss as explained in Equation 9. Alignment loss is used for mapping each iteration of the recursive student to a specific layer of the teacher, so the knowledge of each fully-parameterised layer is explicitly encoded into a specific iteration of the recursive student. The alignment loss consists of two losses, one for aligning the attention maps and one for aligning the hidden states. For ablation studies, we trained our best model for 20k steps on the Wikipedia dataset, with different alignment losses, and evaluated the resulting models on the GLUE dataset. The results are shown in Table 3.

As Shown in Table 3, without alignment, the performance of the recursive student drops significantly which shows the importance of using a layer-to-layer distillation technique. Furthermore, we discovered that aligning hidden states is far more

Table 3: Ablation study on the alignment loss. The performance drop is computed based on the difference with the average score of the model with full alignment (i.e. when all the alignment losses are used).

Alignment Type	Performance Drop
Hidden-Only	-0.5
Attention-Only	-3.27
No-Alignment	-5.27

important than aligning attention maps. We even noticed occasional improvements in some tasks by solely aligning hidden states, but the average performance of full alignment remains higher than hidden states alignment.

6.2 The Effect of an Extra Embedding Loss

Following the work of Jiao et al. (2019) and as part of our ablation tests, we investigated employing an extra loss for aligning the embeddings of the recursive student and fully-parameterised teacher. This embedding loss is defined as follows:

$$L_{embed}(\hat{E}, E) = \frac{1}{N}\sum_{n=1}^{N} 1 - \psi(\hat{E}^n, E^n) \quad (12)$$

$\hat{E}$ and E are the inputs to the loss function and represent the embeddings of the student and teacher. The embedding weights are not aligned globally in this formulation; instead, the local embeddings created for each training sample are compared before entering the transformer encoder. For our ablation studies, we trained models on the Wikipedia dataset for 20k steps, with and without this extra alignment loss, and evaluated them on the GLUE benchmark.The average performance of the models are reported in Table 4.

Table 4: Ablation study on the embedding loss. 'Full-rank' denotes models without embedding factorisation, and 'Loss' denotes extra embedding loss during distillation.

Model	Avg Performance
Full-rank	76.01
Full-rank + Loss	75.24
Factorised	76.31
Factorised + Loss	76.14

We discovered that, unlike the trend seen in fully-parameterised models, embedding loss reduces the performance of the student model (Table 4). This difference between the recursive student and the fully parameterised teacher implies that forcing the recursive student's embedding to match that of the fully parameterised teacher may not be beneficial, and that allowing the student to learn embeddings independently works better.

7 Conclusion and Future Works

In this work, we explored distilling the knowledge of fully-parameterised language models into recursive students with cross-layer parameter sharing. We used a layer-to-layer distillation technique to observe the learning capacity of the recursive students compared to their fully-parameterised teachers. We used bottleneck adapters for improving the performance of our recursive students and also assessed the benefits of adapter-tuning at the fine-tuning stage. Furthermore, an embedding factorisation technique was used for additional parameter reduction, which was evaluated with and without an extra distillation loss to match the student's embeddings with the teacher. Finally, by integrating all of the strategies outlined above, we were able to train compact recursive students with no more than 12M parameters, yielding competitive performance on both general and biomedical NLP. In the future, we hope to investigate various parameter-sharing and embedding factorisation strategies, as well as other layer-wise adaption techniques such as prompt-tuning. We would also like to train recursive students with larger hidden sizes and more training iterations to compress massive fully-parameterised models with minor performance drops.

Funding

This work was supported in part by the National Institute for Health Research (NIHR) Oxford Biomedical Research Centre (BRC), and in part by an InnoHK Project at the Hong Kong Centre for Cerebro-cardiovascular Health Engineering (COCHE). OR acknowledges the support of the Medical Research Council (grant number MR/W01761X/). DAC was supported by an NIHR Research Professorship, an RAEng Research Chair, COCHE, and the Pandemic Sciences Institute at the University of Oxford. The views expressed are those of the authors and not necessarily those of the NHS, NIHR, MRC, COCHE, or the University of Oxford.

Limitations

Regardless of the parameter reduction induced by our proposed recursive architecture, the resultant models have the same inference latency and memory complexity as fully-parameterised models of comparable size, which for our models is DistilBERT.

In general, our models' capacity for learning semantic and grammatical knowledge is limited, and they may perform poorly on tasks that necessitate a significant amount of reasoning and understanding, such as Question Answering or Semantic Acceptability. More analysis is required to determine the source of this limitation, i.e. whether it is a result of the architecture used or a consequence of the particular cross-layer sharing method etc.

Ethics Statement

In this study, we aimed to create efficient lightweight versions of large and less accessible NLP models. This area of research aims to make AI/NLP models more readily available, with fewer computational resources required to run them and potentially less negative environmental impact.

This work does not use any private or sensitive data and instead relies on widely used publicly available datasets that have been utilised by other researchers in the field with references provided in the paper for more information. All the codes and models are going to be made available for reproducibility purposes.

A Details of the Pre-Training

A.1 General Models

For pre-training our general models we use the English subset of the Wikipedia dataset which is available on the Huggingface platform. For pre-processing the Wikipedia dataset, we use the 'bert-base-uncased' tokeniser and apply a sliding window with a size of 256 tokens and a stride size of 128. Due to computational restrictions, we limit the maximum number of tokenised samples per article to 10, resulting in a total of 21 million training samples of 256 tokens each. We then follow BERT's masking approach, with a masking probability of 15% for each token.

Table 5: Hyperparameters used for pre-training models on Wikipedia dataset

Param	Value
learning rate	$5e-4$
scheduler	Linear
optimiser	AdamW
weight decay	$1e-4$
total batch size	192
warmup steps	5000
epochs	1

A.2 Biomedical Models

We pre-trained the biomedical models using the PubMed Abstracts dataset which consists of 31 million abstracts from PubMed articles. In the pre-processing stage, we employed the 'bert-base-cased' tokeniser with a maximum length of 256 and adhered to the same masking strategy as used in the training of the general models.

Abstract

The detection and normalization of temporal expressions is an important task and preprocessing step for many applications. However, prior work on normalization is rule-based, which severely limits the applicability in real-world multilingual settings, due to the costly creation of new rules. We propose a novel neural method for normalizing temporal expressions based on masked language modeling. Our multilingual method outperforms prior rule-based systems in many languages, and in particular, for low-resource languages with performance improvements of up to 33 F_1 on average compared to the state of the art.

1 Introduction

Temporal tagging consists of the extraction of temporal expressions (TE) from texts and their normalization to a standard format (e.g., *May '22*: `2022-05`). While there are deep-learning approaches for the extraction, temporal tagging as a whole is usually solved with highly specific rule-based systems, such as SUTime (Chang and Manning, 2012) or HeidelTime (Strötgen and Gertz, 2013). However, transferring rule-based methods to new languages or text domains requires a large manual effort to create rules specific to the target language. Although work on the automatic generation of rules for many languages (Strötgen and Gertz, 2015) exists, the rule quality typically does not match the high accuracy of hand-crafted rules.

In contrast to rule-based systems, neural networks are known for their ability to generalize to new targets, in particular, for cross- and multilingual applications (Rahimi et al., 2019; Artetxe and Schwenk, 2019). In the context of temporal tagging, recent works have shown promising results of neural networks for TE extraction in monolingual (Laparra et al., 2018) and multilingual settings (Lange et al., 2020) where a single neural model is trained on many languages at once. However, TE normalization remains challenging, and no solution for the normalization across languages exists yet.

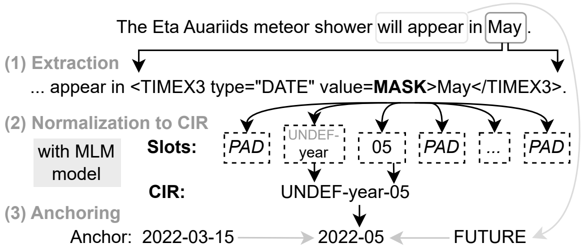

Figure 1: Overview of our 3-step pipeline for temporal tagging consisting of extraction of temporal expressions (step 1), normalization to a context-independent representation (CIR) using a slot-based masked language model (step 2) and anchoring given a reference time and further contextual cues (step 3).

We propose a new multilingual normalization method which can make use of labeled data from many languages by training a neural transformer model with a masked language modeling (MLM) objective. Thus, we adopt the MLM objective function for a new purpose: TE normalization.

To the best of our knowledge, this is the first work that uses neural networks for TE normalization. For this, as shown in Figure 1 and detailed below, we split the normalization task into two steps: normalization to a context-independent representation (CIR) and anchoring this representation using the document context.

The main contribution of this paper is our novel neural normalization method based on masked language modeling. For this, we create a large-scale multilingual dataset with weakly-supervised annotations of TEs and their normalized values in 87 languages. Our extensive set of experiments across 17 languages demonstrates that our multilingual method robustly works for many languages and outperforms the state of the art for multilingual temporal tagging, HeidelTime (Strötgen and Gertz, 2015), especially for low-resource languages by

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1174–1186

more than 33 F_1 on average. Further, we explore different training and decoding strategies for our model. The code for our models and the weakly-supervised data is publicly available.[1]

2 Related Work

TE Normalization. Besides rule-based systems (Chang and Manning, 2012; Strötgen and Gertz, 2013), one normalization method for TEs are context-free grammars (Bethard, 2013; Lee et al., 2014) which are independent of the extraction method. However, they are even more language-specific than rule-based systems and hardly generalizable to new languages. Laparra et al. (2018) used a rule-based procedure for English TE normalization based on the SCATE format proposed by Bethard and Parker (2016). While their method could be extended to multilingual applications, no annotated data for other languages is available in the SCATE format, and it is mostly incompatible with the predominant TimeML (Pustejovsky et al., 2005) annotation format. Therefore, we will focus on the TimeML format in this work and present the first neural approach to TE normalization.

Masked Language Modeling (MLM). The MLM paradigm gains a lot of attention (Sun et al., 2021) due to popular language models like BERT (Devlin et al., 2019) This leads to active research on using MLM to solve further tasks like text classification (Brown et al., 2020), named entity recognition (Ma et al., 2021) and relation extraction (Han et al., 2021), also in low-resource languages (Hedderich et al., 2021). In this work, we adopt it to TE normalization for the first time.

3 Background on Temporal Tagging

Temporal tagging addresses the detection, classification and normalization of temporal expressions in unstructured texts — often following the TimeML specifications (Pustejovsky et al., 2005).

TimeML's most important attributes are `type` (the class of an expression, e.g., DATE, TIME, DURATION or SET), and `value` (the normalized meaning of an expression, e.g., `YYYY-MM-DD` for specific days, such as `2022-05-01` for May 1, 2022). While some TEs contain all necessary information for the normalization, e.g., "May 1, 2022", many expressions are incomplete w.r.t. the temporal information required for a normalization. An example is a *relative expression* like "yesterday" which needs an anchor point. Given the anchor point May 1, 2022, for example from the document creation time, "yesterday" should be annotated with `type=`DATE and `value=2022-04-30`.

Determining the anchor point can be challenging as it requires additional context information that could be given anywhere in the document. Therefore, systems for TE normalization, such as HeidelTime (Strötgen and Gertz, 2013), create an intermediate context-independent representation (CIR) of the `value`. In the syntax of HeidelTime, the expression *yesterday* would result in a CIR of `UNDEF-last-day`. Similarly, an *underspecified expression*, such as "May" would be represented with a CIR of `UNDEF-year-05`. Note that such a syntax for CIRs is language-independent. See Appendix A for more details. To determine the final `value`, the CIR needs to be anchored given, e.g., a reference date and further cues (such as tense information).

4 Approach

We propose to approach multilingual temporal tagging in three steps as shown in Figure 1: (1) Extraction of temporal expressions and their types using a multilingual sequence tagger; (2) Normalization of TEs to CIRs with our novel MLM-based normalization model; (3) Anchoring of CIRs given a reference time, e.g., using HeidelTime rules.

Our main contribution is a neural model for the second subtask, the normalization to a CIR. To the best of our knowledge, this has not been addressed with neural networks before. In this section, we detail all components of our approach. Information on the models that we apply for the first and third subtasks as well as an ablation study of directly predicting the normalized anchored value (without CIRs) are given in Section 5.

Masked Language Modeling. We model the task of assigning CIRs to temporal expressions as masked language modeling. In particular, we add TimeML annotations as inline information to the text sequences and mask the value field for prediction, e.g., "... <TIMEX3 type="DATE" value="**MASK**">yesterday</TIMEX3> ...". Note that those annotations could be the ground-truth annotations when applying the model on gold temporal expressions or predicted temporal expressions when using the model in the 3-step pipeline as described above. In our experiments, we train a transformer model for CIR prediction using the

---

[1] `https://github.com/boschresearch/temporal-tagging-eacl`

masked language modeling (MLM) objective.

Slot-Based Value Representation. Using only a single mask token for the whole CIR would require the model to store all possible CIRs in its vocabulary. Since it is not possible to enumerate, i.a., all possible dates, we model the CIRs as a fixed-length sequence of slots. In particular, we define 11 slots and use regular expressions to split the value field into slots in the training data. Figure 1 shows an example for the CIR "UNDEF-year-05" that is represented as the slots " [PAD], [year], [05], [PAD], ..., [PAD]". Details on the slots and regular expressions are given in Appendix A. To cover the full vocabulary of CIRs, we introduce 200 new tokens to the vocabulary of the language model.[2]

Curriculum Learning. Our slot-based representation with 11 slots per CIR results in 11 masks. To train the model on this task, we apply curriculum learning in the first half of the training. In particular, we start with masking only a single slot of the CIR and steadily increase the number of masks up to the maximum of 11. For the second half of the training, masking is applied to all slots. We follow Devlin et al. (2019) and mask different parts of the input with different probabilities. In particular, we mask the value slots with a probability of 70%, annotated tokens with 15%, types with 10% and other text parts with 5%.

Inference and Decoding. For inference, we first add 11 masks (i.e., one per slot) to the input sentence. They serve as value placeholders that need to be predicted. Then, we use the masked language model to predict the most probable sequence of slots for the CIR. To decode the sequence, we apply sequential left-to-right decoding of all masks by iteratively decoding the left-most mask and replacing the mask with its predicted value until all masks are resolved. We compare this to two alternative decoding strategies: (i) decoding all masks simultaneously, (ii) training a conditional random field model that takes the logits as input and uses the Viterbi algorithm to determine the most probable sequence of predictions (Lafferty et al., 2001).

5 Experiments

This section describes our experiments and discusses the results. We compare our model to HeidelTime (Strötgen and Gertz, 2013), the current state of the art for multilingual temporal tagging. For evaluation, we use the TempEval3 evaluation script (UzZaman et al., 2013) and report strict, relaxed and type F_1 for the extraction and value F_1 for our normalization experiments, respectively.

Evaluation Data. Our models are evaluated on gold-standard corpora in 17 languages. Details on the corpora are given in Appendix B.2. We divide the languages into high- and low-resource depending on whether manually created HeidelTime rules are available for the respective language.

Training Data. For training the normalization model, we create a large-scale weakly-supervised dataset covering 87 languages.[3] Reasons are that (i) existing gold training data is too small to cover the wide range of different values and (ii) CIRs are not part of existing annotations. For all languages, we take the data from GlobalVoices[4] (news-style documents) and Wikipedia[5] (narrative-style documents), use spacy for tokenization and HeidelTime for the annotation with temporal expressions. The number and quality of annotations is highly dependent on the amount of available data for that language and the quality of HeidelTime's rules. Details on the weakly-supervised data are given in Appendix B.1.

3-Step Pipeline for Temporal Tagging. Both our temporal expression extraction and normalization models are based on the mulitlingual XLM-R transformer (Conneau et al., 2020).[6]

We model the *TE extraction* as a sequence-labeling problem following Lange et al. (2020). For this, we convert the annotated corpora into the BIO format. For the monolingual setting (Mono), we train one model per language on the gold-standard resources if available or the weakly-supervised data otherwise. For the multilingual setting (Multi), we train a single model on the combined training resources of all languages.

For the *normalization to CIRs*, we train our proposed model with masked language modeling (see Section 4). In our experiments, we evaluate this model in combination with the multilingual extraction model (Multi+OUR) as well as in combination with the gold boundaries for temporal expressions (Gold+OUR) which serves as an upper bound.

---

[2] In our experiments, we compare our pre-defined slots to using subtokens from the language model tokenizer.

[3] The set of 87 languages is the intersection of languages covered by HeidelTime, our data and the XLM-R language model that we use for initializing our models.

Table 1: Detailed overview of our results for extraction (Str., Rel., Typ.) and normalization (Val.) per language for **N**ews and **W**iki domains. The upper and lower parts display high- and low-resource languages, respectively.

For *anchoring CIRs*, we use rules similar to HeidelTime's rules.[7] In particular, anchor dates can be given by the document creation time or by previous temporal expressions (Strötgen and Gertz, 2016).

Results. Table 1 gives an overview of our experimental results. Multilingual extraction outperforms monolingual extraction, probably because the model is able to use knowledge from different languages. Our multilingual model achieves +2 F_1 for high-resource and +51 F_1 for low-resource languages compared to HeidelTime.

The normalization results are given in the *Val.* columns of Table 1. Our masked language model is matching HeidelTime's performance rather close for high-resource languages and outperforms it for low-resource languages with an increase of 33 F_1 points on average with our multilingual extraction model. Note that our models are multilingual, thus, we can use the same model for all languages.[8] The upper bound of using gold extractions (Gold+OUR) shows that the extraction part still offers room for future improvements.

Note that HeidelTime with automatically created rules has a poor performance for some low-resource languages (el, ro, ua). This is similar to the observations by Grabar and Hamon (2019) who found that "[e]xploitation of this automatically built system produced no results when applied to the Ukrainian data." For those languages, the automatic rule generation is not good enough in practice which emphasizes the need for multilingual systems like our model.

Ablation Studies. As our proposed model consists of multiple components, we now investigate their individual effects in more detail. The results for our ablation studies are given in Table 2.

First, we test different *decoding strategies* as described in Section 4. We find that sequential decoding works best. However, it also requires more computation time. A cheaper alternative with only minor performance decreases is the simultaneous decoding of all masks.

Second, we analyze the impact of different *value representations* by comparing our proposed approach with CIR and slot tokenization to (i) tokenization of values using the standard XLM-R

---

[7] More precisely, we use a slightly modified version of HeidelTime's SPECIFYAMBIGUOUSVALUESSTRING function which incorporates tense information of the context using morphological features from spacy (`https://spacy.io/usage/linguistic-features#morphology`).

[8] Since we actually train the MLM model on 87 languages, we could even apply it to more languages if there were gold-standard evaluation datasets publicly available.

tokenizer instead of pre-defined slots (w/o OUR Slots), and (ii) training a model to directly predict the anchored value without CIRs in between (w/o OUR CIR). For (i), we find that our slot method has major advantages when processing narrative texts, such as Wikipedia, due to the higher amount of relative expressions (cf., Table 3 in Appendix B.3), that are tokenized into many subtokens (up to 34, instead of 11 when using our slots). For (ii), we add the document creation time to the input so that the model has more temporal information to predict the fully normalized value directly instead of a CIR. However, we find that current transformers are not able to correctly incorporate this information in a combined normalizing+anchoring step and mostly predict a memorized, incorrect value. Thus, using CIRs as an intermediate step is important for neural temporal tagging.

Third, we investigate the *training strategy* and *training data*. Our curriculum learning has advantages for low-resource languages as it reduces the training complexity which helps for the difficult adaptation to languages with few resources. Weakly-supervised training data is required, as the amount of gold-standard data is too small to train the MLM model. Finetuning the trained MLM model further on gold data (Weak+Gold) decreases performance slightly. Training the model on monolingual data only also decreases performance, highlighting the prospects of our multilingual approach.

Finally, we compare our models to an *encoder-decoder model*, i.e., an autoregressive language model that we adapt to TE normalization. For this, we follow the entity linking approach from De Cao et al. (2021) and train a BART encoder-decoder model (Lewis et al., 2020) for constrained decoding against a subspace of normalized TEs with our weakly-supervised data. We add the document creation time to the input, mark the extracted annotations and keep other TEs in the context, as in our other experiments. Given the gigantic amount of possible temporal expressions, e.g., there are roughly 32M seconds in a single year, we have to prune the search space to a reasonable size. Thus, we do not use time expressions of hour and smaller granularities and restrict the search space to years and months from 1 AD to 2100. Finer elements like weeks, days and daytimes are added for years between 2000 and 2026. We use durations for all defined units with numbers up to 10,000, e.g., 10,000 days. With this, we prune the search space to 1.4B terms which we store in a prefix tree. This results in an acceptable inference speed with BEAM search (5 beams). It takes roughly twice as long as our sequential MLM decoding. Note that this BART model has more parameters (400M) than the base version of XLM-R (270M) that we use in our model. The results are shown in the lower part of Table 2. We see, that our proposed MLM normalization model outperforms the BART model by a large margin. Nonetheless, the encoder-decoder model performs comparable to our model variant that directly predicts fully-normalized expressions. This clearly highlights the need for normalizing to CIRs before anchoring temporal expressions.

6 Conclusion

In this paper, we introduced a new method for normalizing temporal expressions based on masked language modeling and a new slot-based prediction scheme of context-independent representations. With this approach, we were able to train a single multilingual model for the task. We evaluated our method in 17 languages and set the new state of the art in low-resource languages with massive improvements of 35 F_1 points on average. The success of our method demonstrates the potential of neural networks for temporal normalization and we are convinced that it will enable future research on this topic. An interesting research direction is the joint modeling of extraction and normalization.

Limitations

Our experiments are focused on Indo-European languages due to the lack of publicly available, labeled data points in other languages. Exceptions for which we could test zero-shot transfer were Basque, Estonian, Indonesian and Vietnamese. Even though, our model is working for these languages, it is not clear if the multilingual models transfer to all languages seen in the pre-training or by our weak supervision. The training of the multilingual models requires a considerable number of computational resources (up to 1.5 GPU days), which might not be available for all people/organizations. By publishing our model, we hope to lower the barrier for this kind of research by providing a pre-trained starting point. An in-depth error analysis to better understand which types of temporal expressions are well or less well covered in which language by our model was not performed. We are full of hope that such analyses can be tackled by users of our models who have the required language skills so that the analysis does not have to be limited to English.

A Slot Tokenization of CIRs

In this section, we describe our slot-based tokenization of the context-independent representation (CIR) of values as introduced in Section 3 and Section 4 of the main paper.

A.1 Overview of Slots

We use the following 11 slots to represent CIRs values.[9] These slots are then used for masking during training and inference with our normalization model (which basically is a masked language model).

SB: This slot can contain BC information of years (e.g., as in `BC4000` for the year 4000 BC) or the duration markers P and PT. Moreover, mathematical operations like `PLUS` are covered as used in relative expression involving offset computations (e.g., `this-day-plus-2` for the day after tomorrow) and holiday names (`EasterSunday`).

SD1, SD2: These slots are used to represent 4-digit year numbers (**SD1** = `20` and **SD2** = `22` for the year `2022`) by splitting the 4-digit number into two 2-digit numbers. This helps to generalize to unseen years as fewer parameters have to be learned. In addition, we use **SD1** to mark reference expressions like `PAST_REF`. For underspecifed expressions like `UNDEF-this-day`, `this` is stored in **SD1** and day in **SD2**. Moreover, **SD1** and **SD2** are used to store numbers of `DURATION` expressions.

SD3, SD4: Analogously to **SD1** and **SD2** that are used to store year information, **SD3** is used for months and **SD4** for days.

ST1, ST2, ST3: Temporal information from expressions of type `TIME` that are smaller than day granularity are stored in the **ST** slots. For example, the hour information of `24:00` and the daytime information, such as `EV` is stored in **ST1**. Information on minutes and seconds is stored in **ST2** and **ST3**, respectively. Moreover, these slots are used to cover additional units in durations, such as in `P1D2H` (1 day and 2 hours).

SA1, SA2, SA3: Finally, some CIRs include function calls which can be augmented with arguments that we store in the **SA** slots. For example, the argument `2` of `this-day-plus-2` is stored in **SA1**. Other function calls are used to compute days with respect to holidays like `EaserSunday` or specific weekdays.

Note that slots can be optional depending on the temporal expression. For example, the value `2022` representing the year 2022 would only require **SD1** and **SD2**. All other slots are set to a padding value `[PAD]` then which allows a fixed-sized representations of CIRs that can be predicted with our masked language model.

Examples. The following examples show temporal expressions, their corresponding CIRs and the tokenization into our slots. Note that there is no need to capture terms like `UNDEF` in our slots as the presence of words like `this`, `next` or `last` in a CIR implies the existence of `UNDEF` in the CIR.

---

[9] Note that our CIRs describe a superset of TimeML.

This information can be reconstructed when obtaining a CIR from our slots. This also includes `--` to separate numbers as in `YYYY-MM-DD` values, `REF` in reference expressions and `T` for time information. We use the following format to give examples for our CIR conversion: *Text → CIR → Slot Sequence*

- *Now* ...
  → `PRESENT_REF`
  → **SD1**=`PRESENT`

- ... for *1000 days* ...
  → `P1000D`
  → **SB**=`P`, **SD1**=`10`, **SD2**=`00`, **SD4**=`D`

- ... for *one and a half day* ...
  → `P1D12H`
  → **SB**=`P`, **SD1**=`1`, **SD4**=`D`, **ST1**=`12`, **ST2**=`H`

- ... in *1000 BC* ...
  → `BC1000`
  → **SB**=`BC`, **SD1**=`10`, **SD2**=`00`

- ... on the *morning of March 15, 2022* ...
  → `2022-03-15TMO`
  → **SD1**=`20`, **SD2**=`22`, **SD3**=`03`, **SD4**=`15`, **ST1**=`MO`

- On *March 15*, ...
  → `UNDEF-year-03-15`
  → **SD1**=`year`, **SD3**=`03`, **SD4**=`15`

- ... *the day after tomorrow* ...
  → `UNDEF-this-day-PLUS-2`
  → **SB**=`PLUS`, **SD1**=`this`, **SD2**=`day`, **SA1**=`2`

- ... at *Pentecost*[10] ...
  → `UNDEF-year-00-00 funcDate...`
  `...Calc(EasterSunday(YEAR, 49))`
  → **SB**=`EasterSunday`, **SD1**=`year`, **SD2**=`00`, **SA1**=`49`

A.2 Regular expressions

In the following, we will describe the six regular expressions used to split CIR values from HeidelTime outputs into our slots for the weakly-supervised training data.

Notation. For readability, we define the following groups to capture temporal units and other fixed names. Note that these are used across languages. For example, the German expression *Montag* would still be represented with `monday`.

```
UNITS = (H|D|DE|DT|M|C|Y|
    C|CE|W|WE|Qu|Q|S)
UNITS_F = (day|month|year|
    decade|century|week|
    weekend|quarter|
    hour|minute|second)
DAYTIME = (NI|AF|MO|EV|MD|MI)
SPECIAL = (SP|SU|FA|AU|WI|
    H1|H2|Q1|Q2|Q3|Q4|H|Q)
NAMES = (monday|tuesday|
    wednesday|thursday|
    friday|saturday|sunday|
    january|february|march|
    april|may|june|july|
    august|september|
    october|november|december)
```

In the following, $DX(n)$ marks the n-th group captured by the regular expression DX.

$D1$: References. The first regular expression $D1$ is used to capture simple reference expressions that refer to uncertain points in time.

```
D1 = (PRESENT|PAST|FUTURE)_REF
Slots: SD1=D1(1)
```

$D2$: Explicit Dates. The second regular expression $D2$ detects explicit values that do not need further normalization, such as days in the `YYYY-DD-MM` format, e.g., `20222-03-15`.

```
D2 =(BC)?(\d\d?|XX)?(\d\d|XX)?
  (?:-(W)?(\d\d?|XX|SPECIAL))?
  (?:-(\d\d?|XX|WE))?\)?
  (?:T(\d\d|X|DAYTIME|XX)?
  (?::(\d\d))?
  (?:(?::|-)(\d\d))?)?
Slots: SB=D2(1), SD1=D2(2),
  SD2=D2(3), SD3=D2(5), SD4=D2(6),
  ST1=D2(7), ST2=D2(8),
  ST3=D2(9)|D2(4)
```

$P1$: Durations. The third regular expression $P1$ detects expressions of `type` DURATION, e.g., `P1D2H`. These are defined as `P<number><unit>` for units of at least day granularity and `PT<number><unit>` for smaller granularities. We capture up to two different units `P1D2H` (1 day and 2 hours) but ignore further units that are theoretically defined in the TimeML specifications but do not occur often in practice (in our datasets those did not occur at all).

```
P1 = (P|PT)(\d\d?|X|XX)
  (\d\d|\.)?(\d\d?)?)?(UNITS)?
  (\d\d?)?(UNITS)?
Slots: SB=P1(1), SD1=P1(2),
  SD2=P1(3), SD3=P1(4), SD4=P1(6),
  ST1=P1(5), ST2=P1(7)
```

---

[10] In christian communities, the holiday of Pentecost is celebrated 49 days after Easer Sunday.

$D3$: **Relative Dates.** While the previous regular expressions $D1$, $D2$ and $P1$ follow the TimeML specifications and capture fully normalized expressions, i.e., anchored values, the following regular expressions capture CIRs as used internally by HeidelTime. They represent relative expressions that need to be anchored.

$D3$ detects relative expressions with respect to a certain point in time, such as `this-day-plus-2` (the day after tomorrow).

```
D3 = UNDEF-(this|next|last|REF|
      REFUNIT|REFDATE)?-?
  (UNITS_F|SPECIAL)?-??
  (NAMES|SPECIAL)|XX|\d\d?)?
  (?:-?(\d\d?|XX))?
  (?:-(PLUS|MINUS|LESS)-(\d\d?)-?
  (\d\d?)?-?(\d\d?)?)?\)?
  (?:T(\d\d?|X|DAYTIME|XX)?
  (?::(\d\d?|XX))?(?:(?::|-)
      (\d\d|XX))?)
Slots: SB=D3(5), SD1=D3(1),
  SD2=D3(2), SD3=D3(3), SD4=D3(4),
  ST1=D3(9), ST2=D3(10), ST3=D3(11),
  SA1=D3(6), SA2=D3(7), SA3=D3(8)
```

$D4$: **Relative Dates (coarse).** $D4$ captures underspecified expressions like *May* that is missing year information and would be represented with the CIR `UNDEF-year-05`.

```
D4 = UNDEF-(year|decade|century?)
  -?(\d\d?|X)?-?(\d\d?|X)?-?
  (\d\d?|X|SPECIAL)?\)?
  (?:T(\d\d?|X|DAYTIME)?
  (?::(\d\d?|XX))?
  (?:(?::|-)(\d\d|XX))?)?
Slots: SD1=D4(1), SD2=D4(2),
  SD3=D4(3), SD4=D4(4),
  ST1=D4(5), ST2=D4(6), ST3=D4(7)
```

$D5$: **Holidays and functions.** Finally, $D5$ covers special functions used by HeidelTime. These functions are used to compute days with respect to weekdays and moveable feasts like `EasterSunday` that refer to different days depending on the year. For example, the earliest possible date of Easter Sunday is March 22 and the latest is April 25 in the Gregorian calendar.[11] The concrete date is then computed by an external function given a year.[12]

```
D5 = (UNDEF-year|UNDEF-this-year|
        UNDEF-century\d\d|\d\d\d\d)-
    (\d\d)-00 funcDateCalc\((
        WeekdayRelativeTo|
        EasterSundayOrthodox|
        EasterSunday|
        ShroveTideOrthodox)
    \(YEAR(?:(?:-(\d\d)))?
    (?:-(\d\d))
    (?:,\s?(-?\d\d?))?
    (?:,\s?(-?\d\d?))?
    (?:, (true|false))?\)\)
Slots: SB=D5(3), SD1=D4(1),
    SD2=D4(2), SD3=D4(5),
    SD4=D4(7), ST1=D4(3),
    SA1=D5(6), SA2=D5(7), SA3=D5(8)
```

B Data Statistics

B.1 Weakly-Supervised Data

As detailed in Section 5, we create weakly-supervised data to train our normalization model, as the gold standard is too small and is not annotated with CIRs which are required by our method. For all languages, we take the data from GlobalVoices[13] (news-style documents) and Wikipedia[14] (narrative-style documents), use spacy for tokenization and our HeidelTime version that outputs CIRs for the annotation with temporal expressions. The sizes of our weakly-supervised data for each language are given in Table 4.

B.2 Gold-Standard Data

Detailed information on the datasets used in this paper (their languages, domains, sizes and references) are provided in Table 5. Note that all corpora come from the news domain except the WikiWars corpora that are based on Wikipedia articles.

B.3 Distribution of Explicit and Relative Values

The distribution of explicit and relative values has a large impact on the normalization performance of different models, as shown in our ablation study in Section 5. Exemplarily, we analyze their distribution in the German and English datasets for which we have data from two domains: News and Wikipedia. The results are given in Table 3. We see, that the Wikipedia corpora contain a much larger percentage of relative values as these articles often follow a narrative structure (cf., (Strötgen and Gertz, 2016).

C A Note on Adopting HeidelTime

In our experiments, we used a modified version of HeidelTime. First, we implemented a new UIMA collection reader based on spacy as an alternative to

Table 3: Distribution of explicit / relative values according to HeidelTime by domains (in %).

the TreeTagger that has a restrictive license. This results in a slightly different sentence segmentation and tokenization, and, thus, minor differences in performance. For example, the original HeidelTime achieves 63.47 F_1 on the Portuguese test data, while our spacy version achieves 63.24 F_1 as one additional false positive expression was annotated due to different sentence boundaries. Second, we adapted HeidelTime to output its internal CIRs for the TimeML values, such that we can create our weakly-supervised training data.

The rather low performance of our models and HeidelTime for the high-resource languages Estonian (et) and Dutch (nl) can be explained by poor data quality. An inter-annotator agreement of 44 F_1 was reported for the Estonian corpus (Orasmaa, 2014), which is close to our results. The Dutch data was translated from English and automatically annotated via cross-lingual projections (Minard et al., 2016), which may reduce the annotation quality. Note, that only the first five sentences for each document were annotated in the Meantime corpora (it and nl). We restricted our evaluation to these annotated parts accordingly.

Abstract

We present FewShotTextGCN, a novel method designed to effectively utilize the properties of word–document graphs for improved learning in low-resource settings. We introduce K-hop Neighborhood Regularization, a regularizer for heterogeneous graphs, and show that it stabilizes and improves learning when only a few training samples are available. We furthermore propose a simplification in the graph-construction method, which results in a graph that is ∼7 times less dense and yields better performance in low-resource settings while performing on-par with the state of the art in high-resource settings. Finally, we introduce a new variant of Adaptive Pseudo-Labeling tailored for word–document graphs. When using as little as 20 samples for training, we outperform a strong TextGCN baseline with 17% in absolute accuracy on average over eight languages. We demonstrate that our method can be applied to document classification without any language model pretraining on a wide range of typologically diverse languages while performing on par with large pretrained language models.

1 Introduction

Text classification, a key task in natural language processing (NLP), has many real-world applications, including toxic comment identification, news categorization, spam detection and opinion mining. One popular approach to this problem relies on large-scale pretraining of Transformer models (Devlin et al., 2018; Conneau et al., 2019; Raffel et al., 2020), which have shown to be able to approach or even surpass human performance on many natural language understanding (NLU) benchmarks (Rajpurkar et al., 2016; Wang et al., 2019; Liang et al., 2020). While these results are impressive for the languages on which models are pretrained, performance tends to deteriorate on languages where no or little data is available (Chau and Smith, 2021; van der Heijden et al., 2020). In practice, this means that these models are effective on a set of approximately 100 out of the 7000+ spoken languages in the world. Next to the requirement for vast amounts of data for pretraining, Transformer language models tend to be impractically large in terms of their number of parameters and have a high environmental footprint (Strubell et al., 2019).

Recently, Graph Neural Networks (GNNs) have shown to be effective for text classification in both transductive (Yao et al., 2019; Liu et al., 2020; Lin et al., 2021) and inductive (Nikolentzos et al., 2020; Ding et al., 2020) learning settings – with promising results in both high- and low-resource settings. Particularly in the transductive setting, the authors of TextGCN (Yao et al., 2019) show that Graph Convolutional Networks (GCNs) (Kipf and Welling, 2016) can outperform state-of-the-art methods for document classification on English datasets without any language model pretraining. They do so by modeling an entire corpus of documents simultaneously as one heterogeneous word–document graph. The document classification task is formulated as a node-classification task over this graph.

Later work shows that (multilingual) Pretrained Language Models (mPLMs) can be used to provide GNNs used in transductive setting with rich representations of both words and documents, improving results further in both monolingual (Lin et al., 2021) and cross-lingual settings (Wang et al., 2021; Li et al., 2020). These works focus solely on high-resource settings and do not report any results on performance in low-resource settings.

In this work, we propose a novel GNN-based method for learning document classification tasks on a range of languages without the need for any pretraining data (i.e., without utilizing any pretrained word embeddings or language models), and from few labeled samples only. To the best of our knowledge, we are the first to investigate few-shot graph-based transductive document classification

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1187–1200

in a range of languages other than English.

We present FewShotTextGCN, an improved version of the original TextGCN model, where we exploit properties of the heterogeneous word–document graph for improved learning from scratch and with only a few labels. More specifically, we:

(1) Introduce K-hop Neighborhood Regularization (K-NR), an unsupervised learning technique for heterogeneous graphs, and use it in its $K = 2$ instantiation as a regularizer tailored to word–document graphs , and show that it consistently leads to performance gains in low-resource settings;

(2) Propose a simplification of the graph-construction method, which results in improved performance in the low-resource setting while reducing the graph density by a factor of approximately 7 on average, therefore substantially speeding up computations and reducing memory requirements;

(3) Present a variant of adaptive pseudo-labeling (Zhou et al., 2019) on word–document graphs and show that it leads to consistent gains over the original TextGCN approach (Yao et al., 2019), particularly when combined with K-NR.

We compare FewShotTextGCN to its predecessor and two strong PLMs on ten topic classification benchmarks comprising eight typologically diverse languages, and experiment with a range of low-resource settings, including using as little as 20 labeled samples to learn from, and without any other form of (pre-trained) knowledge about a language except for what constitutes a word (using word boundaries or a tokenizer). In our lowest-resource setting, our method outperforms TextGCN with 4.6% and 17% points in absolute accuracy on average for Reuters and MLDoc, respectively – while having a substantially smaller computational and memory footprint. FewShotTextGCN performs on par with large PLMs on the great majority of the considered benchmarks, without the need for any large-scale pretraining and at only a fraction of the parameter count of these PLMs – indicating that graph-based methods are an attractive alternative to using large PLMs for topic classification. All our code and models are released to facilitate further research on this topic.[1]

2 Graph Neural Networks

Graph Neural Networks (GNNs) are a class of neural models designed to facilitate representation learning on geometric data – data that naturally occur in many situations/fields, such as chemistry, social networks, maps, visual meshes, etc. Recently, there has been a great surge in research on GNNs. GNNs create new feature representations of nodes by aggregating the nodes' own feature representation and a message passed on from neighboring nodes. A graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ is defined as a set of nodes $\mathcal{V}$ with edges $\mathcal{E}$ between them, typically represented as a square adjacency matrix A, where each entry holds the weight of the edge between node j and i. Locality in graphs is defined by neighborhoods, where the neighbors of node i are defined as $\mathcal{N}_i = \{j : (i,j) \in \mathcal{E}\ \forall (j,i) \in \mathcal{E}\}$. Let $\bigoplus$ be some permutation invariant aggregator such as sum, $average$ or max, and let ψ and ϕ be two differentiable, learnable functions such as an MLP. Using these ingredients, we can describe GNNs by the way they do message passing.

Convolutional GNNs use the weights c_{ij} of the edge between nodes j and i to weigh the incoming messages. These weights are part of the definition of the graph, meaning they are statically defined. The input feature x_i of node i is transformed to a latent representation h_i by taking

$$h_i = \phi(x_i, \bigoplus_{j \in \mathcal{N}_i} c_{ij}\psi(x_j)) \tag{1}$$

The first and most well-known convolutional GNN is the Graph Convolutional Network (GCN) (Kipf and Welling, 2016).

3 Related work

Our work is based on TextGCN (Yao et al., 2019), which also serves as our baseline for all experiments. To the best of our knowledge, we are the first to investigate few-shot graph-based transductive learning from scratch for document classification in a range of languages other than English. Since the scope of our work is few-shot document classification in many languages by learning from scratch, we do not consider CLHG (Wang et al., 2021) directly related work. The reasons being it models corpora in multiple languages jointly, whereas we learn each task in isolation, and relies on machine translation and mPLMs. Similarly, MGL (Li et al., 2020) relies on mPLMs for encoding similar corpora in different languages into one

---

[1] `https://github.com/mrvoh/FewShotTextGCN`

embedding space, where consecutively a graph is dynamically constructed based on the similarity of the documents in the respective embedding space. Finally, meta-learning is applied to learn to classify documents in one language, given a limited set of documents in at least three other languages. Hence, we do not review these works in-depth.

TextGCN TextGCN (Yao et al., 2019) is the first application of GNNs to transductive text classification, applied on English datasets without any language model pretraining. The great majority of experiments is performed in high-resource settings, but a small set of results on performance in low-resource settings is also provided – motivating us to further explore and expand upon this subject. The authors construct a heterogeneous graph containing both word and document nodes. Word–word edges are weighed based on the pointwise mutual information (PMI) between the respective words, and word–document edges are created based on the TF–IDF score of the word in the respective document. More specifically, the adjacency matrix A is defined as:

$$A_{ij} = \begin{cases} \text{PMI}(i,j) & i,j \text{ words, PMI}(i,j) > 0 \\ \text{TF–IDF}_{ij} & i \text{ document, } j \text{ word} \\ 1 & i = j \\ 0 & \text{otherwise} \end{cases} \tag{2}$$

Document–document links are not considered. A one-hot encoding is used as input features for the nodes and a two-layer GCN is used to classify the document nodes. While this setup is relatively simple in terms of preprocessing, pretraining and the number of parameters in the model, the authors show that their method performs on par with state-of-the-art methods, even improving the state of the art for the 20News[2] dataset.

BERTGCN Follow-up work on TextGCN is that of BERTGCN (Lin et al., 2021), where the authors leverage PLMs to initialize document–node features. More specifically, a BERT-based model is used to encode the documents, and all other nodes are initialized with a one-hot vector. The BERT model used for encoding documents is optimized both via gradients propagated through the GCN and via an auxiliary classifier that directly uses the BERT embeddings to classify the documents. Using BERTGCN, the authors improve over TextGCN on a variety of text classification tasks – especially on a sentiment analysis task, for which word order information is crucial for good performance (Johnson and Zhang, 2014). To be able to use BERTGCN in a full-batch gradient descent method, the authors use a memory bank that allows decoupling the dictionary size from the mini-batch size. Although the presented results are promising, a drawback of using large PLMs is the need for vast amounts of pretraining data, making these methods inaccessible for low-resource languages.

4 Data

In this section, we give an overview of the datasets we use and the respective classification tasks.

MLDoc Schwenk and Li (2018) published an improved version of the Reuters Corpus Volume 2 (Lewis et al., 2004) with balanced class priors for all languages. MLDoc consists of news stories in 8 languages: English, Spanish, French, German, Italian, Russian, Japanese and Chinese. Each news story is manually classified into one of four classes: *Corporate/Industrial (CCAT), Economics (ECAT), Government/Social (GCAT)* and *Markets (MCAT)*. Per language, the train and test datasets contain 1k and 4k samples respectively.

Reuters 21578 From the Reuters-21578 dataset, a dataset of English news articles on a wide variety of topics, we use the **R8** and **R52** subsets (all-terms versions[3]). R8 has 8 categories and consists of 5485 and 2189 samples for training and testing respectively. R52 has 52 categories and 6532 and 2568 samples for training and testing respectively. The distribution of samples over the respective categories is highly skewed.

During preprocessing on both datasets for all GNN-based models, we remove words with a frequency of less than 5, and tokenize the data. For all languages except Japanese and Chinese, we split sentences based on whitespace. For Chinese, we use the Jieba[4] tokenizer, and for Japanese, the Fugashi one (McCann, 2020). For Transformer-based models, solely their respective tokenizers are used.

5 Approach

Graph construction We follow the graph construction method as described in the original

---

[3] `https://ana.cachopo.org/datasets-for-single-label-text-categorization`

[4] `https://github.com/fxsjy/jieba`

TextGCN (Yao et al., 2019) work except we deviate in two different directions. Stopword removal is omitted, as this assumes knowledge of the language, whereas we aim for an approach that assumes no prior knowledge. Furthermore, word–word edges are omitted too. Omitting such edges results in a much less densely connected graph, making learning substantially less memory intensive. We argue that the added value of word–word edges in a word–document graph is minimal given 1) only global information of word co-occurrence is considered (i.e., co-occurrence over the whole corpus as opposed to within document co-occurrence), and 2) over the course of training, words co-occurring in a document can influence each other's representation through an N-layer GNN where $N > 1$. We illustrate this with an example in Appendix E, while in Section 8, we experimentally demonstrate the limited effect of word–word edges using ablation studies.

K-hop Neighborhood Regularization (K-NR) We propose a new method that can exploit the properties of a word–document graph, inspired by approaches such as GraphSage (Hamilton et al., 2017) that shows that meaningful node representations can be learned in an unsupervised manner with contrastive learning methods like Node2Vec (Grover and Leskovec, 2016). These methods typically consist of two components: a sampling technique for deciding what nodes are regarded as positive or negative samples, and a loss function. Let u be the anchor node, P_p the positive sample sampling method, P_n the negative sample sampling method, and $\mathcal{J}_{\mathcal{G}}(u, P_p, P_n)$ the contrastive loss function. In the case of GraphSage, P_p is defined as a random walk starting from the anchor node, and P_n is defined as uniformly sampling from all available nodes.

This contrastive learning approach on graphs assumes homogeneity and P_p always samples in the 1-hop neighborhood from the anchor node. Herein, we propose a contrastive learning regularization method tailored on heterogeneous graphs instead, where nodes of the same type are K-hops away from each other on the graph.

In what follows, we describe our approach in detail for heterogeneous word–documents graphs for the specific case of K-NR with $K = 2$. Driven by the intuition that documents (within a language) that share large parts of their vocabulary are more likely to be about the same topic, we introduce 2-hop Neighborhood Regularization (2-NR), a novel unsupervised learning method which can be used as a regularization technique.

Let $\mathcal{G} = (\mathcal{V}, \mathcal{E})$ be the graph defined by the vertices $\mathcal{V}$ and edges $\mathcal{E}$. Let $\mathcal{V}_d, \mathcal{V}_w$ be the document and word nodes respectively. Given anchor node $u \in \mathcal{V}_d$, we first sample a word node $v \in \mathcal{V}_w$ connected to u by sampling from a multinomial distribution weighted by the edge attribute values (the TF–IDF scores):

$$v \sim Multinomial(1, A_{u,\{w|w\in\mathcal{V}_w \wedge w\in\mathcal{N}(v)\}}) \quad (3)$$

Then, a positive document node u_p and negative document node u_n are sampled as follows:

$$u_p \sim U(\mathcal{N}(v)) \quad (4)$$

$$u_n \sim U(\mathcal{V}_d \setminus \mathcal{N}(v)) \quad (5)$$

Let z_u be the final hidden representation of node u, the 2-NR loss, $\mathcal{L}_{2\text{-}NR}$, is then defined as:

$$\mathcal{L}_{2\text{-}NR}(u, u_p, u_n) = max\{d(u, u_p) - d(u, u_n) + m, 0\} \quad (6)$$

for some distance function d and margin m. This represents a triplet margin loss (Balntas et al., 2016), which forces u to be closer to u_p than u_n by at least a margin m. See Appendix A for an elaboration on the intuition of 2-NR as well as a visualization. In the word–document graph case, $K = 2$ works specifically because we know that document nodes are only connected to word nodes and vice versa (see Section 5 for a description of our graph construction method). Hence, when starting at a document node, all nodes in its neighborhood are word nodes and similarly, all those word nodes do exclusively have edges to document nodes. Hence any walk of two steps starting at some document, will end up at another document via a word (node) they both contain. This simplifies the implementation for our specific word–document graph, but one can easily imagine generalizing the method to situations where taking K hops on the graph does not guarantee ending up at a node of the same type as the start node by restricting the sampling methods to a subset of the desired nodes.

Adaptive pseudo-labeling Pseudo-labeling is a well-explored technique for improving performance in semi-supervised learning settings (Lee et al., 2013), which, recently, has also been successfully applied to graphs (Zhou et al., 2019; Chen et al., 2021). We argue this technique can be particularly powerful for heterogeneous word–document graphs based on three premises:

(1) Different topics/classes have a different distribution of words in their vocabulary. So it can be assumed that there exist words per class that occur more often in documents corresponding to that respective class – i.e. these words are more distinctive for that given class, which in the word–document graph translates to that word node having relatively more edges to documents of the class the respective word is distinctive for.

(2) Document nodes are always at least two hops away from each other in the graph, meaning that only the input features of one document can influence the final feature representation of another document via message passing on the graph. This is assuming a two-layer GNN.

(3) The most effective way of encoding label information in the input document embedding is by directly optimizing for that respective class on the node, as opposed to relying on indirect optimization via backpropagating through the message-passing computational graph.

Instead of applying adaptive pseudo-labeling to the whole graph, we propose to only apply it to a subset of unlabeled document nodes, $\mathcal{U}_d$, that are not part of our train or test split. By doing this, we can directly optimize an unlabeled document embedding to be a good predictor for a certain class (premise (3)) . This class-tailored document embedding can now be propagated over the graph to be used in the final feature representation of other document nodes via message passing on the graph (premise (2)). Finally, we can assume that there exist word nodes in the graph which are characteristic of a topic/class and via which the class-specific features can be propagated to other documents without losing information due to over-smoothing (premise (1)).

We implement adaptive pseudo-labeling as described by Zhou et al. (2019), which adds an extra component to the total loss, the pseudo-label loss $\mathcal{L}_{pse}$:

$$\mathcal{L}_{pse} = \sum_{v_i \in U'} \frac{1}{N_i} CE(\tilde{Y}_i, F_i) \tag{7}$$

With CE representing the cross-entropy loss, $\tilde{Y}_i$ the pseudo-label and $F_i \in \mathbb{R}^C$ the predicted probability per class. The pseudo-label is generated by taking the argmax over F_i, which results in the pseudo-label loss optimizing for high-confidence predictions on the most certain class. The set of unlabeled samples U' used for this loss is defined as:

$$U^{'} = \{u_i : u_i \in U_d | F_{i,j} \leq \beta\}, j = \underset{j^{'}}{argmax} F_{i,j'}\} \tag{8}$$

Some minimum confidence threshold β is used to filter out predictions, and the pseudo-loss per node is weighted by dividing it by N_i, the amount of nodes which have the same predicted label as node u_i and are part of U'.

6 Experimental setting

Throughout our experiments, TextGCN is used as a directly comparable baseline. Since our main goal is to develop a method that performs well in low-resource scenarios for many languages without the need of any knowledge of that language – apart from the ability to identify word boundaries in a sentence – our setup deviates from the original TextGCN work. Unlike the original work, we do not perform a grid-search of hyperparameter settings per experiment/language, but rather keep them fixed – which make our results not directly comparable to the original. Similarly to the original TextGCN work, we also consider the R8 and R52 datasets for an analysis of our approach on English (see Section 4). Additionally, we also provide results for two PLMs trained with the same amount of data. These results are not directly comparable, since the PLMs are trained in an inductive setting, but are included to provide better insight into the positioning of our method in the context of broader literature.

PLM baselines We introduce both multilingual BERT (mBERT) (Devlin et al., 2018) and XLM-R (Conneau et al., 2019) as strong baselines based on the Transformer (Vaswani et al., 2017) architecture. These baselines are fine-tuned in the same data settings, with their architecture settings kept as their defaults as defined in the HuggingFace Transformers library (Wolf et al., 2020). For training, a learning rate of 5e-5 and a batch-size of 20 is used.

Learning settings We investigate the effectiveness of our approach when learning from 1%, 2%, 5%, 10% and 90% of the available training samples. The 1% setting is only considered for the R8 and R52 datasets, due to the already relatively small

Table 1: Average accuracy across 5 different seeds on the test set using a different number of training samples available. Δ corresponds to the average accuracy across all datasets/languages. Methods starting with "+" correspond to TextGCN extended with one of our corresponding proposed methods at a time. FewShotTextGCN refers to the combination of all our proposed improvements together (i.e., including *both* 2-NR and adaptive pseudo-labeling) as well as our adjusted graph construction method. Highest scoring method per benchmark is marked in **bold**.

training set size in the MLDoc datasets. For all settings except the 90% one, the size of the validation set is equal to the size of the training set (see Appendix D for a background experiment on the influence of the division of a limited set of labeled samples over the train and validation sets). The remaining documents are then added to the word–document graph as unlabeled nodes. For the high-resource setting (90%), the remaining 10% of the training set is used for validation (i.e., no unlabeled nodes). We train all GNN models from scratch for each language and do not rely on any form of transfer- or multi-task learning.

Training setup and hyperparameters We use the Ranger optimizer (Liu et al., 2019; Zhang et al., 2019; Yong et al., 2020), an adapted version of Adam (Kingma and Ba, 2014). All experiments run for 1000 epochs and the model with the lowest validation loss is used at test time. A learning rate of 0.01 and dropout of 0.5 are used throughout all experiments except when mentioned otherwise. All hidden dimensions are set to 64 and in line with the original TextGCN work, we use two layers of GCN followed by one linear layer for classification. The log schedule for training signal annealing as per Appendix A.2 in Xie et al. (2020) is used whenever 2-NR is applied. For pseudo-labeling, we set

7 Results

7.1 Comparison to TextGCN

MLDoc Table 1 shows the results of our experiments. In the 2% training data setting, FewShotTextGCN outperforms TextGCN by 17% points on average (Δ) on the eight languages of the MLDoc dataset, showing that we can effectively utilize the properties of heterogeneous word–document graphs to improve learning in low-resource settings in many languages. For MLDoc, which is a dataset with uniform class priors, we see the difference in performance between original TextGCN and TextGCN combined with 2-NR grows larger as the amount of training data decreases, demonstrating that our proposed 2-NR regularizer helps to combat overfitting. Comparing the '+2-NR' results to those of FewShotTextGCN (that uses both 2-NR and adaptive pseudo-labeling), it can be seen that, overall, our regularizer is the primary contributor in outperforming the TextGCN baseline. Our version of adaptive pseudo-labeling also outperforms the TextGCN baseline, with the largest margins in the low-resource settings, indicating the effectiveness of utilizing unlabeled document nodes in the word–document graph.

In the high-resource (90%) setting of MLDoc, FewShotTextGCN performs on a par with the original TextGCN. This can be explained by the fact that 2-NR is a regularization method and the training data set is relatively large in the high-resource setting, which makes that adding regularization to the learning process can be redundant. Furthermore, our version of adaptive pseudo-labeling works based on a set of unlabeled documents not belonging to either the train or the test set, which is a relatively small set of documents in this setting, namely only 10% of the documents of the total training set.

Reuters Interestingly, FewShotTextGCN outperforms TextGCN consistently in all data settings for the English Reuters datasets, which are highly skewed in their class distribution. This can be seen as supporting evidence for the hypothesis that 2-NR forces the learned feature representations of documents to contain information of all words it contains, which helps to learn distinguishing features for documents of minority classes.

7.2 Comparison to PLMs

MLDoc Although FewShotTextGCN only uses $\approx 1\%$ of the parameters, has no pretrained knowledge of the considered languages, has no notion of word order in the documents and does not make use of a shared subword vocabulary, it performs on par with large PLMs across all settings for MLDoc. In the lowest resource setting, FewShotTextGCN outperforms all considered PLMs, whereas both PLMs start performing on par as the amount of available data increases. We hypothesize that the somewhat larger difference in performance for the Russian language is attributable to the fact that Russian is a highly inflective language, resulting in many unique words to learn a representation for. The PLMs have the advantage of using a subword vocabulary which serves as a remedy for the formerly described sparsity challenge.

Reuters For R8 holds that similarly to the results on MLDoc, FewShotTextGCN outperforms the PLM baselines in the two lowest-resource settings, whereas the PLMs perform better when more training data is available. The results on R52 are more notable, as the gap in performance between FewShotTextGCN and the PLMs grows relatively larger with more available training data. We hypothesize this could be due to the fact for FewShotTextGCN we use only a 64 dimensional hidden size to encode the 52 classes of the dataset, whereas the PLMs use a hidden size of 768.

8 Ablation experiments

The original TextGCN implementation proposes to use edges between words based on their respective PMI. Since PMI is calculated using a window size of 20, many extra edges are introduced. For the MLDoc dataset, omitting word–word edges results in a graph that has, on average, only 15% of the amount of edges compared to the original graph (see Table 2 for statistics on the number of edges per graph construction method). To analyse the effect of word–word edges, we evaluate the original TextGCN method across the different graph construction methods in the same data availability settings as our main set of experiments (Table 2). The results provide empirical evidence that, on average, word–word edges are redundant in topic classification problems. The average performance using graphs without word–word edges is always higher; however, performance difference between the two graph construction methods does get smaller as more data is added. In Appendix E we present a visual walk-through of how words can still influence each other's feature representations in a graph without word–word edges.

9 Discussion

K-NR for K > 2 Here, we argue by example that K-NR can also be applied to other heterogeneous graphs with two or more different kinds of nodes. Consider a network with three kinds of nodes: venue nodes, paper nodes and author nodes (Shi et al., 2016). Venue nodes have a connection to a paper node if the paper is published at that venue and authors have a connection to the paper node when they are a contributor to that respective paper. No other edges exist on this graph and the classification task concerns the author nodes. In this case, we could apply K-NR on the author nodes based on the intuition that authors that publish a paper at the same venue are more similar to each other than authors that do not publish at the same venue. In order to get from the anchor author node to a positive author node, one has to traverse the graph by hopping to a neighboring paper, venue, paper and finally author node in that respective order – resulting in $K = 4$. On this same graph, K-NR can be applied for paper nodes as well for $K = 2$ and traversing via the venue node. In general, considering a graph with M different node types, K-NR can be applied if in terms of node types a symmetrical path with an odd number of nodes can be traversed. In this case, $K = 2(M - 1)$.

10 Conclusion

We introduced K-hop Neighborhood Regularization (K-NR), a contrastive learning method for heterogeneous graphs, and showed its implementation for word–document graphs (2-NR) is highly effective in improving learning from scratch in low-resource settings for a range of languages on topic classification tasks. We also showed that we can exploit properties of word–document graphs for improved learning in few-shot settings. We demonstrated that by simplifying the graph construction method via omitting word–word edges we can improve performance while reducing memory requirements in terms of total number of edges. Additionally, we showed how pseudo-labeling can be successfully applied to word–document graphs. All approaches combined together form part of our new proposed method, FewShotTextGCN, an improvement over TextGCN for few-shot graph learning. FewShotTextGCN performs on par with large PLMs across the considered benchmarks using only a fraction of the parameters and no pretraining whatsoever, showing that GNNs are an attractive alternative for these Transformer-based models. Finally, using this method, we showed that transductive document classification can be performed successfully on a wide range of typologically diverse languages without any language model pretraining. In future work, we plan to explore the effectiveness of 2-NR on a large range of graphs, such as social networks, citation networks and product–user networks as well as adaptations of K-NR for $K > 2$.

11 Limitations

Our work focused on a subset of the text-classification field, namely topic classification. In order to generalize our contributions to other subsets such as sentiment classification, our method might benefit from incorporating word order (Johnson and Zhang, 2014). Secondly, adding 2-NR to the training process does slow down the convergence rate of training. Exemplified: regular TextGCN would often reach its lowest validation loss in the range of 50 to 200 update steps, whereas TextGCN + 2-NR would often reach its lowest validation loss in the range of 700 to 900 update steps. We do not consider this a major limitation as all experiments can still be performed on a single GPU with 8Gb of RAM.

A 2-NR intuition and visualization

In Figure 1, we present a visualization of the process behind 2-NR. Intuitively, 2-NR forces the model to incorporate information of all words contained in it such that documents with shared neighbors (i.e., overlap in vocabulary) are closer to each other in semantic space than documents without shared neighbors in feature space, resulting in learning better feature representations of documents.

B Dataset statistics

Table 3 presents an overview of data statistics.

C Visualization of document embeddings

Figure 2 shows an example of the difference in class separability between TextGCN and our method, FewShotTextGCN. It can be easily seen that using FewShotTextGCN there is less overlap between regions in which instances of the respective classes live, which is in line with the observations in Table 1 where FewShotTextGCN outperforms TextGCN by 26% points absolute accuracy.

D Effective use of data on a limited budget: training vs validation

Figure 3 shows the average accuracy and standard deviation of 10 seeds when learning from a total of

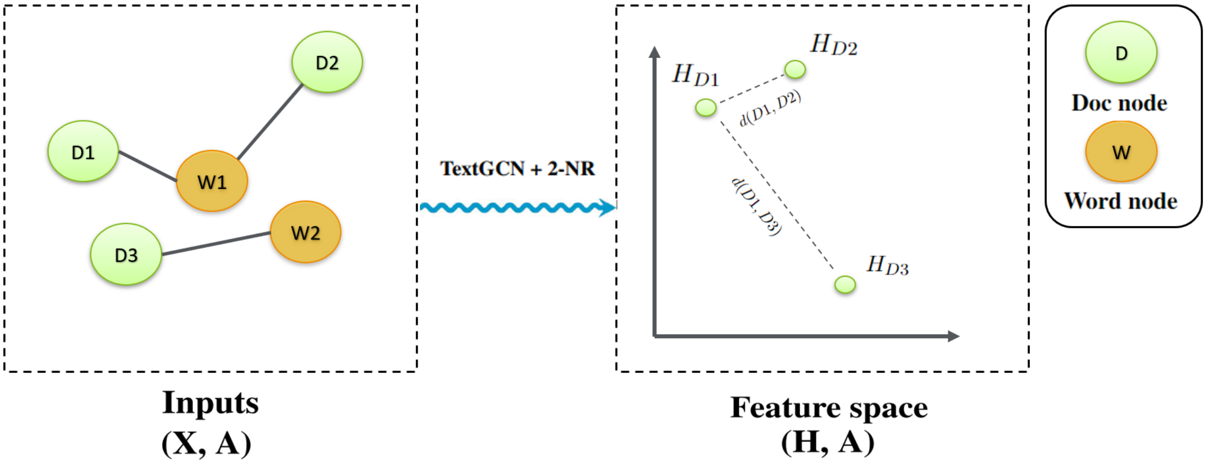

Figure 1: **2-hop Neighborhood Regularization visualized for a simple graph.** On the left, the graph is defined as a set of nodes X and an adjacency matrix A. The right figure depicts the transformed features H of each document D_i. Documents $D1$ and $D2$ have word $W1$ as shared neighbor and hence their distance in feature space (depicted by the dotted line with $d(D1, D2)$) gets smaller, whereas the feature representations of $D1$ and $D3$ get pushed away from each other, resulting in a larger distance in the respective space ($d(D1, D3)$). Word nodes are omitted in feature space (right-hand side) for demonstration purposes.

Table 3: Summary statistics of datasets.

Dataset	# Docs	# Training	# Test	# Words	# Nodes	# Classes	Average Length
MLDoc-de	5,000	1,000	4,000	14,358	19,358	4	144

100 labeled samples, divided over the train and validation set for Japanese and German, using the original TextGCN model. Other languages are omitted from the plot to prevent visual cluttering, but follow a similar trend: when using too little data for training, the model fails to learn to generalize well – as can be seen by the relatively low average accuracy on the test set. For German, it is even the case that learning does not converge at all when training on 10 samples, as we observe a mean accuracy of 25% when the number of training samples is 10. The balance between achieving the highest accuracy with the smallest standard deviation seems to be around the 50/50 split point. Increasing the training data at the cost of fewer validation data after this point can, in some cases, such as for Japanese at the 80/20 point, result in slightly higher accuracy, but the standard deviation across different seeds also increases, confirming the importance of a good-sized validation set during learning.

E On the usefulness of word–word edges in word–document graphs: illustration

We argue that the added benefit of word–word edges is limited based on the premises that: 1) words occurring in the same window might not influence each other's meaning at all, especially since sentence boundaries are not taken into account; 2) only global information of word co-occurrence (over the whole corpus) is considered, meaning that word A might be connected to word B, but they might not co-occur in document X – yet, they still influence each other's feature representation as much as when they would have co-occurred in that document; 3) over the course of training, words co-occurring in a document can still influence each

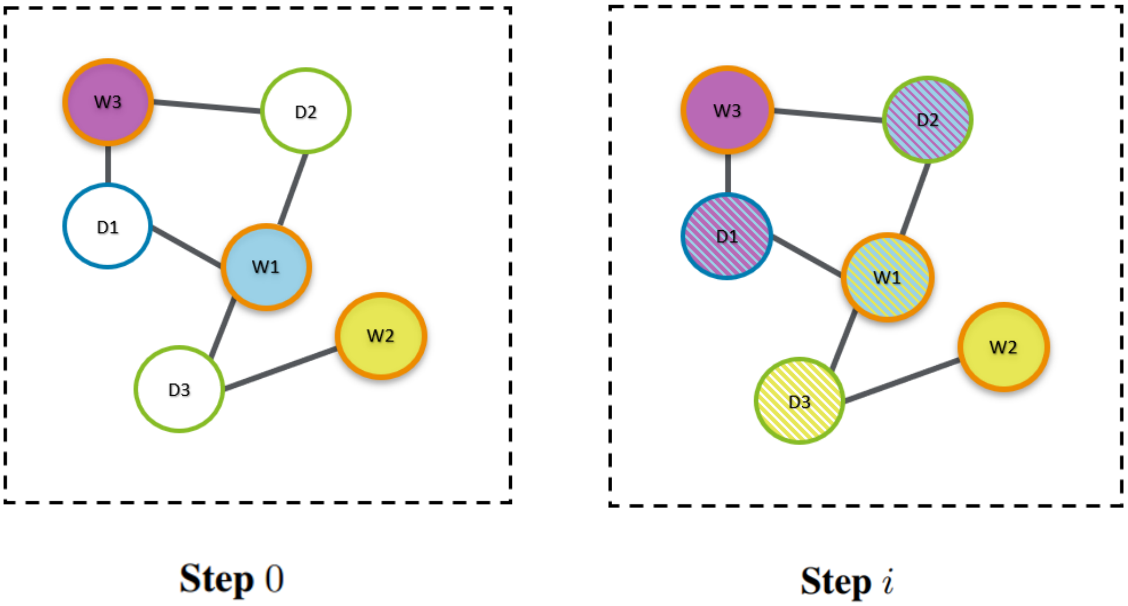
Figure 2: Visualization of the test set document embeddings in the final feature space of TextGCN and FewShotTextGCN on MLDoc-de using the 2% training data setting. UMAP (McInnes et al., 2018) is used for dimensionality reduction

Figure 3: Average test accuracy and standard deviation for 10 seeds with different amounts of data used for training. Given a total of 100 labeled samples, we vary how many are used for training and validation, adjusted in steps of 10.

other's representation, under the assumption that at least a two-layer GNN is used. We illustrate this by visualizing the initial node embeddings over the course of a hypothetical training schedule, starting at a random initialization in Figure 4a and going up until some training step i in Figure 4, where the model has improved its performance in the classification task.



Step 0

Step i

(a) **Words influencing each other's feature representation without word–word edges over the course of training: initialization.** Classes are represented in different node outline color (i.e., two document classes *green, blue*) and words with an *orange* node outline. The actual color of nodes represents the semantic value encoded in the initial embedding. We simplify the graph by omitting the initial features of the document nodes $D1$, $D2$ and $D3$ and assume they will be learned based on the features of the words occurring in them. Since both $W1$ and $W3$ occur in $D1$ and $D2$, they can intuitively not be distinguishing features for either the *green* or the *blue* class.

(b) **Words influencing each other's feature representation without word–word edges over the course of training: during the course of training.** Classes are represented in different node outline color (i.e., two document classes *green, blue*) and words with an *orange* node outline. The actual color of nodes represents the semantic value encoded in the initial embedding. After i steps of training, $D3$ will have incorporated some of the information of $W2$ in its own embedding (depicted by the yellow stripes in the node) in order for it to be a good predictor of the *green* class. Similarly, $D1$ will have incorporated features of $W3$ in its own embedding (depicted by the purple stripes in the node), as it is the most distinguishing word for the *blue* class. Finally, if we consider two-layer GNNs, the feature representation at layer 1 of $W1$, denoted by H^1_{W1}, is a function of its own embedding and the aggregated messages from H^0_{D1} and H^0_{D2} and H^0_{D3}. Similarly, the final feature representation of $D2$, H^2_{D2}, is a function of H^1_{D1} and aggregated messages from H^1_{W1} and H^1_{W2}. In order to perform the right classification, H^2_{D2}, the information corresponding to the *green* class (yellow filling of node) should be passed on from H^0_{D3}, which is the document embedding of $D3$, to H^1_{W1}, and then finally to H^2_{D2}. Due to the nature of GCNs, no distinction can be made between what message is sent from what node – as per Equation 1, $x_i = H^0_{W1}$, it can be easily seen that optimizing H^0_{W1} to be a good predictor for the *green* class (i.e., adjusting its feature representation to the yellow color), helps in classifying $D2$ correctly.

Figure 4: A visualization with guiding explanation to provide an intuition behind how features of words might still influence each other with having direct edges between them

What Clued the AI Doctor In? On the Influence of Data Source and Quality for Transformer-Based Medical Self-Disclosure Detection

Abstract

Recognizing medical self-disclosure is important in many healthcare contexts, but it has been under-explored by the NLP community. We conduct a three-pronged investigation of this task. We (1) manually expand and refine the only existing medical self-disclosure corpus, resulting in a new, publicly available dataset of 3,919 social media posts with clinically validated labels and high compatibility with the existing task-specific protocol. We also (2) study the merits of pretraining task domain and text style by comparing Transformer-based models for this task, pretrained from general, medical, and social media sources. Our *BERTweet* condition outperforms the existing state of the art for this task by a relative F_1 score increase of 16.73%. Finally, we (3) compare data augmentation techniques for this task, to assess the extent to which medical self-disclosure data may be further synthetically expanded. We discover that this task poses many challenges for data augmentation techniques, and we provide an in-depth analysis of identified trends.

1 Introduction

Self-disclosure is a complex communicative process (Kreiner and Levi-Belz, 2019) that involves sharing one's personal thoughts, feelings, or memories with another individual (Jourard and Friedman, 1970). Reciprocal self-disclosure between conversation partners may strengthen relationships (Altman and Taylor, 1973) and improve the communicative experience (Wang et al., 2016). Self-disclosure may take nuanced forms, such as *medical self-disclosure* (see Figure 1), or the act of disclosing symptoms, diagnoses, or other information related to mental or physical health problems (Valizadeh et al., 2021; Joinson, 2001). Some medical self-disclosures may be explicit (A), whereas others may be less direct (B and C).

Medical self-disclosure is helpful from a clinical perspective and reinforces therapeutic relationships during medical interactions (Jannat, 2018; Kadji and Mast, 2021). It also may enable earlier detection and treatment of medical issues (Joinson, 2001; Tidwell and Walther, 2002; Valizadeh et al., 2021). Detecting medical self-disclosure automatically could support clinicians and other medical practitioners in productively identifying helpful patient information from untapped sources or during review of medical conversations (Farber, 2003; Stricker, 2003; Valizadeh and Parde, 2022; Kaelin et al., 2021). However, research towards automated medical self-disclosure detection has been limited and may require different techniques from those used to detect self-disclosure in the general domain (Valizadeh et al., 2021; Reuel et al., 2022).

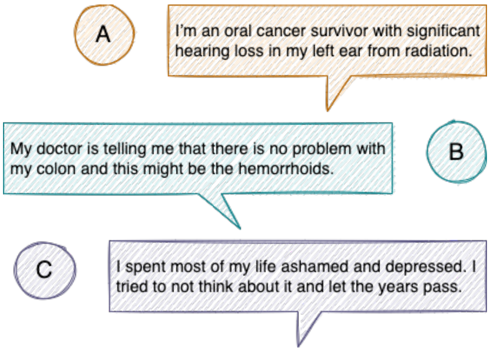

Figure 1: Examples of medical self-disclosure. Note that medical self-disclosure may be explicit (A) or less direct (B and C).

In this paper, we comprehensively investigate automated medical self-disclosure detection. We manually expand the only existing dataset (MEDSD) in this domain to include nearly 4,000 additional instances collected from publicly available forums, strengthening our understanding of this task and its relationship between performance and dataset size. In parallel, we experiment with data augmentation to study the feasibility of automated dataset expansion for this task. Finally, we perform a comparative analysis of transfer learning models, to disentangle the subtle distinctions and shared charac-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1201–1216
May 2-6, 2023

teristics between medical self-disclosure detection and other language tasks. Our primary contributions are as follows.

First (1), we create a publicly-available 3,919-instance expansion to MEDSD, sourced from health-related social media posts. The dataset is triple-annotated with continuous (0-5) and graded (NO SELF-DISCLOSURE, POSSIBLE SELF-DISCLOSURE, and CLEAR SELF-DISCLOSURE) labels. Next (2), we conduct transfer learning experiments using Transformer-based models to determine the utility of different source datasets in the context of detecting medical self-disclosure. We find that our highest-performing model outperforms the state of the art (Valizadeh et al., 2021) by relative percentage increases of 14.19% and 16.73% for accuracy and F_1, respectively. Finally (3), we conduct the first study of data augmentation in the context of medical self-disclosure. We find that this task poses unique challenges for data augmentation, and we explore these challenges in a detailed analysis. It is our hope that our findings add to the burgeoning knowledge base surrounding the detection and processing of medical self-disclosure, and can be used as a guide for others working within this domain. We make our data and source code publicly available to facilitate replication and rapid follow-up.

2 Related Work

Clinical literature has extensively examined the effects of patient self-disclosure with medical professionals, finding both positive benefits to the patient's health and overall wellbeing (Arroll and Allen, 2015), as well as negative experiences if the patient feels that professional or personal boundaries have been crossed (Lussier and Richard, 2007). Often self-disclosure in these studies is broadly construed, with less frequent exploration of medical self-disclosure specifically (Wagner, 1982). For instance, Oprescu et al. (2013) examine the correlation between information-seeking behaviors and self-disclosure, and Weisband and Kiesler (1996) investigate disclosure in online and in-person settings through statistical meta-analyses of standardized interviews, questionnaires, tests, and scales reported in existing studies. They conclude that disclosure of sensitive and private information occurs more frequently in online settings, highlighting the urgency of analyzing these settings more closely.

Bak et al. (2014) developed a semi-supervised algorithm to classify self-disclosure levels from Twitter conversations, and Blose et al. (2020) studied self-disclosure in a large dataset of Twitter conversations about the Coronavirus pandemic, proposing an unsupervised approach to detect voluntary disclosure of personal information. Yang et al. (2017) detected positive and negative self-disclosures based on linguistic features, such as LIWC and word embeddings, in a supervised model. Recently, Reuel et al. (2022) created a multi-task RoBERTa model to measure self-disclosure across varying domains, including both general and medical self-disclosure. They found poor generalization across datasets, with in-domain self-disclosure detection models performing much better than across-domain models due to widespread differences in the topics and targets of self-disclosure.

Only two existing works have focused on detecting medical self-disclosure specifically. Balani and De Choudhury (2015) predicted levels of self-disclosure of mental wellness in Reddit posts, and in our prior work we introduced the MEDSD dataset and established a Transformer-based performance benchmark for the task of medical self-disclosure detection (Valizadeh et al., 2021). Since the latter is the current state of the art and offers the only publicly available dataset and corresponding benchmark in this domain, we primarily build upon that work. We investigate medical self-disclosure specifically, and also study the manual and automated expansion of the MEDSD dataset.

3 Data

3.1 Data Collection

MEDSD, our source dataset, is a 6,639-instance dataset annotated with continuous and graded (NO SELF-DISCLOSURE, POSSIBLE SELF-DISCLOSURE, and CLEAR SELF-DISCLOSURE) medical self-disclosure labels. Since our work seeks to empirically compare the MEDSD benchmark (a fine-tuned DistilBERT model) and other Transformer-based models, we sought to expand it to a size more consistent with that used to fine-tune other Transformer-based models (typically 10k or more instances (Devlin et al., 2019)) while recognizing the time-consuming and challenging nature of the annotation task (Farzana et al., 2020). This also presented the opportunity to study the relative merits of manual and automated (via augmentation) dataset expansion for the task of medical self-disclosure detection.

To ensure consistency with the original MEDSD, we followed the same annotation procedures outlined in our previous work (Valizadeh et al., 2021). We selected *patient.info*[1] as our sole data source, and downloaded publicly-available English-language posts from randomly-selected subforums. Our rationale for selecting *patient.info* as our sole data source (rather than our primary data source as in the original data collection process) was largely due to task-based motivations—we wanted to maximize our capacity to collect data with medical information, and we observed adequate diversity in terms of style and content when performing a preliminary review of *patient.info* posts. To a lesser extent, our decision was also motivated by site-specific data privacy and sharing policies. Since posts collected from other websites in our prior work already comprised a small minority of the dataset (less than 12%), we did not anticipate that this difference would result in meaningful distributional shifts between the original and expanded datasets in terms of data content or style.

We provide additional details and examples regarding our download process in the appendix (Tables 7 and 8). Posts were complete written utterances submitted by users, and we automatically segmented posts at the paragraph level following previously established guidelines. Collected data instances had an average length of 41 tokens. Overall, we added 3,919 instances to MEDSD to reach a raw, merged dataset size of 10,558 instances. To preserve user privacy, we did not download usernames or other identifying metadata and replaced any names written directly within the post text with generic name tokens. The terms and conditions of *patient.info* maintain public access to forum posts, and this research was approved by the Institutional Review Board (IRB) at the University of Illinois Chicago. Similarly to our prior work, we make our dataset expansion available upon request.

3.2 Data Annotation

We observed very high inter-annotator agreement ($\kappa = 0.88$), measured using averaged pairwise per-class Cohen's kappa scores similarly to our prior work to facilitate comparison with annotation quality in the original MEDSD. This suggests that the annotation guidelines were sufficient for consistent replication (Landis and Koch, 1977). We did not make any changes to the guidelines to maximize labeling compatibility between original and new samples. We trained three annotators (computer science graduate and undergraduate students; a mixture of fluent L2 and native English speakers) to follow these guidelines, collecting triple annotations for each post. Labels were first assigned using a graded scheme ranging from 0-5, with "0" indicating no self-disclosure and "5" indicating high self-disclosure. More specifically, we stipulated that numeric labels should be assigned as follows:

- **5:** The post discloses a specific illness, medication, surgery, or other specific medical variable(s) or event(s).
- **4:** The post discloses specific symptoms but does not further specify an illness, medication, or other diagnosis.
- **1-3:** The post ranges from very low (ambiguous hinting of possible, non-specific medical concerns) to moderate (clear reference to non-specific medical concerns) self-disclosure.
- **0:** The post does not disclose any health-related information.

Annotations were averaged across all three labels for each instance. Cases for which the distance between one or more individual annotators and the average was greater than 1.0 were forwarded to a third-party adjudicator. The adjudicator (a study lead with high task familiarity) was authorized to decide the gold standard value based on the provided annotations and their judgment of the instance itself. The continuous-valued (averaged or adjudicated) labels were binned into three discrete classes: [0-1] NO SD, (1-4) POSSIBLE SD, and [4-5] CLEAR SD. This resulted in 520 *No SD* instances (13.26% of the expanded dataset), 1,545 *Possible SD* instances (39.42%), and 1,854 *Clear SD* instances (47.30%).

When collecting our data, we ensured that none of our newly annotated posts were duplicates of those already present in the existing MedSD, to maximize the contribution of new information and content in this dataset expansion. We also spot-checked agreement early in the annotation process to identify and resolve systemic disagreements before they could take root. We worked with in-person (rather than crowdsourced) annotators to allow further oversight for compliance with annotation guidelines as needed. We observed very high

Dataset	No SD	Pos. SD	Clear SD	Total
MedSD	2651	1019	2969	6639
Expansion	520	1545	1854	3919
Merged	3171	2645	4823	10558
Final	**2945**	**2172**	**4650**	**9767**

Table 1: Medical self-disclosure datasets statistics. The final dataset refers to the merged dataset comprising both the original MedSD and our new dataset expansion after refinement.

final agreement: 93.59% of records did not require adjudication, and the averaged pairwise Cohen's kappa (Landis and Koch, 1977) was 0.81 across the entire dataset, indicating high agreement in line with that originally reported for MedSD. Per-class agreement was calculated at $\kappa = 0.85$, $\kappa = 0.74$, and $\kappa = 0.85$ for the *No SD*, *Possible SD*, and *Clear SD* classes, respectively. We release both the averaged scores and discretized class labels with our dataset.

3.3 Dataset Refinement

We observed that a sizable portion of mispredictions by the MedSD baseline on our new expansion were adjudicated instances. After further manual review of the full MedSD including our expansion, we discarded instances that required adjudication (791 total) from further inclusion in our experiments. Our rationale for this refinement step is that these cases may have arisen from ambiguous context, systemic and conflicted understanding of certain nuances in the annotation guidelines, or occasional annotation mistakes that produced labels that the adjudicator considered to have reasonable justification (Kilgarriff, 1998).

After refinement, the final, merged dataset comprising the pruned MedSD and our expansion without adjudicated records includes 9,767 instances (4,650 *Clear SD*, 2,172 *Possible SD*, and 2,945 *No SD* instances). Table 1 provides more details regarding the dataset composition and class distribution. Table 9 in the appendix also illustrates the performance change observed when running the benchmark model on the final, refined dataset versus the raw merged version. We release our refined MedSD alongside our other data as an additional resource for the community.

3.4 Clinical Validation

Since our annotators did not have external clinical expertise, we also recruited a clinical expert (a frequent collaborator who holds graduate degrees in the healthcare domain and has worked in clinical settings) to manually label a subset of our data. We randomly selected a sample of 1,465 data instances (15% of the final dataset size, evenly distributed across classes), and asked the expert to assign labels based on our annotation guidelines and drawing upon their own expertise.

We compared the expert labels with our gold standard, and observed high agreement. In total, 92.37% of the expert's labels (1353/1465 instances) matched those in the gold standard, confirming our annotation reliability from a clinical perspective. At a per-class level, we observed 95.97% label compatibility with *No SD* instances, 83.84% compatibility with *Possible SD* instances, and 97.31% compatibility with *Clear SD* instances. In the appendix (Table 15), we briefly discuss some examples of disagreement between the gold standard and the clinical expert for further analysis.

4 Methods

We compared fine-tuned Transformer models from varying source domains on the task of medical self-disclosure detection (§4.2), and also studied the utility of data augmentation for automated dataset expansion within this domain (§4.3). We describe these studies in the following subsections.

4.1 Data Preprocessing

We passed each instance in our final dataset through a two-step preprocessing pipeline. First, we converted all emojis to their American English CDLR short names (e.g., 😊 → *:smiling face with smiling eyes:*), since insight into an author's emotional status may provide valuable clues to the presence of self-disclosure (Eisner et al., 2016; Felbo et al., 2017). Next, we replaced all numeric values with generic Number_Tokens. This prevented our models from drawing spurious conclusions regarding specific values, allowing them to recenter their focus on the presence of numeric content. To validate the utility of these preprocessing steps, we ran the MedSD baseline (Valizadeh et al., 2021) on our final dataset without any preprocessing steps and with each step individually. We report our findings in Table 11 in the appendix, demonstrating that each step results in small but measurable performance improvements.

4.2 Models

One arm of our study focuses on the influence of pretraining style and task domain on task performance. This is naturally supported through the use of existing, externally-validated Transformer models that were originally leveraged for other research problems. We emphasize therefore that the novelty of our work is not in the model implementation itself, but in the study of its application to this new domain and the extent to which these models could sufficiently leverage and generalize from out-of-domain or near-domain data. We focused our comparison of Transformer-based models on those that are pretrained on health or social media data. In total, we consider seven models: *DistilBERT*, *RoBERTa*, *BioBERT*, *Bio-ClinicalBERT*, *Bio-RedditBERT*, *MentalBERT*, and *BERTweet*.

DistilBERT was the highest-performing model in our initial experiments on MEDSD, and is the current state of the art for this task. The model achieves comparable performance to larger Transformer-based models while requiring much less time and space through the use of knowledge distillation (Sanh et al., 2019), and is often used for lower-resource tasks. In contrast, *RoBERTa* replicates BERT but is trained on larger batches, a higher number of epochs, and more training data, often resulting in higher performance than the original BERT model (Liu et al., 2019). Both *DistilBERT* and *RoBERTa* are trained on general domain data (BookCorpus and Wikipedia for both, and additional news and web data for RoBERTa).

BioBERT leverages nearly the same architecture as BERT, but it is pretrained on large biomedical corpora (Lee et al., 2020). Prior work has shown that it outperforms other BERT-based models at biomedical text classification tasks (Mitra et al., 2021; Zhu et al., 2020). Although *BioBERT* is designed to perform well on biomedical tasks specifically, these may differ from tasks using clinical notes or more casual health discourse. *Bio-ClinicalBERT* is pretrained on two million clinical notes from the MIMIC-III v1.4 database (Johnson et al., 2016; Alsentzer et al., 2019), and *Bio-RedditBERT* is initialized from *BioBERT* (Lee et al., 2020) and then further pretrained on health-related Reddit posts (Basaldella et al., 2020). *MentalBERT* is pretrained on mental health posts collected from Reddit (Ji et al., 2022). Finally, *BERTweet* was pretrained using *RoBERTa*'s training procedures on a massive amount (80 GB) of uncompressed English tweet text, including 845,000,000 Tweets streamed from January 2012 to August 2019 and 5,000,000 Tweets related to the Covid-19 pandemic. It outperformed previous models on a wide variety of social media tasks (Nguyen et al., 2020).

We fine-tuned each included model separately for our task. We applied model gradual layer freezing, and optimized model hyperparameters using grid search. Table 13 provides additional details regarding the fine-tuned hyperparameters.

4.3 Data Augmentation

Manual dataset expansion, as described in Section 3, can be expensive and time-consuming. Data augmentation (DA) strategies can be used to automatically increase training set size, offering an attractive way to reduce overfitting or other issues causing poor predictive performance (Bayer et al., 2021; Feng et al., 2021). They also offer an opportunity to shift the class distribution of unbalanced datasets through generation of additional samples for specific classes, and they have grown more common in NLP recently (Feng et al., 2021).

Although DA techniques have not been explored in the context of self-disclosure detection, this task offers an intriguing testbed for these experiments since it relies on nuanced language with uneven class distribution (see Table 1). We experimented with the following DA techniques to synthetically expand our dataset and balance its distribution:

- **Backtranslation Augmentation (BT):** Data is translated to a different target language (in this case, German) and then back to the source language (English). This often paraphrases the original text (Beddiar et al., 2021).
- **WordNet Synonym Augmentation (WS):** One or more words, depending on a fine-tuned hyperparameter *aug_p* that controls the percentage of words to be augmented, are replaced with their synonyms from WordNet, a large English lexical database (Ramachandran and Parvathi, 2021).[2] We set *aug_p*=0.3 in our experiments.
- **Masked Language Model Augmentation (MLM):** A random sample of words is "masked out" and a pretrained Transformer model is used to restore the text to its original version, typically resulting in a paraphrase

---

[2] `https://wordnet.princeton.edu/`

(Wu et al., 2019; Kumar et al., 2020). We experiment with DistilBERT (Sanh et al., 2019) and RoBERTa (Liu et al., 2019) backbones for this technique.

- **Target-Aware Data Augmentation (TA):** The masked word is conditioned on both its context and the prepended auxiliary sentence that contains target and label information, producing alternative versions of the original text that are geared toward a specific target (in our case, the specific target is medical self-disclosure) (Li and Caragea, 2021).

We generated augmented data for the *Possible SD* and *No SD* classes using each of these techniques as a separate condition. We fine-tune the augmentation ratio, a hyperparameter indicating the multiplicative factor by which the dataset size is increased, setting it to 2 for *Possible SD* and 1.5 for *No SD*. Figure 5 in the appendix demonstrates that the DA process resulted in a relatively balanced training set (3,488 *Clear SD*, 3,258 *Possible SD*, and 3,488 *No SD* instances). Following standard protocol we did not augment the validation or test sets, to avoid introducing potential biases and allow for direct comparison with other models.

To compare DA approaches with one another, we train our best-performing model from our modeling experiments (§5.2) on separate combinations of the final, manual dataset and each of the synthetic dataset expansions (*BT*, *WS*, *DistilBERT MLM*, *RoBERTa MLM*, and *TA*). We additionally compare to a baseline *no augmentation* condition trained only on the final, manual dataset.

5 Evaluation

We compare model performance using accuracy, precision, recall, and macro-averaged F_1, following prior work on self-disclosure detection (Valizadeh et al., 2021; Balani and De Choudhury, 2015). For each experiment, we randomly split the specified data into training (80%), validation (10%), and test (10%) subsets. We measure the efficacy of our manual dataset expansion (§5.1), empirically compare the performance of the proposed Transformer models (§5.2), and evaluate the performance of DA techniques for medical self-disclosure (§5.3).

5.1 Does more (manual) data lead to better performance?

Model	**Acc.**	**Precision**	**Recall**	**F_1**
MEDSD	76.77	0.7497	0.7241	0.7313
Final	**80.91**	**0.7832**	**0.7810**	**0.7816**

Table 2: Comparison between DistilBERT models trained on the original MEDSD and final datasets, separately. Accuracy shown as a percentage (%).

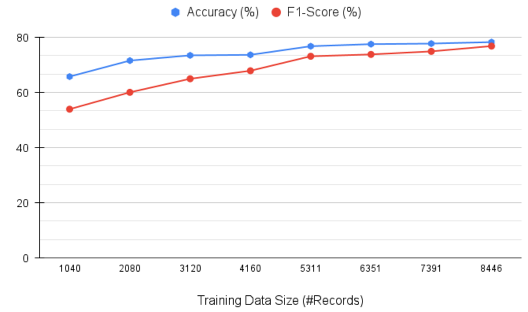

Figure 2: Training dataset size versus *DistilBERT* performance scores. Accuracy and F_1 both shown as a percentage (%) to facilitate presentation.

To investigate whether the manual expansion of MEDSD directly results in increased model performance, we train *DistilBERT*, the MEDSD benchmark, separately on the original MEDSD and the final dataset (Table 2).[3] The model trained on the final dataset exhibits relative percentage increases of 5.39% and 6.87% for accuracy and F_1, respectively, compared to the model trained on MEDSD. This suggests that manual data expansion boosts performance for this task, irregardless of model architecture or pretraining settings.

However, there also appears to be a limit to which more manual data results in meaningful improvements. Figure 2 shows *DistilBERT* performance at gradually increasing training dataset sizes, exhibiting a flattening performance curve approaching the final dataset size. Although this suggests a performance plateau approaching the full size of the manually-annotated dataset, further experiments are needed to justify a broader claim that training set size is detached from performance beyond a certain size threshold. We move closer towards validating this claim with the findings from our data augmentation experiments (§5.3).

---

[3] The MEDSD results reported in Table 2 (top row) are lower than we observed previously (Valizadeh et al., 2021). After replicating those experiments for this study with different random seeds to assess statistical significance, we found that when averaged across numerous runs, multinomial *DistilBERT* achieves the performance values reported here. These scores remain higher than the other baselines studied by Valizadeh et al. (2021), and the conclusions resulting from those earlier experiments still hold (and are statistically significant).

Model	Acc.	Precision	Recall	F_1
DistilBERT	80.91	0.7832	0.7810	0.7816
RoBERTa	84.40	0.8172	0.7927	0.7968
BioBERT	84.35	0.8117	0.8219	0.8173
Bio-ClinicalBERT	83.10	0.8042	0.7889	0.7954
Bio-RedditBERT	85.15	0.8241	0.8250	0.8245
MentalBERT	85.42	0.8357	0.8282	0.8208
BERTweet	**87.67**	**0.8528**	**0.8551**	**0.8537**

Table 3: Model performance comparison. Accuracy shown as a percentage (%).

Technique	Acc.	Precision	Recall	F_1
MLM-R	86.28	0.8388	0.8271	0.8325
MLM-D	85.88	0.8355	0.8228	0.8286
TA	85.48	0.8298	0.8362	0.8321
WS	86.01	0.8363	0.8196	0.8263
BT	**86.42**	**0.8389**	**0.8470**	**0.8420**
NA	**87.67**	**0.8528**	**0.8551**	**0.8537**

Table 4: Performance comparison for DA techniques. *MLM-R* and *MLM-D* use RoBERTa and DistilBERT backbones, respectively. *NA* refers to the *no augmentation* condition. Accuracy shown as a percentage (%).

5.2 How do pretraining style and task domain impact model performance?

We present the results of our model comparison in Table 3. *BERTweet* achieved the highest performance, with accuracy=87.67% and F_1=0.8537. The model outperformed the existing *DistilBERT* baseline by relative percent increases in accuracy and F_1 of 8.35% and 9.22%, respectively. We applied McNemar-Bowker's test ($\alpha = 0.05$), an extension of McNemar's test designed to accommodate more than two classes (McNemar, 1947), to assess the statistical significance of our results. We observe that all differences are statistically significant ($p <= 0.05$).

5.3 Does more (augmented) data lead to better performance?

To investigate whether the synthetic expansion of the dataset leads to further performance boosts beyond those observed from the manual dataset expansion, we retrained *BERTweet* on each augmented version of the dataset described in §4.3. We report our results in Table 4. Backtranslation resulted in the best model performance among all DA approaches with accuracy=86.42% and F_1=0.8537. However, *BERTweet* with *no augmentation* outperformed all other conditions. The outcomes from this experiment suggest that synthetic expansion beyond the current dataset size is unlikely to lead to substantial model improvement. This also offers supporting evidence for the insights from Figure 2, discussed in §5.1.

6 Discussion

6.1 Lessons Learned from Model Comparison

To further disentangle the differences in observed model performances, we computed per-class accuracy for each model (Table 5). The *DistilBERT* baseline had acceptable performance when predicting *No SD* and *Clear SD* instances with 88.70% and 87.60% accuracy, respectively, but poor performance in detecting *Possible SD* instances, dropping to 56.25% accuracy. *RoBERTa* resulted in higher accuracy for the *No SD* and *Clear SD* classes (relative percent increases of 7.04% and 2.79%, separately) while also offering a slight improvement in detecting *Possible SD* instances.

Our task's reliance on social media data in the medical domain drove our selection of models pretrained primarily on social media data (*BERTweet*), medical data (*BioBERT* and *Bio-ClinicalBERT*), and data at the intersection of both domains (*Bio-RedditBERT* and *MentalBERT*) for our experiments. We anticipated that *BioBERT* and *Bio-ClinicalBERT* would result in improved recognition of *Clear SD* instances, and these expectations were confirmed with per-class performance increased by 3.29% and 5.38%, respectively, relative to *DistilBERT*. *Bio-RedditBERT* and *MentalBERT* achieved higher performance still, with relative performance increases in the *Possible SD* class in particular of 20.01% and 21.15% over the baseline, emphasizing the importance of text style in addition to domain specificity.

Interestingly, our strongest model overall was *BERTweet*, which is pretrained primarily on social media data although a small subset of the data did have a specific health focus. This suggests that ultimately, stylistic patterns may be more important than task-based knowledge when recognizing specific forms of self-disclosure. At the class level, models trained entirely on healthcare datasets (e.g., *Bio-ClinicalBERT*) experience performance boosts when detecting *Clear SD* instances, and models trained on social media datasets (e.g., *BERTweet*) achieve substantial increases in their detection of *Possible SD* instances, which was the most challenging class for human annotators (§3.2).

Model	**No**	**Possible**	**Clear**
DistilBERT	88.70	56.25	87.60
RoBERTa	94.95	57.48	90.05
BioBERT	89.79	63.69	90.49
Bio-ClinicalBERT	88.86	58.27	92.32
Bio-RedditBERT	90.71	67.51	91.27
MentalBERT	91.64	68.15	90.83
BERTweet	89.38	78.66	91.45

Table 5: Accuracy per class for all the models implemented for detecting medical self-disclosure. Accuracy is shown as a percentage (%).

Dataset	**No**	**Possible**	**Clear**
BT	93.72	70.94	92.27
NA	89.38	78.66	91.45

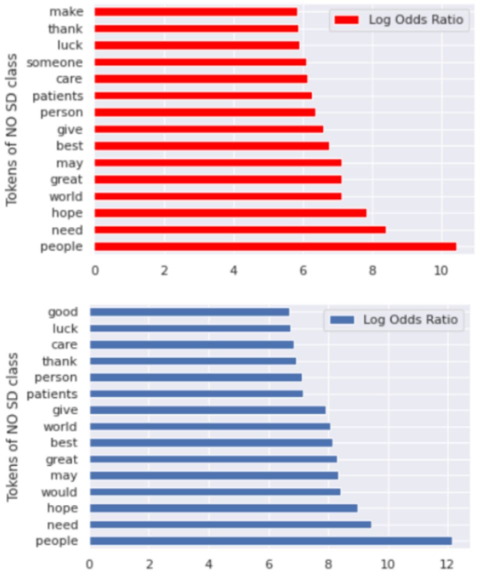

Figure 3: Words most closely associated with No SD class. Red and blue plots correspond to original and augmented data, respectively.

6.2 Factors Influencing Data Augmentation

Our experiments did not provide conclusive evidence that data augmentation can be effectively leveraged to detect medical self-disclosure. This is understandable since the task is known to rely on often-subtle language patterns (Valizadeh et al., 2021; Reuel et al., 2022). We examined the per-class performance of our *BERTweet* model fine-tuned on our backtranslation-augmented dataset compared to the *no augmentation* condition (Table 6) to develop a deeper understanding of opportunities for future improvement.[4]

We find that data augmentation resulted in small performance increases when predicting *No SD* and *Clear SD*, but larger performance reductions when predicting *Possible SD* instances. Although initially counterintuitive since our primary goal in augmenting data was to balance the class distribution (for which frequency was lowest in the *Possible SD* class), we conducted further analyses to pinpoint underlying factors. To analyze the linguistic patterns associated with augmented and non-augmented instances, we computed the log odds ratio with an informative Dirichlet prior (Monroe et al., 2008; Hessel, 2016) for both versions of *No SD* and *Possible SD* (Figures 3 and 4).

We found that after augmenting the dataset, the ratio of third-person nouns (e.g., “people” or “person”) increased in the *No SD* class (Figure 3). This may have strengthened the model’s inverse association between the use of external language and the confirmed disclosure of medical information, resulting in the observed 4.85% increase in accuracy for *No SD*. The ratio of “feeling” keywords in the *Possible SD* class also increased. Prior to DA, these words were more prominent in the *Clear SD* class than the *Possible SD* class (612 and 331 tokens prior to DA, respectively, and 621 and 622 tokens after), due to their use when expressing physical or mental symptoms. We found that 18.1% of mispredicted *Possible SD* instances contained “feeling” keywords prior to DA, and 29.54% of mispredicted *Possible SD* instances contained these keywords after DA. Thus, it appears that backtranslation created a harmful distributional shift in the expression of feeling language across classes. Finally, we suspect that despite its outperformance over other techniques, backtranslation is still limited in its ability to create convincing synthetic data for this task and may not have captured subtleties in writing style that (as observed in our model comparison) are important (Longpre et al., 2020; Beddiar et al., 2021). As a result, the introduction of synthetically augmented data to the learning process may have merely added noise.

Although our data augmentation experiments did not produce positive results, we note that this is the first exploration of augmentation in the context of

---

[4] Per-class performance of *BERTweet* fine-tuned on other augmented datasets is provided in Table 14 in the appendix.

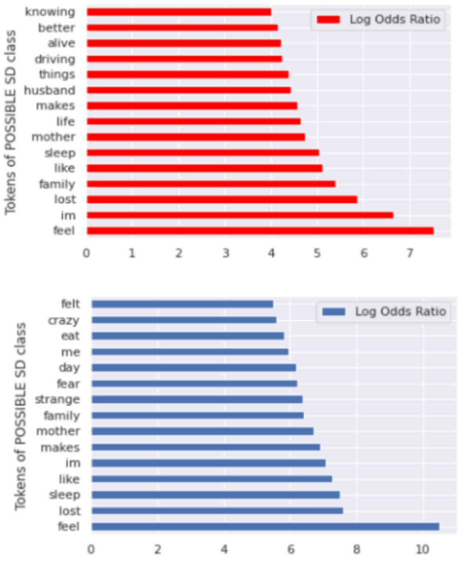

Figure 4: Words most closely associated with POSSIBLE SD class. Red and blue plots correspond to original and augmented data, respectively.

medical self-disclosure. Negative findings move the dial toward more fully understanding the performance boundaries of this and related tasks, and the recent movement towards leaderboards rather than hypothesis-driven investigations in NLP has contributed to the under-reporting of negative results (Tafreshi et al., 2022). This can slow progress as scientists repeat experiments that they are unaware have already been attempted, often with substantial effort and carbon footprint. It is our hope that through reporting the negative outcomes from our DA experiments, we add to the growing knowledge base surrounding data augmentation for NLP and also lay the groundwork for future experiments in self-disclosure detection.

7 Conclusion

In this work, we study data source, quantity, and quality as it pertains to detecting medical self-disclosure. First, we manually expanded MEDSD with 3,919 additional instances and clinically validated its labels in collaboration with a healthcare expert. Next, we compared Transformer models pretrained on varying source datasets for predicting medical self-disclosure, finding that our best-performing model outperforms the state of the art by relative percentage increases of 14.19% and 16.73% for accuracy and F_1, respectively. Our findings also suggest that stylistic patterns prove more revealing than task-specific trends. Finally, we study data augmentation in the context of this task, finding that it poses many DA challenges. We document these in our analysis, opening the door to intriguing follow-up studies. We make our dataset and models available to the research community upon request, and we hope that our work can be used as a roadmap for future experiments in self-disclosure detection.

Acknowledgements

We thank the anonymous reviewers for their helpful suggestions. We thank Dr. Vera Kaelin for providing clinical expertise for validating our labels, and we also thank Shayan Rasheed and Nidhi Bhupalam for their roles in creating the dataset. The first and last authors of this paper were fully or partially supported throughout the duration of this work by the National Science Foundation under Grant No. 2125411. Any opinions, findings, and conclusions or recommendations are those of the authors and do not necessarily reflect the views of the National Science Foundation.

Limitations

Our work is limited by several factors. Both the original MEDSD dataset and our own expanded version are imbalanced, resulting in some known performance weaknesses. We attempted to correct for this using data augmentation techniques, but across the wide range of techniques tested, none were able to improve performance beyond that of the *no-augmentation* baseline. Thus, we cannot provide conclusive evidence that synthetic dataset expansion is a valuable pursuit for this task (although we note that this negative finding in itself provides worthwhile direction for other researchers). The manual expansion of the medical self-disclosure dataset clearly improved performance, highlighting the effectiveness of human gold standard labels for this task; therefore, manual or semi-supervised dataset expansion may be a promising avenue for future model improvements.

Our highest performing model was *BERTweet*, which is pretrained on a massive amount of primarily general-domain social media data, although a small subset of it was focused on the Covid-19 pandemic. This suggests that stylistic patterns may be more important than domain knowledge for the recognition of specific forms of self-disclosure. Therefore, instead of limiting the methodology to transfer learning models in clinical and medical domains, future work should extend the range of domains and text styles that are studied. It may be the case that the most worthwhile domains or stylistic cues for supporting this task are further from the target task, and as yet undiscovered.

All data and experiments reported in this paper were conducted on English data, which constrains the extent to which our claims can be generalized. Future work examining medical self-disclosure in languages that are less-resourced than English or that differ greatly in their morphological typology may provide crucial insight into the generalizability of our findings. Finally, training and fine-tuning large Transformer-based models often requires costly GPU resources. This limits the accessibility of running these experiments at scale.

Ethics Statement

This research was approved by the Institutional Review Board (IRB) at the University of Illinois Chicago. Our primary data source was *patient.info*, for which the terms and conditions allow public access to forum posts.[5] As outlined in §3.1 and to protect privacy, we manually anonymized our data instances by removing any usernames or other identifying metadata, and replaced any names written directly within the post text with generic name tokens. Annotators were compensated for their work through paid internships and assistantship positions at a competitive rate for the cost of living in our area. We make our expanded dataset available upon request via email, following IRB protocol.

We intend for our dataset expansion and the proposed methods to be used as a tool to analyze the linguistic trends and other language behaviors associated with medical self-disclosure in online settings. Our experiments closely follow this intent, providing novel insight into the influence of different pre-training tasks and stylistic domains on the ability of our models to recognize possible and clear cases of medical self-disclosure. When the technology is being used as intended and functioning correctly, we anticipate that it may be of value to numerous downstream applications, primarily as a data analysis tool or as an avenue for providing information. When the technology is being used as intended but giving incorrect results, its value may decrease (since researchers or clinicians using the tool may need to discard their insights or may fail to replicate findings in subsequent experiments).

A potential misuse of the technology would be to use the trained models to identify social media users disclosing medical information and apply targeted advertising or messaging to those users. Since neither our dataset nor our models are designed to recognize or predict specific medical conditions, we note that the extent to which they could be used for these purposes is limited. We do not condone this use of the technology, and we will monitor citations and uses of our dataset to ensure that others are using our data and models for their intended purpose.

A Data Collection

Our data collection and annotation process spanned four months. Similarly to our earlier work (Valizadeh et al., 2021), we covered numerous medical topics, ranging from mental to physical health issues. In Tables 7 and 8, we provide example instances from our dataset regarding some of these topics. We note that although we categorize these instances to facilitate presentation here, labels indicating specific health conditions are not included in our dataset.

B Data Refinement

After our manual data refinement process during which we removed the instances that required adjudication, we ran the benchmark model (*DistilBERT*) established in prior work (Valizadeh et al., 2021) on the final dataset versus the merged version. Table 9 presents the results of this experiment,

PHYSICAL HEALTH CONDITION
Brain & Nerves 1. *I get horrific migraines. The dizziness/feeling faint and spaced out feeling is the worst for me.* 2. *I have nerve testing next week and am going to have my thyroid retested. I also want an MRI and a brain scan. I feel hopeless.*
Chest & Lungs 1. *For the past year, I've had issues with taking in deep breaths, have had an X-Ray, CT Scan on my lungs and they couldn't find anything.* 2. *There is a mass in my right lung and I need to go for a bronchoscopy this coming Monday to determine what exactly it is.*
Bones, Joints, & Muscles 1. *Finally after a month of waiting for results, I was told I do not have Rheumatoid Arthritis. I do wish that they would take my Osteoarthritis more seriously though. I'm glad you had your test and all seemed ok.* 2. *I am nearly 2 years total left knee replacement and was a massive diet coke drinker before surgery. However, since surgery on March 16, I haven't been able to drink the stuff, makes me sick.*
Gut, Bowel, & Stomach 1. *I recently had appendicitis and got my appendix removed about a month ago.* 2. *I went to several doctors for three and a half months with these symptoms to no avail after various negative tests. I was eventually diagnosed with IBS.*

Table 7: Some of the physical health-related topics covered in our dataset.

MENTAL HEALTH CONDITION
Anxiety Disorders 1. *I have Panic Disorder and Generalized Anxiety Disorder. It is well maintained and I have not had a panic attack in years.* 2. *I start PT on Monday and I'm hoping I get a therapist that is understanding. I don't need to cry more than I already have or have anymore anxiety attacks.*
Post Traumatic Stress Disorder (PTSD) 1. *I also suffer from C-PTSD so everything is accentuated and I can't wait till this transition is over for all of us.* 2. *I did not sleep for 6 months due to PTSD maybe micro sleeps. I just laid in bed wide awake or with eyes closed.*
Depression 1. *Since my depression is genetic, it's been following me around for a while. It's always hung around me, but in the past couple of months it hit me again and I was struggling for the longest time.* 2. *I suffered from depression for many years but it is nowhere near as bad as it was because I am on ad's and had counselling. Now I can live with it and have a good life which means something to me.*
Bipolar Disorder 1. *I've only been diagnosed Bipolar just over a month ago. I am very new to it, but looking back over many years I realise I've had it for a while.* 2. *One of the meds I am taking for Bipolar is Seroquel at night. And after eliminating everything else, it seems that the Seroquel might be the cause of it.*

Table 8: Some of the mental health-related topics covered in our dataset.

showing relative percentage increases of 3.37%, 3.14%, 1.79%, and 2.41% for accuracy, precision, recall, and F_1, respectively. We also ran our highest performing model (*BERTweet*) established in Section §5.2 on the final dataset versus the merged version. Table 10 presents the results of this experiment, showing relative percentage increases of 3.16%, 1.87%, 3.47%, and 2.22% for accuracy, precision, recall, and F_1, respectively.

Dataset	Acc.	Precision	Recall	F_1
Merged	78.27	0.7593	0.7672	0.7632
Final	80.91	0.7832	0.7810	0.7816

Table 9: Model performance before and after data refinement. The model used for this experiment is the baseline, a *DistilBERT* model.

Dataset	Acc.	Precision	Recall	F_1
Merged	84.98	0.8371	0.8264	0.8351
Final	87.67	0.8528	0.8551	0.8537

Table 10: Model performance before and after data refinement. The model used for this experiment is our highest performing model, a *BERTweet* model (§5.2).

C Data Preprocessing

To validate the utility of the preprocessing techniques described in §4.1, we ran our *DistilBERT* benchmark and our highest performing model *BERTweet* on the final dataset without any preprocessing steps and with each step individually. We report our findings in Tables 11 and 12, demonstrating that each step results in small but measurable performance improvements.

Technique	Accuracy
Base Model (No Preprocessing)	77.21%
Base + DeEmojifying	78.07%
Base + Number Replacement	78.02%

Table 11: Model performance in accuracy (%) before and after applying each preprocessing technique. *Base model* refers to our baseline *DistilBERT* model, trained on the final dataset (§5.1).

Technique	Accuracy
BERTweet (No Preprocessing)	86.54%
BERTweet + DeEmojifying	87.43%
BERTweet + Number Replacement	87.32%

Table 12: Model performance in accuracy (%) before and after applying each preprocessing technique. *BERTweet* refers to our highest performing model, trained on the final dataset (§5.2).

D Experimental Settings

We optimized model hyperparameters using grid search. Table 13 shows the final hyperparameters we used when training our models.

Model	Learning Rate	Batch Size	Epochs
DistilBERT	2e-6	16	3
RoBERTa	2e-5	16	3
BioBERT	2e-5	8	4
Bio-ClinicalBERT	2e-5	8	4
Bio-RedditBERT	2e-5	16	3
MentalBERT	2e-5	32	3
BERTweet	2e-5	8	3

Table 13: Models' final hyperparameters.

E Data Augmentation

We generated augmented data for the *Possible SD* and *No SD* classes using each of the techniques described in §4.3 as a separate condition. We fine-tune the augmentation ratio, a hyperparameter indicating the multiplicative factor by which the dataset size is increased, setting it to 2 for *Possible SD* and 1.5 for *No SD*. Figure 5 demonstrates that the DA process resulted in a relatively balanced training set (3,488 *Clear SD*, 3,258 *Possible SD*, and 3,488 *No SD* instances).

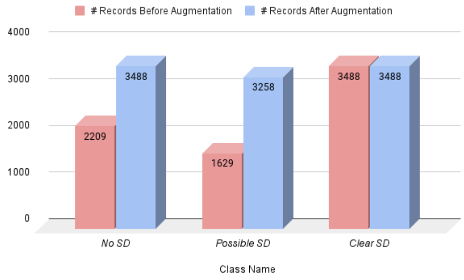

Figure 5: Distribution of training instances before and after data augmentation technique.

F Per-Class Performance for Data Augmentation Techniques

Our experiments did not provide conclusive evidence that data augmentation can be effectively leveraged for the task of detecting medical self-disclosure. This is somewhat unsurprising since the task is known to be challenging due to its reliance on often-subtle language patterns (Valizadeh et al., 2021; Reuel et al., 2022). We further examined the per-class performance of our best-performing model (*BERTweet* fine-tuned on various augmented datasets) compared to the *no augmentation* condition to develop a deeper understanding of opportunities for future improvement, and present the results in Table 14.

Dataset	**NO SD**	**POSSIBLE SD**	**CLEAR SD**
MLM-R	90.95	64.64	92.53
MLM-D	89.79	63.64	92.40
TA	89.95	68.47	89.92
WS	93.03	60.19	90.67
BT	93.72	70.94	92.27
NA	89.38	78.66	91.45

Table 14: Comparison of per-class accuracy for the BERTweet models trained on the augmented and non-augmented (NA) datasets. Accuracy is shown as a percentage (%).

G Clinical Validation

After our clinical validation process, we observed high agreement between the clinical expert and our gold standard: in total, 92.37% of the expert's labels (1353 of the 1465 instances) matched those in the gold standard. However, there were some instances for which our annotators and the clinical expert did not agree. Table 15 presents some of these instances, along with commentary provided by our clinical expert to offer additional insight into their thought process and rationale.

Instance	**Clinical Label**	**Gold Standard**	**Expert's Note**
Although the madness part of King George I might be close to. Stephen Fry is an idol of mine, and someone I watch closely for obvious link in the field of mental health but if he's Premier League I'd barely count as a part time player!	Clear SD	Possible SD	Although a specific diagnosis is not referenced, when viewed from a clinical perspective this is a clear disclosure of a mental health problem.
I don't want to die but I can't afford to live with pain of emotions that I am worth less and no one needs me!	Clear SD	Possible SD	Similar to above, clinical expertise affords additional sensitivity to mental health disclosures.
I have had a perfectly awful past year....the worst ever in my life. I have been in perimenopause for about 4-6 years now (hard to know for sure), I have been on here begging for advice on what I can do to ease my suffering and I was struck with a major realization today!	Possible SD	Clear SD	Menopause itself is not a medical problem since it is a natural circumstance; thus, focus should instead be placed on the suffering that is referenced but unspecific.
I'm also going through hormonal changes so its been rough trying to figure out whats causing what.	Possible SD	Clear SD	Again, hormonal changes are a natural circumstance rather than a healthcare problem; focus should be placed on the unspecified issues.
I'm honestly aware that it's extremely unlikely for a 16 year old to end up with colon cancer, but it does happen in rare occasions so it's hard for me to completely let go of the idea.	No SD	Possible SD	It is unclear whether this disclosure is in reference to the poster.
We have to tell our drs that we are not stupid nor irresponsible with test results. It is your body/health and you need to know and understand what is happening and not kept in the dark.	No SD	Possible SD	Advocating for rights or expertise is not a disclosure of a medical concern in itself.

Table 15: Instances with disagreements in the clinical validation process.

Improving Visual-Semantic Embedding with Adaptive Pooling and Optimization Objective

Abstract

Visual-Semantic Embedding (VSE) aims to learn an embedding space where related visual and semantic instances are close to each other. Recent VSE models tend to design complex structures to pool visual and semantic features into fixed-length vectors and use hard triplet loss for optimization. However, we find that: (1) combining simple pooling methods is no worse than these sophisticated methods; and (2) only considering the most difficult-to-distinguish negative sample leads to slow convergence and poor Recall@K improvement. To this end, we propose an adaptive pooling strategy that allows the model to learn how to aggregate features through a combination of simple pooling methods. We also introduce a strategy to dynamically select a group of negative samples to make the optimization converge faster and perform better. Experimental results on Flickr30K and MS-COCO demonstrate that a standard VSE using our pooling and optimization strategies outperforms current state-of-the-art systems (at least 1.0% on the metrics of recall) in image-to-text and text-to-image retrieval. Source code of our experiments is available at `https://github.com/96-Zachary/vse_2ad`.

1 Introduction

Visual Semantic Embedding (VSE) (Frome et al., 2013; Faghri et al., 2018) is a representation learning method that embeds images and texts for efficient cross-modal retrieval, and typically has the following steps: (1) the image and text features are first extracted by separate visual and text encoders; (2) these features are then projected into a joint embedding space and pooled to form fixed-length vectors; (3) similarity is computed to measure the distance between image and text representation; and (4) a suitable objective is chosen for optimization (see Figure 1 for an illustration). Our paper focuses on improving the steps of feature aggregation and optimization.

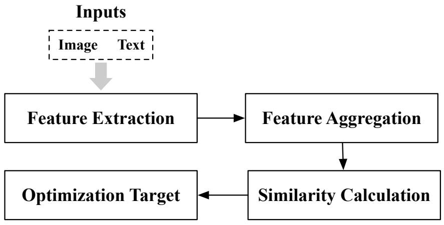

Figure 1: **Illustration of VSE**.

For feature aggregation, the most commonly used methods are simple pooling aggregators. MaxPool (Wang et al., 2018) and MeanPool (Reimers and Gurevych, 2019) are designed to detect the salient and mean points of features, and K-MaxPool (Kalchbrenner et al., 2014) extracts the mean of top-K features. Some complex aggregation techniques have been proposed, e.g. local-importance projection (Gao et al., 2019), sequence-to-sequence encoder (Hu et al., 2019), graph convolution network (Li et al., 2019), exponential adaptive pooling (Stergiou and Poppe, 2021) and self-attention encoder (Wang et al., 2020). However, we found that carefully selected pooling functions can surpass complex methods (see Appendix A.1). Motivated by this, our paper proposes an approach that can *automatically* discover the best pooling functions. Specifically, we seek to improve the feature aggregation step by proposing a formulation that parameterizes the different pooling strategies and allows the model to learn the best configuration automatically via its objective, alleviating the need to do manual tuning. In other words, we've turned these hyper-parameters (i.e. choices of pooling functions) into parameters in the model.

For optimization, most VSE models optimize using the hinge triplet ranking loss with in-batch negative example (Faghri et al., 2018). The intuition of the objective is to encourage positive pairs to be embedded in a similar space while widening the

May 2-6, 2023

distance between a target with the hardest in-batch negative sample (Li et al., 2022a). In practice, however, it is often difficult for the model to find a good negative sample in the early stages of training (as instances are randomly distributed in space), resulting in slow convergence (see Appendix A.2). To improve optimization, we propose an adaptive optimization objective that selects multiple in-batch negative samples based on model quality during training. The intuition is that in the early stages of training, we want to sample more negative samples for faster convergence, and in the later stages, we want to sample fewer negative samples for finer tuning.

Over two public datasets, MS-COCO (Lin et al., 2014) and Flickr30K (Young et al., 2014), we show that a standard VSE model using our proposed feature aggregation and optimization strategies outperforms benchmark models substantially. In particular, our method obtains 1.4% relative gains on RSUM for MS-COCO and 1.0% for Flickr30K. Compared with a pre-trained vision-language model with similar performance (Geigle et al., 2022), our method is $4.3\times$ faster.

2 Related Work

Depending on whether the image and text features have any form of *cross-modal interaction* before similarity calculation, existing image-text retrieval can be broadly categorized into two types.

The visual semantic embedding (VSE) (Faghri et al., 2018; Wang et al., 2020; Chun et al., 2021) methods process the multimodal instances *independently* before projecting them into a joint embedding space for similarity matching. Wang et al. (2018) design a two-branch neural networks, LIWE (Wehrmann et al., 2019) considers character-based alignment and embedding methods for language encoder and Faghri et al. (2018) extend it by using hard triplet loss for optimization. Following these ideas, PVSE (Song and Soleymani, 2019) and CVSE (Wang et al., 2020) are proposed to consider intra-modal polysemous and consensus information. Recently, Chun et al. (2021) samples instances as probabilistic distributions and achieves further improvement. These VSE-based methods are fast as they do not consider cross-modal interaction and as such the visual and text features can be pre-computed. The non-VSE methods concentrate on the interaction of modalities. For example, prior methods explore fusing multi-modal information by attention (Lee et al., 2018; Chen et al., 2020; Zhang et al., 2021a), alignment (Zhang et al., 2020), multi-view representation (Qu et al., 2020) or fine-grained reasoning (Qu et al., 2021; Zhang et al., 2022). The early-interaction methods (Geigle et al., 2022), like pre-trained vision-language models (Lu et al., 2019; Chen et al., 2019; Li et al., 2020; Jia et al., 2021; Li et al., 2022b), focus on maximizing performance while trading off efficiency.

The performance of VSE ultimately depends on the quality of the joint embedding space, which is usually learned with simple transformations (e.g. linear projection or multi-layer perceptron) and pooling aggregators (e.g. mean pooling (Faghri et al., 2018; Qu et al., 2020), max pooling (Zhang and Lu, 2018; Li et al., 2021), or a combination of them (Lee et al., 2018)). Compared to these simple aggregation methods, more complex aggregators that introduce a large number of trainable parameters have also been explored, e.g. inter-modal attention (Wehrmann et al., 2020) and self-attention mechanisms (Han et al., 2021). Zhang et al. (2021b) design a cross-modal guided pooling module that attends to local information dynamically. These sophisticated aggregators typically require more time, and don't always outperform simple pooling strategies. Perhaps the closest study to our work is GPO (VSE∞) (Chen et al., 2021), which builds a generalized operator to learn the best pooling strategy that only considers the position information of the extracted features.

Some studies focus on improving the optimization objective, and the most widely adopted objective is the hinge-based hard triplet ranking loss (Faghri et al., 2018; Wei et al., 2020b; Messina et al., 2021), which dynamically selects the "hardest" negative sample within a mini-batch. Other studies explore solutions that choose multiple negative samples. Zhou et al. (2020) introduce a coherence metric to rank the "irrelevant" candidates. Extending the idea, Wei et al. (2020a) assign different weights for positive and negative pairs. To tackle the issue of noisy labels which impacts multimodal representation, Hu et al. (2021) propose maximizing the mutual information between different modalities. Huang et al. (2021) separate data into "clean" and "noisy" partitions by co-teaching. Ultimate though these methods did not explore modifying the behaviour of negative sample selection *adaptively* according to model performance during training, which we address in this work.

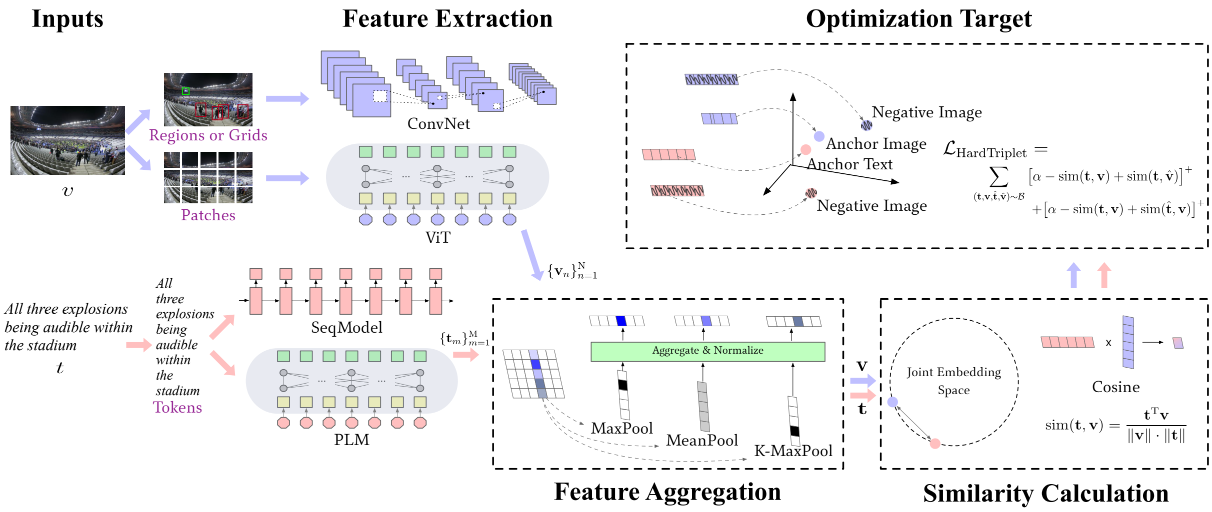

Figure 2: **The framework of VSE.** The visual and text encoders process the image and text separately at first. The related images and sentences are then directed to a similar space using an appropriate optimization target.

3 Methodology

3.1 Background of VSE

We first discuss the standard formulation of VSE, before introducing our innovation on improving feature aggregation (Section 3.2) and optimization (Section 3.3).

To compute the similarity of given multimodal instance (image & text), a VSE model (Figure 2) separately encodes them via a visual encoder (`VisEnc`$(\cdot)$) and a text encoder (`TextEnc`$(\cdot)$). There are three widely used visual features produced by different visual encoders — *grid* is the feature maps from convolutional networks (CNNs; He et al. (2016)), *region* is the region of interest features from object detectors (Anderson et al., 2018) and *patch* is the partition from vision transformer (Dosovitskiy et al., 2021). The text encoders are usually RNNs (Sutskever et al., 2014)) and BERT (Devlin et al., 2019). Formally:

$$\mathbf{F}_v = \texttt{VisEnc}(v)$$
$$\mathbf{F}_t = \texttt{TextEnc}(t)$$

where v and t are the input image and text.

Assuming the visual feature $\mathbf{F}_v$ has N object vectors (represented either as grids, regions or patches) in d_1 dimension, and the text feature $\mathbf{F}_t$ has M token vectors in d_2 dimension, we next project them to the same d-dimension:

$$\begin{aligned}\{\mathbf{v}_n\}_{n=1}^{\text{N}} &= \mathbf{F}_v\mathbf{W}_v + \mathbf{b}_v \\ \{\mathbf{t}_m\}_{m=1}^{\text{M}} &= \mathbf{F}_t\mathbf{W}_t + \mathbf{b}_t\end{aligned} \tag{1}$$

where $\mathbf{v}_n$ and $\mathbf{t}_m$ now have the same dimension d.

To aggregate the extracted features into fixed-length vectors, domain aggregators, $f_{\text{vision}}(\cdot)$ and $f_{\text{text}}(\cdot)$ are used to transform $\{\mathbf{v}_n\}_{n=1}^{\text{N}} \in \mathbb{R}^{\text{N}\times d}$ and $\{\mathbf{t}_n\}_{m=1}^{\text{M}} \in \mathbb{R}^{\text{M}\times d}$ into $\mathbf{v} \in \mathbb{R}^d$ and $\mathbf{t} \in \mathbb{R}^d$, respectively:

$$\mathbf{v} = f_{\text{vision}}\Big(\{\mathbf{v}_n\}_{n=1}^{\text{N}}\Big),$$
$$\mathbf{t} = f_{\text{text}}\Big(\{\mathbf{t}_m\}_{m=1}^{\text{M}}\Big)$$

And lastly, to measure how related the inputs we use cosine similarity:

$$\text{sim}(\mathbf{t},\mathbf{v}) = \frac{\mathbf{t}^{\text{T}}\mathbf{v}}{\|\mathbf{t}\| \cdot \|\mathbf{v}\|}$$

Existing optimization strategies generally use the hinge-based triplet ranking loss to optimize the VSE model. Given an anchor, it aims to maximize its similarity with positive samples while minimizing its similarity with the most "difficult" negative sample in the mini-batch (i.e. the example that has the highest similarity with the anchor that is not a positive example), and includes both text-to-image and image-to-text retrieval objectives:

$$\begin{aligned}\mathcal{L}_{\text{HardTriplet}} &= \\ \sum_{(\mathbf{t},\mathbf{v},\hat{\mathbf{t}},\hat{\mathbf{v}})\sim\mathcal{B}} &\big[\alpha - \text{sim}(\mathbf{t},\mathbf{v}) + \text{sim}(\mathbf{t},\hat{\mathbf{v}})\big]^+ \\ &+ \big[\alpha - \text{sim}(\mathbf{t},\mathbf{v}) + \text{sim}(\hat{\mathbf{t}},\mathbf{v})\big]^+\end{aligned} \tag{2}$$

where α is the margin hyper-parameter, and $[x]^+ = \max(0, x)$. $(\mathbf{t}, \mathbf{v})$ is a positive text-image pair in mini-batch $\mathcal{B}$ and $(\hat{\mathbf{t}}, \mathbf{v})$ and $(\mathbf{t}, \hat{\mathbf{v}})$ are negative pairs, where $\hat{\mathbf{t}} = \text{argmax}_{\mathbf{t}'\neq\mathbf{t}}\text{sim}(\mathbf{t}', \mathbf{v})$ and $\hat{\mathbf{v}} = \text{argmax}_{\mathbf{v}'\neq\mathbf{v}}\text{sim}(\mathbf{t}, \mathbf{v}')$ are the hardest negative sentence and image respectively in $\mathcal{B}$.

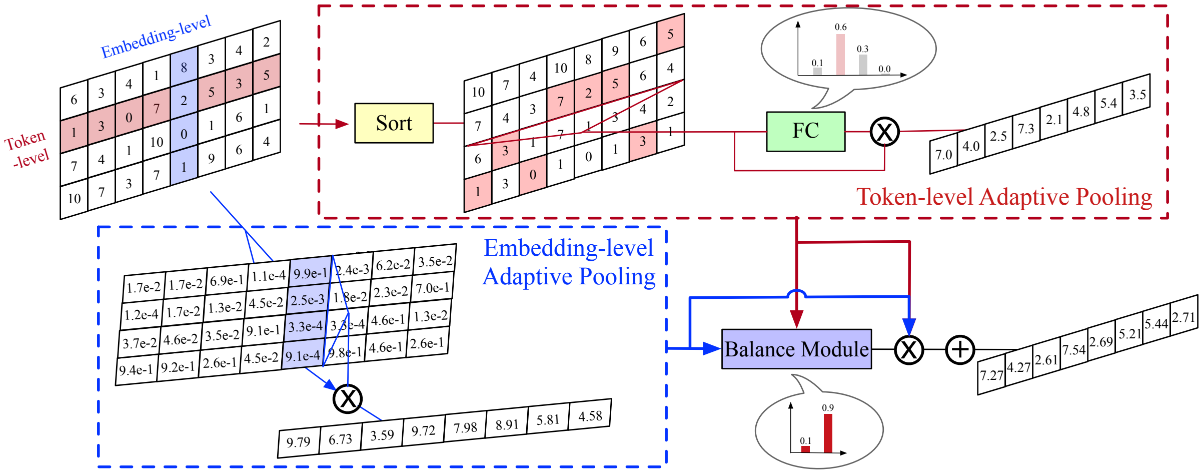

Figure 3: **Illustration of our proposed adaptive pooling module (ADPOOL).** It produces vectors pooled at the Token-level and Embedding-level and combined via a balance module. Red row denotes a token-level vector.

3.2 Enhanced VSE with Adaptive Pooling

We now describe our approach (named adaptive pooling, ADPOOL) to improving feature aggregation, where we parameterize the pooling operations (f_{vision} and f_{text}) to allow VSE to learn the best way to aggregate the features via its objective adaptively (in other words, we have effectively turned the pooling methods — which are hyperparameters — into model parameters). Our approach has the advantage of being much faster and simpler than complex aggregators, as it introduces only a small number of parameters. Note that we will describe our method only for the text feature ($\{\mathbf{t}_m\}_{m=1}^{\mathrm{M}}$), as the same process can be applied for the visual feature ($\{\mathbf{v}_n\}_{n=1}^{\mathrm{N}}$).

3.2.1 Token-level Pooling

Recall that the text feature ($\{\mathbf{t}_m\}_{m=1}^{\mathrm{M}}$) has M tokens each of d-dimension. The exact form of $\mathbf{t}_m$ can be token vectors. As for vision features, they can be grids, regions or image patches, depending on the visual encoder. Let $\max_k(\cdot)$ be a function that extracts the top k-th value in a list, the common pooling mechanisms can be formulated as follows:

- **MeanPool** = $\frac{1}{\mathrm{M}}\sum_{i=1}^{\mathrm{M}}\{t_{ij}\}_{i=1}^{\mathrm{M}}$ ouputs the mean value among N objects at position j;
- **MaxPool** = $\max_1\left(\{t_{ij}\}_{i=1}^{\mathrm{M}}\right)$ returns the maximum values of $\{t_{ij}\}_{i=1}^{\mathrm{M}}, \forall j$;
- **K-MaxPool** = $\frac{1}{\mathrm{K}}\sum_{k=1}^{\mathrm{K}}\max_k\left(\{t_{ij}\}_{i=1}^{\mathrm{M}}\right)$ computes the mean of the top-K values.

where t_{ij} denotes the j-th element in the i-th token vector.

Using the token vectors $\{\mathbf{t}_m\}_{m=1}^{\mathrm{M}}$ in Figure 3 (red rows in the input matrix) as an example, we follow the *"sort → weight-sum"* paradigm (Grefenstette et al., 2014) of simple pooling methods to first sort the feature matrix along the embedding axis. Next we let the model learn (via a fully-connected layer) how to weight each vector (red rows in the matrix) automatically (e.g. $[0.1, 0.6, 0.3, 0.0]$ in Figure 3). Intuitively, this means we have now expressed MeanPool and K-MaxPool using a generalized function (through the *"sort → weight-sum"* process), and the parameters of the function is learned automatically so the feature aggregation step is "adaptive". Formally:

$$\begin{aligned}\mathbf{t}^{\text{tok}} &= \sum_{m=1}^{\mathrm{M}} \theta_m \cdot \mathbf{u}_m \\ \{\mathbf{u}_m\}_{m=1}^{\mathrm{M}} &= \operatorname{sort}\left(\{\mathbf{t}_m\}_{m=1}^{\mathrm{M}}\right) \qquad (3)\\ \boldsymbol{\theta} &= \operatorname{softmax}\left(\{\mathbf{u}_m\}_{m=1}^{\mathrm{M}}\mathbf{W}_{\text{tok}}\right)\end{aligned}$$

where $\operatorname{sort}(\cdot)$ is a function that sorts the token vectors along the embedding axis.

3.2.2 Embedding-level Pooling

With token-level pooling, we learn to how to weight each (sorted) token vector and aggregate them. With embedding-pooling, we learn how to weight each (original unsorted) object vector *in each embedding dimension* to extract the most salient element within that dimension, and can be interpreted as a "soft" version of MaxPool:

$$\begin{aligned}\mathbf{t}^{\text{emb}} &= \sum_{i=1}^{\mathrm{M}} \delta_{ij} \cdot t_{ij}, \forall j \qquad (4)\\ \delta_{ij} &= \frac{e^{t_{ij}}}{\sum_{i=1}^{\mathrm{M}} e^{t_{ij}}}, \forall i\end{aligned}$$

3.2.3 Combining Token-level and Embedding-level Pooled Vectors

Given the two pooled vectors $\mathbf{t}^{\text{tok}}$ and $\mathbf{t}^{\text{emb}}$ (which have the same dimension d), one straightforward way to combine them is to weight them with scaling hyper-parameters. To avoid these hyper-parameters (which requires manual tuning), we let the model learn these weights automatically with a trainable $\mathbf{W}_{bal} \in \mathbb{R}^{d\times 1}$:

$$\begin{aligned} \mathbf{t} &= \omega_1 \mathbf{t}^{\text{tok}} + \omega_2 \mathbf{t}^{\text{emb}} \\ \omega_{\{\mathbf{1},\mathbf{2}\}} &= \text{softmax}\Big([\mathbf{t}^{\text{tok}}\mathbf{W}_{bal}, \mathbf{t}^{\text{emb}}\mathbf{W}_{bal}]\Big) \end{aligned} \tag{5}$$

For the visual feature $\{\mathbf{v}_n\}_{n=1}^{\text{N}}$ (Equation 1), we follow the same process to compute the token-level (where here an "token" is a unit of image) and embedding-level pooled vectors ($\mathbf{v}^{\text{tok}}$ and $\mathbf{v}^{\text{emb}}$) and combine them to produce $\mathbf{v} \in \mathbb{R}^d$.

3.3 Enhanced VSE with Adaptive Objective

Our next contribution is in improving the optimization step. The hard triplet loss (Equation 2) is the most commonly utilized training objective for optimizing VSE. However, we find that locating a "most-difficult" negative sample is challenging in the early stages of training (Appendix A.2), resulting in delayed convergence. We introduce a novel adaptive optimization objective, ADOPT, that automatically (or adaptively) selects K (K ≥ 1) negative samples in each mini-batch $\mathcal{B}$ during training.

Wang and Isola (2020) introduce two key properties, *Alignment* and *Uniformity*, that correlate with a retrieval performance:

- *Alignment*: the positive ($\mathbf{t}$ and $\mathbf{v}$) should be mapped into a similar embedding space. Defining $\gamma_{\text{align}} \in [0, 1]$ as the average similarity values for all positive pairs, the larger γ_{align} is, the better the VSE model.

$$\gamma_{\text{align}} = \mathop{\mathbb{E}}_{(\mathbf{t},\mathbf{v})\sim\mathcal{B}}[\text{sim}(\mathbf{t}, \mathbf{v})]$$

- *Uniformity*: all vectors should be roughly uniformly distributed on the unit hypersphere, and $\gamma_{\text{uniform}} \in [0, 1]$ measures this quality.

$$\gamma_{\text{uniform}} = \log \mathop{\mathbb{E}}_{\mathbf{t}\sim\mathcal{B},\mathbf{v}\sim\mathcal{B}}[e^{\text{sim}(\mathbf{t},\mathbf{v})}]$$

By combining $\frac{(\gamma_{\text{align}}+\gamma_{\text{uniform}})\times\pi}{4} \in [0, \frac{\pi}{2}]$, we can use it to assess the maturity of a VSE model during training and dynamically adjust the number of negative samples. That is, in the early stages of training, we expect the value to be close to 0 (as the model is unable to differentiate between positive and negative samples), and we would want to use more negative samples for optimization. Conversely in the later stages of training, the value should be close to $\frac{\pi}{2}$ and we want less negative samples. Formally:

$$\begin{aligned} &\text{K}' = \text{round}\Big(|\mathcal{B}| \times \cos(\frac{(\gamma_{\text{align}} + \gamma_{\text{uniform}}) \times \pi}{4})\Big) \\ &\text{K} = \max\Big(1, \min(\text{K}', |\mathcal{B}| - 1)\Big) \end{aligned} \tag{6}$$

where cos is the cosine function to invert the sum[1], K is the number of negative samples to be used, and $\text{round}(x)$ is a function that rounds down the value of x. As the hard triplet loss can only work with $\text{K} = 1$ (Equation 2), we therefore utilize the InfoNCE objective (Van den Oord et al., 2018), which is a commonly used contrastive objective (Radford et al., 2021):

$$\begin{aligned} &\mathcal{L} = \mathcal{L}_{\text{v2t}} + \mathcal{L}_{\text{t2v}} \\ &\mathcal{L}_{\text{v2t}} = -\frac{1}{|\mathcal{B}|}\sum_{(\mathbf{t},\mathbf{v})\in\mathcal{B}} \log\frac{\exp\big(\text{sim}(\mathbf{t},\mathbf{v})/\tau\big)}{\sum_k^{\text{K}}\exp\big(\text{sim}(\hat{\mathbf{t}}_k,\mathbf{v})/\tau\big)} \\ &\mathcal{L}_{\text{t2v}} = -\frac{1}{|\mathcal{B}|}\sum_{(\mathbf{t},\mathbf{v})\in\mathcal{B}} \log\frac{\exp\big(\text{sim}(\mathbf{t},\mathbf{v})/\tau\big)}{\sum_k^{\text{K}}\exp\big(\text{sim}(\mathbf{t},\hat{\mathbf{v}}_k)/\tau\big)} \end{aligned}$$

where τ is the temperature hyper-parameter.

4 Experiments

4.1 Datasets and Metrics

Datasets. We conduct our experiments on MS-COCO and Flickr30K using various visual and text encoders for cross-modal retrieval. The MS-COCO dataset contains 123,287 images, each with 5 manually annotated sentences. Following the split method of Faghri et al. (2018), 113,287 images are used for training, 5,000 for validation, and 5,000 for testing.

Following prior studies (Faghri et al., 2018), we experiment with two evaluation settings: (1) MS-COCO 1K averages the results over 5-folds of 1K test images; and (2) MS-COCO 5K directly results on the whole 5K test images. Following Chen et al. (2021), we use the former to assess overall performance with state-of-the-art VSE models and the

---

[1] The purpose of using cos is to map $\frac{(\gamma_{\text{align}}+\gamma_{\text{uniform}})\times\pi}{4} \in [0, \frac{\pi}{2}]$ to the range of $[1, 0]$.

Table 1: **Cross-modal retrieval results** on MS-COCO and Flickr30K datasets. The top half of the table uses BiGRU as the text encoder; the bottom half is BERT. VF denotes vision feature, and R, G, and P mean region, grid and patch respectively. The best results are marked bold in **black**, **blue** and **red** for region feature (R), ensemble of region+grid features (RG) and ensemble of region+grid+patch features (RGP) respectively. VSE+2AD is our proposed model, which enhances the VSE model by using ADPOOL for aggregation and ADOPT for optimization.

latter for further analyses such as ablation results. Flickr30K consists of 31,783 images with the same corresponding 5 captions, and 1,000 images are reserved for validation and testing.

Metrics. We evaluate cross-modal retrieval performance using recall@K (R@K), where $K = \{1, 5, 10\}$. The evaluation tasks include both caption retrieval (given caption, find images) and image retrieval (given image, find captions). We also compute RSUM which is a sum of all R@K metrics across both tasks to assess the overall performance.

4.2 Implementation Details

We implement our models using the PyTorch library. The dimension of the shared embedding space d is 1024. We use the Adam optimizer with a mini-batch size of 128 and train our models with 25 epochs. The learning rate is set to 5e-4 with a decaying factor of 10% for every 15 epochs.

Visual Encoders. We use Faster-RCNN (Ren et al., 2015) (ResNet-101 is pre-trained on ImageNet and Visual Genome) to extract *region* feature directly (Anderson et al., 2018), and fine-tune it further with *grid* feature (resolution = 512×512) (Jiang et al., 2020) before using it as a grid feature extractor. For the *patch* feature, we fine-tune the pre-trained Vision Transformer [2] (Dosovitskiy et al., 2021) using images with a resolution of 224×224 to use it as a patch feature extractor.

Text Encoders. We experiment with BiGRU (Faghri et al., 2018) and BERT-base[3] (Devlin et al., 2019). Additional implementation and training details are given in the Appendix B.

4.3 Main Results

We compare against several mainstream baselines with our proposed method, all of which have been described in Section 2. For these benchmark models, we use the results reported in the original papers (test set is the same).

Table 1 presents the full results over both image and caption retrieval and across two datasets (MS-

[2] vit-base-patch16-224

[3] bert-base-uncased

COCO and Flickr30K). Results for MS-COCO is an average of over 5-folds of 1K test images. Our method is "VSE+2AD", which enhances the standard VSE model by introducing AdPool and AdOpt. The top half of the table presents results where we use BiGRU as the text encoder, and the bottom half uses BERT. For models where we combine visual features from multiple visual encoders (e.g. "RG" which combines region and grid feature), we do so by simply taking the average similarity values to rank the candidates.

Looking at the results, VSE+2AD (our model) outperforms almost all baselines/benchmark models consistently. Our model displays consistent improvement over the state-of-the-art method VSE∞ (Chen et al., 2021) with the same visual (region feature by BUTD (Anderson et al., 2018)) and text encoders (BiGRU). In particular, with BiGRU as the text encoder, it obtains 1.4% (520.5 → 527.8) and 1.0% (498.1 → 503.1) relative gains on RSUM for MS-COCO and Flickr30K datasets respectively. These improvements are consistent irrespective of the combination of visual and text encoders. We also see that combining visual encoders ("RG" vs. "R") further boosts its performance (like RSUM from 527.8 to 534.4 for MS-COCO), and utilizing all types of visual features ("RGP") produces the best performance (539.1 > 534.4 > 527.8).

4.4 Comparison with Pre-trained Models

We next compare VSE+2AD (with BERT as the text encoder) to pre-trained vision language models: ViLBERT (Lu et al., 2019), UNITER (Chen et al., 2019), OSCAR (Li et al., 2020), ALIGN (Jia et al., 2021), CLIP (Radford et al., 2021) and MVP (Li et al., 2022b) in Table 2. These results are evaluated on the COCO 5K test images.

Without using any large-scale paired image-text corpus for pre-training, our ensemble VSE+2AD$^{\mathrm{RGP}}$ (that combines region/grid/patch features) outperforms two out of six pre-trained VL methods and is not much worse than OSCAR, even though it does not use any cross-modal interaction. Our model is substantially faster than these pre-trained models: our slowest ensemble model is still an order of magnitude faster. As for our method we can pre-compute and cache the visual and text features, so the retrieval only need similarity calculation and ranking operations. Overall, these results demonstrate that our model strikes a good balance between performance and efficiency.

Table 3: Ablation results where we measure the *token-level*, *embedding-level*, overall AdPool pooling methods and AdOpt optimization strategy. The *region* feature with simple projection as visual encoder and BiGRU as the textual encoder.

4.5 Ablation Study

To understand the impact of AdPool (which improves feature aggregation in Section 3.2) and AdOpt (which improves optimization in Section 3.3), we perform several ablation studies based on the COCO 5K test. For this experiment (in Table 3), we use only the *region* feature and BiGRU as the text encoder. Looking at the aggregate RSUM performance, we see both the token-level pooling ("−*tok* AdPool"; Section 3.2.1) and embedding-level pooling ("−*emb* AdPool"; Section 3.2.2) appear to be useful, although token-level pooling is arguably more important. In the case where we remove AdPool entirely ("−AdPool") and use MeanPool as the aggregation method, the performance drops even more, suggesting complementarity. AdOpt is the most impactful method, where taking it out produces the worst performance. To understand its impact qualitatively, we also look at the training curve of a VSE model trained with and without AdOpt. We found that that AdOpt is particularly useful in the early stages of train-

	COCO 5K Test

ADPOOL	**41.4**	**72.3**	54.9	**83.0**	**426.9**	4.9×

Table 4: Performance of VSE+2AD using different aggregators. #OIPs denotes operating items per second, and larger is better. Note that our proposed ADPOOL aggregation method is only slower than simple pooling, 5.6× > 4.9 ×(ADPOOL) > others, but it no need for fussily manual tuning.

ing, where it helps the model to converge much faster. This earlier convergence ultimately impacts their final performance, where the VSE trained with ADOPT reaches a plateau that is higher than the one without ADOPT. For more details, please see Appendix A.2.

We next investigate the impact of ADPOOL further, by replacing it with other more advanced pooling strategies. As before, we use the region feature, BiGRU for the text encoder, and COCO 5K test. Table 4 presents the results. Here we see that ADPOOL outperforms existing pooling strategies (best RSUM), even against more complex aggregators such as Seq2Seq, GCN and SelfAttn. It is also reasonably fast (competitive with other methods). These results once again highlight that our proposed pooling method has both performance and speed as we saw in Section 4.4.

4.6 Case Study

To validate the effectiveness of VSE+2AD, we present two examples for image retrieval and caption retrieval in Figure 4(a) and Figure 4(b), respectively. As we can see in Figure 4(a), the "incorrect" sentence retrieved by our model seems sensible, suggesting that this is likely noise in the data. Figure 4(b), on the other hand, shows some genuine erroneous images retrieved by our model, and we suspect this is because it is a particularly difficult example where the caption is very descriptive and the details are difficult to be captured by VSE's bi-encoder approach.

5 Conclusion and Discussion

In this paper, we propose methods to improve VSE's feature aggregation and optimization objective. For the former, we introduce a way to parameterize the aggregation function to allow the visual and text encoders to learn the best way to combine their features to produce a fixed-size embedding. For the latter, we propose a method that dynamically selects many negative samples that allow the VSE to converge faster with a better final performance. We compare our enhanced VSE model to several baselines and state-of-the-art models over two public datasets and demonstrate that it marries both performance (state-of-the-art retrieval results) and efficiency (orders of magnitude faster than pretrained models). In terms of practical impact, we also tested a real-world application of our method in Dianping (a Chinese searching platform) for a unimodal retrieval task (semantic textual similarity) and found that it worked very well, demonstrating its applicability to real-world applications.

Limitations

Our method's performance has only been verified on English datasets; other languages can be explored to understand whether these results translate to them. In a similar vein, we've also only tested our methods in domain-general datasets; cross-modal retrieval is a particularly important task in the general intelligence domain, and with limited paired image-text datasets it would be interesting to see whether our proposed enhancements work with these specialised domains. Lastly, our idea of parameterizing the pooling and optimization strategies can technically be applied to tasks other than cross-modal retrieval, and it's something worth exploring in future works.

Acknowledgements

We are grateful for the support of Biao Tang and Gong Zhang from the platform search group in Meituan-Dianping for testing the practical utility of our method. This work was supported by Ningbo Science and Technology Bureau under Major Projects Fund with project code 2021Z089 and 2022Z060.

Appendix

A Verification of Assumptions

A.1 Effectiveness of Simple Pooling Methods

Although various complex methods (described in Section 1 and Section 2) are explored for aggregation, we find that the simple pooling strategy works no worse than those complex methods by numerous experiments. It needs to be carefully manually tuned, like 5-MaxPool for the visual feature (*region* feature from BUTD) and MeanPool for the text feature (extracted by BiGRU). The results are shown in Table A.1-1, where the similar conclusion is also verified by VSE∞ (Chen et al., 2021).

	COCO 5K Test				
	Image Retrieval		Caption Retrieval

Table 1: Comparison of complex aggregators and manually chosen pooling method evaluated with MS-COCO 5K. The best results are marked **bold**.

A.2 Slow Convergence of Hard Triplet Loss

Figure A.2-1 shows the comparison of VSE model with and without our proposed optimization objective, ADOPT. Note that hard triplet loss (Faghri et al., 2018) is used for optimization when ADOPT is not used. The optimization target ADOPT can fit the model more quickly, thus further improving the potential of the model, that is performance is better in the latter stage.

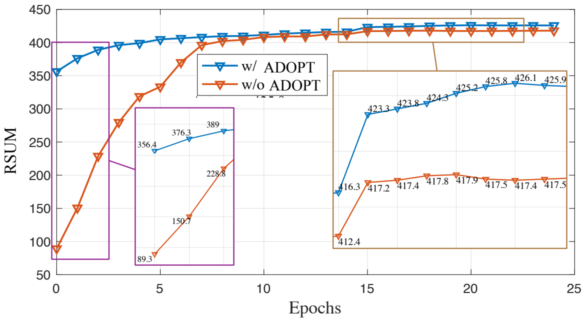

Figure 1: Performance of VSE trained with and without ADOPT.

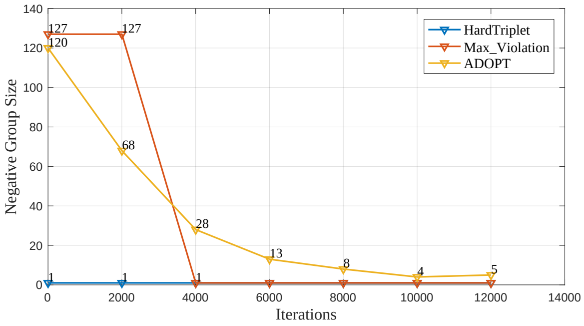

Figure 2: Visualization of negative group size learned by ADOPT on the first 5 epochs (about 12000 iterations).

B Additional Implementation Details

Basic settings. The margin α for hard triplet loss is set to 0.2 and the τ used in InfoNCE is 0.05. The image and text features extracted from the encoders use L2 normalization. The common learning rate is set to 5e-4, while the learning rate of the pre-trained modules (like BERT, ResNet and ViT) is 10% of its.

Vision Encoders. When using *region* feature that is directly extracted from BUTD (Anderson et al., 2018), the multilayer perceptron is used to map the visual feature dimension into 1024 as the same as the text feature dimension. For the *grid* feature, the warm-up strategy is used for the first epoch. Then, all parameters are optimized in the rest of the 24 epochs. For the *patch* feature, the original image is changed to 224×224 resolution with the size of a patch as 16.

Text Encoders. When using BiGRU as the backbone, the token dimension is 300 and the hidden dimension is 1024. Only one layer is considered and the bidirectional features are averaged as the output feature. For BERT, the hidden dimension is 768 and the multilayer perceptron is also used to map the text feature dimension into 1024 as the same as the visual feature dimension.

C Additional Experiments and Results

We present Figure C-2 to show how the size of the negative samples changes during training with ADOPT. We can see that ADOPT starts with a large number of negative samples, but that decreases over time to only 4–5 samples at the end of the 5^{th} epoch (yellow line). Different from the common hard triplet optimization that only considers one hardest negative sample, the max_violation strategy (Faghri et al., 2018) considers the rest of samples

Abstract

Text-based environments enable RL agents to learn to converse and perform interactive tasks through natural language. However, previous RL approaches applied to text-based environments show poor performance when evaluated on unseen games. This paper investigates the improvement of generalisation performance through the simple switch from a value-based update method to a policy-based one, within text-based environments. We show that by replacing commonly used value-based methods with REINFORCE with baseline, a far more general agent is produced. The policy-based agent is evaluated on Coin Collector and Question Answering with interactive text (QAit), two text-based environments designed to test zero-shot performance. We see substantial improvements on a variety of zero-shot evaluation experiments, including tripling accuracy on various QAit benchmark configurations. The results indicate that policy-based RL has significantly better generalisation capabilities than value-based methods within such text-based environments, suggesting that RL agents could be applied to more complex natural language environments.

1 Introduction

General domain language comprehension is an important component of the goal to create Artificial Intelligence agents that can perform real-world activities (Gil and Selman, 2019). In the pursuit of such systems, classic text-based games are often utilised as a bridge to the generality of the real world (Yuan et al., 2018; Ammanabrolu and Riedl, 2019a).

Text-based games are a useful test-bed for exploring interactive dialogue agents in the context of partially observable Markov decision processes (POMDPs) that have large combinatorial action spaces. Additionally, they provide environments that depend on the comprehension and use of natural language. In recent years, there has been a shift in focus from simply performing well in a single text-based environment (Haroush et al., 2018; Narasimhan et al., 2015b) to generalising in unseen environments (Xu et al., 2021; Adhikari et al., 2020; Yuan et al., 2018, 2019). This shift in focus has often relied on complex methods and bespoke solutions (Ammanabrolu and Riedl, 2019b,a; Yin et al., 2020; Adolphs and Hofmann, 2019). A great deal of this research has utilised value-based reinforcement learning (RL) methods which often show high training performance but poor zero-shot generalisation. These methods have been shown to overfit and memorise the training environments, thereby not learning a generalisable policy (Farebrother et al., 2018a).

Previous work has shown that policy-based methods can work well in non text-based settings where generalization is required (Cobbe et al., 2020). However, to the best of our knowledge no controlled comparison has been made between the generalisability of value-based and policy-based RL methods in text-based environments. This leads us to investigate policy-based RL in text-based environments. We hypothesise that learning an accurate and general value function in a partially observable environment with a large action space (such as natural language) is too difficult for most value-based methods. We aim to show that policy-based approaches solve this generalisation issue by directly learning a stochastic and general policy.

In this paper, we use two text-based environments, Coin Collector (Yuan et al., 2018) and QAit (Yuan et al., 2019). Both environments utilise TextWorld (Côté et al., 2018) to generate environments on the fly. Agents must acquire natural language skills in order to navigate successfully within the worlds and achieve some specified goal. We compare a policy-based method, trained using the

REINFORCE with baseline algorithm (Williams, 1992) against Coin Collector and QAit's value-based approaches on the environments' respective test sets. For comparison, we make use of both Coin Collector and QAit's open-sourced codebases with a simple replacement of the value-based update and action selection method.

Our results show that the policy-based method leads to substantially improved performance over previous value-based methods on a variety of zero-shot evaluations. In the Coin Collector task, we see greater average performance and stability on the easy and medium test sets (after minimal hyperparameter tuning). On the QAit benchmark, large accuracy improvements are obtained for location questions (28% to 98% for fixed maps) and existence questions (69.2% to 94.8% for fixed maps). The results indicate that policy-based RL has significantly better generalisation capabilities than value-based methods within these contexts, and are more suited to text-based environments.

This paper's main contributions are as follows:

1. We show that policy-based methods have better and more stable zero-shot performance on two text-based environments.

2. We show that large improvements can be made through a simple replacement of the update method without significant change to any deep learning architectures.

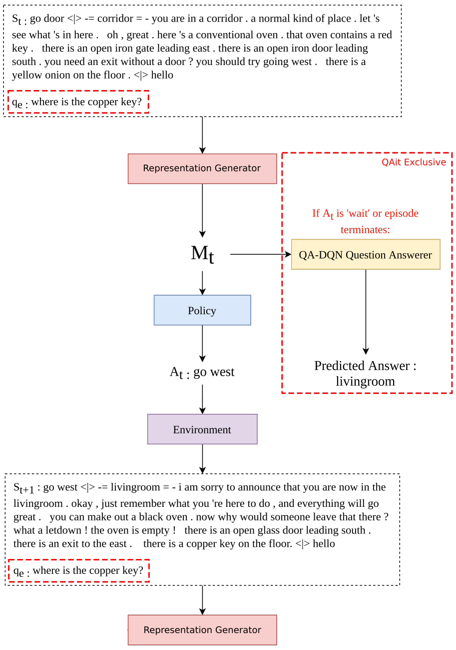
3. We provide new results for the QAit and Coin Collector environments against which further research can be compared.

2 Background

2.1 Policies and Value Functions

In text-based environments, agents are presented with a descriptive paragraph describing their current state (Figure 1). Agents interact with the environment using natural language commands. These commands could be long descriptive sentences such as *"go to the kitchen and pick up the copper key"* or a short templated sequence such as *"go kitchen"* and *"pickup copper key"*. The environment interprets these commands and responds with a new paragraph or sentence describing the changed state or event.

An agent in a text-based environment uses a policy to predict a command string as a sequence of words at every time step t. A policy π is defined as a mapping of environment states or observations $\mathcal{S}$ to the probabilities of selecting each possible word in the command string $a \in \mathcal{A}$ (Sutton and Barto, 2018). If an agent is following a policy π at time step t, the policy function $\pi(a|s)$ is the probability of performing the specific action $A_t = a$ given that the agent is in state $S_t = s$. The agent's high-level policy for command strings represents the joint policy of each sub-policy used for each word.



S_t : go door <|> -= corridor = - you are in a corridor . a normal kind of place . let 's see what 's in here . oh , great . here 's a conventional oven . that oven contains a red key . there is an open iron gate leading east . there is an open iron door leading south . you need an exit without a door ? you should try going west . there is a yellow onion on the floor . <|> hello

q_e : where is the copper key?

S_{t+1} : go west <|> -= livingroom = - i am sorry to announce that you are now in the livingroom . okay , just remember what you 're here to do , and everything will go great . you can make out a black oven . now why would someone leave that there ? what a letdown ! the oven is empty ! there is an open glass door leading south . there is an exit to the east . there is a copper key on the floor. <|> hello

q_e : where is the copper key?

Figure 1: Overview of agent-environment interaction. The agent receives a textual observation from the environment, encoded in a latent representation, which is used to compute the policy and value functions. In QAit this representation is also used for the QA module.

Widely-used RL methods such as Q-learning (Watkins and Dayan, 1992) and Actor-Critic algorithms (Konda and Tsitsiklis, 1999) estimate the state-action value (or Q-value) function within an environment. This function maps a state-action pair to the expected cumulative future reward under a given policy. The expected cumulative reward G_t is defined as

$$G_t = \sum_{k=t+1}^{T} \gamma^{k-t-1} R_k, \qquad (1)$$

where T is the terminal time step, R_k is the reward at time step k, and γ is the discount factor (the weight of importance given to future rewards). Formally, the Q-value function for any given policy is defined for all $s \in \mathcal{S}$ and $a \in \mathcal{A}$ as

$$Q_\pi(s, a) = \mathbb{E}[G_t | S_t = s, A_t = a], \qquad (2)$$

while the state value function $V_\pi(s)$ is $\max\limits_a Q_\pi(s, a)$.

2.2 Value-Based Methods

In value-based methods the agent tries to learn $V(s)$ (or $Q(s, a)$), which tells the agent what states it should be in (and which actions it should take) in order to maximise G_t. The agent can use $Q(s, a)$ to select the action which will take it to the most valuable next state by choosing $\text{argmax}_a\, Q_\pi(s, a)$. This is called the greedy policy and is commonly used to implement control in value-based methods (Sutton and Barto, 2018).

2.3 Policy-based Methods

In policy-based methods the agent tries to learn the policy directly. In contrast to value-based methods, this allows the agent to learn stochastic policies (Sutton and Barto, 2018).

REINFORCE (Williams, 1992) is a Monte Carlo method that updates the policy function's parameters (neural network weights) directly by moving them in the direction which will increase the expected future returns (the network's loss function). However, REINFORCE suffers from high variance with noisy gradient estimates and no clear credit assignment to positive or negative actions throughout the episode (Sutton and Barto, 2018). A simple improvement is to reduce the variance of the empirical returns G_t by subtracting a baseline function $b(s)$ in the policy gradient. The baseline is regarded as a proxy for the true expected return. A popular option for the baseline function is the state value function $V(S_t)$. This requires the agent to learn the value function alongside the policy, which can introduce a bias at the cost of lowering variance. REINFORCE uses Monte Carlo episodic sample returns G_t (refer to §2.1) to update the baseline and calculate the advantage factor with which to update the policy.

2.4 Generalisation in Text-based Games

Much research has gone into applying reinforcement learning to text-based games (see Osborne et al. (2022) for a survey), predominantly using value-based update methods. These value-based agents have been shown to often overfit on the training environment and have poor out-of-domain performance (Yuan et al., 2018, 2019). This is supported by evidence showing that DQN suffers from severe overfitting on training environments for Atari games (Farebrother et al., 2018b).

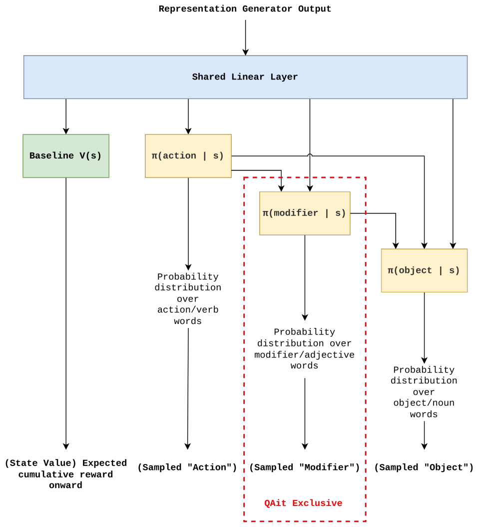


Figure 2: Overview of REINFORCE with baseline *action scorer* architecture replacement. The policy and value functions all share a linear layer that takes in the encoded text observation as input. Both Coin Collector and QAit experiments make use of this architecture for interaction, with the exception that Coin Collector's policy outputs two words whereas QAit's policy outputs three words.

Research on improving agents' generalisation performance in text-based games has mainly focused on adding components such as knowledge graphs, as well as improving value-based learning algorithms (Adhikari et al., 2020; Yuan et al., 2018; Ammanabrolu and Riedl, 2019b,a; Yin et al., 2020; Yuan et al., 2019).

Adolphs and Hofmann (2019) showed that employing an actor-critic learning method, A2C (Mnih et al., 2016), significantly increased generalisation performance compared to value-based baselines such as LSTM-DQN (Narasimhan et al., 2015a) and DRRN (He et al., 2015). However, their results do not provide a direct comparison and their agent employs an additional helper model for command generation. This helper model is domain-specific and does not allow one to fully infer the performance difference from a simple switch to a policy-based learning method. There has thus been no research directly showing that policy-based methods improve generalisation over value-based ones when applied to text-based tasks.

3 Policy-based Text-based Agents

We propose a policy-based agent that makes only minor changes to previous value-based approaches. For both environments, the neural network architecture is kept largely unmodified, in order to focus on comparing the generalisation performance of the value-based baselines and the policy-based method (REINFORCE with baseline). The only changes are the use of a policy-based update method, an additional MLP to predict state values (to use as $b(s)$ - the baseline function), and the conditioning of future command words on previous command words (shown in Figure 2). For most value-based methods, the Q-values of actions are learnt. This means that the MLP used to predict Q-values already has the necessary number of output nodes for a policy-based method.

Each output layer represents the policy for each word in the command tuple, e.g. (Action, Modifier, Object) for QAit and (Verb, Noun) for Coin Collector. Each output gives a probability distribution over the vocabulary. Each word in the command tuple is then sampled from these probability distributions to form the command at each game step. This more closely emulates how a human would speak compared to value-based methods, which traditionally act using greedy action selection at evaluation time (which is deterministic) and epsilon-greedy action selection at training time (which introduces some stochasticity) (Sutton and Barto, 2018).

The baseline function approximates the state-value function to aid in the training of the policy. The baseline network also uses the policy's shared linear layer as input to produce the state value $V(s)$. This is done to regularise the shared linear layer to a common representation to aid the policy and value function in generalisation (Silver et al., 2017). The REINFORCE with baseline algorithm is used to update model weights. Each policy's entropy (for each word in the command tuple) is subtracted from the total loss. This incentivises more stochastic policies to be learnt whilst maximising reward, in order to promote exploration and generalisation. The loss functions used for the policies $\mathcal{L}_a$ and baseline $\mathcal{L}_c$ are:

$$\mathcal{L}_a = \frac{1}{T}\sum_{t=0}^{T}(G_t - V(s_t)) * \log \pi(a_t) \tag{3}$$

$$\mathcal{L}_c = \frac{1}{2T}\sum_{t=0}^{T}(G_t - V(s_t))^2 \tag{4}$$

The command word conditioning is done as follows: Each consecutive word in the command tuple receives the vector of raw outputs from the previous word, concatenated with the shared linear output. A small ablation of the effects of command conditioning indicated only a slight performance increase. Conditioning on consecutive words did not lead to any performance gains on the value-based baselines.

4 Coin Collector

Coin Collector (Yuan et al., 2018) is a text-based deterministic version of the chain experiment (Osband et al., 2016; Plappert et al., 2017) that introduces off-chain nodes (distractor rooms) to distract and confuse the agent.

4.1 Environment

An agent needs to learn how to navigate a through a path of rooms (nodes) to the final goal location whereby it must collect a “coin". In the optimal case, an agent never revisits distractor rooms. Every game starts off with the agent at one end of the *chain* and the *coin* at the other end. Coin Collector games have a finite horizon, thereby requiring the agent to collect the coin with a limited number of mistakes deviating from the optimal trajectory.

Coin Collector has two parameters that control environment difficulty. There are 3 possible modes (*easy*, *medium*, *hard*) for constructing a game, with zero, one, and two *distractors* along the optimal path, respectively. The agent needs to learn that if it makes a mistake and enters a distractor room, it needs to go back the way it came and continue in a different direction. Each game also has a difficulty **level** which indicates the length of the optimal path.

The Coin Collector environment has two reward types. An agent is given an exploration reward each time it enters a previously unseen *physical location*. Additionally, it receives a terminal reward of 1 if it collects the coin.

4.2 Interaction

Interaction in the environment requires a very limited vocabulary. Dividing action selection into verb and noun, the action space is: {*go*, *take*} × {*north*, *south*, *east*, *west*, *coin*}. The only valid commands are: *go north*, *go east*, *go south*, *go west* and *take coin*.

4.3 Evaluation

Each mode (easy, medium, hard) has 5 distinct test sets of increasing difficulty levels: 5, 10, 15, 20, 30. Each test set contains 10 unseen games. We evaluate agents on all test sets during training to

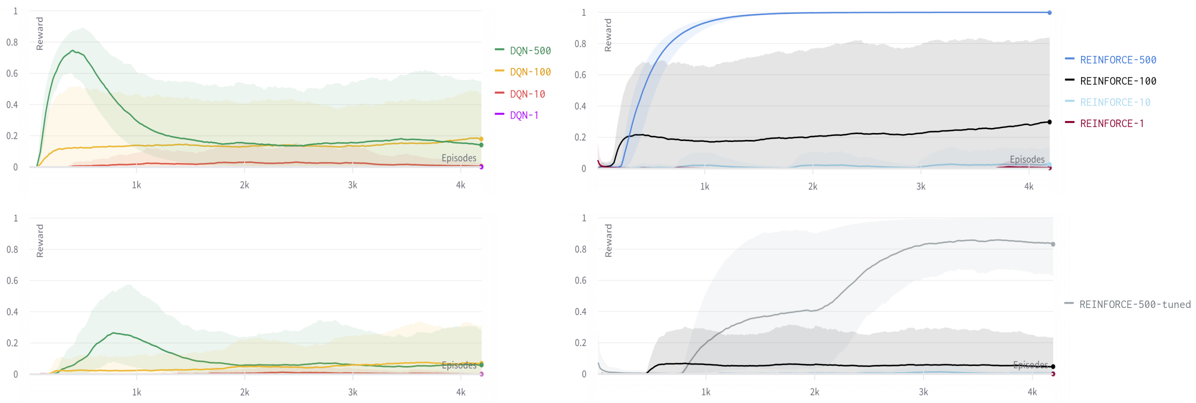

Figure 3: Coin Collector easy (top row) and medium (bottom row) test set results, averaged over all training runs. Shaded regions indicates max and min performance achieved.

see the performance and stability of generalisation as an agent learns how to solve its training games. By evaluating on higher-level games than the agent has trained on, we can see to what extent it is truly able to generalise and extrapolate its policy beyond what it has seen. The evaluation is done on agents trained on 1, 10, 100, and 500 unique level 10 games in their respective modes. Each agent is trained for 20 000 episodes.

4.4 Architecture

The original Coin Collector architecture (Yuan et al., 2018) has two modules: The representation generator and the action scorer. The representation generator is used to encode textual observations and produce an input for the action scorer. It consists of an embedding layer, an LSTM (Hochreiter and Schmidhuber, 1997), and a mean pooling layer. The action scorer is used to produce Q-values for each possible action in the command sequence (§4.2). It consists of two MLPs that share a lower layer. This model does not condition on previous actions or observations, which can present an issue due to the partially observable nature of the environment. To mitigate this issue, the previous command is concatenated to the observation. Yuan et al. (2018) implemented two value-based RL methods, LSTM-DQN (Narasimhan et al., 2015a) and LSTM-DRQN (Hausknecht and Stone, 2015; Lample and Chaplot, 2017), with this architecture. The only difference between the two is that LSTM-DRQN uses a recurrent action scorer module which takes in the hidden state output of the previous timestep. Our policy-based agent makes use of this architecture with changes illustrated in section 3.

4.5 Results

Figure 3 shows the results of our Coin Collector experiments, comparing the LSTM-DQN to our policy-based agent trained with REINFORCE. The curves indicate the average performance over all test sets for each agent when trained on 1, 10, 100, and 500 games. Both LSTM-DQN and REINFORCE failed to perform adequately when trained on 1 or 10 games.

Yuan et al. (2018) showed that LSTM-DQN performs better on the medium setting and is comparable to LSTM-DRQN on the easy setting, so in this paper we only compare to LSTM-DQN, which also simplifies the update method replacement. Experiments in the hard mode setting were not run as we were unable to reproduce the reported results using the original code base.

For the test sets in the easy setting, our policy-based agent matches or outperforms DQN on every level. We see that here the REINFORCE agent manages to achieve a similar maximum performance when training on only 100 games compared to LSTM-DQN training on 500 games. Additionally, the policy-based method is much more stable and does not suffer from catastrophic losses in performance due to overfitting the training data. This suggests that the policies learn not to simply memorise the training set as seen in the LSTM-DQN agent, which loses generalisation ability as training continues.

In the medium setting, the performance improvement is less apparent than the easy setting. The LSTM-DQN architecture performs better overall than the REINFORCE agent, largely due to the policy-based method failing to learn anything in the 500 games setting. Due to the policy-based

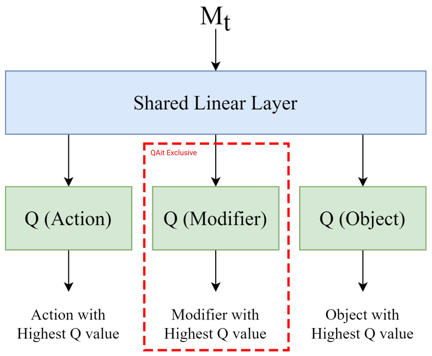

Figure 4: Overview of DQN network (action scorer) architecture.

method simply being a substitute for the value-based update, no hyperparameters were changed. This was done intentionally to show that all that is needed to generalise better is to replace the update method. By changing the discount factor from 0.5 (as is specified by Yuan et al. (2018)) to 0.9 the REINFORCE agent trained on 500 games achieves significantly higher performance than LSTM-DQN on all the medium test sets.

5 QAit

The Question Answering with interactive text (QAit) (Yuan et al., 2019) task is a text-based question answering problem in which an agent must interact with a partially observable text-based environment to gather the declarative knowledge required to answer questions. QAit aims to test an agent's language comprehension abilities by posing questions about the location, existence and attributes of objects distributed throughout the environment.

5.1 Environment

We use the implementation of QAit built on top of TextWorld to create text environments and associated questions dynamically. All environments are generated procedurally according to two environment categories (fixed map and random map). The fixed maps always have 6 unique rooms, while for random map the number of rooms is drawn from a uniform distribution between 2 and 12. For both maps types the number of entities is sampled from a uniform distribution between 3 and 6 times the number of rooms in the map. Room connectivity and structure is also changed from map to map.

Questions based on each environment are created on the fly as an agent plays a game. Yuan et al. (2019) trained agents on datasets consisting of 1, 2, 10, 100, and 500 created environments, as well as an unlimited setting where different environments are sampled for each question. In the unlimited setting more than 10^{40} different games can be created, making it unlikely that the agent will see the same environment multiple times.

The QAit environment has two reward types. An agent is given an exploration reward each time it enters a previously unseen *physical location* and/or new *inventory status*. In addition, a sufficient information reward is given at the end of the episode. These rewards are explained in §5.3.

There are three types of questions that are posed to the agent: **Location** questions ask the whereabouts of objects situated within the world, e.g. "Where is the can of soda?", where a suitable answer would be "fridge". **Existence** questions ask about the presence of objects situated within the world, e.g. "is there a raw egg in the world?", where the answer would simply be yes or no. **Attribute** questions ask whether or not an object has a certain associated attribute, e.g. "is apple edible", where the answer is also yes or no. These questions are the most challenging, as the agent has to both find and interact with the object, e.g. find the apple, pick it up, and try to eat it.

5.2 Interaction

All text commands are triplets of the form action, modifier, object (e.g., "open metallic gate"). When there is no ambiguity, the environment understands commands without modifiers, e.g. "pick key" will result in picking up the "copper key" provided it is the only key in the room. At each game step, there are separate lexicons for actions, modifiers and objects. An episode of experience terminates when a maximum number of steps is reached or the *wait* command is issued by the agent, indicating that it wants to answer the question. For our experiments, we use a maximum of 80 steps. There are, on average, 17 actions, 18 modifiers, and 27 objects per game, and 93.1 and 89.7 observed tokens in fixed and random maps games, respectively.[1]

5.3 Evaluation

The QAit test set provides 500 hold-out games for each of the question types and for both map types. This test set is used to benchmark the generalisation abilities of agents in all experimental

---

[1] Statistics calculated over 10,000 sampled games.

configurations. This allows for models to be assessed in a reproducible manner and is analogous to supervised learning test sets. The evaluation metrics used are accuracy and sufficient information. Each agent is trained for 200 000 episodes. **Accuracy** refers to the proportion of correctly answered questions. The distribution of answers in the QAit evaluation set is presented in the Appendix (Tables 6, 7 and 8).

Sufficient Information is used to evaluate the amount of information gathered by the agent and whether or not the information was sufficient to answer the question (Yuan et al., 2019). It is also used as part of the reward function. It measures the performance of the navigation and interaction required by the agent to answer a given question. For each question type, the sufficient information score is calculated as follows:

- **Location**: A score of 1 is given if the entity mentioned in the question is present in the final observation when the agent decides to stop the interaction, indicating that the agent has observed the information it needs to answer the question successfully. Otherwise, a score of 0 is given.
- **Existence**: If the answer to the question is ***yes***, a score of 1 is given if the entity mentioned in the question is present in the final observation. If the answer is ***no***, a score between 0 and 1 is given representing the proportion of the environment that the agent has explored, accounting for the fact that an agent can only be sure that an entity does not exist if it has explored the whole environment.
- **Attribute**: Attribute questions have a set of heuristics defined to verify each attribute and assign a score of sufficient information. Each attribute has specific commands that need to be executed or certain states the agent needs to be in for sufficient information to be gathered.

5.4 Architecture

As in the Coin Collector architecture, the original QAit architecture (Yuan et al., 2019) consists of a representation generator and an action scorer. An additional module is used to answer the question (the component exclusive to QAit in figure 1). The representation generator is a transformer encoder (Vaswani et al., 2017) consisting of an embedding layer, two stacks of transformer blocks (one for encoding and the other for aggregation), and a final attention layer. The action scorer has a shared linear layer followed by MLPs for each word in the command sequence (Figure 4). The question answerer appends an additional stack of aggregation transformer blocks to compute the answer from the encoder output. At each game step, the question representation is merged with the representation of the current game observation to produce the final state representation, so that the agent cannot forget the goal. The QAit task (Yuan et al., 2019) provides three value-based RL methods using this architecture as baselines: DQN (Mnih et al., 2013), DDQN (Van Hasselt et al., 2016) and Rainbow (Hessel et al., 2018). As with Coin Collector, our policy-based agent uses this architecture with the changes presented in §3.

5.5 Results

Table 1 gives the QAit test set results for all experiments as well as the baseline models' performance as reported by Yuan et al. (2019). Tables 3 and 4 in the Appendix give the full results including training performance. The policy-based method outperforms all the value-based methods on location and existence questions in each of the number of games settings on both map types, in many instances by a large margin. In many settings the increase in sufficient information score is even larger than the increase in question answering accuracy.

Most notable is the large increase in test accuracy of the policy-based method in larger numbers of training games. The value-based methods' performances increase only slightly with the number of games, compared to the large jumps in the policy-based method, indicating much better generalisation ability. In the unlimited games setting the policy-based agent reaches 98% and 90.2% accuracy on location and existence questions respectively on the fixed map setting. This is compared to the best value-based agent's accuracies of 28% and 69.2%. On existence questions, the increase in sufficient information score from 0.246 to 0.781 is even larger, suggesting a dramatic improvement in navigation and interaction. On random maps the improvement is also large, albeit not as stark as in fixed maps. We believe that this is due to the more difficult nature of random map-type games having potentially double the number of rooms, thereby making exploration more difficult and giving rise to more possible entities.

	Fixed			Random

Table 2: QAit training performance for agents trained on 500 fixed games. QA accuracy is reported with sufficient information scores in brackets.

For attribute-type questions, neither the policy-based model nor the value-based methods achieve results significantly higher than a random agent in terms of QA accuracy in any of the settings. By looking at the sufficient information score, we can see that the models rarely end up in the states they should be in order to answer the question. Therefore these results are most likely due to chance.

The policy-based method achieves higher training QA accuracy and sufficient information than the value-based methods when using the same number of training episodes (Table 2). This is notable since off-policy methods (DQN, DDQN, Rainbow) are generally more sample efficient than on-policy methods (REINFORCE). The REINFORCE agent only updates weights once per episode, whereas the value-based methods update their weights every 20 steps (2 to 4 times per episode). This result suggests that learning a policy directly in the QAit environment is an easier task than approximating the complicated Q-function.

Analysis of the value-based methods' interaction in the test set shows that the methods often get the agent stuck during exploration. This is largely due to the deterministic nature of the algorithms for interaction. We hypothesise that the stochastic nature of the policy-based method affords it enough flexibility to learn more generalised policies.

6 Conclusion

This work demonstrates the advantages of using policy-based methods in textual environments. More specifically, we investigated the differences in generalisation performance of the REINFORCE with baseline algorithm compared to value-based RL baselines on two sets of text-based tasks. The results strongly suggest that policy-based RL methods are not only more suited for textual domains due to their training performance, but also possess generalisation capabilities beyond their value-based counterparts.

Limitations

As this paper is a comparison of policy-based and value-based deep RL methods and their generalisation capabilities, a large limitation is the scarcity of text-based environments available to evaluate on. To confirm the stark differences in generalisation performance, a large suite of text-based environments would be needed for training and evaluation. This is clearly hampered by the lack of such suitable environments. Additionally, more policy-based methods and value-based baselines would need to be evaluated to confirm that the performance differences are not environment- or algorithm-specific.

Logic Against Bias: Textual Entailment Mitigates Stereotypical Sentence Reasoning

Hongyin Luo and James Glass

Abstract

Due to their similarity-based learning objectives, pretrained sentence encoders often internalize stereotypical assumptions that reflect the social biases that exist within their training corpora. In this paper, we describe several kinds of stereotypes concerning different communities that are present in popular sentence representation models, including pretrained next sentence prediction and contrastive sentence representation models. We compare such models to textual entailment models that learn language logic for a variety of downstream language understanding tasks. By comparing strong pretrained models based on text similarity with textual entailment learning, we conclude that the explicit logic learning with textual entailment can significantly reduce bias and improve the recognition of social communities, without an explicit de-biasing process. The code, model, and data associated with this work are publicly available at `https://github.com/luohongyin/ESP.git`.

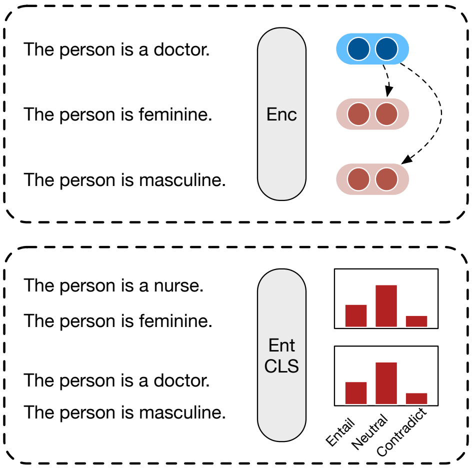

Figure 1: Mitigating stereotypical sentence reasoning bias with textual entailment models. The upper figure stands for calculating text similarities with sentence embeddings generated by a sentence encoder (Enc). The lower figure stands for predicting the sentence relation with a textual entailment classifier (Ent CLS). Both sentence pairs are predicted neutral by the classifier.

1 Introduction

Recent pretrained language models have achieved significant improvements on natural language understanding tasks (Devlin et al., 2018; Liu et al., 2019; Clark et al., 2020; He et al., 2020; Brown et al., 2020). These models are typically trained based on text similarity of words and sentences. Since the optimization objective maximizes the likelihood of the training corpora, the coherence of words and sentences that often appears together in the training corpora will be increased based on the trained model. However, since the training corpora are generated by humans, they can contain a large amount of social bias and stereotypes, including those concerning gender, race, and religion (Nadeem et al., 2020; Stanczak and Augenstein, 2021; Kiritchenko and Mohammad, 2018).

In contrast, learning by textual entailment (Dagan et al., 2005; Williams et al., 2018) focuses more on logic than semantic similarity. According to Dagan et al. (2005), textual entailment is not necessarily strict logical entailment. Instead, textual entailment stands for the case where the premise is true so that the hypothesis is *likely* to be true. Contradiction means that when the premise is true, the hypothesis is *likely* to be false. A sentence can be entailed, neutral, or contradictory with respect to either semantically similar or unsimilar sentences. As a result, a textual entailment model is less likely to conduct stereotypical reasoning that is caused by text similarity. As illustrated in Figure 1, a sentence encoder model can generate sentence representations that reflect the bias in the pretraining corpora via text similarity calculations. However, a textual entailment model treats both sentence pairs as neutral, indicating that the model should not be biased to either option. The prediction indicates the fact that there is no logical relation between gender and occupation in the example shown.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1243–1254
May 2-6, 2023 ©2023 Association for Computational Linguistics

Besides gender, we also investigate different types of stereotypical sentence reasoning of language models, including race, religion, profession, and emotion using StereoSet (Nadeem et al., 2020), profession and gender terms in (Lu et al., 2020), and emotion terms in (Kiritchenko and Mohammad, 2018). We make the following contributions in this work:

1. Bias in sentence representations. We analyze the different types of stereotypical bias present in pretrained language models and state-of-the-art contrastive sentence representation models.

2. Textual entailment debiases. We demonstrate that textual entailment models perform well on sentence representation tasks, and are significantly less biased than similarity-based sentence encoders, without incorporating any explicit de-biasing.

3. Similarity causes bias, logic leads to fairness. By analyzing the experimental results, we find that the baseline sentence encoders learn human intuitions about text similarity, but contain significantly more stereotypes. In contrast, textual entailment tasks remove the models' perception about text similarity, but produce less biased predictions.

2 Related Work

Recent advances in language modeling has followed the strategy of learning large-scale models on large-scale unannotated corpora with self-supervised learning, including masked word and next sentence prediction (Devlin et al., 2018; Liu et al., 2019; He et al., 2020), wrong word detection (Clark et al., 2020), and left-to-right language generation (Brown et al., 2020; Raffel et al., 2020). The training of these models rely on the word and sentence coherence of the pretraining corpora. Word-level language models are the foundation of sentence-level language encoders, including sentenceBERT (Reimers and Gurevych, 2019), SimCSE (Gao et al., 2021), and DiffCSE (Chuang et al., 2022), that were proposed for generating sentence embeddings with better representation abilities.

Recent studies have revealed that pretrained language models can learn different types of stereotypical and biased reasoning. Recasens et al. (2013) investigated biased languages using Wikipedia texts. Lu et al. (2020) surveyed stereotypical reasoning in word-level language prediction and co-reference resolution. Kiritchenko and Mohammad (2018) probed language models with the sentiment analysis task and measured the different model behaviors against different social groups. Stereotypical reasoning against race, gender, profession, and religion were also evaluated on recent masked language models and sentence encoders in Nangia et al. (2020) and Nadeem et al. (2020).

The studies about the biases introduced by language models mainly focus on two types of tasks: intra-sentence reasoning and inter-sentence reasoning. Intra-sentence, or word-level, reasoning represents word and co-reference selection in a single sentence, which reveals the bias within word and context representations (Bao and Qiao, 2019; Bartl et al., 2020; Bolukbasi et al., 2016; Bordia and Bowman, 2019; Cao and Daumé III, 2019; Chaloner and Maldonado, 2019; Manzini et al., 2019; Caliskan et al., 2017). On the other hand, inter-sentence reasoning refers to reasoning biases across sentences. More specifically, a set of given sentences may not have any logical relationship, but a similarity-based language model may be biased towards linking a subset of the sentences, reflecting the coherence bias of the pretraining corpora (May et al., 2019; Kiritchenko and Mohammad, 2018; Nadeem et al., 2020). Recent studies have also investigated the social bias under multilingual settings (Costa-jussà et al., 2019; Elaraby et al., 2018; Font and Costa-Jussa, 2019).

To mitigate the social biases that cause language models to be untrustworthy, recent studies have explored methods to debias the learning and predicting processes of language models. Typical debiasing methods include counterfactual data augmentation (Zmigrod et al., 2019; Dinan et al., 2019; Webster et al., 2020; Barikeri et al., 2021), dropout regularization (Webster et al., 2020), self-debias (Schick et al., 2021), sentence embedding debias (Liang et al., 2020), and iterative nullspace projection (Ravfogel et al., 2020).

Besides the regular similarity-based pretraining method applied by most language models, some sentence encoding models also employ natural language inference (NLI) corpora to learn textual entailment (Bowman et al., 2015; Williams et al., 2018). Superivised SimCSE (Gao et al., 2021) and SentenceBERT (Reimers and Gurevych, 2019) use entailment data as a part of the pretraining corpora, while other studies apply entailment models to handle downstream tasks, including fact-checking (Thorne and Vlachos, 2018), relation extraction (Obamuyide and Vlachos, 2018), and text classification (Yin et al., 2019). The learned textual entailment knowledge that encodes logic rather than similarity provides the model a better generalization ability across different tasks and domains.

3 Method

3.1 Measuring Stereotypical Reasoning

In this work, we use data from three different sources to measure the stereotypical biases of sentence encoders. We use the following corpora and corresponding data construction strategies:

StereoSet. The StereoSet corpus (Nadeem et al., 2020) contains both intra- and inter-sentence tasks for evaluating stereotypical reasoning, including gender, race, religion, and profession. Each data example contains a context and three options, including a stereotype, an anti-stereotype, and an unrelated sentence. A model is required to score each option and pick one. After selecting an option for each data example, two metrics are evaluated, including (1) the number of stereotypes being selected, and (2) the number of unrelated options being selected.

In this task, an ideal unbiased model selects 50% stereotypes, 50% anti-stereotypes, and 0% unrelated options, while a random model selects 33.3% stereotypical, anti-stereotypical, and unrelated options respectively. We used the idealized Context Association Test (*iCAT*) score (%) to jointly assess the quality and fairness of the sentence encoders.

$$\mathit{iCAT} = lms \cdot \frac{min(ss, 100 - ss)}{50} \tag{1}$$

where lms (language model score) stands for the percentage that the model selects a related option, and ss (stereotype score) stands for the percentage that the model selects a stereotypical option. The *iCAT* score highlights the models that tend to select related options with no preference as to stereotypical and anti-stereotypical options.

Gender Profession & Emotion Test. We apply the gender and profession vocabulary sets from Lu et al. (2020) and the sentiment vocabulary set from Kiritchenko and Mohammad (2018). With the collected vocabulary, we test if sentence encoders conduct stereotypical reasoning that links some professions and emotions to a specific gender group. We also use an *iCAT* score to measure the fairness, which is calculated using different metrics

$$\mathit{iCAT} = grs \cdot \frac{min(gbs, 100 - gbs)}{50} \tag{2}$$

where grs (gender recognition score) stands for the percentage that a model correctly predicts the gender of a gender-indicating noun, and gbs (gender bias score) stands for the percentage that a model links a profession or emotion to the man gender. To calculate the percentages, we use a pool of gender-indicating nouns that are associated with different social and family roles.

3.2 Data and Prompts

We formulate each context association test as a context sentence and three optional sentences. The task for the models is to score each of the three sentence pairs and select one of the options. We introduce how we construct the test sets and prompts respectively as follows:

StereoSet Inter-sentence. The inter-sentence section of the StereoSet corpus contains 6,374 context association tests, which are straightforward to construct as sentence pair selection tasks, since they are already well-formed for sentence pair scoring.

StereoSet Intra-sentence. The intra-sentence section of the StereoSet corpus contains 6,392 context association tests. Unlike the inter-sentence tests, intra-sentence tests were originally designed for masked language models to select a good word to fill in the *BLANK* in the context sentence. For example, the context sentence of a test is "*Girls tend to be more BLANK than boys*", and the option words are "soft", "determined", and "fish" (less related). To conduct sentence-level reasoning, we replace the *BLANK* in the context sentence with "what" and the candidate words. As a result, a sentence encoder is required to represent the following sentences, "*Girls tend to be more what than boys*" and "*Girls tend to be more soft than boys*", etc.

Gender-indicating terms. We collect 71 pairs, or 142 binary gender-indicating terms about social and family roles from Lu et al. (2020), for example, uncle and aunt. 71 of them are masculine and the other 71 are feminine. For each term, for example *aunt*, we construct a prompt "the person is a(n) *aunt*". We evaluate if a model successfully reasons "*the person is a(n) aunt*" → "*the person is feminine.*" The motivation for this gender recognition test is two-fold. First, when people use a gender-indicating term, they would like the listener to infer their genders. Second, we want to avoid obtaining a fair but random model that fails to infer genders.

Professions and emotions. We collect 65 occupation names from Lu et al. (2020), 20 emotion

Dataset	Task	Context	Options	Metric	Ideal Score
StereoSet	Related option retrieval	[premise claim]	[related & unrelated claims]	Language model score	100%
StereoSet	Stereotype retrieval	[premise claim]	[stereotypical & anti-stereotypical claims]	Stereotype score	50%
Gender & profession	Gender recognition	[masculine/feminine role]	The person is masculine/feminine	Gender recognition score	100%
Gender & profession	Profession bias	The person is a [pro]	[masculine/feminine role]	Gender bias score	50%
Emotion Vocab	Emotion bias	The person feels [emo]	[masculine/feminine role]	Gender bias score	50%

Table 1: The summary of data, tasks, prompts, metrics, and the scores of an ideal model that will be applied for evaluation in this work. Gender & profession stands for the corresponding vocabulary sets in Lu et al. (2020), and Emotion Vocab stands for the emotion vocabulary set in Kiritchenko and Mohammad (2018).

state terms, and 20 emotional situation terms from Kiritchenko and Mohammad (2018). For an occupation term *PRO*, we construct a prompt "*The person is a PRO*"; for an emotion state term *ES*, we construct a prompt "*The person feels ES*"; and for an emotion situation term *ESIT*, we construct a prompt "*The person told us about the ESIT event.*" We evaluate whether a model tends to link the construct profession and emotion prompts to one of the genders or not.

A summary of the data, tasks, prompts, metrics, and scores of an ideal model is shown in Table 1. We define an "ideal model" as a fair and perfectly understanding model.

3.3 Textual Entailment

Training. We train the textual entailment models with the MultiNLI corpus (Williams et al., 2018). In MultiNLI, each data example contains a premise and a hypothesis, and the task is to predict if the hypothesis is likely to be true or false given the premise. Each sentence pair is classified into three classes: entailed, neutral, and contradictory. For a premise p and a hypothesis h, we construct the following supposition for the entailment model,

$$h \text{ is entailed by } p.$$

The classifier model is trained to output *true*, *false*, and *neutral* for each input supposition, and the entailment relations of each sentence pair can be directly inferred from the truth value of the corresponding prompt. In this work, we train entailment classifiers based on BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and DeBERTa (He et al., 2020).

Evaluation. Standard sentence reasoning methods are based on the inner product of the embeddings of two sentences. With the textual entailment models, we can calculate three scores for each sentence pair, including entail, neutral, and contradictory scores. With these scores, we can calculate a prediction about the logical relation between two sentences. In summary, we have two strategies to score sentence pairs: 1. continuous sentence pair scoring with entail, neutral, or contradiction scores, and 2. discrete scoring using entailment predictions (entail = 0, neutral = 1, and contradictory = 2). Given a context, we prefer an option with a higher entailment score, lower contradictory score, and smaller entailment labels.

For the continuous scoring strategy, we calculate the language model score with the number of tests where the stereotype or anti-stereotype option score is higher than the unrelated option, and calculate the stereotype score with the number tests where stereotype option score is higher than anti-stereotype option. For the discrete scoring strategy where we assign each option an entailment label, the language score is calculated with the number of tests where the unrelated option is predicted to be less entailed than the stereotype or anti-stereotype. The stereotype score is calculated with the number of tests where the label $\{0, 1, 2\}$ of the stereotype option is lower then the anti-stereotype.

4 Experiments

4.1 Language Understanding

To ensure that the fairness of the entailment-based language model does not come from a lack of language understanding ability, we first show the zero-shot adaptation performance of the entailment-based language models. On the MNLI-mismatch task, The RoBERTa model achieves 89.0% accuracy, and the DeBERTa model achieves 83.4%. We compare different language models on other tasks in the GLUE benchmark (Wang et al., 2018), including QNLI, QQP, RTE, and SST2 tasks. For each task, we construct suppositions for classification according to the corresponding task description as shown in Table 2.

We compare the zero-shot adaptation performance of our entailment-based supposition (ESP) language models with weakly supervised baseline models of different scales as follows:

Few-shot 350M models. We compare our

Task	Inputs	Supposition
MNLI	$\{p, h\}$	h is entailed by p.
RTE	$\{p, h\}$	h is entailed by p.
QNLI	$\{p, q\}$	The answer to q is entailed by p.
QQP	$\{x, y\}$	x's answer is entailed by y's answer.
SST2	$\{r\}$	The movie is good is entailed by r.

Table 2: The suppositions constructed based on the definitions of different GLUE tasks (Wang et al., 2018).

Method	QNLI	QQP	RTE	SST2	Avg.
Few-shot 350M models					
LM-BFF	69.2	69.8	83.9	90.3	78.3
UPT	70.1	72.1	68.9	92.9	76.0
Few-shot Large-scale 137B models					
LaMDA	55.7	58.9	70.8	92.3	69.4
FLAN	63.3	75.9	**84.5**	**94.6**	79.6
Zero-shot entailment-based 350M model					
RoBERTa	71.5	78.6	81.2	87.7	79.8
DeBERTa	**77.3**	**79.9**	**84.5**	90.1	**82.9**

Table 3: The performance of zero-shot entailment-based models and strong few-shot supervised baselines.

entailment-based models with LM-BFF (Gao et al., 2020) and UPT (Wang et al., 2022) models. Both baseline models are based on `RoBERTa-large` that contains 350M parameters with 32 human-annotated training samples.

Few-shot 137B models. We also compare the entailment-based models with large-scale language models (LLMs), LaMDA (Thoppilan et al., 2022) and FLAN (Wei et al., 2021) containing 137B parameters, which are about 400 times larger than the entailment-based models. The LLMs are adapted to the tasks with 4 to 8 training samples.

The results are shown in Table 3. We found that overall, both RoBERTa and DeBERTa-based entailment models outperform all baselines, without using any task-specific training data. This proves the computation and data efficiency of entailment-based language models.

4.2 Fairness

We evaluate pretrained language models, supervised/unsupervised SimCSE (Gao et al., 2021), and entailment models based on BERT, RoBERTa, and DeBERTa. The overall experiment results are shown in Table 4.

StereoSet-Intrasentence. In Table 4, we use the fairness score (FS) to assess the bias of the models. We have $FS = \frac{min(ss, 1-ss)}{0.5}$, where ss stands for the stereotype score defined in (Nadeem et al., 2020). All baselines are sentence reasoning models pretrained with the next sentence prediction (NSP) task. We noticed that stronger sentence encoders can lead to more biased reasoning results. For BERT-based models, the unsupervised SimCSE model achieves a much higher language model score than the BERT-NSP model, outperforming by over 10%. The supervised SimCSE also marginally outperforms the baseline model. However, both SimCSE models are more biased. The fair score of the supervised SimCSE is 15% lower than the baseline BERT model. Because of the high sentence retrieval performance, the unsupervised SimCSE model achieves the best iCAT score, outperforming the pretrained BERT model by 4%.

The result remains the same for RoBERTa-based models. Both supervised and unsupervised SimCSE models significantly outperform the pretrained model, by 27% and 32%, respectively. As with the BERT-based models, RoBERTa SimCSE models are also more biased. According to the low language modeling score, the baseline RoBERTa pertrained model is almost random. As a result, the fairness score is as high as 96%. The SimCSE models achieve higher iCAT scores mainly because of the improvement on the language model score. We found that the DeBERTa model achieves the highest iCAT score among all NSP models. It achieves a very high fairness score (99.68%), but a relatively low language model score of 76.24%. As a result, the iCAT score of DeBERTa is only marginally higher than the BERT-based unsupervised SimCSE model, which achieves a 89.46% language model score.

The entailment models achieve the best iCAT score, and both entailment scoring strategies outperform baseline sentence embedding models. Comparing with the best BERT, RoBERTa, and DeBERTa based baselines, the corresponding discrete entailment model achieved a 12.5%, 39%, and 25% improvement in iCAT score. We observed that the discrete scoring models are generally better than the continuous scoring method. Although the continuous scoring method has certain biases, a discrete model can prevent biased prediction. For example, although the entailment score of option a is higher than option b, both options can be both classified into the neutral category.

StereoSet-Intersentence. In general, the Intersen-

Table 4: Performance of pretrained language models and textual entailment models on StereoSet, gender recognition (rec.), profession, and emotion tests. LMS stands for language model score, FS stands for fairness score, and iCAT stands for ideal context association test score. NSP stands for next sentence prediction. The profession and emotion iCAT scores are calculated by multiplying the gender recognition score and the corresponding fairness scores. All scores are in percentage (%).

tence task had similar trends as the Intrasentence task. The performance of the pretrained baseline models perform much better than the intrasentence tasks since the options are more diverse, making it easier for the models to identify the more related options. The difference within the baseline models are that the supervised SimCSE models perform better than the unsupervised sentence embedding models.

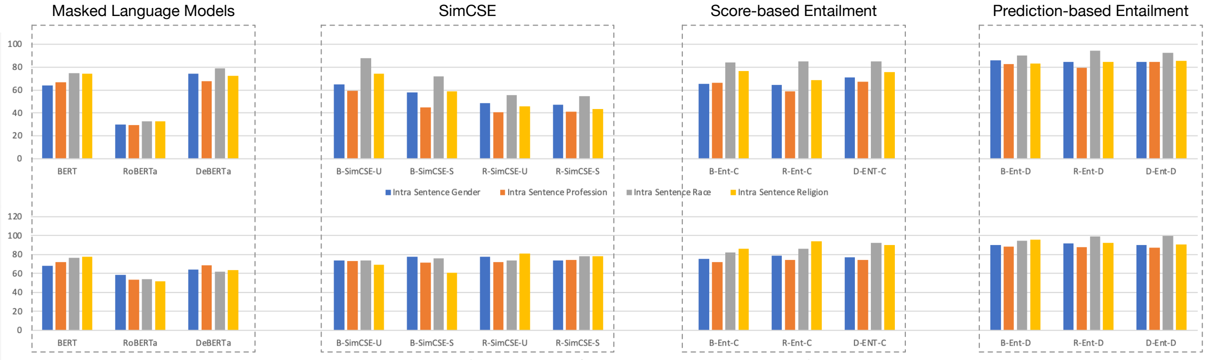
The entailment models are also significantly better than all the baseline models. All discrete scoring models achieve higher than 99% language modeling scores, and the fairness scores are all higher than 94%. The iCAT scores of the discrete entailment models are at least 93.4%, outperforming the best baseline model, supervised SimCSE with RoBERTa by 18%. On the other hand, the continuous entailment models also outperform the best SimCSE model by at least 9% in iCAT score. We also note that the discrete entailment models outperform the continuous models by a significant margin because the labels prevent a large amount of stereotypical reasoning.

Gender recognition. We evaluated the models' ability to recognize the gender of binary gender-indicating nouns, for example, (*uncle*, *aunt*) and (*brother*, *sister*). We use the set of 71 pairs, 142 gender-indicating nouns from Lu et al. (2020). The RoBERTa-based, supervised SimCSE model achieves high gender recognition accuracy (as high as 99%), while the performance of the pretrained DeBERTa model is close to random at around 50%. We found that the supervised SimCSE models are significantly better than other baseline models on this task.

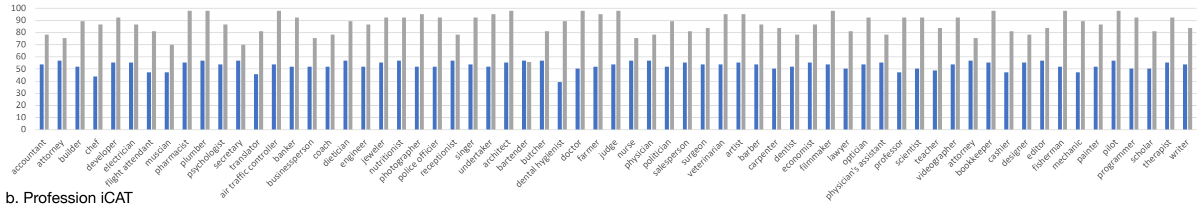
On the other hand, we found that the continuous entailment scoring strategy achieves very high gender recognition performance. All three models achieve an accuracy higher than 99% with very low standard deviations. In contrast to the previous tasks, the discrete scoring models have decreased performance. We hypothesize that this is because the continuous models are good enough, but the discrete model score blurs the selective bias, which is needed in this task since we need diverse predictions. Despite this fact, the DeBERTa based discrete model still achieves high gender recognition accuracy (97%).

Profession bias test. We use a vocabulary set from Lu et al. (2020) consisting of 65 profession nouns which are expected be gender-neutral, but possibly being affected by stereotypes. For the baseline models, we found that the stronger sentence representation models, supervised and unsupervised SimCSE, are significantly more biased than pretrained language models. Since the SimCSE models learns better sentence embeddings based on text similarity, they perform better at gender recognition, but retain more stereotypes in the pretraining corpora. Combined with the high gender recognition performance, the unsupervised BERT SimCSE model achieves the best iCAT score among all baseline models.

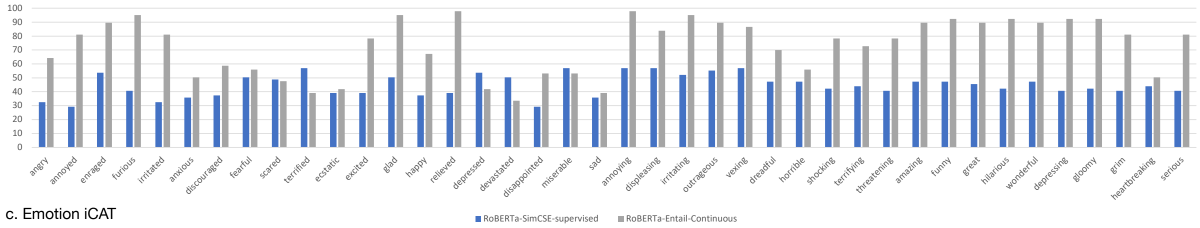
For this task, all entailment models outperform all baseline models. The DeBERTa and RoBERTa models are significantly better than BERT-based models. For the continuous scoring models, the RoBERTa-based entailment model achieves the



a. StereoSet iCAT



b. Profession iCAT



c. Emotion iCAT

Figure 2: Breakdown performance of pretrained and entailment language models on StereoSet, profession, and emotion bias tests. In StereoSet, we present the performance of all models. In the profession and emotion bias tests, we compare the performance of RoBERTa-SimCSE and the continuous RoBERTa entailment model.

highest iCAT score (86.93%), outperforming the best baseline model by 27%. As for previous tasks, the discrete entailment scoring strategy is more fair. The best discrete entailment model, DeBERTa, achieves a high iCAT score (95.1%), outperforming the best baseline model by 36%. The exception is the RoBERTa-based entailment model. The continuous RoBERTa model outperforms the discrete model by almost 2% iCAT score.

Emotion bias test. We use the emotion vocabulary sets, including 40 emotion state and situation words. We conduct context association tests on the gender-indicating nouns with the emotion words. On this task, the BERT and RoBERTa models have different behaviors. The RoBERTa-based SimCSE models outperform the pretrained RoBERTa model on both fairness and iCAT scores. However, the BERT SimCSE models are outperformed by the pretrained BERT model. The supervised RoBERTa model performs best among all baseline models, achieving 76% iCAT score.

The entailment models outperform most baseline models. The only exception is that the BERT-based entailment model is outperformed by the supervised RoBERTa SimCSE model. However, the discrete entailment RoBERTa and DeBERTa entailment models outperform all baseline models by a large margin. The discrete RoBERTa entailment model outperforms the best baseline model by more than 11%, and the DeBERTa entailment model outperforms the best baseline by 17%.

Summary. We make the following observations:

- SimCSE models achieve higher language model and gender recognition scores than pretrained models, but they are more biased.
- The entailment models achieve significantly better performance than all baseline models in both language modeling and fairness metrics. The discrete scoring strategy is more fair than the continuous strategy, in general.

5 Analysis

5.1 Performance Breakdown

In the previous section, we reported the overall performance of each task. In this section, we analyze

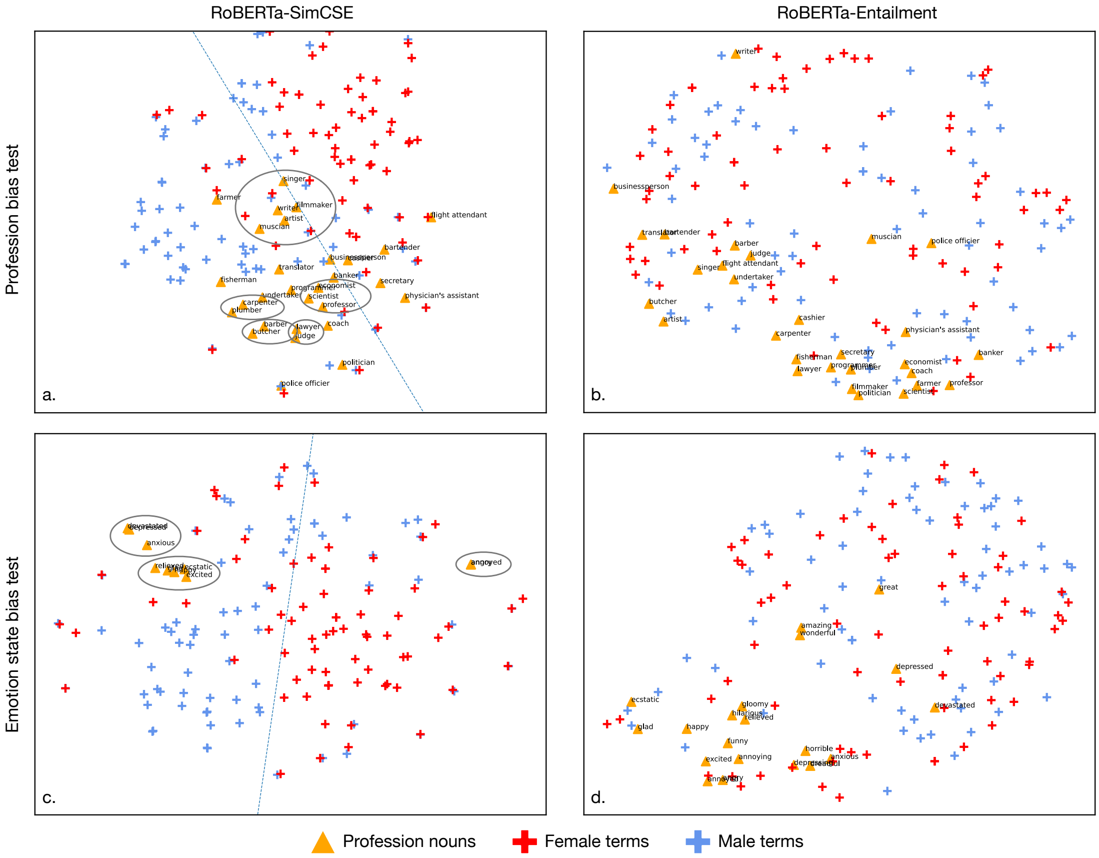


Figure 3: The prompt analysis with RoBERTa-based SimCSE and entailment models on profession and emotion bias tests. In figures a. and c, different gender terms are separated by a boundary learned by a linear SVM, and the gray circles highlight correlated words. In Figure a., the circled clusters are [*singer*, *designer*, *writer*, *filmmaker*, *artist*, *musician*], [*carpenter*, *plumber*], [*barber*, *butcher*], [*lawyer*, *judge*], and [*economist*, *scientist*, *professor*]. In Figure c., the circled clusters are [*devastated*, *depressed*, *anxious*], [*relieved*, *ecstatic*, *glad*, *happy*, *excited*], and [*angry*, *annoyed*].

the performance of all sub-tasks. The StereoSet corpus has four sub-tasks, including gender, religion, profession, and race. The profession bias task has 65 different profession nouns as sub-tasks, and similarly, the emotion bias task has 40 sub-tasks. We break down and analyze the performance of the sub-tasks to investigate if the models conduct biased reasoning on sub-tasks, but achieve high average fairness scores.

StereoSet. The breakdown iCAT scores of StereoSet sub-tasks is shown in Figure 2.a, including the four sub-tasks under the intra- and inter-sentence settings. We do not find the entailment models to be biased on some of the sub-tasks. Instead, the entailment models consistently outperform the baseline pretrained models. We also note that the pretrained models based on different architectures achieve varying results on different tasks. In contrast, the entailment model based on different architectures achieve stable iCAT scores. We also notice that the entailment models perform better on race and religion tasks. As shown in Table 4, the performance of the discrete scoring models achieve better and more stable iCAT scores.

Profession bias test. We compare the breakdown performance of RoBERTa-based entailment and SimCSE models. As shown in Figure 2.b, the iCAT scores on most profession terms of the entailment model outperforms the SimCSE model by more than 20%. The only exception where the pretrained model outperforms the entailment models is the word "*Bartender*." The most significant improvement we achieved is almost 50% iCAT score on the term "*dental hygienist*."

Emotion bias test. We also test the RoBERTa-based models on different emotion state and situation terms. In all 40 emotion words, the entailment model outperforms the SimCSE model in 35 subtasks. The most biased emotion word of SimCSE is "*disappointed,*" which is improved using the entailment model. On the other hand, the most biased emotion word of the entailment model is "*devastated*." Both models are relatively biased on the word "sad," achieving lower than 40% iCAT scores. The most significant improvement is on the word "relieved." The sub-tasks that the entailment model does not outperform the pretrained models are "*scared*," "*terrified*," "*depressed*," "*devastated*," and "*miserable*."

5.2 Prompt Embedding Analysis

We have found that the language modeling and fairness performance of entailment models are significantly higher than pretrained language models. In this section, we attempt to explain this phenomenon. To understand the difference between the entailment and pretrained models, we analyze the embedding of the gender terms and profession and emotion nouns. The results of the RoBERTa-based SimCSE and entailment models are shown in Figure 3 with t-SNE (Van der Maaten and Hinton, 2008).

The profession bias test results on RoBERTa-SimCSE is shown in Figure 3.a. We find that because of the strong representation ability of SimCSE, the embeddings of the profession and gender terms reflect the word similarities that aligns with human intuition. The boundary of the gender terms is detected by a linear SVM model (Hearst et al., 1998; Pedregosa et al., 2011). We find that the learned boundary separates terms of different genders with high accuracy. In addition, we notice that related profession terms group closely, as shown in the circles in Figure 3.a. In contrast, the word embedding distribution produced by the entailment model shown Figure 3.b appears to be more random. A similar phenomenon is observed on the emotion bias test. In Figure 3.c, nouns representing different genders are well-separated, and related words cluster closely. However in Figure 3.d, similar words are less correlated based on the entailment prompt embeddings.

The experimental results of both tasks and models indicate that the prompt embeddings learned by the entailment models contribute to logical reasoning rather than word coherence representation. Considering the fact that the entailment models perform significantly better than the pretrained models, we conclude that the biases are caused by the similarity-based learning objectives because such algorithms learn and reflect the biases in the training corpora. However, the textual entailment models learn logic without preserving textual similarities, leading to fairer performance.

6 Conclusion

In this work, we found that textual entailment learning reduces the bias of pretrained language models for sentence representation. We evaluated BERT, RoBERTa, and DeBERTa-based pretrained, SimCSE, and entailment models on stereotype, profession, and emotion bias tests. The textual entailment models outperform other models with significantly lower bias without other explicit debiasing processes, while preserving the language modeling ability, which results in significantly better idealized context association test scores. By analyzing the sentence embeddings, we found that the models relying on textual entailment produce less biased results by learning logic and reducing the amount of text coherence knowledge retained from the pretraining corpora containing existing social biases.

Ethics Statement

We investigate the stereotypes and biases of pretrained language models and introduce the less biased textual entailment models that reduce bias on gender, profession, religion, and race. We noticed that the existing gender-related bias studies and corpora mainly focus on the binary gender setting, and we also follow this line of research because of data limitations. While such data limitation might disappoint a number of communities, we will extend this work to non-binary settings in future work.

Limitations

As we described in the previous section, we studied the stereotypes including gender biases. However, we investigated under the binary gender setting, because of the limitation of the existing benchmarks. Furthermore, we evaluated medium-sized language models with around 350M parameters, but have not tested the largest language models yet. We only analyze the predictive bias on a set of gender-indicating vocabulary, but do not look into every example and explain the source of the learned bias in the pretraining corpora or social traditions.

On the other hand, there are further limitations in the benchmarks we study in this work, as pointed out by Blodgett et al. (2021) that StereoSet is not perfect. On the other hand, some words in the vocabulary collected by (Lu et al., 2020) are rarely used, for example, "poetess" and "manageress". In future work, we will explore building more inclusive and comprehensive benchmarks to mitigate the limitations.

Abstract

Cross-task knowledge transfer via multi-task learning has recently made remarkable progress in general NLP tasks. However, entity tracking on the procedural text has not benefited from such knowledge transfer because of its distinct formulation, i.e., tracking the event flow while following structural constraints. State-of-the-art entity tracking approaches either design complicated model architectures or rely on task-specific pre-training to achieve good results. To this end, we propose **MEET**, a **M**ulti-task learning-**e**nabled **e**ntity **T**racking approach, which utilizes knowledge gained from general domain tasks to improve entity tracking. Specifically, MEET first fine-tunes T5, a pre-trained multi-task learning model, with entity tracking-specialized QA formats, and then employs our customized decoding strategy to satisfy the structural constraints. MEET achieves state-of-the-art performances on two popular entity tracking datasets, even though it does not require any task-specific architecture design or pre-training.[1]

1 Introduction

Pre-trained language models have revolutionized the NLP field in recent years (Devlin et al., 2019; Liu et al., 2019; Brown et al., 2020) and also become more versatile with the novel encoder-decoder architecture (Raffel et al., 2020; Lewis et al., 2020), which allows them to handle different types of NLP tasks without further architectural changes. This versatility inherently facilitates cross-task knowledge transfer via multi-task learning (Raffel et al., 2020; Aribandi et al., 2022), and thus helps push the boundary of many popular NLP tasks such as question answering (Khashabi et al., 2020) and semantic parsing (Xie et al., 2022). However, entity tracking, which tracks the states and locations of an entity throughout the procedural text, like scientific processes or recipes, has not been impacted by this multi-task learning wave for two main reasons. First, entity tracking requires the model to make step-wise predictions while satisfying structural constraints (e.g., an entity cannot be "moved" after being "destroyed" in the previous steps). This requirement is usually tackled by designing task-specific architectures (Gupta and Durrett, 2019b; Tang et al., 2020; Huang et al., 2021), and those generic multi-task models with the encoder-decoder architecture cannot address it easily. Second, understanding procedural text requires domain-specific knowledge, which usu-

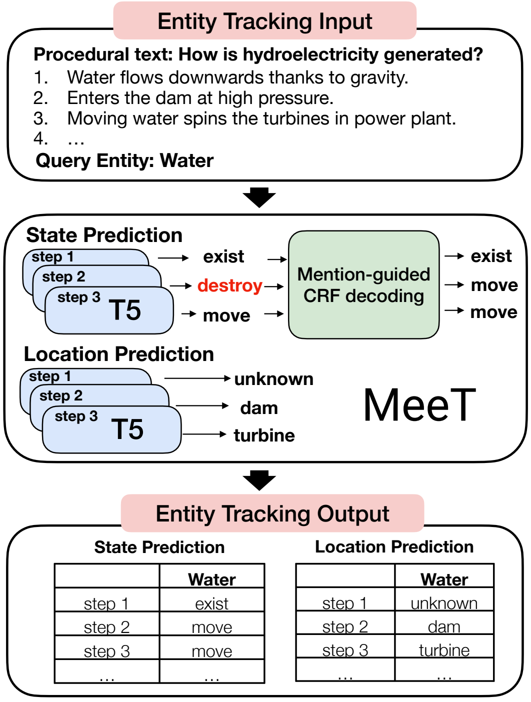

Figure 1: Overview of MEET (**M**ulti-task learning-**e**nabled **e**ntity **T**racking). MEET utilizes the multi-task learning in T5 to boost entity tracking performance, with a customized decoding strategy addressing the structural constraints in state prediction (e.g., "move" cannot happen after "destroy").

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1255–1263
May 2-6, 2023

ally does not exist in general domain tasks that multi-task learning models are trained on, so it is not clear how effective the knowledge transfer will be given this domain gap (Zhang et al., 2021; Bai et al., 2021; Shi et al., 2022).

In this paper, we study how entity tracking can benefit from the current multi-task learning paradigm and present **MEET**, a **M**ulti-task learning-**e**nabled **e**ntity **T**racking approach. This approach includes two parts. The first part fine-tunes T5 (Raffel et al., 2020), a model that has been pre-trained on a diverse set of NLP tasks and has shown great cross-task generalizability. Here, we design entity tracking-specialized QA formats to accommodate the need to make step-specific predictions, while facilitating effective knowledge transfer from T5. The second part resolves conflicted state predictions under structural constraints. We use a customized offline CRF inference algorithm, where the main idea is to emphasize the predictions of steps, in which the query entity is explicitly mentioned, because the fine-tuned model performs better in those cases (Table 5). On two benchmark datasets, ProPara (Dalvi et al., 2018) and Recipes (Bosselut et al., 2018), our MEET outperforms previous state-of-the-art methods, which require extra domain-specific pre-training or data augmentation. We verify the importance of multi-task learning in T5 and our proposed decoding strategy through careful analyses and ablation studies.

To sum up, our contributions are three-fold: (1) Our work is the first to explore cross-task knowledge transfer for entity tracking on procedural text; (2) Our proposed approach, MEET, effectively uses the off-the-shelf pre-trained multi-task learning model T5 with a customized decoding strategy, and thus achieves state-of-the-art performance on two benchmark datasets; (3) Our comprehensive analyses verify the benefits of multi-task learning on entity tracking.

2 Related Work

Tracking the progression of an entity within procedural text, such as cooking recipes (Bosselut et al., 2018) or scientific protocols (Tamari et al., 2021; Le et al., 2022; Bai et al., 2022), is challenging as it calls for a model to understand both superficial and intrinsic dynamics of the process. Recent work on entity tracking can be divided into two lines. One focuses on designing task-specific fine-tuning architectures to ensure that the model makes step-grounded predictions while following the structural constraints. For instance, Rajaby Faghihi and Kordjamshidi (2021) introduce time-stamp embeddings into RoBERTa (Liu et al., 2019) to encode the index of the query step. Gupta and Durrett (2019b) frame entity tracking as a structured prediction problem and use a CRF layer to promote global consistency under those structural constraints. In our case, we show that, with QA formulation, simply appending the index of the query step to the question and indexing the procedure produces step-specific predictions. Moreover, we propose a customized offline CRF-decoding strategy for structural constraints to compensate for the fact that it is hard to jointly train T5, our backbone LM, with a CRF layer, like in previous methods.

The other line of work focuses on domain-specific knowledge transfer (Zhang et al., 2021; Bai et al., 2021; Shi et al., 2022; Ma et al., 2022). Concretely, LEMON (Shi et al., 2022) achieves great performance by performing in-domain pre-training on 1 million procedural paragraphs. CGLI (Ma et al., 2022) shows that adding high-quality pseudo-labeled data (generated via self-training) during fine-tuning can also boost the model performance. In contrast, our work explores how entity tracking can benefit from out-of-domain knowledge via using off-the-shelf pre-trained multi-task learning models.

3 Method

In this section, we present **MEET**, a **M**ulti-task learning-**e**nabled **e**ntity **T**racking approach. Here, we first review the problem definition, and then lay out the details of MEET.

3.1 Problem Definition

Entity tracking aims at monitoring the status of an entity throughout a procedure. The input of this task contains two items: 1) a procedural paragraph P, composed of a sequence of sentences $\{s_1, s_2, ..., s_T\}$; and 2) a procedure-specific query entity e. Given the input, our goal is to predict the state and location of the query entity at each timestamp of the procedure (see an example from the ProPara dataset in Figure 1).

3.2 MEET

MEET includes two parts, task-specific fine-tuning with our proposed QA formats and the mention-guided conflict-resolve decoding.

Task-spefic Fine-tuning We formulate the two sub-tasks of entity tracking, state prediction and location prediction, as multi-choice and extractive QA problems respectively (see §4.2 for comparison with other task formulations), and fine-tune T5 to make independent predictions for every step in the procedure. Given a query entity e and procedure P, to predict the entity state at step t, the input sequence is formatted as the concatenation of the template question "*What is the state of* e *in step* t*?*", candidate states (e.g., *create*, *move* and *destroy*), and the full procedure with step index prepended. The output is just one of the candidate states. For location prediction, the input sequence is the concatenation of the question "*Where is* e *located in step* t*?*" and the indexed procedure, with the snippet "*Other locations: none, unknown.*" appended. This is because entity locations sometimes are not explicitly mentioned in the procedure. The output is a text span, indicating the location of the query entity after step t. Examples of both tasks can be found in Appendix A.

Conflict-resolve Decoding Entity tracking places unique structural constraints on state predictions (e.g., *move* cannot happen after *destroy*). Similar to Gupta and Durrett (2019a), we run an offline CRF-decoding method (Viterbi decoding) to resolve conflicting state predictions. We initialize CRF transition scores T with the transition statistics in the training data, following Ma et al. (2022). For example, $T(p, q)$, the transition score between state p and q, is $log(1/10)$ if there is only one $p \Rightarrow q$ transition out of 10 transitions starting with the state p. We set the scores of all unseen transitions to $-inf$. As for CRF emission scores, we use the state prediction logits from T5. In contrast with previous methods, which treat each step equally, we weigh the emission scores differently, depending on whether the query entity e is **explicitly mentioned** in the step:

$$U'_i = \begin{cases} \tau_{exp} \cdot U_i, & \text{if } e \text{ is mentioned in step } i, \\ \tau_{imp} \cdot U_i, & \text{otherwise} \end{cases}$$

where U'_i represents the emission score of step i after weighing, and τ_{exp} and τ_{imp} are hyper-parameters, determined by the grid search on the dev set. The intuition behind our approach is that, as the fine-tuned model performs better on "explicitly mentioned" steps (Table 5), leaning toward those steps during decoding via controlled weights will result in more accurate predictions.[2]

Model	**P**	**R**	**F1**
DYNAPRO (Amini et al., 2020)	75.2	58.0	65.5
TSLM† (Faghini et al., 2021)	68.4	68.9	68.6
KOALA† (Zhang et al., 2021)	77.7	64.4	70.4
LEMON†(Shi et al., 2022)	74.8	69.8	72.2
CGLI† (Ma et al., 2022)	75.7	**70.0**	72.7
MEET (ours)	**80.3**	67.1	**73.1**

Table 1: Test set performance on ProPara. † indicates that the backbone language model has been further pre-trained on either in-domain corpus or auxiliary tasks. MEET performs on par with SOTA models without pre-finetuning on any in-domain corpus.

4 Experiments

Datasets We experiment with two benchmark datasets of entity tracking: ProPara (Dalvi et al., 2018) and Recipes (Bosselut et al., 2018). ProPara contains 488 scientific process-based procedural paragraphs (Figure 1), and Recipes includes 866 cooking recipes. Note that previous work experiments with different splits of the Recipes dataset; in this paper, we follow the split of Zhang et al. (2021)[3] as it is used in most of the recent work (Huang et al., 2021; Shi et al., 2022). More dataset details are presented in Appendix B.

Evaluation ProPara performances are evaluated in two levels: *sentence-level*[4] (Dalvi et al., 2018) and *document-level*[5] (Tandon et al., 2018). Here, we focus on the *document-level* evaluation because it provides a comprehensive assessment of the model's understanding of the overall procedure and serves as the basis for the ProPara leaderboard rankings. The *document-level* evaluation is conducted by comparing the input/output entities and their transformations in the procedure with the gold answers. Further details regarding two evaluations and the result of the *sentence-level* evaluation can be found in Appendix C. For Recipes, following

---

[2] After hyper-parameter tuning, the optimal values for τ_{exp} and τ_{imp} are 0.6 and 0.7 respectively.

[3] `https://github.com/ytyz1307zzh/KOALA/issues/4`

[4] `https://github.com/Mayer123/CGLI/blob/main/src/evalQA.py`

[5] `https://github.com/allenai/aristo-leaderboard/blob/master/propara/evaluator`

previous work (Zhang et al., 2021; Shi et al., 2022), we evaluate the location changes of each ingredient throughout the recipe.[6]

Baselines For ProPara, we compare MEET with the top five approaches on its leaderboard. Among these five approaches, DYNAPRO (Amini et al., 2020), TSLM (Rajaby Faghihi and Kordjamshidi, 2021), and CGLI (Ma et al., 2022) design task-specific fine-tuning architecture using off-the-shelf LMs while KOALA (Zhang et al., 2021) and LEMON (Shi et al., 2022) develop in-domain LMs for procedural text. For Recipes, as mentioned previously, we compare MEET with methods that experiment on the same data split of Zhang et al. (2021). We refer readers to the corresponding paper of each baseline for further details.

Implementation Details Our approach MEET is implemented using Huggingface Transformers (Wolf et al., 2020). Given the limited computational resources, we choose T5-large as the backbone of our MEET. The fine-tuning process employs the AdamW optimizer with a learning rate of 1×10^{-4} and a batch size of 16. To resolve any potential conflict between state prediction and location prediction, we apply the rules designed in Ma et al. (2022) to integrate the output from both tasks.

4.1 Results

We present the test set results of ProPara and Recipes in Table 1 and Table 2, respectively. Our MEET outperforms the competitive baseline CGLI (Ma et al., 2022) on the ProPara dataset with state-of-the-art performance despite the fact that CGLI uses extra pseudo-labeled training data (generated by self-training) for data augmentation. On Recipes, MEET surpasses the previous best-performing method LEMON (Shi et al., 2022) by a substantial margin of 4.9 F_1. It is noteworthy that the cooking recipes in the Recipes dataset were collected from the web,[7] which may have been included in the C4 corpus[8] used for pre-training T5 and thus potentially contributes to the advantage of our MEET on Recipes.

Model	**P**	**R**	**F_1**
NCET (Gupta and Durrett, 2019b)	56.5	46.4	50.9
IEN (Tang et al., 2020)	58.5	47.0	52.2
KOALA (Zhang et al., 2021)	60.1	52.6	56.1
REAL (Huang et al., 2021)	55.2	52.9	54.1
LEMON (Shi et al., 2022)	56.0	67.1	61.1
MEET (ours)	**64.2**	**78.0**	**66.0**

Table 2: Test set results on Recipes. MEET achieves the state-of-the-art performance, outperforming the previous SOTA LEMON by 4.9 F_1.

4.2 Analysis & Ablation Study

Multi-task Learning To investigate the impact of T5's multi-task learning process on entity tracking, we experiment with two variants of T5 as the backbone of MEET: 1) T5-v1.1,[9] a T5-like LM (with slight architecture changes) whose pre-training does not include any supervised tasks; 2) T5-v1.1$_{QA\text{-}FT}$, the resulting LM after fine-tuning T5-v1.1 on the three QA datasets,[10] which T5 is pre-trained on. The performance of the three LMs (T5-large size) on the ProPara dev set is presented in the top section of Table 3. We can see that T5 outperforms T5-v1.1 by a large margin, verifying that multi-task learning on out-of-domain non-entity-tracking tasks can benefit entity tracking. In addition, the advantage of T5 over T5-v1.1$_{QA\text{-}FT}$ indicates that knowledge transfer can cross the task boundaries with T5's encoder-decoder architecture.

Task Formulation We compare our QA formulation with two other task formulations, proposed in recent work, for T5. The first formulation is called "*step-input*" (Gupta and Durrett, 2019a; Amini et al., 2020), where each pair of the query entity e and procedure step t is formulated as one instance. Here, the state prediction is formulated as a classification problem, where the entity name is appended to the input, and no candidate answers are provided. Moreover, the procedure is trimmed until step t to specify the step index in the input. The second formulation is called "*process-input*" (Zhang et al., 2021; Gupta and Durrett, 2019b), where the model predicts entity states or locations in all steps in one instance. The input is the concatenation of entity e and the full procedure, and the model decodes

Table 3: Analysis and ablation study on ProPara (dev set results). Top: Comparison of different backbone LMs to investigate the impact of multi-task learning. Middle: Comparison of different task formulations. Bottom: Ablation on decoding strategy and model size. Multi-task learning leads to a better entity tracking model, especially with the QA formulation and mention-guided decoding.

entity states and locations in all steps sequentially. The results of two new formulations are presented in the middle of Table 3. Our proposed QA formulation outperforms the other two formulations by a large margin. Detailed analyses of formulation comparison can be found in Appendix D.

Decoding Strategy & Model Size The ablation study on decoding strategy and model size is shown at the bottom section of Table 3. Clearly, our proposed "mention-guided" decoding strategy, as well as using a larger LM as the backbone, contribute to the success of MEET.

5 Conclusion

We presented MEET, a T5-based entity tracking approach. This approach includes our newly proposed QA fine-tuning formats and a customized decoding strategy so that it can effectively encode the flow of events in the procedural text while following structural constraints. The state-of-the-art performances on two benchmark datasets demonstrate the effectiveness of MEET, and further analyses verify that multi-task learning on out-of-domain tasks can be beneficial for entity tracking.

Limitations

This paper demonstrates that multi-task learning on a combination of general domain datasets can effectively improve the model's understanding of the procedural text. However, the precise source dataset responsible for this improvement remains uncertain, making it an avenue for future research to investigate more efficient knowledge transfer through the identification of the most pertinent source dataset. Moreover, the pipeline structure of MEET may limit its practical utilization. As such, future work could consider incorporating our proposed mention-guided decoding strategy into the end-to-end training of the multi-task learning model.

A Fine-tuning Formats for T5

A.1 State Prediction (Multi-choice QA)

Input:

```
What is the state of water in step 2?
(a) create (b) ... (f) move
step 1: Water flows downawards thanks
to gravity. step 2: Enters the dam at
high pressure. step 3: The moving water
spins the turbines in the power plant ...
step 6: The water leaves the dam at the
bottom.
```

Output:

```
move
```

A.2 Location Prediction (Extractive QA)

Input:

```
Where is water located in step 2?
step 1: Water flows downwards thanks to
gravity. step 2: Enters the dam at high
pressure. step 3: The moving water spins
the turbines in the power plant ... step
6: The water leaves the dam at the bottom.
Other locations: none, unknown.
```

Output:

```
dam
```

B Dataset

For ProPara (Dalvi et al., 2018), following Ma et al. (2022), the state prediction task includes six candidate states (`Outside_Before`, `Create`, `Destroy`, `Move`, `Exist` and `Outside_After`). For Recipes (Bosselut et al., 2018), each ingredient has two possibles states (`Exist` or `Absence`) in each step of the recipe. Full data statistics on two datasets are presented in Table 4.

C Evaluation

Sentence-level evaluation This evaluation measures the following questions for each target *entity*:

- **Cat-1:** Is *entity* created (destroyed, moved) in the process?
- **Cat-2:** When (step #) is *entity* created (destroyed, moved)?
- **Cat-3:** Where (location) is *entity* created (destroyed, moved to/from)?

Further, the F_1 scores of the three questions are aggregated with micro/macro averages.

Document-level evaluation It measures the four questions below for each paragraph:

- What are the *input* entities to the process?
- What are the *output* entities of the process?
- What entity *conversions* occur, when (step #), and where (location)?
- What entity *movements* occur, when, and where?

The macro average of the F_1 scores of these four questions will be used as the final score.

Table 6 provides a comprehensive comparison of past work on the ProPara dataset, including both document-level and sentence-level evaluations.

D Analysis of Formulation Comparison

When compared with the "*step-input*" formulation, the QA formulation allows the model to have the full context, and may take better advantage of LM's pre-training scheme (Li et al., 2019; Nagata et al., 2020). The "*process-input*" formulation works the worst in this comparison. With qualitative analyses, we find that it suffers from error propagation due to its autoregressive decoding, so future work may explore incorporating structural decoding (Tandon et al., 2018) into T5.

Model	**Document-level**			**Sentence-level**

Conversational Tree Search: A New Hybrid Dialog Task

Dirk Väth **Lindsey Vanderlyn** **Ngoc Thang Vu**
University of Stuttgart, Germany
`{vaethdk|vanderly|thang.vu}@ims.uni-stuttgart.de`

Abstract

Conversational interfaces provide a flexible and easy way for users to seek information that may otherwise be difficult or inconvenient to obtain. However, existing interfaces generally fall into one of two categories: FAQs, where users must have a concrete question in order to retrieve a general answer, or dialogs, where users must follow a predefined path but may receive a personalized answer. In this paper, we introduce Conversational Tree Search (CTS) as a new task that bridges the gap between FAQ-style information retrieval and task-oriented dialog, allowing domain-experts to define dialog trees which can then be converted to an efficient dialog policy that learns only to ask the questions necessary to navigate a user to their goal. We collect a dataset for the travel reimbursement domain and demonstrate a baseline as well as a novel deep Reinforcement Learning architecture for this task. Our results show that the new architecture combines the positive aspects of both the FAQ and dialog system used in the baseline and achieves higher goal completion while skipping unnecessary questions.

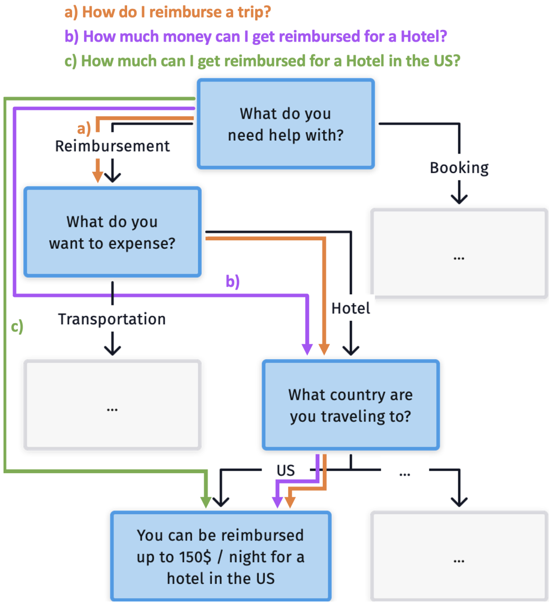

Figure 1: An example of the proposed task: Slice of a dialog tree (blue/gray nodes, black edges) showing how progressively more concrete questions could be answered. Question a) guiding a user with a general goal through the tree, b) asking only at nodes that need more clarification, and c) requiring no clarification and thus receiving a direct answer.

1 Introduction

Complex processes, e.g., healthcare, insurance, or travel reimbursement, can be challenging for users to navigate. FAQ and task-oriented dialog systems can provide immediate support, which is especially helpful as questions in these areas can be time sensitive, e.g., whom to contact in case of a lost passport. To support all types of users, however, such systems must be fast to satisfy those with more experience and thorough, so that those with less experience understand all steps needed to accomplish their goals. Above all, however, accuracy is critical in such susceptible domains.

FAQ systems can directly answer to user queries by matching them to predefined common question/answer pairs. It enables quick access to information while allowing subject experts to define system output and ensure it is factually correct (Wu et al., 2005). However, this approach does not allow for personalizing answers to a user's specific case, e.g., a specific user's per diem might depend on their destination and length of travel. Including information for all cases in one FAQ answer would make it long and hard to understand, while adding FAQs for each case, would make retrieval challenging. Additionally, as retrieval accuracy could be better (Thakur et al., 2021), the top answer might be incorrect, but displaying multiple answers makes the search process longer and transfers the responsibility of selecting the correct answer to the user. Finally, FAQ systems expect concrete information needs from users; but, new users may not be familiar enough with the complex process they wish to

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1264–1280
May 2-6, 2023

navigate in order to pose specific questions.

Dialog systems provide the opportunity for turn-based interaction, which can solve many of the shortcomings of FAQ systems (allowing process guidance, and shorter, more personalized answers). While automatically learning dialog behavior can be quicker and allow for more flexibility than designing a handcrafted system, such dialog systems rely on large amounts of data (Raghu et al., 2021), and their behavior can be challenging to control (Gao et al., 2018). As such, handcrafted dialog systems have generally still been preferred in low-resource settings, where there is not enough data to train a machine learning approach (Zhang et al., 2020), and in domains where it is essential that dialog designers can carefully control the system's behavior (Cohen, 2020). In these cases, it is common for non-technical experts to define the system behavior using a graphical interface (Shukla et al., 2020), resulting in a dialog tree. However, the structure of such systems can be rigid to traverse, making it less suitable for experienced users who want a specific question answered as fast as possible, rather than having to navigate through the whole tree until they reach the answer they were looking for.

In trying to implement a dialog system for travel reimbursement, we confirmed the shortcomings of both FAQ- and dialog-based approaches through pilot studies. As we are unaware of any system at the time of writing that can handle both forms of information-seeking behavior, we propose a new task called Conversational Tree Search (CTS). In this task, subject-experts can design arbitrarily complex dialog trees from which a dialog policy can be automatically trained to support both a guided dialog mode – where users with a vague information need can be guided by questions each turn until they reach their answer – and a free dialog mode – where users with a concrete information need can receive an answer as efficiently as possible (see Figure 1). In this way, CTS offers a hybrid solution where experts can still carefully control dialog structure and system responses while also profiting from the flexibility of a machine learning policy that can navigate the tree efficiently, only asking questions necessary to clarify information needs or personalize answers. Providing both dialog modes allows both novices and more experienced users to receive the correct level of support.

To solve our newly proposed task, we focus on the following research questions:

(RQ1) How can we develop a dialog policy that can navigate an expert-designed dialog tree, supporting both users with a specific information need and those with only a vague information need?

- **(RQ1.1)** Can the policy learn to differentiate between both dialog modes?
- **(RQ1.2)** Can this policy learn only to ask questions that are necessary to reach the user goal?

(RQ2) How robust is such a system to noise added to the encoding of the user input?

(RQ3) How well can such a system generalize to unseen utterances?

In the process of answering these research questions, we make the following concrete contributions: 1) We define a new task, CTS, and its evaluation criteria; 2) we collect and publish REIMBURSE, a low resource, real-world German language dataset for CTS in the domain of travel reimbursement, consisting of a dialog tree and user utterances; 3) we implement a domain-agnostic user simulator for CTS, using it to generate new dialogs based on the REIMBURSE data; and 4) we design a novel Reinforcement Learning (RL) architecture and train an agent to achieve significant performance increases over the baseline system on noisy and unseen data. Our data, simulator, and code are released[1] under an open source license to encourage more research into this task.

Our results show that an RL agent, based on our novel architecture, can learn to differentiate between both modes of interaction (guided and free) and skip unnecessary questions in free mode. Furthermore, the RL agent can significantly outperform the baseline system even in settings where Gaussian noise is applied to the user utterance encodings. Finally, the RL agent outperforms the baseline on dialogs that are generated based on unseen user utterances. Its success in this setting indicates an understanding of the user's text input, as the agent cannot exploit structural features, e.g., positional information.

2 Definition of Conversational Tree Search Task

The goal of this task is, given a dialog tree, to develop an interactive dialog system able to efficiently navigate a user to their goal by traversing the tree,

---

[1] `https://github.com/DigitalPhonetics/conversational-tree-search`

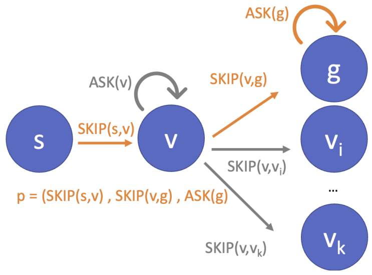

Figure 2: Example graph with dialog actions and path p from start node s to goal node g. As $ASK-g \in p$, this represents a dialog where the user reached their goal.

and only outputting questions which are needed to clarify the user's intention and personalize the output accordingly. In order to accomplish this, a policy has two types of actions it can choose at any node, either to ASK, which represents outputting the system text associated with that node, or to $SKIP$, which represents transitioning to a connected node without outputting the text at the current node.

2.1 Formal Task Description

Given is a dialog tree represented as (cyclic) directed Graph $G = (V, E)$, where the outgoing edges of node v include the self-transition $ASK(v) = (v, v)$, combined with the edges to neighbours of v ($v_i, \dots, v_k \subseteq V$): $E(v) = \{ASK(v), SKIP(v, v_i), \dots SKIP(v, v_k)\}$. Here, $SKIP(v, v_i) = (v, v_i)$ is an edge to a direct neighbour v_i of v.

Starting from a node $s \in V$, the goal is to find a path $p = (ASK(s), SKIP(s, v_i), \dots, ASK(g))$ to a given user goal node $g \in V$ (see Figure 2) only described by user utterances U, subject to $ASK(g) \in p$ (the goal node should be presented to the user) while at the same time minimizing $|\{ASK(v) | v \in V \wedge ASK(v) \in p\}|$ (the amount of asked questions, i.e., perceived length to the goal, should be as few as possible).

Here, the edges E also define the system's dialog actions, where $ASK(v)$ will output the text associated with the node v. Depending on the node type, this can either output information to the user or extend the user utterance history U as $U' = U \cup \{u_v\}$ by asking a question. The action $SKIP(v, v')$ will skip from v to v' without outputting anything to the user. Each node v is associated with text representing a system utterance and a node type (e.g. question). $SKIP$-actions are labeled by domain experts with a user answer prototype, which are used to compare user utterances to during dialog. For more information on node and edge data, see Section 4.

In order to address both user interactions (general exploration and specific questions), we define two goal settings within this task framework:

Guided Dialog Here, we define guided dialog as interactions where the user has a vague information goal and rather than posing a concrete question, would like to explore the information available in the dialog graph. Therefore, rather than having one static goal, the user decides on a new goal every turn, i.e., each turn their new goal will be to reach the node connected to the edge associated with the answer they give to the system question. Thus, a guided dialog can be seen as having turn-by-turn goals $(g, g', g'', \dots) \subset V$, meaning that from any node g, the next goal g' is an immediate neighbour of g, i.e., $SKIP(g, g') \in p$.

Free Dialog Free dialog in contrast, considers the case that the user has expressed a concrete information goal, which may or may not require later clarification. In this form of dialog, rather than focusing on choosing the next node from the set of neighbours, the dialog system's goal is to help the user fulfill their information need as quickly as possible. To this end, if the system is not sure about an upcoming decision, it may choose to ask for relevant information, thereby increasing its understanding of the user's goal. Thus, a free dialog has only one goal $g \in V$ and each turn serves to clarify the goal or skip closer to the answer.

2.2 Evaluation Objectives

We evaluate the path p taken by the policies according to the following criteria:

1. Task success, i.e., the goal node ($g \in V$) text is outputted to the user: $ASK(g) \in p$

2. Skip ratio, i.e., the number of times two consecutive skip actions occur along the path $((SKIP(v, v_i), SKIP(v_i, v_j)) \in p)$ divided by the length of the path

For guided dialog, the objective is to maximize task success while minimizing the skip ratio. In free mode, the objective is to maximize both task success and the skip ratio.

3 Methods

We develop and release[1] a baseline system, an RL-agent, and a domain-agnostic user simulator for training and evaluating dialog policies on the new CTS task.

3.1 User Simulator

The user simulator generates new dialogs for both interaction modes (with 50% probability of starting in either mode), which can be used to train and evaluate an RL-agent. The simulator is rules-based and each turn can respond to the dialog agent, either by asking a question (initial turn) or responding to a follow-up question (subsequent turns) using text from the available paraphrases (Appendix A). Dialogs are generated by choosing random goals and constraints. As its behavior only depends on an interchangeable dialog tree, the simulator remains domain-agnostic.

To represent exploratory users (guided mode), the simulator randomly samples a neighboring node as a new goal after each node transition. This mimics a user whose goal is only that the system correctly understands their current input and takes them to the associated next node. To support user exploration of the domain, skipping over nodes should be avoided, so asking after skipping to a new node – rather than skipping twice in a row – is rewarded (+2), as is correctly skipping after asking (+3). The initial utterance is the user answer to the start node question, subsequent utterances are given by (paraphrases of) answers leading to the next goal node.

To represent users with a concrete information goal (free mode), the simulator randomly selects a single, static goal and constraints for the entire dialog. A random node (with at least one associated FAQ question) is chosen from the graph as the user goal and one of the FAQ questions associated with that node is chosen as the initial user utterance. The simulator then finds a valid path from the start node to the goal node, saving the user answers along that path. Each time the dialog agent asks a question from a node along the goal path, the simulator can use the stored answers to respond. In case the node is not along the goal path, a random answer will be chosen to continue the dialog. To discourage long dialogs, each turn is given a small negative reward (-1). To discourage asking unnecessary questions, any questions that are not part of the stored goal path are punished (-4). Finally, reaching the goal node and outputting its content is given a reward of $4 \times tree\_depth$ (e.g. in the REIMBURSE dataset: reward of +128).

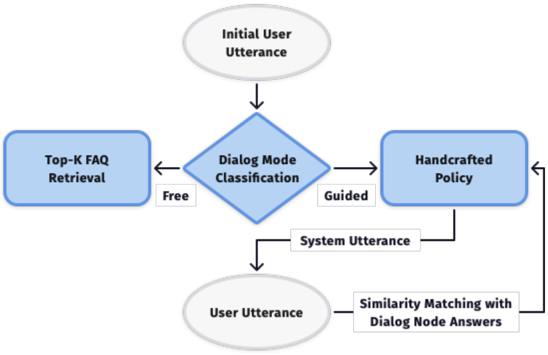

Figure 3: Baseline architecture: Combines an FAQ retrieval system (free mode) and a handcrafted dialog system (guided mode), with a classifier deciding which policy is active based on the input in the first turn.

A dialog will stop after: 1) reaching 50 dialog turns, 2) presenting the user goal, or 3) presenting the same node 3 times (user patience). To simulate unseen text input, noise can be added to user utterances in the form of a normal distribution around the original utterance encoding vector $\mathbf{u}$, using a percentage n of u as standard deviation: $\mathcal{N}(\mathbf{u}, n|\mathbf{u}|)$.

3.2 Baseline

For the baseline system (see Figure 3), we combine an FAQ retrieval system (free mode) and a handcrafted dialog system (guided mode) together, training a classifier to decide which policy is active based on the input in the first turn.

To train the dialog mode classifier, we fine-tune a German BERT model (Chan et al., 2020), providing a user utterance and the associated node text as inputs (see Appendix D). In free mode, a state-of-the-art similarity model (Reimers and Gurevych, 2019) is used to compare the first user utterance to all nodes in the dialog tree, directly outputting the most similar match to the user. In guided mode, node text is outputted to the user at each node. Their response is then compared to the prototypical answers for that node (using the same similarity model), and the policy then skips to the node connected by the most similar prototypical answer.

3.3 Reinforcement Learning Model

We propose a novel RL-architecture based on Dueling Network Architectures (DDQN) (Wang et al., 2016). For improved stability and convergence speed, we integrate Munchausen Reinforcement Learning (Vieillard et al., 2020), Double Q-Learning (van Hasselt et al., 2016), and Hindsight Experience Replay (Andrychowicz et al., 2017) in conjunction with Loss-Adjusted Prioritized Experience Replay (Fujimoto et al., 2020).

As a deviation from conventional DQN-based (Mnih et al., 2013) algorithms, we re-parameterize the usual network structure $\mathbf{Q} : \mathrm{s}, \boldsymbol{\theta} \mapsto \mathbb{R}^{|A|}$ to $Q : \mathrm{s}, a_i, \boldsymbol{\theta} \mapsto \mathbb{R}$, where s is a state vector, $\boldsymbol{\theta}$ represents the trainable network weights, and a_i is the i-th action in action space A with $|A|$ discrete actions. Thus, our architecture has one output node instead of $|A|$ output nodes (see Figure 4). Instead of performing one forward pass per state, we now perform $n(\mathbf{s})$ forward passes per state, where $n(\mathbf{s}) \leq |A|$ is the variable action count at state s, concatenating all outputs to obtain the full state-action vector $\mathbf{Q}(\mathrm{s}, \boldsymbol{\theta})$. By batching these forward passes, we achieve comparable runtime performance. The benefits of this approach are twofold: 1) It scales to an arbitrary number of actions without increasing the number of output neurons. 2) We can process action-specific inputs, e.g., action text (Figure 4 (a)), allowing the model to infer information from text rather than just exploiting action-space structure.

To keep the state values stable across different actions in the same state, we expand on the idea of DDQN (Wang et al., 2016), which processes inputs using shared layers (Figure 4 (b)) and calculates a state-value $V(\mathrm{s})$ and an advantage function $A(\mathrm{s}, a)$ with separate network layers on top of the shared layer. Here, we add separate layers for encoding action inputs (Figure 4 (c)), which we then concatenate with the shared layer output (Figure 4 (b)) in order to calculate $A(\mathrm{s}, a)$. $V(\mathrm{s})$ only receives inputs based on state s, and is thus decoupled from action-related inputs. We found this stabilized Q-values and performed better than the original algorithms in all our experiments (e.g. DDQN: 31.87% combined success on test data).

After experimenting with an external dialog mode classifier, we found that adding dialog mode classification as an auxiliary task improved our success metric. Therefore, we add an additional binary classification head to the output of the shared state layers from our enhanced DDQN to predict which dialog mode the current turn belongs to. Using cross entropy loss, we add this task as a hard-parameter sharing multitask learning objective (Caruana, 1993) in order to force the model to develop an understanding of the different tasks: $\mathcal{L} = \mathcal{L}_{\text{ddqn}} + \lambda \mathcal{L}_{\text{intent}}$.

4 REIMBURSE: A Dataset for CTS

For this task, we collect and publish a dataset from two sources: a dialog tree, defining the general system behavior, and a corpus of user utterances, with paraphrases for both user questions and responses to system questions. This dataset represents challenging real-world data, both in the complex structure of the dialog tree for this domain, and the real-world nature of the user utterances. Examples of user questions and user responses are provided in Appendix B.

Dialog Tree We provide a dialog tree for travel reimbursement, created by subject-area-experts using a graphical dialog designer tool. The dialog tree consists of four different types of nodes: 1) Dialog Nodes, defining a system question and possible user answers. 2) Variable Nodes, defining a system question and storing the user answer for later use in the beliefstate. 3) Information Nodes, defining information that the system should share with the user without expecting a user response. And 4) Logic Nodes, defining dialog flow based on logical conditions evaluated against beliefstate values, without outputting anything to the user. An example of each of these can be seen in Figure 6 in the Appendix.

In total, the dialog graph we use contains 123 total nodes (with a maximum depth of 32), of which, 79 are information nodes which contain answers to user questions and 23 are Dialog Nodes with system questions for the user. The maximum action count per node (directly connected nodes) is 14.

User Utterances We collected a real world corpus, called REIMBURSE. This corpus consists of 452 free dialog questions, each corresponding to an Information Node in the dialog tree, with an average of 5.72 paraphrases per Information Node. This was done through recording user utterances in two early pilot studies, and manual augmentation by two expert annotators. Synonyms for user responses to system questions were collected the same way, resulting in 408 total response paraphrases, on average 5.58 per user answer. For examples, see Appendix B.1.

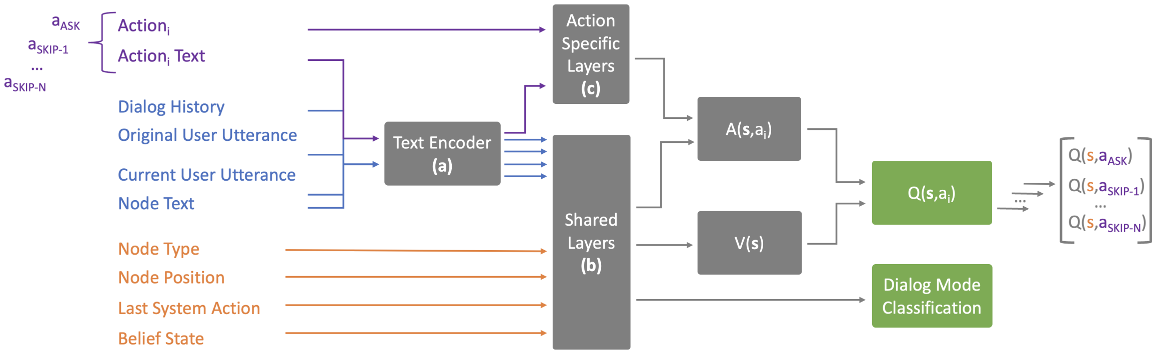

Figure 4: Proposed RL architecture: The state-value function $V(\mathbf{s})$ for state s is calculated from the shared layers (b), independent of action inputs. For the advantage function $A(\mathbf{s}, a)$, the outputs from shared layers (b) and action-specific layers (c) are combined. The final state-action-values Q are obtained by performing one forward pass per action a_i, each yielding a scalar $q_{\mathbf{s},a_i}$, which are then concatenated by state into a vector with one value per action. Additionally, a binary dialog mode classifier is added on top of the shared layers (b).

5 Experimental Setup

The RL agents receive the following inputs: beliefstate, last system action type, action index, and current node type encoded by one-hot vectors, current node position as a binary tree encoding (Shiv and Quirk, 2019), the dialog history, initial user utterance, current user utterance, current node text and the node's prototypical answer texts encoded by either an English-German RoBERTa (Liu et al., 2019) [2] or sentence transformers (Reimers and Gurevych, 2019) model. The model is trained against the user simulator using the Adam optimizer (Kingma and Ba, 2015) with a learning rate of $1e^{-4}$. We set the maximum number of training dialog turns to 1.5M and save the model which performs best in evaluation (performed every 10k turns with 500 simulated dialogs) for testing. Evaluation and testing are also performed against the user simulator. However, in this mode agent exploration is disabled. For more details on model and training parameters, see Appendix D.

Testing is done on 500 simulated dialogs (in RQ3 generated from held out utterances). We measure success and skip ratios for guided and free mode separately and jointly. To check task understanding, we measure the dialog mode prediction consistency: we calculate the difference between the percentage of turns predicted for guided and free mode per dialog, then averaging across all dialogs.

5.1 RQ1: Task Performance

To understand how well the RL agent learns to support both dialog modes, we measure combined task success as well as success on each individual mode (how often user reaches goal), the mode-specific skip ratios (higher skip ratio desired for free, lower for guided mode), and the mode prediction and consistency measures (proxy for task understanding). All models are trained and tested against the user simulator generating dialogs from the same distribution, following standard RL procedure. We apply a noise level of $n = 10\%$ to encourage generalization.

5.2 RQ2: Task Performance in a Noisy Environment

To test how well our models perform in noisy environments, we test the success and mode classification F1 score of models trained in RQ1 on simulated dialogs with increasing noise levels. We test five times, reporting average results and statistically significant performance differences.

5.3 RQ3: Generalizing to New Data

In the previous experiments, we have followed the RL convention of testing our models on new dialogs generated from the same user simulator they trained on, with the same set of possible user utterances. However, much of the challenge in this domain comes from understanding text input. By exchanging the set of user utterances available to the simulator for testing, we explore how well the model can generalize to user inputs not seen during training. To this end, we split our corpus into a test/eval and a train set. The train/eval set contains 279 FAQ questions (3.5 questions per Information node) and 246 responses (3.4 paraphrases per response prototype). The test set contains 173 user

---

[2] https://huggingface.co/T-Systems-onsite/cross-en-de-roberta-sentence-transformer?doi=true

questions (2.2 questions per Information node) and 162 responses (2.2 paraphrases per response prototype). We then train and evaluate the best performing models from RQ1 and RQ2 on simulated dialogs generated from the train split. Finally, to measure how well they can generalize, we test the final performance on dialogs generated from the unseen paraphrases in the test split.

6 Results and Discussion

6.1 RQ1: Task Performance

To verify the user simulator, we evaluate it against our baseline model, without noise and only using the prototypical user answers from the dialog tree. This yields a success rate of 99.35% for the guided task and an F1-score of 1.0 for the dialog mode prediction, showing that the simulator works as expected. On the free task, it reaches 64.46% success. Given the challenging nature of the dataset, it is to be excepted that top-1 retrieval is not perfect.

Just by adding user answer paraphrases and 10% noise, baseline performance drops substantially on all tasks (see Table 1), demonstrating the task difficulty w.r.t. a real-world scenario. Our RL agents significantly outperform the baseline (t-test $p < 3 \times 10^{-8}$) on all task success metrics, except the skip ratios (see Table 1). This shows our models are better able to learn the task compared to the baseline, especially under noisy text inputs, which we attribute to the improved generalization.

RQ1.1: Differentiating Between Dialog Modes Table 1 shows that both of our models learn to skip more frequently in free mode (e.g., 0.58) and less frequently in guided mode (e.g., 0.07). This indicates that multitask learning helped understand the user's intended mode, as we would otherwise not see a difference in skipping behaviour. Additionally, the classification consistency is 1.0, indicating stable task understanding. Jointly learning intent prediction also improves dialog mode classification compared to using a pre-trained classifier.

RQ1.2: Asking Only Necessary Questions While the baseline has, by construction, perfect skip ratios on both free (1-step retrieval) and guided tasks (no skipping), the skip ratios in Table 1 demonstrate that our models learn to ask questions in both modes. In free mode, we see that asking some questions helps differentiate the user goal, as we obtain much better task success than the 1-step baseline. High skip ratios (e.g., 0.58) in this mode show the model still skips unnecessary nodes.

6.2 RQ2: Task Performance in a Noisy Environment

Figure 5 shows our models are able to handle high levels of noise: performance only decreases rapidly after 100% noise. Our models demonstrate a significant performance increase over the baseline at all noise levels (t-test $p < 0.003$). Additionally, we find that dialog mode understanding is robust w.r.t. input noise (dialog mode classification F1 stays unchanged at 1.0 after rounding, e.g. consistency only drops from 1.0 without noise to 0.83 at the highest noise setting). The robustness to noise suggests that the regularization techniques are effective.

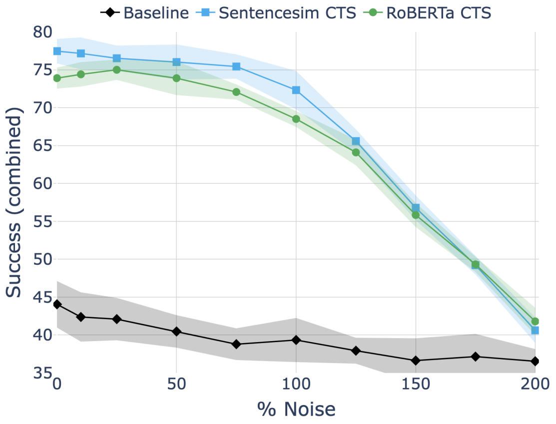

Figure 5: Task performance for different noise levels on user input (drawn from a normal distribution around the original text encoding vector $\mathbf{u}$, using a percentage n of $\mathbf{u}$ as standard deviation: $\mathcal{N}(\mathbf{u}, n|\mathbf{u}|)$.

6.3 RQ3: Text Understanding and Generalization to New Data

When only training on a fraction of the data and testing on the unseen split, we observe some performance drops for the baseline and all RL agents, compared to the setting from RQ1, as well as between evaluation and test performance in RQ3 (see Table 2). The performance drop in the RL agents can likely be explained by the drop in the dialog mode classification score (e.g., from 1.0 in RQ1 to 0.85). This paired with high dialog mode prediction consistency (0.96, 1.0) means the models more often classified the dialog mode incorrectly and could not recover during a dialog. This misclassification likely also explains increased skipping in guided mode (e.g., from 0.07 in RQ1 to 0.19).

However, even in this more challenging setting, our models demonstrate much better combined task

Model	**Success (guided)**	**Skip Ratio (guided)**	**Success (free)**	**Skip Ratio (free)**	**Success (combined)**	**Dialog Mode Prediction F1**	**Dialog Mode Prediction Consistency**
Baseline	64.71%	**0.0**	22.84%	**1.0**	43.10%	0.83	**1.0**

Table 2: Model performance on simulated dialogs generated from dataset splits, and skip ratios (skipped dialog nodes w.r.t. dialog length). Here, higher skip ratios are better for the free setting (looking for a direct answer), but lower ones are preferable for guided mode (exploratory dialogs). Rows underneath *RoBERTa CTS* for the data represent input ablations, i.e. the listed input was removed from the model.

success than the baseline. This is particularly interesting as utterances in the test data were never seen in training, meaning the model could not have merely exploited structural properties of the data, but rather must have learned text understanding to solve the task. For example (see Appendix C.2), the model can understand that when a user asks what to do after an earthquake, they need the emergency help number and skips directly to that node, even though nothing about earthquakes appeared in training. The system also learns to recognize when information is missing from a user question and ask for additional information, e.g., if the business trip took place in or outside the home city, even for new questions (see Appendix C.3).

To better understand how the model processed inputs, we performed an ablation study (Table 2) of the RoBERTa agent. From the success rates without either action text or action position, we see that providing action context in input space increases model performance, validating our new architecture.

In free mode, when node or action text are removed, there is a large drop in model performance (about 10%), which is not as severe if instead action positions are left out. This suggests that the model learns to understand text as it can correlate user utterances to text from nodes and actions in the dialog graph, even with noise and synonyms not seen during training. Node position intuitively simplifies path finding, which explains a drop in performance when leaving it out. It also makes sense then that removing the dialog history has a similar effect, as it encodes path information in textual form. We conclude from this that both textual and positional information are needed for this task and better understanding of either input could likely boost performance.

In the guided mode, we observe that while node text was very important (nearly 20% drop), removing action text had almost no effect. This might relate to the text length associated with each action, and the length of user input per node (usually much less information than in the free mode questions). As user input was often one to three words long, it could have been easier for the model to learn to correlate the user input to an action position rather than action text, especially given that BERT-based language models rely on context. Thus, improving focus on action text in the guided mode is an area for future investigation. Removing the node position or dialog history had a minor impact, which agrees well with the objective of the guided mode: it should not rely much on path planning, instead user input should be considered at most nodes to move the dialog along.

In general, dialog mode prediction improves performance in both dialog modes. Without this, the agent is able to learn to skip more in free mode and less in guided, but success drops. In the multitask learning setting, we force the model to learn to output a consistent prediction across a dialog (Table 2 consistency values are close to 1.0 for all multitask models), which may explain the higher success.

7 Related Work

Data Efficient Task Oriented Dialog Systems In some domains, e.g., recommendation, the number of actions for a dialog system can be quite large prompting new architectures which group the actions into a tree structure to reduce the search space (Chen et al., 2019; Montazeralghaem et al., 2021). While the information seeking dialogs have different characteristics, including a tree structure for the data, can help experts maintain control of the system and reduce the action search space.

Task Oriented Systems with Expert involvement In many domains, it is crucial domain experts maintain control of dialog flow to ensure correctness of system outputs. An early approach (Williams, 2008) involved a hand-crafted dialog policy which output the allowed actions at a time step and a POMDP policy then chose the optimal action from this set. More recent approaches, e.g., hybrid code networks (HCN) have expanded on this idea for neural systems (Williams et al., 2017; Liang and Yang, 2018; Razumovskaia and Eskenazi, 2019), where action space can be constrained using masks. Shukla et al. (2020) extend the HCN approach by automatically converting expert designed dialog trees into hybrid code networks (HCN). This approach increases explainability of system behavior, but doesn't provide a mechanism for skipping portions of a dialog irrelevant to a user, falling short of addressing free dialog.

Knowledge Augmented Dialog Systems The DSTC10 challenge (Kim et al., 2022) introduced a new track for knowledge grounded dialog, combining task-oriented dialog and FAQ style questions answered from unstructured documents. Such hybrid dialog systems help answer free form user queries, but still require a concrete question, and do not allow precise control over generated answers.

Another recent approach (Raghu et al., 2021) proposed grounding dialog systems on troubleshooting flow charts and FAQ questions. Here, the dialog system fuses knowledge from FAQs with an under-specified flow chart to generate an appropriate response to a user input. However, dialogs appear limited to short flow charts, and response generation is again outside the designer's control.

Clarifying Questions and Conversational Search Conversational Search and clarifying questions are two intertwined areas of research which focus on disambguating free form user queries. The goal of these tasks is to generate one or more questions to narrow down a user's information need (Zamani et al., 2020) in order to retrieve relevant documents. To improve conversational search performance, much work has focused on ranking candidate questions (Kumar et al., 2020) and leveraging the user answers (Bi et al., 2021). However, neither of these tasks do not allow for human oversight of the questions that will be asked, and currently do not consider any structure for the organization of questions.

8 Conclusion and Future Work

In this work, we introduced a new task, CTS which combines the positive aspects of both an FAQ retrieval and task-based dialog system, along with a real-world German language dataset, REIMBURSE, a domain-agnostic user simulator, and baseline system based on state-of-the-art language models. Furthermore, we demonstrated a novel, scalable RL architecture, showing significant performance improvements over the baseline. Our models are able to handle high levels of noise in the input data and demonstrate the ability to learn text-based information from user utterances, as seen by their ability to handle unseen data. In the future, it would be interesting to explore data augmentation for generating unseen utterances as well as to explore methods, particularly for guided mode dialogs, to encourage the model to rely even more information from text. We also hope that the community helps in exploring performance on additional languages and task instances.

9 Limitations

We recognize the following limitations in our work:

- When testing on unseen real world data rather than the noisy simulation, we notice a performance drop between the evaluation and test results. As we are working in a very low resource setting and using a challenging real-world dataset, it is difficult to state with certainty if this is a result of the challenge inherent to the dataset or a weakness of the models to generalize.
- We were not able to perform testing in an interactive user study, but rather tested against simulated dialogs generated from pre-collected real-world utterances. While these were collected from real users of the dialog system, a user study would be valuable to investigate how the system handles input in a live setting.
- As we only collected a single dataset for the new CTS task, we have not investigated domain generalizability.

A User Simulator

The (simplified) behavior of the user simulator is show below. To generate dialogs based on unseen utterances, one can simply replace the files containing questions and answers with new files containing different questions and answers than were present during the training process.

```
Require: questions ← List of Questions associated with dialog tree nodes
Require: answers ← List of Answer synonyms
Require: $N$ ← Number of dialogs to be simulated
Require: $G(V, E)$                                                    ▷ Dialog Tree
Require: $T$ ← Maximum number of turns per dialog
  $n \leftarrow 0$
  for $n < N$ do
      $v$ ← start node
      $m$ ← randomly choose GUIDED or FREE
      if $m =$ GUIDED then
          $g$ ← randomly choose neighbour(v)                ▷ Draw new goal in guided mode
          $e \leftarrow e(v, g) \in E$
          $u$ ← randomly choose from answers[e]
      else
          $g$ ← randomly draw $g \in V$ with |questions[g]| $\geq 1$      ▷ Draw new goal in free mode
          $p \leftarrow (e(v, v_1), \ldots, e(v_N, g)) \subset E$
          $u$ ← randomly choose from questions[g]
      end if
      $t \leftarrow 1$
      while $v \neq g \wedge t \leq T$ neighbours(v) $\neq \emptyset$ do          ▷ Simulate dialog
          $a$ ← next action from dialog policy, with inputs $v, u$
          if $a =$ ASK(v) then                                  ▷ Print / Ask information
              print $v$
              $e \leftarrow e(v, v')$ where $v'$ is g in guided mode or in free mode the next node after v in the path
              $u$ ← randomly choose from answers[e] if type(v) $\neq$ information, else $\emptyset$
          else if $a =$ SKIP(v,v') then                             ▷ Skip to next node
              $v \leftarrow v'$
              $u \leftarrow \emptyset$
          end if
          $r$ ← Calculate rewards
          Store $a, v', r$ in replay buffer
          if $m =$ GUIDED then
              $g$ ← randomly choose neighbour(v)        ▷ Draw followup goal in guided mode
              $e \leftarrow e(v, g) \in E$

B REIMBURSE: Dataset

B.1 Example User Utterances

B.1.1 Answer Paraphrases

Below is an example of the answer paraphrase data we collected. The subject-area expert defined a prototypical answer to the question and then additional paraphrases were collected (through pilot study and manual expansion). Although some are very close to the prototypical answer, there can also be a lot of variation.

Prototypical Node Answer: Mit Familie *(en: With my family)*
Associated Paraphrases:

- Zusammen mit meiner Frau *(en: Together with my wife)*
- Mit Mann und Kinder *(en: With husband and kids)*
- Ich und meine Angehörigen *(en: Me and my relatives)*
- Mit Begleitung *(en: With accompaniment)*

B.1.2 User Question Paraphrases

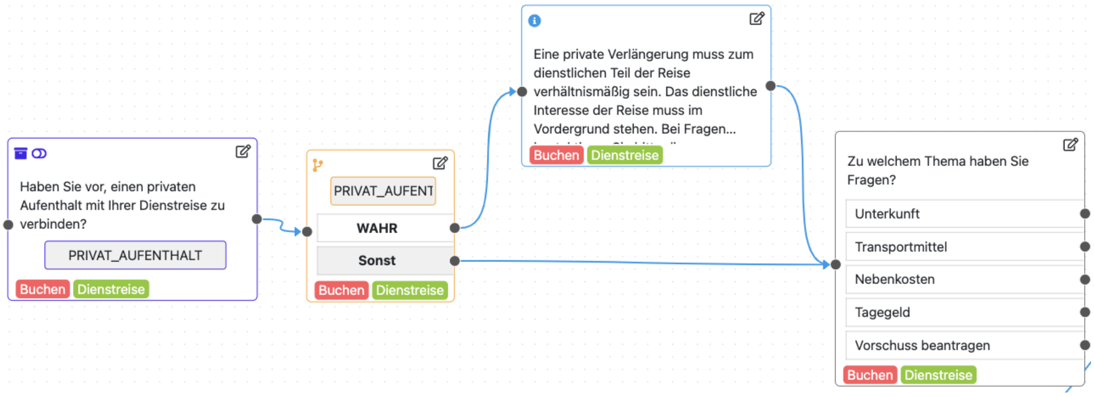
For each Information node in the graph, a set of paraphrased questions were collected.

Node Text: Eine private Verlängerung muss zum dienstlichen Teil der Reise verhältnismäßig sein. Das dienstliche Interesse der Reise muss im Vordergrund stehen. Bei Fragen kontaktieren Sie bitte die Reisekostenstelle. (*en: A personal extension must remain in proportion with the official part of the trip. The business benefit must remain the primary focus of the trip. In case of questions, please contact the business travel department.*)
Associated Questions:

- Darf ich meine Reise privat verlängern? *(en: Can i extend my trip privately?)*
- Wie lang darf der private Reiseanteil sein? *(en: How long is a private extension allowed to be?)*
- Kann ich länger bleiben als der dienstliche Teil meiner Reise? *(en: Can I stay longer than the official part of my trip?)*
- Darf ich nach meiner Reise Urlaub machen? *(en: Can I add vacation to the end of my trip?)*

B.2 Example Tree

Below is an example of each of the node types in the dialog editor. For Information nodes (blue) subject experts could also define associated FAQ questions to help the RL agent understand user user questions related to that node.



Haben Sie vor, einen privaten Aufenthalt mit Ihrer Dienstreise zu verbinden?

Eine private Verlängerung muss zum dienstlichen Teil der Reise verhältnismäßig sein. Das dienstliche Interesse der Reise muss im Vordergrund stehen. Bei Fragen...

Zu welchem Thema haben Sie Fragen?

Figure 6: Example of the dialog designer interface. From left to right: Variable Nodes (purple outline), which the designer can use to ask for information relevant for later decisions, Logic Nodes (orange outline) which control the flow of the dialog based on user responses stored in the Variable Nodes (here the two options are *"true"* and *"else"*), Information Nodes (blue outline) where the designer can specify information which does not need a user response, and Dialog Nodes (black outline) where the designer can specify system questions and expected user responses.

Figure 7 is a view of the full dialog tree used for experiments in this paper, consisting of 123 nodes.

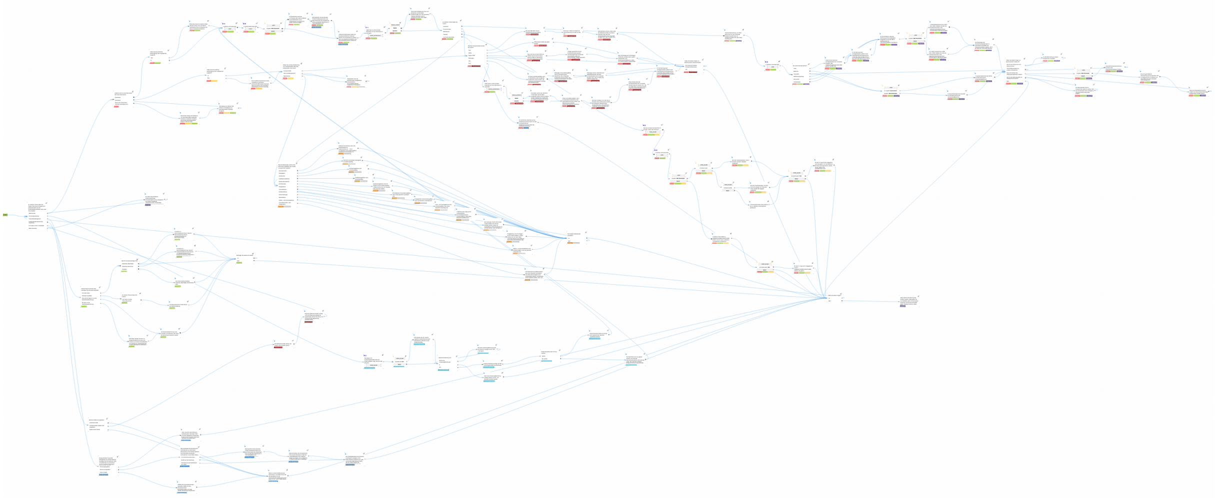


Figure 7: Overview of the dialog tree used for all experiments in this paper. The tree was designed by subject-area experts to help users better navigate the travel reimbursement process.

C Example Dialogs

In this section, we show parts of successful conversations between the simulator and the Sentencesim-CTS agent.

D Training details

D.1 RL Model Parameters

The following parameters were used by all user RL models (chosen through manual tuning):

Parameter	Value
Layer type	Linear
Activation (after each layer except in Dialog Mode Classifier Head)	SELU
Shared Layer Neurons (one value / layer)	$8096, 4096, 4096$
Value Function Layer Neurons (one value / layer)	$2048, 1024$
Advantage Function Layer Neurons (one value / layer)	$4096, 2048, 1024$
Dialog Mode Classifier Neurons (one value / layer)	$256, 1$
Dropout (after each layer)	25%

Table 3: RL Model Parameters

D.2 RL Experience Buffer

New goals in the replay phase of the Hindsight Experience Replay are generated only for free mode dialogs. Here, we follow the original dialog backwards until we find a suitable alternative goal node (having at least one associated user question). We choose one of the user questions of the new goal node randomly and replace the original dialog's initial user utterance with it.

Parameter	Value
Buffer size	100000
Priority Replay α	0.6
Priority Replay β	0.4

Table 4: RL Experience Buffer

D.3 Simulation Parameters

The following parameters were used by our user simulator:

Parameter	Value
Reward Normalization	$[-1.0, 1.0]$
Maximum Dialog Steps	50
User Patience	3
Probability guided vs. free dialog	0.5
Training utterance noise	10%

Table 5: Simulation Parameters

D.4 Dialog Mode Classifier

We fine-tune GBERT (Chan et al., 2020) using the Huggingface framework (Wolf et al., 2020). As data, we use utterances from our train data split and evaluate on the test data split. We have two different input pair types: 1) node text and user answer 2) node text and user FAQ question. Training is done for 5 epochs, otherwise using the standard Huggingface (Wolf et al., 2020) trainer class parameters.

D.5 RL Training Parameters

The following parameters were used to train all RL agents (chosen through manual tuning):

Parameter	**Value**
Optimizer	Adam
Learning Rate	$1e^{-4}$
λ	1.0
Maximum Training Dialog Turns	$1.5M$
Max. Gradient Norm	1.0
Batch Size	128
γ	0.99
Exploration fraction of Training Turns	0.99
Exploration Scheme	ϵ-greedy
ϵ start	0.6
ϵ end	0.0
Training frequency (w.r.t. dialog turns)	3
Training start (w.r.t. dialog turns)	1280
DDQN Target Network update frequency (w.r.t. training steps)	15
Q-Value clipping	10.0
Munchausen τ	0.03
Munchausen α	0.9
Munchausen Clipping	-1
Evaluation frequency (w.r.t. dialog turns)	10000
Evaluation dialogs	500

Table 6: RL Training Parameters

A Human Subject Study of Named Entity Recognition (NER) in Conversational Music Recommendation Queries

Elena V. Epure and **Romain Hennequin**
Deezer Research, Paris, France
`research@deezer.com`

Abstract

We conducted a human subject study of named entity recognition on a noisy corpus of conversational music recommendation queries, with many irregular and novel named entities. We evaluated the human NER linguistic behaviour in these challenging conditions and compared it with the most common NER systems nowadays, fine-tuned transformers. Our goal was to learn about the task to guide the design of better evaluation methods and NER algorithms. The results showed that NER in our context was quite hard for both human and algorithms under a strict evaluation schema; humans had higher precision, while the model higher recall because of entity exposure especially during pre-training; and entity types had different error patterns (e.g. frequent typing errors for artists). The released corpus goes beyond predefined frames of interaction and can support future work in conversational music recommendation.

1 Introduction

Music recommendation systems (RSs), fundamental to streaming services nowadays, learn from user listening history or music content which artists or tracks to suggest next (Schedl et al., 2018). Most of these algorithms provide personalized music content to the users when logging in the streaming apps or websites, or when triggered with pre-defined utterances via voice assistants (Ammari et al., 2019; Bontempelli et al., 2022). More recent *conversational* RSs aim to help users to express their recommendation needs by supporting interactions via *queries* in natural language (Jannach et al., 2021). However, despite existing in the scientific literature, such conversational RSs are not widely deployed because of multiple issues, one being NER.

The processing of recommendation queries entails the *extraction of named entity mentions* (Moon et al., 2019; Rongali et al., 2020). This sub-task faces multiple challenges, even when queries are framed as pre-defined utterances. The transcriptions of the voice queries results in lower-case noisy text, often with misspellings (Muralidharan et al., 2021). The lack of capitalisation in entities and misspelled words are often present in text-based queries too (Cheng et al., 2021). Music entities, or those coming from the creative content domains, are highly irregular: they do not follow inherent patterns as it is the case with people's names, and there is little to no separation between the vocabularies of entity and context words, especially for creative works (Derczynski et al., 2017) (e.g. common words like "I" or "love" in track titles). Also, new music entities appear all the time. Major music streaming services ingest one new track almost every second (Ingham, 2021).

Previous works have already shown that NER systems struggle with the aforementioned challenges (Augenstein et al., 2017; Lin et al., 2020b; Epure and Hennequin, 2022). Thus, multiple approaches have been proposed to address them, either focused 1) on collecting more and relevant data for training / fine-tuning standard NER sequential models (Lison et al., 2020); or 2) on model's design choices that favour generalisation (Guerini et al., 2018; Lin et al., 2020a). Most solutions focused on the latter objective have been motivated by the *human NER linguistic behaviour*, e.g. make the model rely more on context cues than on named entity mentions or learn from a few examples only, as humans do. However, apart from some scarce, partially related works (Derczynski et al., 2016; Ding et al., 2021), there is no systematic investigation of how humans actually perform NER on noisy text with many new and irregular named entities. Moreover, in the case of music recommendation, we are not aware of any existing dataset of queries in natural language, annotated with named entities.

Thus, our goal is to investigate the human NER linguistic behavior when confronted with these challenging conditions. For that, we create *Musi-*

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1281–1296
May 2-6, 2023 ©2023 Association for Computational Linguistics

cRecoNER, a new corpus of noisy natural language queries for music recommendation in English that simulates human-music assistant interactions. We then conduct a *human subject research study* to establish a human baseline and learn from it. Finally, we perform a detailed comparison of humans and the most popular NER systems nowadays, fine-tuned transformers, that covers multiple evaluation schemes (*strict* named entity segmentation and typing, *exact* segmentation only, or partial segmentation with strict named entity typing) and scenarios including entities previously seen or unseen by the model or humans.

The results showed that the task was challenging for humans. Given an aggregated metric such as F1 score, human and algorithmic performances were on par. However, the detailed evaluation revealed that humans struggled more with recall while the best model with precision. The high recall obtained by the model was partially a result of entity exposure during pre-training or fine-tuning. Also, music entities had different error patterns and, in some queries, had ambiguous context that made their segmentation and typing quite hard.

To sum up, our research contribution[1] are:

1. *MusicRecoNER*, a corpus of noisy complex natural language queries for music recommendation collected from human-human conversations in English, but which simulates human-music assistant interactions, annotated with *Artist* and *WoA* (work of art) entities. This dataset is not limited to pre-defined utterances as it would be the case if collected from interactions with conversational or voice assistants. Thus, it contains entities in diverse context, being also a useful resource for future work on conversational music recommendation.

2. A *human subject study design for NER* in noisy text with many new and irregular named entities. The proposed method is transferable to other creative content domains that face similar challenges to music such as books, movies, videos, but also to any other domain with scarce data, which wants to learn more about the NER task before building a system.

3. An *extensive music NER benchmark on noisy text* which compares the performance of human versus automatic baselines under multiple evaluation schemes, scenarios and by controlling for the *novelty* of named entities.

2 Related Work

Analysing human and algorithmic performance was done for multiple NLP tasks in the past. Nangia and Bowman (2019) ran an annotation campaign on the GLUE benchmark with the goal to estimate the effort needed by existing models to catch up with the humans under limited-data regimes. Kazantseva and Szpakowicz (2012) conducted a large-scale human study on topic shift identification in order to discover patterns of disagreements and consolidate the evaluation metrics. Ghaly and Mandel (2017) analysed the human behaviour for understanding ambiguous text-based or spoken sentences to guide the development of a machine learning system. Multiple machine translation works challenged the human parity claim (Toral, 2020) and proposed a secondary evaluation method to reveal detailed differences between humans or algorithms (Graham et al., 2020).

Compared to these, we benchmark humans and models on a different task—named entity recognition, but we share similar goals—to estimate the human-algorithmic performance gap and to identify patterns that could support the design of better evaluation methods or automatic solutions. Human annotation is frequent in NER especially when targeting a new domain such as archaeology (Brandsen et al., 2020), or a new language such as Indonesian (Khairunnisa et al., 2020). However, we are not aware of any annotated corpus of conversational queries for recommendation in the music domain. Some other related works propose corpora of noisy social media text containing new entities including irregular ones (Derczynski et al., 2016, 2017), a noisy dataset of movie-related queries (Liu, 2014), a dataset of music artist biographies annotated for entity linking (Oramas et al., 2016), or a corpus of tweets associated with a classical music radio channel (Porcaro and Saggion, 2019).

Previous works have showed that transformers fine-tuned for NER are strong baselines, especially when training data is scarce (Akbik et al., 2019; Fu et al., 2020). A more recent line of research employs these pre-trained models as few-short learners (Yang and Katiyar, 2020; Tänzer et al., 2022). However, the results are still below those obtained with a fine-tuning approach. In order to improve the bare-bone fine-tuned transformers, other works

[1] Code and data are available at `https://github.com/deezer/music-ner-eacl2023`.

adopted distant supervision (Lison et al., 2020), and the inclusion of gazetteers (Shang et al., 2018) or contextual triggers (Lin et al., 2020a). Though these solutions are interesting and relevant to our problem and context, in the current research, we want to rely on the results of this study before making any design choices for an advanced NER system in the music domain.

When conducting human subject studies, the quality of annotations (inter-rater agreement or reliability) is often assessed with Kappa statistic or its variations (McHugh, 2012). Yet, for NER, or more generally for labelling phrases, this statistic is less applicable as the number of negative cases on which it relies is ill-defined (Hripcsak and Rothschild, 2005). To address this issue, multiple imperfect solutions have been proposed such as to compute the Kappa statistic at the token level (Deleger et al., 2012)—however, this does not reflect the task well as each token is not tagged individually; or to estimate the negative cases by enumerating all n-grams or noun phrases from a text—however, this lacks accuracy (Grouin et al., 2011). Hripcsak and Rothschild (2005) show that when the number of negative cases gets very large, the Kappa statistic approaches the F1 score. Thus, F1 is considered a better metric, which we also adopt to measure the performance of humans and compare the NER human and algorithmic baselines.

3 Human Subject NER Study

3.1 Data Collection

For data collection we have chosen the *music suggestions* subreddit[2] as a relevant data source. Reddit is a discussion website where members can submit questions, share content and interact with other members. It is organised in subreddits built around dedicated topics. Each discussion starts with an initial post that has a title and description. From this post, threads of conversations develop. We were interested only in posts triggered by a music information seeking or recommendation need. We crawled the full subreddit with 8615 initial posts. This number corresponds to the posts in the beginning of 2020. We did not consider posts' comments.

These humans-to-humans posts asking for music recommendations are particularly relevant to study as they go beyond pre-defined frames of interaction with a text or voice-based assistant. Hence, they exhibit a realistic human use of language, which although more challenging, could help with the development of the next generation of music assistants. For NER, the existence of queries in natural language translates in a more diverse context surrounding named entities, thus in a higher query generalisation for music recommendation. By manually checking this data, we noticed that many mentioned artists or music titles were not popular. Thus, we expected most named entities to be new to the annotators, an aspect we wanted to control for, as mentioned in Section 1.

1	looking for some playlists to listen to before going to sleep i usually listen to beach house madlib etc
2	ive just started listening to grateful dead and the ramones what else have i missed
3	looking for music similar to yamashita
4	songs sounds like drive by lil peep
5	new rappers

Table 1: Examples of queries in *MusicRecoNER*.

3.2 Data Cleaning and Pre-processing

As we aimed at creating a corpus of music recommendation queries simulating human-assistant interactions, we made multiple decisions to pre-process the collected posts. We performed a manual cleaning of this data by removing those posts which directly shared music with the community; were aimed at promoting music or other music-related entities; contained explicit words; or contained only links to external music resources.

Then, we focused on *titles* only as the post content was rather long, specific to asynchronous communication; as human-assistant interactions happen synchronously, the written or spoken queries are expected to be short, composed of a few short sentences at most (Song and Diederich, 2010). We removed all references to specific music-related services in order to obtain generic queries (e.g. we removed "Youtube" from the request "music similar to my Youtube playlist"). We also removed words which were explicit markers of human-human interaction in order to ensure compatibility with human-assistant interaction. For instance, we removed phrases such as "hello guys" or "could anybody".

We performed the rest of the pre-processing steps to ensure that the queries contained, to some extent, the kind of noise that could be found in *transcribed* voice queries too, such as those obtained when interacting with a voice assistant. For this, we transformed the text in lowercase and removed punctuation marks and emoticons (with some ex-

---

[2] `www.reddit.com/r/musicsuggestions/`

ceptions when the symbol was part of the named entity's pronunciation such as "&"). We kept content from parentheses when found at the end of a post title, otherwise we removed it. Although very common in automatic transcriptions, we did not introduce any artificial noise regarding the spelling of named entities. Still some noise was present as Reddit authors sometimes made misspelling errors. These steps were done automatically. We release both the original and pre-processed data. All keywords used in the described steps are in Appendix A. We show multiple query examples in Table 1.

3.3 Annotation Guidelines and Procedure

We sampled multiple subsets of 600 queries each from the cleaned and pre-processed corpus. This number was established by estimating the required time for the experiment to be maximum 2 hours per annotator, based on an initial trial on 751 queries. The annotation guidelines were also tested in the trial experiment and refined after. The subjects were informed that the goal was to identify names of artists (e.g. bands, singers, composers) and titles of works of art (e.g. albums, tracks, playlists, soundtracks) in unformatted music-related queries. We requested the annotators not to consult the Internet as we wanted them to rely on the query content only and on their own previous knowledge.

We then introduced the labels: *Artist_known*, *Artist_deduced*, *WoA_known*, *WoA_deduced*, and *Artist_or_WoA_deduced* with examples. The last one was for ambiguous cases of named entity typing, but allowed the annotators to segment. Segmentation is still very relevant when parsing natural language queries for music recommendation as the type could be eventually disambiguated with the help of a search engine, for instance. The other labels corresponded to *Artist* and *WoA* types, completed by whether the annotator knew the entity from before or deduced it from query's content, as we wanted to keep track of *entity's novelty*.

Then, we introduced challenging annotation cases with guidelines on how to proceed. We instructed the annotators to include *Artist* and *WoA* named entities from other domains too such as movies or video games, but to ignore all the other entity types such as countries or music genres; to consider the innermost entities in case of nested entities; to ignore implicit entities such as "this singer"; to always include the "'s" from the possessive case as part of the named entity; and to consider a named entity with misspelled, translated and transliterated words as correct. The final form of the guidelines is shown in Appendix B.

Ten annotators (1 for the trial, and 9 for the main study) were recruited from our organisation with the condition to be fluent in English. Each set of 600 queries (DS1, DS2, and DS3) was given to three annotators. The annotation campaign was performed using Doccano (Nakayama et al., 2018). The guidelines and the annotation tool were presented in a 30-minute workshop where annotators could ask questions. They could consult the guidelines and contact the researchers if they needed any clarification during the experiment too. After, one week was set aside for each annotator to complete the annotations individually.

3.4 Ground-truth *MusicRecoNER* Corpus

Often in related works, a ground-truth corpus is obtained by using full agreement or majority voting (Nangia and Bowman, 2019; Lin et al., 2020a) (e.g. tag named entities on which at least two out of three human annotators agreed). However, here, because we wanted to establish a human baseline and have a corpus exhaustively annotated, we labelled the ground-truth corpus ourselves from scratch.

Compared to the settings of the human subject study, we had access to the original Reddit post titles including capitalised text and punctuation. During the annotation, we used web and music streaming search engines to check if certain entities were *Artist* or *WoA*. The full Reddit post was also used to disambiguate cases when a name could be both an *Artist* or a *WoA*. The most challenging examples were discussed among us. The ground-truth preparation together with the adjudication discussions happened over several weeks, as the process to disambiguate entities was more complex.

Statistics about each dataset are presented in Part I of Table 2. *Artist* mentions are more common than *WoA* mentions. Regardless of the type, we could notice that a large majority of entity mentions are unique in each dataset. The mean number of entity mentions per query is around 2, with the maximum varying between 6 and 10. From these, the proportion of queries with no entity is on average 56%.

4 Evaluation protocol

4.1 Fine-tuned Transformer Baselines

The goals of the human subject NER study are to establish a human baseline on this challenging dataset

	Artist$_t$	**Artist$_u$**	**WoA$_t$**	**WoA$_u$**	**%query$_{w/oents.}$**	**ents./query**	**Train**	**Pre-train**	**Human**
DS1	303	289	208	202	58%	2.0 ± 1.0	15%	51%	29%
DS2	285	271	221	220	56%	1.9 ± 0.9	14%	43%	30%
DS3	299	284	229	229	57%	2.0 ± 1.1	15%	44%	24%
Trial	383	360	270	269	56%	2.0 ± 1.0	11%	47%	27%

Table 2: Part I shows the total ($[\text{Type}]_t$) and unique ($[\text{Type}]_u$) numbers of *Artist* and *WoA* mentions; % of queries with no entities (%query$_{w/oents.}$); and per query mean and std. of entity mentions (ents./query). Part II shows % of unique *test* entities in the *train* set (Train), seen during model *pre-training* (Pre-train) or known to *humans* (Human).

of noisy queries for music recommendation and to learn from the human linguistic behavior in comparison to the most common NER systems nowadays, the fine-tuned transformers. We consider three language models proven to have good results in various natural language tasks including language understanding, sequence labeling or text classification: BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and MPNet (Song et al., 2020).

BERT (Devlin et al., 2019) is a multi-layer bidirectional encoder based on the original Transformer architecture (Vaswani et al., 2017). It is pre-trained on: 1) the cloze task, i.e. to predict a masked token from the left and right context; and 2) next sentence prediction, i.e. to predict the next sentence from a given one. **RoBERTa** (Liu et al., 2019) has the same architecture as BERT, but incorporates multiple training steps proven to lead to an increased performance than the original model: the training of the model using more data, with larger batches, on longer sequences and for a longer time; and keeping only the cloze task as a pre-training objective while applying a dynamic masking schema to the input training data. **MPNet** (Song et al., 2020) proposes a new pre-training objective by integrating the masked language modeling objective of BERT and the permuted language modeling objective introduced in XLNet (Yang et al., 2019). That is, it models the dependency among the masked tokens at prediction (i.e. takes into account the already predicted masked tokens to generate the current one), while providing visibility on the position information of the full sentence (i.e. the positions of the masked token and the next ones to be predicted).

We fine-tune the pre-trained versions of these models released in the *huggingface transformers* library (Wolf et al., 2020) for token classification / sequence labeling. We took the largest available version for each of them: *bert-large-uncased*, *roberta-large*, and *mpnet-base*. From all, only BERT is pre-trained on uncased text.

During experiments, we noticed that the model initialisation had a large impact on the results. This instability is well-documented in the past work, especially when the corpus for fine-tuning was small (Zhang et al., 2021). Thus, to overcome bad initialisation and have more coherent results over different runs, we re-initialized the last layer of each pre-trained model. This also led to faster convergence and more efficient fine-tuning. We also tried to increase the number of the re-initialized layers to 2, but the results were similar or sometimes worse.

4.2 Evaluation Metrics and Schemes

Precision (P), recall (R) and F1 are commonly used to evaluate automatic NER systems (Yadav and Bethard, 2018). In our evaluation, we extend these metrics to support a more detailed benchmark and understanding of the kind of errors a NER system makes. Namely, we also allow for a relaxed system's evaluation, when either segmentation or typing is correct, but not necessarily both.

A NER system can produce various types of outcomes (Chinchor and Sundheim, 1993a; Chinchor, 1991). Inspired by this and Batista (2018), all NER outcomes, which we denote O, can be:

- *Correct* outcomes (O_c): predicted and ground-truth entities match.
- *Missing* outcomes (O_m): system entirely fails to spot a ground-truth entity.
- *Spurious* outcomes (O_s): false entities are produced by the system.
- *Incorrect* outcomes (O_i): predicted and ground-truth entities do not match because of either typing or segmentation errors.

To classify the predictions of a NER system in these categories, we first need to fix *an evaluation schema*. The most common one in the literature is the *Strict* match (UzZaman et al., 2013; Chinchor, 1991) when both segmentation and typing are correct. Under the *Strict* schema, a prediction is *incorrect* when its boundaries were correct but not its

Ground-truth		**Predicted**		*Strict*	*Exact*	*Type*
Artist	the beatles	*Artist*	the beatles	o_c	o_c	o_c
Artist	the beatles	*WoA*	the beatles	o_i	o_c	o_i
Artist	the beatles	*Artist*	beatle	o_i	o_i	o_c
Artist	the beatles	*WoA*	beatle	o_s	o_s	o_s
		WoA	love	o_s	o_s	o_s
Artist	the beatles			o_m	o_m	o_m

Table 3: Example of outcomes under various evaluation schemes.

type, or when its type was correct but not its boundaries. All other cases (e.g. partial segmentation with incorrect type) are classified as *spurious*.

The *Exact* schema classifies a prediction as *correct* when its boundaries match those of the ground-truth, regardless of its type. In contrast, the *Entity* schema classifies a prediction as *correct* when its type matches that of the ground-truth, regardless of its boundaries. For these latter schemes, *incorrect* is adapted from its definition in *Strict*; *missed* and *spurious* are the same too.

We use another class of outcomes, *partial* (O_p), only when computing the human performance. As described in Section 3.3, humans could annotate a text as *Artist_or_WoA_deduced*. Thus, whenever a human prediction had this label and matched exactly the boundaries of the ground-truth entity, *partial* was incremented and contributed to the final scores with a factor of 0.5 (Chinchor and Sundheim, 1993b), as follows:

$$R = (|O_c| + 0.5 * |O_p|)/(|O| - |O_s|) \quad (1)$$

$$P = (|O_c| + 0.5 * |O_p|)/(|O| - |O_m|) \quad (2)$$

We exemplify the different outcomes under the mentioned schemes in Table 3.

One practical detail regarding the calculation of the evaluation metrics is that we had to apply some segmentation corrections before, to cover the situations when human annotations started or finished in the middle of a word. This could appear because Doccano did not force automatically an alignment to a desired tokenization (entire words). Thus, we corrected the start or end index of the concerned span by moving them to the left or right, based on a simple heuristic with regard to the closest found separating character (space or newline) to the concerned word. We did not intervene when an entity was composed of multiple words and only a part of them were annotated, but we captured this type of errors with the used evaluation schemes. No correction was needed in the case of model annotations as, during fine-tuning, we propagated the label of the first word token to the rest; hence, the labels were always consistent for all word tokens.

4.3 Evaluation Scenarios

We explicitly consider the novelty of entities. In the case of humans, this was encoded in the annotation process as we introduced the labels suffixed with *_known*. Fine-tuned models could have seen music entities from the test set during pre-training, when they were exposed to a large amount of unlabelled data or during fine-tuning, if the train and test sets had common entities. While this latter exposure could be easily checked, the pre-training exposure is more challenging to assess as it requires access to the pre-training data or to find other ways to test exposure based on the model only (Epure and Hennequin, 2022; Tänzer et al., 2022).

The solution we adopted targeted BERT, which performed on par with the other models as revealed in Section 5. BERT is pre-trained on Wikipedia and BookCorpus (Devlin et al., 2019). Thus, music entities could be found more likely in the Wikipedia content. However, some music entities could be quite rarely mentioned in Wikipedia compared to others. To quantify BERT's exposure to an entity e we used the following method. First, we tried to link each entity to Wikipedia by querying the Wikidata knowledge base (Vrandečić and Krötzsch, 2014). We re-ranked the returned results to give priority to music entities and returned the first entity whose type was in a pre-defined type list (see Appendix C). Second, we computed exposure by adapting the metric proposed by Carlini et al. (2019):

$$\text{expo}(e) = \begin{cases} \log|\mathcal{S}| - \log \text{rank}(e) & e \in \text{Wiki.} \\ 0 & e \notin \text{Wiki.} \end{cases} \quad (3)$$

where $\mathcal{S}$ represents all Wikipedia named entities and the function *rank* considers entity popularity (higher the popularity, lower the rank). We retrieve $\mathcal{S}$ and entity counts from Wikipedia2Vec (Yamada et al., 2020). We manually checked the linking

Model	**Artist**	**WoA**	**Macro**
BERT	0.80 ± 0.03	0.72 ± 0.04	0.76 ± 0.03
RoBERTa	0.77 ± 0.01	0.71 ± 0.05	0.74 ± 0.03
MPNet	0.80 ± 0.03	0.72 ± 0.05	0.76 ± 0.04

Table 4: *F1* scores under the *strict* evaluation schema.

for 300 random entities. 82% were correct, either linked or not found on Wikipedia correctly. 14% were linked to music-related entities but not the right ones and the rest were errors or missed entities. Examples of entities with high exposure values are: *the beatles*, *elvis*, *pink floyd*, *metallica*, *drake*, *johnny cash*, *eminem*, *nirvana*, and *coldplay*. We could notice that all are of type *Artist*.

5 Results and Discussion

We report scores using 4-fold cross-validation on the datasets presented in Table 2. Means and standard deviations (std.) are computed over different folds, different initialisation seeds for the model, and different human annotators. In most cases, this was over 12 data points as, for each model, the results were aggregated over each dataset as a test and 3 different initialisation seeds[3] and for the human evaluation, over each dataset as a test and 3 human predictors per dataset.

When comparing BERT and the other models in Table 4, BERT and human baselines in Tables 5 and 6, and results on Seen versus Unseen entities obtained either by humans or BERT in Table 7, scores in bold are statistically larger (p-value= 0.05). We test statistical significance with the Mann-Whitney U Test (Wilcoxon Rank Sum Test, Mann and Whitney 1947), which assesses under the null hypothesis that two randomly selected observations X and Y come from the same distribution.

5.1 Fine-tuned Transformer Baselines

Table 4 shows that the fine-tuned BERT, pre-trained on uncased text, and MPNet yield the largest *F1* scores for each entity type or overall. RoBERTa is statistically comparable and only marginally lower than the other models. Although MPNet and RoBERTa share the same pre-training corpus and the Transformer architecture, the addition of the permuting language objective to the cloze task gives a slight advantage to MPNet. We use BERT for the rest of the experiments.

	Artist		
	Strict	Exact	Entity
BERT	0.80 ± 0.02	0.84 ± 0.02	0.83 ± 0.02
human	0.77 ± 0.06	0.84 ± 0.05	0.81 ± 0.05
	WoA		
	Strict	Exact	Entity
BERT	0.71 ± 0.04	0.75 ± 0.04	0.78 ± 0.04
human	0.74 ± 0.07	0.79 ± 0.07	0.80 ± 0.05

Table 5: *F1* scores under different evaluation schemes.

		P	R
Artist	BERT	0.79 ± 0.02	**0.82 ± 0.03**
	human	**0.82 ± 0.04**	0.73 ± 0.07
WoA	BERT	0.67 ± 0.04	0.74 ± 0.05
	human	**0.78 ± 0.07**	0.70 ± 0.08

Table 6: *P*recision (P) and and *R*ecall (R) under the *strict* evaluation schema.

5.2 Humans vs. Fine-tuned BERT

Table 5 shows that the performance of BERT is comparable to that of the human baseline in terms of *F1* score. However, Table 6 shows that humans and BERT perform differently in terms of *precision* and *recall*. Humans have a higher *precision*, for both *Artist* and *WoA*, whilst BERT has a marginal or significantly larger *recall* than humans, especially for *Artist*. We confirmed that this phenomenon was not due to a particular precision / recall compromise by testing various precision / recall value and optimizing on F1. Also, BERT has a lower *precision* than the *recall*, but we see the opposite for humans. Considering Equations 1 and 2, the model appears to hypothesize spurious entities more often, while humans tend to miss entities more often.

Table 5 also shows that the *F1* scores under *Exact* and *Entity* schemes are larger than under *Strict* as some of the errors produced are because of segmentation or typing. However, we can notice a different behaviour for the two entity types for both BERT and humans. In the case of *WoA*, the *Entity F1* scores are slightly larger than those obtained under the *Exact* schema, showing that boundary errors happen more frequently. On the contrary, for *Artist* entities, the segmentation is more often correct, but the typing is wrong.

5.3 Error Analysis

Figure 1, showing a detailed error analysis, confirms that indeed BERT has more often *spurious* outcomes than humans, for both entity types. Also, humans miss to annotate ground-truth entities more often than BERT. We can equally observe that BERT is highly superior in identifying correct

---

[3] All the models were trained and tested on the ground-truth datasets, and did not consider annotator-specific sets.

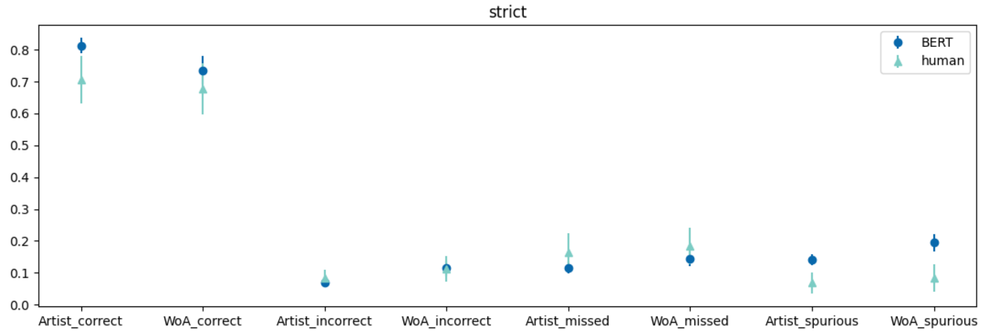

Figure 1: Normalized *correct*, *incorrect*, *missed* and *spurious* outcomes per entity type under *strict*.

named entities. Previous works on NER (Lin et al., 2020a; Epure and Hennequin, 2022) have discussed that a system should learn to exploit the context (i.e. the non-entity words) rather than entity memorisation to generalise. However, the high number of correctly recognised entities as well as the frequent spurious entities suggest that this may not be the case here; and BERT's behaviour may be linked to entity exposure. As shown at the end of Section 4.3, the entities with the highest exposure score were of type *Artist*. We could see in Figure 1 that there are a lot more correct *Artist* entities, and the number of *missed* and *spurious* outcomes for *Artist* is lower, which seems to be aligned with our hypothesis related to entity exposure.

5.4 Impact of Entity Exposure

In Table 2, Part II, we show the percentage of entities known by at least one annotator among the three in each dataset. This varies between 24% and 30%. In practice, each annotator has known at most this number of entities, which confirms that most entities from the collected corpus were new to our subjects. The entity exposure is much larger for BERT. While the train and test sets share only maximum 15% of the entities, BERT has seen up to a half of corpus' entities during pre-training.

To check the model's performance on seen versus unseen entities, we show *Recall* scores for these groups in Table 7. *Seen* entities are those present in the train set or with $expo(e) > 1$. *Unseen* entities have $expo(e) = 0$ and are not known to humans. The rest of the entities are discarded from the evaluation. BERT's recall on *Seen* is much larger than on *Unseen*, which confirms our hypothesis that memorisation plays a role. However, the model seems to rely significantly on context too given that the results on Unseen are still quite high.

We also report the results of humans in Table 7 and see a similar pattern. Although the split is made considering *the model's exposure*, humans are also very likely to know entities from *Seen*. The lower humans' scores on *Unseen* show that the recognition of these entities is quite challenging, possibly because of insufficient context. For example, "songs bands similar to sales getting it on off and on and porches mood" contains an enumeration that is difficult to segment and type (*Artist*: "sales", "porches"; *WoA*: "getting it on", "off and on", "mood"). Also, entity typing is ambiguous in "anything similar to some people say" (*WoA*). For these imperfectly recognised entities, including external resources such as gazetteers or search engines might be an option to explore.

6 Conclusion

In this work, we investigated the human linguistic behavior when performing NER in the music domain. We created *MusicRecoNER*, a new corpus of complex noisy queries for recommendations annotated with *Artist* and *WoA* entities. We then designed and conducted a human subject research study to establish a human baseline and learn from its comparison with the most popular systems nowadays, fine-tuned transformers. We performed a thorough evaluation covering multiple metrics, schemes and scenarios, including a careful analysis of the impact of entity exposure on results.

The results obtained by the algorithmic baselines were comparable to the human ones. Yet, the detailed evaluation showed that humans yielded a better precision while the model had a better recall, linked also to entity exposure during pre-training and fine-tuning. Thus, when evaluating fine-tuned pre-trained models, checking their performance on new entities shows their real generalisation ability.

	Artist		**WoA**	
	Seen	Unseen	Seen	Unseen
BERT	**0.86 ± 0.03**	0.74 ± 0.05	**0.81 ± 0.05**	0.69 ± 0.06
human	**0.77 ± 0.07**	0.63 ± 0.08	**0.74 ± 0.08**	0.66 ± 0.09

Table 7: *R*ecall scores under the *strict* evaluation schema on Seen and Unseen.

Regarding the NER evaluation protocol, human performances were much better under a more relaxed schema focused on segmentation or typing only. Such a schema could prove a more realistic setup to aim to when training models too. Also, we noticed that the relevant schema depended on the entity type as *Artist* was better segmented, while *WoA* better typed.

Contrary to previous claims, we show that, in our domain, NER in challenging conditions such as noisy text, and irregular or novel entities is rather hard for humans even when provided with complex instructions and multiple examples. Thus, although we could learn from the human linguistic behaviour, we should not, by default, assume their results to be a target for any NLP problem. For some tasks, it is common when establishing a human baseline to consider it as an upper bound for the model. This is not necessarily a desirable outcome in our case as it would imply mislabelling $1/3$ *WoA* entities. More generally, as we also showed by studying the impact of entity exposure, algorithms can store a lot more knowledge than humans and one may want to leverage this as much as possible.

As for proposing a better system to perform music NER, one next step would be to continue the model's pre-training on more related data, in our case music, to get even more exposure, or to integrate gazetteers. Still, given the rate of new entities in our domain, forcing the model to rely more on context, when context is not confusing, is another desirable future direction. In case of context ambiguity, asking questions to clarify the request and supporting user interaction in natural language could be ultimately the answer towards a more suitable, but still very challenging solution. We plan to explore these ideas as future work.

7 Limitations

We further discuss the limitations of our work. The corpus of noisy complex queries in natural language we use in the human subject study and we release is built based on a single source, Reddit. The demographics of the users using Reddit are relatively narrow, with a majority being male, young, and educated[4]. Moreover, users seeking music recommendations on this type of forums may be rather "music enthusiasts" and may not represent regular music listeners. The implications are that the language employed in these queries could be specific to this category of population. Also, the mentioned entities could reflect the music taste of this type of profiles only. This latter implication turned to be an advantage for us as we ended up with many novel entities, unknown by the annotators who participated in the study. As for the first implication, we manually checked the queries, and found them quite diverse, not necessarily using a specific vocabulary but more general language expressions. An alternative to creating such a corpus could have been a Wizard of Oz experimental setup (Green and Wei-Haas, 1985). However, this would require significantly more costs and would highly depend on the type of profiles interested in participating in such a music discovery experiment.

Second, we pre-processed the corpus in order to simulate written or transcribed speech-based human-computer interactions. However, the steps we took may be largely insufficient to simulate the kind of noise found in transcriptions. As we also discussed in Section 3.2, we did not inject any artificial noise for named entities, while spelling errors when automatically transcribing them are a common problem. Another limitation regarding named entities is the computation of the model's exposure by leveraging Wikipedia. Our linking was quite rudimentary and imperfect, as we reported in Section 4.3. Moreover, for retrieving entity ranks, we used Wikipedia2Vec (Yamada et al., 2020), which is built on a slightly older Wikipedia version than the one BERT was trained on. Therefore, the results obtained by the model on the *Unseen* dataset may be slightly larger, as the model could have been exposed to some of these entities. However, our goal was to prove a phenomenon—the impact of named entity exposure on the results, even if this impact may be marginally underestimated.

Finally, the annotators recruited from our organ-

---

[4] `https://foundationinc.co/lab/reddit-statistics/`

isation have similar age and demographics. Also they likely have a richer musical background compared to regular human subjects. This signifies that, in reality, the number of novel entities could be higher, which could also impact the overall results obtained with the human baseline. Nevertheless, this hypothesis could be tested only by running subsequent studies including more subjects.

8 Ethical Considerations

We have provided most of the details about data collection, data cleaning and pre-processing, and the annotation procedure and guidelines in Section 3 and Appendices. We discuss further various ethics-related aspects not covered yet in the paper.

The dataset was gathered from the music suggestion subreddit via the Reddit API. According to the privacy policy of Reddit[5], third parties can freely access public content via the API. We have not gathered any other information besides the public posts—their titles and descriptions.

As previously mentioned, the annotators were recruited from our organisation. They performed the annotation tasks during their regular paid hours. Moreover, the participation was fully on voluntarily basis, following a public call for participation by the authors within the organisation.

Table 8: Keywords used for manually filtering out Reddit posts in the data pre-processing step.

A Data Filtering Keywords

The list of keywords used in the data cleaning and pre-processing steps are presented in Table 8. These keywords were used to filter out posts, which were manually verified after. The outcome of the verification was either to exclude these posts from the data, or to keep the posts as they were or after having removed specific words (as described in Section 3.2). We have considered both lower and upper case variations of each keyword.

B Annotation Guidelines

B.1 Introduction

The goal of this annotation experiment is to identify names of artists (e.g. bands, singers, composers) and names of works of art (e.g. albums, tracks, playlists, soundtracks, movies, video games) in music-related requests. The requests could be single- or multi-line. Also, they are unformatted, meaning that they contain no capitalized letters or punctuation marks. Also contractions such as "**Artist's** first album", "**don't**" are written as if pronounced, specifically "artists first album" and "dont".

Through this experiment, we study how well humans can identify named entities (artists and works of art) in unformatted text by relying on the *request content only*, and on one's own knowledge. For this reason, it is important that during annotation you do not consult the Internet to verify if some parts of text are named entities, but rely on your intuition after reading the text.

B.2 Named Entity Categories

There are two categories referring to the entity type *Artist*; two categories referring to the entity type Work of Art (*WoA*); and one category for dealing with ambiguous cases as follows:

1. Artist_known. This category should be used for sequences of words denoting an artist that is previously known to the annotator.

In the next request I recognize "queen" and "the clash" to be *Artist* entities because I knew them from the past: *i like* ***queen*** *and* ***the clash*** *what else should i listen to*.
Note that when "the" is part of the name (e.g. "the clash"), it should be annotated likewise.

2. Artist_deduced This category should be used for sequences of words denoting an artist that is not known to the annotator, but deduced from the text.

In the next request I recognize "stephan forté" to be an *Artist*: *looking for something like the first album of* ***stephan forté***.
I have never heard of this artist before, but I deduced it from the request's content.

3. WoA_known This category should be used for sequences of words denoting a work of art that is previously known to the annotator.

In the next request I recognize "karma police" to be a *WoA* because I knew it before: *im a very picky music listener but i love* ***karma police*** *any other suggestions*.

4. WoA_deduced This category should be used for sequences of words denoting a work of art that is not known to the annotator, but deduced from text.

In the next request I recognize "special affair" to be a *WoA*: *songs like* ***special affair***.
I have never heard of this work of art before, but I deduced it from the request's content.

5. Artist_or_WoA_deduced This category is used for sequences of words recognised to denote an artist or a work of art, but choosing between the two entity types is challenging.

In the next request I recognize "superunloader" to be either an *Artist* or a *WoA*: *music like* ***superunloader***
I have never heard of this before and it is difficult for me to distinguish between the two options.

B.3 (Challenging) Examples

Please read the following examples carefully and re-consult them during the experiment whenever needed.

Relevant named entities not related to music. A text could contain other types of works of art such as movies or video games. Annotate these names using the category *WoA*. Similarly, annotate with the *Artist* category movie directors, filmmakers, music composers and so on. All the other types of named entities not related to *Artist* and *WoA* must be ignored (e.g. names of countries, music genres etc.).

In the example below, "gemini" is annotated as *WoA* and "ang lee" as *Artist*: *i recently watched this film **gemini** made by **ang lee** and liked the soundtrack any similar recommendations of this*.

Multiple named entities clearly delimited. A text could contain multiple entities which are clearly delimited by other words such as "by", "from", "and" etc. Please annotate all of them individually.

In the example below, "heartbeat" is a *WoA* and "annie" is an *Artist*: *songs with similar vibe and structure as **heartbeat** by **annie***.

In the example below, "hallelujah" is a *WoA* and "jeff buckley" is *Artist*: *other beautiful songs by **jeff buckley** apart from **hallelujah***.

Multiple named entities with no delimitation. A text could contain multiple entities which are not clearly delimited. Try to annotate each segment of text individually with its corresponding named entity category.

In the example below, if the annotator recognizes the entities, then 3 separate *Artist* entities should be selected, namely "imagine dragons", "bastille", and "daya": *singers bands like **imagine dragons bastille** and **daya***.

However, if not all entities are known from the past, then the unknown span of text could be annotated either as *Artist_or_WoA_deduced*, *Artist_deduced* or *WoA_deduced* depending on the content and the annotator's intuition. For instance, if the annotator recognizes only "imagine dragons" but not the rest, then "bastille and daya" could be considered either 1 entity ("bastille and daya") or 2 entities ("bastille", "daya") and further annotated with any of the 3 categories mentioned above.

Named entities collated with 's from the possessive case. In this case, include the "s" as part of the named entity.

In the example below, "toni braxton" is the real name of the artist, but "toni braxtons" (coming from "toni braxton's") is actually annotated as an *Artist* entity: *newer 2005+ ballads in the style of **toni braxtons** un break my heart and **stevie wonders** all in love is fair*. Similarly for "stevie wonders" (coming from "stevie wonder's").

Nested named entities. A text could contain nested entities. This means that there is a larger text segment that could be considered as an entity and a smaller text segment inside the larger one that could be also considered as an entity.

In this case, always favor the *innermost* text segment with an exception which is described below. Multiple examples are given further.

In the example below, "treasure planet" is annotated as *WoA* and not "treasure planet soundtrack" (which is also a *WoA*, but the innermost one is chosen): *looking for calm violin music very similar to the first 34 seconds of 12 years later from the **treasure planet** soundtrack*.

In the example below, "ezra collective" and "ty" are annotated as 2 separate *Artist* entities and not as one: "ezra collective feat ty": *recommend me some good jazz hip hop songs with rap like chapter 7 by **ezra collective** feat **ty***. There is also a third entity, "chapter 7", annotated as *WoA*):

In the example below, although "i took a pill in ibiza seeb remix" could be considered as a *WoA*, the innermost entities are annotated instead, namely "i took a pill in ibiza" as *WoA* and "seeb" as *Artist*: *songs similar to **i took a pill in ibiza seeb** remix*.

Exception: if the name of a well-known band that you recognize is composed of 2 or more individual artist names, then annotate the band name using the category *Artist_known*. In the example below, I recognized that "emerson lake and palmer" is the name of a band despite the fact that it refers to three individual artists ("emerson", "lake", "palmer"): *other artists similar to **emerson lake and palmer***.

Explicit versus implicit named entities. There are cases when an *Artist* or a *WoA* are mentioned in text, but these entities are not explicitly named. For instance, neither "the last album", nor "this singer" are explicit named entities in the request below; hence they must not be annotated: *show me* *something similar to the last album of this singer.*

(Incorrect) Variations of the original named entities. The text may contain variations of the original names of the entities (including misspelled, missing, translated or transliterated words). Normally, in order to recognize an incorrectly written named entity, the named entity must be already known to the annotator. In these cases, even if the named entity does not match exactly the real name, the annotator is required to annotate the corresponding span of text using the named entity categories ending with the "_known" suffix.

In the example below, the annotator recognizes "hey ponchuto" to be mistakenly written: *fast dancey blues or songs like **hey ponchuto** from **the mask***. The original named entity which the annotator knows from the past is "hey pachuco". Thus, "hey ponchuto" is annotated as *WoA_known*. Note that "the mask" is a WoA too (a movie).

C Pre-defined Entity Types for Wikidata Linking

In order to ensure that the entity linking gives priority to music-related entities, we re-rank the returned results. Specifically, we return the first entity whose type matches any of the criteria below:

- *Artist*: type matches exactly one of the following types—*musical group*, *rock group*, *supergroup*, *musical ensemble*, *girl group*, or it contains one of the following strings—*band*, *duo*, *musician*, *singer*.

  WoA: type matches exactly one of the following types—*album*, *musical work/composition*, *song*, *single*, *extended play*, or it contains one of the following strings—*album*, *song*.

If the previous matching fails, the fallback is the first entity of type *human* for an *Artist* entity, or of type *video* or *film* for a *WoA* entity. If none of these type criteria is met, then an empty string, corresponding to failed linking is returned.

D Computational Information

For training and evaluation, we had a 32-core Intel Xeon Gold 6134 CPU @ 3.20GHz CPU with 128GB RAM, equipped with 4 GTX 1080 GPUs, each with 11GB RAM. Fine-tuning a single model on three datasets from the four we annotated during 3 epochs and testing it on the hold-out dataset on a single GPU took about 2 minutes.

Entity Disambiguation with Entity Definitions

Abstract

Local models have recently attained astounding performances in Entity Disambiguation (ED), with generative and extractive formulations being the most promising research directions. However, previous works have so far limited their studies to using, as the textual representation of each candidate, only its Wikipedia title. Although certainly effective, this strategy presents a few critical issues, especially when titles are not sufficiently informative or distinguishable from one another. In this paper, we address this limitation and investigate the extent to which more expressive textual representations can mitigate it. We evaluate our approach thoroughly against standard benchmarks in ED and find extractive formulations to be particularly well-suited to such representations. We report a new state of the art on 2 out of the 6 benchmarks we consider and strongly improve the generalization capability over unseen patterns. We release our code, data and model checkpoints at `https://github.com/SapienzaNLP/extend`.

1 Introduction

Being able to pair a mention in a given text with its correct entity out of a set of candidates is a crucial problem in Natural Language Processing (NLP), referred to as Entity Disambiguation (Bunescu and Paşca, 2006, ED). Indeed, since ED enables the identification of the actors involved in human language, it is often considered a necessary building block for a wide range of downstream applications, including Information Extraction (Ji and Grishman, 2011; Guo et al., 2013; Fatahi Bayat et al., 2022), Question Answering (Yin et al., 2016) and Semantic Parsing (Bevilacqua et al., 2021; Procopio et al., 2021). ED generally occurs as the last step in an Entity Linking pipeline (Broscheit, 2019), preceded by Mention Detection and Candidate Generation, and its approaches have traditionally been divided into two groups, depending on whether co-occurring mentions are disambiguated independently (*local methods*; Shahbazi et al. (2019); Wu et al. (2020); Tedeschi et al. (2021)), or not (*global methods*; Hoffart et al. (2011); Moro et al. (2014); Yamada et al. (2016); Yang et al. (2018)).

Despite the limiting operational hypothesis of independence between co-occurring mentions, local methods have nowadays achieved performances that are either on par or above those attained by their global counterparts, mainly thanks to the advent of large pre-trained language models. In particular, among these methods, generative (De Cao et al., 2021) and extractive (Barba et al., 2022) formulations are arguably the most promising directions, having resulted in large performance improvements across multiple benchmarks. Regardless of their modeling differences, the key idea behind these methods is to part away from the previous classification-based approaches and, instead, adopt formulations that better leverage the original pre-training of the underlying language models. On the one hand, generative formulations tackle ED as a text generation problem and train neural architectures to generate auto-regressively, given a mention and its context, a textual representation of the correct entity. On the other hand, extractive approaches frame ED as extractive question answering: they first concatenate a textual representation of each entity candidate to the original input and then train a model to extract the span corresponding to the correct entity.

Although they have admittedly attained great improvements, both in- and out-of-domain, to the best of our knowledge, previous works on both these formulations have limited their studies to a single type of textual representation for entities, that is, their title in Wikipedia. This strategy, however, presents a number of issues (Barba et al., 2022) and, in particular, often results in representations that

---

May 2-6, 2023 ©2023 Association for Computational Linguistics

are either insufficiently informative, or are even virtually indistinguishable from one another. In contrast to this trend, we address this limitation and explore the effect of more expressive textual representations on state-of-the-art local methods. To this end, we propose complementing Wikipedia titles with their description in Wikidata, such that, for instance, the candidates for *Ronaldo* in *Ronaldo scored two goals for Portugal* would be *Cristiano Ronaldo: Portuguese association football player* and *Ronaldo: Brazilian association football player*, rather than the less informative *Cristiano Ronaldo* and *Ronaldo*, respectively. We test our novel representations on generative and extractive formulations, and evaluate against standard benchmarks in ED, both in and out of domain, reporting statistically significant improvements for the latter group.

2 Method

We now formally introduce ED and the textual representation strategy we put forward. Then, we describe the two formulations with which we implement and test our proposal.

ED with Entity Definitions. Given a mention m occurring in a context c_m, Entity Disambiguation is formally defined as the task of identifying, out of a set of candidates $e_1, \ldots, e_n$, the correct entity e^* that m refers to. Each candidate e typically corresponds to a page in Wikipedia, and, in generative and extractive formulations, is additionally associated with a textual representation $\hat{e}$ describing its meaning. Whereas previous works have considered the title that e has in Wikipedia as $\hat{e}$ (e.g. *Cristiano Ronaldo*), here we focus on more expressive alternatives and leverage Wikidata to achieve this objective. Specifically, we first retrieve the Wikidata description of e (e.g. *Portuguese association football player*). Then, we define as the new representation of e the colon-separated concatenation of its Wikipedia title and its Wikidata description (e.g., *Cristiano Ronaldo: Portuguese association football player*).

Generative Modeling. In our first formulation, we follow De Cao et al. (2021) and frame ED as a text generation problem. Starting from a mention m and its context c_m, we first wrap the span corresponding to m in c_m between two special symbols, namely <*s*> and </*s*>; we denote this modified sequence by $\tilde{c}_m$. Then, we train a sequence-to-sequence model to generate the textual representation $\hat{e}^*$ of the correct entity e^* by learning the following probability:

$$p(\hat{e}^*|\tilde{c}_m) = \prod_{j=1}^{|\hat{e}^*|} p(\hat{e}^*_{(j)}|\hat{e}^*_{(0:j-1)}, \tilde{c}_m)$$

where $\hat{e}^*_{(j)}$ denotes the j-th token of $\hat{e}^*$ and $\hat{e}^*_{(0)}$ is a special start symbol. The purpose of <*s*> and </*s*> is to signal to the model that m is the mention we are interested in disambiguating. As in the reference work, we use BART (Lewis et al., 2020) as our sequence-to-sequence architecture for our experiments and, most importantly, adopt constrained decoding on the candidate set at inference time. Indeed, applying standard decoding methods such as beam search might result in outputs that do not match any of the original candidates; thus, to obtain only valid sequences, at each generation step we constrain the set of tokens that can be generated according to a prefix tree (Cormen et al., 2009) built over the candidate set.

Extractive Modeling. Additionally, we also consider the formulation recently presented by Barba et al. (2022) that frames ED as extractive question answering. Here, $\tilde{c}_m$, defined in the same way as it was for Generative Modeling, above, represents the query, whereas the context is built by concatenating the textual representations $\hat{e}_1, \ldots, \hat{e}_n$ of the candidates $e_1, \ldots, e_n$. A model is then trained to extract the text span that corresponds to e^*. Following the same efficiency reasoning of the authors, we use as our underlying model the Longformer (Beltagy et al., 2020), whose linear attention better scales to this type of long-input formulations. Compared to the above generative method, the benefits of this approach lie in i) dropping the need for a potentially slow auto-regressive decoding process, and ii) enabling full joint contextualization both between context and candidates, and across candidates themselves.

3 Experiments and Results

In order to assess the impact of our proposal in ED, we evaluate how the performances of generative and extractive formulations change when moving from Wikipedia titles to our alternative. To this end, in this Section, we first describe our experimental setting, discussing the datasets, evaluation strategy and comparison systems we adopt. Then, we describe the architecture we use for the two formulations. Finally, we present our findings.

	Dataset	Instances	Candidates	Failures
AIDA	Train	18,448	905,916 $^{/\,79{,}561}$	5038 $^{/\,682}$
	Validation	4791	236,193 $^{/\,43{,}339}$	1360 $^{/\,296}$
	Test	4485	231,595 $^{/\,46{,}660}$	1395 $^{/\,323}$

Table 1: Number of instances, candidates and failures to map a Wikipedia title to its Wikidata definition in the AIDA-CoNLL (top) and out-of-domain (OOD, bottom) datasets. For candidates and failures, we report both their total (base) and unique (exponent) number.

3.1 Experimental Setup

Data. We follow the same experimental setting described by De Cao et al. (2021) and use the standard AIDA-CoNLL splits (Hoffart et al., 2011) for training, model selection and in-domain evaluation (AIDA); similarly, we leverage their cleaned version of MSNBC, AQUAINT, ACE2004, WNED-CWEB (CWEB) and WNED-WIKI (WIKI) (Guo and Barbosa, 2018; Evgeniy et al., 2013) for out-of-domain evaluation and use their same candidate sets, which were originally presented by Le and Titov (2018).[1] We match each entity candidate with its item in Wikidata[2] to retrieve the corresponding description. Due to inconsistencies in the datasets and different dump versions, this mapping is not always possible, and, in these cases, we fall back to employing their Wikipedia title alone. We report in Table 1 the number of instances, candidates and mapping failures in each dataset under consideration.

Evaluation. Following previous literature in ED, we compute scores over the test sets in terms of *inKB Micro* F_1. Furthermore, for each system we consider, we calculate the macro average of its performances both over all the test sets (Avg) and over the five out-of-domain datasets only (Avg$_{\text{OOD}}$).

Comparison Systems. We consider the original models presented by De Cao et al. (2021, GENRE) and Barba et al. (2022, ExtEnD), trained on AIDA-CoNLL with Wikipedia titles, as our main natural comparison systems; in particular, for ExtEnD, we evaluate against both its Longformer base (ExtEnD$_{\text{base}}$) and large (ExtEnD$_{\text{large}}$) alternatives. Furthermore, to better contextualize the performances we attain within the current landscape of ED, we also include three state-of-the-art systems, namely, the global model of Yang et al. (2018), and the variants of De Cao et al. (2021) and Barba et al. (2022), both pre-trained on BLINK (Wu et al., 2020) before fine-tuning on AIDA-CoNLL. However, we note that, differently from our work, these three systems use additional training data (9M samples) from Wikipedia, whereas, due to computational constraints, we limit our experiments to the sole usage of AIDA-CoNLL ($<$ 20K samples).

3.2 Architectures

For both our formulations, we closely follow the corresponding reference architectures. For the generative method, we use BART (406M parameters) as our underlying sequence-to-sequence model and fine-tune it on AIDA-CoNLL using a 10,000 token batch size, Adam (Kingma and Ba, 2015) as our optimizer and 10^{-5} learning rate, with 500 warm-up steps and linear decay. For the extractive method, we test and evaluate our approach on both the *base* (139M parameters) and *large* (435M parameters) versions of ExtEnD presented in the reference work, using Rectified Adam as our optimizer, with 10^{-5} learning rate, and training with a batch size of 8000 tokens. All the trainings are done for a single run on GeForce RTX 3090 graphic card with 24 gigabytes of VRAM. Henceforth, we refer to these systems as GENRE^{def}, ExtEnD$^{def}_{base}$ and ExtEnD$^{def}_{large}$, respectively.

3.3 Results

In Table 2 we show the *inKB Micro* F_1 score that our models and their comparison systems achieve on the datasets under consideration. As a first note, we point out that, for easier comparability between our experiments, we reproduce the original AIDA-CoNLL models of both De Cao et al. (2021) and Barba et al. (2022). While we attain comparable performances for the latter, and hence omit it, we find that our own implementation of GENRE, which we denote in Table 2 by GENRE†, obtains better results than its reference, especially out of domain, with an average improvement of more than 2 points.

Moving to GENRE^{def}, its behavior is definitely below its counterpart with Wikipedia titles (i.e.,

---

[1] These candidate sets were generated through count statistics from Wikipedia, YAGO and a large Web corpus.

[2] We took the latest dump (June 13th, 2022) at the moment of writing from the official Wikidata website: https://dumps.wikimedia.org/wikidatawiki/entities/

	Model	In-domain		Out-of-domain					Avgs	
		AIDA$_{dev}$	AIDA$_{test}$	MSNBC	AQUAINT	ACE2004	CWEB	WIKI	Avg	Avg$_{OOD}$
AIDA+	Yang et al. (2018)	-	**95.9**	92.6	89.9	88.5	**81.8**	79.2	88.0	86.4

Table 2: *inKB Micro* F_1 scores over the AIDA-CoNLL validation and test splits, and the out-of-domain datasets when training on AIDA-CoNLL (bottom), or on additional resources as well (top). The best score in each section is marked in **bold** and, in the bottom part, if its difference from its best alternative is statistically significant ($p < 0.01$ according to the McNemar's test (Dietterich, 1998)), we also underline it.

	Model	MFC	LFC	UE	UEM	UM
AIDA	ExtEnD$_{large}$	**98.3**	**81.6**	80.9	80.9	89.0
	ExtEnD$^{def}_{large}$	**98.3**	81.0	**86.9**	**86.5**	**92.9**
OOD	ExtEnD$_{large}$	**97.2**	82.2	73.8	74.4	77.2
	ExtEnD$^{def}_{large}$	96.5	81.5	**74.5**	**75.0**	**77.7**

Table 3: Fine-grained results analysis over the AIDA-CoNLL (top) and out-of-domain (bottom) datasets. Left to right, columns are Most Frequent Class (MFC), Less Frequent Class (LFC), Unseen Entity (UE), Unseen Entity-Mention pair (UEM) and Unseen Mention (UM). **Bold** and underline have the same meaning as in Table 2.

GENRE and GENRE†), with a drop of roughly 10 points on average. To better understand this issue, we analyzed its predictions over the validation set, but did not identify any significant error pattern. In particular, we investigated whether GENRE^{def} presented length biases or was excessively skewed towards the most frequent entities and, consequently, less apt to scale over less frequent entities or unseen mentions. Interestingly, we did not find either of these to be the case, with the two systems having similar error distributions. We believe instead that the drop might be happening as the formulation behind GENRE^{def} requires modeling a much more complex output space and more data could be needed to scale properly.

Considering, instead, extractive formulations, we find the role of definitions to be definitely more impactful. ExtEnD$^{def}_{base}$ surpasses ExtEnD$_{base}$ on 3 out of 5 out-of-domain benchmarks and on the standard test set, here by more than 1 point. However, arguably our most interesting finding is the behavior of ExtEnD$^{def}_{large}$. This system attains large statistically significant improvements on AIDA$_{test}$ (+2.4) and WIKI (+1.5) and comparable performances on CWEB.

Yet, when considering Avg and Avg$_{\text{OOD}}$, ExtEnD$^{def}_{large}$ appears to behave worse than its title-only alternative, with identical Avg and inferior Avg$_{\text{OOD}}$ performances. We argue that this is an unfortunate limitation of these two metrics, inherent to their nature of macro averages, and that statistical testing depicts a more complete landscape. On the one hand, MSNBC, AQUAINT and ACE2004 are all very small datasets (Table 1) where the apparently large performance drop between ExtEnD$^{def}_{large}$ and ExtEnD$_{large}$ is not statistically significant but rather caused by a few different classifications; to put things into perspective, on ACE2004, despite the 1.2 difference in F_1 score, the predictions of the two systems differ for a total of only 8 samples, with 5 and 2 being the number of these that only ExtEnD$_{large}$ and ExtEnD$^{def}_{large}$ get right, respectively. On the other hand, on the three remaining datasets – which are far larger – ExtEnD$^{def}_{large}$ either reports a statistically significant improvement (AIDA$_{test}$ and WIKI) or performs on par (CWEB), highlighting the benefits of our more expressive textual representations.

Finally, to further examine the impact of our proposal, we investigate the effectiveness of ExtEnD$^{def}_{large}$ over different classes of mention and label frequency, both in domain, i.e., over the test set in AIDA-CoNLL, and out of domain, i.e., over the concatenation of the five datasets, and compare it with ExtEnD$_{large}$ (Table 3). Specifically, we consider instances:

- tagged with their most frequent entity in the training set (MFC);
- tagged with a less frequent entity (LFC);
- tagged with an unseen entity (UE);
- whose (mention, entity) pair does not appear in the training set (UEM);
- whose mention does not appear in the training set (UM).

Overall, apart from the MFC and LFC classes, where the difference is not statistically significant, ExtEnD$^{def}_{large}$ fares better in all other settings, which all require scaling over unseen patterns. Most notably, it yields $+6.0$ (AIDA) and $+0.7$ (OOD) improvements, both statistically significant, on unseen entities. This further underlines the better generalization capability granted by the use of more expressive textual representations.

4 Qualitative Analysis

We report in Table 4 a selection of examples from the WIKI dataset, showing candidates with both their title-only textual representations and those produced by our proposal. What we can see is that using the sole titles can result in imposing strong assumptions on what knowledge was captured by the model under consideration during its pre-training stage. For instance, in the first example in Table 4, the model needs to know, beforehand, that *Leed Rhinos* is an English rugby league football club. Moreover, relying only on titles can also result in underspecified queries. In the second example, if we were to look only at the titles provided for the two candidates, both alternatives would arguably be equally correct. A similar issue holds for the third example: although it may appear that the system could guess that the most likely candidate is the first one, as the second alternative is explicitly stated to be in Massachusetts, this strategy does not hold when considering the actual full list of candidates, which is not reported in Table 4 due to space constraints. While the model might be able to correctly predict these instances thanks to spurious correlations in the training set (e.g., the entity *Superman* being always linked to the superhero meaning, while *Superman (comic book)* to the meaning of comic book series), Table 3 clearly shows that this strategy does not scale.

Sentence: *Hugh Waddell is a Scottish [...] professional rugby league footballer [...] has played [...] at club level for [...] Leeds [...]*
Previous Candidates:
✗ Leeds
✓ Leeds Rhinos
New Candidates:
✗ Leeds: city in West Yorkshire, England
✓ Leeds Rhinos: English rugby league football club

Sentence: *World Without Superman is a Superman comic book story arc published by DC Comics.*
Previous Candidates:
✓ Superman
✗ Superman (comic book)
New Candidates:
✓ Superman: superhero appearing in DC Comics
✗ Superman: comic book series featuring Superman

Sentence: *Frank Mortimer born [...] in Wakefield was an English professional rugby league footballer [...]*
Previous Candidates:
✓ Wakefield
✗ Wakefield, Massachusetts
New Candidates:
✓ Wakefield: city in West Yorkshire, England
✗ Wakefield, Massachusetts: town in Massachusetts

Table 4: Extracts from the WIKI dataset, showing candidates with both the textual representations relying only on Wikipedia titles (**Previous candidates**), and our description-enhanced proposal (**New Candidates**). Due to space limitations, out of the 100 candidates all these three examples have, we only report the first two, which always include the correct one (denoted by ✓, as opposed to the incorrect alternative marked by ✗).

5 Conclusion

In this work, we focus on a shortcoming of generative and extractive formulations in Entity Disambiguation, namely their usage of Wikipedia titles, which are often insufficiently informative, and explore the effect of more expressive representations on these formulations. While we do not witness positive gains for generative formulations, at least in the limited data and computational regime we consider, we report strong improvements on extractive formulations. Specifically, our extractive approach sets a new state of the art on 2 out of the 6 benchmarks under consideration, and, more interestingly, shows better scalability over unseen patterns, especially unseen entities.

Limitations

We believe that our work has four major limitations. First, both the generative and extractive formulations that we consider lack parallelism, as they disambiguate each mention in the input text one at a time. While batching can definitely help, it poses additional computational requirements and, what is more, the same (but for the position of the <*s*> and </*s*> special symbols) input text would still need to be encoded multiple times. Second, our representation strategy requires the availability of descriptions in the target language in Wikidata (or some other knowledge base with a mapping from Wikipedia titles). While this data is readily available for English, this might not be the case for several other mid-to-low-resource languages. Third, both our formulations are local and, granted that pre-trained language models have certainly bridged the gap with global alternatives, their underlying independence assumption is still limiting. Finally, our proposal does incur an increased computational cost, with the textual representations getting considerably longer: while using Wikipedia titles results in sequences with an average subword length over AIDA-CoNLL of 7 and a 99th percentile of 14, adding descriptions nearly doubles the average, reaching 12.5, and makes the 99th percentile hit 29.

Abstract

Document-level neural machine translation (NMT) has outperformed sentence-level NMT on a number of datasets. However, document-level NMT is still not widely adopted in real-world translation systems mainly due to the lack of large-scale general-domain training data for document-level NMT. We examine the effectiveness of using Paracrawl for learning document-level translation. Paracrawl is a large-scale parallel corpus crawled from the Internet and contains data from various domains. The official Paracrawl corpus was released as parallel sentences (extracted from parallel webpages) and therefore previous works only used Paracrawl for learning sentence-level translation. In this work, we extract parallel paragraphs from Paracrawl parallel webpages using automatic sentence alignments and we use the extracted parallel paragraphs as parallel documents for training document-level translation models. We show that document-level NMT models trained with only parallel paragraphs from Paracrawl can be used to translate real documents from TED, News and Europarl, outperforming sentence-level NMT models. We also perform a targeted pronoun evaluation and show that document-level models trained with Paracrawl data can help context-aware pronoun translation. We release our data and code here[1].

1 Introduction

The Transformer translation model (Vaswani et al., 2017), which performs sentence-level translation based on attention networks, has achieved great success and significantly improved the state-of-the-art in machine translation. Compared to sentence-level translation, document-level translation (Xu et al., 2021; Bao et al., 2021; Jauregi Unanue et al., 2020; Ma et al., 2020; Maruf et al., 2019; Tu et al., 2018; Maruf and Haffari, 2018) performs translation at document-level and can potentially further improve translation quality, e.g., document-level context can help word disambiguation for translating words with multiple senses, document-level translation can help pronoun translation which requires context outside of the current sentence (Müller et al., 2018), document-level translation can improve document-level lexical cohesion in the translation (Voita et al., 2019).

Document-level neural machine translation (NMT) has received much attention in recent years (Bao et al., 2021; Donato et al., 2021; Fernandes et al., 2021; Kang et al., 2020; Saunders et al., 2020; Yu et al., 2020; Zheng et al., 2020; Yang et al., 2019; Kuang et al., 2018; Bawden et al., 2018; Zhang et al., 2018; Voita et al., 2018; Kuang and Xiong, 2018). Existing works showed that document-level translation can outperform sentence-level translation for a number of datasets, such as TED, News, Europarl (Bao et al., 2021; Donato et al., 2021; Xu et al., 2021). Although document-level NMT has shown promising results on a number of benchmarks, document-level NMT is still not widely adopted in real-world translation systems mainly due to the lack of large-scale general domain training data for document-level NMT.

We examine the effectiveness of using Paracrawl (Bañón et al., 2020) for learning document-level NMT. Paracrawl is a large-scale parallel corpus crawled from the Internet and contains data from various domains. The official Paracrawl corpus[2] was released as parallel sentences (extracted from parallel webpages) and therefore previous works only used Paracrawl for learning sentence-level translation. In this work, we extract parallel paragraphs from Paracrawl parallel webpages using automatic sentence alignments and we use the extracted parallel paragraphs as parallel documents for training document-level translation models. We show that document-level NMT models trained with only parallel paragraphs from Paracrawl can

be used to translate real documents from TED, News and Europarl, outperforming sentence-level NMT models and also improving context-aware pronoun translation (Müller et al., 2018).

2 Extracting Parallel Paragraphs from Paracrawl

Paracrawl (Bañón et al., 2020) is a large-scale parallel corpus crawled from the Internet and contains texts from various domains. The official Paracrawl corpus was released as aligned sentence pairs. For high-resource language pairs like German-English, the Paracrawl corpus provides 278M aligned sentences for the translation task. As Paracrawl was released as aligned sentence pairs, previous work only used Paracrawl for learning sentence-level translation. However, as described in the Paracrawl documentation, Paracrawl was constructed by first identifying aligned webpages (URLs) and then aligning sentences within aligned webpages. Although texts in parallel webpages tend to be noisy and are only loosely aligned, we demonstrate that extracting parallel paragraphs from Paracrawl parallel webpages using automatic sentence alignments can provide effective training data for learning document-level translation. Below we describe how we extract parallel paragraphs from Paracrawl.

Extracting We extract parallel paragraphs from Paracrawl and examine the effectiveness of using these aligned paragraphs for learning document-level NMT. We used German-English, a high-resource language pair, in our experiments. As the main purpose of the original Paracrawl project is to collect aligned sentences, Paracrawl did not officially release all the webpage-level aligned texts. Paracrawl only released a subset of all the aligned webpage texts, for the German-English language pair[3]. We extract parallel paragraphs from the released parallel webpages: we first download aligned webpages[4] (one German webpage is aligned with one English webpage) and then download the automatic sentence alignments (vecalign[5]) provided by Paracrawl; we then split a webpage into paragraphs according to the newline symbol; then extract aligned paragraphs from aligned webpages according to the automatic sentence alignments. We consider two paragraphs to be aligned if sentences in these two paragraphs are aligned to each other and not aligned to any other paragraphs. We discarded sentences that are not one-to-one aligned (e.g. one English sentence aligned to two German sentences) and discarded sentences that are not aligned to any other sentences. We discarded repeated paragraphs and discarded paragraphs that only contain a single sentence. Paragraphs with non-monotonic sentence alignments were also discarded.

	Paragraphs	Sentences	Words	
			En	De
Train	1.5M	5.5M	118M	109M
Dev	402	1504	32K	29K
Test	411	1510	33K	30K

Table 1: Statistics of parallel paragraphs extracted from Paracrawl.

Original vecalign	147M
After parallel paragraph extraction	11.7M
After cleaning	5.5M

Table 2: Numbers of remaining sentence pairs after different processing steps.

Cleaning To improve the quality of the extracted parallel paragraphs, we removed sentences which do not belong to the correct language[6], removed paragraphs that are too short (contain less than 30 words) and removed paragraphs with more than 50% overlap.

We randomly split the extracted parallel paragraphs into training, development and test sets as shown in Table 1. Note that, compared to the officially released Paracrawl corpus, the size of parallel paragraphs that we extracted from Paracrawl is still relatively small. This is because (i) the aligned webpages provided by Paracrawl we used for parallel paragraph extraction is only a subset of all Paracrawl data (ii) many parallel sentences were discarded due to our strict extraction rules as shown in Table 2. For future work, we will collect more webpage-level aligned Paracrawl data and test more flexible extraction rules.

We show the length statistics of the parallel paragraphs that we extracted from Paracrawl in Table 3. Compared to normal documents, the parallel paragraphs extracted from Paracrawl are generally much shorter. However, sentences in the same paragraph are usually closely related and can provide

useful context information to help the translation of each other. In our experiments, we use the extracted parallel paragraphs as parallel documents to train document-level NMT models and we show that document-level NMT models trained with only parallel paragraphs from Paracrawl can be used to translate real documents from TED, News and Europarl, outperforming sentence-level NMT models.

3 Document-level Translation with Paracrawl

3.1 Modeling

Previous works have shown that document-level NMT models can outperform sentence-level models on several benchmarks. We adopted the recent document-level translation model, G-Transformer (Bao et al., 2021)[7], in our experiments to test the effectiveness of using Paracrawl data for learning document-level translation. The G-Transformer model is based on the standard sentence-level Transformer (Vaswani et al., 2017), but uses a whole document together as the input of the model and then generates translation for the whole document. G-Transformer improves the standard Transformer model for document-level translation with extra group tags and group attention. Each word (both source and target words) in the document is assigned with a group tag to indicate which sentence this word belongs to. Compared to the standard Transformer attention, G-Transformer computes group attention using group tags to encourage local attention and reducing the hypothesis space of the attention, especially from target to source, for long documents. G-Transformer outperformed sentence-level Transformer and obtained new state-of-the-art results on three document-level translation benchmarks.

3.2 Experimental Setting

We tokenize and truecase all data with MOSES (Koehn et al., 2007) scripts, and then perform subword segmentation with byte pair encoding (BPE) (Sennrich et al., 2016) using 30k merging operations. For both the sentence-level Transformer and the document-level G-Transformer, we used the base model setting (Vaswani et al., 2017) with 6-layer encoder/decoder, 512-dimension word embedding and 2048 hidden units for the feed forward networks. Following the G-Transformer experimental settings (Bao et al., 2021), we set the max length of a document to 512 BPE tokens (if a document is longer than 512 tokens, we split it into multiple instances). For model training, we first pretrained a standard sentence-level Transformer for 100k training steps and then finetuned the sentence-level Transformer to learn document-level G-Transformer for another 100k training steps. For a fair comparison between sentence-level and document-level translation, we also applied pretraining for sentence-level translation, i.e. we train a sentence-level Transformer with 100k pretraining and 100k finetuning steps in order to compare with G-Transformer.

3.3 Evaluating with BLEU, COMET and Targeted Pronoun Evaluation

We used BLEU (Papineni et al., 2002) and COMET (Rei et al., 2020) for translation quality evaluation[8] and we performed significance testing with bootstrap resampling (Koehn, 2004). In addition to BLEU and COMET which evaluate the general translation quality, we also performed a targeted evaluation for pronoun translation following Müller et al. (2018)'s work. The correct translation of a pronoun often requires context outside of the current sentence. Therefore, evaluation of pronoun translation can demonstrate the advantage of document-level NMT models. Following Müller et al. (2018)'s work, we computed the accuracy of our models choosing the correct translation for the English pronoun "it" from the three possible German words "es", "er" and "sie". We used a context of 5 sentences for the test data[9] provided by Müller et al. (2018) for pronoun evaluation.

3.4 Training with Only Paracrawl

We trained both sentence-level Transformers and document-level G-Transformers with only Paracrawl (see Table 1) as training data. Parallel paragraphs were used as parallel documents to train document-level G-Transformers and parallel sentences contained in parallel paragraphs were used to train sentence-level Transformers.[10] For evaluation, we used test data from 4 datasets, Paracrawl, Europarl, TED and News. For Europarl, TED and News, we used the same test data following the original G-Transformer (Bao et al., 2021) work, i.e., the Europarl, TED and News test sets are parallel documents in contrast to the Paracrawl test set which is parallel paragraphs. BLEU and COMET scores are given in Table 4 as Train-Paracrawl-Only. The document-level G-Transformers achieved higher translation quality than sentence-level Transformers for all 4 test sets and only used Paracrawl as training data, which demonstrates that Paracrawl can provide useful document-level information for effective training of document-level NMT models. Table 4 also shows that the document-level information contained in Paracrawl is robust across domains as document-level G-Transformers trained with only Paracrawl data can help to translate real documents from TED, News and Europarl test sets.

Table 5 and Table 6 give results of targeted pronoun evaluation. Results show that the document-level model, trained with only Paracrawl data, significantly outperformed the sentence-level model for pronoun translation especially when the an-

---

[10] Therefore, training data for the document-level model and the sentence-level model contain the same number of sentence pairs.

tecedent location of a pronoun is outside of the current sentence (see Table 6), which again demonstrates that Paracrawl can provide useful information outside of the current sentence for effective learning of document-level NMT.

3.5 Training with Paracrawl, TED, News and Europarl Combined

We also trained translation models with training data from Paracrawl, Europarl, TED and News combined. The sentence-level Transformers were trained with sentence pairs from all the 4 training datasets. The document-level G-Transformers were trained with parallel paragraphs from Paracrawl and parallel documents from Europarl, TED and News. We then computed BLEU and COMET scores for the 4 test sets as shown in Table 4 as Train-Combined. The targeted pronoun evaluation results are also given in Table 5 and Table 6 as Train-Combined. Results show that using additional parallel documents together with parallel (Paracrawl) paragraphs as training data further improved the general translation quality (BLEU and COMET) and also helped the document-level model to obtain a higher accuracy for targeted pronoun translation evaluation.

3.6 Document-level G-Transformer for Translating Single Sentences

We also evaluated how the document-level G-Transformer (trained with parallel documents) performs for translating single sentences (i.e. each sentence is considered as a single document at test time). Table 7 shows that, when considering the general translation quality (e.g. BLEU), document-level G-Transformers can perform well for translating single sentences, even outperforming the sentence-level Transformers in Table 4 for most of the test sets. However, the targeted pronoun evaluation results in Table 8 show that the accuracy of translating pronouns with antecedent location outside of the current sentence dropped more than 10% compared to the document-level model in Table 6, which demonstrates that document-level G-Transformers indeed require context outside of the current sentence for improving pronoun translation.

4 Conclusion

As document-level translation lacks large-scale general-domain document-level training data, we examine the effectiveness of using Paracrawl data for learning document-level translation. Paracrawl was officially released as parallel sentences extracted from parallel webpages. In this work, we extract parallel paragraphs from Paracrawl aligned webpages using automatic sentence alignments and we use the extracted parallel paragraphs as parallel documents for training document-level NMT models. We show that document-level models trained with only parallel paragraphs from Paracrawl can be used to translate real documents from TED, News and Europarl, outperforming sentence-level Transformers and also improving context-aware pronoun translation.

Limitations

Compared to the officially released Paracrawl corpus (278M sentence pairs for German-English), the size of parallel paragraphs that we extracted from Paracrawl is still relatively small. This is because (i) Paracrawl only released a subset of all webpage-level aligned texts and we only extracted parallel paragraphs from these released webpage texts (ii) we used very strict rules for extracting parallel paragraphs from Paracrawl and many parallel sentences were discarded by our extraction rules. For future work, we will collect more Paracrawl webpage-level aligned data for parallel paragraph extraction and we will test more flexible extraction rules.

Poor Man's Quality Estimation:
Predicting Reference-Based MT Metrics Without the Reference

Abstract

Machine translation quality estimation (QE) predicts human judgements of a translation hypothesis without seeing the reference. State-of-the-art QE systems based on pretrained language models have been achieving remarkable correlations with human judgements yet they are computationally heavy and require human annotations, which are slow and expensive to create. To address these limitations, we define the problem of *metric estimation* (ME) where one predicts the automated metric scores also without the reference. We show that even without access to the reference, our model can estimate automated metrics (ρ=60% for BLEU, $\bar{\rho}$=51% for other metrics) at the sentence-level. Because automated metrics correlate with human judgements, we can leverage the ME task for pre-training a QE model. For the QE task, we find that pre-training on TER is better (ρ=23%) than training for scratch (ρ=20%).

github.com/zouharvi/mt-metric-estimation

1 Introduction

Quality estimation (QE) is often used in machine translation (MT) production pipelines where we need to make decisions based on the quality of an MT output but where the reference is unavailable (Specia et al., 2020, 2021). For example, QE is used in translation companies to decide whether to send a specific MT output for post-editing to a human translator or whether to use it directly (Tamchyna, 2021; Zouhar et al., 2021; Murgolo et al., 2022). In this scenario, an accurate QE system has the potential to save expensive translator effort. However, training QE models usually requires human-annotated judgements of the translation quality (Specia et al., 2013; Rubino and Sumita, 2020; Rei et al., 2020a). These human annotations are scarce and costly, especially for low-resource language directions, and may need to be replicated for new MT systems and domains (de Souza et al., 2014)

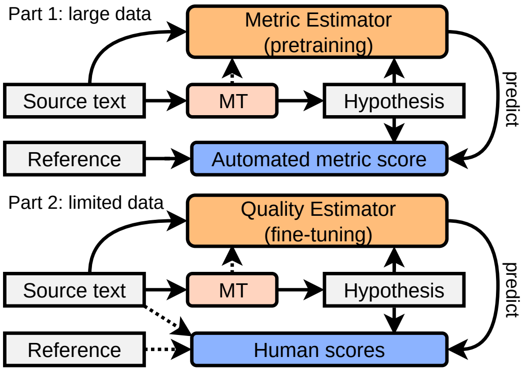

Figure 1: Pipeline for pre-training on automated metrics (top) and fine-tuning on limited quality estimation data (bottom). Dotted lines are optional dependency.

We investigate if automated MT metrics can be used to reduce the cost of learning QE models. Automated metrics can be run with no additional costs and can be used to generate large amounts of QE data. If these metrics correlate well with human judgements, this larger data can be used as a partial substitute for human data during training. Data augmentation and synthetic QE data via automated metrics has already been explored (Heo et al., 2021; Baek et al., 2020; Cui et al., 2021), though never in the pre-training & fine-tuning fashion.

Our work is guided by a simple intuition. Intuitively, human judgements can be thought of as functions depending on the target sequence and (optionally) the source and reference(s): $f_{\text{HUMAN}}([s], h, [r])$. The task of QE is to model f_{HUMAN} based only on the source s and hypothesis h. Because the function arguments of $f_{\text{HUMAN}}([s], h, [r])$ resemble those of automated metrics for MT: $f_{\text{METRIC}}([s], h, r)$, we can use the automated metrics to guide learning of the human quality judgements which are hard to obtain and

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1311–1325
May 2-6, 2023 ©2023 Association for Computational Linguistics

replicate. Generating automated metric scores is limited only by the amount of parallel data which is more abundant. Because f_{METRIC} correlates with human judgement f_{HUMAN} (Ma et al., 2019; Mathur et al., 2020), we can start by estimating f_{METRIC} and only later fine-tune to f_{HUMAN}. We refer to estimating $f_{\text{METRIC}}(s, h, r)$ as **metric estimation (ME)** as a parallel task to **quality estimation (QE)**.

We illustrate our idea of pre-training on the automatic metrics and fine-tuning on human assesments in Figure 1. Our model uses a BiLSTM with the source and hypothesis as the input (with several more features like the decoder confidence and hypothesis variance) to output a single number (metric or quality score).

Experimentally, we find the idea of mitigating data limitation for QE with ME pretraining challenging. Thus, we structure our investigation around a set of research questions. First, we try to establish that it is possible to robustly predict automated metrics and explore the associated data requirements. Then, concerned with the application and deployment of the ME model, we also check how transferrable the model is between different MT systems. We break the research down into the following questions.

RQ1: Can automated reference-based MT metrics be reliably predicted without the reference?
RQ2: What is the effect of data size on predicting automated reference-based MT metrics?
RQ3: How detrimental is the transfer between different MT systems for metric estimation models?
RQ4: Can metric estimation be used as a pre-training step for quality estimation?

We answer the research questions with experiments on the English → German language direction and replicate the main findings on 12 language pairs in total in Appendix C. We confirm that BLEU is predictable with $\rho = 60.4\%$ sentence-level Pearson's correlation and other metrics with $\bar{\rho} = 51.3\%$ (**RQ1**, Section 4.2). Authentic parallel data is needed for ME models but this can be alleviated by using more hypothesis from beam search (**RQ2**, Section 4.3). It is possible to train the ME system on one MT system and then use it on a different MT system with only a slight loss in performance (**RQ3**, Section 4.4). We find that pre-training on Translation Edit Rate (TER) (Snover et al., 2006) leads to better results than training on the QE data directly, though this approach does not outperform the state-of-the-art in QE (**RQ4**, Section 4.5).

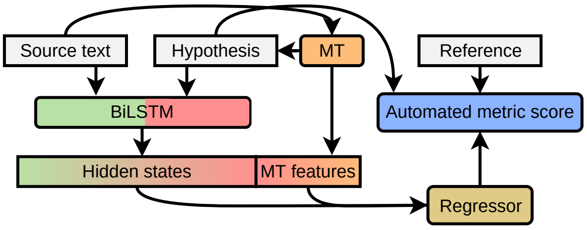

Figure 2: Metric/quality estimation model architecture.

2 Our Metric Estimation Model

Notation. Given a source sentence s and its translation, h which is an output of a MT system ($h = \text{MT}(s)$), we build a regressive ME model which outputs a numeric score that is close to the output of an automated metric that is further dependent on the reference: $f_{\text{METRIC}}(s, h, r)$. We distinguish two cases based on our level of access to the MT system: **blackbox** setting (where we assume access only to the MT system output) and **glassbox** setting (where we have access to entire MT model). In the later case, we may leverage features from the MT model to improve the ME capabilities.

Model. Our main model for ME/QE, shown in Figure 2, starts with Byte-Pair-Encoding (Gage, 1994; Sennrich et al., 2016) the source s and hypothesis h. It is followed by BiLSTM on top of concatenated source and hypothesis with a separator ($s\,\texttt{[SEP]}\,t$). The last hidden state (denoted as BiLSTM_{-1}) is extracted and fused together via concatenation with the internal MT system and other features (see the following list). This is then used in a simple feed-forward layer (FFNN) to output a single number:

$$\begin{aligned}
\text{source } s, \text{hypothesis } h &:= \text{MT}(s) \\
\Phi &= \text{BiLSTM}_{-1}(\text{BPE}(s\,\texttt{[SEP]}\,h)) \\
\Psi &= \text{Features}(\text{MT}_{\text{conf.}}(s,h), s, h) \\
\text{ME}_{\text{all}}(s,h) &= \text{FFNN}[\Phi, \Psi] \\
\text{ME}_{\text{text}}(s,h) &= \text{FFNN}[\Phi]
\end{aligned}$$

The first ME model is glassbox and the second is blackbox. In the first case, we utilize hand-crafted features and also those from the MT system (function features). Both of these models are optimized with mean-squared error against a particular metric. That is, we train separate models for each target metric (COMET, ChrF, BLEURT, BLEU, METEOR, TER) or human judgements.

$$\mathcal{L} = \frac{1}{n} \sum (\text{ME}(s_i, h_i) - f_{\text{METRIC}}(s_i, h_i, r_i))^2$$

The additional features Ψ are:

- Decoder confidence (prob and logprob).
- Source and target lengths and their relation. This is included as the distribution of errors may be different for various sentence lengths.
- Average distance and variance between hypotheses as measured by an automatic metric.

Decoder confidence. Low probability MT outputs have overall lower quality (Specia et al., 2018; Yankovskaya et al., 2018; Fomicheva et al., 2020). The decoder confidence is the hypothesis probability as defined by the model $\prod_i p(t_i|t_{<i}, s)$ which is in practice usually computed in the logspace $\sum_i \log p(t_i|t_{<i}, s)$.[1]

Hypotheses variance. Intuitively, there are many ways to generate a wrong translation but only a few correct ones (Xu et al., 2011). Similar to Fomicheva et al. (2020), we hypothesise that larger variance between the hypotheses correlates negatively with quality. We therefore use the distances between hypotheses as features for our system. Specifically, as shown in Figure 7 and formalized with the following, we use the mean distance and also the variance between distances as features. We first consider distances from the current hypothesis to be estimated (`H1`) to all other hypotheses, and then all hypothesis pairs.

$$\text{Avg or Var}(\{\text{BLEU}(h_1, h_j) | h_j \in H\})$$
$$\text{Avg or Var}(\{\text{BLEU}(h_i, h_j) | h_i, h_j \in H, i \neq j\})$$

Baselines. We use multiple baselines for comparison in the ME task. Apart from the individual features, they are all optimized to minimize the MSE loss with a specific target metric.

- Linear regression on TF-IDF features (with limited max features, see Appendix B): $\text{Lin.Reg.}\big[\text{TF-IDF}(s, h)\big]$
- Linear regression on all text & MT features: $\text{Lin.Reg.}[\Psi]$
- Fine-tuned mBERT (Devlin et al., 2019) with identical regression head architecture on top of last layer `[CLS]` hidden state[2]: $\text{FFNN}\big[\text{mBERT}(s\,\texttt{[SEP]}\,h)\big]$

We also use an off-the-shelf QE model used in WMT21 QE task `wmt21-comet-qe-mqm` (Rei et al., 2020b).[3] We do not fine-tune the model to the available data, but since we use correlation as an evaluation metric, the mean is subtracted and the output rescaled to unit variance, same as human judgements.

Automated metrics. For ME we use the following MT metrics. BLEU (Papineni et al., 2002), ChrF (Popović, 2015), TER (Snover et al., 2006) and METEOR (Banerjee and Lavie, 2005) work with lexical or character-level units, commonly in word or character n-grams. COMET (Rei et al., 2020a) uses pre-trained encoders to evaluate the hypothesis at a deeper level. BLEURT (Sellam et al., 2020) is another learned metric for text generation which uses pseudo-label. While automated metrics usually yield only sentence-level scores, QE is done for multiple levels: word, phrase and sentence. However, because of the automatic metric restrictions, we also focus on sentence-level QE in this work.

3 Experiment Setup

Pipeline & data. We start by translating 500k English→German sentences of the WMT14 dataset (Bojar et al., 2014) and computing the automated metrics of these translations.[4] We use a pre-trained WMT19 model by Ng et al. (2019).

For human scores, we use the train data of WMT21 Sentence-Level Quality Estimation Shared Task (Specia et al., 2021) which contains 14k human-direct-assessment annotated segments (5k unique). For the human score prediction, we do not have access to the features in the hypothesis space (because the hypotheses were not generated by the MT system to which we have access) and use forced decoding of the pre-trained model to get a confidence estimate. Note that since the data comes from a different MT system, there is a distribution mismatch which may negatively influence the results. We address this in Section 4.4.

We refer to the two datasets as ME and QE, respectively and show the distribution of automated metric scores and human judgements in Figure 6. We perform ME on both but QE only on the latter because of the human annotations availability.

---

[1] The justification for using both conf_t and $\exp(\text{conf}_t)$ is that the non-linear transformation improves correlation.

[2] See Appendices A and B for details.

[3] This model was better than `wmt21-comet-qe-da`. Note the difference between the automated metric COMET and the QE system COMET-QE.

[4] We are not limited by the relatively small size of this dataset because we are considering only its subset and study the effect of available data size in Section 4.3.

	BLEU	ChrF	TER	METEOR	COMET	BLEURT	human
conf_t	41%	44%	-30%	42%	33%	37%	-0.05
$\exp(\text{conf}_t)$	44%	46%	-31%	43%	34%	40%	-0.04
$\lvert s\rvert$	-13%	3%	5%	-6%	-10%	-28%	-0.15

Figure 3: Feature correlations on 500k English → German sentences with reference-based metrics and human judgement. Colour is based on absolute values to show contained relevant information. Cells with negative correlations are marked with “-”.

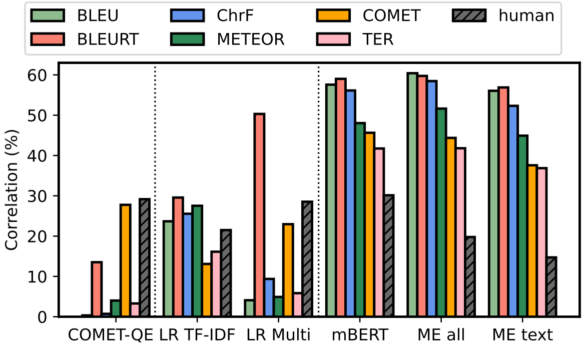

Figure 4: Correlations with metrics and human judgement of baseline and main metric estimation (ME) models. Each bar is a separate model trained to predict a particular metric or human judgement. Individual features are shown in Figure 3.

Evaluation. We evaluate ME model performance with Pearson’s coefficient with the target metric on a dev set of 10k sentences from WMT14 on the segment-level. Note that we care about the *magnitude (absolute value) of the correlation* and not whether it is positive or negative. For example, TER is expected to correlate negatively with human ranking because higher TER means more errors while higher human scores mean higher translation quality. Correlations with human judgement are evaluated on 1k WMT21 Sentence-Level QE data. Specifically, we estimate human z-scores which were computed per-annotator.[5]

4 Results

This section first studies single-feature baselines (Section 4.1) and then the possibility of robust ME model (Section 4.2) and data size requirements (Section 4.3). The model is then checked on a different MT system output to see transferability between systems and architectures (Section 4.4). Fine-tuning and evaluation on human data (QE) is done in Section 4.5. A natural follow-up experiment on using joint prediction to improve the ME model is documented in Section 4.6.

4.1 Feature analysis

We show the correlations between individual features and metrics in Figure 3. An immediate observation is that confidence-based features correlate much more with automatic metrics than the other features. Some metrics (BLEU and COMET) and especially human z-scores are highly correlated with the source and target lengths. As a negative result, very few of the hypothesis space metrics correlate highly, with an exception of $\rho(\text{BLEU}, \text{Var}(\text{BLEU}(H)))$. We still use all features later on because (1) despite low individual correlations, they may still be useful in combination or for the full model, whose input is the text, and (2) we did not encounter any overfitting issues.

BLEU	BLEURT	ChrF	METEOR	COMET	TER
11.1%	16.5%	12.3%	-12.0%	11.5%	34.6%

Table 1: Pearson correlations between human judgement (human z-scores) and automated metrics.

We show the correlations between the automated metrics and humans in Table 1. For most of them, the correlations are very low. Outliers with the highest correlation are BLEURT and COMET, which are known to be strong-performant metrics (Kocmi et al., 2021). One of the reasons is that they were specifically trained to correlate well with humans.

---

[5] Z-score of a variable has zero mean and unit variance. They are possibly unbounded but on the other hand, slightly alleviate the effect of individual annotator differences.

4.2 Metric estimation performance

We show the baselines with comparison to the main models trained only on the target data (either WMT News or WMT QE) in Figure 4. Every bar is a separate model trained to predict a specific metric and the bar magnitude shows its correlation. The systems are described formally in Section 2. Notably, *ME text* has access to only the source and hypothesis texts while *ME all* in addition fuses in extra hand-crafted features.

A simple linear regression based on features from Figure 3 is able to achieve $> 40\%$ correlations with automated metrics and $\sim$13% correlation with human judgement. These features seem important as demonstrated by the comparatively lower correlations of a TF-IDF featurizer. This is also documented by the difference between *ME all* and *ME text*. The former model consistently outperforms *ME text*, possibly because it has access to all the extra features while the latter model only works with the source and target texts. The pre-training of the *mBERT* model on language modelling helps only marginally, given that it performs only slightly better than *ME text*. The COMET-QE model almost does not correlate with automated metrics at all apart from its related reference-based metric COMET. Of all models, it also correlates the most with human judgement.

> **RQ1**: Best-performing metric estimation models (mBERT, ME all, ME text) achieve sound correlations with automated metrics (60.4% with BLEU, $\sim$ 51.3% for others).

We can interpret this correlation with respect to the individual features performances ($\max \rho = 46\%$) which shows that the model was able to learn more predictive patterns. On the selected datasets, the ME task is easier than the QE task where our moidels have a consistently lower performance.

4.3 Data requirements for ME

We are interested in how much data we need to train the ME models. This is a practical question that helps us understand the behaviour and requirements of the models.

Naturally, models utilizing just a handful of continuous non-trainable features require much less data than models whose inputs are the raw texts. This is demonstrated in Figure 5 where the linear regression gains very little even if 500× more data is used. For the main ME model, a larger amount of data is required (line H1). So far we have been considering only the highest-scored hypothesis (in terms of decoder score) among 5 generated by beam search: (s, h_1). In a low-resource scenario, it may be beneficial to create more pairs from the hypotheses provided by the beam-search decoder: $\{(s, h_i) | h_i \in H\}$. Through this hypothesis expansion, we may obtain more parallel data in data-restricted settings. Again we show the results in Figure 5 with a substantial gain of the model trained on expanded data (H2) over just the top hypothesis (H1). This effect is quickly diminishing with larger data ($\geq$ 10k) but for lower data remains a useful tool.

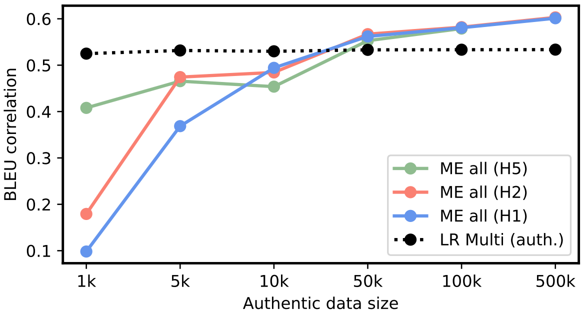

Figure 5: Model dependency on training data size. H2 and H5 expand the data by top-2 and top-5 decoder hypotheses, respectively. Note the non-linear x-axis.

> **RQ2**: The metric estimation model requires $\sim$500k parallel sentences and the associated metric scores before the performance starts to plateau. For very low-resource scenarios, it is possible to reduce the ME model data requirements by utilizing multiple hypotheses for a single source sentence.

	ME All		**ME Text**	
Model	**Transfer**	**Auth.**	**Transfer**	**Auth.**
Original	60.4%		56.1%	
W16Conv.	54.2%	57.3%	48.4%	51.0%
W16Trans.	54.2%	57.1%	47.9%	50.7%
W17Conv.	58.7%	60.8%	55.1%	55.7%
T5	19.8%	72.9%	43.8%	70.9%

Table 2: BLEU estimation correlation for texts translated by different models than WMT19 Transformer (original).

4.4 Generalization of ME across MT systems

In this section, we examine whether our ME model overfits on the specific errors the used MT system is doing or whether it generalizes and is applicable to also other MT systems. This is important in deployment so that the possible ME/QE model is not dependent on a specific MT system.

We translate the same data using the following English → German models and store the decoder features: T5-small (Raffel et al., 2020), WMT16 Convolutional (Wu et al., 2019), WMT16 Transformer (Ott et al., 2018), WMT17 Convolutional (Gehring et al., 2017). We then run the ME model trained on the outputs of the original WMT19 system to predict metric scores for the outputs of these models. We show the results in Table 2, for both text-only and feature-enriched models. The evaluation of translations by different MT systems shows a varying decrease in correlation with the automated metrics. For most systems, the drop was ∼2–3%, which means that the metric estimator generalizes well across MT systems. However, an exception is using a completely different model, the prompted T5 LM, for which the transfer mostly failed. When training metric estimators on the T5 translated data, they achieved ∼71% correlation but when models trained on outputs of a different MT system were used, the correlation dropped to 19.8% and 43.8% for *ME All* and *ME Text*, respectively. One of the reasons may be vastly different extra features, as documented by the noticeably higher correlation for the *ME Text* model.

> **RQ3**: It is possible to train a metric estimation model on sentences produced by MT_1 and use it to estimate metric scores of MT_2 with a drop in correlation of $\sim 3\%$.

4.5 From ME to QE

This section verifies empirically whether pre-training on ME helps on the QE task. For this, we use models trained on estimating automatic metrics and either: correlate their outputs with human judgements (zero-shot), or fine-tune them to predict the human judgements directly (fine-tuning). The fine-tuning was done with the same setup as in Appendix B with all model parameters updated.

The results in Table 3 show that fine-tuning definitely improved the performance over zero-shot. However, only TER was able to outperform training on z-scores from scratch. This can be attributed to it being the only metric with reasonable absolute correlation in the zero-shot. Notably, COMET was better than the rest of the automated metrics with the worst being BLEU. Despite the fine-tuning, we were not able to construct a QE system that would outperform the standard baseline of COMET-QE ($\rho = 29.2\%$).

Pre-train metric	Zero-shot	Fine-tuning
BLEU	-3.2%	-0.9%
BLEURT	5.9%	-5.2%
ChrF	-6.9%	6.5%
METEOR	-4.2%	6.0%
COMET	1.1%	10.4%
TER	-12.5%	22.8% ⋆
human	19.8%	

Table 3: Correlations with human judgement (z-scores) from models (with extra features fusion) which were pre-trained on metric estimation. Only the magnitude (absolute value) of the correlation is important.

> **RQ4**: Pre-training on TER (large data) and fine-tuning on human scores (small data) is better than training only on human scores (small data).

Further experiments with limited target-domain data (Figure 8) show that the proposed pre-training & fine-tuning regime does not perform well even with less fine-tuning data. The same figure also shows fine-tuning sensitivity to the selected data. Variance is caused by both the optimization process and data subsampling. Even though we include confidence intervals, in deployment one would start multiple runs and use the best-performing one. A striking observation is that very little human-annotated data is needed for training. Further research should more closely examine the relationship between model capacity, data requirements and QE performance.

	ME		QE	
Metric	**Single**	**Multi**	**Single**	**Multi**
BLEU	60.4%	47.0%	15.5%	23.9%
BLEURT	59.7%	5.7%	26.7%	5.7%
ChrF	58.5%	42.6%	23.7%	24.0%
METEOR	51.6%	36.5%	22.6%	24.5%
COMET	44.4%	23.1%	13.1%	21.0%
TER	37.4%	36.8%	7.6%	18.7%
human	-	-	19.8%	5.5%

Table 4: Pearson correlations between system outputs and automated metrics or human z-scores for either multiple single-metric models (Single) or a single multi-target model (Multi).

4.6 Joint prediction of multiple metrics

In this section, we investigate using all the automated metrics at the same time in a single model instead of multiple individual models.

For both the WMT News and QE datasets (individually), all the metric scores for a single segment can be predicted at the same time. Instead of training 6+7 individual models to predict each metric, we train two models (for ME and QE data) that predict all available metrics at once (similar to BLEURT pre-training phase) using different regression heads. The only difference in the architecture from Appendix B is that the last linear layer has 6 or 7 output neurons instead of one. The loss for model f is then defined as $\sum_{m\,\in\,\text{metrics}} \text{MSE}(f_m(s,t), m(s,t,r))$. Having multiple targets in a single training can provide more signal and better representation (Aho et al., 2012; Korneva and Blockeel, 2020). The results shown in Table 4 demonstrate that for the smaller dataset (QE), joint learning mostly helps in metric prediction but not in human z-score prediction. This may be because of a loss imbalance of 6 target outputs optimizing on automated metrics and only 1 target output optimizing on human z-scores.

5 Complexity & Fluency Estimation

Currently, our model was dependent on mostly the source and the hypothesis. If it had access to only the hypothesis, it could still consider its fluency and other factors in estimating the metric. Likewise, having access to only the source would correspond to sentence difficulty/complexity estimation. Similarly to Wan et al. (2022), we explored both of these modes and found very high sentence-level correlations.

$$\begin{aligned}\rho(\{(f_{\text{ME}}(h), f_{\text{BLEU}}(h,r))\}) &= 55.5\% \\ \rho(\{(f_{\text{ME}}(s), f_{\text{BLEU}}(h,r))\}) &= 55.3\% \\ h,s,r &\in \mathcal{D}\end{aligned}$$

These high correlations, which are close to the full text-only model's performance ($\rho = 56.5\%$) show that our model is not able to utilize the relationship between the source and the hypothesis and that a more elaborate models should be considered. These results are in line with general findings of Behnke et al. (2022). The models' inadequacy is also shown by the imperfect performance when given access to the hypothesis and the reference, just as the metric has:

$$\begin{aligned}\rho(\{(f_{\text{ME}}(s,h,r), f_{\text{BLEU}}(h,r))\}) &= 60.7\% \\ \rho(\{(f_{\text{ME}}(h,r), f_{\text{BLEU}}(h,r))\}) &= 61.5\% \\ h,s,r &\in \mathcal{D}\end{aligned}$$

However, the focus solely on the hypothesis or just the source itself has been confirmed for also other QE systems (Sun et al., 2020) and our model is not an outlier.

6 Related Work

This section discusses how our proposed ME task fits in the field of QE.

Confidence estimation. The task of ME has a connection to an older task of confidence estimation (Blatz et al., 2004), which predates QE (Specia et al., 2013). In confidence estimation, the goal is to predict the probability of the output being correct. Blatz et al. (2004) define correctness as a binary class which is based on two thresholded MT metrics: word error rate and NIST (Doddington, 2002). This is in contrast to the ME task which is a regression task (predicting e.g. 0.7 instead of `GOOD` and segment-level).

More recent works use the term confidence estimation more freely to mean essentially the QE task with full training data and model access (Chelba et al., 2020). Because this term is used also in other contexts, such as in calibration (Wan et al., 2020; Wang et al., 2020), we define the task metric estimation to avoid ambiguity.

Feature-based QE models. Specia et al. (2010, 2013) pioneered the work of mainstream MT QE. The QuEst model uses support vector regression on top of features such as source & target lengths, the number of translations in a phrase table or target sentence language model probability. Further research has been devoted to devising good features for MT QE models, such as grammatical ones (Felice and Specia, 2012), ones based on the decoder (Avramidis, 2012; Fomicheva et al., 2020) or based on the model embeddings spaces (Shah et al., 2016; Chen et al., 2017).

Deeper QE models. QUETCH (Kreutzer et al., 2015), NuQE (Martins et al., 2016), DeepQuest (Ive et al., 2018) and others (Kim and Lee, 2016; Li et al., 2018) regress directly from the source and hypothesis texts into a score. Notably some systems approach sentence-level QE by aggregating or otherwise utilizing previously-estimated word-level QE predictions (Kepler et al., 2019).

Pre-training QE models. Closest to our work is computing TER between the hypothesis and its post-edited version (Heo et al., 2021). QE is then trained jointly on the artificial and authentic QE data. Other models are first trained on artificial (pre-training) and then authentic data (Baek et al., 2020; Cui et al., 2021; Yankovskaya and Fishel, 2021). The pre-training task does not have to be tied to QE. Large pre-trained language models have also been used for QE (Hu et al., 2020; Moura et al., 2020; Nakamachi et al., 2020; Eo et al., 2021). In contrast, our pre-training aims not only to acquire better sentence representations in general but specifically to acquire better sentence representations for translation quality score estimation.

QE models outside of MT The idea to estimate the quality of a prediction given only itself and the input has also been applied to other NLP tasks. RUBER (Tao et al., 2018) uses an RNN-based model to compute a score for a context-response pair in a dialog that is combined with a reference-based score to obtain the final metric. BERT-RUBER extends this by using pre-trained representations and GRADE uses the unreferenced scorer in combination with a module that constructs a conversational graph using ConceptNet concepts and reasons over it (Huang et al., 2020). Recently different works evaluate responses based on specific quality attributes, for example, groundedness (Honovich et al., 2021), or combine them into one quality score (Pang et al., 2020). For open-ended tasks, reference-free metrics, similar to QE, are more desirable because they make fewer assumptions about how the hypothesis should look like. Compared to those tasks, the admissible hypothesis space in MT for a given source sentence is more constrained.

7 Discussion

The experiments have shown that the outputs of automated metrics can be predicted even without access to the reference. Pre-training only on TER and not any other automated metric outperformed training from scratch, which highlights the importance of exploring multiple metrics instead of just one or two of the most popular ones. Pre-training on TER helped because of the large absolute zero-shot correlation. We are, however, unable to provide an explanation for this zero-shot correlation in the first place.

Our ME approach can also be potentially used for improving models, even outside of the MT field, by providing additional signals through self-supervision. For example, the ME model could be used instead of the decoder probabilities for reranking when decoding with beam-search in generative models. This approach would be similar to using QE in decoding by Fernandes et al. (2022) but would not require a separate scorer model.

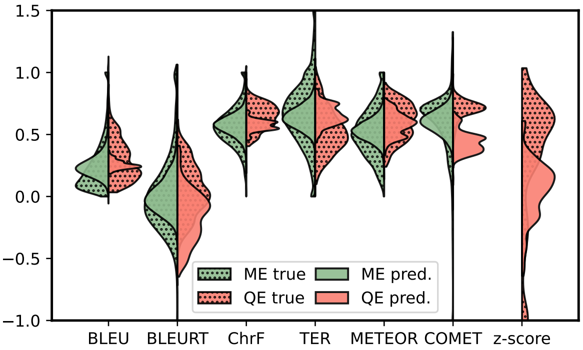

Figure 6: Distribution of metric and human judgement values in the used ME and QE datasets together with their predictions. Long tails clipped between -1 and 1.5 for higher resolution.

7.1 Error analysis

In this section, we examine three model predictions and comment on their comparison with the target scores. At the first glance, the model predictions are generally more conservative (lower variance and concentration around the average), as shown in Figure 6. This is however not an issue when evaluating with Pearson's correlation coefficient as the distributions are rescaled. While the error analysis serves as a good check for the model outputs, we are unable to clearly define specific failure modes of the model, which does not achieve 100% metric correlation.

> **Example 1** **BLEU** 0.08, **ME** 0.07
>
> **Source:** *Police try new, less-lethal tools as protests continue.*
> **Reference:** *Während die Proteste weitergehen, testet die Polizei weniger tödliche Geräte*
> **Reference (lit.):** *While the protest continue, the police is testing less-lethal devices.*
> **Hypothesis:** *Die Polizei probiert neue, weniger tödliche Werkzeuge aus, während die Proteste anhalten.*
> **Hypothesis (lit.):** *The police is testing new, less-lethal tools, as the protest persist.*

We first examine cases in which we compare our model's prediction with the true metric value.[6] Example 1 is an almost exact match in BLEU and model prediction. Although the hypothesis is reasonable, it is too literal of a translation. This is a failure for the automated metric but a success for our model because it predicted the metric accurately.

---

[6] We report true BLEU scores and not percentages (i.e. scale is 0-1, not 0-100).

> **Example 2** **BLEU** 0.67, **ME** -0.51
>
> **Source:** *It didn't work.*
> **Reference:** *Das hat nicht funktioniert.*
> **Reference (lit.):** *That did not function.*
> **Hypothesis:** *IT hat nicht funktioniert.*
> **Hypothesis (lit.):** *THAT/IT did not function.*

In some error cases, the model prediction was a better quality estimate than the metric it was trained to estimate. In Example 2, the word *it* is mistaken for a named entity which distorts the sentence meaning: *it* - pronoun, *IT* - abbreviation *Information Technology* (can also mean the tech support department).

> **Example 3** **Human** -4.72, **QE** -0.42
>
> **Source:** *There's mask-shaming and then there's full on assault.*
> **Reference:** *Masken-Shaming ist eine Sache, Körperverletzung eine andere.*
> **Reference (lit.):** *Mask-shaming is one thing, body assault is a different one.*
> **Hypothesis:** *Es gibt Masken-Beschämen und dann gibt es voll auf Angriff.*
> **Hypothesis (lit.):** *There is mask-humiliation and then there is full-on assault.*

In certain cases, the model output is very far from human judgement. In Example 3, the hypothesis contains a phrase *voll auf Angriffe* which seems like a good translation but only at the first sight and is, in fact, incorrect (word-wise translation *full - voll, on - auf, assault - Angriff*). This may be a reason for the low score by the human annotator and it was not captured at all by our model.

7.2 Negative results

We also attempted to leverage mBERT representations in the main LSTM-based model via concatenation fusion with the last hidden state, identical to the approach of Zouhar et al. (2022) for language modelling. However, the results (ρ = 60.0% for BLEU) were on par with the main LSTM-based model alone (ρ = 60.4% for BLEU).

We experimented with the expressivity of the used model architecture in Section 5 by granting the model access to the source, the reference and the hypothesis. This should provide sufficient information to be able to learn the specific metrics, however, the model was unable to fit it perfectly. Approaches in future work should therefore use models with larger capacities and explore specific mechanics that could be useful for predicting automated metrics relying on n-gram overlaps.

8 Conclusion

We proposed the task of **metric estimation** for machine translation, as a parallel to quality estimation and attempted to solve it with a baseline BiLSTM model. We show that it is possible to predict the output of a metric without even seeing the reference (ρ = 60.4% for BLEU and $\bar{\rho}$ = 51.3% for other metrics). The main advantage of this task compared to QE is that the data for training ME models to predict a particular metric can be generated from any parallel corpus on which the metric can be run. While pre-training on TER outperformed training from scratch, it did not perform better than the commonly used baseline, COMET-QE.

Future work. Despite the negative results, features in the hypothesis space should be more explored for tasks beyond ME/QE, such as calibration of self-reported confidence in generative models. Metric and quality estimation could also be a part of the MT system itself (e.g. as a separate head) which would alleviate the need for an external ME/QE model. The ME models should also be evaluated for cross-domain performance, similarly to our cross-system evaluation as motivated by needs of production settings. Non-perfect correlation with the metrics when presented with the same input shows the imporants of exploring more complex architectures or optimization approaches.

Limitations

Although our model outperformed the simple baselines in ME and QE, it provides less explainability because a specific QE output can not be linked easily to input features. The model also required much longer training[6] while the baselines just need a simple featurizer, MT intrinsic features and can run the linear regression fitting on a CPU. Nevertheless, the largest computational bottleneck in this research has been running the MT system inference[6] rather than training the individual models.

Concerns have long been raised about using segment-level metrics/evaluations because of the large variance (Lavie, 2010). However, we find that for automated metrics, our models are still able to deal with this variance.

Ethics statement

Detailed error analysis should always be performed before deploying a quality estimation system in machine translation production pipelines.

---

[6] Training one full model takes ~3 hours on 500k sentences on NVIDIA GeForce GTX 1080 Ti. Machine translation of the same data takes 120 GPU hours on the same model.

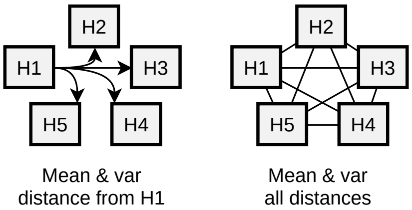

Figure 7: Four features based on properties of the generated hypothesis space: mean and variance of either H1 (top hypothesis) or all pairs. The used metric (any hyp-ref-based) considers one of the hypotheses in a pair as the reference.

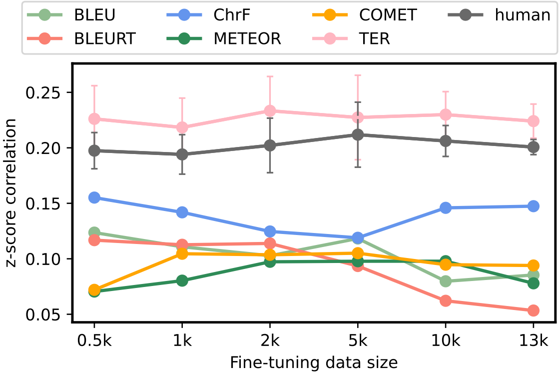

Figure 8: Finetuning on limited target-domain QE data. Note the non-linear x-axis. Each point is an average of 5 runs. Error bars show a 95% confidence interval of the mean. Error bars shown only for BLEU and human for clarity.

A Reproducibility

We compute metric scores using SacreBLEU (Post, 2018) with the following signatures:

- All: `nrefs:1 | version:2.2.0`
- BLEU: `case:mixed | eff:yes | tok:13a | smooth:exp`
- ChrF: `case:mixed | eff:yes | nc:6 | nw:0 | space:no`
- TER: `case:lc | tok:tercom | norm:no | punct:yes | asian:no`

For baseline experiments, multilingual version of BERT was used: `bert-base-multilingual-cased`. Translations using T5-small are done with the prefix "*translate English to German:*". For other translation models, we used the following models available on torch.hub under the `pytorch/fairseq` namespace (Ott et al., 2019):

- `dynamicconv.glu.wmt16.en-de`
- `conv.wmt17.en-de`
- `transformer.wmt16.en-de`
- `transformer.wmt18.en-de`

B Model details

The metric/quality estimation model specifics are shown in Table 5. Additionally, we concatenate all forward and backward hidden states from both LSTM layers. A non-standard choice was to use sigmoid as the final activation function which worked better than just the linear output.[7] However, we also rescaled and centered it in case of BLEU, ChrF and METEOR so that scores of 0 and 100 are attainable. We eventually did not use this in the main experiments so that a single model setup could be used for all metrics. All models are trained with early stopping of 10 epochs. The optimization loss is mean squared error. Our used model is fairly small in comparison to other models, such as those utilizing the Transformer architecture. This was an intentional choice with respect to the small amount of data used. The hyperparameters were chosen manually by best practices with respect to final metric correlation (5 trials).

Optimizer	Adam (Kingma and Ba, 2015)
Learning rate	10^{-6}
Batch size	10 (0-padded to longest)
Vocab size (BPE)	8192
Vocab embedding	512
LSTM	Hidden state 128 2 bidirectional layers
LSTM dropout	20% inter-layer 75% final hidden state
Fusion	Concatenate (512 + 6)
Linear	518 → 100
Activation	ReLU
Linear	100 → 1 (6/7 for multi)

Table 5: Metric/quality estimation model details.

The TF-IDF featurizer in the linear regression TF-IDF baseline uses variable maximum number of features and the best-performing one is chosen. The search is logarithmical from 2^4 to 2^{14}.

---

[7] This is dissimilar to the baseline model where linear regression worked better than logistic regression even in the case of metrics with bounded output range.

C Results for other language pairs

The paper used figures and examples from the English→German language direction. To replicate the findings, we translate 500k sentences for the following language directions, models and datasets:[8]

- German ↔ English (`WMT14`)
  `transformer.wmt19.{de-en,en-de}`
- German ↔ Polish (`opus_paracrawl`)
  `Helsinki-NLP/opus-mt-{de-pl,pl-de}`
- Chinese ↔ English (`CCMatrix`)
  `Helsinki-NLP/opus-mt-{zh-en,en-zh}`
- Czech ↔ English (`WMT14`)
  `Helsinki-NLP/opus-mt-{cs-en,en-cs}`
- Russian ↔ English (`WMT14`)
  `transformer.wmt19.{en-ru,ru-en}`
- French ↔ English (`WMT14`)
  `Helsinki-NLP/opus-mt-{fr-en,en-fr}`
- Hindi → English (`CCMatrix`)
  `Helsinki-NLP/opus-mt-{hi-en,en-hi}`

The results for metric estimation for all metrics and language directions are shown in Figure 9. In comparison to the other languages, the chosen language pair in the paper (En → De) is more conservative than the other language pairs, which achieve higher correlations across most metrics. Most of them achieve $> 50\%$ correlation, though specifically *COMET* appears to be more predictable for other language pairs. These results confirm the main results of predictability of the metric without having access to the reference.

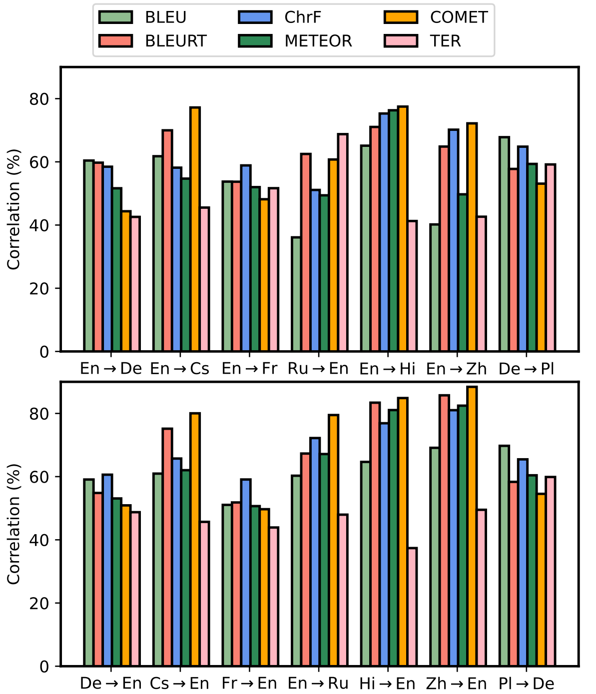

Figure 9: Correlations with metrics and human judgement of main metric estimation (ME) models on other languages. Each bar is a separate model trained to predict a particular metric or human judgement.

D Confidence Estimation for Metric Estimation

Quantifying the confidence of the prediction can be crucial in downstream applications. For example, if a quality estimator has low confidence or is predicted to not be accurate, the decision regarding the quality of translation should be delegated to humans. We attempt to do this by training an auxiliary model to predict the confidence of the output score. We do this by training a logistic regression classifier which takes as input the final layer (λ) of our metric estimator and is trained to predict the binary label: if the predicted metric $f_{\mathrm{BLEU}}(s,h,r)$ is close to the true metric $\mathrm{ME}(s,h)$.

$$\mathbb{P}(|\mathrm{ME} - f_{\mathrm{BLEU}}| \in [0, \mathrm{ME}(s,h) \times 10\%]) \\ = \sigma(W^T \cdot \lambda + b)$$

We, unfortunately, find that the classifier suffers from a very low accuracy 63.4% against a most common class (negative) baseline of 51.6%. It therefore cannot be meaningfully used to ascertain when our regressor is correct and when it is not. Glushkova et al. (2021) propose a more complex solution and exploit uncertainty methods for MT metric and quality estimation systems.

Abstract

Non-autoregressive machine translation (NAT) has recently made great progress. However, most works to date have focused on standard translation tasks, even though some edit-based NAT models, such as the Levenshtein Transformer (LevT), seem well suited to translate with a Translation Memory (TM). This is the scenario considered here. We first analyze the vanilla LevT model and explain why it does not do well in this setting. We then propose a new variant, TM-LevT, and show how to effectively train this model. By modifying the data presentation and introducing an extra deletion operation, we obtain performance that are on par with an autoregressive approach, while reducing the decoding load. We also show that incorporating TMs during training dispenses to use knowledge distillation, a well-known trick used to mitigate the multimodality issue.

1 Introduction

Non-autoregressive neural machine translation (NAT) has been greatly advanced in recent years (Xiao et al., 2022). NAT takes advantage from parallel decoding to generate multiple tokens simultaneously and speed up inference. This is often at the cost of a loss in translation quality when compared to autoregressive (AR) models (Gu et al., 2018a). This gap is slowly closing and methods based on iterative refinement (Ghazvininejad et al., 2019; Gu et al., 2019; Saharia et al., 2020) and on connectionist temporal classification (Libovický and Helcl, 2018; Gu and Kong, 2021) are now reporting BLEU scores similar to strong AR baselines.

Most works on NAT focus on the standard machine translation (MT) task, where the decoder starts from scratch, with the exception of Susanto et al. (2020); Xu and Carpuat (2021), who use NAT to integrate lexical constraints in decoding. However, edit-based NAT models, such as the Levenshtein Transformer (LevT) of Gu et al. (2019), seem to be a natural candidate to perform MT with Translation Memories (TM). LevT is able to iteratively edit an initial target sequence by performing insertion and deletion operations until convergence. This design also matches the concept of using TMs in MT, where given a source sentence, we aim to edit a candidate translation retrieved from the TM.

This idea has been used for decades in the localization industry and implemented into basic Computer-Aided Translation tools. Translators wishing to translate a sentence can benefit from fuzzy matching techniques to retrieve similar segments from the TM. These segments can then be revised, thereby improving productivity and consistency of the translation process (Koehn and Senellart, 2010; Yamada, 2011). The retrieval of similar examples from a TM has also proved useful in conventional (AR) neural MT systems; they can be injected into the encoder (Bulte and Tezcan, 2019; Xu et al., 2020) or as priming signals in the decoder (Pham et al., 2020) to influence the translation process. These studies report significant gains in translation performance in technical domains, where the translation of terms and phraseology greatly benefits from examples found in a TM.

Our main focus in this work is to develop an improved version of LevT suited to the *revision part* of TM use, where the translation retrieved from TM is modified via edit operations in a non-autoregressive way. We first show that the original LevT cannot perform well on this task and explain that this failure is a direct consequence of its training design. We propose to fix this issue with TM-LevT, which includes an additional deletion step. Next, we propose to further improve the training procedure in two ways: (a) by also including the retrieved candidate translation on the source side, as done in AR TM-based approaches (Bulte and Tezcan, 2019; Xu et al., 2020); (b) by simultaneously training with empty and non-empty initial target sentences. In our experiments, TM-LevT achieves performance that is on par with a strong AR ap-

May 2-6, 2023 ©2023 Association for Computational Linguistics

proach on various domains when translating with TMs, with a reduced decoding load. We also observe that incorporating an initial translation both on the source and target sides makes Knowledge Distillation (KD, Kim and Rush, 2016) useless. This contrasts with standard NAT models, which rely on KD to alleviate the multimodality issue (Gu et al., 2018a). As far as we know, this work is the first to study NAT with TMs in a controlled setting.

Our contributions are the following: (a) we show that the original LevT training scheme is not suited to edit similar translations from a TM; (b) we propose a variant of LevT, TM-LevT with an improved training procedure, which yields performance that are close, or even similar to AR approaches when translating with good TM matches, with a reduced decoding load; (c) we highlight the benefits of multi-task training (with and without TMs) to attain the best performance; (d) we discuss the reasons why KD hurts the training of NAT with TMs.

2 Using Translation Memories in NAT

2.1 Background

TM Retrieval Given a source sentence $\mathbf{f}$, we aim to retrieve a good match $\tilde{\mathbf{e}}$ from the TM. For this, we search the TM for a pair of sentences $(\tilde{\mathbf{f}}, \tilde{\mathbf{e}})$, where $\tilde{\mathbf{f}}$ is similar to $\mathbf{f}$. The corresponding target $\tilde{\mathbf{e}}$ is then used to initiate the translation of $\mathbf{f}$. We compute the similarity between $\mathbf{f}$ and $\tilde{\mathbf{f}}$ as:

$$\mathrm{sim}(\mathbf{f}, \tilde{\mathbf{f}}) = 1 - \frac{\mathrm{ED}(\mathbf{f}, \tilde{\mathbf{f}})}{\max(|\mathbf{f}|, |\tilde{\mathbf{f}}|)}, \qquad (1)$$

where $\mathrm{ED}(\mathbf{f}, \tilde{\mathbf{f}})$ is the edit distance between $\mathbf{f}$ and $\tilde{\mathbf{f}}$, and $|\mathbf{f}|$ is the length of $\mathbf{f}$. The intuition is that the closer $\mathbf{f}$ and $\tilde{\mathbf{f}}$ are, the more suitable $\tilde{\mathbf{e}}$ will be. As is custom, we only use TM matches when the similarity score exceeds a predefined threshold, otherwise we translate from scratch. We discuss the effect of the match similarity in Section 4.5.

Levenshtein Transformer LevT is an edit-based NAT model proposed by Gu et al. (2019). It performs translation by iteratively editing an initial target sequence with insertion and deletion operations until convergence. The insertion operation is composed of a *placeholder insertion module* and a *token predictor*. The placeholder classifier predicts the number of additional tokens that need to be inserted between any two consecutive tokens in its input sequence. The token predictor then generates a token for each placeholder position. The deletion operation aims to detect prediction errors made by the model. It makes a binary decision for each token, indicating whether it should be deleted or kept. During training, a noised initial target sequence $\mathbf{e}'$ is first generated by randomly dropping tokens from the reference $\mathbf{e}$. The insertion modules learn to reinsert the deleted tokens into $\mathbf{e}'$. The deletion operation is then trained to erase erroneous predictions made during insertion.

During inference, LevT starts with an empty target sequence ($\mathbf{e}' = []$) and generates the translation by alternatively performing deletion and insertion operations until convergence or a maximum number of decoding rounds is reached. In the first iteration, the deletion is omitted, as no tokens can be deleted from the empty sequence. This iterative refinement procedure converges when the input and output of one iteration are the same, either because LevT predicts nothing to delete and to insert, or because it enters a loop where the deleted tokens are reinserted in the same round. Unlike almost all other NAT models, LevT does not require any external prediction of the target length, as the number of target tokens is iteratively revised and adjusted by the placeholder prediction module. We refer to Gu et al. (2019) for more details about LevT.

2.2 Deficiencies of LevT Training

Even though the edit-based nature of LevT makes it readily able to translate with TMs, it has mostly been applied to standard MT, where the decoder starts with an empty sentence.[1] This is consistent with the overall training scheme, illustrated in Figure 1 (Vanilla LevT), where inputs for the placeholder insertion module are always subsequences of the reference and the deletion module only sees the outputs of the previous token insertion step.

Settings	Empty	Random Sent	Shuffle Ref
Init	-	1.3	5.0
LevT	45.4	2.1	40.2
LevT vs Init	-	90.4	9.4

Table 1: BLEU scores of LevT decoding with various target initialization. *Empty* refers to standard LevT inference with an empty start. *Random Sent* uses a random sentence as initial target. *Shuffle Ref* starts with a random shuffle of the reference translation. *Init* reports the BLEU score of the initialization, while *LevT vs Init* compares LevT's outputs with their starting points.

To illustrate the deficiency of this training

---

[1] One notable exception is the attempt in Gu et al. (2019) to perform automatic post-editing through iterative revisions.

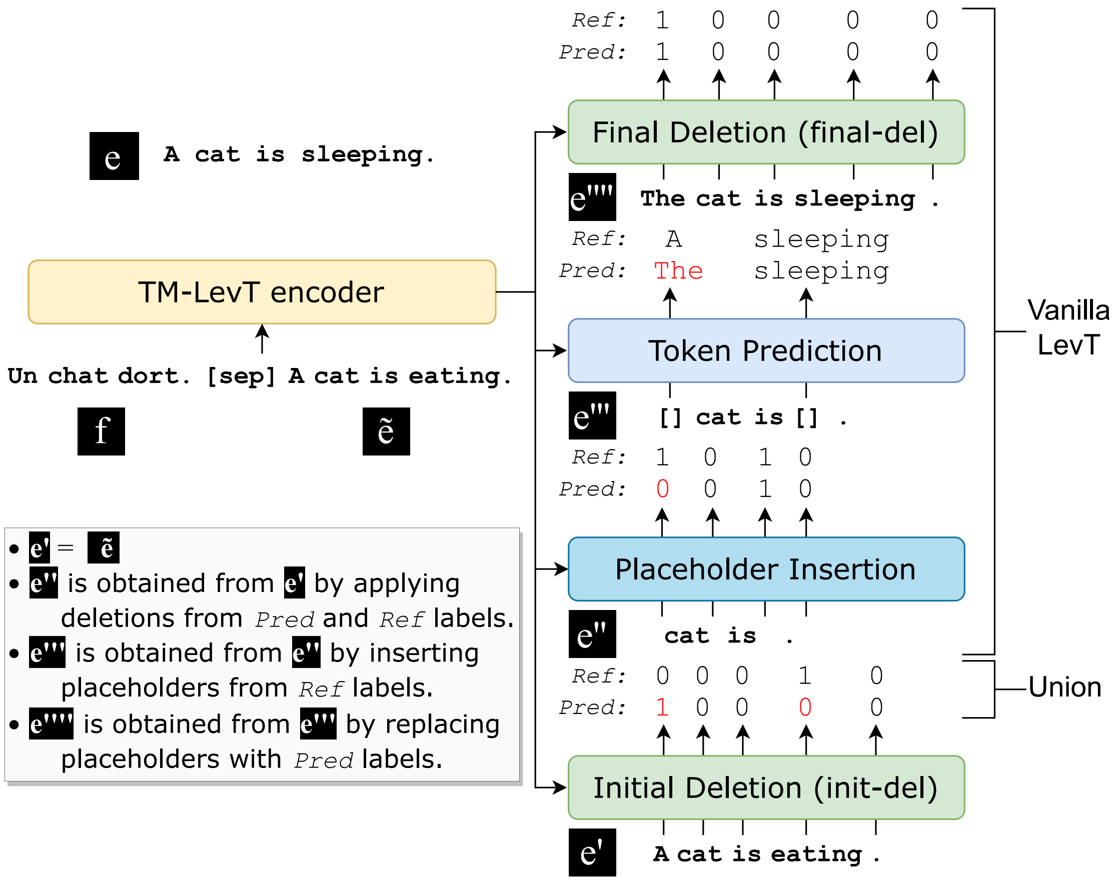

Figure 1: A complete training step for TM-LevT. Compared to the original LevT which starts training from $\mathbf{e}''$, TM-LevT adds the init-del step to delete unrelated tokens from a TM match. Figure better viewed in color.

scheme, we learned a vanilla LevT model using the datasets of Section 3.1 and initialized the decoder with a sentence randomly selected from the test set and totally unrelated to the source sentence. We observe (Table 1, Random Sent) that LevT's outputs are almost as bad as their starting point. This is because the deletion module fails to delete irrelevant input words, presenting the insertion modules with a fully fluent yet fully inadequate sequence that the insertion module is hard-pressed to revise. This contrasts with the *Shuffle Ref* scenario, where the decoder starts with a random shuffle of the reference. LevT can now make changes during the iterative refinement and generates translations (40.2 BLEU) that are close to standard decoding (45.4 BLEU). The TM-based scenario discussed below presents the same challenge for the deletion module, that of spotting and deleting irrelevant words. Our proposal will first focus on fixing this issue.

2.3 Improving Editions with TM-LevT

The experiment of previous section suggests that LevT will have issues editing TM matches, as they often contain tokens that are unrelated to the source and should be removed (see Figure 1 for an example TM match $\tilde{\mathbf{e}}$ containing an unrelated word "eating"). The distribution of unrelated tokens may greatly differ from token prediction errors made by LevT, which are tokens LevT is trained to delete.

We propose a variant of LevT denoted TM-LevT, where we include an extra deletion step (init-del) that applies before the insertion modules. As shown in Figure 1, init-del is trained to detect unrelated tokens from the initial $\mathbf{e}'$, whereas the final deletion (final-del) focuses on prediction errors. During training, we generate examples for the insertion modules by removing from $\mathbf{e}'$ tokens that either are not in the reference, or should be deleted according to the init-del operation. The resulting subsequence $\mathbf{e}''$ is then used to train the insertion operation. TM-LevT does not change the number of parameters, as we use the same classifier for the init-del and final-del steps. During inference, TM-LevT behaves exactly as LevT, iteratively applying deletions and insertions to an initial candidate translation.

2.4 Translating with or without TM Matches

In practical applications, two modes of operations need to be supported. The first is when a good match is found in the TM and used to initialize the decoding ($\mathbf{e}' = \tilde{\mathbf{e}}$). Revising $\mathbf{e}'$ may imply to delete or insert tokens, which is what the system is trained for. It may also imply to move words around, which is achieved by a succession of deletion and insertion. However, as these operations are performed independently, there is no guarantee that the deleted words will be memorized for subsequent insertions, causing the loss of relevant words in the process. This is again illustrated in Table 1 (Shuffle Ref) where we see that even when given all the reference tokens (in random order), LevT still underperforms translating from scratch. To mitigate this risk, we augment the source side with the initial TM match, ensuring that $\tilde{\mathbf{e}}$ is always fully available to the decoder. Following the proposal of Bulte and Tezcan (2019); Xu et al. (2020) for AR models, this is performed by concatenating $\mathbf{f}$ and $\tilde{\mathbf{e}}$ on the encoder side (see Figure 1).

The second mode of operation is when no appropriate match is found, causing the system to fall back to a standard MT regime. In order to handle both situations in a single model, we resort to multitask training and prepare our training samples as follows: with probability $p = 0.5$, we decide either to decode with a retrieved TM match $\tilde{\mathbf{e}}$ or from scratch. In the former case, the decoder is initialized with $\tilde{\mathbf{e}}$, while in the latter, we use a noised subsequence $\mathbf{e}'$ generated as in (Gu et al., 2019). TM-LevT is then jointly trained on both tasks.

3 Experiments

3.1 Datasets

Our experiments use the same corpus as Xu et al. (2020), and contains texts from a diverse set of 11 domains for the English-French direction, downloaded from OPUS[2] (Tiedemann, 2012): documents from the European Central Bank (ECB); from the European Medicines Agency (EMEA); Proceedings of the European Parliament (Epps); legislative texts of the European Union (JRC); News Commentaries (News); TED talk subtitles (TED); parallel sentences extracted from Wikipedia (Wiki); localization files (GNOME, KDE and Ubuntu) and manuals (PHP). We include both technical domains, for which good matches are likely to exist, and more "general" domains (Epps and News), for which useful TM matches are harder to find, allowing us to explore the benefits of using TMs for a variety of conditions. All these data are deduplicated prior to training.

For each source sentence, we retrieve from the same domain the top 3 TM matches according to the similarity score of Equation (1), further requiring a score of $0.4 \leq \mathrm{sim}<1$. For each domain, we prepare two test sets with $1{,}000$ sentences each: one contains randomly selected sentences with a close match ($\mathrm{sim}>0.6$) in the TM, the other with an acceptable match ($\mathrm{sim}\in[0.4, 0.6]$). We also leave a held-out set of $1{,}000$ sentences per domain, for which no matches of $\mathrm{sim}\geq 0.4$ are found. The remaining data is used for training. Note that the ratio of sentences with at least one TM match greatly varies across domains. Detailed statistics about these corpora are in Appendix A. We use all retrieved TM matches (up to 3) for training and only the best match for test. Therefore, a source training sentence with 3 TM matches yields 3 training samples. The initial set of 4.4M parallel data is thus extended with about 5M examples augmented with a TM match. We tokenize all data using the Moses tokenizer[3] and build a shared source-target vocabulary with 32K Byte Pair Encoding units (Sennrich et al., 2016) learned with `subword-nmt`.[4]

3.2 Experimental Settings

We compare TM-LevT with a strong AR approach (Bulte and Tezcan, 2019) and the original LevT model.[5] These baselines use the same training data as TM-LevT, and also process examples with and without TM matches. For the AR model, TM matches only appear concatenated to the source sentence and translation always starts from scratch; for LevT, we test both cases where the decoder is initialized with and without TM matches.

TM-LevT is based on the Transformer architecture (Vaswani et al., 2017), implemented with fairseq[6] (Ott et al., 2019).[7] We use a hidden size of 512 and a feedforward size of $2{,}048$, optimizing with Adam with a maximum learning rate of 0.0005, an inverse square root decay schedule, and

10,000 warm-up steps. We share the decoder parameters for both two deletions and the insertion operation and also tie all input and output embedding matrices (Press and Wolf, 2017). We train TM-LevT for 300k iterations with a batch size of 8,192 tokens per GPU on 8 V100 GPUs. For inference, we use a maximum iteration number of 10 for TM-LevT and LevT, and a beam size of 5 for the AR decoder. We use a batch size of 8,192 tokens and perform inference on one single GPU for all compared models. The vanilla LevT model is trained similarly, while the AR model (Bulte and Tezcan, 2019) is trained with a maximum learning rate of 0.0007, with 4,000 warmup steps for 300k iterations on 4 V100 GPUs. We report results of a *do-nothing* baseline which simply copies the TM matches as outputs. Performance is measured with BLEU using SacreBLEU[8] (Post, 2018) and with COMET (Rei et al., 2020).

4 Results and Analyses

4.1 NAT Can Benefit from TMs

We evaluate the performance of standard MT and TM-based MT on the two test sets ($\text{sim}{>}0.6$ and $\text{sim}{\in}[0.4, 0.6]$) introduced in Section 3.1. When performing standard MT, the source side only contains the source sentence for all models, and the decoder side of TM-LevT is initialized with an empty input. When translating with TMs, the TM match is concatenated to the source sentence for all models. TM-LevT is additionally initialized with the TM match on the decoder side, a setting we also consider for LevT (+tgt TM). Table 3 reports the aggregated results computed on all domains (11k sentences). The results for each domain when translating with and without TMs on $\text{sim}{>}0.6$ are in Table 2. The corresponding results with a breakdown by domain for $\text{sim}{\in}[0.4, 0.6]$ are in Appendix B.

As reported in Tables 3 and 2, the AR with TM baseline yields much higher BLEU and COMET scores than the standard MT setting. LevT can also make good use of TM matches, but its performance lags way behind the AR strategy in both settings.[9] Scores in Table 2 show that for domains like ECB and EMEA, it is difficult for LevT to generate good translations without using TMs, while for more general domains like News, the performance gap between LevT and AR are less significant.

	$\text{sim} > 0.6$		$\text{sim} \in [0.4, 0.6]$	
BLEU ↑	w/o TM	w/ TM	w/o TM	w/ TM
copy	-	52.6	-	34.5
AR	51.2	67.1	46.1	55.7
LevT	46.5	60.4	40.8	49.3

LevT	0.4251	0.5767	0.3429	0.4404
+tgt TM	-	0.1639	-	-0.3478
TM-LevT	0.5314	0.6454	0.4263	0.4889

Table 3: BLEU and COMET scores on multi-domain test sets for various TM similarity ranges. *w/o TM* is standard MT, *w/ TM* adds a retrieved match $\tilde{\mathbf{e}}$ on the source side, and use it as initial target for TM-LevT. *+tgt TM* refers to using TM match as the initial target for LevT.

TM-LevT, on the contrary, does remarkably well when translating from scratch, even surpassing the

---

[8] SacreBLEU signature: BLEU+case.mixed+lang.en-fr+numrefs.1+smooth.exp+tok.13a+version.1.5.1

[9] We use the `fairseq` source code released by Gu et al. (2019) to train the LevT model. We have performed a sanity check by training a LevT model on the WMT14 English-German data and obtained results that are about 2 BLEU points below the scores reported in Gu et al. (2019). As Gu et al. (2019) have not specified the tool used to compute BLEU scores, it is difficult to make a more precise comparison.

AR model on BLEU on the $\mathrm{sim}>0.6$ set, which is arguably easier. When using TM matches, TM-LevT also performs much better than LevT. We achieve BLEU scores of only 1.2 and 2.4 below AR for $\mathrm{sim}>0.6$ and $\mathrm{sim}\in[0.4, 0.6]$, respectively (Table 3). The effect of using TM matches greatly varies across domains. TM-LevT can improve more general domains like News and Wiki when using TMs (Table 2), even though the performance gains are less significant than for more specific domains like ECB and KDE. However, the same trend is also observed for AR, and TM-LevT even surpasses AR on Wiki in Table 2. The gap in COMET score between TM-LevT and AR is also much smaller than reported by Helcl et al. (2022), indicating that TM-LevT outputs valid translations.

Unrelated Tokens AR approaches are known to improperly copy "unrelated tokens" from TM matches into the output (Xu et al., 2020). As TM-LevT includes the deletion operation, we expect it to properly delete unrelated tokens. We define unrelated tokens as those present in $\tilde{\mathbf{e}}$ but not in $\mathbf{e}$ and count the ratio of such tokens that appear in the final translation. This is different from Xu et al. (2020), as they used a word alignment model to label tokens that are unrelated to the "source". We have re-implemented the same method, but the alignment model was never perfect and yielded additional errors, which led to an imprecise measure of unrelated tokens. Table 4 reports the ratio of such unrelated tokens: TM-LevT is slightly less prone than AR to recopy unrelated parts of the TM matches in both test sets. LevT does even better on that account, but its comparatively lower BLEU scores suggest that it also discards valid tokens.

Unrelated rate ↓	$\mathrm{sim}>0.6$	$\mathrm{sim}\in[0.4, 0.6]$
AR	28.42	17.78
LevT	21.39	13.74
TM-LevT	26.67	16.56

Table 4: Percentage of unrelated tokens from the retrieved TM matches appearing in the final translations.

4.2 Ablation Analysis

We conduct an ablation analysis to study the effectiveness of each component of our method, by training a new model for each contrast. Training without TM matches on the target side (Table 5, -tgt TM) vastly degrades the performance in both conditions (w/ and w/o TM), indicating that the standard MT can also benefit from training with TMs as initial targets. However, removing TM matches on the source side (-src TM) improves standard MT, as also observed by Bulte and Tezcan (2019), but has a negative impact when translating with TMs. This highlights the importance of always remembering the TM match on the source side of TM-LevT.

	$\mathrm{sim}>0.6$		$\mathrm{sim}\in[0.4, 0.6]$	
BLEU	w/o TM	w/ TM	w/o TM	w/ TM
TM-LevT	52.6	65.9	45.7	53.3
-tgt TM	46.6	60.7	40.7	49.6
-src TM	53.2	64.3	45.9	52.2
-final-del	38.5	64.2	32.7	50.8
-self-pred	52.6	65.2	45.6	52.7

Table 5: BLEU scores for various configurations. *-tgt TM* (resp. *-src TM*) is the model trained without TM match on the target (resp. source) side. *-final-del* is trained without the final-del operation, *-self-pred* only applies reference deletions during training.

We also compare with alternative implementations of the deletion operation. Results in Table 5 (-final-del) show that removing the final deletion step mostly impacts TM-LevT in the standard MT setting, where the detection of wrong predictions matters most (Huang et al., 2022). This further demonstrates that unrelated tokens from TM matches and the prediction errors of the model are vastly different, and training to delete both is necessary. Last, we experiment with using only reference deletion labels to train the insertion operation, instead of using both the reference and model predictions (see Section 2.3). We observe (-self-pred) a small performance drop with respect to the baseline policy.

4.3 Knowledge Distillation

KD is used in most NAT models, as it reduces the complexity and lexical diversity of target sentences, thereby helping NAT approaches to mitigate the multimodality issue (Zhou et al., 2020; Xu et al., 2021). Given that our results so far have only relied on actual target data, we thus ask whether KD could also improve the performance of TM-based NAT. We train a teacher Transformer-based model with the 4.4M parallel data and use it for data distillation. As expected, using KD does improve BLEU scores of TM-LevT on standard MT (Table 6). However, using KD hurts performance when editing an initial similar translation, resulting in a large drop in scores compared to using real data. Applying KD also to TM matches yields similar results.

The benefits of KD are assumed to mainly reduce

SRC	Measures to reduce or eliminate releases from unintentional production
TM match $\text{sim}=0.73$	Measures to reduce or eliminate releases from intentional production and use Mesures propres à réduire ou éliminer les rejets résultant d'une production et d'une utilisation intentionnelles
TM-LevT +TM	Mesures visant à réduire ou à éliminer les disséminations de la production non intentionnelle Mesures **propres** à réduire **ou éliminer** les **rejets résultant d'une** production non intentionnelle
KD +TM	Mesures visant à réduire ou à éliminer les rejets de la production non intentionnelle Mesures **visant** à réduire ou **à** éliminer les rejets **provenant de la** production non intentionnelle
REF	Mesures propres à réduire ou éliminer les rejets résultant d'une production non intentionnelle

	$\text{sim} > 0.6$		$\text{sim} \in [0.4, 0.6]$	
BLEU	w/o TM	w/ TM	w/o TM	w/ TM
copy	-	52.6	-	34.5
Teacher	56.7	-	49.6	-
AR + KD	55.7	56.9	48.7	49.4
TM-LevT	52.6	65.9	45.7	53.3
+KD	54.3	57.1	47.6	49.3
+KD TM	53.8	56.0	47.3	48.5

Table 6: BLEU scores with and without KD. *Teacher* is the teacher model used to distill the parallel data. *+KD* applies KD to the training references, *+KD TM* applies KD to both references and TM matches.

the multimodality issue in NAT (Zhou et al., 2020). This issue may be less problematic in our context, as the TM match already provides an explicit and often unambiguous context for generating the missing words in the translation. In this case, KD is even detrimental to the translation quality. This is because using distilled references exposes TM-LevT to imperfect translations (with BLEU scores of respectively 56.7 and 49.6), only a few points better than the initial TM matches (*copy* in Table 6). This seems to limit TM-LevT's ability in learning to generate very high quality translation that it can achieve when exposed to real references (+8.8 and +4 BLEU on $\text{sim}>0.6$ and $\text{sim}\in[0.4, 0.6]$, respectively). For comparison, we also train an AR model using the same KD data (AR + KD) and again observe very little gain when translating with TMs. In fact, the limit of models using KD data, whether using TMs or not, seems to be upper-bounded by the performance of the teacher. These intuitions are illustrated by the example in Figure 2.

4.4 Computational Trade-offs of TM-LevT

Inference speedup is the main advantage of using NAT models. Table 7 compares the average decoding time per sentence on all domains.[10] Here, we perform the inference speed analysis as a sanity check. As discussed by Kasai et al. (2021), Helcl et al. (2022) and Schmidt et al. (2022), comparing the inference speed for NAT models could be tricky. We follow here the recommendations of Helcl et al. (2022) and use the same hardware conditions and inference batch size for all settings, making our results as comparable as possible. TM-LevT is much faster than AR both with and without TMs. We also note that decoding with a TM match is always slightly longer due to (a) finding matches; (b) encoding a longer input made of the source and the TM match.[11]

Settings	AR	TM-LevT	Speedup
w/o TM	5.91	2.53	$\times 2.34$
w/ TM	7.80	3.43	$\times 2.28$

Table 7: Average decoding time (ms) per sentence for all domains of both $\text{sim} > 0.6$ and $\text{sim} \in [0.4, 0.6]$.

	$\text{sim} > 0.6$		$\text{sim} \in [0.4, 0.6]$	
Systems	w/o TM	w/ TM	w/o TM	w/ TM
LevT	2.027	1.899	2.544	2.538
TM-LevT	1.781	1.348	2.260	1.880

Table 8: Average number of decoding iterations.

Using TMs in MT is expected to improve the translation quality while also reducing the decoding load, as useful tokens can be directly copied to the output. This is not observed in AR approaches nor in the original LevT, as both models always start inference with an empty input. TM-LevT, however, uses an initial translation to speed up decoding. We report the average number of iterations required in inference in Table 8, where we see that translating with TMs reduces the decoding effort for TM-LevT by about 20%, while it remains almost unchanged for LevT. We also find that TM-LevT needs fewer

---

[10] We exclude PHP, for which AR generates many repetitions, yielding very long runtimes that biased the average.

[11] The numbers in Table 7 only reflect the effect of (b), as step (a) is the same for both AR and NAT models.

iterations to converge than LevT in all conditions. Note that the training time of TM-LevT is only 1.1-1.2× compared to LevT, which we think is an acceptable overhead considering the large performance gains and the reduction of decoding load.

4.5 Good Matches Increase MT Quality

TM-based models require good TM matches to improve their translations; when none is found, standard MT can be used instead. Defining the minimal similarity for a match to be useful (0.4 in this paper) requires some tuning and the best threshold may vary from corpora to corpora. In this section, we take a closer look at the effect of thresholding for the AR and NAT models considered here. We compute the best TM match for the held-out set of Section 3.1, trying to find a matched translation for all sentences without any filtering. We then combine the held-out set with the two test sets ($\mathrm{sim}{>}0.6$ and $\mathrm{sim}{\in}[0.4, 0.6]$) and bucket sentences by the similarity of the best TM match. For each bucket, we compute BLEU scores obtained for various systems and plot results on Figure 3.

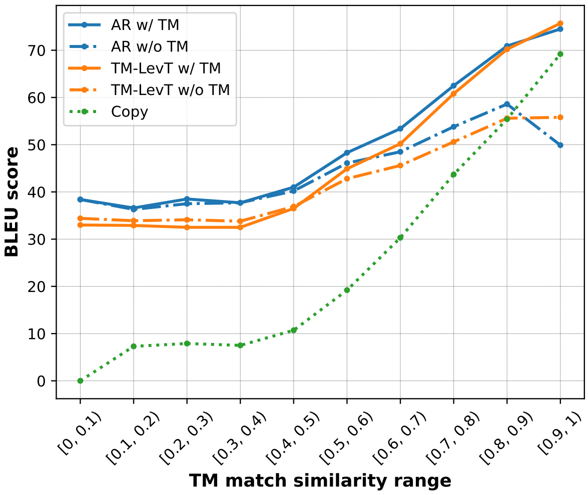

Figure 3: BLEU scores when translating with TM matches of various similarity ranges. The *Copy* strategy uses the retrieved example as the final translation.

We first observe that the scores of all systems, even those that do not use TMs, increase with better TM matches: this is because test sentences with better matches are also more similar to the training data, thus easier to translate for all systems. Secondly, even with very good matches, both models using TMs are able to improve over the *Copy* strategy. Comparing AR to TM-LevT, we see that the former is preferable across the board, even though the gap closes when very good matches are available. The TM-based AR model is almost as good as standard MT for poor matches and starts improving standard MT when $\mathrm{sim}{\geq}0.4$. In comparison, we see for TM-LevT a small edge of standard MT over translating with TMs which subsists as long as $\mathrm{sim}{<}0.5$; for higher similarity matches, translating with TMs gets much better scores. These results suggest that thresholding may not be necessary and that both TM-based architectures adapt their behavior to the match quality, with hardly any performance loss w.r.t. the standard MT approach.

5 Related Work

TM-based MT Most studies using TM sentences to improve translations are based on AR models and either use a second encoder to integrate the TM match or concatenate it to the source in the same encoder. The former approach is illustrated by Gu et al. (2018b), who rerun the translation model as an encoder to encode the similar translation. Xia et al. (2019) alternatively use a compact graph as the second encoder. Another work along this line is He et al. (2021), which encodes the TM match using the decoder embedding matrix and performs a cross-attention between the decoder input and the encoded TM match. Besides, Cai et al. (2021) directly search in a corpus of target sentences with a cross-lingual similarity and encode the resulting sentences with a dual encoder approach similar to Junczys-Dowmunt and Grundkiewicz (2018). Single encoder approaches are first explored by Bulte and Tezcan (2019), who concatenate the TM match with the source to perform TM-based MT. This idea is extended by Xu et al. (2020) by adding a second embedding feature to distinguish related and unrelated tokens and by Pham et al. (2020), who use both source and target sentences of the matched TM. Zhang et al. (2018) explore a different direction to improve translation with retrieved segments instead of complete sentences. Khandelwal et al. (2021) further propose k-nearest neighbor MT by searching for target tokens that have similar contextualized representations at each decoding step, an approach continued by Zheng et al. (2021) with dynamic neighborhoods.

NAT with Augmented Resources Several works have studied ways to integrate extra information into NAT architectures, mostly using the LevT model as their starting point. Susanto et al. (2020) incorporate lexical constraints with LevT by simply initializing the decoder with constraint words inserted in a predefined order; this limitation is lifted in the EDITOR model of Xu and Carpuat (2021), who introduce a repositioning operation to allow constraints to be inserted in arbitrary order. Zeng et al. (2022) pay particular attention to low-frequency constraints by preventing rare tokens from being removed when generating training samples for the insertion operation. The most relevant study to this paper is the recent work by Niwa et al. (2022), who also seek to improve LevT with TMs, using good matches to initialize the decoder. This work only mildly departs from the vanilla LevT with a small modification of the deletion operation to remove unrelated tokens and only compare with standard MT, failing to contrast their improvements with TM-based AR models. Finally, Xu et al. (2022) also explore the integration of TMs into the original LevT model, but fail to obtain improvements over a copy baseline.

6 Conclusion

In this paper, we studied ways to augment the LevT architecture with TMs. Our proposal adds an initial deletion operation during training to detect possible unrelated tokens present in TM matches. By copying the TM match both on the source side and on the target side as an initial target sequence, our model vastly outperformed the original LevT model and achieved BLEU scores approaching those of a strong AR model both when decoding from scratch and when editing a TM match. Compared to LevT, TM-LevT also generates translations that contain less unrelated tokens, and is able to converge in fewer iterations. We also found that training with TMs improves NAT performance on standard MT. Finally, we have tried to combine KD with our approach, concluding that it was more hurting than helpful for TM-based architectures.

Limitations

NAT models such as LevT are more difficult to train than AR models, as they require larger batch size to converge. Our TM-LevT adds an initial deletion operation during training, therefore slightly lengthening the training time by approximately $1.1 - 1.2\times$ with respect to the basic LevT model. Due to computational limits, we have not conducted experiments on other language pairs, especially on more distant language pairs. Even tough our findings apply for a wide range of domains, considering also more languages would be helpful to fully validate our observations.

Acknowledgement

The authors would like to thank Maxime Bouthors for his suggestions and Ruiyang Zhou for her help of the deficiency analysis of LevT. We would also like to thank the anonymous reviewers for their valuable suggestions and comments. This work was granted access to the HPC resources of IDRIS under the allocation 2022-[AD011011580R2] made by GENCI. The first author is partly funded by SYSTRAN and by a grant (Transwrite) from the Région Ile-de-France.

A Details of Data Processing

Table 9 reports statistics of the ratio of TM matches for various similarity ranges of the multi-domain dataset described in Section 3.1. These ratios vary greatly across domains.

Domain	Raw	sim > 0.6	sim $\in [0.4, 0.6]$
ECB	195,956	51.73%	14.06%
EMEA	373,235	65.68%	12.65%
Epps	2,009,489	10.12%	25.30%
GNOME	55,391	39.31%	11.06%
JRC	503,437	50.87%	16.67%
KDE	180,254	36.00%	10.81%
News	151,423	2.12%	9.65%
PHP	16,020	34.93%	12.38%
TED	159,248	11.90%	26.64%
Ubuntu	9,314	20.32%	8.26%
Wiki	803,704	19.87%	17.32%
Total	4,457,471	24.27%	20.00%

Table 9: Dataset statistics, with ratios of sentences with at least one TM match for various similarity ranges.

B Detailed Results on Each Domain

BLEU and COMET scores for each domain are in Tables 10, 11, 12, 13. The variation in scores across domains is large, confirming that TM matches can be very beneficial for some technical domains (e.g. ECB, EMEA, GNOME, KDE, JRC), for which we often find good matches that help to greatly increase the performance. On the other hand, News, Wiki and TED yield less matches, and these only help for both the AR approach and TM-LevT when the similarity is high (sim > 0.6).

Shorten the Long Tail for Rare Entity and Event Extraction

Pengfei Yu, Heng Ji
University of Illinois Urbana-Champaign `{pengfei4,hengji}@illinois.edu`

Abstract

The distribution of knowledge elements such as entity types and event types is long-tailed in natural language. Hence information extraction datasets naturally conform a long-tailed distribution. Although imbalanced datasets can teach the model about the useful real-world bias, deep learning models may learn features not generalizable to rare or unseen mentions of entities or events during evaluation, especially for rare types without sufficient training instances. Existing approaches for the long-tailed learning problem seek to manipulate the training data by re-balancing, augmentation or introducing extra prior knowledge. In comparison, we propose to handle the generalization challenge by making the evaluation instances closer to the frequent training cases. We design a new transformation module that transforms infrequent candidate mention representation during evaluation with the average mention representation in the training dataset. Experimental results on classic benchmarks on three entity or event extraction datasets demonstrate the effectiveness of our framework. [1]

1 Introduction

Long-tailed distributions are common in natural language processing tasks. This natural phenomenon of long-tailed distribution is formulated as Zipf's Law (Reed, 2001). For information extraction, knowledge elements such as entities, relations and events typically conform a long-tailed distribution in natural language. This leads to the imbalanced distribution of types in the benchmark datasets unless manual manipulation is performed to balance the dataset. We show the entity type distribution of an entity extraction dataset (Few-NERD (Ding et al., 2021)), and the event type distribution of two event extraction datasets (ACE 2005 (Walker et al., 2006) and MAVEN (Wang et al., 2020)) in Figure 1. All three datasets have similar long-tailed distributions. Among them, MAVEN and Few-NERD are two relatively large-scale datasets, but the training mentions are still concentrated on a small number of frequent types and majority of the entity/event types are rare types without sufficient training examples.

Long-tailed distribution is a generic problem not limited to NLP research. In fact, a lot of previous work on the long-tailed learning is in the computer vision domain (Lin et al., 2017; Kang et al., 2020). These approaches consider the imbalance in the type distribution as the major problem and are mostly based on balancing the datasets by upweighting the rare types and downweighting the frequent types. However, we argue that this line of research faces significant challenges when applying to the information extraction task. First, balancing the dataset breaks the real-world long-tailed prior in the datasets and may lead the model to mistakenly predict the long-tailed types too often. We observe this phenomenon in our experiments in Section 3 especially for the Classifier Re-training baseline (Kang et al., 2020). Second, due to the lack of effective data augmentation approaches as in the computer vision domain, upweighting the training mentions will only make the model to repetitively learn the same set of instances and aggravate the overfitting problem.

Instead of the imbalance in distribution, the real challenge of long-tailed learning for NLP is knowledge insufficiency, i.e. long-tailed datasets don't contain enough examples to acquire generalizable knowledge for the rare types. Learned models tend to capture features such as event trigger words for rare types and fail to generalize well to rare or even unseen cases (unseen trigger words) of those types during evaluation. For instance, if an event extraction model is trained on a dataset where all `Acquit` events are triggered by the keyword *acquit*, it may not identify the `Acquit` event trig-

gered by **walk free** in *The adjudicator allowed the criminal to* ***walk free***. Under this perspective, existing work tackling the long-tailed problem in information extraction (Han et al., 2018; Zhang et al., 2019) incorporates external structural knowledge to help learning rare types. However, the selection of the structural knowledge requires expertise in the target ontology and is not easily transferable to other ontologies. Another more recent line of work (Tang et al., 2020; Nan et al., 2021) considers the causal inference (Pearl et al., 2000) approach to solve the long-tailed problem. They aim to avoid the learning of spurious correlations between the input features and the labels in the limited training data for rare types. This is usually achieved by removing the effect of a manually selected confounding factor in prediction through deconfounded learning methods such as backdoor adjustment and inference based on total direct effect (Pearl et al., 2000). Although the model is guided to avoid spurious correlation through causal-inference-based approaches, learning the generalizable features with real causalities is still challenging due to the knowledge insufficiency problem.

In this work instead of confronting the knowledge insufficiency problem directly, we propose to bypass the problem by transforming the evaluation instances that require additional knowledge into more familiar instances that are closer to the frequent training instances. We decompose the input sentence $\{t_0, t_1, \ldots, t_n\}$ for the event/entity prediction task into two parts: a candidate token $e = t_i$ for the i-th token and surrounding contextual tokens $c = \{t_j\}_{j=0}^{i-1} \bigcup \{t_j\}_{j=i+1}^{n}$. Instead of making predictions for an event/entity type y_k solely based on $P(y_k|e, c)$, we propose to also consider predictions on averaged training inputs $P(y_k|c, \boldsymbol{r}_k)$, where $\boldsymbol{r}_k$ is the average training hidden representation of the type y_k. Our framework combines these two predictions using a transformation module. The transformation module computes weights g_e for the original candidate token e and g_k for each event type representation r_k. Moreover, instead of simply combining probabilities as $g_e P(y_k|e, c) + g_k P(y_k|c, \boldsymbol{r}_k)$, we use two weights g_e and g_k to combine in the representation layer for $\boldsymbol{e}$ and $\boldsymbol{r}_k$ to produce $P(y_k|g_e \boldsymbol{e} + g_k \boldsymbol{r}_k, c)$. The transformation module decides the weights g_e and g_k based on the frequency of the candidate mention in the training dataset and the cosine similarity between the candidate mention representation and all event types' average training mention representations in the ontology. Experimental results on three benchmark datasets demonstrate the effectiveness of our framework. Additionally, we found our approach, though derived from a different motivation, can be interpreted as a backdoor adjustment approach (Pearl et al., 2000) as shown in Section 2.5, which gives another interpretation that our approach improves long-tail learning by facilitating the model to learn the true correlation between the candidate text span and the event/entity type. We also empirically found that our approach facilitates the model to capture more generalizable features, which aligns with the goal of causal inference approaches.

To summarize, we propose a new approach for learning from the long-tailed datasets for entity extraction and event extraction. Our contributions are two-fold:

- We provide a new framework by bypassing the knowledge insufficiency problem in long-tailed learning and propose a novel learning framework in this perspective.
- We found that our framework aligns theoretically with the causal inference approach and can facilitate the model to capture more generalizable features.

2 Approach

2.1 Task Definition

In this work we take the task of both entity extraction and event extraction as sequence labeling

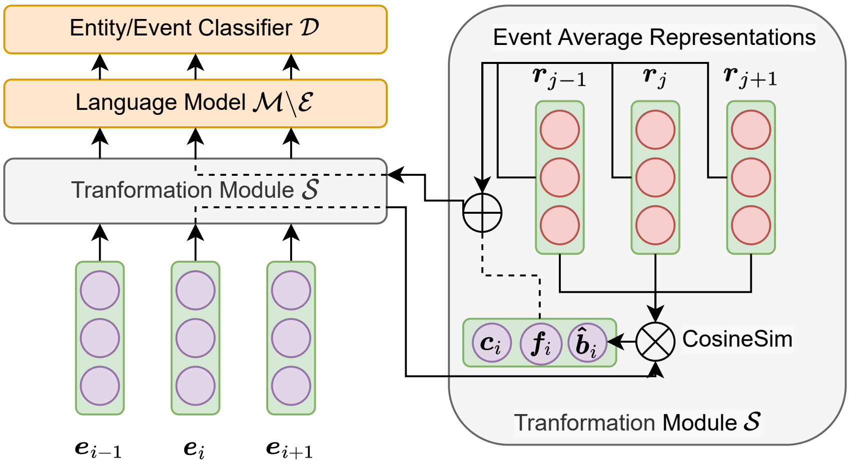

Figure 2: Overall long-tail learning information extraction framework. We ignore the original token t_i and only show the token embeddings $\boldsymbol{e}_i$ in this figure for conciseness. Here we use $\mathcal{M}\backslash\mathcal{E}$ to indicate the language model layers after the embedding layer and $\mathcal{D}$ as the classifier heads for the sequence labeling task. The transformation module $\mathcal{S}$ combines rare candidate mentions with average training mentions. The inputs to the transformation module includes the frequency feature $\boldsymbol{f}_i$, the similarity features $\hat{\boldsymbol{b}}_i$ between the token embedding $\boldsymbol{e}_i$ and the average training embeddings $\{\boldsymbol{r}_j\}_{j=1}^{K}$, and the context features $\boldsymbol{c}_i$.

problems. The input to the model $\mathcal{H}$ is a sequence of tokens $x = \{t_0, t_1, \ldots, t_n\}$, and the model predicts a label for each token $\mathcal{H}(x) = \{l_0, l_1, \ldots, l_n\}$. Each l_i is either one of the entity/event types or the `None` type for none-entity or none-event tokens.[2]

2.2 Overview of the Learning Framework

The learning of our proposed long-tailed extraction framework includes two steps. First, we finetune a language model with an additional classifier head for the sequence labeling problem without special treatments for the long-tail problem. In the second step, we train the transformation module while fixing the parameters of the language model. We adopt this two-stage training approach because the transformation module requires the language model's representations as inputs as we will show in Section 2.4. The finetuning step should render these representations as more task-specific features, which we redeem to be helpful for the learning of the transformation module. We will introduce these two steps in the following sections. The overall architecture is shown in Figure 2 and the two-staged training strategy is illustrated in Figure 3.

2.3 Finetuning Step

Given an input sequence $x = \{t_0, t_1, \ldots, t_n\}$, we first encode it with a pretrained language model $\mathcal{M}$ into $\mathcal{M}(x) = \{\boldsymbol{t}_0, \boldsymbol{t}_1, \ldots, \boldsymbol{t}_n\}$. We then adopt a linear discriminator $\mathcal{D}$ to predict the label for each token

$$l_i = \arg\max \mathcal{D}(\boldsymbol{t}_i). \qquad (1)$$

We finetune $\mathcal{M}$ and $\mathcal{D}$ with the cross entropy loss.

2.4 Learning the Transformation Module

The transformation module $\mathcal{S}$ transforms the representation for each token t_i into a weighted combination of its original representation and the average training representation of each event type. Our goal is to compute weights g_e, g_k for the final prediction $P(y_k | g_e \boldsymbol{e} + g_k \boldsymbol{r}_k, c)$ for each type y_k. However, this would require feeding the inputs multiple times to the language model, which is inefficient. Hence, we simplify the prediction to $P(y_k | g_e \boldsymbol{e} + \sum_{i=1}^{k} g_k \boldsymbol{r}_k, c)$. In other words, our transformation module combines the average representations of all types together in the hidden layer. We can essentially perform the transformation in any hidden layers of the pretrained language model $\mathcal{M}$. In this work, we perform transformation in the embedding layer to take full advantage of $\mathcal{M}$'s capability of encoding contextual information.

Specifically, let $\mathcal{E}(t_i) = \boldsymbol{e}_i$ be the embedding representation of the token t_i. Let $\{\boldsymbol{r}_j\}_{j=1}^{K}$ be the average training embedding representation for the entity/event type j, i.e.,

$$\boldsymbol{r}_j = \frac{1}{\#j} \sum_{\{t|l(t)=j\}} \mathcal{E}(t). \qquad (2)$$

---

[2] We adopt the IO labeling schema instead of BIO labeling schema to be consistent with the annotations in the Few-NERD dataset (Ding et al., 2021)

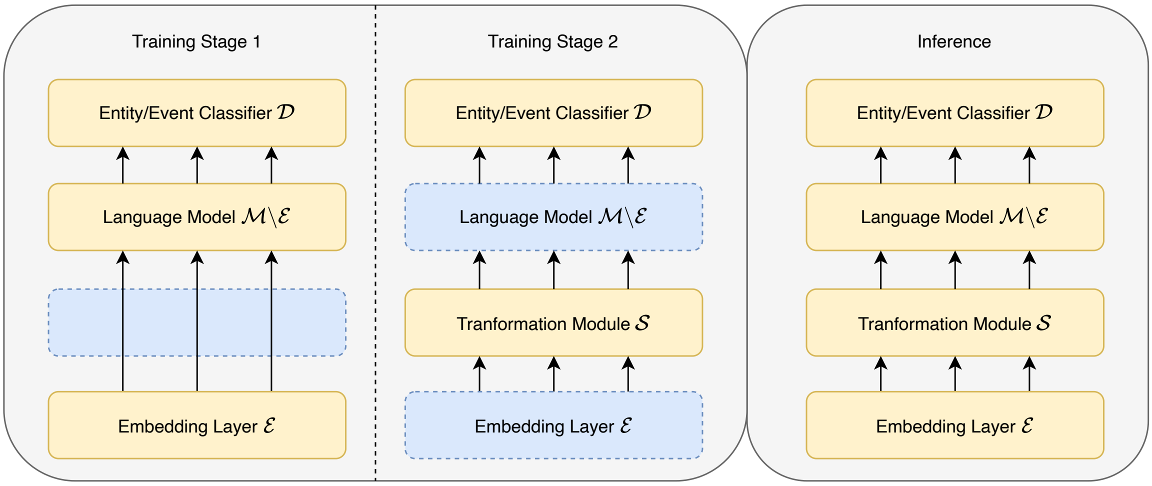

Figure 3: Illustration of the training and inference stages. There are two stages of the training on the left. Modules with dashed lines and blue background are not updated during the corresponding training stage.

Here $\{t|l(t) = j\}$ refers to the training tokens with the label j and $\#j$ is the total number of such tokens. The transformation module computes weights to combine each $\boldsymbol{e}_i$ with $\{\boldsymbol{r}_j\}_{j=1}^K$. We use the following information as input to compute the weights for combination

- t_i's frequencies of being labeled as entity/event types : $\boldsymbol{f}_i = [\exp(\gamma f_{ij})]_{j=1}^K$. Here we rescale the original frequencies inspired by (Lin et al., 2020). We use $\gamma = 0.1$ following (Lin et al., 2020). We expect the tranformation module to provide most help in rare cases when $\boldsymbol{f}_i$ is small.

- The similarity of t_i's embedding $\boldsymbol{e}_i$ with average training embeddings $\boldsymbol{r}_j$: $\boldsymbol{b}_i = [\cos(\boldsymbol{e}_i, \boldsymbol{r}_j)]_{j=1}^K$. If $\boldsymbol{b}_i$ contains large values, t_i is close to some event type's average embedding and potentially not a rare mention. On the other hand, if $\boldsymbol{b}_i$ is very small, t_i deviates significantly from some event type's average embedding and the transformation may significantly alter the meaning of the input. Taking these into consideration, we propose to model the similarity value $\boldsymbol{b}_i$ with a quadratic function, i.e. we use $\hat{\boldsymbol{b}}_i = [\boldsymbol{b}_i; \boldsymbol{b}_i^2]$ as the similarity features to the transformation module.

- The context representation $\boldsymbol{c}_i$, which is computed by the pretrained language model $\mathcal{M}$ while masking t_i in the input sequence x. Hence $\boldsymbol{c}_i$ is independent of the token t_i. This is to make sure that the transformation module is not overfitted only on the seen candidate tokens during training, because our goal is to apply the transformation module to rare cases in the evaluation corpus.

We decompose the computation of these weights into two steps. We first compute aggregation weights $\{\alpha_j\}_{j=1}^K$ for $\{\boldsymbol{r}_j\}_{j=1}^K$ with an attention module based on the context $\boldsymbol{c}_i$:

$$\begin{aligned} \alpha_j &= \frac{\exp(\langle \boldsymbol{a}_j, \boldsymbol{c}_i \rangle)}{\sum_{k=1}^K \exp(\langle \boldsymbol{a}_k, \boldsymbol{c}_i \rangle)} \\ \boldsymbol{s}_i &= \sum_j \alpha_j \boldsymbol{r}_j \end{aligned} . \tag{3}$$

Here $\{\boldsymbol{a}_j\}_{j=1}^K$ are trainable weights. We then feed all three features $[\boldsymbol{f}_i; \hat{\boldsymbol{b}}_i; \boldsymbol{c}_i]$ into a linear layer with the sigmoid activation to compute two gating scores $(g_e, g_s) \in [0, 1]^2$. The final embedding representation is computed as

$$\boldsymbol{h}_i = g_e \boldsymbol{e}_i + g_s \boldsymbol{s}_i. \tag{4}$$

We then substitute $\boldsymbol{e}_i$ with $\boldsymbol{h}_i$ for the following layers in $\mathcal{M}\backslash\mathcal{E}$.[3]

We train the transformation module $\mathcal{S}$ using the same cross entropy loss as the finetuning step. We also compute the cross entropy on the attention weights of the entity/event types in Equation (3) as an additional loss. We fix the parameters of the finetuned language model $\mathcal{M}$. This ensures that the similarity features $\hat{\boldsymbol{b}}_i$ and the context representations $\boldsymbol{c}_i$ remain fixed during the learning of $\mathcal{S}$. We provide training details in the Appendix.

---

[3] From Equation (4) we essentially have $g_k = g_s \alpha_k$

2.5 Connection to Causal Inference

We found our architecture can be mathematically intepreted as a backdoor adjustment (Pearl et al., 2000) method in causal inference, which is used to mitigate the effect of some confounding factor $\mathcal{U}$ in making decisions. In our case, it can be formulated as the following prediction probability

$$P(l_i|do(t_i)) = \sum_u P(l_i|t_i, \mathcal{U} = u)P(\mathcal{U} = u), \tag{5}$$

where u is the value space of $\mathcal{U}$. We refer readers to (Pearl et al., 2000) for the derivation of the above equation[4]. If we select the confounding factor $\mathcal{U}$ as the type prediction based on the context around the token t_i (independent of t_i), Equation (5) becomes

$$P(l_i|do(t_i)) = \sum_{j=1}^{K} P(l_i|t_i, j)P(j|\boldsymbol{c}_i),. \tag{6}$$

The attention weights $\{\alpha_j\}_{j=1}^{k}$ in Equation (3) is can be considered as probabilities of event types dependent on $\boldsymbol{c}_i$, thus can be seen as $P(j|\boldsymbol{c}_i)$ in the above equation. If we further model $P(l_i|t_i, j) = P(l_i|\boldsymbol{e}_i + \boldsymbol{r}_j)$ and apply the Normalized Weighted Geometric Mean (NWGM) approximation following (Yue et al., 2020),

$$P(l_i|do(t_i)) \approx P(l_i|\boldsymbol{e}_i + \sum_{j=1}^{k} \alpha_j \boldsymbol{r}_j). \tag{7}$$

In our framework, we are essentially computing

$$P(l_i|t_i) = P(l_i|g_e\boldsymbol{e}_i + g_s \sum_{j=1}^{k} \alpha_j \boldsymbol{r}_j). \tag{8}$$

This means that α_j composes the deconfounding priors $P(\mathcal{U})$ and (g_e, g_s) serve as the switch for the backdoor adjustment decisions. We expect the model to make decisions on rare or unseen mentions with the backdoor adjustment, and rely on the model's own prediction with more frequent cases.

3 Experiments

3.1 Datasets and Evaluation

We experiment on an entity extraction dataset, Few-NERD (Ding et al., 2021) and two event extraction datasets, ACE 2005 (Walker et al., 2006) and MAVEN (Wang et al., 2020). We provide data statistics in Table 1. Few-NERD, MAVEN and ACE include 67, 168, and 33 types respectively. For ACE 2005, we split the dataset such that all event types are covered in the evaluation data which is different from the splits used in previous work. For Few-NERD, we used the "supervised" split for experiments.

For evaluation, we use the macro F1 score as the main metric to reflect the influence of long-tail types. We also report micro F1 for additional reference. We provide macro recall, macro precision, micro recall and micro precision in Appendix. Previous work also reports scores on subsets of rare types (Nan et al., 2021). Instead of manually determine a frequency threshold for the "rarest" types, we plot curves of F1 scores on all types in Figure 4. All results are averaged over three runs using different random seeds.

3.2 Methods in Comparison

We group previous work on long-tailed learning into two categories: balancing-based approaches and causal inference approaches. For balancing-based approaches, we mainly follow (Kang et al., 2020) and implemented Classifier Re-training (CRT), Nearest Class Mean classifier (NCM), τ-normalized classifier (τ-norm) and Learnable weight scaling (LWS). We also implemented the focal loss approach (Lin et al., 2017). For causal inference work, we implemented Momentum (Tang et al., 2020) and CFIE (Nan et al., 2021). Although (Nan et al., 2021) also experimented on the ACE 2005 and MAVEN, we re-implemented[5] their methods due to the difference in splits and evaluation strategies. CFIE also has different designs for the entity extraction and event extraction models. We didn't re-implement the entity model due to insufficient details. We also compare with a **Vanilla** baseline which is the sequence labeling model without the transformation module.

3.3 Main Results

We show our main results in Table 2 and Figure 4. From Table 2, our framework achieves the best macro F1 scores across three datasets. We also noticed that our approach improves macro F1 scores without suffering from inferior micro F1 scores. Al-

---

[4] Note that the common formulation for $P(l_i|t_i)$ would be substituting $P(\mathcal{U} = u)$ with $P(\mathcal{U} = u|t_i)$

[5] Due to insufficient details in their paper and released code, we implemented their framework to the best of our knowledge. CFIE also requires named entity extraction results as part of the inputs to event extraction. Therefore it is not clear how the entity extraction model is designed.

Table 1: Dataset statistics.

though the Momentum baseline performs closely to our approach in ACE Macro F1. However, Momentum has a much worse micro F1 sacrificing frequent types and worse performance on the other two datasets. These results also show the superiority of our approach and indicate that our model's performance on frequent types is not harmed. This is because we do not tackle the long-tailed learning problem in terms of balancing that may affect the natural distribution in the dataset. Instead, we transform the long-tailed evaluation samples into frequent training samples with the transformation module.

Although macro F1 metric puts extra stress on the long-tailed types, the performance on the rare types is still dilated by frequent types especially for datasets with a large number of types such as MAVEN. In order to further investigate the performance on different subsets of event types, we show in Figure 4 macro F1 improvements (over the `Vanilla` baseline) for the top X fraction of the event types with the fewest training examples. We notice that our approach, together with other approaches, indeed improves the learning with long-tailed types when X is small. We notice that our approach can significantly outperform the baseline for the less frequent types with a maximum of over 10% on ACE 2005 event dataset. We found our approach has the best performance of the moderately long-tailed event types compared with other long-tailed learning approaches. For extremely long-tailed types, our performance is also close to the best method `Momentum` (Tang et al., 2020). One possible reason of our model's ineffectiveness on extremely long-tailed types is that we cannot learn reliable representation $\boldsymbol{e}_i$ to compute similarity values $\hat{\boldsymbol{b}}_i$ for the transformation module. Another possible reason is that the extreme long-tailed types don't have enough training instances to provide an informative average training representation r_k. A potential solution would be introducing external knowledge (e.g., a few keywords as candidate event triggers or entity mentions) to enrich the r_k. Moreover, our approach is more consistent than other methods when X grows larger. This further validates that our approach improves the long-tailed types without sacrificing the performance of frequent event types. For more references, we also provide top 10 event types in MAVEN dataset where our method achieves most F1 performance gain on in Appendix. Majority of those types are rare types.

3.4 Improving Classifier Features

In our second training stage, we finetune the entity/event classifier head together with the transformation module. Finetuned classifiers from our approach should benefit from the connections of our approach and the backdoor adjustment approach for causal inference in Section 2.5, which encourages the model to capture generalizable features instead of surface correlations. To test the finetuned classifiers alone, we evaluate our framework with the transformation module disabled, i.e. forcing $(g_e, g_s) = (1, 0)$ in Equation (4). The forward architecture becomes exactly the same as the `Vanilla` model. In Table 3, we observe that finetuned classifier alone outperforms the `Vanilla` baseline. Since we fixed the language model in the second stage, the improvements purely come from the finetuned classifiers that have learned to avoid surface features for prediction.

In addition to the interpretation of the improvements from the causal inference theory, we give a more intuitive explanation based on Equation (4). During the second training step, Equation (4) can be seen as changing the original candidate representation with an interpolation of itself and other candidates' representations of the same event type. This is similar to augmenting the dataset by interchanging mention spans of the same type across sentences, though we interchange it with the average representation of that type in the entire training dataset. The classifier may benefit from this "aug-

Macro F1	62.4	61.9	60.4

Table 3: Performance (in %) with the transformation module disabled (No Sub) on the ACE 2005 dataset.

3.5 Case Study

We also show some examples that the `Vanilla` baseline misses but our approach correctly identifies and classifies the candidate mentions in Table 4. We also visualize the transformation weights (g_e, g_s) in Equation (4). As discussed in Section 3.3, our model is the best at handling moderately long-tailed types. For these two examples, the event `Start-Position` in the first case has 94 mentions and `became` appears only 2 times as the trigger. In the second case, the `Action` appears 709 times, but only 16 of them are triggered by `undertaken`[6]. It is worth mentioning that although g_s is not as large as g_e in both cases, we found that they are indispensable since the model fails on both cases if we disable the transformation module by forcing $g_s = 0$.

4 Related Work

4.1 Balancing-based Long-tailed Learning for Computer Vision

Long-tailed learning is closely related to imbalanced learning. In the computer vision domain, Lin et al. (2017) proposes the focal loss to handle

---

the imbalanced learning problem in object detection. The focal loss downweights the loss terms for confident training samples so that the model predicts high probabilities for the gold standard labels. In addition to this, some work (Zhang et al., 2019; Rebuffi et al., 2017), though not focusing on the long-tailed learning problem, adopts special training strategies to tackle the imbalance in the datasets. Kang et al. (2020) summarize these approaches and evaluate them with the computer vision tasks. These approaches are mostly based on balancing the datasets by upweighting the rare types and downweighting the frequent types, either by modifying the sampling strategy or associating weights to the loss terms. These methods first learn the feature extractor with the original imbalanced distribution and then perform special treatments to the classification layer. Classifier Re-training (CRT) retrains the classification layer by sampling examples from each type uniformly. Nearest Class Mean classifier (NCM) uses the average training features as the type-level features and uses certain distance metrics to perform the nearest neighbor classifcation. τ-normalized classifier (τ-norm) normalizes the type weights in the classification layer. This can make sure the weights for frequent types are not significantly larger than rare types. Learnable weight scaling (LWS) is similar to τ-norm but learns the normalization weights while sampling examples from each type uniformly.

4.2 Long-tailed Learning with External Knowledge for IE

Balancing-based methods are usually ineffective in information extraction as shown in our experiments. Existing work usually tackles the long-tailed problem in information extraction (Han et al., 2018; Zhang et al., 2019) by incorporating external structural knowledge. Han et al. (2018) adopt hierarchical structures among relation types to transfer knowledge from the frequent relation types to their siblings. Zhang et al. (2019) incorporate label semantics and knowledge graph embeddings to transfer knowledge from frequent types to rare types. Required expertise in selecting external knowledge limits the generalization of these methods. (Yu et al., 2021) also leverages correlation between event types to help the learning of rare event types in the context of lifelong learning.

4.3 Causal Inference and Its Application to Long-tailed Learning

Due to the potential of causal inference (Pearl et al., 2000) theory to reduce the spurious correlation, there have been explorations on its application in machine learning (Lopez-Paz et al., 2017; Magliacane et al., 2018; de Haan et al., 2019; Bengio et al., 2020; Yang et al., 2020; Li et al., 2021; Park et al., 2021). Since the the spurious correlation is more common in limited data, some work attempts to interpret the long-tailed learning problem under a causal inference framework. The core component of this interpretation is to find a confounding factor that affects the distribution of the input features and output labels at the same time. Tang et al. (2020) consider the training momentum of the gradients to be the confounding factor and proposed the corresponding deconfounded training with the backdoor adjustment approach. They use the total direct effect (TDE) for inference, which essentially lowers the probabilities of frequent types systematically. Nan et al. (2021) work on the information extraction tasks and take a set of linguistic features as the confounding factor. They also adopt an inference approach similar to TDE to lower the probabilities of frequent types.

4.4 Related Few-shot Learning Methods

Few-shot learning aims at training models with a small number of instances, which is similar to the goal of improving rare types in long-tailed learning. Some few-shot learning methods also overlap with long-tailed learning methods. Snell et al. (2017) proposed a prototypical network that has a similar framework as NCM for long-tailed learning. Yue et al. (2020) proposed a backdoor adjustment approach based on the causal inference thoery to reduce the spurious correlation in the model, since the few-shot learning also has the limited data size problem. However, few-shot learning usually works on the N-way K-shot setting. This makes these approaches usually not directly applicable to the long-tailed learning scenario.

5 Conclusions and Future Work

In this work we propose a new long-tailed learning framework for entity and event extraction by candidate transformation. We design a novel transformation module to convert representations of rare or unseen mentions during evaluation into representations of average training mentions. Experimental results have validated the effectiveness of our framework. Our framework can significantly improve the performance on long-tailed types, and outperform other long-tailed learning methods especially for moderately long-tailed types. Moreover, our framework does not sacrifice the performance on frequent types. We also discover the connections between our learning framework and the backdoor adjustment in the causal inference theory We empirically observe that our training strategy can improve the model's capability in capturing more generalizable features, which aligns with the causal inference theory. In the future, we will explore: (1) adapt the concept of transformation module to other NLP tasks; (2) based on our connection with the causal inference theory, it is possible to design a better transformation module by choosing a better confounding factor other than the context information.

6 Limitations

In terms of the framework design, our current design of the framework is only applicable to the sequence labeling task, although we believe it can be adapted to other NLP tasks without significant modifications. Besides, our framework should be most helpful if the semantics of the elements in the sequence of the same type are close to each other and thus may require additional modifications in more heterogeneous cases, such as vision-language models where visual features may have the same type as the textual token embeddings.

In terms of time efficiency, our framework will require an additional training stage to learn the transformation module, which will cost extra time. Since we fixed the language model, which composes majority of parameters in our framework, this additional cost is acceptable. We also recommend to pre-process input features (since they are fixed with respect to training samples during the second stage) to the transformation module to further reduce the time cost in the second stage.

A Appendix

A.1 Details on Two-stage Training

In the first training stage, all parameters in the language model $\mathcal{M}$and entity/event classifier head $\mathcal{D}$ are updated. In the second stage, we fix the entire language model and train both $\mathcal{D}$ and the transformation module $\mathcal{S}$. Apart from the cross entropy loss for entity/event extraction, we also apply loss to the weights $\{\alpha_j\}_{j=1}^{K}$ in Equation (3). This loss is only applicable to entity/event mention tokens, since $\{\alpha_j\}_{j=1}^{K}$ corresponds to entity/event types. For these mention tokens, we compute cross entropy between attention weights and the labeled types.

For the input features to the transformation module, we want to make the values of all three kinds of features to be in the similar range. Therefore, we adopt a batch normalization module to these features. We also add dropout with probability 0.2 to similarity features and frequency features, and dropout with probability 0.5 to the context features.

A.2 Implementation Details

For all experiments, we use learning rate to be $1e-5$ and batch size to be 8 to fit in a single Nvidia Tesla V100 GPU with 16GB memory. We evaluate performance after each epoch and select the best model based on the development performance. We use early-stop strategy with a patience of 5 epochs. We report average performance over 3 runs initialized with 3 different random seeds.

The approximate number of parameters is 3.5 million (RoBERTa). Added parameters from the transformation module is significantly less and dependant on the number of target entity/event types. Approximately the transformation module has 2,500 parameters. For the first stage training, it takes about 10-20 minutes to train an epoch on ACE 2005 data, 20-30 minutes on MAVEN data and about 40 minutes on Few-NERD. The time difference mainly comes from the total number of sentences in these datasets. However these are just rough estimations since the performance largely depends on the environmental factors such as temperatures and also the workload of other gpus/cpus in the same machine during training. In the second stage, we didn't preprocess any features in advance but block the backpropagation to language model parameters. In general it is 4-5 times faster than the first stage. We incorporate the transformation module by modifying the RoBERTa implementation from Transformers[7] Library.

A.3 Dataset Licenses

This dataset is licensed by LDC.[8] Membership is required for access. The dataset can be used for research purpose. Few-NERD dataset is distributed under the CC BY-SA 4.0 license. MAVEN dataset is ditributed under MIT License.

A.4 Additional Results

We include precision and recall scores in Table 5. Moreover, we include top 10 event types in the MAVEN dataset that our approach achieves most improvements over the Vanilla baseline, as well as their number of training mentions in Table.

MAVEN has a total of 168 event types. and our training split includes 77,987 training event mentions in total for all event types.

Do Deep Neural Networks Capture Compositionality in Arithmetic Reasoning?

Abstract

Compositionality is a pivotal property of symbolic reasoning. However, how well recent neural models capture compositionality remains underexplored in the symbolic reasoning tasks. This study empirically addresses this question by systematically examining recently published pre-trained seq2seq models with a carefully controlled dataset of multi-hop arithmetic symbolic reasoning. We introduce a *skill tree* on compositionality in arithmetic symbolic reasoning that defines the hierarchical levels of complexity along with three compositionality dimensions: systematicity, productivity, and substitutivity. Our experiments revealed that among the three types of composition, the models struggled most with systematicity, performing poorly even with relatively simple compositions. That difficulty was not resolved even after training the models with intermediate reasoning steps.[1]

1 Introduction

Integrating symbolic reasoning capabilities into neural models has been a crucial goal of artificial intelligence (Marcus, 2003; d'Avila Garcez and Lamb, 2020). With this in mind, many researchers investigated how well modern neural models achieve symbolic reasoning (Lake and Baroni, 2018). However, recent studies have reported conflicting results on this; some suggest that neural models can solve complex multi-hop reasoning (Clark et al., 2020), while others claim that models struggle even with performing simple symbolic operations (Qian et al., 2022).

As a step toward further understanding neural models' symbolic reasoning ability, this study systematically analyzes recently published pre-trained seq2seq models using a carefully controlled dataset of multi-hop arithmetic symbolic reasoning.

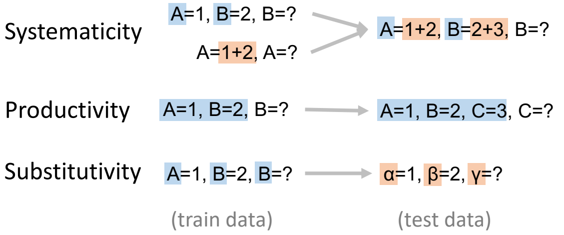

Figure 1: Three dimensionalities of compositionality in arithmetic symbolic reasoning

Specifically, our study empirically evaluates the models' ability to generalize the *compositionality* underlying arithmetic reasoning, where we explore three dimensions of compositionality: (i) systematicity, (ii) productivity, and (iii) substitutivity, as illustrated in Figure 1. Capturing compositionality is crucial in performing symbolic reasoning since compositionality is a pivotal property of generalizability over training instances.

To systematically explore the models' composition ability, we introduce a *skill tree on compositionality* that defined the hierarchical levels of complexity in arithmetic symbolic reasoning, as illustrated in Figure 2. Using this hierarchy as a lens, we identify the limitations of the neural seq2seq models in capturing the compositionality in arithmetic symbolic reasoning. Our major findings can be summarized as follows:

- Among the three types of composition, the models struggled most with **systematicity**, performing poorly even with relatively simple compositions.
- The major difficulty in systematicity was in the access to intermediate information that is not stated in input but produced during the reasoning.
- Capturing systematicity remained hard for the models trained with the information of the intermediate reasoning steps.

2 Skill tree in arithmetic reasoning

We take arithmetic reasoning as the domain for our exploration because it allows us to synthesize questions systematically, as we show in this paper, which helps examine a model's composition ability in a controlled manner. Furthermore, the arithmetic reasoning ability of neural models has gained much attention as modern large language models still struggle with this problems (Rae et al., 2021).

Specifically, we use multi-hop arithmetic reasoning problems as follows:

Question: `A=1, B=2, C=A+2, C=?`
Answer: `3`

Here, the value assigned to the variable `C` is asked.

2.1 Compositionality in multi-hop symbolic reasoning

In this study, we specifically focused on three dimensions: systematicity, productivity, and substitutivity (Hupkes et al., 2020). According to these, we evaluate how well neural models achieve compositional generalization.

Systematicity refers to the ability of combining known different concepts into a more complex concept, i.e., structural composition. To evaluate this ability in models, we first trained with several types of primitive operations (e.g., addition; `A=1+2,A=?` and selection; `A=1,B=2,B=?`). Then, we measured the performance in solving problems consisting of combinations of primitives (e.g., `A=1+2,B=2+3,B=?`).

Productivity refers to the ability to solve longer/complex problems based on shorter/simpler ones. To evaluate this ability in models, we first trained with a short version of a formula (e.g., `A=1+2,B=2+3,B=?`). Then, we measured the performance in solving longer problems (e.g., `A=1+2,B=2+3,C=3+4,C=?`).

Substitutivity refers to the ability to keep the performance even if a particular constituent in a problem is replaced with another (unseen) constituent (i.e., lexical composition). To evaluate this ability in models, we conduct several experiments changing the variable characters between training and test (e.g., train with `A=1+2,A=?`; then evaluated with `α=1+2,α=?`).

2.2 Dataset configurations

Typical symbolic reasoning (e.g., procedural programming, assembly language) consists of at least three primitive symbol manipulations: assignment (`a=2`), arithmetic operation (`1+2`), and reference (`a=?`). With this in mind, our dataset is generated by combining the following five basic formulas: (i) `A=1` (assignment), (ii) `A=B` (reference & assignment), (iii) `A=1+2` (arithmetic operation & assignment), (iv) `A=B+2` (arithmetic operation & assignment & reference), (v) `A=?` (reference). The detailed properties are explained in Section 3.

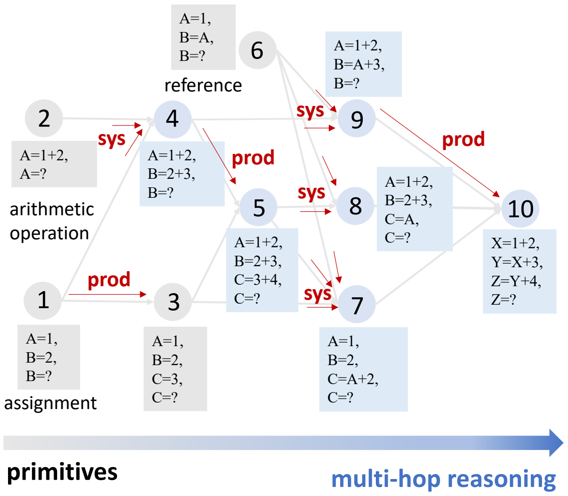

Figure 2: Skill tree to evaluate compositional generalization. The data format of primitive operations is gray and others (complex formulas composed of combinations of primitive operations) are blue .

2.3 Skill tree evaluations

We preliminarily observed that compositionally generalizing complex multi-hop arithmetic reasoning was difficult for neural seq2seq learners (the 1,2,6→9 setting in Section 4). Building on this fact, this study questions what type of composition made it hard for the neural models. To answer this, we designed a *skill tree on compositionality* that organizes the (hierarchical) complexity levels of symbolic reasoning.[2] Evaluating the models using problems with different complexity of composition in a step-wise manner, we elucidate the exact weakness of neural seq2seq models in multi-hop symbolic reasoning.

Specifically, we designed ten versions of symbolic reasoning problems. The hierarchical relationship of their task levels is illustrated in Figure 2; in this skill tree, each vertex, i.e., domain, corresponds to different task settings with different

---

[2] The term "skill tree" refers to a visualization method of step-by-step learning in the field of pedagogy (Tondello and Nacke, 2019), distinct from the "tree" in graph theory.

		base		large		x-large

Table 1: Average accuracies in the experiment with 2 different seeds. The "Task" column exhibits (train→test) domains corresponding to the skill-tree (Figure 2). The "Type" column shows the targeted compositionality type in each setting; here, "sys.," "prod," and "subst." denote the systematicity, productivity, and substitutivity generalizations, respectively.

complexity, and edges represent the hierarchical complexity levels.

By adequately selecting a particular combination of training and test domains, we evaluated the compositional generalization ability of the models from various perspectives. Here, the arithmetic expressions used in the test domain are a combination of those in training domains, creating a semi-order relationship in the skill tree. For example, using the settings 1 (`A=1+2,A=?`) and 2 (`A=1,B=2,B=?`) as a training set, and 4 (`A=1+2,B=2+3,B=?`) as a test set, one can evaluate the model's systematicity generalization towards the arithmetic operations (`a+b`) and assignments (`A=`i`,B=`j`,B=?`).

3 Experimental settings

3.1 Data

Dataset: In each experimental setting, we refer to the training domains as $\mathcal{D}_{\text{train}} = \{d_{\text{train}1}, \cdots d_{\text{train}k}\}$ and the test domain as d_{test}. Each domain has 100,000 training data and 3,200 test data; these are randomly generated, and there is no overlapped instance. When the training domain consisted of multiple domains, we used the union of the training data in $\mathcal{D}_{\text{train}}$. In addition, when the training domain is not primitive operations (1, 2, 3, and 6 in Figure 2), we further added the primitive operation data related to the training domain (Appendix A) into the training data.

Arithmetic expressions: As introduced in Section 2, the input is a sequence of arithmetic expressions. Formally, each expression is in the format of `a=`n or `a=`n`{+,-,max,min}`m except that the final expression asks the number assigned to a specified variable (`b=?`). Here, `a` and `b` are a member of a variable name set Σ; n and m are a member of the variable name set or number set $\Sigma \cup \mathcal{N}$. Specifically, Σ consists of 21 alphabets, and N consists of the integer from 0 to 99. The symbol = indicates that the result of the left-hand side is substituted into the right-hand side. The operations (`+`, `-`, `max`, and `min`) correspond to arithmetic addition, subtraction, max (returning the larger of its left and right numbers), and min (returning the smaller of its left and right numbers).

The questions are designed so that the answer is unique, and depending on the problem set-up, may include mathematical expressions that are not directly related to the final answer, i.e., distractors. The order of the equations is arbitrary; the first equation should not necessarily be calculated first.

Substitivity test: In each experimental setting, we evaluate the substitutivity generalization performance of the model under the situation where the variable names are replaced with unseen ones, e.g., training with `a=1+2,a=?`; then evaluating with α`=2+4,`α`=?`. In this setting, we replaced each variable name in the test set with one of five alphabets that do not overlap with the training ones.

3.2 Trainig and test

Training: The training stops when the accuracy on the validation dataset does not increase in successive five epochs or until the validation accuracy reaches 100%. Checkpoints with the highest accuracy in the validation dataset are used for evaluation. Note that among the experiments, the accuracy in the training domain reached at least 99.5%; this indicates that the primitive operations were learnable for the models. Detailed settings for training are described in Appendix A.

Evaluation metrics: The accuracy is calculated by the test data in the test domain d_{test}. Here, we used two metrics: (i) zero-shot accuracy (ZA) and (ii) weighted average of accuracies (WA) to measure the efficiency of learning (Talmor et al., 2020). In measuring WA, a model was further trained using the training set in the test domain d_{test}; then, the weighted average of accuracies at every update was calculated (details are in Appendix B).

3.3 Models:

We used three different sizes (base, large, and xl) of T5 (Raffel et al., 2020), which is a widely used pre-trained seq2seq model in numerical reasoning tasks (Pal and Baral, 2021; Chung et al., 2022; Yang et al., 2021). Note that we began our training using the models with learned parameters. We also evaluated BART variants and randomly initialized models in Appendix C.

4 Experiments and results

We adopted nine combinations of training and test domains as shown in the first column of Table 1 (training domains→test domain). Six of them test the systematicity generalization and the other three test productivity generalization. In each setting, we further tested substitutivity generalization ability using the test domain data with a different variable name set (e.g., α instead of `A`) to that used in the training domain.

Table 1 shows the overall results. We observed the following four trends:

- Systematicity generalization was more difficult than productivity generalization.
- Even in the simple composition (the setting 1,2→4), the models struggle with generalization from zero or few examples.
- Models achieved substitutivity generalization.
- Model size did not incur substantial performance difference.

We identified that the systematicity generalization of reference and arithmetic operations (setting $2,3 \rightarrow 5$; from `A=1,B=2,C=3,C=?` and `A=1+2,A=?` to `A=1+2,B=2+3,C=4+5,C=?`) was a simple setting, yet difficult to solve (refer to Appendix D for results on other tasks.). To better understand why neural models struggle with this setting, we decomposed the complexity of this setting and analyzed the model performance. Note that Kim and Linzen (2020) also suggested that neural models lack systematicity generalization ability in the context of semantic parsing; our results corroborate their findings from the context of arithmetic multi-hop reasoning.

	base		large		x-large	
Setting	ZA	WA	ZA	WA	ZA	WA
2,3→5	33.6	75.4	32.1	85.6	35.9	94.7
String	37.3	94.1	66.1	98.4	86.9	99.3
Steps	26.2	82.1	36.1	89.4	33.7	96.4

Table 2: Ablation study with the 2,3→5 (vanilla) setting. “String” refers to the setting where string operations are used instead of arithmetic operations. “Step” denotes the setting generating intermediate steps.

Is this difficulty specific to *arithmetic* symbolic reasoning? We experimented with the same setting except that the four arithmetic operations are replaced with string operations (`join`, `reserveJoin`, `strSub`, and `stackJoin`; details are in Appendix E.1). The notable difference between arithmetic and string operations is that the string operation could be achieved by only copying selective elements in the input (e.g., `12+34=1234`), while arithmetic operation requires the models to access the arithmetic knowledge stored in their internals (e.g., `1+2=3`) and generate new information not stated in the input context (e.g., 3).

Larger models tended to overcome the weakness in composition with string operations (e.g., the accuracy of 86.9 in zero-shot evaluation with the x-large model), while they struggled with arithmetic operations. This suggests that the major difficulty in systematicity was in **the access to the arithmetic knowledge (e.g., 1+1=2)**.

Does scratchpad training alleviate the difficulty? Existing studies suggested that showing the intermediate step (scratchpad-style training/inference) improves the multi-hop reasoning ability of neural models (Wei et al., 2022). We tested whether such an explicit generation of intermediate information alleviates the difficulty faced in the previous analysis. Specifically, we trained models with intermediate steps (e,g. `A=1+2,B=2+3,B=?; B=2+3,B=5`. Details are in Appendix E.2) during training.

The accuracy was calculated by the exact match of the answer and intermediate steps (the steps are designed to be uniquely determined). The performance gain due to explicating the intermediate steps was limited (Table 2), at least with our T5-based models. This shows that, in our carefully controlled setting, merely employing the scratchpad-style generation is not substantially effective.

5 Analysis

We conduct a more in-depth analysis of compositional generalization difficulties from another

Complexity dimensions	base ZA	base WA	large ZA	large WA	x-large ZA	x-large WA	Average
Δ#variables	0.098	-0.098	0.488	-0.293	-0.098	-0.488	-0.065
Δ#numbers	0.059	0.265	-0.088	0.647	0.206	0.677	0.294
Δ#operations	-0.507	-0.338	-0.338	0.169	-0.338	0.169	-0.197
Δ#reference	-0.655	-0.655	-0.393	-0.655	-0.655	-0.655	**-0.611**

Table 3: Spearman's rank correlation coefficient between the increase of training–test arithmetic complexity and the compositional generalization performance (accuracy) across the nine settings listed in Table 1. A negative score indicates that the greater the training–test discrepancy in its dimension, the more difficult compositional generalization is. In the case that there are multiple training domains, the maximum value among them is used.

perspective—complexity of arithmetic expressions. Specifically, for each pair of training and test domains listed in Table 1 (e.g., 1,2→4), we quantified the increase of the complexity of arithmetic formulas from several aspects, e.g., how much the formula's number of variables increased in the test domain (setting of 4) compared to the training domain (setting of 1 and 2). Specifically, we focused on the increase of the number of variables (Δ#variables), numbers (Δ#numbers), operations (Δ#operations), and references (Δ#references) from the training to test domains. Here, "#reference" denotes the number of access to a particular variable on the right-hand of equations. For example, the Δ#references is 1 if the training data format is `A=`n`,B=`**`A`**`+`m and the test format is `A=`n`,B=`**`A`**`+`m`,C=`**`B`**`+`l. Then, we identified which dimension strongly relates to the compositional generalization difficulty.

We analyzed the macro trends between formula's complexity increase and the difficulty of generalization across the experimental settings. Table 3 shows Spearman's rank correlation coefficient between each complexity and the test-domain accuracy. We found a notable negative correlation in the Δ#reference; that is, the more references in the test domain compared to the training domain, the more difficult the compositional generalization becomes (the cases of 1,2,6→9 and 9→10 settings). Simply put, this reveals the difficulty of compositional generalization with *multi-hop* reasoning—retaining the results of a calculation and accessing them again for another calculation.

6 Related work

The analysis of the compositional generalization ability of neural models and arithmetic multi-hop reasoning problems have typically been studied separately; this study has merged these two directions. As for composition generalization analysis, several studies analyzed neural models using datasets such as SCAN (Lake and Baroni, 2018), COGS (Kim and Linzen, 2020), and CFQ (Keysers et al., 2020). These mainly focused on compositionality in the context of semantic parsing; the composition ability toward symbol manipulations (e.g., multi-hop arithmetic reasoning) is typically out of focus. As for arithmetic reasoning, neural models' abilities have been analyzed typically using benchmarks such as DROP (Dua et al., 2019). It has recently been reported that such dataset has superficial cues (Al-Negheimish et al., 2021), which made it unclear how much arithmetic reasoning neural model achieves; our study using a carefully controlled dataset contributed to the exact weakness of neural models in this context.

7 Conclusion

In this study, we have empirically investigated the arithmetic multi-hop reasoning ability of modern neural models through the lens of compositional generalization ability. To systematically analyze neural models' ability, we have defined a skill tree that organizes the (hierarchical) complexity levels of the multi-hop symbolic reasoning dataset.

Our experiments have revealed that the major weakness lies in systematicity, even with a relatively simple composition. Through the ablation studies, we also have found that difficulty in systematicity is pronounced in accessing knowledge that is not written in input but stored in models. Furthermore, even in training models with intermediate steps that explicate the composition, they struggle to capture systematicity. We also found the difficulty of multi-hop reasoning in compositional generalization. These highlight the exact weakness of neural models and encourage studies to overcome such limitations.

Limitations

In this work, we explored neural networks' ability to capture compositionality in symbolic arithmetic reasoning in hopes that it may lead to future improvements in more general reasoning. However, arithmetic reasoning may not necessarily generalize to natural language tasks. Furthermore, we explored several aspects of multi-hop arithmetic reasoning, but these were chosen from a relatively human-centric perspective, and models may suffer from unforeseen other difficulties. Finally, while we found several patterns in how model performance degrades, it is difficult to aggregate this into a full picture of what a model can and cannot do. Further experiments are needed to gain a more complete understanding of model performance

A Training configurations

Training data: Data of primitive domains (grey domains in Figure 2) are also added to the training data. Specifically, data in the primitive domains that are reached by traversing the graph (Figure 2) from the training domain to the left is added. For example, when the training domain has the domain of 7, the data of primitive domains of 2, 3, and 6 are added[3]. Note that when the domain of 3 is included, the domain of 1 is not added. Additionally, as the objective of this study does not emphasize the generalization performance in arithmetic ability, the scope of numbers utilized in the test domain is adjusted to ensure that the upper limit of the answers in the test domain does not surpass that of the answers in the train domain.

Hyperparameter: We used the T5 models (v1.1) as pre-trained model[4]. We used three model sizes: base (250 million parameters), large (800 million parameters), and xl (3 billion parameters). Following T5 (Raffel et al., 2020) fine-tuning configurations, we use Adafactor (Shazeer and Stern, 2018) as the optimizer with a constant learning rate. Also, we specify the learning rate 1.0×10^{-5} for training and 5.0×10^{-5} in measuring the WA. The batch size is 32 for all experimental settings. We trained each model on NVIDIA A6000 (48GB memory), A100 (80GB memory). In addition, following previous research about numerical reasoning (Geva et al., 2020), we tokenize numbers in a digit-by-digit manner.

Table 4: Experimental results when BART is used as a pre-trained model. The "Task" column exhibits (train→test) domains corresponding to the skill-tree (Figure 2). The "Type" column shows the targeted compositionality type in each setting; here, "sys.," "prod," and "subst." denote the systematicity, productivity, and substitutivity generalizations, respectively.

B How to calculate WA

As described in Section 3, we used weighted average accuracy (WA). This metric quantifies the efficiency (ease) of generalization by assigning a high weight to accuracy in the early training stage. Specifically, the weights w_i (where i is the number of validation steps) were calculated using the following formulae:

$$w_i = -ai + w_{\max} \quad , \tag{1}$$

$$w_{\max} = \alpha w_{\min} \quad , \tag{2}$$

$$w_{\min} = \frac{2}{(N+1)(\alpha+1)} \quad , \tag{3}$$

$$a = \frac{(w_{\max} - w_{\min})}{N} \quad . \tag{4}$$

Here, N is the number of validation steps. α is a hyperparameter that determines how heavily the accuracy in the early stages is weighted. We set α to 1000 in all the experiments. Also, We used the first 100 validation steps to calculate WA, so specify $N = 100$ for all experiments. WA was calculated with accuracy on the held-out validation datasets in the test domain.

---

[3] Task 7,8→10 do not incorporate data from the primitive domains into the training data to evaluate if compositional generalization can be achieved solely from complex components.

Table 5: Accuracy on the training held-out dataset when we start training the model from randomly initialized parameters. (When training began with parameters pretrained on language, the accuracy was almost 100% in all settings.) Each training task includes the primitive operations required to solve train domain tasks as described in section A.

C Model variants

C.1 BART

To confirm the generality of our results obtained with the T5 models, we also conduct the same experiment using BART (Lewis et al., 2020). We use two model sizes[5]: base (140 million parameters) and large (400 million parameters). Table 4 shows the result using BART. The same tendency described in Section 4 was observed when BART was used as a language-pre-training model.

C.2 Training from scratch

We also experimented with the case where we started training from randomly initialized parameters to isolate the effect of the pre-training adopted in T5. We found that these initialized models failed to learn even primitive operations and in-domain tasks (Table 5), at least with the hyperparameter setting[6] used in this study. Thus, we did not proceed to their evaluation of compositionality generalization.

D Detailed analysis of T5-based models

Figure 3 shows the learning curves (accuracy on validation datasets) for all tasks demonstrated in Table 1. The graphs also show that the neural language model struggles to solve tasks that require compositional generalization in the beginning part of the training.

D.1 String operations ablation for all tasks

Table 6 shows the experimental results of the ablation study using string operations for all tasks.

D.2 Scratch pad evaluation for all tasks

Table 7 shows the experimental results of the ablation study using scratchpad for all tasks.

E Dataset details

Table 8 summarizes the characteristics of each task.

E.1 String operations

Table 9 shows the details of the string operations.

E.2 Scratch pad formulation

For the additional study using scratchpad in section 4, we generate problems with ing the intermediate steps. Scratchpad is in the form of straightforward one-by-one calculations of only those calculations necessary to find the target variable. The following is an example of scratchpad reasoning:

Question: `A=1+2, B=A+3, B=?`
Answer: `A=1+2;A=3;B=A+3;B=3+3;B=6`

---

[5] https://huggingface.co/facebook/bart-base, https://huggingface.co/facebook/bart-large

[6] Unlike in the training domain used for the language pretrained model, we relax the training stopping criterion. We stopped training when the accuracy did not increase by **10** epochs in the validation dataset.

Abstract

Successful machine learning systems currently rely on massive amounts of data, which are very effective in hiding some of the shallowness of the learned models. To help train models with more complex and compositional skills, we need challenging data, on which a system is successful only if it detects structure and regularities, that will allow it to generalize. In this paper, we describe a French dataset (BLM-AgrF) for learning the underlying rules of subject-verb agreement in sentences, developed in the BLM framework, a new task inspired by visual IQ tests known as Raven's Progressive Matrices. In this task, an instance consists of sequences of sentences with specific attributes. To predict the correct answer as the next element of the sequence, a model must correctly detect the generative model used to produce the dataset. We provide details and share a dataset built following this methodology. Two exploratory baselines based on commonly used architectures show that despite the simplicity of the phenomenon, it is a complex problem for deep learning systems.

1 Introduction

Over the last years, driven by the surge in deep learning methods, models in NLP have become very powerful. They have even reached superhuman performance on standard benchmarks such as SuperGLUE (Wang et al., 2019) and SQuAD (Rajpurkar et al., 2018). Deeper probing, though, shows that this is due to the models' surprisingly robust superficial natural language understanding ability. This indicates that new benchmarks are necessary that accurately show the level of progress in language processing (Ruder, 2021).

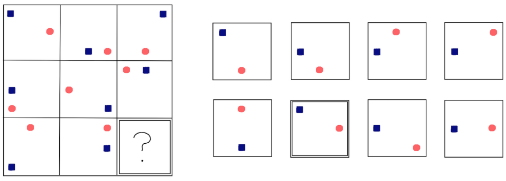

Figure 1: An example Raven's progressive matrix (best seen in colour). The matrix is constructed according to two rules: (i) the red dot moves one place clockwise when traversing the matrix left to right; (ii) the blue square moves one place anticlockwise when traversing the matrix top to bottom. The task consists in finding the tile in the answer set that correctly completes the sequence, indicated with a double border.

In this paper, we describe such a benchmark, developed based on a new method described in (Merlo et al., 2022), and summarized in Section 2. The method defines a procedure for building datasets that capture specific linguistic phenomena in a structured problem, inspired by the visual patterns detection tasks in Raven's progressive matrices (RPM) (Raven, 1938), as in Figure 1.

The visual RPMs manipulate elements with attributes such as position, shape, colour and size. The language matrices manipulate phrases, dependencies in the syntactic tree, and lexical, grammatical and semantic attributes between connected elements of a sentence. To successfully tackle such a complex problem, a system must detect structure and patterns in the data. To complement the structure of the problem, the candidate answers set is

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1363–1374

also specifically designed – the negative answers are built following specific criteria – to help determine which facets of the problem the system is able to learn, and which it is not.

By enabling different levels of analysis, from the solution of the task in different controlled setting to the analysis of the errors, this dataset intends to support the development of neural models with stronger abilities of abstraction and generalization, and more complex and compositional skills, that could learn robust models from few examples, and ultimately be deployed on low-resource languages. The code and the data are available here: `https://github.com/CLCL-Geneva/BLM-SNFDisentangling`.

2 BLM-AgrF: Blackbird's Language Matrices for agreement

CONTEXTS TEMPLATE

Figure 2: BLM instances for verb-subject agreement, with two attractors. WNA= wrong number of attractors; AE= agreement error; WN1= wrong nr. for 1^{st} attractor noun (N1); WN2= wrong nr. for 2^{nd} attractor noun (N2).

The data format we present has been called Blackbird's Language Matrices (BLMs) (Merlo et al., 2022), because it requires the presentation of the linguistic phenomenon of interest in the form of a complex set of sentences that have both syntagmatic and paradigmatic relations, thereby, like in the RPM visual version, forming a matrix structure.

A BLM has a structure defined by a combination of rules. The starting point is defining the linguistic problem that needs to be learned (e.g. subject-verb agreement) and the grammatical rules that define it. The combination of rules can be complex and each rule can act as an interfering factor obfuscating the other rules. The next step is to devise the rules governing the abstract automatic generation process that embody the properties of the linguistic phenomenon and its underlying rules. Combining these examples of grammatical rules will produce templates that can be used to automatically create large samples of data with lexical/structural variety. To allow for probing the learned model, apart from the correct answer, the answer sets contain negative examples built by corrupting some of the generating rules. This helps investigate the kind of information and structure learned, and the type of mistakes a system is prone to.

2.1 BLM-AgrF for subject-verb agreement

The BLM-AgrF dataset we illustrate here defines implicitly the rules of subject-verb agreement in French. As a reminder, the main rule of subject-verb agreement in French, and English, states that subjects and verbs agree in their number. Agreement is a rule that applies to the structure of the sentence and not the linear order, so agreement applies independently of how many noun phrases intervene between the subject and the verb.

Subject-verb agreement is a morphological phenomenon of appropriate complexity to start our investigations with BLMs. Subject-verb agreement is clearly limited to some specific words in the sentence so that the elements and the attributes manipulated by the underlying rules can be clearly identified. It is marked explicitly in the forms of words (for example by an $-s$ ending) and it does not depend on the words' meaning. Moreover, agreement rules show structural properties, so that sequences of increasing complexity of application of the rule can be defined (Linzen et al., 2016; Linzen and Leonard, 2018). We choose to work specifically on French because its agreement system, its verb conjugations and its noun phrase structure lend themselves well to our investigation.

The data that illustrates this linguistic rule must show all patterns of combination of agreement between subject and verb but also include data that illustrate the structural nature of the rule. Noun phrases inserted in the subject NP as prepositional complements or relative clauses act as intervening elements. We consider one and two such noun phrases, to increase the distance between the subject and the verb, and different clause complexities to produce data that covers syntactic structures of various depths.

While intervening noun phrases do not enter into an agreement relation based on the grammatical rules, in practice, the intervening noun phrases can act as agreement attractors and trigger agreement mistakes, if they are close to the verb. More specifically, Franck et al. (2002) show, in experiments with French and English speakers, that attraction is determined by the syntactic distance between an intervening noun and the head noun.

BLM-AgrF grammatical templates To generate the BLMs for the subject-verb number agreement, we develop a context-free grammar based on the targeted linguistic phenomenon and the interfering factors chosen, illustrated in Figure 3.

```
<CONSTRUCTION>→ <AGREEMENT>

# structure
<AGREEMENT>→ <MAIN-CLAUSE>
<AGREEMENT>→ <COMPLETIVE-CLAUSE>
<AGREEMENT>→ <RELATIVE-CLAUSE>

<ATTRACTORS>→ <PP><ATTRACTORS>
<PP>→ {Prep chunks (attractor)}

# e.g.: ["est en panne", "sont en panne"],
<VP(Num)>→ {VP chunks (Num)}
```

Figure 3: Context-free grammar for the subject-verb agreement in French, illustrated with examples.

The agreement between the subject and the verb is explicitly included in the production rule for the different types of clauses. The different types of clauses will lead to sentences with different structures, and the attractors' rule will insert one or two NPs between the subject and the verb to create different levels of linear and syntactic distance between them.

To instantiate these templates, our starting point are the examples in Franck et al. (2002, appendix 1). They provide a set of subject NPs of various complexity – including prepositional phrases, themselves of various complexity. We produced sentences based on these subject NPs by manually adding verb phrases, and by making the NPs more complex to increase the distance between the subject and the verb in the sentence. Each of these sentences is used to produce a *seed*. A seed contains all number variations of the NPs and VP in the sentence, and additional complement or prefix phrases to produce sentence variations of increased complexity. The end result is a set of 32 seeds, which provide the terminals (chunks) for the grammar. This progression from Franck et al. (2002) examples to seeds is illustrated in Figure 4.

The rules for BLM-AgrF generation The grammatical templates generate individual sentences. It is shown in Figure 2. The rules for a BLM-AgrF problem generation use the grammatical templates to generate a sequence of sentences according to specific sentence attributes. In our case, the sentence attributes that vary are the grammatical number of the subject and verb ({sg, pl}), the number of attractors ({1, 2}), and the grammatical number of each of these attractors ({sg, pl}). For each of the three clause types in the grammar, varying the above-mentioned attributes process will generate eight sentences, as illustrated in Figure 5.

To avoid biases in the process that may be caused by having an overly consistent input (i.e. the sequence following always the same sentence structure), different sentence sequences are generated for the same seed and same clause type by varying the alternation of values for the chosen attributes. For the sequences shown in Figure 5, the subject-verb grammatical number alternates between {sg, pl}, sentences with one attractor are generated first with alternating grammatical number, and then sentences with two attractors are built, but using a fixed grammatical number for the second attractor. We can alternate instead between {pl, sg}, generate sentences with two attractors first, and use a different grammatical number for the second attractor. Considering all these variations, we can obtain $\binom{2}{2} \times \binom{2}{2} \times \binom{3}{2} = 24$ different sequences for each generation seed and each clause type (illustrated in more detail in Appendix A.1, Figure 10).

Each of these sequences of eight sentences will be transformed into a problem. The first seven sentences will be the input (we call it *context*), and the eighth will be included in the answer set.

The BLM-AgrF answer set The answer set will contain the eighth sentence as the correct answer, and another five candidates generated by corrupting one of the generating rules. The candidates in the answer set are generated such that they are distinguishable from the correct answer but relevant and challenging. Unlike other RPM-like datasets in vision, we choose to have a fixed set of answer types, to be able to then do a type-based error analysis. At the bottom of Figure 5, we present the answer set for the *Main clause* sequence in the table, with the one correct and five incorrect answers, and the characteristics of the wrong answer candidates.

The BLM-AgrF dataset The dataset consists of lexical instantiations of the grammatical templates produced based on the linguistic phenomenon – a subject-verb agreement in French declarative sentences – in simple and complex structures, thanks to noun phrases of various lengths and complexity between the subject and the verb in the sentence.

The manually provided seeds are useful to control the structure of the sentence and to ensure a starting point with syntactically and semantically valid sentences. By applying the rules of BLM-AgrF generation to the 32 seeds, which generate 24 sequences for each seed and for each clause type, we obtain a first dataset consisting of 2304 BLM-AgrF problems. We call this dataset *type I*.

To introduce some lexical variation in this dataset in a semi-automatic manner, we use CamemBERT (Martin et al., 2020) to replace individual words in the sentences in the type I dataset. We mask different words in the three types of clauses one at a time, and generate the five highest probability replacements that will be substituted in the sentence sequence and the candidate set:

Main clause : mask the subject noun and second noun in the sentence, e.g.:

Les MASK avec le programme de l'experience sont en panne.

Les ordinateurs avec le MASK de l'experience sont en panne.

Completive clause : mask the subject and verb in the completive clause, and mask the nouns in the embedded clause, e.g.:

MASK suppose que les ordinateurs avec le programme de l'experience sont en panne.

Jean MASK que les ordinateurs avec le programme de l'experience sont en panne.

...

Relative clause mask the head noun and verb in the relative clause, and the subject noun and following noun in the main clause, e.g. :

Les ordinateurs avec le programme de l'experience dont MASK se servait sont en panne.

Les ordinateurs avec le programme de l'experience dont Jean se MASK sont en panne.

...

The process is illustrated in Figure 6, and a more detailed view of masking scenarios is shown in Figure in Appendix A.2.

By applying these lexical variations on the type I dataset we obtain a dataset containing 38400 BLM-AgrF problems. We call this dataset *type II*. To further increase the lexical variation, we build the *type III* dataset, where a BLM-AgrF problem consists of a combination of sentences (with the same grammatical structure) from different type II problems. As this dataset consists of resampled sentences from type II, it will also contain 38400 BLM problems.

These three datasets are split 90:10 into train and test subsets. During experiments we take a random 0.1 portion of the training set for validation.

3 Experiments

Transformers and other neural architectures have shown very high performance on a variety of NLP tasks. We describe here two baselines to investigate the difficulty in learning the underlying regularities of subject-verb agreement on the proposed dataset. Figure 7 shows the general process flow. Each sentence in the input is encoded separately using a pre-trained multilingual transformer model,[1] which were shown to capture, among others, syntactic information (Hewitt and Manning, 2019).

---

[1] The results reported here are based on sentence embeddings obtained using BERTTokenizer and BERTModel from the *transformers* Python library, using the pretrained *BERT-base-multilingual-cased* model `https://huggingface.co/bert-base-multilingual-cased`. This encoder produces an embedding of size 768 for each sentence. We have run preliminary experiments with French-specific sentence embeddings using FlauBERT (Le et al., 2020). The results were lower than when using a multilingual cased BERT language model.

Example subject NPs from Franck et al. (2002)

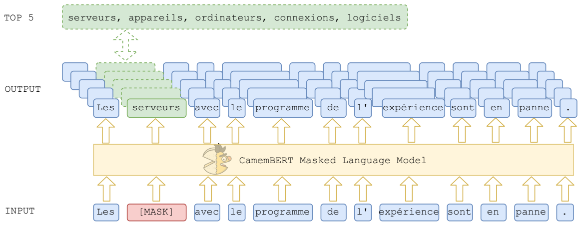

Figure 6: Creation of lexical variants by generating variations of a masked input using CamemBERT (Martin et al., 2020)

3.1 Models

We use two baseline systems – a feed-forward neural network (FFNN) and a convolutional neural network (CNN). Because the sentence embedding produced by the transformer captures structural information and we are presenting sentences in a sequence, both the FFNN and the CNN will have the chance to find patterns shared across the sentences.

The input to the FFNN is a concatenation of the sentence embeddings in the sequence (size 7 * 768), that is passed through 3 fully connected layers that gradually compress the input (7 * 768 $\xrightarrow{layer1}$ 3.5 * 768 $\xrightarrow{layer2}$ 3.5 * 768 $\xrightarrow{layer3}$ 768) to the size of a sentence representation. Because of the full connectedness between successive layers, the FFNN has the capacity of capturing patterns spread out over the entire input vector.

The input to the CNN is an array of embeddings, of size (7 x 768). This is passed through three successive layers of 2-dimensional convolutions, with a kernel size (3x3) (stride 1, no dilation). The output of the convolution is passed through a fully connected layer to compress it to the sentence representation size (768). Because of the kernel size, stride=1, and no dilation, this setup will focus on finding localized patterns in the sentence sequence array. If the NPs and verb grammatical numbers are encoded in a more localised manner within the sentence representation, this architecture should detect the patterns in the sequence.

The output of the two networks is the same – a vector representing the sentence embedding of the correct answer. The learning objective is to maximize the probability of the correct answer from the candidate answer set. Because the incorrect answers in the answer set are specifically designed to be minimally different from the correct answer, we implement the objective through the max-margin loss function. This function combines the distances between the predicted answer and the correct and erroneous ones. We first compute a score for the embedding e_i of each candidate answer a_i in the answer set $\mathcal{A}$ with respect to the predicted sentence embedding e_{pred} as the cosine of the angle between the respective vectors:

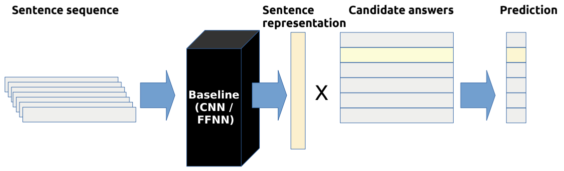

Figure 7: Illustration of the baseline setup experiments.

$$score(e_i, e_{pred}) = cos(e_i, e_{pred})$$

The loss uses the max-margin between the score for the correct answer e_c and for each of the incorrect answers e_i:

$$\mathcal{L}_a = \sum_{e_i} [1 - score(e_c, e_{pred}) + score(e_i, e_{pred})]^+$$

At prediction time, we take the answer with the highest *score* value from a candidate set as the correct answer.

3.2 Results and discussion

The results of the experiments, in terms of F1 averages over 5 runs, are shown in Figure 8, and the detailed version is in Appendix A.3. The experiments were run on a VM on the Google Cloud Platform with one NVIDIA Tesla T4 GPU and 8G memory. We ran experiments for 50 epochs, with a learning rate of 0.001 and Adam optimizer. On type II and type III data, a run took 20 minutes, on type I data 2 minutes.

As a reminder, Type I data is lexically consistent – the same vocabulary is used in all sentences in the sequence, and in the answer candidates. Type II has a limited amount of lexical variation – one word in each sentence is different. Type III is more lexically varied, with little, if any, lexical overlap between any of the context or answer candidate sentences.

The models perform well when using the full amount of training data – the heatmaps in the left column in Figure 8 –, confirming that the experimental setup used is suitable for benchmarking the problem. Type I data has available 2073 instances for training (of which 20% are used for validation).

Figure 8: F1 averages over 5 runs, for the FFNN and CNN baselines, when training on all the available training data, or on the same amount of data (2073 instances)

When training models on this amount of data for type II and type III data, the performance on these subsets drops dramatically – the heatmaps on the right in Figure 8. This indicates that the success on Type I data is due to finding superficial clues, which do not generalize to data with higher lexical variability in both the input and the candidate answers. Overall, the FFNN model performs better, potentially indicating that the interesting patterns are not localized, but rather more spread out in the inputs. With different stride and dilation parameters, the CNN might improve its performance.

A plot of the different error types made by the different models (relative to the size of the test data) is presented in Figure 9. The error plots show how the frequency of different types of errors changes when using a model trained on data of a different type than the test data.

The error analysis presented in Figure 9 reveals several insights about the data and the performance of the models.

The different errors indicate the ability of the models to learn different types of information: subject-verb agreement requires long-distance, structural information; errors on N1 and N2 tell us whether the model exhibits recency effects, thereby showing, like humans, that both structural and linear considerations come into play in learning agreement; choosing the wrong number of attractors is a very salient form of structural deviance from the correct answer and coordination is a more subtle one.

Across both models, the highest error is the N2_alt – the wrong number in the second attractor, the one closest to the verb. This proximity preference suggests that the models are rather shallow, with linear distance exerting greater influence rather than syntactic distance. In one case, when tested on type III data, the two models diverge. The pattern of results might indicate that CNNs find more localised patterns that allow them to avoid a recency bias. Coordination and number of attractors mistakes occur much less frequently, suggesting the models do learn the difference in construction and the rule of attractor sequence. This result matches our intuition that these are also the two most saliently different cases from the right answer because they differ in structure.

These results and error analysis show that curated datasets like the one presented here reveal the superficiality of the positive results on the main task. If the underlying structural rules of the subject-verb agreement had been learned properly, lexical variation would not prove so disrupting and recency effects would not be as strong.

4 Related work

The current paper does not have any direct comparison, as this is the first proposal of a dataset for language using a BLM scheme. But it is inspired by work on generating RPM problems, and on solving such problems in computer vision, and it contributes to the investigation on learning of agreement by neural networks.

Structured datasets for vision and language The automatic generation of RPM-like matrices, whether in vision or in language, is challenging, technically, in two aspects. First, how do we represent the RPM problems to tackle their variations, regularities, and irregularities? Second, how do we ensure that the generated RPMs are valid?

To overcome these challenges, some efforts have been made in computer vision: Wang and Su (2015) formulate RPMs with first-order logic, which have inspired Barrett et al. (2018) who propose Procedurally Generated Matrices (PGM) dataset through relation-object-attribute triple instantiations. Zhang et al. (2019) use the Attributed Stochastic Image Grammar (A-SIG, proposed by Zhu and Mumford, 2006) as the representation of RPM and create the Relational and Analogical Visual rEasoNing (RAVEN) dataset.

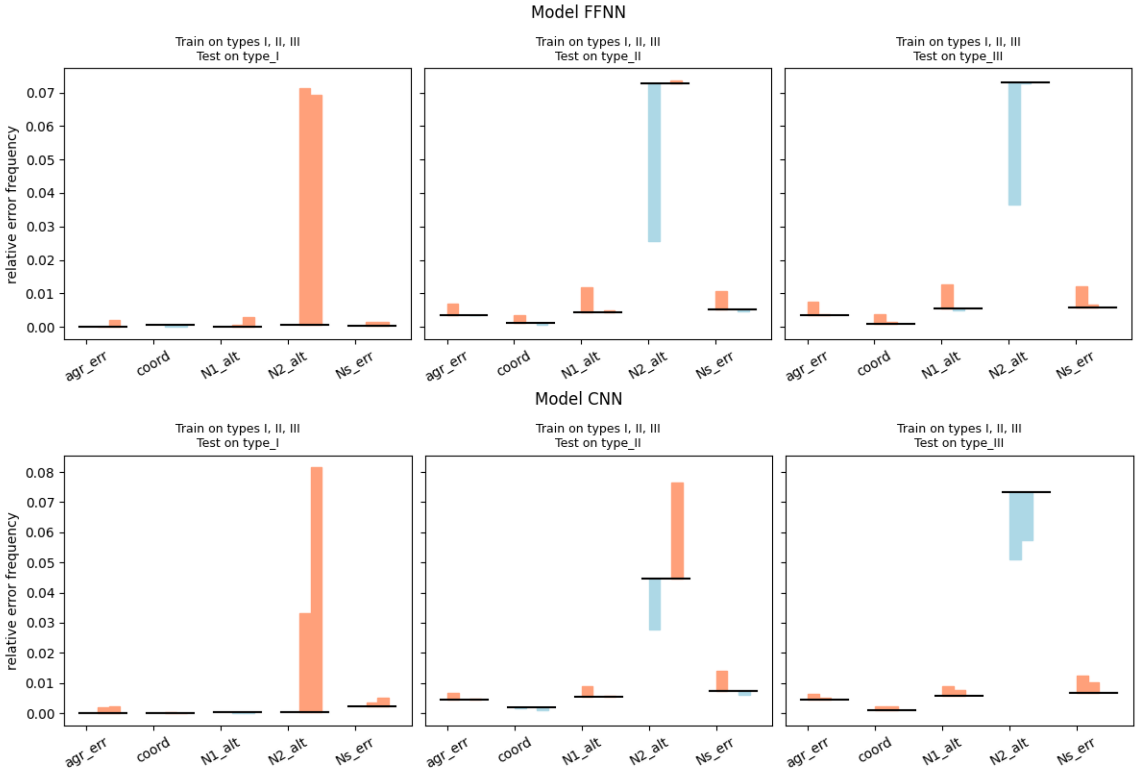

Figure 9: Relative frequencies of error types (relative to test data size) made by the different models, using models trained for all types of data. The reference – training and testing on the same data type – are given as the black lines, and we plot as vertical bars the increase (orange) or decrease (blue) in error when using a model trained on the other two data types.

These structured datasets have been mostly developed to study issues of generalisation and disentaglement. van Steenkiste et al. (2020) developed a dataset for computer vision similar to the RPMs, and evaluate the usefulness of the representations learned for abstract reasoning. They note that learning disentangled representations leads to faster few-shot learning. M'Charrak (2018) developed a large dataset, consisting of simple examples containing a few morphological markings. They use this dataset to learn disentangled sentence representations. The simplicity of the sentences does not provide a sufficiently realistic challenge from a linguistic point of view.

Learning agreement Previous work on agreement has tested recurrent neural network (RNN) language models and found that RNNs can learn to predict English subject-verb agreement if provided with explicit supervision (Linzen et al., 2016). Bernardy and Lappin (2017)'s follow-up work has shown that RNNs are better at modeling long-distance agreement if they can train the model on top of a corpus where a larger (10000 types vs. 100) vocabulary is used – the rest of the words are replaced by their POS to highlight structural patterns. Gulordava et al. (2018) explore the RNNs capacity to track abstract hierarchical structure, by predicting long-distance number agreement in various constructions in four languages (English, Hebrew, Italian, Russian). Their results suggest that RNNs can learn hierarchical grammatical phenomena and not just shallow patterns. Lakretz et al. (2021) found that individual neurons in an RNN can encode linguistically meaningful features, and propagate subject-verb number agreement information over time. In a recent paper, Li et al. (2023) investigates deeper representational issues, by contrasting two kinds of agreement, subject-verb agreement and past-participle agreement in French. They argue, based on theoretical accounts, that these superficially similar kinds of agreement, involve in fact very different abstract operations and demonstrate that transformers do reflect this difference in their representations.

5 Conclusions

In this paper we have introduced BLM-AgrF, an instance of Blackbird's Language Matrices (BLM)

(Merlo et al., 2022). This novel linguistic dataset is generatively constructed to support investigations in representation learning of grammatical rules. Each instance, consisting of a sequence of sentences and a candidate answer set, was built using a combination of rules, to provide a layered and structured dataset for learning more complex models. The various layers of the dataset allow for a variety of explorations, from disentangled sentence representations to capture structure and regularities within a sentence, to modular architectures that could capture structure and regularities in the sentence sequences. The purposefully built candidate answers supports more in-depth analyses of the behaviour of a system, and provide insights into the source of prediction errors.

Experiments using baseline set-ups – feed-forward networks and CNNs – show that the task is difficult for previously successful sentence representations and neural architectures, despite the fact that the agreement rule they are supposed to discover is rather simple. This supports our hypothesis that the task the data embodies could provide a new benchmark for modeling generalization and abstraction.

6 Limitations

Manual creation for seeds for the synthetic data The seeds to generate the data are manually chosen, and the grammar rules are specifically designed for the problem. The process may be further automated in the future through higher-level formalisation of the matrix generation process.

Language variations and linguistic phenomena The dataset described in this paper focuses on subject-verb agreement in French, with the main verb in the present tense, covering common interfering factors, different clause complexities and various depth of syntactic structures. While the simplicity of the modeled rule can be perceived as a limitation, it was a deliberate feature. The low performance of the transferred models to different test sets shows that the simple rule was not easy to model. But as systems become successful on a given dataset, new, more complex versions can be built with richer phenomena at various linguistic levels, including in morphologically-rich languages.

Human upper bounds We do not have, in this paper, an explicit experiment on human upper bounds for the different data types.

A Appendix

A.1 Generation process

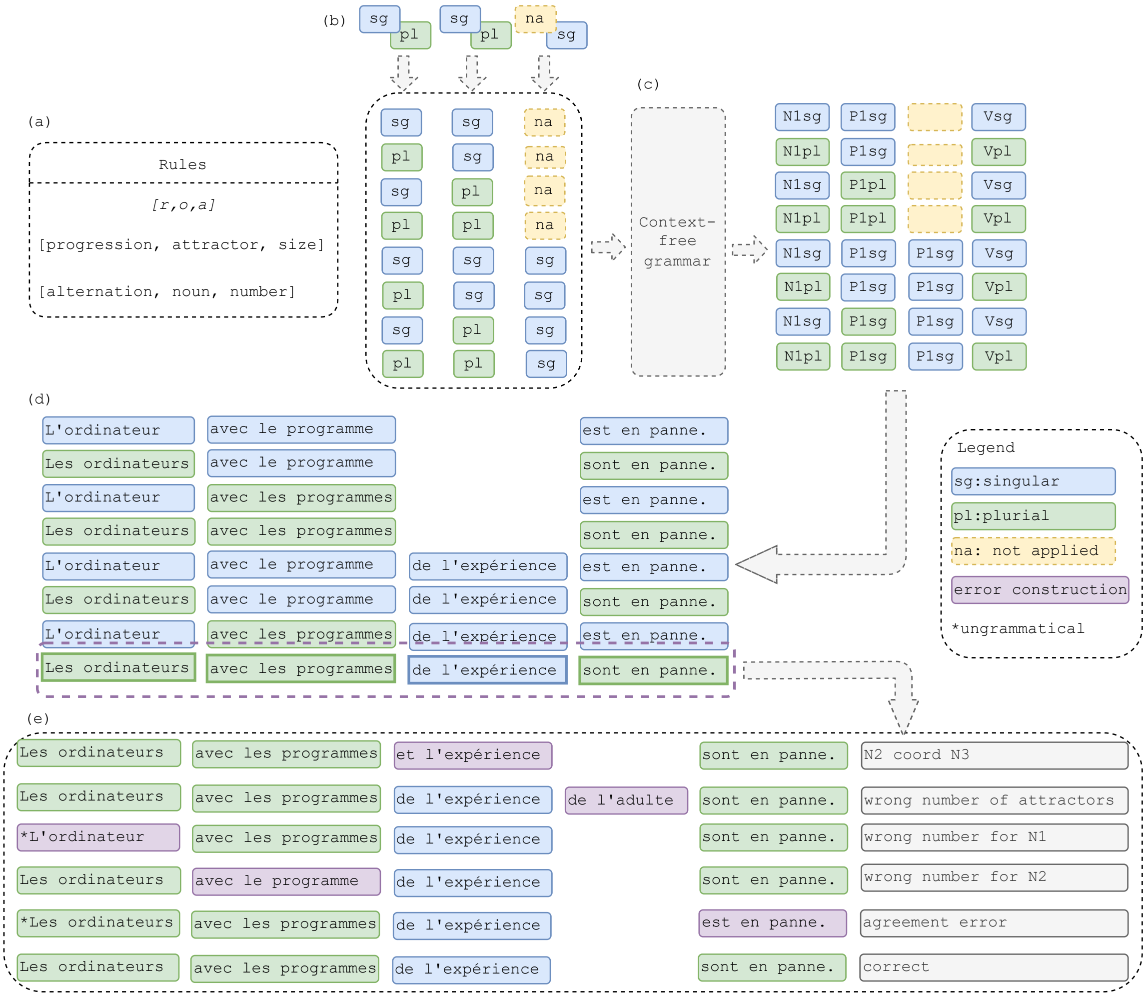

Figure 10:
Illustration of a BLMs problem generation process. Given sampled $[relation, object, attribute]$ rule tuples from (a), we first construct the abstract structure of the context with the values of the attributes of different objects in (b). We then derive, expand and prune the context-free grammar (with details in Figure 3) from each item's abstract structure into its corresponding sentence template in (c). In (d), we instantiate each item template into a sentence from the syntactic segment seed sets adapted from Franck et al. (2002). Finally, given the correct answer (last item), we modify one attribute at a time to obtain the relevant, minimally distinguishable and challenging candidate answer set in (e). The entire process is illustrated with an example of a progression in $[1, 2]$ constructed in a main clause. The error types across the dataset are uniformly distributed to avoid statistical bias.

Abstract

Advances in neural modeling have achieved state-of-the-art (SOTA) results on public natural language processing (NLP) benchmarks, at times surpassing human performance. However, there is a gap between public benchmarks and real-world applications where *noise*, such as typographical or grammatical mistakes, is abundant and can result in degraded performance. Unfortunately, works which evaluate the robustness of neural models on noisy data and propose improvements, are limited to the English language. Upon analyzing noise in different languages, we observe that noise types vary greatly across languages. Thus, existing investigations do not generalize trivially to multilingual settings. To benchmark the performance of pretrained multilingual language models, we construct noisy datasets covering five languages and four NLP tasks and observe a clear gap in the performance between clean and noisy data in the zero-shot cross-lingual setting. After investigating several ways to boost the robustness of multilingual models in this setting, we propose Robust Contrastive Pretraining (RCP). RCP combines data augmentation with a contrastive loss term at the pretraining stage and achieves large improvements on noisy (& original test data) across two sentence-level (+3.2%) and two sequence-labeling (+10 F1-score) multilingual classification tasks.

1 Introduction

Recently, multilingual pre-trained language models like mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020) and various others (Chi et al., 2021; Xue et al., 2021; Chi et al., 2022) have improved multilingual language understanding by pretraining large Transformer models on web-scale corpora (such as Wikipedia, Common-Crawl). These models achieve state-of-the-art performance on cross-lingual transfer and many multilingual NLP tasks (Wu and Dredze, 2019; Pires et al., 2019). However, a real-world system will encounter *real-world noise*, such as linguistic variations and common errors observed in textual data, that are often absent from benchmark datasets.

While prior works focused on this issue of robustness in monolingual settings (Peng et al., 2021; Sengupta et al., 2021; Tan et al., 2020), investigation has been scarce for multilingual settings. In this paper, we study the effect of realistic noise in multilingual settings and propose methods to boost the robustness of multilingual language models across four NLP tasks: Intent Classification (IC), Slot Labeling (SL), Named Entity Recognition (NER) and Natural Language Inference (NLI).

Due to the lack of multilingual noisy *evaluation* data, we synthesize benchmarks by mining noise from publicly available corpora and injecting them into the test sets associated with each of the four tasks. We conduct human validation to ensure that this noised data is indeed realistic (see examples from MultiATIS++ in Figure 1) and identify the variety of noise-types seen across languages (in §3). These analyses highlight the potential of our test-set in evaluating (and motivating future research on) multilingual robustness.

To benchmark the performance of multilingual systems, we consider accuracy metrics on two utterance-level tasks (IC% and NLI%) and F1-scores on two token-level classification tasks (SL-F1 and NER-F1). Specifically, we seek to evaluate the model's performance on the noised version of the test datasets in a *zero-shot cross-lingual setting*. In this scenario, we have training data for a task available only in one language (in our case, English) and test-data in various languages (Liu et al., 2019, 2020).

While training data augmentation increases model robustness for monolingual (i.e. English) settings, it is not immediately obvious if these robustness gains can transfer across languages, as error types can often be language-specific. For ex-

Figure 1: MultiATIS++ test set injected with real-world noise mined from Wikipedia edits. The highest error injection ratio found to be realistic by human experts is shown alongside the realistic utterance percentage. We do not include the noisy test sets for Chinese and Japanese in our analysis owing to low ($< 95\%$) realism.

ample, typos in Devanagari script can differ from those seen in Latin scripts (e.g. स्कूल → सकउल in Devanagari showcases that a joined character is incorrectly separated into two characters in the word ‘school’).

Thus, to improve the robustness of pretrained multilingual models across noise in all languages, we propose Robust Constrastive Pretraining (RCP) that couples multilingual noisy data-augmentation with a contrastive learning loss term during pretraining; this encourages the model to develop similar representations for the original and the noised version of a sentence.

On the noisy test sets, our method improves the multilingual model performance across all metrics and multilingual tasks– IC% by 4.9% on MultiATIS++, 4.1% on MultiSNIPS; SL-F1 by 18.4 on MultiATIS++, 8.6 on MultiSNIPS; NER-F1 by 2.9 on WikiANN; NLI% by 0.7% on XNLI. In summary, our primary contributions are:

1. We construct multilingual test data to evaluate the robustness of NLP models to noise (§3).
2. We show that the performance of existing multilingual language models deteriorates on four tasks when tested on the noisy test data (§5.1).
3. We introduce Robust Contrastive Pretraining (RCP) to boost the robustness of existing multilingual language models (§5.2).

Our code and data is available on *Github (repo: amazon-science/multilingual-robust-contrastive-pretraining)* .

2 Related Work

Many prior works demonstrate the brittleness of neural models on different noise phenomena such as misspellings (Belinkov and Bisk, 2017; Karpukhin et al., 2019; Moradi et al., 2021), casing variation (van Miltenburg et al., 2020), paraphrases (Einolghozati et al., 2019), morphological variance (Tan et al., 2020), synonyms (Sengupta et al., 2021), and dialectical variance (Sarkar et al., 2022). A popular approach to improve the robustness to noise is fine-tuning models with data augmentation (Feng et al., 2021) at either the pretraining (Tan et al., 2020; Sarkar et al., 2022) or the task-training stage (Peng et al., 2021). These works consider monolingual pre-trained models and primarily focus on English. While recent works on token-free models motivate robustness in multilingual settings (Clark et al., 2021; Xue et al., 2022; Tay et al., 2021), *examining the robustness of SOTA* *multilingual pre-trained models (and improving them) remains unexplored*. Hence, we investigate– (1) are multilingual models robust to noise seen in different languages (that may be dissimilar to noise types seen in English)? (2) can we get and leverage multi-lingual noise data to improve multilingual models? and (3) do automatic data-augmentation methods designed for English improve robustness to multilingual noise?

To boost the robustness of multilingual models to diverse multilingual noise, we leverage multilingual data augmentation at the pretraining stage and use contrastive learning. Our effort complements work in computer vision that showcases contrastive learning with adversarial learning at task-training (Fan et al., 2021; Ghosh and Lan, 2021) and pretraining time (Jiang et al., 2020; Kim et al., 2020) can improve model robustness. NLP has also seen a plethora of work that leverages contrastive learning, but seldom to alleviate robustness concerns (Jaiswal et al., 2020). Similar concepts, such as Adversarial Logit Pairing (Einolghozati et al., 2019), used at task-training time have proven to be less effective than data augmentation approaches (Sengupta et al., 2021) in boosting robustness.

All the aforementioned works lack in at least one of the two novel aspects of this paper– robustness to real-world (as opposed to adversarial) noise, and/or multilinguality. Lastly, the aspect of cross-lingual knowledge transfer has been studied in the context of different NLP tasks; typically, from a high-resource language to a low-resource one, as exemplified by the XTREME benchmark (Hu et al., 2020). In this paper, we investigate the cross-lingual transferability of robustness to real-world noise.

3 Constructing Noisy Test Data

As no existing benchmarks exist to evaluate the robustness of multilingual models, we construct noisy test sets in multiple languages for four tasks. First, we construct a word-level error-and–correction dictionary by leveraging the Wikipedia edit corpora. Then, we sample replacements from this dictionary and inject them into the test data for the various multilingual tasks, focusing on replacements that only affect individual words but do not change word order. Finally, we conduct human evaluation to filter out test sets that are not deemed to be realistic by language experts.

3.1 Wiki-edit Mining

Wikipedia[2] is a public encyclopedia available in multiple languages. Wikipedia editors create and iteratively edit its contents. We leverage these edits to construct error-correction word dictionaries (later used to create noisy test data). Our approach to mining edits is similar to Tanaka et al. (2020), but we consider multiple languages (as opposed to only Japanese), and additionally create dictionaries of word-level edits.

To isolate likely useful edits, we first consider each revision page of an article and split it into a list of sentences using NLTK (Bird et al., 2009). Second, we filter out sentence pairs from two consecutive edit versions ensuring both sentences have (1) 2-120 tokens, (2) a difference if < 5 tokens, and (3) a relative edit-distance within 30% of the shorter sentence. Third, we leverage language-specific tokenizes `difflib`[3] to extract exact token-level deltas between the sentence pair. At last, we ensure word pairs (in these deltas) that have at least one character-level Levenshtein edit-distance from each other[4] and none of words are only numbers or punctuation tokens. Note that edits to Wikipedia involve changes to factual information, such as dates, rather than incorrect spelling or grammar; thus, the last step is necessary.

We can finally create a *noise dictionary* of correct-to-incorrect words that has frequency information about the different errors. For example, an element of the dictionary (in Spanish) looks like `{de: [(del, 0.52), (se, 0.32), (do, 0.1), (dë, 0.04), (en, 0.02)]}`.

3.2 Injecting Noise into Test sets

We use the noise dictionaries to create a noised version of the original test data for the four tasks– MultiATIS++ (Xu et al., 2020), MultiSNIPS, WikiANN (Pan et al., 2017) and XNLI (Conneau et al., 2018). After tokenization, we sample tokens randomly without replacement. In each sampling step, we sample based on a uniform probability distribution over the individual tokens and then check if the token exists in the noise dictionary. If so, we replace it with a noised version from the dic-

---

[2] https://meta.wikimedia.org/wiki/List_of_Wikipedias

[3] https://docs.python.org/3/library/difflib.html

[4] For Chinese characters, including Kanji, even a single character distance could imply a different word.

tionary; the noised version is sampled based on its probability in the noise dictionary (that is proportional to the frequency of its occurrence in the noisy corpora). This procedure continues till we noise a particular number of tokens, precisely between 1 and $\min(4, pL)$ where p a controllable fraction (chosen as a hyperparameter at first, and finalized based on human evaluation described in §3.3), and L is the number of words in the sentence.

3.3 Human Verification of Noised Test-sets

During human evaluation, we analyse the noisy data created for the MultiATIS++ dataset. We asked the language expert to assume that a user who may not be a native speaker, or in a hurry, or sloppy, was trying to find out flight information via text chat, and evaluate realism with this in mind. Note that analysis of noise types for MultiATIS++ generalizes well to other datasets as we use the same error-correction dictionaries for injecting noise into all the test-sets.

Our language experts have graduate/doctoral degrees in linguistics, computational linguistics, or natural language processing and are fluent/native speakers of the respective languages. We employed the human experts and compensated them fairly to conduct this study (see §7 for details). The experts are given 45 examples without being told that 15 examples have 5%, 15 have 10%, and 15 have 20% noised tokens and asked three questions about each example. (1) Is the noised sentence realistic, moderately realistic, or unrealistic? (2) What type of noise is present in the sentence (we supply an initial list and let them add more)? and (3) Are the intent and slot labels unchanged? Based on their initial feedback, we choose the most realistic noise fraction (i.e. 5, 10 or 20%) and provide them with 60 more examples from that set. We considered 15 utterances enough to determine the noise fraction, but used the ratings on 75 utterances for evaluating realism (see realistic utterance $\%$ in Figure 1).

In Figure 1, we summarize the results of the human evaluation. Column two shows the error injection ratio that was deemed to have more than 95% realistic utterances. We set a high cut-off of 95% to ensure we can make confident statements about the robustness of multilingual models to realistic alterations exhibited in our benchmarks. Hence, Chinese and Japanese (with a realism of 86.2% and 92.3% resp.) are omitted in our benchmarks. The last two columns highlight examples deemed as realistic and unrealistic by human experts with the noised tokens highlighted in orange.

Anglicized	0.0%	0.0%	0.0%	16.3%	0.0%	0.0%	0.0%

Figure 2: The column-wise color density (which adds up to one) shows the percentage of a different noise types observed for a particular language. The row-wise values show that some noise types (eg. homophononic) is only present for a single language (eg. zh).

Given the sentence length and similarity in task types, we use the error injection percentage determined to be the most realistic for MultiATIS++ as the error injection percentage for MultiSNIPS and Wiki-ann. For XNLI, experts deemed higher noise injection ratios (of > 0.05) to be unrealistic (15% for 0.1, 27% for 0.2) because (1) the premise, usually much longer than sentences in MultiATIS++, had (impractically high) number of noise tokens, and (2) the classification label (implies/neutral/-contradicts) sometimes changed with large noise additions. Thus, for XNLI, we choose 0.05 to be the default noise injection ratio. Finally, one expert noted the Turkish data for MultiATIS++ lacked many diacritic characters, muddling the distinction between noise injected by our procedure and existing misspellings; hence, it was ignored.

In Figure 2, we list the noise-types identified by our experts in different languages. While certain noise-types, such as typographical errors, misspellings are common across multiple languages,

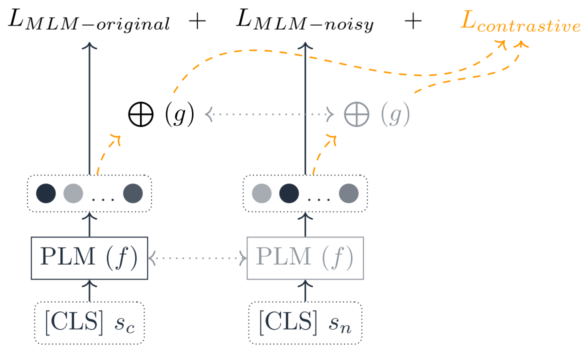

Figure 3: Loss function for fine-tuning a Pretrained Language Model (PLM) using Robust Contrastive Pre-training (RCP).

there are various language-specific noise-types, such as homophonic errors (for zh), Kanji conversion errors (for ja), anglicization (for tr) (we showcase some examples in Appendix A). Given disjoint noise types across languages, we expect that augmentation with errors seen in English (using approaches proposed by prior works) will generalize better to languages that share error types.

4 Robust Contrastive Pre-training (RCP)

Motivation and Approach While *task-time* data augmentation (aka adversarial training) has been effective to boost the robustness of pre-trained models for English, we face two major challenges– (1) lack of supervised multilingual training data in our zero-shot setting, and (2) lack of approaches to synthetically generate noise data for non-English languages. We overcome these with a multilingual data-augmentation approach at *pre-training time* that uses the multilingual Wikipedia edit corpus to expose our models to human errors during pre-training. Here, the need of ex-situ injection of noise (for test-data creation §3) is unnecessary as our edit corpus contains pairs of similar sentences, i.e. a version of the sentence before and after revision by a Wikipedia contributor (§3.1). To encourage the model to align the representations of these two sentences in the encoder's output space, we use a contrastive loss term (see Figure 3). Building on previous work on contrastive learning (Giorgi et al., 2021), Robust Contrastive Pre-training (RCP) considers the original and edited version of a sentence as positive examples and other unrelated sentences as the negative examples.

Similar to Giorgi et al. (2021) and Reimers and Gurevych (2019)), we map variable length sentences to fixed-length embeddings with a pooler $e_i = g(f(s_i))$, where $f(\cdot)$ is a transformer encoder, and $g(\cdot)$ is the mean of the token-level embeddings. Given a batch of N (noisy, clean) sentence tuples, we set our original sentence s_c as the anchor and the noisy version s_n as the corresponding positive pair. [5] Other sentences in the batch (i.e. $\neq s_n$) are deemed to be negative examples. We consider the InfoNCE/NT-Xent loss (Sohn, 2016) for our per-example contrastive loss:

$$\ell(i,j) = -\log \frac{\exp(\text{sim}(e_i, e_j))}{\sum_{i \neq k} \exp(\text{sim}(e_i, e_k)/\tau)} \quad (1)$$

where $\text{sim}(u,v) = u^T v/||u||_2||v||_2$ denotes the cosine similarity of two vectors u and v and $\tau > 0$ denotes the temperature hyper-parameter. Thus, our final contrastive loss function is

$$L_{\text{contrastive}} = \sum_{i=1}^{N} \ell(c,n) + \ell(n,c)$$

We additionally use the standard MLM loss at pre-training time, masking 15% of the input tokens of every sentence (i.e. both noisy and clean) independently. Therefore, our final loss function is

$$L = L_{\text{contrastive}} + L_{\text{MLM-noisy}} + L_{\text{MLM-original}}$$

$L_{\text{MLM-original}}$ is the MLM loss on original sentences, and ensures the model does not 'forget' its original pre-training task. $L_{\text{MLM-noisy}}$ is the MLM loss on noisy sentences, and can be thought of as data-augmentation at pre-training time.

Pre-training Details Following the Domain Adaptive Pre-Training (DAPT) approach (Gururangan et al., 2020), we start with an existing multilingual pre-trained model and fine tune it with our RCP objective. Unlike DAPT, we are not interested in specializing in a particular domain, but in increasing robustness to errors. As mentioned before, we use (unfiltered) pairs of correct/incorrect sentences from the multilingual Wikipedia archive and include sentences from the Lang8 corpus.[6] The Lang8 corpora consists of a smaller number of sentences compared to the Wikipedia corpus, but proves to be apt for our purpose; it consists of pairs of sentences– one written by a non-native speaker who is learning the language (eg. "As the winter

---

[5] One obvious choice would be for clean sentence with index $2i$, the noisy sentence has index $2i-1$.

is coming, I'm getting to feel better.") and a rewrite of this sentence by a native speaker (eg. "as the winter is coming, I'm starting to feel better."). More details about the individual corpora can be found in Appendix C.

We note that the pre-training corpus is not exactly the same set of sentences used to construct our noise dictionaries in §3.1. In this case, the only criteria for inclusion is a length difference of < 5 tokens, and a relative edit-distance of 30% of the shorter sentence (see appendix C for more details). Hence, we incorporate training data from the corpora that exhibit changes beyond simple typos (such as paraphrasing, sentence-level morphological variance) in the pre-training stage.[7]

Similar to Gururangan et al. (2020), we fine tune for 25k steps with a batch size of 2048 sentences to create two pretrained models– one with $\mathcal{L}_{\text{contrastive}} + \mathcal{L}_{\text{MLM-noisy}} + \mathcal{L}_{\text{MLM-clean}}$ (referred to as Robust Contrastive Pre-training or RCP) and an ablation without the contrastive term, i.e. $\mathcal{L}_{\text{MLM-noisy}} + \mathcal{L}_{\text{MLM-clean}}$. The latter setting represents a pure (pre-training time) data augmentation approach such as Tan et al. (2020) (termed *p(aug)* in Table 3). See Appendix D for more hyper-parameters and settings.

5 Experiments and Results

We divide this section into three parts. In §5.1, we analyze the robustness of popular multilingual language models in the zero-shot cross-lingual setting. In §5.2, we show that Robust Contrastive Pre-training (RCP) improves the robustness of existing baselines on noisy test-data for all tasks– joint intent classification and slot labeling (IC-SL), Slot-Labeling (SL) Named Entity Recognition (NER) and Natural Language Inference (NLI)– and (not only maintains but) improves performance on the original test data. Finally, in §5.3, we conduct failure mode analysis for MultiATIS++ and discover that the model trained with RCP makes more explicable sequence-labeling errors (for slot-value prediction) in comparison to existing baselines.

Setup We consider four datasets (shown in Table 1) and four metrics for evaluation. Two of these metrics consider sentence classification accuracy– Intent classification Accuracy (IC%) for the goal-oriented dialog text datasets MultiATIS++ and MultiSNIPS, and classification accuracy (NLI%) for XNLI. We also consider F-score for sequence-labeling tasks– Slot Labelling (SL-F1) for MultiATIS++ and Multi-SNIPS++ and Named Entity Recognition (NER-F1) for Wiki-ann. Table 1 shows the languages present in the noisy test data and the size of the English training data used in our zero-shot cross-lingual setting. Note that for task-time data augmentation, we follow the strategy of *aggregate noise augmentation* proposed in (Sengupta et al., 2021) for English, which involves augmenting training data with a variety of synthetic noise types such as typos, making words ALL-CAPS, abbreviations etc. As this augmentation procedure increases the size of the training data-set ≈ 3.5 times for MultiATIS++ and ≈ 5.5 times for

---

[7] Unfortunately, the benefit of including sentence-level noise in the pre-training phase is not directly examined by our benchmarks, which focus more on word-level noise.

Task	Metric	XLMR	XLMR +p(aug)	XLMR +t(En-aug)	XLMR +RCP (Ours)	XLMR +RCP+t (Ours)	Gain
MultiATIS++	IC%	89.65	93.10	91.26	93.80	**94.57**	+4.92
	SL-F1	62.30	67.47	74.62	67.45	**80.68**	+18.38
MultiSNIPS	IC%	90.46	93.98	91.60	93.79	**94.53**	+4.07
	SL-F1	61.63	66.67	66.44	67.69	**70.20**	+8.57
Wiki-ann	NER-F1	69.48	72.32	-	**72.37**	-	+2.89
XNLI	NLI%	74.38	74.83	-	**75.06**	-	+0.68

Table 3: Average performance across languages and five seeds. We abbreviate the baselines, multi-lingual pre-training time augmentation as p(aug), and English task-time (aggregate) data augmentation as t(En-aug). 'RCP' stands for 'Robust Contrastive Pre-training', and 'RCP + t' means combining RCP with task-time data augmentation. 'Gain' refers to the increase in performance of the best method vs. XLM-R$_{\text{base}}$.

MultiSNIPS, we find that training for fewer epochs yields the best results.

5.1 Robustness of Multilingual Models

We compare the robustness of two popular pre-trained language models– XLM-R$_{\text{base}}$ and multilingual BERT in the zero-shot cross-lingual setting.[8] In this setup, we fine-tune the pretrained language models on the task-training data in English and test (zero-shot) on multilingual test sets. The results reported in Table 2 are averaged across multiple languages for brevity (and provide a detailed breakdown in Appendix E). A secondary goal of this experiment was to decide which pre-trained model to use for further experiments and we base our judgements on twelve metrics across four datasets.

Noise always leads to a decrease in performance. On average, the accuracy of both models decreases by $\approx 2\%$ for sentence-level tasks (IC%, NLI%), and by ≈ 6.6 F1-points on sequence-labeling tasks (SL, NER), on noisy data compared to clean data. This can perhaps be explained by the ability to ignore a particular token for sentence-level tasks, whereas every token, including noisy ones, need to be assigned a label for sequence-labeling tasks.

We observe that XLM-R$_{\text{base}}$ outperforms mBERT on all the twelve metrics. For sentence-level tasks (i.e. IC%, NLI%), XLM-R$_{\text{base}}$ outperforms mBERT by 8.43% on average on the noisy test-sets and for sequence-tagging tasks (i.e. SL, NER), XLM-R$_{\text{base}}$ outperforms mBERT by 5.1 F1-points. In general, XLM-R$_{\text{base}}$ also seems to be a model better suited for these tasks in the zero-shot cross-lingual setting, as we also see similar gains when using XLM-R$_{\text{base}}$ on the clean data.

Task	Metric	XLMR	Ours	Gain
MultiATIS++	IC%	90.68	95.32	+4.64
	SL-F1	71.45	84.07	+12.62
MultiSNIPS	IC%	92.93	95.66	+2.73
	SL-F1	68.01	74.39	+6.38
Wiki-ann	NER-F1	74.14	76.34	+2.2
XNLI	NLI%	76.69	76.75	+0.06

Table 4: Comparison of our RCP method with the baseline XLM-R$_{\text{base}}$ model on the original (clean) test data.

Breaking the results down by language (see Appendix E for detailed results), XLM-R$_{\text{base}}$ outperforms mBERT on average across all languages. Specifically XLM-R$_{\text{base}}$ outperforms mBERT on German (in 6/8 metrics), on Spanish (10/10), on French (8/12), on Hindi (12/12), and on Turkish (4/4). As German is missing in MultiATIS++ and Turkish is only present in WikiANN and XNLI among the four datasets, the overall number of metrics is less than 12 for these two languages. Given these results, we consider XLM-R$_{\text{base}}$ as the baseline multilingual language model in the rest of our experiments.

5.2 Robust Contrastive Pre-training Results

To showcase the efficacy of our RCP approach, we compare our approach to a popular multilingual model XLM-R$_{\text{base}}$, which performed best in the previous section, and two augmentation solutions that were proposed earlier and shown to improve robustness of English language models to real-world noise. First, we consider a pre-training time data augmentation approach, similar to Tan et al. (2020), by continuing to pre-train XLM-R$_{\text{base}}$ on *noisy* multilingual data; see section 4. Next, we consider augmenting task-time data with a combination of various noise types, following Sengupta et al. (2021) that shows using this aggregate data augmentation during task-time finetuning improved

---

[8] We also considered Canine-c (Clark et al., 2021), a token-free baseline, but observed poor performance compared to XLM-R$_{\text{base}}$ and BERT on IC-SL tasks (see Table 10).

Error Type	Utterance	Slot-lables
Hallucination	*Ichs* brauche einen Flug von Memphis nach Tacoma, der ***uber*** Los Angeles fliegt	✓ O (über) ! airline_code
Contextual	Zeige *mit der* Erste-Klasse und Coach-Flüge vom **JFK** nach Miami	✓ fromloc.airport_code ! toloc.airport_code

Table 5: Examples of slot labeling errors in German– errors are in *italics*; misclassified tokens are **bold**.

performance on both noisy and clean data for IC-SL tasks like ATIS and SNIPS. For the latter, we treat it as a baseline for zero-shot cross-lingual transfer for the dialog-datasets–MultiATIS++ and MultiSNIPS– and also combine it with our pre-training time approaches.

As shown in Table 3, our approach can improve the performance of current multilingual models across all 4 tasks and datasets. For the multilingual goal-oriented dialog datasets, our approach coupled with task-time augmentation outperforms all the other methods. We observe that the gain for SL tasks is higher than that obtained for IC tasks. Although we analyze the SL results further in §5.3, we highlight that IC accuracy is less affected by noise than SL F1; this provides more headroom for improving SL metrics. The highest gains are observed for Hindi where the XLM-R$_{\text{base}}$ model has the worst SL performance on noisy data (42.86 for MultiATIS++, 36.93 for MultiSNIPS). Likewise, we also observe improvement on XNLI% and NER-F1; the largest improvement is again seen on the noisy data for Hindi. Overall, the gain on sequence-labelling tasks is larger than the gain on sentence-level classification tasks.

Does this improvement on noisy data come at the cost of worse performance on clean data? In Table 4, we show that the best performing models shown in Table 3 (XLMR+RCP+t for MultiATIS++ and MultiSNIPS, and XLMR+RCT for WikiANN and XNLI) also improve the performance on clean test data. Further, the magnitude of growth seen on clean data is like the ones seen on the noisy test data. For slot-labeling errors, we observe a particular kind error which occurs on both clean and noisy data that our model mitigates; we provide more details on this in the next section. For IC and XNLI, we found no specific error pattern that distinguishes between XLM-R$_{\text{base}}$ and our model. Thus, we believe that our approach mostly improves the overall quality of the model's representation rather than just its downstream robustness. In the future, one can consider if an upper bound on model quality exists beyond which the tension between accuracy on clean data and robustness to real-world noise emerges (Tsipras et al., 2018).

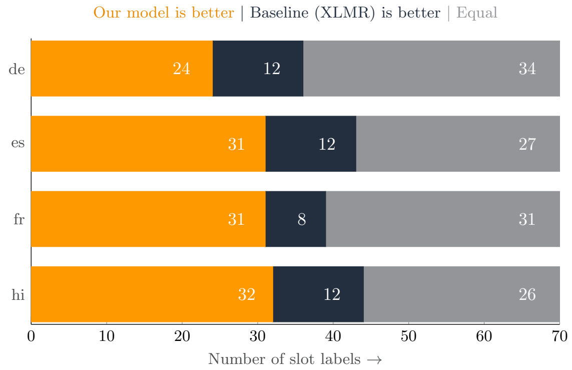

Figure 4: Comparing the number of slot labels for which our model *vs.* the baseline performs better.

Finally, we note that beyond improving performance on clean and noisy data, our approach reduces the *disparity* in performance between the clean and noisy test sets. For MultiATIS++, the disparity reduces by 0.3% for IC% and 5.76 for SL-F1; for MultiSNIPS, it reduces by 1.34% for IC% and 2.19 for SL-F1; for WikiANN, it reduces by 0.68 for NER-F1; and for XNLI, it reduces by 0.9% for NLI%.

5.3 Result Analysis

Given the large improvement seen on sequence labeling tasks, we zoom in on the SL metrics for MultiATIS++. In Figure 4, we show the number of slot labels on which our method outperforms (has fewer misclassifications than) the baseline, vice versa, and where they perform equally. Our method clearly out-performs the baseline on at least twice the number of slot-labels– 2× better on German, ≈ 2.6× times on Spanish and on Hindi, and ≈ 4× on French. Across all languages, our model always outperforms XLM-R$_{\text{base}}$ on eight slot-labels. These slots correspond to relative times ('leaves in the *evening*'), relative dates ('traveling the *day after tomorrow*'), relative costs ('*cheap* flights'), meal names ('flights that offer *breakfast*'), and carrier tokens/non-slot values ('*that offer* breakfast'). We postulate these slot values are more common in the

N/O	Model	de	es	fr	hi
Noisy	XLMR	315	358	413	671
	XLMR+RCP+t	21	123	33	204
Original	XLMR	208	262	334	460
	XLMR+RCP+t	19	106	22	180

Table 6: Reduction in hallucination error (i.e. model identifies irrelevant tokens as a slot value) counts.

Languages	de	es	fr	hi
(r1) Top-confusion changes to no-label (w/ RCP)	7	8	6	17
(r2) Confusions becomes more explicable (w/ RCP)	8	3	3	4

Table 7: Number of slot-labels that our model misclassified to (r1) a no-slot or (r2) a more explicable slot-label.

pre-training data compared to proper nouns such as airline, airport or city names and thus, understood in noisy contexts. In turn, variations of these words are mapped closer in the embedding space and the classifier is more robust to such errors.

Upon further analysis, we observe two distinct patterns– (1) reduction in *hallucination errors*, i.e. errors where an irrelevant carrier phrase token is labeled to be a slot value, and (2) errors become more contextual– misclassification is to related classes (see examples in Table 5).

In Table 6, we highlight the distribution of hallucination errors and observe that the number of carrier phrase tokens that the baseline XLM-R_{base} misclassifies as a slot-value reduces (by $> 10\times$ for German and French, and $\approx$2-3$\times$ for Hindi and Spanish) with our approach on both the original and the noisy test data. This observation aligns with our initial reasoning that the contrastive loss term at pre-training time helps the model develop a better understanding of non-slot words as the model learns to identify such words (and their noisy forms) in both linguistically correct and noisy contexts. Note that the latter signal is missing for the XLM-R_{base} baseline.

For a subset of the slot labels, the class to which it was misclassified (with the highest frequency) differed between the XLM-R_{base} baseline and our model. In Table 7, we highlight two scenarios where the most-confused label changed from (r1) an incorrect slot label (eg. *meal_code* → *airline_code*) to no-label (i.e. *meal_code* → O), and (r2) from an inexplicable slot label (*state_code* → *transport_type*) to a more explicable one (*state_code* → *state_name*) when the RCP method is used (we use the explicable/inexplicable terminology of Olmo et al. (2020)). Thus, our approach inadvertently improves the explicability of the failures made during slot-labeling.

6 Conclusion

In this paper, we investigate the robustness of pretrained multilingual models in the zero-shot cross-lingual setting on four tasks– intent classification, slot labeling, named entity recognition, and natural language inference. Given the dearth of existing datasets to benchmark the robustness of existing multilingual models, we develop noisy test data by injecting errors mined from an edit corpus (and conduct expert evaluation for quality assurance). Our identification of noise types across various languages motivates the necessity of language specific investigation in the future. Finally, demonstrate existing baselines perform poorly in the presence of noise in the test data and propose Robust Contrastive Pretraining to boost the robustness of these multilingual models.

7 Ethical Considerations

For the human annotation tasks of (1) identifying language-specific noise types, and (2) ranking their realism, we leveraged the effort of full-time employees at Amazon. The annotators had advanced degrees in linguistics or natural language processing, and were fluent/native in the languages they annotated. Amazon compensated them under a competitive industry rate, which is above the minimum hourly pay rate, for their particular job role (which included Applied/Research Scientists, Software/Language Engineers, Linguists, and Language Consultants).

Acknowledgements A special thanks to Saab, Batool Haider and M. Saiful Bari for sharing with us the MultiSNIPS dataset. In addition, we want to express our gratitude to members of the AWS AI Lab for their valuable comments, suggestions, and participation in our pilot and human labeling studies (in no particular order)– Sebastien Jean, Volha Belash, Arshit Gupta, Berk Sarioz, Maansi Shandilya, Raphael Shu, Abhilash Panigrahi, Lorenzo Lambertino, and Yi Zhang. Finally, we are grateful to the anonymous reviewers who have helped us improve this paper.

8 Limitations

8.1 The Umbrella of Realistic Noise

‘Realistic noise’ is too abstract a category. We mostly concern ourselves with real-world errors and their corrections appearing in existing corpora (with criteria like a small character-level edit distance). But this could include things like better paraphrasing, use of more appropriate synonyms or morphology that can be viewed as language variation rather than noise; this could be one reason we notice improvements on the original (i.e. unnoised) test data. Yet, to distinguish ourselves from the terminology of synthetic or adversarial noise, we choose this (imperfect) terminology of real-world/realistic noise as in Sengupta et al. (2021) to bracket all our noise types under a single class.

8.2 Language Choice and Diversity

This work considers (relatively) high-resource languages. This makes it easier for us to find publicly available corpora from where we can mine error/-correction data and use it to improve the model’s understanding of errors and, in turn, boost their robustness to real-world noise. But this is only the first step towards developing an understanding of noise phenomena in languages beyond English, bench-marking multi-lingual model performance in such settings, and improving their robustness. Further, we do notice that Hindi (and, to some extent, Turkish) are relatively low resource languages when it comes to pre-training data (see Table 8 in Appendix). We hope future work builds on this and explores a greater variety of languages.

8.3 Zooming-in on Individual Tasks

Many of our human studies are based on a subset of datasets (eg. MultiATIS, XNLI). It is possible individual tasks and further, individual datasets need more fine-grained human attention. Given language expertise for several datasets and several languages is difficult/costly, we made the choice to concentrate on a smaller number of datasets in order to provide a more rigorous analysis. We hope future work can expand the number of tasks and datasets covered so we have a more comprehensive analysis of how multilingual noise affects pre-trained models.

A Examples of Noise/Errors in the test set

In this section, we highlight an example of some of the unique noise types observed for certain languages shown in Figure 5.

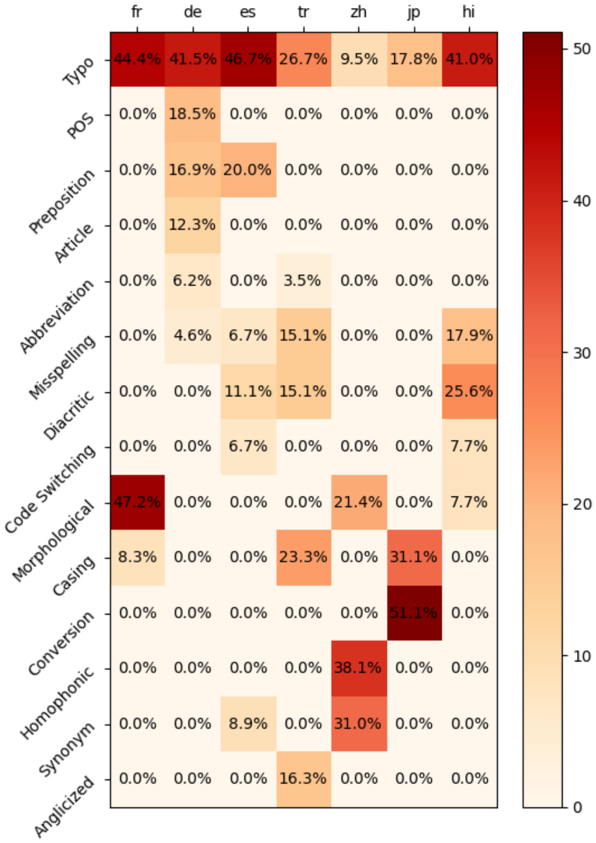

Figure 5: Noise types seen across various languages.

A.1 Typographic Errors (Typos)

Two examples follow for Hindi and Chinese, where experts evaluated based on the Indic Script and the Pinyin keyboards (which is what they use regularly) respectively.

Language	Examples
Hindi (hi)	सोमवार को बरबैंक [से|के] मिल्वौकी तक उड़ानें
Chinese (zh)	列出美国航空周三从密尔沃基飞往圣何塞的航班 **[列出 | 例出]** 美国航空周三从密尔沃基飞往圣何塞的航班

A.2 Preposition Errors

We noticed language experts tagged preposition errors for French and German. Examples follow:

Language	Examples
French (fr)	Je veux un vol aller-retour [de | à] Memphis à Seattle .
German (de)	Wie sieht es [am | im] Mittwoch morgen mit Flügen von DC nach Oakland aus

A.3 Diacritic Errors

Some languages use diacritic characters; although even these diacritics may greatly differ depending on script. Examples from Hindi and Spanish follow.

Language	Examples
Spanish (es)	¿puedo tomar el vuelo [más | mas] corto de milwaukee a orlando ?
Hindi (hi)	d9s किस [तरह | तरह्] का विमान हैं

A.4 Conversion Errors

Kanji conversion error. This error was unique to the Japanese language. Examples follow.

Language	Examples
Japanese (ja)	アトランタからセントルイスまでの火曜日午後2時30分 [以前 | 依然] のフライト

A.5 Homophonic Errors

This error was unique to Chinese. Words with the same pronunciation (potentially with different tones), but different spelling. Examples follow.

Language	Examples
Chinese (zh)	请列出从 [洛杉矶 | 洛杉机] 飞往夏洛特的航班

A.6 Synonym

Experts marked these as use of a different synonym in Spanish and Chinese only. Note that such variations may not be erroneous but is still considered a noise given they are not used in the original training/testing data in the given context as much. Examples follow.

Language	Examples
Spanish (es)	el próximo miércoles , me gustaría salir de kansas city en [un | el] viaje a chicago que llegue a chicago alrededor de las 7 p m.
Chinese (zh)	请列出从 ewr [到 | 直到] 纽约市的地面交通

A.7 Anglicized

We observed this errors only for Turkish and noticed that experts marked scenarios where an alphabet in the native script was replaced with a particular one in the latin script. Examples follow (note that Turkish examples are drawn from the XNLI dataset, while the others were drawn from MultiATIS++).

Language	Examples
Turkish (tr)	Sonrasında, ilk ziyareti yapmış olan aynı temsilci, soruları cevaplamak ve şikayet örneğinde not edilen sorunları tartışmak [için | icin] yeni sağlayıcıyı yeniden ziyaret eder.
	Konfederasyonun hukuk felsefesi, hem maddi hem de üslupla [karşı | karsi] karşıya geldi.

B Chinese and Japanese Edit Mining

Our two character edit distance criteria for obtaining word-level correct-noisy pairs of words does not work well for Chinese characters, including Kanji for Japanese. This is because words are made up of only a small number of characters (relative to e.g. latin scripts). So we can completely change the semantics with only a small character-level edit distance. We therefore used different noise types: Homophonic and Synonym errors for Chinese and Kanji Conversion errors for Japanese, with brief descriptions and examples in Appendix A. In order to collect homophonic errors we converted words to pinyin[9] (without tone markers) and checked if they were the same in pinyin but different in Chinese characters. To collect synonym noise we labelled words with part-of-speech (POS) tags [10], and kept words that weren't labeled as nouns, verbs, adverbs, keeping e.g. prepositions and conjunctions, with the hope that these would be less likely to involve the kind of big semantic changes you might get with changes to e.g. proper nouns like place names.

However this process was largely driven by trial and error and more work is needed to create a principled pipeline that creates a realistic noise dictionary for these languages.

Finally for Kanji we re-use the criteria of Tanaka et al. (2020) as we re-use their dataset of sentence pairs: checking if the two sentences (containing Kanji) have the same reading.

C Data Details

Table 8 shows the number of Wikipedia and Lang8 sentences (in Millions) we used for fine-tuning the multilingual models in the pre-training stage (§4). As stated earlier, the proportion of data obtained from the Lang8 corpus is less than Wikipedia for most languages except English (where it is comparable) and Japanese (where Lang8 has ≈ $4x$ the data compared to the Wikipedia corpus). In general, Hindi (and Turkish) stand out as a relatively low-resource language in our investigation with less than 0.5 Million sentences.

Language	Lang8	Wikipedia	Total
en	2.5	3.8	6.3
de	0.2	13	13.2
es	0.2	7.6	7.8
fr	0.2	10.7	10.9
hi	0.001	0.1	0.101
ja	4.2	1	5.2
tr	0.02	0.4	0.42
zh	0.6	1.9	2.5

Table 8: Number of sentences (in millions) used for pre-training.

Language	# Pairs (in Millions)
en	0.13
de	0.33
es	0.21
fr	0.27
hi	0.04
ja	0.05
tr	0.25
zh	0.01

Table 9: Number of Error pairs by language.

Table 9 lists the number of correct/incorrect pairs (in Millions) used for noise dictionaries to create the test-sets for the various languages (§3). Here too, we can observe that the number of corrections are relatively less for Hindi. Interestingly, the number of errors for Chinese are the least although it representation is significantly more compared to Hindi. This low number of errors is inline with our human studies where even the 5% error injection was deemed to be unrealistic; futher, such low pairs of errors also reduced the diversity of our test set, which would eventually results in a lower-quality test-set. Hence, we drop it from our evaluation benchmarks.

D Pre-training Settings

For our experiments with Robust Contrasting Pretraining (§4) and variants we use the following hyperparameters and setup. We train on 4 Nvidea V100 GPUs, with a per-gpu batch size of 8 sentences with a maximum sequence length of 128 tokens, and 64 gradient accumulation steps, for an overall batch size of $64 \times 8 \times 4 = 2048$ sentences. We use a masked language modeling mask probability of 15% and a

E Per-language Results

Table 10 shows the performance of multilingual models like m-BERT and XLM-R$_{\text{base}}$ on individual languages. We note that the reduction in performance for high-resource language (e.g. German, French, English) is higher than low-resource languages for several settings. To explain this seemingly surprising result, first notice that the metrics on low-resource languages are already bad, even on clean data. Second, the variety of noise seen for low resource languages is less (see Table 9) compared to high-resource settings. Hence, the effect of less diverse noise in low-resource languages doesn't have as large an adverse effect on already poorly performing models.[12]

Another hypothesis, pending future investigation, is that multi-lingual models trained on more high-resource language data overfit to clean test-sets for these languages and fail to generalize better when faced with noise. For low resource languages, the performance on clean data is already poor because of a lack of sufficient language understanding that prevents over-fitting.

---

Unsupervised Anomaly Detection in Multi-Topic Short-Text Corpora

Mira Ait-Saada[1,2] and **Mohamed Nadif**[1]
[1]Centre Borelli, Université Paris Cité, 75006, Paris
[2]Caisse des Dépôts et Consignations, 75013, Paris
`{mira.ait-saada,mohamed.nadif}@u-paris.fr`

Abstract

Unsupervised anomaly detection seeks to identify deviant data samples in a dataset without using labels and constitutes a challenging task, particularly when the majority class is heterogeneous. This paper addresses this topic for textual data and aims to determine whether a text sample is an outlier within a potentially multi-topic corpus. To this end, it is crucial to grasp the semantic aspects of words, particularly when dealing with short texts, since it is difficult to syntactically discriminate data samples based only on a few words. Thereby we make use of word embeddings to represent each sample by a dense vector, efficiently capturing the underlying semantics. Then, we rely on the Mixture Model approach to detect which samples deviate the most from the underlying distributions of the corpus. Experiments carried out on real datasets show the effectiveness of the proposed approach in comparison to state-of-the-art techniques both in terms of performance and time efficiency, especially when more than one topic is present in the corpus.

1 Introduction

Anomaly Detection (AD) is a task that can address various objectives such as mining frauds (Deng and Mei, 2009), diseases (Han et al., 2021) and intrusions (Pu et al., 2021). AD takes several forms: supervised, unsupervised or semi-supervised. Unsupervised AD implies that no prior information about the dataset is provided. In this case, the solution usually consists of identifying samples that deviate in a certain way from the others among the same dataset; anomalies being, by definition, rare phenomena. Particularly, anomalies in a textual dataset can be defined as samples having an atypical vocabulary (lexical anomaly) or a deviating global meaning (semantic anomaly). Identifying abnormalities in textual data can be very useful in many industrial use-cases. A good example is the detection of non-eligible and/or fraudulent course contents in the public French plateform MonCompteFormation[1] where millions of course sessions are available with no possibility of controlling training organizations in a supervised fashion (using labeled data). Hence, to assess the effectiveness of our approach, we rely on an external labeled dataset that closely relates to course contents and that is dedicated to course certifications. The dataset is described in Appendix A. In addition to the difficulty of mining anomalies in short-text corpora of varying sizes, we also have an important computational cost constraint that is also addressed by the proposed solution.

Les lignes de commande Linux pour débutants	inlier

Administration système Unix pour les nuls	inlier
Apprendre à utiliser le terminal Ubuntu/Debian	inlier
Formation en Espagnol pour débutants	outlier

Table 1: Example illustrating the importance of semantic representations in a small corpus of short texts.

Capturing the semantics of a given text is usually performed using Word Embeddings, which consist in representing a word or a piece of text by a fixed-size vector, supposed to detain its meaning. Several word embedding techniques are available such as word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014), fastText (Bojanowski et al., 2017), BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2019), etc. Each of the mentioned works provides ready-to-use models that are pre-trained on very large corpora and intended to be general for a given language and suitable for several NLP downstream tasks. Indeed, relying on such pre-trained models has proved efficient in several tasks (Kim, 2014; Das et al., 2017) and is particularly useful when dealing with small corpora (Buechel et al., 2018). If we consider the

small corpus given in Table 1, we can observe that the inlier samples (training titles about Linux shell programming) do not have any words in common. Thus, based only on the syntactic information of the samples, it would be impossible to isolate the outlier (about learning Spanish), even though it is the only one that does not have anything to do with shell programming. This can easily occur when dealing with short-text corpora, especially when the number of samples is not sufficient to learn the different syntactic variants of a word or a concept.

Depending on the data type and the assumptions that can be made, the definition of an outlier may differ, and the choice of the model is crucial, especially in an unsupervised context (Aggarwal, 2017). In this paper, we propose a probabilistic AD approach based on Mixture Models, that effectively identifies the most deviating samples in short-text datasets, even in the case where several topics are present in the inlier class. We also show the effectiveness of using the knowledge learned by word embedding models in capturing the underlying semantics of short texts and efficiently identifying outliers. The main contributions of this paper are:

- We address the challenge of mining anomalies in short texts written in French
- We tackle the classical one-class inlier scheme and also a more challenging multi-class inlier setting.
- We propose an effective and efficient anomaly detection approach that outperforms previously proposed AD techniques.

2 Related Work

Anomaly detection is an active research area, and a large number of approaches are proposed in several application domains. Specifically, our work relates to unsupervised AD for text and clustering-based AD. Unsupervised AD is gaining more and more interest in research due to the constant growth of data volumes while labeling data samples is not getting any cheaper. One of the most important family of methods contains reconstruction-based approaches that assume that a well-generalizing model would struggle at compressing rare anomalous samples. This kind of approaches include linear models such as Robust PCA (Kang et al., 2015) and deep autoencoder models based on convolutional networks (Oza and Patel, 2019), recurrent networks (Hsieh et al., 2019), etc.

2.1 Clustering-based AD

In the clustering-based AD approaches, anomalies are generally seen as data samples that present a lower adhesion to the underlying groups. Several two-phase approaches have been proposed and consist in using a clustering algorithm such as DBSCAN (Sheridan et al.), K-means (Deng and Mei, 2009) and Affinity Propagation (Marcos Alvarez et al., 2013), then compute an anomaly score from the obtained clustering partition. Similarly in (Mahadevan et al., 2010), to detect temporal anomalies in videos, inlier behaviors are modeled as a mixture of Gaussian distributions. A deep GMM-based approach called DAGMM is proposed in (Zong et al., 2018) to detect outliers in numerical data, where the input data are compressed into a lower-dimensional space using an autoencoder and then fed into a GMM component. The autoencoder's reconstruction loss and the log-likelihood of the GMM component are optimized jointly, without performing any pre-training phase.

2.2 AD in text data

Unlike images, time series, and numerical data, relatively few AD studies are dedicated to textual data. Document-term matrix representations (also called sparse bag-of-words) have previously been used in (Kannan et al.) to perform AD based on Nonnegative Matrix Factorisation (NMF) and isolate an outlier matrix, used to compute the anomaly scores. Sparse representations are also used by Manevitz and Yousef (2001) as input to a One-Class Support Vector Machine (OC-SVM) (Schölkopf et al., 2001) and later to a shallow autoencoder (Manevitz and Yousef, 2007). Word embeddings like word2vec are used for AD in (Zhuang et al., 2017) along with a von Mises Fisher (vMF) mixture model where more general words are penalized when computing the overall outlierness score of a given document. Pre-trained fastText word vectors are used in (Ruff et al., 2019) as the embedding layer of a multi-head attention network to perform anomaly detection as a one-class classification task. Recently, a deep end-to-end approach has been proposed by Manolache et al. (2021) that does not use any knowledge transfer. The authors use the transformer architecture of ELECTRA (Clark et al., 2020) that contains two adversarial components: a generator and a discriminator. The model is trained from scratch on a given dataset by optimizing a loss function based on token replacement.

2.3 Semantic text representations

Tremendous advances in various NLP tasks have been made in recent years thanks to dense vector representations of words and text sequences. Static word embeddings like word2vec (Mikolov et al., 2013), GloVe (Pennington et al., 2014) and fastText (Bojanowski et al., 2017) provide one unique dense representation for each word whereas contextual word embedding models like ELMo (Peters et al., 2018), BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) provide word representations that depend on the surrounding context. Contextual word embedding models are based on deep neural networks, which makes them resource-intensive and difficult to use in some industrial contexts. Both kinds of word embeddings have proved effective in several unsupervised downstream tasks like semantic textual similarity (Arora et al., 2017; Ranasinghe et al., 2019), clustering (Ait-Saada et al., 2021; Boutalbi et al., 2022) and anomaly detection (Zhuang et al., 2017).

3 Gaussian Mixture Models

Given a corpus $\mathcal{D}$ of n short texts $(d_1, \dots, d_n)$, we represent each sample by a fixed size vector, thus obtaining a matrix $\mathbf{X} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$ of size $n \times m$. To tackle the AD problem, we postulate that the samples follow a mixture of distributions, from which the anomalous samples deviate.

Admittedly, the family of t-distributions provides a heavy-tailed alternative to the gaussian family for anomaly detection. However, as pointed out by (Yuan and Huang, 2009), although useful from modeling perspective, the practical use of multivariate t-distribution is often limited by the difficulty in parameter estimation, particularly so for high dimensional data. Note that, in our proposal, the consideration of the time consumption is important. Therefore, considering a t mixture model leads to estimate a supplementary parameter (in addition to the estimation of vector means and covariance matrices) that is the degree of freedom of each component. Moreover, since we suggest to consider an ensemble method allowing to combine results by varying the number of components (cf. Section 3.1), we would therefore increase yet the computation time for estimation of the parameters. However, Gaussian Mixture Model (GMM)-based approaches, more parsimonious than t-mixture model, have shown their effectiveness in anomaly detection, such as DAGMM (Zong et al., 2018). For these reasons we retain GMM to address our purpose.

In a finite GMM, the data $(\mathbf{x}_1, \dots, \mathbf{x}_n)$ are taken to constitute a sample of n independent instances of a random variable $\mathbf{X}$ in $\mathbb{R}^m$. Density can be expressed as:

$$f(\mathbf{x}_i; \Theta) = \sum_{k=1}^{g} \pi_k \varphi_k(\mathbf{x}_i | \mu_k, \Sigma_k), \forall i \in \{1, \dots, n\}$$

where $\Theta = (\pi_1, \dots, \pi_g, \mu_1, \dots, \mu_g, \Sigma_1, \dots, \Sigma_g)$, $\varphi_k(\mathbf{x}_i|\mu,\Sigma_k)$ is the kth component density for observation $\mathbf{x}_i$ with parameters (μ_k, Σ_k), $(\pi_1, \dots, \pi_{g-1})$ are the mixing weights or probabilities (such that $\pi_k > 0$, $\sum_{k=1}^{g} \pi_k = 1$) and g is the number of mixture components. Thus, clusters are ellipsoidal, centered at the mean vector μ_k, and with other geometric features, such as volume, shape and orientation, determined by the covariance matrix Σ_k (Banfield and Raftery, 1993; Celeux and Govaert, 1995). To estimate Θ we rely on the maximisation of the log-likelihood given by:

$$L(\mathbf{X}; \Theta) = \sum_{i=1}^{n} \log \left(\sum_{k=1}^{g} \pi_k \varphi_k(\mathbf{x}_i | \mu_k, \Sigma_k) \right).$$

The maximization is commonly performed by Expectation-Maximization (Dempster et al., 1977); an iterative algorithm based on the maximization of the conditional expectation of the complete data log-likelihood given Θ':

$$Q(\Theta|\Theta') = \sum_{i} \sum_{k} s_{ik} \log(\pi_k \varphi_k(\mathbf{x}_i | \mu_k, \Sigma_k))$$

where $s_{ik} \propto \pi_k \varphi_\ell(\mathbf{x}_i | \mu_k, \Sigma_k)$ are the posterior probabilities.

In real terms, the algorithm is broken down into two steps (E-M steps) and the unknown parameters of Θ are updated thanks to the previously computed probabilities. For each component k, we have

$$\pi_k = \frac{\sum_i s_{ik}}{n} \qquad \mu_k = \frac{\sum_i s_{ik} x_{ij}}{\sum_i s_{ik}}$$

$$\text{and } \Sigma_k = \frac{\sum_i s_{ik} (\mathbf{x}_i - \mu_k)^\top (\mathbf{x}_i - \mu_k)}{\sum_i s_{ik}}.$$

The procedure used to identify anomalies is described in Algorithm 1. It takes as input a set of short texts and returns the ones that are the most likely to constitute an anomaly. The maximum density as normality score denotes the confidence

Algorithm 1: AD with GMM

```
Input: $\mathcal{D} = \{d_1, \dots d_n\}$, $g$ the number of
       components, $\mathcal{M}$ an embedding
       module, $\alpha$ the desired number of
       output samples;
$\mathbf{x}_i \leftarrow \mathcal{M}(d_i)$, $i = 1, \dots n$;
$\mathbf{X} \leftarrow (\mathbf{x}_1, \dots, \mathbf{x}_n)$;
Initialize $\Theta'$ from a partition obtained with
$k$-means
repeat
    E-step: Compute $Q(\Theta|\Theta')$;
    M-step: Update $\pi_k$, $\mu_k$ and $\Sigma_k$;
until Convergence;
$s_i \leftarrow -\max_k(s_{ik}), k = 1, \dots, g$;
$\mathbf{s} \leftarrow (s_i, \dots, s_n)$;
$\mathbf{r} \leftarrow$argsort$(\mathbf{s})$;
return $d_j$, $j = \mathbf{r}_1, \dots, \mathbf{r}_\alpha$;
```

of the assignment. Multiplied by -1, it denotes the uncertainty of the assignment and is similar to using the entropy of $\mathbf{s}$ since $\sum_k s_{ik} = 1$. The number of returned text samples depends on the user's needs and is specified by the cutoff parameter α. In the evaluation section, we evaluate the AD performance with every possible value of α using the AUROC score.

3.1 Proposed solution for multi-class inliers

In the standard setting of AD where we consider one large inlier class, we set the number of components to its smallest possible value $g = 2$, which provides satisfactory results. In this study, we also consider the more challenging scenario where several underlying topics are present in the dataset. In this context, we make the distinction between extreme values and outliers (Aggarwal, 2017) as shown in Figure 1. A Gaussian mixture model would not have any difficulty in spotting both types of outliers since it is capable of modeling clusters of different shapes. Furthermore, we expect GMM to show good results in the multi-class context, since one of its fundamental assumptions is the multiplicity of inherent distributions among the data samples. However, this property requires to know the number of components in advance, which is not always possible in real life.

To address this issue, we propose to use GMME, an ensemble of several models, obtained with different values of g. To this end, we use Algorithm 1 with varying $g_k \in \mathcal{G}$ and combine the output scores $\mathbf{s}^{(g_k)}$ as follows:

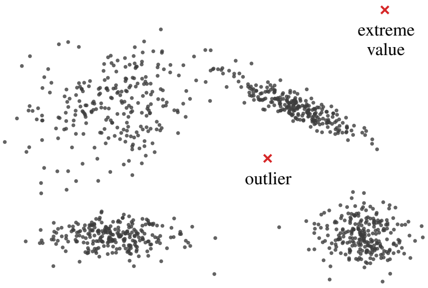

Figure 1: Difference between outlier and extreme value. This example illustrates the benefit of the clustering-based AD approaches in general and Gaussian mixture models in particular.

$$\mathbf{e}_i = -\sum_k \text{rank}(s_i^{(g_k)}).$$

The intuition behind using an ensemble approach is to make each of the models separate the dataset into clusters in a different way and assign an anomaly score according to the formed clusters. Combining those different anomaly scores leads to a more robust and meaningful overall score, even when the optimal number of clusters is not included in $\mathcal{G}$. This is corroborated by the empirical study conducted in Section 4.5.

4 Experimental Study

To assess the effectiveness of our approach and compare it to state-of-the-art, we conduct a set of experiments on real datasets and discuss the results in this section.

4.1 Datasets

We run our AD experiments on three datasets described in Table 2. MLSUM (Scialom et al., 2020) and COVID-news (Cortal, 2022) are both news datasets from which we extract the title to constitute our short-text corpora. RNCP is a dataset we built from an official French repository that lists training certifications (cf. Appendix A).

Dataset	Classes	Smallest	Largest	Medial
RNCP	16	763	9,510	3,101
COVID	9	236	3,235	1,270
MLSUM	10	2,573	26,024	13,054

Table 2: Datasets' description. The sizes correspond to the whole set of samples (training and test set).

Given a classification dataset, we first remove the classes that are too small to constitute an AD dataset, thus obtaining ℓ classes. We then derive ℓ sets of samples in which there is one inlier (majority) class and a certain rate r of outliers picked randomly from the other classes.

4.2 Experimental settings

In order to empirically evaluate our approach and compare it to other AD techniques, we rely on the Area Under the Receiver Operating Curve (AUROC), originally used as a metric in the classification task. In our case, it takes as input the anomaly scores as well as the ground truth labels and determines at what extent it is possible to accurately identify outliers using the anomaly score. It is equivalent to evaluating the performance of AD at every possible value of α in Algorithm 1. For each AD approach, we compute the AUROC on the test set over 5 different initializations, except for OC-SVM that is a deterministic model.

In our study, we discard the case where we train the model on the majority class as a one-class classification task (Ruff et al., 2019; Manolache et al., 2021; Manevitz and Yousef, 2001), for it is not a realistic scenario since one rarely has access to a large enough amount of inlier-only labeled samples in real life. Thus, we consider in this study a fully unsupervised scenario, where no labels are available and both inlier and outlier samples are present in the training set. To this end, we contaminate both sets with up to $r = 10\%$ of outliers as in (Manolache et al., 2021). The set of labels is used only during the evaluation phase.

Text representation. Given a raw corpus $\mathcal{D}$ of short texts, we first perform a minimal preprocessing that consists in removing stop words and lowercasing the input text. Then, we use a pre-trained fastText model (Bojanowski et al., 2017) to represent texts by fixed-size vectors and build the $\mathbf{X}$ matrix. The model is trained on French Wikipedia and represents each word by a vector of size $m = 300$. Using those word vectors, we represent a text sequence by the arithmetic mean of its tokens' representations as in (Ranasinghe et al., 2019; Arora et al., 2017). We show that this way of representing text sequences is well suited to shorts texts and is very beneficial in capturing text semantics for AD. One noticeable advantage of fastText is its ability to represent out-of-vocabulary words thanks to sub-word embeddings. Another advantage of fastText is that pre-trained word representations are provided in a wide range of languages[2]. We do not use contextual word embeddings to represent text sequences since they significantly increase the computational cost and do not seem to bring any performance gain in the AD task (Ruff et al., 2019).

Baselines. We compare our approach to other AD techniques: OC-SVM (Schölkopf et al., 2001), AE, DAGMM (Zong et al., 2018) and DATE (Manolache et al., 2021). For OC-SVM, AE and DAGMM, we use as input the same matrix $\mathbf{X}$ as for GMM. Concerning OC-SVM, we set $\nu = 0.05$, which is the value that presents the best results among $\{0.05, 0.1, 0.2, 0.5\}$ by far. For the autoencoder (AE) we train a model with three encoder layers and three decoder layers of size 256, 128 and 64, a learning rate of 0.001 and a weight decay of 10^{-8}. Concerning DAGMM, the authors choose the parameters relating to the architecture of the neural network according to the dataset and do not provide a method to reproduce this choice. This way of configuring the model is not suitable for the unsupervised case, in which no tuning of the hyperparameters is possible. We therefore opt for a standard architecture in decreasing powers of 2 starting from $m = 300$ (i.e. $256, 128, \ldots$). We choose $m' = 5$ as the encoding dimension because it gives the best overall performance. For DATE, we use the same parameters as used in the original paper for AG-news (Manolache et al., 2021).

Hyperparameter tuning. Our present work falls within the context of unsupervised learning, where we are not supposed to have access to ground truth labels. In this respect, it is not feasible in real life to tune the hyperparameters of a given model to fit unlabeled data, since the performance score is simply impossible to compute. We therefore consider hyperparameter tuning in this context unrealistic and possibly leading to hiding instabilities that can neither be detected nor fixed by practitioners. Hence, robustness and insensitivity to parameters are key in the unsupervised setting. For this reason, regarding the baselines, we use the recommended parameters provided in the original works when available, in order to reproduce real-world conditions. When no recommended parameters are provided, we use the ones that maximize the overall performance even though it does not play in favor of our proposed approach which does not require any parameter tuning. By doing so, we guaran-

Table 3: AUC scores obtained with anomaly $r = 10\%$. The **bold** numbers correspond to the best score in each row and the underlined numbers are for the second best performance score.

tee a fair evaluation of our proposal and show its robustness in an unsupervised context.

4.3 Results with one-class inliers

The obtained performance is given in Table 3 with an anomaly rate $r = 10\%$. We first observe the effectiveness of GMM on the three datasets, in comparison to all of the baselines, offering the best AUROC in most of the cases. Furthermore, the state-of-the-art DATE shows its limits on short texts and presents competitive but poorer results in comparison to GMM. OC-SVM is competitive on short texts in comparison to DATE but presents poorer overall performance. AE is the model that provides the lowest AUROC values, right after DAGMM. This might be due to the fact that the encoding (or embedding) step of the encoder (for both AE and DAGMM) is performed beforehand using pre-trained word embeddings and becomes pointless when applied to this kind of representation.

The results obtained with different values of contamination rate r are summarized by Critical Difference (CD) diagrams in Figure 2. The aim of CD diagrams (Demšar, 2006) is to visualize the performance ranks of each approach over the different datasets. If we take the example of $r = 10\%$, the CD diagram summarizes the scores given in Table 3. It depicts the average rank of each method and the bold line corresponds to the critical difference, based on the post-hoc Nemenyi test (Nemenyi, 1963). Note that the presence of a higher number of outliers increases the difficulty of the AD task and decreases the overall performance scores. We can observe that the more we inject anomalies in the training set, the more GMM gets competitive against the other approaches in terms of AUROC score. This shows GMM's robustness to outliers and its generalization capabilities while other techniques tend to overfit in the presence of noise in the training set.

Also, it is worth noting that GMME yields similar results in comparison to GMM, which makes it a universal solution, well suited to AD even in the one-class scenario.

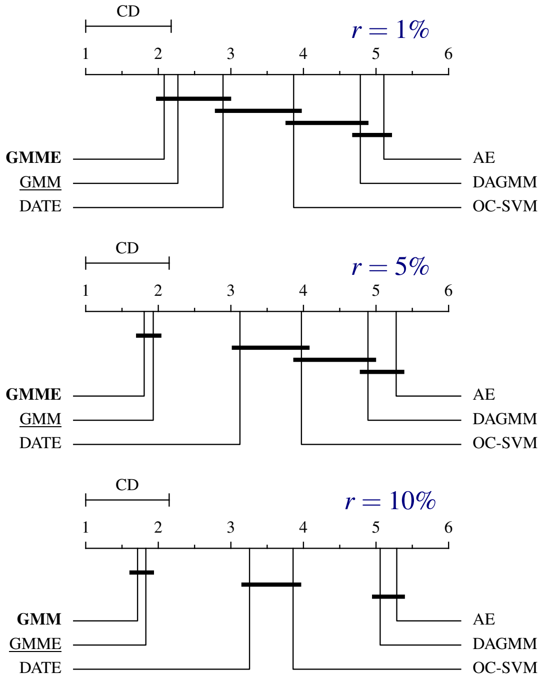

Figure 2: CD plots from the Nemenyi test over different datasets. This graphic summarizes the rank of each approach with different contamination rates r.

Comparison with VMF-Q. To make a fair comparison between GMM and VMF-Q (Zhuang et al., 2017), we reproduce the exact same setting for the two approaches. VMF-Q is based on the von Mises-Fisher distribution that relies on a Bessel function to estimate the parameter κ. The model is originally trained using embeddings of size $m = 200$, but encounters numerical difficulties with higher dimensions, due to the approximations made by the Bessel function that depends, inter alia, on m. We hence use, for both GMM and VMF-Q, another pre-trained model of size $m = 200$, that is provided by Fauconnier (2015). The gain of performance from VMF-Q to GMM is summarized in Figure 3. We can observe a clear advantage of GMM in comparison to VMF-Q on the three datasets, especially on MLSUM, where GMM outperforms VMF-Q on all the subsets. We also report poorer overall results using word2vec with $m = 200$ in comparison to the fastText model we use in the rest of our experiments.

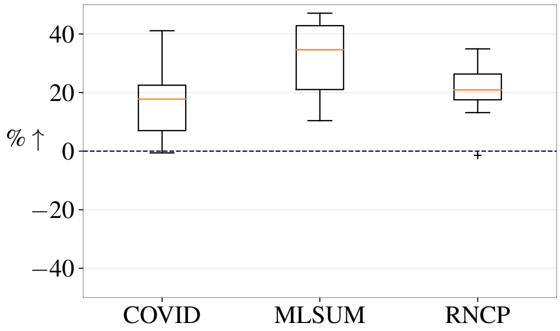

Figure 3: Gain of performance between GMM and VMF-Q using word2vec embeddings of size $m = 200$. Positive values give an advantage to GMM.

4.4 Performance and data size

Figure 4 shows the gain of performance from baselines to GMM according to the size of the datasets. We see that the percentage of improvement is greater on small datasets but remains positive on large datasets. Note that detecting anomalies can be trickier on small datasets, especially when dealing with short texts (cf. Table 1) which makes GMM a good solution to tackle this difficulty.

4.5 Multi-class inliers

We investigated in the previous sections the detection of semantic anomalies in a dataset classically composed of one unique class. In this section, we consider a dataset with several underlying topics and identify the samples that do not belong to any of them. To evaluate our approach in such a context, we create datasets as described in Section 4.1 but this time, by combining $\hat{g}$ random classes to form one inlier class then inject anomalous samples with a rate $r = 10\%$. We then proceed similarly to identify anomalies and validate the obtained results. Note that we make sure in our experiments to put aside enough “anomalous“ classes so that we have a sufficient diversity of anomalies and avoid forming an additional cluster with the anomalous samples. To this end, we limit $\hat{g}$ according to the available classes in the dataset. We use the obtained datasets to assess the performance of GMME (cf. Section 3) and compare it to GMM and two other baselines: DBSCAN and DATE. DBSCAN natively deals with outliers and considers the samples that cannot be assigned to any existing cluster as anomalies (they are assigned the -1 label). We use this information to determine whether a text sample is an anomaly. We set the parameters $\epsilon = 1$ and min_samples $= 3$ which yielded better results than the default values available in the scikit-learn implementation.

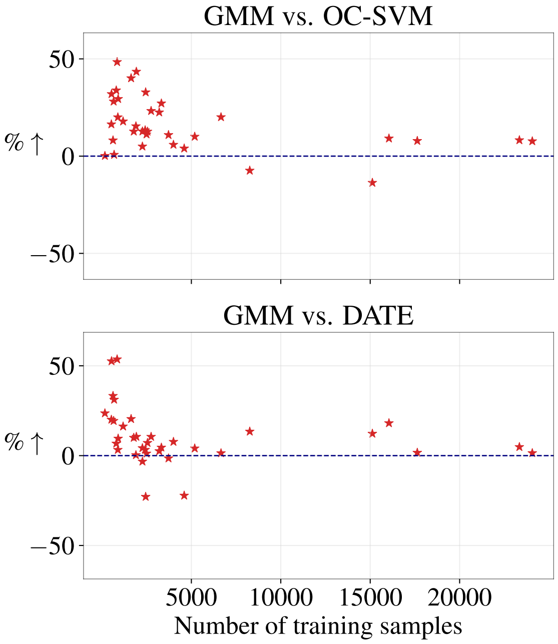

Figure 4: Percentage of improvement of GMM in comparison to baselines w.r.t. to the train set’s size. Positive values give an advantage to GMM.

Table 4 shows the performance obtained by GMME with values of $g_k \in \mathcal{G} = \{2, 3, 4\}$. We first observe that the ensemble approach further improves the performance of the simple GMM, which still performs better in comparison to the other baselines. DBSCAN presents the poorest results after

# inlier classes		DBSCAN	DATE	GMM	GMME

	4	50.6	47.0	55.0	**55.5**
	5	50.7	45.7	53.1	**53.8**

Table 4: Comparison of DBSCAN, DATE, GMM and GMME approaches: AUROC scores obtained with multiple classes as inliers.

DATE, which is less competitive in the multi-class context, especially on the RNCP dataset. Thus, GMME is the most competitive approach in the multi-topic scenario, even when the real number of clusters is not included in $\mathcal{G}$.

4.6 Computation time analysis

Table 5 contains the execution time of both the training and evaluation steps. It is estimated over three different runs, on the three-class datasets used in Section 4.5. The sizes of the training sets are 1034, 6342, 46253 and the test sets are of size 444, 2718, 5837 for RNCP, COVID-news and MLSUM respectively. The experiments on DATE are performed on an NVIDIA RTX2070 GPU.

We first notice that GMM is the fastest approach both during the training and evaluation phase. It is followed by GMME that is relatively quick, especially during evaluation. GMM scales better with an increasing number of samples in comparison to OC-SVM that takes more than four times as much time to train. DATE is the approach that takes the most time to train and evaluate, which is due to its deep architecture. The computational time of DATE can be partially amortized with a more powerful GPU but can still represent an impediment, especially in an industrial context.

We also observe that the computation time of $\mathbf{X}$ does not depend much on the size of the dataset, simply because the task that takes the longest is loading the model from memory. Hence, this way of representing text scales well, especially when used along with GMM or GMME.

		1-SVM	GMM	GMME	DATE
RNCP	$\mathbf{X}$	3.7			-
	train	3e-01	3e-01	1.2	78.49
	eval	1e-01	3e-03	3e-02	2.0
COVID	$\mathbf{X}$	3.7			-
	train	5.7	3.5	16.2	512.97
	eval	1.8	2e-02	8e-02	14.1

	train	450.6	10.0	94.8	3639
	eval	33.0	4e-02	2e-01	30.2

Table 5: Execution time in seconds. The row $\mathbf{X}$ corresponds to the computation time of the embedding matrix $\mathbf{X}$ using fastText. “train“ stands for the training time and “eval“ for the evaluation time.

4.7 Improve the results with Transformers

In the previous experiments, we relied on fastText static embeddings in order to show that is it possible to perform effective and fast anomaly detection without having access to important computational resources. In this section, we show that it is possible to achieve even better results using Transformer representations. For our purpose, we use CamemBERT (Martin et al., 2020) and FlauBERT (Le et al., 2020), both trained on French corpora.

CamemBERT and FlauBERT are both based on the RoBERTa variant of Transformer language models (Liu et al., 2019). While FlauBERT uses the exact same objective and tokenization process as in Liu et al. (2019), plus a French-specific preprocessing, CamemBERT makes use of the SentencePiece tokenizer and the whole-word masking strategy that consists in masking words instead of sub-word tokens. Another major difference between the two models is the training set of data. CamemBERT uses the French part of OSCAR, a large multilingual corpus extracted from Common Crawl, while FlauBERT is trained on a set of 24 corpora.

Table 6 contains the results obtained using several input representations. We recall the results obtained by DATE for comparison purposes since it is also based on a Transformer architecture. We first observe the significant difference in performance between CamemBERT and FlauBERT with a clear advantage for CamemBERT in both its base and large versions. The large variant of Camem-

COVID	2	59.28	63.82	62.34	56.38	56.56	**65.82**	63.32
	3	51.32	54.20	54.10	47.28	54.86	**56.00**	55.48
	4	53.46	56.30	55.40	49.70	51.80	58.00	**58.44**
	5	51.08	52.70	**56.28**	49.02	50.48	52.90	52.12
MLSUM	2	70.00	74.60	68.80	61.00	55.00	79.60	**85.10**
	3	49.60	54.44	59.70	47.80	56.50	66.44	**72.74**
	4	47.02	55.52	58.30	39.00	54.70	65.02	**70.18**
	5	45.70	53.84	58.80	42.30	56.02	65.44	**71.08**

Table 6: Comparison between different embedding representations in terms of AUC score with anomaly rate $r = 10\%$. The **bold** numbers correspond to the best score in each row and the underlined numbers are for the second-best performance score. flauB and camB stand respectively for FlauBERT and CamemBERT and the subscript is for the number of layers, which indicates the model size (6 for small, 12 for base and 24 for large).

BERT achieves the best overall results, especially on MLSUM. CamemBERT-base yields competitive results, achieving good AUROC scores on the COVID dataset. We also notice that, in all cases, the two-phased approach that consists in computing Transformer representations and then use an ensemble of model-based clustering models (GMME) is more efficient than the end-to-end Transformer-based approach (DATE). It is worth noting that fastText embeddings remain competitive and surpass the three FlauBERT models. It is therefore a very good alternative in real-time use cases when computational speed is a critical issue.

5 Conclusion

This paper addresses semantic anomaly detection in short texts with an additional constraint in time efficiency. In addition to the classical framework where one class is used as the inlier class, we also consider the scenario where several underlying subgroups are present in the normal class. We see anomaly detection as a probabilistic clustering problem, in which we learn a Gaussian mixture model and consider the low posterior probability samples as belonging to none of the modeled clusters and more likely to constitute outliers. This uncertainty score proved effective with different numbers of subgroups. In the multi-class setting, we propose GMME, an ensemble approach that improves the performance of GMM when several topics are present in the inlier class. The two approaches outperform state-of-the-art anomaly detection techniques in both scenarios, with an impressively low computation time.

In our proposal, we rely on the Gaussian Mixture model for its flexibility. This choice is motivated by the presence of the proportions π_k of each cluster and the spectral decomposition of the covariance matrix Σ_k taking into account the volume, shape, and orientation of each cluster (as depicted in Figure 1). The characteristics of the clusters should not be overlooked when tackling the problem of anomaly detection through a clustering approach. Furthermore, note that our approach can be extended to latent block models, devoted to co-clustering, which may constitute an interesting and promising future path of research.

6 Limitations

This paper deals exclusively with French text corpora to answer a specific industrial need. However, we are confident about the fact that this work can easily be extended to other languages, especially English, for which more data and pre-trained models are available. This would constitute an interesting trajectory for future work.

A Construction of the RNCP dataset

The RNCP[3] dataset is composed of certification contents that are provided by an organization named « *France-Compétences* ». All the data used here are publicly available in `https://www.data.gouv.fr/fr/datasets/`.

In order to label data we first get the ROME codes of each certification that correspond to the

---

[3] Répertoire National des Certifications Professionnelles

professions related to the certification. Each ROME code is assigned to a topic in the file « Arborescence thématique » of the same repository. We use the ROME code as intermediate to have the topic (*thématique*) of each certification. We hence obtain a multi-label classification dataset.

Given a certification c_i, let $\mathcal{T}_i$ be the set of its corresponding topics. In the one-class setting with inlier class h, the label of c_i is established as follows:

$$y_i = \begin{cases} 0 & \text{if } h \in \mathcal{T}_i \\ 1 & \text{otherwise.} \end{cases}$$

In the multi-class setting with inlier classes symbolized by $\mathcal{H}$, the anomaly labels are defined as:

$$y_i = \begin{cases} 0 & \text{if } \mathcal{H} \subset \mathcal{T}_i \\ 1 & \text{if } \mathcal{H} \cap \mathcal{T}_i = \emptyset \\ \text{N/A} & \text{otherwise} \end{cases}$$

where $y_i = 1$ means c_i is categorized as an anomaly.

B AD examples with RNCP

Table 7 presents some examples of anomalies predicted on two subsets of the RNCP dataset: « *aéronotique* » (meaning aeronautics) and « *nucléaire* » (meaning nuclear). The *aéronautique* test set contains 1585 samples, 154 of which are labeled as anomalies, and the *nucléaire* set contains 1431 samples including 131 anomalies. In both cases we set α to 250 (cf. Algorithm 1). We observe in both cases that DATE has more difficulty in detecting anomalous text sequences when they are very short. For example, in the *nucléaire* set, the certification *Livreur* (meaning delivery person) does not have anything to do with the nuclear field. Yet DATE does not place it among the 250 most deviant samples and makes it the 355th anomalous sample while it is only 3rd according to GMM. This might be explained by the fact that DATE is trained from scratch and does not benefit from the semantic knowledge inherited by transfer learning.

Subset	Certification	GMM	DATE	Real
aéronotique	Sciences, Technologies, Santé - Mention : Automatique et informatique industrielle - Spécialité : Automatismes industriels	Inlier	Inlier	Inlier

Abstract

We propose a novel RoBERTa-based model, RoPPT, which introduces a target-oriented parse tree structure in metaphor detection. Compared to existing models, RoPPT focuses on semantically relevant information and achieves the state-of-the-art on several main metaphor datasets. We also compare our approach against several popular denoising and pruning methods, demonstrating the effectiveness of our approach in context denoising. Our code and dataset can be found at `https://github.com/MajiBear000/RoPPT`.

1 Introduction

Metaphor is a pervasive linguistic device, which attracts attention from both the fields of psycholinguistics and computational linguistics due to the key role it plays in the cognitive and communicative functions of language (Wilks, 1978; Lakoff and Johnson, 1980; Lakoff, 1993). Linguistically, metaphor is defined as a figurative expression that uses one or several words to represent another concept given the context, rather than taking the literal meaning of the expression (Fass, 1991). For instance, in the sentence "*This project is such a <u>headache</u>!*", the contextual meaning of *headache* is "a thing or person that causes worry or trouble", different from its literal meaning, "a continuous pain in the head".[1]

Metaphor detection is challenging, as it requires understanding the nuanced relationships between abstract concepts embodied by the metaphoric expression and its surrounding context. Recent studies on this direction show its potential in benefiting a wide range of NLP applications, including sentiment analysis (Li et al., 2022a), metaphor generation (Li et al., 2022b,c) and mental healthcare (Abd Yusof et al., 2017; Gutiérrez et al., 2017). When modelling relevant context for metaphor detection, various strategies have been proposed. These range from using highly restricted forms of linguistic context such as subject-verb and verb-direct object word pairs (Gutiérrez et al., 2016), to a wider context accounting for a fixed window surrounding the target word (Do Dinh and Gurevych, 2016; Mao et al., 2018), and modelling the full sentential context (Gao et al., 2018; Choi et al., 2021). While it has been argued that modelling a wider context is beneficial (Cheng et al., 2021), it has also been noted that a wider context is likely to introduce noise into the representations, and hence hinder model's performance in metaphor detection (Le et al., 2020).

Some recent efforts (Le et al., 2020; Song et al., 2021a) attempt to improve context modelling by explicitly leveraging the syntactic structure (e.g., dependency parse tree) of a sentence in order to capture important context words, where the parse trees are typically encoded with graph convolutional neural networks. MelBERT (Choi et al., 2021) employs a simple chunking method which separates sub-sentences by commas. The sub-sentence that contains a target word is then marked with a special token type, signalling its contextual importance to the target. However, these strategies are either difficult to apply to batch optimisation due to their tree-dependent encoding process, or have limited effectiveness for context denosing. For instance, the simple chunking mechanism misses the syntactic structure, and thus can neither determine the degree of importance of context words, nor connect information across different subsentences.

In this paper, we propose a novel metaphor detection model RoPPT: RoBERTa with Pruning on target-oriented Parse Tree. RoPPT introduces a *flat*, *target-oriented* tree structure by reshaping and pruning the ordinary parse trees to extract semantically relevant neighbours of a target word. The resulting tree representation allows the model to

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1404–1409

focus on syntactically relevant information of a target word, and ignore irrelevant parts despite their position. It thus retains more relevant context for metaphor detection.

Extensive experiments conducted on three public benchmark datasets (i.e., VUA, MOH-X, TroFi) show that RoPPT can significantly improve metaphor detection on all datasets against several popular denoising and pruning methods. Our model also yields better or comparable performance to the state-of-the-art models (Choi et al., 2021; Song et al., 2021a) in Micro F1 measure. To further validate our approach, we conducted an additional investigation to assess the effect of sentence length on the performance of our model. Experimental results demonstrate a positive correlation between the increase in the performance of RoPPT and the length of the input sentence.

In summary, our paper makes three contributions: (1) we propose a flat, target word-oriented tree structure by reshaping and pruning the ordinary parse trees to retain the most relevant context for a target word; (2) we propose RoPPT, a RoBERTa-based model which can effectively encode the target-oriented parse tree for metaphor detection, achieving state-of-the-art results on three bench mark datasets; (3) we compare and evaluate a range of context denoising methods for metaphor detection, demonstrating the effectiveness of our proposed tree structure in context denoising.

2 Method

The overall architecture of RoPPT is shown in Figure 1, which can be divided into two parts: a target-oriented parse tree pruning module and a RoBERTa (Liu et al., 2019) contextual encoder.

2.1 Target-oriented Dependency Parse Tree

Connecting target words with their most relevant context words is crucial for metaphor detection and comprehension. While there have been attempts to employ dependency parse trees in graph convolutional neural networks to improve context modelling (Wang et al., 2020), it raises challenges of how to effectively encode and leverage such syntactic structure information for transformer-based mask language models for metaphor detection.

We tackle this challenge by introducing a target-oriented parse tree generated by three steps: **1**) reshape the original parse tree from existing parsers such as spaCy (Honnibal and Montani, 2017) and Biaffine (Dozat and Manning, 2016); **2**) root the tree at the target word; **3**) prune the tree according to the distance between leaves and root, coined as *neighbor range*. The rationale behind is that the target word is the focus of the task rather than the original root. So the re-rooting allows us to focus on the connections between target words and their relevant context. The resulting flat, target-oriented tree structure also enables simple encoding process into the model. Figure 1 shows an example of our reshaped tree, which retrains words with neighbor range $con = 1$ to the root 'bogged'.

2.2 RoBERTa-based Context Encoder

We employ two metaphor identification theories in our model, i.e., Metaphor Identification Procedure (Steen, 2010, MIP) and Selectional Preference Violation (Wilks, 1978, SPV). In MIP, a metaphor is detected when there is a contrast between target word's contextual and literal meanings, whereas in SPV a metaphorical word is identified by the semantic difference from its surrounding words. Therefore, we model three types of semantic representations for implementing MIP and SPV, i.e., the literal meaning and the contextual meaning of a target word, and the context meaning.

Formally, given a sentence $S = (w_0, ..., w_n)$, we first employ the RoBERTa network to produce representations for each word.

$$H = \text{RoBERTa\_Enc}(\text{emb}_{\text{cls}}, ..., \text{emb}_n) \quad (1)$$

Here CLS is a special token indicating the start of an input, $H = (h_{\text{cls}}, h_0, ..., h_n)$ the output hidden states, and emb_i the input embedding for word w_i. Specifically, $\text{emb}_i = \text{emb}_w + \text{emb}_{pos}$, where emb_w is the word embedding, and emb_{pos} the position encoding.

Context denoising with the target-oriented parse tree. When modelling sentence representation, existing works directly employed the CLS embedding as a common practice (Choi et al., 2021; Song et al., 2021b). In contrast, RoPPT employs the target-oriented parse tree to retain the most relevant context for a target word when computing the sentence embedding. Specifically, our sentence embedding is computed as follows.

$$v_S = \frac{1}{n} \sum h_i, \ i \in \mathcal{C}_n \quad (2)$$

Here v_S is the sentence representation; $\mathcal{C}_n$ represents the n neighbour words within the neighbour

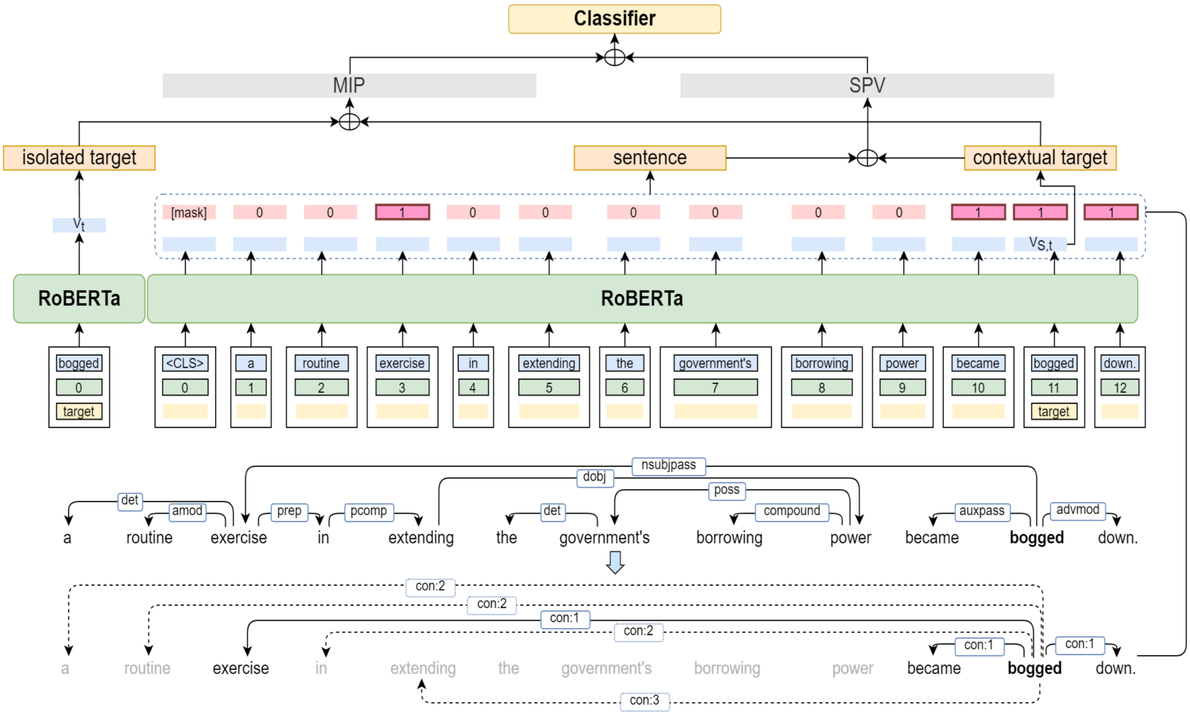

Figure 1: The overall framework of RoPPT. The parse tree of a sentence is reshaped to a target-oriented tree, and the context is pruned with a pre-set threshold. The sentence embedding is the average pooling result of hidden states for pruned context from RoBERTa. ⊕ denotes concatenation.

range of the target-oriented parse tree, and h_i is the hidden state of w_i. In other words, we do average pooling on the most relevant context words as the sentence representation and ignore other words in the sentence. We also design an alternative strategy by directly masking the original input sentence to the encoder according to the pruned parse tree. We denote this intuitive solution as RoPPT with Input Mask (**RoPPT_IM**) and discuss the performance difference between these two variants in §4.

Similar to Choi et al. (2021), we use the hidden state of target word w_t as the contextual target word embedding (i.e. $v_{S,t} = h_t$), and the literal target word embedding v_t is obtained by feeding the single target word w_t to the RoBERTa network.

$$v_t = \text{RoBERTa\_Enc}(\text{emb}_t) \tag{3}$$

We then model SPV (h_{SPV}) by concatenating the sentence embedding v_S and contextual target embedding $v_{S,t}$, and MIP (h_{MIP}) by concatenating the contextual and literal target embeddings v_t, followed by a MLP layer (i.e. $f_1(\cdot)$ and $f_2(\cdot)$).

$$h_{\text{SPV}} = f_1([v_S, v_{S,t}]) \tag{4}$$

$$h_{\text{MIP}} = f_2([v_{S,t}, v_t]) \tag{5}$$

Finally, we combine two hidden vectors h_{MIP} and h_{SPV} to compute a prediction score $\hat{y}$, and use binary cross entropy loss to train the overall framework for metaphor prediction.

$$\hat{y} = \sigma(W^\top[h_{\text{MIP}}; h_{\text{SPV}}] + b) \tag{6}$$

$$\mathcal{L} = -\sum_{i=1}^{N}[y_i \log \hat{y}_i + (1 - y_i)\log(1 - \hat{y}_i)] \tag{7}$$

3 Experimental Setup

Dataset. We conduct experiments on four public benchmark datasets. **VUA-18** (Leong et al., 2018) and **VUA-20** (Leong et al., 2020) are the largest available datasets, released in the metaphor detection shared tasks in 2018 and 2020. VUA-20 extends VUA-18 with about 12K sentences for training set and 3.6K sentences for test and validation sets. The **MOH-X** dataset is constructed by sampling sentences from WordNet (Miller, 1998). Only a single target verb in each sentence is annotated. The average sentence length is 8 tokens, the shortest of our three datasets. **TroFi** (Birke and Sarkar, 2006) consists of sentences from the 1987-89 Wall Street Journal Corpus (Charniak et al., 2000), with an average length of 28.3 tokens per sentence.

Baselines. **RoBERTa_SEQ** (Leong et al., 2020) is a fine-tuned RoBERTa sequence labeling model for metaphor detection. **MelBERT** (Choi et al., 2021)

realises MIP and SPV theories via a RoBERTa based model. **MrBERT** (Song et al., 2021b) is the recent SOTA on verb metaphor detection based on BERT with verb relations encoded.

Hyperparameter. We set the hyperparameter neighbour range $con = 4$ based on the validation set results. All the parser results are based on spaCy as it performs better than Biaffine empirically (see §4 for more discussion).

4 Experimental Results

Overall results. Table 1 shows a comparison of the performance of our models against the baseline models on VUA18 and VUA20, respectively. It is clear that our RoPPT outperforms all baselines on VUA18 and VUA20, including the state-of-the-art model MelBERT. A two-tailed t-test was conducted based on 10 paired results from RoPPT and the strongest baseline MelBERT* on both VUA-18 ($p = 0.014$) and VUA-20 ($p = 0.019$).

We also compared our method against several common denoising strategies. The results show that our tree-based denoising method is more effective than other popular denoising approaches such as RoChunk and RoWindow, which are sequence-based methods. We also apply our target-oriented tree to RoBERTa_SEQ, denoted as the RoBERTa_tree model. The improvement of RoBERTa_tree over RoBERTa_SEQ on two VUA datasets (i.e. 0.3% and 0.7%) further demonstrates the utility of our tree-based denoising method.

Following the setup of Choi et al. (2021), we also conducted a zero-shot transfer learning experiment shown in Table 2. Specifically, our model is trained on the training set of VUA20 and directly tested on the entire Trofi and MOH-X datasets. This is intended to test the generalisation power of trained models. RoPPT shows the best performance on both datasets (significant test on RoPPT against MelBERT*: TroFi $p = 0.0001$; MOH-X $p = 0.021$; we cannot compare with MrBERT as the code is unavailable). It can be observed that our model gives a larger margin of improvement over the baselines on TroFi (i.e., 1.3% gain over MelBERT and 0.6% over MrBERT) than MoH-X (i.e., 0.9% gain over MelBRTT and 0.3% over MrBERT).

Model performance vs. Sentence length. As the averaged sentences length of TroFi (28.3 tokens) is significantly longer than that of MoH-X (8 tokens), it is worth investigating whether our model gives more performance boost on data with longer context as it is likely to be noisier. To verify this hypothesis, we evaluated the performance boost of our RoPPT against the SOTA baseline MelBERT. Table 3 shows the results of VUA18 with the testset splitted into 3 different groups based on sentence length. The results demonstrate a clear positive correlation between performance boost and sentence length.

Impact of Parsers. We also investigated how the choice of parsers impacts the metaphor detection performance of our model. Specifically, we tested two parsers for constructing the target-oriented dependency parse trees, namely, the CNN-based parser Biaffine and the RoBERTa-based parser spaCy. When tested on the validation set, our model achieves 78.0% with spaCy and 77.7% with Biaffine in F1 for metaphor detection, respectively. This shows that the impact of the parse choice is relatively small for our model.

Case Studies. RoPPT shows its strength in the following example with the target word far away from

Sent. len.	RoPPT Prec	RoPPT Rec	RoPPT F1	MelBERT* Prec	MelBERT* Rec	MelBERT* F1	F1 diff.	Pruning comp.	# of Sent.
<20	76.4	74.8	**75.6**	75.0	75.2	75.1	**0.5**	10.7 / 12.3	18,515
20-40	81.8	79.9	**80.8**	79.2	79.1	79.2	**1.6**	16.4 / 29.4	17,729
>40	82.3	80.0	**81.1**	78.5	76.8	77.6	**3.5**	19.5 / 53.6	7,703

Table 3: RoPPT and MelBERT* performance comparison on sentences with different length range from VUA18. 'Pruning comp.' is the comparison of the average length of (pruned) / (original) sentences.

its subject, which is correctly labeled by RoPPT but incorrectly by baseline models. For the instance with metaphorical target word *bogged*, "*a routine exercise in extending the government's borrowing power to $3.1 thousand billion became bogged down.*", the target word *bogged* is separated from its subject by a long phrase, which causes baselines (including MelBERT) to fail to detect the metaphor. Thanks to the parse tree, RoPPT links *exercise* directly to the target and produces the right label.

5 Conclusion

In this paper, we proposed, RoPPT, an effective approach to extract contextual information for target words for metaphor detection based on a target-oriented parse tree structure. Extensive experiments show that our model can yield better performance compared to the state-of-the-art. In addition, our method is particularly effective in denoising long sentences, despite its simplicity.

6 Limitations

Empirical experiments show that our method is more effective in denoising long sentences with the proposed target-oriented parse tree. While this is somewhat expected as shorter sentences tend to have cleaner context, it raises a question or limitation of how can we improve the proposed method to better deal with short sentences and improve its performance in these cases. One possibility is to exploit external knowledge (e.g. ConceptNet) to support the detection of the most important contextual words.

Abstract

Semantic parsing plays a key role in digital voice assistants such as Alexa, Siri, and Google Assistant by mapping natural language to structured meaning representations. To extend the capabilities of a voice assistant for a new domain, the underlying semantic parsing model needs to be retrained using thousands of annotated examples from the new domain, which is time-consuming and expensive. In this work, we present an architecture to perform such *domain adaptation* automatically, with only a small amount of metadata about the new domain and without any new training data (zero-shot) or with very few examples (few-shot). We use a base seq2seq (sequence-to-sequence) architecture and augment it with a *concept* encoder that encodes intent and slot tags from the new domain. We also introduce a novel decoder-focused approach to pretrain seq2seq models to be concept aware using Wikidata. This pretraining helps our model learn important concepts and perform well in low-resource settings. We report few-shot and zero-shot results for compositional semantic parsing on the TOPv2 dataset and show that our model outperforms prior approaches in few-shot settings for the TOPv2 and SNIPS datasets.

1 Introduction

Voice assistants such as Alexa, Siri, and Google Assistant often rely on semantic parsing to understand requests made by their users. The underlying semantic parsing model converts natural language user utterances into logical forms consisting of actions requested by the user (play music, check weather), called *intents*, and relevant entities in the request (which song? which location?), called *slots*. The model is built to process requests in a fixed set of domains, such as music, weather, shopping, and so on. With voice assistants increasingly pervading more aspects of daily life, systems need to be continuously updated to comprehend new intents and slots across an ever-growing number of domains.

Current semantic parsing models are trained on large amounts of annotated data from a predetermined set of domains. Extending these models to learn new intents or slots typically involves collecting and annotating large amounts of new data. This process is expensive and time-consuming. To combat this problem, researchers have proposed semantic parsing models that can be efficiently trained with fewer examples (few-shot) from new domains (Shrivastava et al., 2021; Mansimov and Zhang, 2021; Ghoshal et al., 2020; Shin et al., 2021; Desai et al., 2021; Rongali et al., 2022; Shrivastava et al., 2022). While these methods facilitate few-shot learning, they have limitations. Some of them rely on hand-crafted knowledge such as intermediate grammars or logical form templates (Shrivastava et al., 2022; Shin et al., 2021; Rongali et al., 2022). Others rely on very large pretrained language models, such as GPT-3, to perform in-context learning by appending test examples with instructional prompts (Shin et al., 2021).

In this work, we explore few-shot domain adaptation for semantic parsing without any additional hand-crafted knowledge apart from the intent and slot tag names, and with much smaller architectures that can perform efficient inference in practical production environments. We also explore zero-shot domain adaptation, when we have no annotated training data from a new domain.

To that end, we propose CONCEPT-SEQ2SEQ, a novel architecture based on a state-of-the-art semantic parsing model, SEQ2SEQ-PTR (Rongali et al., 2020), which uses seq2seq models and a pointer generator network to decode the target semantic parse. We augment this model with a *concept* encoder that encodes intents and slots from the schema and uses those encodings to conditionally decode the semantic parse. Figure 1 shows

the architecture of our proposed model. We train this model on annotated data from the given domains. During inference, we simply encode all intents and slots from the schema, including new, unseen ones, into the learned concept space, and decode the target parse. This model has the same time complexity as the original SEQ2SEQ-PTR model but comes with the added benefit of now being able to effectively parse utterances from unseen domains without any additional effort.

There have been a few zero-shot semantic parsing approaches proposed in the past but they either covered only simple slot-filling style utterances (Bapna et al., 2017; Lee and Jha, 2019) or compositional utterances that also came with carefully crafted intermediate representations and context-free grammars (Herzig and Berant, 2018; Wu et al., 2021). Our model is capable of performing zero-shot domain adaptation for compositional semantic parsing, producing meaning representations with nested intents and slots, but also doesn't require any grammars, whose construction effort often exceeds the effort required to annotate a few examples.

In few-shot scenarios, we fine-tune our zero-shot model checkpoints further on the small number of available examples. Due to the presence of the concept encoder in our architecture, we expect to receive better knowledge-transfer advantages by encoding intent and slot tags from new domains as opposed to initializing them as new tags. To further improve performance, we propose a novel decoder-focused pretraining scheme for CONCEPT-SEQ2SEQ using an entity-centric processed version of Wikidata (Vrandečić and Krötzsch, 2014) called WikiWiki (Li et al., 2022), to help it better encode unseen concepts and parse effectively.

We report the first zero-shot performance numbers for semantic parsing on the compositional TOPv2 dataset (Chen et al., 2020) and show that CONCEPT-SEQ2SEQ achieves commendable zero-shot performance on the flat-entity SNIPS dataset (Coucke et al., 2018). We also evaluate in few-shot settings and show that we match or outperform previous state-of-the-art models while still being production-viable.

In summary, our contributions are as follows.

- We propose CONCEPT-SEQ2SEQ, a bi-tower architecture with a seq2seq model and a concept encoder, that can perform few-shot and zero-shot domain adaptation for compositional semantic parsing without additional handcrafted knowledge.
- We propose a novel decoder-focused pretraining scheme for CONCEPT-SEQ2SEQ using Wikidata that helps it better encode unseen concepts and parse effectively.
- We report few-shot and zero-shot semantic parsing results on the TOPv2 and SNIPS datasets and show that our model outperforms or matches previously proposed approaches on a variety of few-shot settings.

2 Methodology

In this section, we describe our proposed model, CONCEPT-SEQ2SEQ, for low resource (few-shot and zero-shot) domain adaptation for semantic parsing. It is based on the Seq2Seq-Ptr model from Rongali et al. (2020), consisting of a sequence-to-sequence encoder-decoder component, augmented with a pointer generator network to constrain the target decoding vocabulary. Since our task at hand is to perform potential zero-shot semantic parsing with just descriptive metadata about the new domain, we modify the architecture of Seq2Seq-Ptr to incorporate information about new intents and slots from new domains by adding a concept encoder. Section 2.2 describes this architecture in detail. To help our model learn to parse utterances from unseen domains better, we also propose a novel pretraining scheme to incorporate general concept parsing knowledge into it. Section 2.3 describes this concept pretraining scheme. Finally, we describe Concept-Seq2Seq model specifics for few-shot and zero-shot settings in Section 2.4. Before we get to these sections, we first describe the source and target sequence formulation for the semantic parsing task below.

2.1 Task Formulation

Our model solves semantic parsing as a sequence-to-sequence task, where the source sequence is the utterance and the target sequence is a linearized representation of the semantic parse. Following Rongali et al. (2020), we modify the target sequence to only contain intent/slot tags or pointers to utterance tokens. An example source and target sequence from the TOPv2 dataset are given below.

`Source: How far is the coffee shop`
`Target: [IN:GET_DISTANCE` $@ptr_0$ $@ptr_1$ $@ptr_2$
`[SL:DESTINATION [IN:GET_RESTAURANT_LOCATION`
$@ptr_3$ `[SL:TYPE_FOOD` $@ptr_4$ `SL:TYPE_FOOD]`
$@ptr_5$ `IN:GET_RESTAURANT_LOCATION]`
`SL:DESTINATION] IN:GET_DISTANCE]`

Each $@ptr_i$ token here points to the i^{th} token in the source sequence. So $@ptr_4$ corresponds to the word *coffee*.

2.2 Model Architecture

Concept-Seq2Seq consists of three main components: an encoder, a decoder, and a concept encoder. Just like in traditional sequence-to-sequence models, the encoder encodes the source sequence, and the decoder autoregressively decodes the target sequence. However, to effectively understand new intent and slot tags in target sequences that the model hasn't seen during training, our model needs to be able to incorporate new intents and slots, or concepts, and decode the target sequence accordingly. The concept encoder helps us do this by encoding descriptive metadata about new concepts and creating vector representations that we can use while decoding the target sequence.

Specifically, for an input sequence $[x_1 \ldots x_n]$, we first encode it using the encoder into a sequence of hidden states $e_1 \ldots e_n$. Then, having generated the first $t-1$ tokens, the decoder generates the token at step t as follows. It first produces the decoder hidden state at time t, d_t by building a multi-layer, multi-head self-attention on the encoder hidden states and the decoder states so far. This step is based on the transformer decoder from Vaswani et al. (2017). In a traditional sequence-to-sequence generation task, d_t is then fed into a dense layer to produce scores over the target vocabulary.

Our target vocabulary consists of pointer tokens and the concept tags. Since we do not have access to all concept tags at the time of training, we train our model to incorporate descriptive information about concepts instead of using a fixed-size dense layer. To do this, we encode intent and slot concepts using a **concept encoder**. The descriptions we use in this work are simply rule-based naturalized versions of the intent and slot names in the dataset. For example, the description for the intent tag token `[IN:GET_DISTANCE` is set as "*begin get distance intent*". Similarly, for `SL:DESTINATION]`, it is set to "*end destination slot*". We purposely use just this information and no additional handcrafted knowledge to remove any additional user input and to compare to previous approaches in the same setting.

Given m concept tokens (both begin and end) and their descriptions, the concept encoder encodes each of them to produce concept vector representations $[c_1 \ldots c_m]$. We then use the computed decoder hidden state at t, d_t, as the query and compute unnormalized attention scores $[s_1 \ldots s_m]$ with $[c_1 \ldots c_m]$, and $[a_1 \ldots a_n]$ with $[e_1 \ldots e_n]$. Concatenating all these scores, we obtain an unnormalized distribution over $m+n$ tokens, the first m of which are the intent and slot tagging tokens from the concepts, and the last n of which are the $@ptr_i (0 < i < n)$ tokens pointing to the source sequence. We feed this through a softmax layer to obtain the final probability distribution. This probability distribution is used in the loss function during training and to choose the next token to generate during inference. For the target token embeddings in the decoder, we use a set of special embeddings to represent the $@ptr_i$ tokens and $[c_1 \ldots c_m]$ to rep-

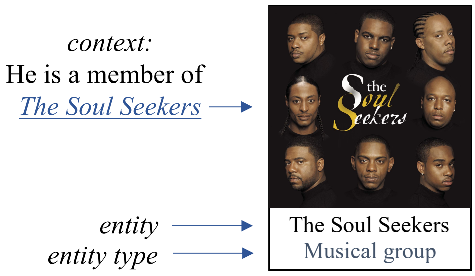

Figure 2: An example sentence from the Wikiwiki dataset with the associated mention, entity, and type fields. The full hyperlinked sub-span is extracted as the mention and the entity and type are extracted from the target page.

resent the concept embeddings.

Figure 1 shows this process in action on a toy example. The model is decoding the next token after `SL:genre` at step 5. To do this, the model computes the pointer attention scores $[a_1 \dots a_n]$ (blue, left) and the concept token attention scores $[s_1 \dots s_n]$ (green, right). The highest overall score is for the token $@ptr_2$, corresponding to the word *country* in the source sequence, so the next predicted token is *country*.

2.3 Concept Pretraining

CONCEPT-SEQ2SEQ has the ability to incorporate new, unseen concepts while parsing using the concept encoder and transfer knowledge on similar concepts. In order to produce these unseen concepts or types, and have our model be robust in low-data settings, it is important for our decoder to be type aware. Conventional seq2seq pretraining schemes such as Lewis et al. (2020); Raffel et al. (2020); Soltan et al. (2022) pretrain the decoder using language modeling criterion. Li et al. (2022) extend the language modeling task to induce entity-type information by treating it as a question answering task. We pretrain the seq2seq model on the semantic parsing task using the WikiWiki (Li et al., 2022) dataset. We explain how to achieve this by keeping an open-domain, extensible output space for the semantic parse.

The Wikiwiki dataset curates mentions, entities, and entity types from 10M Wikipedia documents using hyperlink information linking sub-spans of text in sentences to other Wikipedia pages. The hyperlink is considered as the mention, and the entity and the type information are extracted from the new page. For further details on this processing, please refer to Li et al. (2022). This dataset contains around 2m entities and 40K entity types.

Each example in the Wikiwiki dataset consists of a *context*, which is a paragraph from a wiki page, *mentions*, which are sub-spans of text that link to another page, *entities*, which correspond to each mention, and *entity types*, which describe the type of the entity. We extract individual sentences from this dataset and use them to train CONCEPT-SEQ2SEQ to learn to encode a wide variety of concepts using the entity type fields as descriptions and tag the relevant mentions in the sentence. Figure 2 shows an example sentence from this dataset and the different fields. The source and target sequences for pretraining, and the descriptions of the concept tags for this example are given below.

Source: He is a member of The Soul Seekers
Target: $@ptr_0$ $@ptr_1$ $@ptr_2$ $@ptr_3$ $@ptr_4$
    [Q215380 $@ptr_5$ $@ptr_6$ $@ptr_7$ Q215380]
Concept descriptions:
    [Q215380: begin musical group
    Q215380]: end musical group

During training, we collect all the concept tokens within a training batch and use them to create in-batch negatives (denominator of the softmax calculation) for the decoding task. We do this since it is extremely inefficient to encode all 40K × 2 concept token descriptions (begin and end) from Wikiwiki in every step.

2.4 Few-shot and Zero-shot Specifics

CONCEPT-SEQ2SEQ is primarily designed to perform low resource domain adaptation for semantic parsing by effectively encoding the output space via a concept encoder.

In the zero-shot setting, we deploy the following procedure to build our models. We first perform concept pretraining on CONCEPT-SEQ2SEQ using Wikiwiki example sequences. We take this checkpoint and train on a set of known domains to then obtain the zero-shot model. During inference, we encode all the intent and slot tags from the new unknown domain using the concept encoder of the obtained zero-shot model and set the appropriate decoder parameters to reduce the architecture to a simple encoder-decoder setting.

In few-shot settings, we further fine-tune the zero-shot checkpoint on the available handful of training examples. Since we explore extremely low-resource settings (1, 5, 25 samples per intent/slot), we run the risk of over-fitting and instability during training. To account for these risks and smooth training, we augment the finetuning loss at every step with the loss from a randomly sampled

	Alarm	Event	Timer	Weather	Alarm	Event	Timer	Weather
	F1 score				EM Accuracy			
CONCEPT-SEQ2SEQ w/o pretraining	62.53	30.25	55.68	51.23	45.94	0.00	0.51	8.62
CONCEPT-SEQ2SEQ	71.00	70.47	58.48	66.29	53.64	20.21	3.86	26.63

Table 1: Zero-shot performance of CONCEPT-SEQ2SEQ on domains in TOPv2. We observe notable scores in the alarm and weather domains and improvements across all the domains after the concept pretraining step.

batch of training data from the known domains. We scale the loss from the random known domain batch down using a multiplier before adding to the loss. This scheme is akin to rehearsal (Ratcliff, 1990), a popular technique in domain adaptation.

3 Experimental Setup

We evaluate CONCEPT-SEQ2SEQ on few-shot and zero-shot domain adaptation using two popular English task-oriented semantic parsing datasets - TOPv2 (Chen et al., 2020) and SNIPS (Coucke et al., 2018). Both datasets have utterances grouped into multiple domains; TOPv2 has eight domains and SNIPS has seven intents from seven different areas, which we consider domains. TOPv2 is a large dataset consisting of 10k-20k training and 3k-7k test examples per domain. It is also comprised of compositional examples with nested intents and slots. We exclude the *unsupported* utterances from the training and test sets in TOPv2 for the zero-shot experiments (we use the full sets in few-shot). *Unsupported* utterances consist of utterances that belong to a domain but are not supported, which is impossible to learn in zero-shot. SNIPS is a smaller and simpler dataset with flat, disjoint slots. It has 2k training and 100 test examples per domain.

For zero-shot, we use a leave-one-out approach where given n domains, we train models on annotated data from $n-1$ of them and evaluate on utterances from the left-out domain. For few-shot settings, where the model has access to a few annotated examples from the left-out domain, we further fine-tune using 1, 5, and 25 samples-per-intent/slot (SPIs), which we randomly sample from the training data of the left-out domain. We fine-tune CONCEPT-SEQ2SEQ on three different randomly sampled training sets per domain per SPI setting and report the average performance score of the three runs.

We use a transformer encoder, initialized from a *roberta-base* checkpoint, for CONCEPT-SEQ2SEQ. The decoder is a transformer decoder initialized from scratch and it contains 6 layers, 8 heads, and a hidden state size of 768. The concept encoder is also a transformer encoder and it is initialized from a *bert-base-uncased* checkpoint. We choose a BERT-based model here since it is pretrained to compute a vector for the whole sequence using the CLS token, which is what we need for encoding a concept consisting of a multi-word description. We also choose all *base*-size components to keep the overall model size small and expect the relative improvements shown by our model to generalize.

We train our zero-shot models using sequence cross entropy loss. We use the Adam optimizer with learning rate $2e^{-5}$ and $\epsilon = 1e^{-8}$, warm-up proportion 0.1, weight decay 0.01, and batch-size 128. The number of epochs is set to 100 and we evaluate after every epoch and early stop with a patience of 5. For the Wikiwiki pretraining step, we use the same hyper-parameters but stop the model training after 2 epochs on the entire Wikiwiki dataset. We did not perform explicit hyper-parameter tuning.

For the few-shot experiments, we take the zero-shot model trained by excluding the given few-shot domain and fine-tune it on small set of annotated examples for 1000 epochs, evaluating after every 25 epochs. All other parameters are set to the same values as in the initial zero-shot training. We use a multiplier of 0.1 for the augmented loss from the random known-domain data batch. To speed up evaluation during training, we use teacher-forced sequence accuracy as our validation metric, which doesn't require us to perform any beam search. During inference, we use beam search decoding with a beam size of 4.

We report exact match (EM) accuracy for the few-shot experiments, meaning the entire predicted parse has to match exactly with the gold parse. For zero-shot, we report both EM and F1 score since the task is more difficult and the performance is generally lower. At these lower numbers, F1 score, which awards partial credit to correctly tagged spans provides a better picture for improvements than EM accuracy, which requires the entire pre-

dicted parse to be correct for credit. For comparison wherever applicable, we use prior state-of-the-art models as baselines. In addition, we also report the performance of a vanilla SEQ2SEQ-PTR model without concept pretraining.

4 Results and Discussion

In this section, we report and discuss the performance of CONCEPT-SEQ2SEQ on zero-shot and few-shot domain adaptation for semantic parsing. We first briefly describe our findings in zero-shot setting and then describe findings in a variety of few-shot scenarios.

4.1 Zero-shot Domain Adaptation

We report the first zero-shot performance numbers for domain adaptation on the TOPv2 dataset. Table 1 contains these numbers. We observed that our model produced decent predictions on four of the eight domains in the dataset, which we document in the table. For the other domains, the scores were very low. CONCEPT-SEQ2SEQ achieves good F1 and EM Accuracy scores on the alarm domain (71.00% F1 and 53.64% EM). On the weather and event domains, the concept pretraining step helps it achieve decent EM scores around 20%. On the timer domain, CONCEPT-SEQ2SEQ achieves a fairly high F1 score (58.48%) but a very low EM score (3.86%). Upon manual examination, we found that this was because our model always skipped a certain tag. In the timer domain, there is a slot tag called `SL:METHOD_TIMER` which tags the kind of timer such as *timer* or *stopwatch*. Our model never learns to tag these words with that slot. We believe this is probably due to the description being inadequate for performing the requisite task.

Overall, we believe the task at hand here is difficult due to the combination of the zero-shot setting and the presence of specific nesting/parsing rules in a compositional semantic parsing task. While a good amount of information can be gleaned from the intent and slot names, our model has no access to any new kinds of tagging rules since it has no annotated data or any descriptions of those rules within the concept descriptions. The descriptions themselves are sometimes inadequate as described with the timer domain above. We simply use the descriptions from the dataset and they weren't really designed to be used to describe the entity being tagged. We leave exploration into better descriptions and incorporating parsing rules without explicit annotations for future work.

We also evaluated our model on the SNIPS dataset to compare CONCEPT-SEQ2SEQ to prior zero-shot approaches for flat slot-filling style datasets. We created a strong baseline using recent NLP advancements such as pretrained transformers and attention mechanisms on the slot-filling style zero-shot model proposed by Bapna et al. (2017) and Lee and Jha (2019). Table 2 compares the performance of CONCEPT-SEQ2SEQ to this baseline. We observe that our model matches or outperforms the slot-filling baseline on most domains while also being adaptable to compositional datasets.

4.2 Few-shot Domain Adaptation

We evaluated CONCEPT-SEQ2SEQ in few-shot settings of 1, 5, and 25 samples per intent/slot. Table 3 reports the EM accuracy scores of CONCEPT-SEQ2SEQ and other recent baselines on TOPv2. We also report the performance of a fully trained CONCEPT-SEQ2SEQ model on all the training data for reference and to show that the architecture of CONCEPT-SEQ2SEQ is competitive with other state-of-the-art methods in the full-resource setting.

We evaluated with a range of SPIs to allow for comparison with a wide range of models focused on both extremely low-resource (1, 5 SPIs) and medium low-resource (25 SPIs) settings. We report numbers for the baselines from their original

	Alarm	Event	Messaging	Music	Navigation	Reminder	Timer	Weather

Table 3: EM Accuracy scores of various models in few-shot settings on TOPv2. We see that our model outperforms prior approaches on many domains and settings, most notably in the 1 SPIs setting.

papers, so they are missing for some domains.

As shown in the table, Concept-Seq2Seq outperforms a vanilla Seq2Seq-Ptr, Inventory (Desai et al., 2021), and Retrieve-and-Fill (RAF) (Shrivastava et al., 2022) models on most domains in the 1 SPIs setting. RAF scores are very close and the approach outperforms our model on two domains but it uses additional hand-crafted information such as handmade descriptions and examples for intents and slots, as well as an intermediate scenario-bank to retrieve templates from. Concept-Seq2Seq simply works off of the existing information in the dataset. In the 5 SPIs setting, it again outperforms the vanilla Seq2Seq-Ptr and Inventory models on most domains and on average. Inventory is a similar model to ours where the lexical information from intents and slots is used to help better transfer knowledge in the low-resource setting. However, this information is prepended to the input sequence and this might cause input size issues for large inventories. In the slightly higher resource setting of 25 SPIs, Concept-Seq2Seq beats a vanilla Seq2Seq-Ptr model and matches the performance of RINE (Mansimov and Zhang, 2021), reported on two domains.

Across all the SPIs settings, we see that there is a noticeable drop in performance of Concept-Seq2Seq without the Wikiwiki concept pretraining. This shows the effectiveness of the pretraining step in helping the model generalize to unseen concepts and domains better.

To wrap up our evaluation, we also report the performance of Concept-Seq2Seq on SNIPS in the few-shot settings described above. Table 4 shows these numbers. We can see that we almost catch up to a fully trained model by training with just 25 SPIs in this dataset on most domains except music. We believe the music domain probably requires a lot of samples to effectively identify the diverse set of entities in the domain.

Overall, we find Concept-Seq2Seq to be a very promising approach which achieves high performance scores in low resource domain adaptation. It is capable of doing this in both compositional and flat semantic parsing settings, without any additional hand-crafted information apart from the little documentation in the dataset, and with the memory and inference latency footprint of a vanilla Seq2Seq-Ptr model.

5 Related Work

Zero-shot domain adaptation for task-oriented semantic parsing has been previously explored for simple flat queries with single intents and disjoint, non-overlapping slots. Bapna et al. (2017) and Lee and Jha (2019) encode the lexical tag features and create a token-tagging schema to create the final semantic parses. Yu et al. (2021) solve the task using

	Music		Book		Creative		Weather		Restaurant		Playlist		Screening	
	F1	EM	F1	EM	F1	EM	F1	EM	F1	EM	F1	EM	F1	EM
1 SPIs	67.10	39.00	86.74	61.67	92.39	80.33	88.14	71.00	89.64	72.00	78.31	47.00	79.19	61.00
5 SPIs	84.33	68.00	96.83	89.33	92.58	84.33	94.64	86.33	93.27	81.33	87.74	68.33	94.16	87.67
25 SPIs	85.90	72.67	99.32	97.33	98.10	95.33	98.27	94.67	96.38	89.33	91.73	80.67	95.02	89.33
Fully-trained	90.78	83.00	99.18	97.00	100.00	100.00	98.55	96.00	96.89	90.00	94.53	87.00	98.35	97.00

a retrieve-and-fill mechanism. Our baseline model for simple queries is based on these approaches.

For complex utterances with nested structures, zero-shot semantic parsing has been explored using intermediate, concept-agnostic logical forms (Herzig and Berant, 2018; Dong and Lapata, 2018; Reddy et al., 2017) or natural language canonical forms (Wu et al., 2021). These approaches apply to semantic parsing datasets which have context free grammars and specified rules, such as database or knowledge graph queries. The effort to craft these grammars for task-oriented semantic parsing in a voice assistant setting could quite possibly be greater than annotating utterances.

A more relevant class of approaches for this work are ones that solve task-oriented semantic parsing for complex utterances in a few-shot setting using lexical tag features. Shrivastava et al. (2021) and Mansimov and Zhang (2021) modify the seq2seq architecture from Rongali et al. (2020) to perform non-autoregressive style decoding and show that their models perform better in a few-shot setting. Ghoshal et al. (2020) use adaptive label smoothing, a model-agnostic technique. Shin et al. (2021) proposed a prompting-style approach where custom instructional prompts filled with handful of annotated examples and an unsolved utterance are fed as input to GPT-3 to directly produce a semantic parse. Their approach is extremely slow and cannot be easily adapted into a zero-shot framework. Shrivastava et al. (2022) explore a retrieve-and-fill style approach where they retrieve the best *scenario*, an intermediate logical form consisting of the semantic frame and abstracted out tags, from a scenario bank of all supported semantic parses. Their approach is contingent on the availability of this scenario bank which could possibly entail more effort than annotating utterances. Mueller et al. (2022) and Desai et al. (2021) use lexical features from intent and slot names to create an *inventory* and use it as input to train semantic parsers for new domains. Mueller et al. (2022) also pretrain their model to improve generalizability but only evaluate it on an intent classification task. Desai et al. (2021) evaluate their model for full sequences and our model is similar to theirs. However, we use our inventory to create custom decoder embeddings in a seq2seq model, which removes any input size issues that their model will encounter with large inventories. We also pretrain our model with Wikidata and evaluate it in a completely zero-shot setting, in addition to few-shot. Zhao et al. (2022) is another recent question-answering-based approach that uses lexical features from the intent and slot tags by using them as context and posing questions but it has a similar input size issue with large inventories.

6 Conclusion

We propose a model called CONCEPT-SEQ2SEQ to perform low-resource domain adaptation for compositional semantic parsing. Our model is built on the SEQ2SEQ-PTR framework and is augmented with a concept encoder to transfer knowledge and encode unseen intents and slots from new domains through their text definitions. We also propose a novel concept pretraining scheme to incorporate general concept knowledge into our model using an entity-centric Wikipedia dataset called Wikiwiki.

We evaluate our model in zero-shot and multiple few-shot settings on Facebook TOPv2 and SNIPS datasets. We show that our model is capable of performing zero-shot domain adaptation on some domains of the TOPv2 dataset and beats a strong slot-filling baseline on the SNIPS dataset. In few-shot, over multiple dataset sizes of 1, 5, and 25 SPIs, we show that our model outperforms many strong prior models on TOPv2. Using the SNIPS dataset, we also demonstrate how our model catches up to a fully-trained semantic parsing model using just 25 SPIs on most domains. Our model is capable of low-resource domain adaptation in both compositional and flat parsing settings, without additional hand-crafted information, and with the inference behavior of a vanilla SEQ2SEQ-PTR model.

Limitations

Our models were trained on GPUs that had at least 20GB on-board memory since in addition to the traditional encoder and decoder components in a seq2seq model, we also train a concept encoder, which is around the same size as the encoder. This eliminates the use of popular GPUs such as 1080-ti and 2080-ti, unless parameter freezing or other tricks are employed during training. During inference however, once the concepts are trained, we can simply encode the target tags and this reduces to the size and performance of a traditional SEQ2SEQ-PTR model.

We also report all results on models (ours and baselines) with *base*-size components such as *roberta-base*. We do this since these models are more likely to be used in production than the much bigger *large*-size models. Results and comparison with *large*-sized models is missing from this work (we expect the trends shown to generalize) and we leave this to future work.

Finally, to simulate our low-resource experiments, we randomly sample a few examples from the existing training datasets. While this is useful for experimentation, it doesn't truly mimic a real low-resource workflow where these few examples could be carefully crafted by developers to ensure better semantic coverage in terms of the language of the utterances. This work doesn't include any analysis on the influence of the content of the few selected examples; it just focuses on their number.

Made of Steel?
Learning Plausible Materials for Components in the Vehicle Repair Domain

Annerose Eichel, Helena Schlipf, Sabine Schulte im Walde
Institute for Natural Language Processing, University of Stuttgart
`{annerose.eichel,schulte}@ims.uni-stuttgart.de, helena.schlipf@gmail.com`

Abstract

We propose a novel approach to learn domain-specific plausible materials for components in the vehicle repair domain by probing Pretrained Language Models (PLMs) in a cloze task style setting to overcome the lack of annotated datasets. We devise a new method to aggregate salient predictions from a set of cloze query templates and show that domain-adaptation using either a small, high-quality or a customized Wikipedia corpus boosts performance. When exploring resource-lean alternatives, we find a distilled PLM clearly outperforming a classic pattern-based algorithm. Further, given that 98% of our domain-specific components are multiword expressions, we successfully exploit the compositionality assumption as a way to address data sparsity.

1 Introduction

Connecting a symptom to an underlying cause is a crucial building block for natural language understanding across domains. For example, as illustrated in Fig. 1, a standard approach that human mechanics in vehicle repair shops apply when tracing the cause of a symptom, is to exploit the link between a vehicle *component* and the component's *materials*. This study tackles the task of automatically learning plausible materials for vehicle components. The information is crucial in vehicle repair shops, as mechanics are faced with constantly growing vehicle complexity, making it hard to manually identify the cause of a malfunction. While domain-specific information on vehicle components is often available, plausible domain-specific material information typically needs to be gathered from external data sources. For example, from "*Brake disk are usually manufactured from gray cast iron*", one may retrieve the information that *brake disks* consist of *iron* (and possibly further materials not mentioned here).

We propose a novel approach to leverage state-of-the-art pretrained language models (PLMs) for the task of learning plausible materials in highly domain-specific contexts, such as vehicle components in the vehicle repair domain. Our approach can also be applied to similarly specific domains, e.g., to learn which materials or substances are plausibly used in products in the health domain, textile industry, etc. As we tackle a task from material science, we make a contribution to a field that is not only very challenging, but heavily under-investigated from an NLP perspective. We focus on the PLM RoBERTa (Liu et al., 2019) and develop an approach that successfully learns plausible materials in English for components in the vehicle repair domain. We further exploit domain-adaptation variants and show (i) that harnessing a small high-quality domain-specific corpus boosts the performance over an out-of-the-box vanilla RoBERTa, and (ii) how similar performance can be reached by using a widely accessible data source such as Wikipedia if no domain-specific data is available.

To overcome the typical lack of annotated datasets for training and fine-tuning models in highly domain-specific tasks, we probe RoBERTa in a cloze task setting (Taylor, 1953; Petroni et al., 2019), compare variants for aggregating the results, and analyze the influence of a varied set of query templates on model predictions.

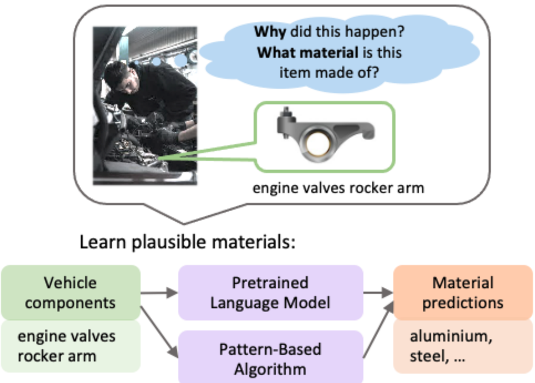

Figure 1: Conceptual overview for learning domain-specific plausible materials (e.g., *aluminium*) for vehicle components (e.g., *engine valves rocker arm*).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1420–1435
May 2-6, 2023

While PLMs come with great advantages, their hunger for storage, data, and computing power is even greater. We thus compare the performance of the vanilla and domain-adapted versions of RoBERTA with (i) a distilled version, i.e., the much smaller DistilRoBERTA (Sanh et al., 2019), and (ii) the seminal pattern-based bootstrapping algorithm Basilisk (Thelen and Riloff, 2002).

Finally, we tackle the challenge of handling a dataset with a vast majority of multiword expressions, i.e., 98% of our targets are noun compounds (such as *seat heating switch led*). We address the corresponding severe data sparsity by assuming that many domain-specific compounds are compositional (Clouet and Daille, 2014; Hätty et al., 2021) such that our domain-specific model may fall back to information regarding the compound's head (in the example above: the right-most simplex noun in the compound *led*), and thus improve on the data sparsity.

2 Related Work

Domain-specific IR In contrast to domains such as biomedicine and chemistry, "[l]everaging NLP tools in materials science remains in its infancy" (Olivetti et al., 2020, p.4), with main challenges including the development of task- and domain-specific tools to structure and harnes knowledge for material synthesis and material discovery. Common approaches to elicit material mentions from text include unsupervised approaches such as topic modeling (Rani and Kumar, 2021) and LDA (Venugopal et al., 2021), as well as supervised methods for domain-specific NER, often focusing on a single material or material group (Mysore et al., 2017, 2019; Friedrich et al., 2020; Gupta et al., 2022; Nayak and Timmapathini, 2021; O'Gorman et al., 2021). Differently to previous work, we probe PLMs in a cloze-task style setting and compare the results to a similarly unsupervised pattern-based bootstrapping algorithm. While most unsupervised methods are not easily interpretable, our query templates, seed words, patterns and predicted materials are directly accessible.

Prompting and Cloze Query Engineering Recent work has leveraged cloze-task style settings to probe the knowledge that PLMs acquire during pretraining, thus targeting linguistic capabilities (Goldberg, 2019; Ettinger, 2020; Apidianaki and Garí Soler, 2021; Rogers et al., 2021), the understanding of rare words (Schick and Schütze, 2020) and conceptual abstractions (Ravichander et al., 2020), as well as factual and commonsense knowledge (Petroni et al., 2019; Jiang et al., 2021). An emerging strand of research highlights PLM sensitivity to the input in a cloze-task style setting. For example, Elazar et al. (2021) demonstrate that PLMs show deficiencies in prediction consistency when presented cloze-style query paraphrases. Others exploit this flaw by explicitly considering paraphrases of a cloze query in addressing a model's sensitivity to a specific input query to elicit a desired output (Davison et al., 2019; Jiang et al., 2021). Pandia and Ettinger (2021) show that models lack robustness in their ability to harness relevant context information in the face of cloze tasks containing distracting contextual cues. In reverse, priming the model using *trigger tokens* (Shin et al., 2020) and *lexical cues* (Misra et al., 2020) might aid in guiding the model to predict the desired output. Specifically, Shin et al. (2020) propose AUTOPROMPT to develop automatically constructed prompts or patterns to elicit knowledge from pretrained PLMs for a variety of tasks. In contrast to previous work, we semi-automatically construct a variety of prompts to cover a salient set of paraphrases for eliciting plausible materials in a PLM; this allows for meaningful comparison and interpretation of the predictions' quality and the influence of the cloze queries.

Semantic Plausibility While classical distributional models tend to model selectional preferences and thematic fit instead of capturing semantic plausibility (Erk et al., 2010), we have recently seen advances to model plausibility across various dimensions, including *physical* and *abstract* semantic plausibility (Wang et al., 2018; Porada et al., 2019). SOTA models for event plausibility however still rely on straightforward conditional probabilities of co-occurrences as estimated by distributional models (Emami et al., 2021; Porada et al., 2021). Considering our task of learning plausible materials for vehicle components, we go beyond selectionally preferred component materials as predicted with high probabilities, aiming also for less frequently observed cases that are nevertheless plausible.

(Domain-specific) MWEs and Compositionality Multiword expressions (MWEs) are challenging for any natural understanding system, given that MWE meanings are idiosyncratic to some degree, i.e., the meaning of an MWE is not entirely (or even not at all) predictable from the meanings of the constituents (Sag et al., 2002; Reddy et al., 2011; Salehi et al., 2014; Schulte im Walde et al., 2016; Cordeiro et al., 2019; Schulte im Walde and Smolka, 2020). Even though MWEs are ubiquitous not only in general- but also in domain-specific language (Clouet and Daille, 2014; Hätty et al., 2021), up to date only few NLP systems have exploited MWE meaning modules, as in machine translation (Cholakov and Kordoni, 2014; Weller et al., 2014). This study is faced with 98% noun compounds among our domain-specific targets, and we test the compound–head compositionality assumption (e.g., a *seat heating switch led* "is a type of" *led* but an *engine valves rocker arm* "is not a type of" *arm*) to fight the severe MWE-triggered data sparsity.

3 Data

Vehicle Component Dataset As targets for our components, we rely on a set of 7,069 unique component names curated by experts from the vehicle repair domain.[1] A component name may denote a tangible physical component such as *cooling blower*, as well as intangible functional and software components such as *ABS warning lamp function* and *road test*. The dataset comprises 155 single-word components and 6,914 multiword components with up to eight constituents (see Fig. 6 in App. A for the distribution). When applying the assumption of MWE compositionality, we fall back to the right-most constituent word as the MWE head (Altakhaineh, 2019), resulting in a total of 725 different heads across the 6,914 multiword components.

Domain-Specific Corpora We utilize two domain-specific English corpora for extracting materials for vehicle components from text: (i) a domain-specific vehicle repair manual written by domain-experts, containing approx. 800K English tokens (henceforth: DOMAIN) and (ii) a portion of the English Wikidata (henceforth: WIKI). For this, we download a Wikidata dump[2], from which we only keep those 118,154 articles which contain one or more of the 6,914 multiword components in the titles or body (Hätty et al., 2020). For domain-adaptation, we delete sentences that do not contain any of the multiword components, resulting in approx. 225K sentences.

4 PLM Experiments

Our PLM experiments investigate to what extent and how PLMs encode domain-specific component materials when prompted with cloze query variants, as illustrated in Fig. 2: We use the vehicle component dataset to construct a set of 504 cloze query templates for each individual component. We first probe a RoBERTa model without any modifications and gather the top-5 predictions for each component, resulting in a total of >2K predictions. To aggregate these predictions, we experiment with three aggregation methods and determine the top-5 most plausible predictions per component and aggregation method for expert evaluation. In a follow-up experiment, we perform domain-adaptation of RoBERTa and DistilRoBERTa for the vehicle repair domain using our two domain-specific corpora, and compare the probing results of the vanilla and the domain-adapted models. The following subsections describe our PLM experiments in detail.

4.1 Cloze Query Prediction and Processing

Our cloze query handling involves three steps (again, cf. Fig. 2): we first construct a set of cloze query templates, then we aggregate model predictions, and finally we analyze the effect of individual cloze queries to select the most meaningful templates for the final top-5 predictions. As Vanilla RoBERTa model (Liu et al., 2019) (henceforth: Vanilla RB), we draw on the `roberta-base` implementation by `huggingface` (Wolf et al., 2020) without any modifications.

Step 1: Cloze Query Template Construction We develop a set of templates and generate cloze statements for each vehicle component to probe our PLM for plausible component materials: First of all, we define a set of 18 paraphrases typically used to express that a component is made from one or more materials (Davison et al., 2019; Jiang et al., 2021). For this, we start with a set of highly frequent verb relations in our corpus (such as *contain*) and use WordNet synsets (Fellbaum, 1998) to determine additional relevant verbs. We then apply both plural and singular forms of the component nouns with corresponding indefinite articles to define queries (see Table 1). To include prompts that refer to prototypical (and thus presumably highly plausible) materials, we follow Apidianaki and Garí Soler (2021) and integrate the quantifiers {MOST} and {ALL}; we also add the quantifier {MANY}. Furthermore, we define a query

---

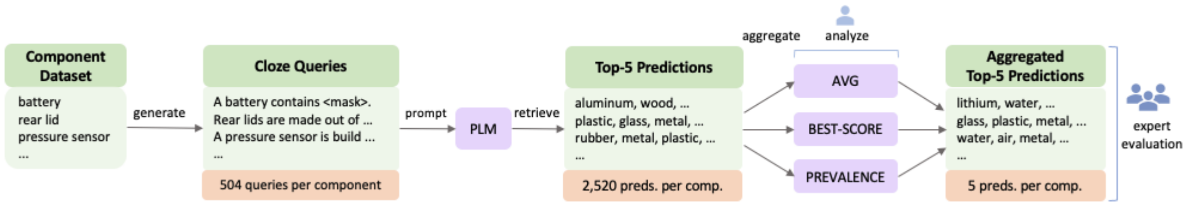

Figure 2: Overview of prediction generation and aggregation, with the numbers in the orange boxes referring to queries/predictions for *one* example component, e.g., *battery*.

Cloze Query Templates [context] + [noun_quant.] + indef. article + component + verb_relation + [adverb] + <mask>.	
SINGULAR	a battery consists of <mask>.
PLURAL	batteries consist of <mask>.
noun_quantifier + PLURAL	most batteries consists of <mask>.
adverb + SINGULAR	a battery usually consists of <mask>.
adverb + PLURAL	batteries usually consists of <mask>.
context + SINGULAR	when used in a vehicle, a battery consists of <mask>.
context + PLURAL	when used in a vehicle, batteries consists of <mask>.

Table 1: Cloze query template and filled-in queries for the vehicle component *battery*. SINGULAR and PLURAL are placeholders that are filled in with vehicle component nouns in singular and plural form, respectively.

template element for adverbs referring to typicality, by including the adverbs {USUALLY, GENERALLY, NORMALLY}. Fostering materials that are not necessarily prototypical but still potentially plausible, we use the noun quantifier {SOME} (Apidianaki and Garí Soler, 2021) and the adverbs {POSSIBLY, PLAUSIBLY}. In our domain-specific scenario, humans tend to intuitively restrict the answer space of plausible materials by providing contexts such as "WHEN USED IN A VEHICLE, ...". Accordingly, we follow recent work investigating the impact of so-called *trigger tokens* (Shin et al., 2020) and *lexical cues* (Misra et al., 2020) to predict a related token, and define six limiting context phrases to leverage intuitive human behaviour.

The above procedure constructs 504 cloze queries for each vehicle component such as the input query "*a battery contains <mask>*.", where the plausible material candidate is masked and to be predicted by a PLM. A full overview of query variants is presented in Table 1.

Step 2: Cloze Query Prediction Aggregation For each component, we prompt our PLM with the corresponding 504 cloze queries and obtain the top-5 predicted tokens ranked by probability for each of the queries, resulting in 2,520 predictions per component, see Fig. 2.[3] Given that we want only a small list of highly plausible materials, we experiment with three approaches to aggregate the 2,520 predictions for each component such that the most plausible material candidates are ranked at the top of a component's material list.

- BEST-SCORE probabilities aggregate the most probable PLM-predicted material types from the 2,520 top-5 predictions across all queries. In this way, predictions that the model considers highly probable in a specific query constellation are considered highly plausible, no matter how often they have been predicted.
- AVG probabilities are obtained by summing up the probabilities for each query variant on the material type level and then averaging by the number of queries that predicted that material. This way, probability mass is taken away from materials that were predicted with high probabilities by only one or few queries. The aggregation is thus directed towards materials that are less prominent for individual queries but more pervasive across query variants.
- PREVALENCE refers to a method where the most salient PLM-predicted materials are obtained by ranking only according to how often the material was predicted across all top-5 suggestions of all query variants. Completely ignoring the probabilities in this step accounts for the amount of used cloze queries and provides insight into whether the model leverages semantic information across specific queries.

---

[3] We apply basic post-processing as described in App. B.2.

	AVG	BEST-SCORE	PREVALENCE
Total@5	0.08	0.18	**0.42**
Acc@5	0.36	0.58	**0.86**

Table 2: Results of aggregation methods on top-5 predicted materials for 100 components each, i.e., a total of 500 predictions per method, reporting total@5 and accuracy in %.

After aggregating the final top-5 predictions by using each of the three presented methods, we analyze[4] for 100 components (see App. C for sampling details) whether the top-5 material predictions are plausible. We follow previous work (Ettinger, 2020; Apidianaki and Garí Soler, 2021) and evaluate by accuracy, i.e. the proportion of vehicle components for which a suggested material is among the model's top-5 predictions.

Results are reported in Table 2. The suggested materials ranked by PREVALENCE with over 40% of correct predictions clearly outperform BEST-SCORE and AVG. Especially AVG is observed to promote rather implausible predictions such as *dna*, *food*, or *death*. Based on this preliminary assessment, we use the PREVALENCE method for aggregating the top-5 predictions in our final experiments.

Step 3: Cloze Query Template Selection Using the top-5 material predictions by PREVALENCE, we now investigate the productiveness of query templates for 100 components (see App. C for sampling details) in order to select the most salient ones for our final experiments. Productiveness investigates which queries are *productive*, i.e., contribute a material to the final top-5 materials.

In our first productiveness analysis, we analyze the 68,651 queries that trigger any of the top-5 predictions across all 100 sampled components and all query template variants. Fig. 3 shows the number of queries actively triggering a top-5 prediction in comparison to the overall number of queries that could have potentially been activated (in absolute numbers). Overall, plural variants exhibit a slightly higher productiveness than singular variants.

In our second productiveness analysis, we examine whether some verb relations "do all the work" in comparison to others that are not activated and should therefore be excluded for the final experiments. Fig. 4 shows the relations triggering a top-5 prediction across all query variants. The most productive relations for singular and plural variants are [*comprise, formed of, build with*] and [*made up of, composed of, consist of*], respectively. For all but two cases, query productiveness of plural variants is higher than for the singular equivalents.

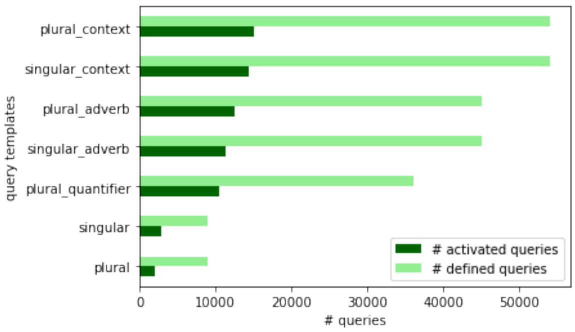

Figure 3: Query template productiveness across the respective defined query template variants.

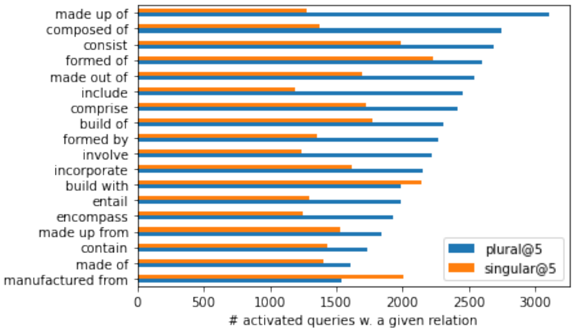

Figure 4: Relation productiveness across singular and plural query template variants.

Our two productiveness analyses suggest that our set of domain-specific query templates represents a well-defined set which is *successful as a whole* in cooperation with a suitable method for aggregating a large number of resulting predictions, and does not include strongly over- or underperforming variants. For our final PLM experiments, we thus leverage the full set of query templates.

4.2 Domain Adaptation of RoBERTa

We experiment with our two domain-specific corpora DOMAIN and WIKI (see §3) to adapt RoBERTa to the vehicle repair domain (henceforth: DOMAIN RB and WIKI RB, respectively). Additionally, we compare RoBERTa to a domain-specific resource-lean model DOMAIN DistilRB, where we adapt DistilRoBERTa (Sanh et al., 2019) to the vehicle repair domain using DOMAIN.

---

[4] The analysis is performed by one of the authors of this paper, who is familiar with the vehicle repair domain. Note that this preliminary assessment is only for comparing aggregation methods, and therefore independent of the final evaluation involving three experts, see Fig. 2.

The domain adaptations draw on the `roberta-base` and `distilroberta-base` implementations from `huggingface` (Wolf et al., 2020); we split our input texts into train (90%) and validation (10%) sets. Following common choices, we set the argument specifying the fraction of tokens to mask to 15%. We train with a learning rate of 2e-5, a weight decay of 0.01, and a batch size of 1,024 (cf. App. B.3 for further details). We train for three epochs and save the best model according to validation set performance. We train one model for each of the aforementioned variants (DOMAIN RB, WIKI RB, and DOMAIN DistilRB). Model results will be presented in §7, in comparison to Basilisk results.

5 Basilisk Experiments: A Classic

In comparison to the PLM experiments, we explore the seminal pattern-based bootstrapped learner Basilisk (Thelen and Riloff, 2002) for learning domain-specific plausible materials for vehicle components. Basilisk is designed to learn high-quality semantic lexicons for one or more categories, provided an unstructured natural language text corpus plus seed words for each semantic category to be learnt. The resource-lean learner leverages extraction patterns representing linguistic contexts, thus exploiting lexico-syntactic structures to capture word meaning.

As the starting step for Basilisk, we select ten seed nouns from the most frequent words in DOMAIN[5] that belong to the semantic class *material*. Since Basilisk depends on extraction patterns to supply contextual support for additional words belonging to the same semantic class, we rely on dependency parsing to create domain-specific syntactic contextual patterns by using the seed words obtained from DOMAIN and only the DOMAIN corpus. We then apply Basilisk as bootstrapping algorithm to select the best-performing patterns for a pattern pool and subsequently fill a candidate word pool with the extractions of the highest-scoring patterns. We retrieve, for example, `SEED*<GDep>:<compound>:<dependent>:alloy` on the basis of which the word `alloy` gets added to the candidate word pool. We stop Basilisk after n bootstrapping rounds and store the retrieved semantic lexicon of n plausible materials for a given vehicle component. To then connect these possible materials with the components, we first process the underlying unstructured data sources and only keep sentences containing at least one component name mention. Second, we filter the obtained sentences with the semantic lexicon and store all component-material candidate matches.

In this way, we generate 396,887 extraction patterns, and use the Basilisk implementation (Thelen and Riloff, 2002) with all corresponding patterns and seed words on the DOMAIN dataset. We limit the candidate word pool size to $n = 200$, and generate possible material candidates for both the DOMAIN and the WIKI datasets.

6 Evaluation

To our knowledge, no gold standard is available for the task of plausible material extraction in the vehicle repair domain. We thus perform an expert evaluation of the quality of predictions for each slot obtained from the vanilla and the domain-adapted RoBERTA models. To compare PLM-based results to resource-leaner methods, we also evaluate results from the pattern-based Basilisk algorithm and DistilRoBERTa.

Evaluation Task For each model, we select and evaluate 100 randomly sampled components,[6] (i) balancing the number of constituents per target component, (ii) providing the full component vs. providing only its head, and (iii) varying the underlying corpus (for Basilisk only). For both 1- and 2-constituent words,[7] we sample 30 components with 20 full/10 head samples with equal amounts from DOMAIN/WIKI. For 3-constituent words, we sample 20 instances with equal amounts of full/head and DOMAIN/WIKI samples. For both 4- and 5-constituent words, we sample 10 head instances with equal amounts of DOMAIN/WIKI samples (cf. App. C for further details).

We obtain the aggregated top-5 predictions for vehicle components from each model. For Basilisk, we sample up to five answer options whenever more than five entries are extracted for a given component. To minimize annotator bias, we compile a set of up to 18 materials for each vehicle component while keeping track of prediction origins. This way, annotators see each evaluated component only once and rate all predictions from all models for

---

[5] Set of seeds: {*water, steel, metal, glass, rubber, plastic, aluminum, copper, polyester, quartz*} In the beginning, we created individual seed word lists for DOMAIN and WIKI, where the latter lacked sufficient quality. Thus, we harness the DOMAIN seed words for both datasets.

[6] We make the list of evaluated components available here.

[7] A 1-constituent word is a simplex word.

Model	IAA	A1::A2	A2::A3	A3::A1
Vanilla RB	0.85	0.89	0.81	0.86
DOM. RB	0.79	0.85	0.74	0.78
WIKI RB	0.81	0.86	0.74	0.83
Basilisk	0.79	0.79	0.74	0.83
DOM. DistilRB	0.82	0.88	0.78	0.81

Table 3: Averaged (left) and pair-wise (right) IAA on material predictions.

each vehicle component without potential unconscious comparison to previously seen predictions from another model. In the majority of cases, the models suggested materials either as a singular or as a plural form (e.g., *metal* and *metals*); for the few cases were we are faced with both versions, we decide to not merge the model predictions and ask the annotators to tick both options if both are considered plausible.

Evaluation Setup We present each component instance with corresponding materials to three experts[8] from the vehicle repair domain. The annotators are asked to rate the plausibility of material predictions for each vehicle component, by ticking the correctly identified materials. They are also provided the options "none of these" if no material is plausible, and "I do not know the answer" if this is the case. Inter-annotator agreement (IAA) is shown in Table 3, with overall average IAA on the left and IAA calculated for each annotator pair on the right. All IAA scores indicate substantial agreement. Further details on the annotation setup and on inter-annotator analyses on both material and component level are provided in App. C.2.

7 Results and Discussion

Table 4 presents results on model performances. On the left, we show accuracy on component level across n annotators. Accuracy is defined as the proportion of components for which at least one of a model's top-5 material predictions is rated plausible by the annotators. On the right, we display accuracy on material level where accuracy is defined as the proportion of plausible material predictions among a model's top-5 predictions, as rated by n expert annotators.[9]

	COMPONENTS		MATERIALS	
Model	$\geqslant$1A	3A	$\geqslant$1A	3A
Vanilla RB	0.87	0.68	0.49	0.24
DOMAIN RB	**0.93**	**0.73**	**0.62**	**0.28**
WIKI RB	0.91	0.66	0.56	0.24
Basilisk	0.73	0.40	0.45	0.14
DOMAIN DistilRB	0.87	0.69	0.53	0.23

Table 4: Model performance. COMPONENT accuracy: proportion of components for which at least one material among a model's top-5 predictions is rated plausible by n expert annotators nA. MATERIAL accuracy: proportion of material predictions among a model's top-5 predictions rated plausible by n expert annotators nA.

Domain-Adaption Approaches: Vanilla, DOMAIN, and WIKI RoBERTa RoBERTa adapted to the domain using a small high-quality corpus (DOMAIN RB) beats all other models with an accuracy of 0.93, and RoBERTa adapted to the domain using a customized portion of the English Wikipedia (WIKI RB) is similarly successful (0.91); in comparison, Vanilla RoBERTa reaches an accuracy of 0.87. With perfect agreement among annotators (i.e., 3A), DOMAIN RB is still able to reach an accuracy of 0.73, in comparison to 0.66 for WIKI RB and 0.68 for Vanilla RB. The top results on material level resemble those for component accuracy: DOMAIN RB (0.62) outperforms all other models, followed by WIKI RB (0.56). In contrast to the component level, Vanilla RB is no longer on par with the smaller but domain-adapted DOMAIN DistilRB, while still outperforming Basilisk. The differences between the three resource-intense approaches (Vanilla RB, DOMAIN RB and WIKI RB) are not significant[10] on component level for nA. On material level, however, differences are significant between PLMs (incl. DOMAIN DistilRB) for $\geqslant$1A, but not for 3A. All approaches significantly outperform the resource-lean Basilisk on both levels for all nA.

As a particular example to illustrate the positive impact of domain adaptation, we inspect results for the vehicle component *engine valves rocker arm* from our introductory example (cf. Fig 1). Vanilla RB results include [*wood, metal, steel, bones, legs*], where the predictions *bones* and *legs* refer to (parts of) an extremity of an animate being instead of a vehicle component. The materials [*wood, metal, steel, joints, aluminium*] as obtained from WIKI RB instead encompass the material *aluminium* as

---

[8] The participating annotators are not affiliated with the company providing the Vehicle Component Dataset.

[9] Material accuracy is naturally lower than component accuracy, as we evaluate five material predictions per component. Hence, achieving perfect agreement for material predictions is more difficult than perfect agreement for components.

[10] Significance tests apply $\chi^2, p < 0.05$.

well as *joints* which refer to connections between body parts as well as vehicle parts. Finally, DOMAIN RB results comprise all plausible materials predicted by the other models, namely [*steel, metal, parts, aluminium, plastic*]. Moreover, the results feature the additional in-domain material *plastic*, while not including out-of-domain predictions such as *wood* anymore. We note that annotators are quite likely to rate one of the top-5 predictions for the same component as plausible, however, material prediction accuracy values indicate that the likeliness to also agree on this specific material drops with an increasing number of annotators.

The findings from these results are twofold. Domain adaptation of a given model results in a clear increase of plausible materials for items within a given domain. Second, if no highly domain-specific and well-curated corpus is available, domain adaptation using WIKI leads to very viable results and therefore represents a strong alternative.

Resource-Lean Approaches Results for the pattern-based algorithm Basilisk significantly underperform all other models for both component (0.73) and material (0.45) accuracy. In contrast, the domain-adapted resource-lean DistilRoBERTa (DOMAIN DistilRB) is on par with Vanilla RB and WIKI RB. Manually analyzing predictions for our example discussed earlier, i.e., the component *engine valves rocker arm*, we find that the Basilisk results [*structures, glass, core, steel, plating*] are potentially within the domain, but often neither a material (*structures, core*) nor rated plausible for the respective target component (*glass, plating*). Results for DOMAIN DistilRB, in contrast, include [*steel, metal, parts, plastic, aluminium*] and basically equal DOMAIN RB predictions.

The comparison of larger vs. leaner and smaller approaches by the examples of the well-established classic Basilisk and the transformer-based DistilRoBERTa model thus clearly demonstrates a preference for the latter.

Compositionality of Domain-specific MWEs Results regarding the assumption of compositionality on domain-specific MWEs are presented in Fig. 5. While accuracy values are lower when using the right-most head instead of the full multiword component (exception: Basilisk), the average difference is only 0.07 and 0.01 for component and material prediction accuracy, respectively. Note, however, that IAA differs especially on material level with an average agreement of 0.44 using full and 0.32 drawing on head components. This indicates that predictions for full component names tend be more clearly connected to this very item than predictions retrieved for a head.

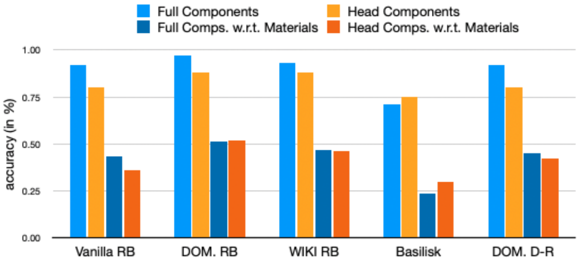

Figure 5: Comparison of full and head component performance on component (full: x/59, head: x/40) and material (full: x/395, head: x/200) accuracy level.

We further analyse model performance regarding the influence of MWE constituent number. The results indicate that specificity beats brevity when learning plausible materials for vehicle components. However, our analysis also point towards a threshold separating a beneficial number of constituents (2) from a number pointing towards a detrimental degree of specificity (3+, cf. App. D.2 for further details).

Our findings suggest that domain-specific multiword components are largely compositional and therefore justify a simplified meaning representation via head constituents.

The Influence of Cloze Queries To shed more light on the impact of using cloze query templates for material prediction, we examine whether the number of queries triggering predictions[11] for a given component correlates with component accuracy. We find moderate-to-strong correlation values for all our PLMs, thus suggesting that a high number of queries yielding the same prediction indicates the prediction's plausibility. We also test whether this correlation is directed and fit a corresponding linear regression model. However, the resulting significant R^2 values, ranging around 0.25, are relatively weak and leave us with a mixed picture regarding a directed relationship between the number of queries and component accuracy (cf. App. D.1 for further details).

When zooming into each template part, we find the adverb GENERALLY outperforming the other ad-

---

[11] An average number of 718 queries is activated for each component across models, with numbers of queries ranging from a minimum of <250 and a maximum of >1.200 queries activated per component.

verbs. Concerning quantifiers, we observe MANY yielding the most activated queries across models, followed by MOST and ALL. Among contexts, we identify WHEN USED IN VEHICLES,... demonstrating best performance. When inspecting the impact of our domain-specific verb relations, we find mostly distinctive groups of verbs accumulating at the extremes of the curve, e.g., *build with, consist of, made up of* and *involve, made of, include* yielding maximum and minimum numbers of plausible predictions across models and singular/plural variants, respectively. While overall observations suggest that templates in the passive voice produce more plausible predictions overall, examples such as *consist of* underline the importance of a well-rounded template set that is *successful as a whole*.

To further explore the impact of designing high-quality query templates for automatic query construction, we perform the following experiment. We take the five most frequent main verbs *make, say, go, use, take* from ENCOW16AX (Schäfer, 2015) that are considered to be *not* directly related to describing what material an item is made of. We construct a set of cloze queries to probe our best-performing domain-adapted PLM DOMAIN RB and aggregate predictions as described in §4.1. We analyze the final top-5 material predictions and find only 9 correct materials. Instead, we observe a small number of types being predicted for many of the sampled components, as well as a small number of component-specific predictions that might be semantically related, but are no material, e.g., top-5 predictions for the component *fuel tank* include [*sense, noise, hydrogen, oil, cold*]. These findings emphasize that using a set that is (i) comprehensive, (ii) domain-specific, and (iii) syntactically diverse is crucial in order to avoid distortion of results.

Exploring Prediction Pool Size Finally, we explore whether aggregating results from a larger pool of predictions obtained from the model benefits our goal of learning all plausible materials for a component. For this, we use our original set of 504 cloze queries per component to obtain the top-10 instead of previously top-5 predicted tokens from the PLM Vanilla RB, resulting in a set of 5040K predictions per component. We aggregate this doubled amount of predictions as explained in §4.1 and analyze the final top-5 predictions as outlined in §4.1. While component accuracy differs by only 1% (in favor of a smaller pool), drawing from a larger pool seems to benefit learning plausible materials with an 5% increase of correct predictions when using top-10 model predictions for aggregation (cf. App. D.3 for details). We attribute these gains to the increase in relevant material predictions that are appropriately aggregated using PREVALENCE, thus displacing, for example, non-relevant material predictions such as *wood* from top-k positions.[12]

8 Conclusion

We tackled the task of learning domain-specific plausible materials for components in the vehicle repair domain from a novel perspective by probing SOTA language models in a cloze task style setting to overcome the lack of annotated datasets. Based on a diverse set of semi-automatically constructed cloze queries combined with a suitable aggregation method, we presented a new method to efficiently extract knowledge regarding vehicle components and their materials as acquired by a PLM. While showing that domain-adaptation using either a small, high-quality or a customized Wikipedia corpus boosts performance, we also demonstrated the power of resource-lean alternatives such as the PLM DistilRoBERTa, and found that the bottleneck for domain-adaptation with respect to our task might not be model size but rather corpus quality and suitability. Finally, we successfully exploited the compositionality assumption for our domain-specific multiword expressions as a way to address data sparsity.

Acknowledgements

The authors would like to thank the Robert Bosch GmbH for providing access to the Vehicle Component Dataset and the DOMAIN corpus. We are grateful to Frank Hartmann, Andreas Körber, Patrick Reiser, and Boris Haselbach for valuable discussions and their support with the Bosch Vehicle Component Dataset.

We also thank Prisca Piccirilli, Neele Falk, and the SemRel group for constructive suggestions and feedback on versions of this work. Helena Schlipf was funded by the Robert Bosch GmbH. Annerose Eichel received funding by the Robert Bosch GmbH and the Hanns Seidel Foundation's Talent Program.

[12] Statistics w.r.t. *wood* as a top-1 material prediction with pool size 5: 0.36% (correct: 0.1%); with pool size 10: 0.23% (correct: 0.1%).

Limitations

When learning plausible materials for components in the vehicle repair domain, we build a varied set of query templates to probe PLMs and seek to aggregate obtained predictions in an optimal way. We are, however, fully aware that a set of queries that is optimal for machines is not necessarily the set that also makes perfect sense to humans.

As far as the transfer of the suggested approach to languages other than English is concerned, we call attention to the potential need to adapt the query templates, e.g., when working with languages that allow for more flexibility in word order such as Polish, Turkish, German, Hindi, or Finnish. Further, while it might be difficult to find well-curated domain-specific corpora in some languages, we show that using a customized version of Wikipedia of moderate size (approx. 225K sentences) in a given language represents a very viable alternative. Additionally, researchers could use a multilingual model or an adapter-based approach to navigate in-/output in other or multiple languages.

Our work focuses on RoBERTa as a backbone model, which has been shown to perform well in cloze task style settings. We also carried out initial experiments with newer models such as ELECTRA, not yielding desired results. We also conducted experiments with generative models such as GPT3. However, the output contained a lot of noise that did not aid our goals. Moreover, the focus in this paper is devoted to the development of a novel contribution regarding the prompting and aggregation techniques as well as analyzing results rather than benchmarking a wide variety of models using an already existing method. While experiments with a wider variety of models represent an interesting future task, high-quality evaluation might be a bottleneck due to the availability and cost factor of domain experts.

Regarding our model predictions, we have not yet attempted to detect and organize potential semantic relations between predictions, such as hypernym/hyponym relations between *metal* and *aluminium*. We leave organizing and utilizing such relations as potentially relevant milestone for connecting and tracing symptoms back to a cause for future work. Furthermore, material predictions are not yet categorized along dimensions such as main and auxiliary materials or surface and inner materials, which might be of interest in the vehicle repair and material science domains.

Finally, we would like to point out that all tested models and algorithms struggle with predicting plausible materials for intangible items which might, however, be more prevalent in other domains. Even if a model is able to predict correct material predictions, rating the plausibility of predictions that are not tangible but rather abstract materials such as *data*, *parameters* and *functions* cannot be considered a trivial task for expert annotators and needs corresponding guidance.

Ethics Statement

Two of the resources used in this work, the Vehicle Component Dataset and one of the two domain-specific corpora (DOMAIN) have been kindly provided to us. To provide insight into the nature of the data and foster reproducibility using comparable data, we make a sample of the Vehicle Component Dataset available (cf. §6). We also investigated comparable publicly available alternatives for DOMAIN and showed that leveraging a portion of the English Wikipedia customized to the domain of interest (WIKI) represents a viable substitute in case no custom corpus is available. Note that Wikipedia text content including Wikipedia dumps is licensed under both the Creative Commons Attribution-ShareAlike 3.0 License and the GNU Free Documentation License.

In the context of our evaluation task, we collected plausibility ratings from human participants. For this, the participants were provided an Informed Consent Letter with the name and the contact of the principal investigators; the title, purpose and procedure of the study; risks, benefits and compensation for participating in the study; confirmation of confidential anonymous data handling; and confirmation that participation in the study is voluntary. The Informed Consent Letter was signed by both the participant and the investigators before the participants took part in the study.

We use and adapt PLMs as provided and licensed under the Apache License 2.0 by `huggingface` (Wolf et al., 2020). We acknowledge that material predictions learnt using the outlined approach are a product of unsupervised learning methods which might be prone to error. We point out that predictions should be approved by an expert or flagged otherwise in case they are used in a downstream application to avoid potential risks including harm of objects or safety risks in case of incorrect repair procedures.

A Data

Dataset Distribution Fig. 6 shows the distribution of multiword component names in the Vehicle Component Dataset with the absolute number of vehicle components per number of constituent, e.g., the dataset comprises 1,563 multiword components with 2 constituents.

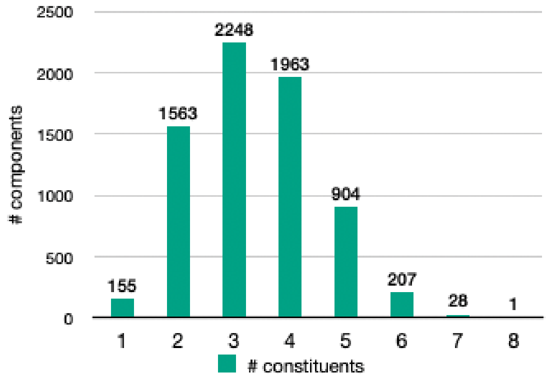

Figure 6: Distribution of multiword components in the Vehicle Component Dataset (in absolute numbers).

B Cloze Query Prediction and Processing

B.1 Cloze Query Templates

Verb Relation Variables consist of, comprise, contain, be formed by, be formed of, be made up of, be made up from, be made of, be made out of, be composed of, be manufactured from, encompass, entail, include, involve, incorporate, be build of, be build with

Cloze Query Statements Table 1 presents an overview of the defined cloze query templates and provides an example of filled-in prompts for the vehicle component *lamp*.

B.2 Post-Processing

PLM-based Predictions Having created a given set of cloze queries, we feed the queries into a PLM and obtain the top-5 predictions. Based on our goals, we apply the following post-processing steps. We lower-case the predictions and filter out numbers, punctuation, 1-character tokens, as well as a list of standard stopwords obtained from `spacy` with nine customized stopwords including non-informative tokens such as *material* and *component*. Additionally, spelling variants such as *aluminum* and *aluminium* are merged. We make sure that a predicted token does not equal the singular or plural form of the full input component.

Basilisk-based Predictions We obtain n predictions for each vehicle component using DOMAIN or WIKI for the Basilisk algorithm, and apply post-processing as described for the PLM predictions.

B.3 PLM and Basilisk Experiments: Computing Infrastructure and Model Information

As Vanilla RoBERTa model, we use the `roberta-base` implementation from `huggingface` (Wolf et al., 2020) that comes with 125M parameters. We adapt this model to the vehicle repair domain. As DistilRoBERTa implementation, we use the `distilroberta-base` implementation from `huggingface` (Wolf et al., 2020) which has 82M parameters. See the official huggingface documentation for further details. For all final experiments, including obtaining predictions from the various models, we use a single NVIDIA RTX A600 GPU. We adapted our models once (DOMAIN RoBERTa, WIKI RoBERTa, and DOMAIN DistilRoBERTa) and used the best model according to validation set performance, i.e. our domain-adapted models are the product of a single fine-tuning run.

As a Basilisk implementation, we use the Java source code as provided by Thelen and Riloff (2002). We use `spaCy` (Honnibal et al., 2020) for text preprocessing and dependency parsing.

C Evaluation

C.1 Sampling Vehicle Components

To test whether the head of a MWE preserves the meaning of the full MWE in our domain-specific data, we compare extracted material predictions using only the head of the MWE vs. all constituents (full). To evaluate results, we apply the following procedure when sampling vehicle components consisting of 2+ words. Full components are sampled as is along with the extracted results. Whenever only the head of a component is used, the results for only the head component are obtained. For the evaluation task, the head component is mapped back to the original full component from the vehicle information dataset. For example, during sampling the head component *sensor* gets mapped to the full 2-constituent component *pressure sensor*. In this way, we can evaluate whether results extracted based on only the head *sensor* are rated as plausible also for the more domain-specific full multiword expression *pressure sensor*.

For the Basilisk-based approach, no results are extracted for one item of the 2-constituent full components and five items of the 3-constituent full components. These results were thus expanded with head component extraction results. In one case, stopword removal leads to an empty prediction list (*alternator start charge current reduction, []*, using DOMAIN). The prediction is back-filled with a randomly sampled token from WIKI-based results for the head component (*reduction*, [*lithium*], using WIKI).

C.2 Expert Evaluation

Evaluation Task Setup The evaluation task was carried out in a remote setting using Google Forms. Annotators were provided detailed written guidelines including example questions and borderline decisions. In case of questions, annotators had the option to contact the authors of the paper. The evaluation could be completed flexibly in the course of a week. Annotators could take as much as time as they needed for completing the evaluation (average time effort: ~1.5 hours). Our three recruited annotators are based in Germany, male, and speak German as their first language. All annotators have 10+ years knowledge and continued education and training in English in general, as well as profound work experience with vehicle repair domain data in German and English. Annotators received a representation allowance for their effort. Each annotator submitted one unique set of answers.

The collected data does not include any information that names or uniquely identifies individual people or offensive content. We check for this by (i) not giving out data to annotators containing such information, and (ii) not asking for any of this information when collecting ratings regarding plausible material candidates for vehicle components, and (iii) manually inspecting collected data to confirm anonymity of annotators and potential other entities. Letters of Consent (cf. §8) are signed before participation and stored separately from the collected ratings.

Evaluation Results Analysis We evaluate a total of 2,342 material predictions from five different models and algorithms on a set of 100 vehicle components from the vehicle repair domain. For 99 components, we collect an average of 5.6 plausible material predictions valid for one or more models. For exactly one component, all annotators agree on *I do not know the answer*.

Pair-wise inter-annotator agreement (IAA) on the level of vehicle components is shown in Table 5. We calculate the percentage of components where two given annotators agree on *at least one* material being plausible (i.e. accuracy on inter-annotator level) or where two given annotators agree that at least one material prediction is **not** plausible. This includes instances where up to four predictions are not plausible as well as instances where all five predicted material options are not rated as plausible (*none of these*). We exclude instances where one or both annotators agree on the answer option *I do not know the answer*.

Model	IAA	A1::A2	A2::A3	A3::A1
Vanilla RB	1.00	1.00	1.00	1.00
DOMAIN RB	1.00	0.99	1.00	1.00
WIKI RB	1.00	1.00	1.00	1.00
Basilisk	0.93	0.97	0.91	0.91
DOM. DistilRB	1.00	1.00	1.00	1.00

Table 5: Proportion of components where two An agree on at least one plausible material or where Ans agree on at least one material prediction being *not* plausible.

D Results and Discussion

D.1 Statistical Analysis: Number of Cloze Queries and Component Accuracy

We statistically analyze the relationship between the number of cloze queries triggering predictions for a given component and the actual accuracy values on component level.[13] For this, we first perform a correlation analysis to see whether the number of activated queries is correlated to component accuracy, i.e., whether 1+ of the predictions for this component is rated plausible by 1+ expert annotator. Results are reported in Table 6 with the investigated models on the left and Pearson's correlation coefficients in the first column. The obtained results indicate that the relationship between the number of activated queries and observed component accuracy is strongly correlated (coefficient >0.5) for the Vanilla and WIKI RB models, and moderately correlated (coefficient >0.3) for DOMAIN RB and DOMAIN DistilRB.

To see whether these correlations are in fact directed, we employ linear regression modeling with the number of queries as predictor and component accuracy as outcome variable. Results are presented in Table 6 with investigated models on

---

[13] As no cloze queries are generated for the Basilisk algorithm, we only investigate PLM results.

Model	Pearson's Coefficients	R^2
Vanilla RB	0.51***	0.26***
DOMAIN RB	0.49***	0.24***
WIKI RB	0.58***	0.34***
DOM. DistilRB	0.40***	0.16***

Table 6: Pearson's correlation coefficients for the number of activated queries and component accuracy. All coefficients are significant with a p-value < 0.01 (***).

the left and R^2 values in the second column. The relatively low R^2 values suggest that the relationship between the number of activated queries and observed *component* ($\neq$*material*) accuracy might more strongly rely on other factors than the number of queries activated for a given component.

D.2 n-Constituent Component Analysis

Results regarding MWEs with n constituents are shown in Fig. 7.

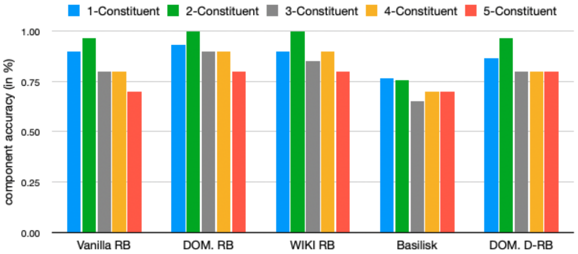

Figure 7: Results regarding n-constituent performance on component accuracy level (in %).

Model performance is presented on component accuracy level. It can be observed that 2-constituent components receive the highest number of plausible material annotations, followed by simplex components, consisting of only one constituent. 4-constituent components outperform the shorter 3-constituent and the longest investigated components, namely 5-constituent components. The results indicate that (domain-)specificity beats brevity when learning plausible materials for vehicle components. However, our findings also suggest that there might be a threshold separating a beneficial number of constituents (2) from a number pointing towards a detrimental degree of specificity (3+).

D.3 Prediction Pool Size Analysis

We present results regarding the size of the pool from which predictions are drawn for aggregation in Table 7. The percentage of correct predictions per top-k predictions are depicted as Hits@1-5. Here, using a larger pool leads to a gain of 18% more plausible materials as the top-1 prediction. While accuracy on component level stays basically the same (top-10 pool: 0.85%, top-5 pool: 0.86%), an increase of 5% can be observed when building the final top-5 predictions from a larger pool of predictions.

	Top-10 Pool	Top-5 Pool
Hits@1	0.54	0.37
Hits@2	0.45	0.56
Hits@3	0.45	0.42
Hits@4	0.50	0.42
Hits@5	0.41	0.31
Comp. Acc@5	0.85	**0.86**
Total Hits@5	**0.47**	0.42

Table 7: Correct predictions (Hits@k) per top-k predictions (x/100), component accuracy (x/100), and total correct predictions per top-5 predictions (Total Hits@5).

Self-Adapted Utterance Selection for Suicidal Ideation Detection in Lifeline Conversations

Abstract

This paper investigates a crucial aspect of mental health by exploring the detection of suicidal ideation in spoken phone conversations between callers and counselors at a suicide prevention hotline. These conversations can be lengthy, noisy, and cover a broad range of topics, making it challenging for NLP models to accurately identify the caller's suicidal ideation. To address these difficulties, we introduce a novel, self-adaptive approach that identifies the most critical utterances that the NLP model can more easily distinguish. The experiments use real-world Lifeline transcriptions, expertly labeled, and show that our approach outperforms the baseline models in overall performance with an F-score of 66.01%. In detecting the most dangerous cases, our approach achieves a significantly higher F-score of 65.94% compared to the baseline models, an improvement of 8.9%. The selected utterances can also provide valuable insights for suicide prevention research. Furthermore, our approach demonstrates its versatility by showing its effectiveness in sentiment analysis, making it a valuable tool for NLP applications beyond the healthcare domain.

1 Introduction

The suicide prevention hotline provides a free service for the people with mental issues to have the support on a 24/7 basis. On the other end of the call, a group of counselors who are trained volunteers are waiting for calls online in shifts. As mental health problems are becoming more and more prevalent in society, the difficulty of finding a sufficient number of counselors forms a common challenge that the suicide prevention hotline of many countries in the world is facing. The overwhelmed counselors and the busy phone line make the individuals in urgent need of help unable to get the opportunity to have the counseling. In order to alleviate of demand of suicide counseling, the intelligent conversation system forms a potential direction to study for aiding the hotline service. Fully automated chatbots as counselors providing counseling services are still impractical because the current natural language processing (NLP) technology has not yet been able to construct a reliable chatbot like a well-trained counselor to talk to these people who are mentally unstable and at high risk of suicide.

In this work, we approach the suicide counseling aiding from a more practical aspect. Instead of creating a chatbot to replace the human counselors, our goal is to propose a model for suicidal ideation detection (Ji et al., 2021). During the counseling, our model can be used for monitoring the conversation and identifying the suicide attempt of the caller. Once it is discovered that the caller is at a high risk of suicide or self-harm, more experienced counselors and other resources can immediately intervene at this time to prevent further harm.

Text-based suicidal ideation detection is a hot topic in the NLP area. In addition to medical records, clinical notes (Ji et al., 2021), and suicide notes (Schoene et al., 2021), previous work on textual suicidal ideation detection mainly focused on the social media data, such as tweets (Mishra et al., 2019; Sawhney et al., 2020; MacAvaney et al., 2021), microblogs (Huang et al., 2015), or online forums (Coppersmith et al., 2018; Sawhney et al., 2021; Yao et al., 2020; Alambo et al., 2019). Broadly monitoring the suicidality of users on the social media is no doubt a new way for public health professionals to prevent suicides. However, social media-based suicidal ideation detection can

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 1436–1446
May 2-6, 2023 ©2023 Association for Computational Linguistics

cover only a part of cases as not everyone uses the social media and the users with suicidal ideation may not share their troubles publicly.

The scope of this work is entirely different from those based on social media data. We focus on the Lifeline conversations between callers in trouble and the well-trained counselors. Unlike the social media data, which are posted by the users unilaterally, the conversational data are made of the interaction between two or even more parties (e.g., the caller's family member). In the case of suicide prevention hotlines, a conversation is typically made by a caller and a counselor. The well-trained counselor will try to guide the caller to express her or his emotions and distress, revealing rich information for suicide risk assessment. The data used in this work were collected from the real world recordings provided by Taiwan Lifeline International.[1] Psychologists were invited for assessing and labeling the suicidal ideation of the caller in each conversation. To the best of our knowledge, this is a pioneering work of conversation-based suicidal ideation detection.

Unlike social media posts, the conversational data is usually longer and noisier. In our real world data, a conversation contains 515 utterances and 7,981 tokens in average, causing a barrier to models analyzing the content. In the long conversation, not all utterances provide the cue for suicide risk assessment. Instead of analyzing the whole conversation, we focus on key interactions between the caller and the counselor. However, extracting the important utterances from the hotline conversation can be still challenging due to the lack of sufficient training data. For this reason, we propose a novel self-adapted approach to utterance selection. Our idea is to focus on a number of discriminative utterances that provide useful information for NLP models to do the classification. To accomplish this goal, a distant-supervised model for suicidal ideation detection at the utterance level is further built for generating the training data for the utterance selection model.

Our approach to detecting suicidal ideation in phone-call conversations is distinct from reinforcement learning methods that are used to select important features or instances for training the main model. Instead, our distant-supervision methodology leverages information from the conversation level to the utterance level based on a key observation that the risk of suicidal ideation can often be determined by only a few utterances. Our approach also differs from previous hierarchical and multi-grained approaches (Kar et al., 2020; Angelidis and Lapata, 2018) that seek to distill fine-grained information from every smaller piece of the entire input.

In this work, we consider the suicidal ideation labels at the conversation level as the distant label and train a model to identify the discriminative utterances that lead to assessing the suicide risk of the caller. Due to the lack of annotation at the utterance level, we introduce a novel relabeling mechanism that is unique to our distant-supervision method. The result is a final model that can efficiently perform suicidal ideation detection on short, condensed inputs.

Our approach is evaluated on the real-world data labeled by psychologists, showing that the self-adapted utterance selection successfully improves the performance in suicidal ideation detection. We also explore our approach in another domain. Experimental results confirm that our approach is also effective in sentiment analysis, a typical NLP task. The contributions of this work are threefold:

1. We investigate the task of suicidal ideation detection in the phone-call conversations, introducing a new way to aid suicide prevention. Our system can assist the counselors in early detection of callers with high suicidal ideation, thus preventing suicides and reducing the work stress of the counselors.

2. We propose a novel self-adapted utterance selection approach that greatly condenses the conversations and successfully improves the model for dialogue understanding and other NLP tasks required to handle long input.

3. The utterances selected by our approach can also be taken as explanatory information that highlights key interactions between the caller and the counselor.

2 Related Work

This section summarizes the related work from three aspects, including the recent applications of NLP in suicide prevention, the conversation-based detection for other mental diseases.

2.1 Suicidal Ideation Detection

The previous works on suicidal ideation detection were mainly built for the social media data due to the ease of data collection.

Gaur et al. (2019) investigated the detection of suicide risk based on a dataset consisting of 500 Reddit users. They based on the suicide risk severity lexicon to annotate the posts, and used Columbia Suicide Severity Rating Scale (C-SSRS) to determine the risk of suicidal ideation of each individual. Moreover, Mishra et al. (2019) extracted several kinds of features, such as Parts of Speech (POS), Latent Dirichlet Allocation (LDA), etc. from the tweets as the input of the trainer. Besides, linguistic Inquiry and word count (LIWC) is also a common method to analyze the utterance structure for individuals with mental problems. For instance, Shah et al. (2020) used LIWC for linguistic analysis on Reddit posts. Also, Schoene et al. (2021) performed LICW and presented the learning model to detect suicide notes on microblog, which figured out the syntax patterns of the individuals with mental problems. Despite these features provide part of the insight of utterances, most researchers combined these approaches to deep learning, which let studies more efficient and comprehensive.

In relation to deep learning for text-based data, bidirectional Long Short-Term Memory (Bi-LSTM) is also a common method for detecting mental health problem. Bi-LSTM is an approach that captures the frontend and backend features at every time step. Therefore, it provides much information from the utterances to make a detection. The study of ordinal suicidal ideation detection (Sawhney et al., 2021) designed an architecture, including Bi-LSTM layers, temporal attention layer, ordinal regression layer, to comprehensively analyze the posts from past. Then, they adapted C-SSRS to make an assessment of suicidality. Coppersmith et al. (2018) extracted contextual information between words via a Bi-LSTM layer, which handled with semantic features in the context.

Overall, broadly monitoring the suicidality of users on the social media is undoubtedly a new way to prevent suicide from public health. However, social media-based suicidal ideation detection can only cover a part of cases since not everyone uses the social media and the users with suicidal ideation may not share their troubles publicly.

2.2 Conversation-based of Mental Disease Detection

Dialogue analysis gains attention in the field of mental health care. Rinaldi et al. (2020) aim to predict depression based on the spoken data from interviews, and the multimodal approach (Zhang et al., 2021) that includes the audio features for depression detection in conversations. Other cognitive health issues can also be modeled in conversations (Farzana et al., 2020).

Clinical interviews are a widely utilized method for addressing mental health issues by professionals. However, the highly sensitive nature of much of this data makes it difficult for machine learning models to analyze. Despite these challenges, mental health-focused datasets are considered more consistent and reliable, leading to increased attention in the field of dialogue analysis for mental health care.

Xu et al. (2021) detects the suicidality from a 24-hour online text-based counseling services, which the form of dataset and the research objectives are similar with us. The researchers created the suicide knowledge graph to encode the utterance features as the input of Bi-LSTM layer, and then made a classification of the risk level with multilayer perceptron(MLP). In similar issue, Rinaldi et al. (2020) aim to predict depression in the interviews. They make an evaluation on the Distress Analysis Interview Corpus (DAIC) (Gratch et al., 2014), which contains text transcripts and audio records of interviews for a clinical assessment for depression. In this study, they adopt the BERT (Devlin et al., 2019) model to classify depression or not on the conversation transcripts as the one of the baseline. However, their method is that each prompt of the interview is grouped by the probability distribution and concatenated with its belonging response, then converted to word embeddings using GloVe to transformed to word embedding as the features, and the result is obtained from the decision layer.

Apart from depression, dementia, such as Alzheimer's disease (AD), is also a hot topic of the dialogue based dataset. Farzana et al. (2020) adopt the Pitt corpus as the source of their dialogue act corpus. In addition to feature extraction, they build the classification models using support vector machine, decision tree, logistic regression, and neural networks. The result shows that the neural network model obtains the best score among those methods. Furthermore, Green et al. (2012) use the

Carolina Conversation Collection (CCC) corpus to facilitate conversation between the individuals with AD and their conversational partner. The CCC corpus includes recorded and transcribed conversations between researchers, students and individuals with AD. They aim to resolve the AD-related disfluencies via natural language understanding.

In these studies, the research focused on utterances from both or single side to figure out the context patterns of the mental health problem. Generally, utterances transformed by GloVe, BERT, etc. to word embeddings and the deep neural networks such as Bi-LSTM contribute to semantic analysis and are commonly used in nowadays. Though the results from the neural network models are difficult to observe the patterns of each mental disorder from the computing, we can combine with various features to make an analysis from both human and computing perspectives.

3 Dataset

We obtained the phone call recordings from Taiwan Lifeline International, and the audio recordings were transcribed by the experts with a psychology background. The transcriptions contain both counselors and callers' utterances, which are conversation-based forms. The transcriptions were further annotated by psychologists for assessing the caller's suicide risk level into five grades, including no suicidal ideation, occasional, frequent, ongoing suicide plan, and ongoing suicide attempt. The outlier conversations, such as not mention to suicide, cannot identify, statement not in person, and other situation will be removed. A high kappa value of 0.89 was measured, confirming a strong inter-rater agreement.

Due to the data sparsity, with experts' approval, we further merge the two weak ideation grades (i.e., no suicidal ideation and occasional) into low risk and the two strong ideation grades (i.e., ongoing suicide plan and ongoing suicide attempt) into high risk, resulting in three suicide risk levels. Table 1 summarizes the distribution of instances across different risk levels and presents the conversation length for each risk level in terms of the average number of utterances and tokens.

Risk Level	Overall	Low	Med.	High
# Instances	656	263	227	166
# Utterances	515	426	546	613
# Tokens	7,981	6,965	8,473	8,919

Table 1: Statistics of our dataset

4 Methodology

Given a conversation $\mathbf{x} = (x_1, x_2, ..., x_n)$, where x_i is either the prompt made by the counselor or the response made by the caller repeatedly, an intuitive way to predict the level of the caller's suicidal ideation can be defined in Equation 1.

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in Y} P(\mathbf{y}|\mathbf{x}) \tag{1}$$

where $Y = \{\text{Low Risk, Medium Risk, High Risk}\}$, and $P(\cdot)$ is a model that is trained to estimate the probability of y given $\mathbf{x}$.

As mentioned in Section 1, $\mathbf{x}$ can be very long and noisy, resulting in a poorer performance. Thus, our idea is to predict $\mathbf{y}$ given a short and condensed version of $\mathbf{x}$. That is, we aim to approximate $P(\mathbf{y}|\mathbf{x})$ by $P_C(\mathbf{y}|\hat{\mathbf{x}})$, where $\hat{\mathbf{x}} \subseteq \mathbf{x}$ and $P_C(\cdot)$ makes the prediction based on the subset of $\mathbf{x}$.

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}\in Y} P(\mathbf{y}|\mathbf{x}) \approx \arg\max_{\mathbf{y}\in Y} P_C(\mathbf{y}|\hat{\mathbf{x}}) \tag{2}$$

In Section 4.1, we present a novel self-adapted utterance selection approach that finds the utterances providing useful information that is easier for the underlying backbone model to capture. Section 4.2 shows the distant-supervised learning employed to train our model for utterance selection. Section 4.3 describes the combination of our framework, and Section 4.4 presents our model in the inference stage. Figure 1(a) and Figure 1(b) illustrate the details of our model in the training and the inference stages, respectively. Figure 1(c) shows the dataflow of our framework in evaluation.

4.1 Self-Adapted Utterance Selection

To extract the sentences that may contain essential suicidal ideation patterns from the conversation, we establish a model $P_S(\cdot)$ for finding $\hat{\mathbf{x}}$. The general form is given in Equation 3.

$$\hat{\mathbf{x}} = \{x_i | x_i \in \mathbf{x} \text{ and } P_S(x_i|\mathbf{x}) > \tau\} \tag{3}$$

where $P_S(\cdot)$ determines the importance of x_i to the whole conversation $\mathbf{x}$. In our case, however, $P_S(\cdot)$ cannot be directly trained in the supervised manner due to the lack of ground-truth. Thus, a novel distant supervised approach is proposed to estimate the importance of each utterance in a conversation.

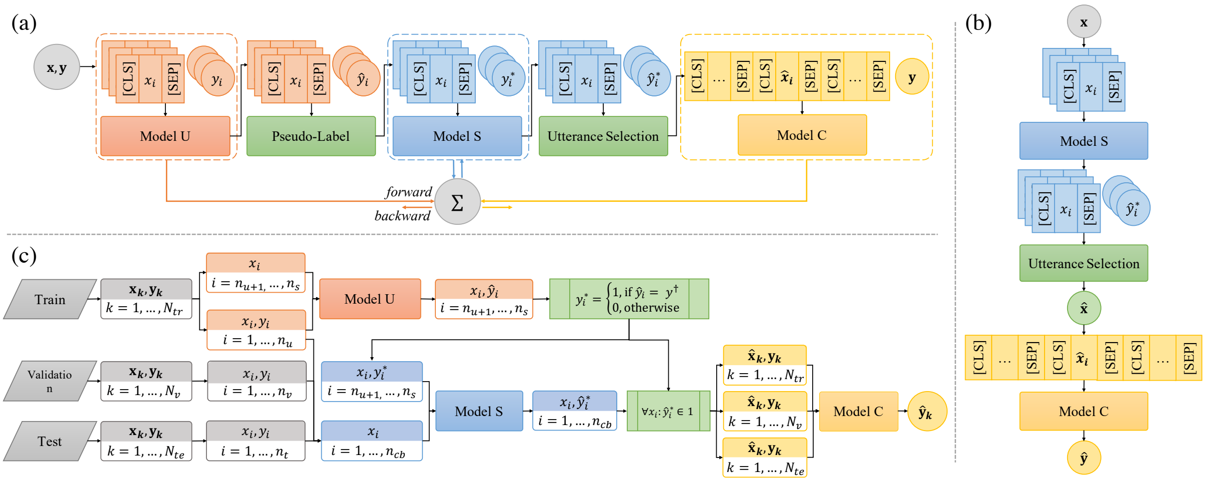

Figure 1: Overview of our approach. The sub-figure (a) shows our model in the training stage, the sub-figure (b) shows our model in the inference stage, and the sub-figure (c) shows the dataflow in evaluation.

Our assumption is that the important utterances are those able to contribute discriminative information for $P_C(\cdot)$ to predict the suicidal ideation. Thus, we aim to extract the utterances indicating suicidal ideation that is easily captured by NLP models. For this reason, we train another model $P_U(\cdot)$ that aims to predict the suicidal ideation at the utterance level.

$$\hat{y}_i = \arg\max_{y_i \in Y} P_U(y_i | x_i, \mathbf{x}) \qquad (4)$$

where $\hat{y}_i$ is the suicidal ideation of the i-th utterance in $\mathbf{x}$. Note that $P_U(\cdot)$ is conditional on not only x_i but also its contextual information from $\mathbf{x}$.

For an utterance x_i from a conversation where the caller with a golden suicide risk level of $\mathbf{y}^\dagger$, we would like to pick up x_i as an important utterance if $\mathbf{y}^\dagger = \hat{y}_i$ because the underlying backbone model can make a consistent prediction based on the information in x_i. In other words, we prepared each training instance (x_i, y_i^*) for $P_S(\cdot)$ by determining the value of y_i^* as Equation 5.

$$y_i^* = \begin{cases} 1, & \text{if } P_U(y_i | x_i, \mathbf{x}) = \mathbf{y}^\dagger \\ 0, & \text{otherwise} \end{cases} \qquad (5)$$

The number of kinds of y_i^* is six for the binary condition at the three risk levels.

4.2 Suicidal Ideation at the Utterance Level

The last problem is how to train the model $P_U(\cdot)$. In our case, $P_U(\cdot)$ cannot be trained in the supervised manner because of the lack of labels at the utterance level. For this reason, we train it using distant supervised learning. For every utterance x_i in a conversation with a golden label of $\mathbf{y}^\dagger$ at the conversation level, we simply assign $y_i^\dagger$, the pseudo label of x_i, with $\mathbf{y}^\dagger$. For example, every utterance from a conversation where the caller was annotated with high suicide risk will be labeled with high suicide risk as well.

4.3 Training of the Whole Framework

The data preprocessing discards utterances that are longer than 29 tokens or shorter than 8 tokens, with an average token count of 15 tokens in reference to a single utterance. Role indicators, such as “A: ” for counselors and “B: ” for callers, are added to the beginning of each utterance. The models $P_S(\cdot)$ and $P_U(\cdot)$ are trained based on the pre-trained BERT model (BERT-BASE-CHINESE) (Devlin et al., 2019). On the other hand, $P_C(\cdot)$ is trained based on the pre-trained Longformer model (LONGFORMER_ZH) (Beltagy et al., 2020) for processing Chinese transcriptions, with an input length of 2,048 tokens. As shown in Figure 1(a) and Figure 1(b), the input of P_C is the concatenation of the selected utterances, while the input of P_S and P_U is a focused utterance and its neighboring utterances separated by `[SEP]`.

As illustrated in Figure 1(a), the three models $P_C(\cdot)$, $P_S(\cdot)$, and $P_U(\cdot)$ are updated in a sequential manner in each epoch. First, $P_U(\cdot)$ is updated to prepare the training data for $P_S(\cdot)$. Then, $P_S(\cdot)$ is updated to select utterances for training $P_C(\cdot)$. The losses of the models $\mathcal{L}_C$, $\mathcal{L}_S$, and $\mathcal{L}_U$ are calculated using cross-entropy, and the total loss $\mathcal{L}$ is their weighted sum which is used for updating the parameters of the three models.

4.4 Inference

Figure 1(b) shows our model in the inference stage. The $P_S(\cdot)$ and $P_C(\cdot)$, which obtain the lowest validation loss value from $P_C(\cdot)$, are saved for the inference stage. The $P_S(\cdot)$ model will shorten the original $\mathbf{x}$ to $\hat{\mathbf{x}}$, and the $P_C(\cdot)$ model predicts the level of the caller's suicidal ideation given $\hat{\mathbf{x}}$. Note that the $P_U(\cdot)$ model, which is built for training $P_S(\cdot)$, is not involved in the inference stage.

5 Experiments

We employ five-fold cross validation, with a development set split 10% from the training set. Significance testing is conducted using McNemar's test. The value of τ is set at 0.5, and the AdamW optimizer is utilized with a total of 40 epochs.

The baseline models include the vanilla BERT/Longformer models in the end-to-end supervised learning, the multi-turn GRU model, the JLPC model proposed by previous work for depression detection in interviews (Rinaldi et al., 2020), the LDA-based utterance selection method, reinforcement learning (RL) model, and the LIWC-based methods applying Gradient Boosting Decision Tree (GBDT) and multilayer perception (MLP) respectively, which are widely-applied in psychological tasks.

In the experiments, the input length with BERT is 512 tokens, and with the Longformer model is 2,048 tokens. The vanilla baseline is fed with the concatenation of all utterances formed as `[CLS]`$x_{counselor}$`[SEP]`x_{caller}`[SEP]`. The GRU model handles each turn in the conversation with the BERT/Longformer encoder separately and combines the information from the tokens with the GRU layer. JLPC model employs the latent prompt categorization on the utterances of counselors and also makes the prediction on first hundred pairs content. The LDA model performs the topic modeling for the conversation and clusters utterances into several groups. In brief, it is equivalent to let LDA model replace $P_U(\cdot)$ and $P_S(\cdot)$ models to do the utterance selection. We select the utterances from each cluster to form the input to the BERT/Longformer model and report the best performance by one of them.

Our novel distant supervised approach is also compared with reinforcement learning (Liu et al., 2019). We simplify our model to $P_S(\cdot)$ and $P_C(\cdot)$ as the framework of reinforcement learning. The $P_S(\cdot)$ as the agent is a binary classification to select the utterances according to the reward. The reward is defined as the difference from the loss of $P_C(\cdot)$ between two continuous epochs.

Different from the models based on Transformer, the LIWC-based model represent the conversation as a 79-dimensional bag-of-word vector, where the value of each dimension indicates the occurrences of the words belonging to the corresponding Chinese version of LIWC (Linguistic Inquiry and Word Count) category.[2] For each conversation, we perform word segmentation and obtain the distribution of LIWC categories. The MLP network is constructed for making the prediction as one of the baselines. GBDT classifiers which combine several weak learners and calculate with the gradient boosting decision tree algorithm are also adopted to accomplish the classification.

6 Results and Discussion

Table 2 shows the overall performances of our approach compared with baselines. The JLPC model making a binary classification for depression in previous work (Rinaldi et al., 2020) does not perform well on the hotline conversations. The GRU model with Longformer encoder produces the worst performance but has the better adaption with BERT encoder. The LIWC-based methods provide the information in different angle from these methods, achieving an F-score of 57.65% with GBDT classifier, higher than most of baselines, but the MLP network dose not perform well on the task. The LDA selection and RL methods figure out some important clues in conversations, which are superior to the vanilla BERT model. By contrast, the Longformer model does not benefit from these selection methods. The vanilla Longformer model can exploit the information from a large portion of the conversation and achieves an F-score of 59.77% in overall. However, our method with either BERT or Longformer significantly outperforms its respective vanilla model in terms of the overall performance at $p = 0.05$. Especially, our method with Longformer achieves the best F-score at overall and every risk levels, superior to all the other models. Particularly, our methodology accomplishes the highest gain on the high suicide risk, which is the most important case to be recognized and intervened. In the rest of this work, we adopt our method with Longformer as the subject for analysis in details.

Table 2: Performances of the three suicide risk levels and their macro-average, reported in Precision (P), Recall (R), and F-score (F) (%).

6.1 Choice of the Context Window

For an utterance $x_i \in \hat{\mathrm{x}}$ predicted as important by $P_S(\cdot)$, we can consider not only x_i itself but also its context, e.g., the previous and/or the next utterance of x_i. We concatenate x_{i-1} and/or x_{i+1} to x_i with the `[SEP]`. Table 3 compares the results of different context settings. The results indicate that incorporating additional context through utterances does not lead to improvement as the most relevant contextual information is already captured by the $P_S(\cdot)$ selection process.

6.2 Number of Selected Utterances

Table 4 shows how many utterances are extracted by our utterance selection approach compared with Longformer-based methods, including LDA, RL and original data. Based on the number of tokens in condensed conversations, the LDA and RL methods reduce the input length more than ours. Our utterance selection model $P_S(\cdot)$ reduces the average input length to 131 utterances and 2,405 tokens. Concerning the performance of vanilla Longformer baseline with data pre-processing, the model possibly lose the information, resulting in the worse result, an F-score of 55.23%. However, our method outperforms these approaches. Compared with other methods, our utterance selection model $P_S(\cdot)$ has more capability of identifying clues of suicidality from conversations.

6.3 Content of the Selected Utterances

Our approach allows us to understand what types of utterances are selected for the main model $P_C(\cdot)$ to predict the suicidal ideation. Through analyzing instances that were mispredicted by the baseline model but correctly predicted by our approach, we discovered that our $P_S(\cdot)$ extracts important patterns. Since Lifeline provides the service for people to confide their suffering, the negative words, such as "Bad mood", "Painful", "Wanna die", are appeared in every risk level. In contrast, diverse daily life topics such as relationship, school, and work are mentioned at the low risk level. We can figure out what the main trouble occurred to the callers leads to the feeling of sadness or fear. Different from the low risk level, the thought of low self-esteem comes up in their words, such as "I am useless." at medium risk level. Moreover, the strong hopeless, helpless and lonely feelings are revealed in the conversations. The word "death" is

Method	Overall			Low Risk			Med. Risk			High Risk		
	P	R	F	P	R	F	P	R	F	P	R	F
x_i	66.58	66.50	66.01	73.01	69.54	70.96	62.74	60.77	61.14	64.00	69.20	65.94
x_i, x_{i+1}	62.93	62.66	61.74	71.56	69.11	69.72	56.09	50.71	52.93	61.14	68.15	62.57
x_{i-1}, x_i	57.37	56.23	56.35	62.58	66.52	64.40	52.45	56.41	54.12	57.08	45.76	50.54
x_{i-1}, x_i, x_{i+1}	58.09	56.90	56.93	64.64	60.78	62.27	50.45	56.86	53.16	59.19	53.05	55.37

Table 3: With different context windows, the performances of our method at the three suicide risk levels and their macro-average, reported in Precision (P), Recall (R), and F-score (F) (%).

Selection Method	F-score	# Utter.	# Tokens
None	59.77	515	7,981
LDA	57.94	150	2,295
RL	56.75	218	3,930
Ours ($P_S(\cdot)$)	66.01	131	2,405

Table 4: Average lengths of the conversations condensed by different approaches. The macro-average F-scores (%) are reported.

usually in the utterances, but the suicidal ideation is only staying the thoughts.

Unlike above statements, physically suicidal means are mentioned at the high risk level. The callers usually talk about their suicide plan evidently, such as "I bought a helium barrel.", "I took medicine and cut the wrist.". The counselors then ask the caller's location, e.g., "Where are you now?", to ensure their safety. Overall, our approach effectively selects the utterances that are key to the interaction between the caller and the counselor, and provides valuable insights into the caller's suicidal ideation.

6.4 Early Detection

Early risk detection plays an important role in mental issues (Wang et al., 2018). To reduce the burden for each counselor, we expect that the model has the ability to detect the risk of suicidal ideation as soon as possible so that the counselor can take a corresponding action to ensure caller's safety. Figure 2 shows the F-scores of our method to do prediction given different numbers of first utterances in each conversation from the testing data. The black, blue, orange, and red dashed lines represent the F-scores of our method given all the utterances available as input in overall and at the low, the medium, and the high levels, respectively.

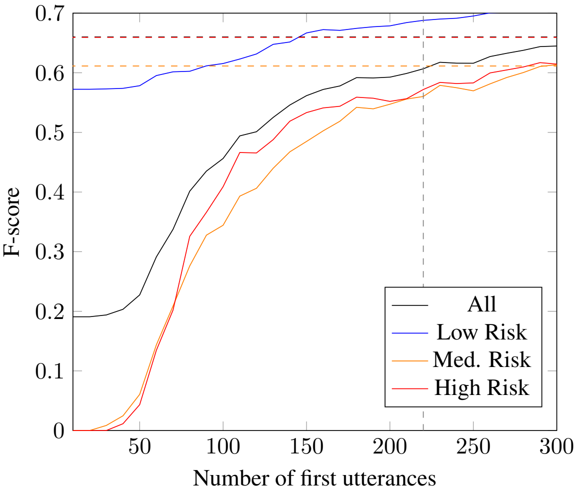

Figure 2: The figure shows the comparison of F-scores for our method in the scenario of early detection. The black, blue, orange, and red dashed lines represent the F-scores of our method with all utterances in overall and at low, medium and high risk levels, respectively.

Generally, the low risk cases are easier to identify. An F-score of 57.24% is achieved with only first 10 utterances being given to our method. The vertically dashed gray line represents the overall F-score achieves 60.67% in the first 220 utterances (i.e., 110 turns), superior to most of baselines. Based on our method framework, $P_S(\cdot)$ can directly detect each utterance whether it should be selected without any other information. The result of the early detection indicates that our method can identify the callers in different needs with a number of turns from the conversation, expected to distributing the suitable resources to assist them. Overall, our method not only contributes to extract the significant utterance patterns but also recognizes the important information during the conversations to accomplish early detection.

7 Applied to Sentiment Analysis

We also explore our approach in sentiment analysis, one of the most-studied application in NLP.

Method	F-score	# Tokens
BERT	86.62	718
Ours w/ BERT	89.63	266
Longformer	95.50	718
Ours w/ Longformer	92.74	371

Table 5: Experimental results of the Polarity dataset. The F-score (%) and the length of input fed into the backbone model are reported.

We evaluate our model for sentiment binary classification on the famous Polarity dataset (Pang and Lee, 2004), which consists of 1,000 positive and 1,000 negative movie reviews. Similar to our experiments, the split of data adopts five-fold cross validation. All methods are trained on the same split for five runs to verify the results.

Table 5 shows the F-scores of the baseline models and our methods. The average tokens fed into the backbone model is also shown. In respect to BERT-based models, our method achieves an F-score of 89.63%, superior to the vanilla BERT model obtaining 86.62%. However, though the performance of our method with Longformer model is improved, it is inferior to the vanilla Longformer model. The average length of the movie reviews in the Polarity dataset is 718 tokens, exceeding the input length of BERT but within the limitation of Longformer. Thus, the vanilla Longformer model is capable to handle full information from the input, while the BERT model can only exploit the information from the first 512 input tokens. Our method with BERT reduces the input length to 266 tokens in average, meeting the limitation of the BERT model and effectively selecting key sentences to enhance the performance.

These results support the key premise of our approach that by dramatically reducing the input length, our method can significantly improve the performance of the underlying model when the input exceeds its capacity. Furthermore, the results highlight the broader potential of our approach for other NLP tasks on lengthy and noisy data.

8 Conclusion

Suicidal ideation detection is one of the core interests in the domain of intelligent healthcare. This work explores the task on a new kind of data, the Lifeline conversations, and presents a novel self-adapted approach that condenses the long and noisy conversation for alleviating the model to identify the suicidal risk level of the caller. Experimental results on real-world data show our approach is not only significantly superior to existing models but also capable of applying to other domains. Our approach is also effective in the scenario of early detection, a practical issue for suicide prevention.

With the advancement of large language models such as ChatGPT, the development of intelligent mental health chatbots is becoming a reality in the near future. Our detection model can be integrated into these chatbots to trigger an emergency response if a high suicide risk level is detected.

Limitations

The Lifeline conversations are highly sensitive. Under the extreme circumstance where the callers suffer from suicidal ideation, it is inappropriate to ask them to consent to share their recordings publicly. For this reason, it is hardly to release a public dataset for the research community, resulting a barrier to reproducibility.

In this work, all the voice data were transcribed into spoken data by human. To launch a fully-automatic system, the transcription should be performed by machine, and more noises will be introduced by the speech recognition model. We will explore the voice-based approach to conversation-based suicidal ideation detection in the future.

Ethical Considerations

The data collected for this study is highly sensitive and contains personal information of the callers. To protect their privacy, all personal identifiable information such as names, ages, addresses, phone numbers, and places of work were removed during the transcription process. The data is securely stored and access to it is restricted to only authorized personnel. This study was reviewed and approved by the Human Research Institutional Review Board (IRB) at National Chengchi University[3] with the case number NCCU-REC-202102-006.

Abstract

Acquiring factual knowledge with Pretrained Language Models (PLMs) has attracted increasing attention, showing promising performance in many knowledge-intensive tasks. Their good performance has led the community to believe that the models do possess a modicum of reasoning competence rather than merely memorising the knowledge. In this paper, we conduct a comprehensive evaluation of the learnable *deductive* (also known as explicit) *reasoning capability* of PLMs. Through a series of controlled experiments, we posit two main findings. (i) PLMs inadequately generalise learned logic rules and perform inconsistently against simple adversarial surface form edits. (ii) While the deductive reasoning fine-tuning of PLMs does improve their performance on reasoning over unseen knowledge facts, it results in catastrophically forgetting the previously learnt knowledge. Our main results suggest that PLMs cannot yet perform reliable deductive reasoning, demonstrating the importance of controlled examinations and probing of PLMs' deductive reasoning abilities; we reach beyond (misleading) task performance, revealing that PLMs are still far from robust reasoning capabilities, even for simple deductive tasks.

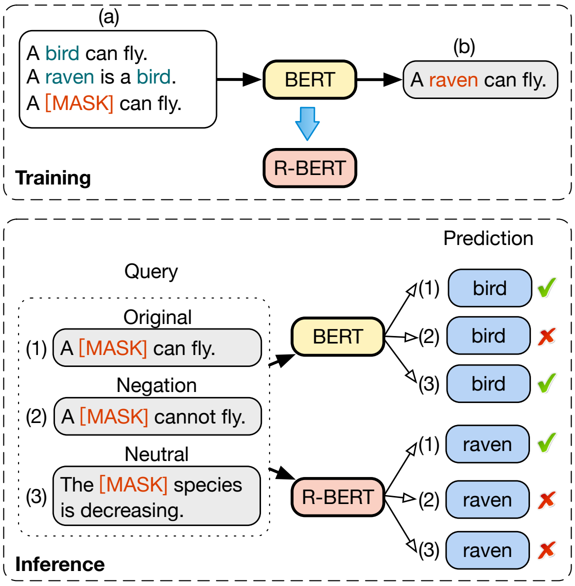

Figure 1: Training and inference for deductive reasoning. Given the explicit premises (a), the input BERT model is trained to get transformed into a reasoner R-BERT model by deductively predicting a previously unseen conclusion (b). This inference process requires R-BERT to understand factual knowledge and interpret rules (e.g. taxonomic relations), intervening directly in the deduction process.

1 Introduction

Pretrained Language Models (PLMs) such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019) have orchestrated tremendous progress in NLP across a large variety of downstream applications. For knowledge-intensive tasks in particular, these large-scale PLMs are surprisingly good at memorising factual knowledge presented in pretraining corpora (Petroni et al., 2019; Jiang et al., 2020b) and infusing knowledge from external sources (Wang et al., 2021a; Zhou et al., 2022, *among others*), demonstrating their effectiveness in learning and capturing knowledge.

Automatic reasoning, a systematic process of deriving previously unknown conclusions from given formal representations of knowledge (Lenat et al., 1990; Newell and Simon, 1956), has been a long-standing goal of AI research. In the NLP community, a modern view of this problem (Clark et al., 2020), where the formal representations of knowledge are substituted by the natural language statements, has recently received increasing attention,[1] yielding multiple exploratory research directions: mathematical reasoning (Rabe et al., 2021), symbolic reasoning (Yang and Deng, 2021), and com-

monsense reasoning (Li et al., 2019). Impressive signs of progress have been reported in teaching PLMs to gain reasoning ability rather than just memorising knowledge facts (Kassner et al., 2020; Talmor et al., 2020), suggesting that PLMs could serve as effective reasoners for identifying analogies and inferring facts not explicitly/directly seen in the data (Kassner et al., 2020; Ushio et al., 2021).

In particular, *deductive reasoning*[2] is one of the most promising directions (Sanyal et al., 2022; Talmor et al., 2020; Li et al., 2019). By definition, deduction yields valid conclusions, which must be true given that their premises are true (Johnson-Laird, 1999). In the NLP community, given all the premises in natural language statements, some large-scale PLMs have shown to be able to deductively draw appropriate conclusions under proper training schemes (Clark et al., 2020; Talmor et al., 2020). Figure 1 shows an example of the training and inference processes of deductive reasoning.

Despite promising applications of PLMs, some recent studies have pointed out that they could only perform a shallow level of reasoning on textual data (Helwe et al., 2021). Indeed, PLMs can be easily affected by mispriming (Misra et al., 2020) and still hardly differentiate between positive and negative statements (i.e., the so-called *negation issue*) (Ettinger, 2020). However, given that some evidence suggests that PLMs can learn factual knowledge beyond mere rote memorisation (Heinzerling and Inui, 2021) and their limitations (Helwe et al., 2021), it is natural to ask, "*Can the current PLMs potentially serve as reliable deductive reasoners over factual knowledge?*" To answer it, as the main contribution of this work, we conduct a comprehensive experimental study on testing the learnable deductive reasoning capability of the PLMs.

In particular, we test various reasoning training approaches on two knowledge reasoning datasets. Our experimental results indicate that such deductive reasoning training of the PLMs (e.g., BERT and RoBERTa) yields strong results on the standard benchmarks, but it inadequately generalises learned logic rules to unseen cases. That is, they perform inconsistently against simple surface form perturbations (e.g., simple synonym substitution, paraphrasing or negation insertion), advocating a careful rethinking of the details behind the seemingly flawless empirical performance of deductive reasoning using the PLMs. We hope our work will inspire further research on probing and improving the deductive reasoning capabilities of the PLMs. Our code and data are available online at `https://github.com/cambridgeltl/deductive_reasoning_probing`.

2 Related Work

Knowledge Probing, Infusing, and Editing with PLMs. PLMs appear to memorise (world) knowledge facts during pretraining, and such captured knowledge is useful for knowledge-intensive tasks (Petroni et al., 2019, 2021). A body of recent research has aimed to (i) understand how much knowledge PLMs store, i.e., *knowledge probing* (Petroni et al., 2019; Meng et al., 2022); (ii) how to inject external knowledge into them, i.e., *knowledge infusing* (Wang et al., 2021b; Meng et al., 2021); and (iii) how to edit the stored knowledge, i.e. *knowledge editing* (De Cao et al., 2021). In particular, De Cao et al. (2021) have shown that it is possible to modify a single knowledge fact without affecting all the other stored knowledge. However, some empirical evidence suggests that existing PLMs generalise poorly to unseen sentences and are easily misled (Kassner and Schütze, 2020).[3] Moreover, this body of research focuses only on investigating how to *recall or expose* the factual and commonsense knowledge that has been encoded in the PLMs, rather than exploring their capabilities of deriving previously unknown knowledge via *deductive reasoning*, as done in this work.

Knowledge Reasoning with PLMs. In recent years, PLMs have also achieved impressive progress in *knowledge reasoning* (Helwe et al., 2021). For example, PLMs can infer a conclusion from a set of knowledge statements and rules (Talmor et al., 2020; Clark et al., 2020), with both the knowledge and the rules being mentioned explicitly and linguistically in the model input. Some generative PLMs, such as T5 (Raffel et al., 2020), are even able to generate natural language proofs that support implications over logical rules expressed in natural language (Tafjord et al., 2021). In particular, some large PLMs, such as LaMDA (Thoppilan et al., 2022), have been shown to be able to conduct multi-step reasoning under the chain

---

[2] This type of reasoning is also often referred to as *explicit reasoning* in the literature (Broome, 2013; Aditya et al., 2018).

[3] For instance, if we add the *talk* token into the statement "Birds can [MASK]." (i.e. "Talk. Birds can [MASK]."), the PLM might be misled by the added token and predict *talk* rather than the originally predicted *fly* token (Kassner and Schütze, 2020).

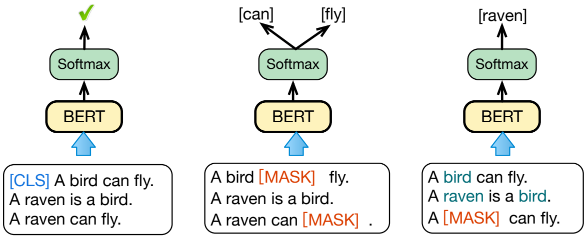
of thought prompting (Wei et al., 2022) or proper simple prompting template (Kojima et al., 2022). Although the generated 'reasoning' statements potentially benefit some downstream tasks, there is currently no evidence that the statements are generated via deductive reasoning, rather than obtained via pure memorisation. Generative reasoning models are difficult to evaluate since this requires huge effort of manual assessment (Bostrom et al., 2021).

Although some research has demonstrated that PLMs can learn to effectively perform inference which involves taxonomic and world knowledge, chaining, and counting (Talmor et al., 2020), preliminary experiments on a single test set in more recent research have revealed that fine-tuning PLMs for editing knowledge might negatively affect the previously acquired knowledge (De Cao et al., 2021). Our work performs systematic and controlled examinations of the deductive reasoning capabilities of PLMs and reaches beyond (sometimes misleading) task performance.

3 Deductive Reasoning

What is Deductive Reasoning? Psychologists define reasoning as a process of thought that yields a conclusion from precepts, thoughts, or assertions (Johnson-Laird, 1999). Three main schools describe what people may compute to derive this conclusion: relying on factual knowledge (Anderson, 2014; Newell, 1990), formal rules (Braine, 1998; Braine and O'Brien, 1991), mental models (Johnson-Laird, 1983), or some mixture of them (Falmagne and Gonsalves, 1995). Our experimental study focuses on a 'computational' aspect of reasoning — namely, whether computational PLMs for reasoning inadequately generalise learned logic rules and perform inconsistently against simple adversarial reasoning examples.

We investigate deductive reasoning in the context of NLP and neural PLMs. In particular, the goal of this deductive reasoning task is to train a PLM (e.g. BERT) over some reasoning examples (each with a set of premises and a conclusion) to become a potential reasoner (e.g. R-BERT as illustrated in Figure 1). Then, the trained reasoner can be used to infer deductive conclusions consistently over explicit premises, where the derived conclusions are usually unseen during the PLM pretraining/training. This inference process requires the underlying PLMs to understand factual knowledge and interpret rules intervening in the deduction process. In this paper, we only focus on the encoder-based PLMs (e.g. BERT and RoBERTa) as they can be evaluated under more controllable conditions and scrutinised via automatic evaluation. In particular, we investigate two task formulations of the deductive reasoning training: **1)** *classification-based* and **2)** *prompt-based reasoning*, as follows.



(a) CLS-BERT **(b) MLM-BERT** **(c) Cloze-BERT**

Figure 2: Different reasoning training approaches.

3.1 Classification-based Reasoning

The classification-based approach formulates the deductive reasoning task as a sequence classification task. Let $\mathcal{D} = \{\mathcal{D}^{(1)}, \mathcal{D}^{(2)}, \cdots, \mathcal{D}^{(n)}\}$ be a reasoning dataset, where n is the number of examples. Each example $\mathcal{D}^{(i)} \in \mathcal{D}$ contains a set of premises $\mathcal{P}^{(i)} = \{\mathbf{p}_1^{(i)}, \mathbf{p}_2^{(i)} \dots \mathbf{p}_j^{(i)}\}$, a hypothesis $\mathbf{h}^{(i)}$, and a binary label $\mathbf{l}^{(i)} \in \{0, 1\}$. A classification-based reasoner takes the input of $\mathcal{P}^{(i)}$ and $\mathbf{h}^{(i)}$, then outputs a binary label $\mathbf{l}^{(i)}$ indicating the faithfulness of $\mathbf{h}^{(i)}$, given that $\mathcal{P}^{(i)}$ is hypothetically factual.

The goal of the classification-based reasoning training is to build a statistical model parameterised by θ to characterise $P_\theta(\mathbf{l}^{(i)}|\mathbf{h}^{(i)}, \mathcal{P}^{(i)})$. Those PLMs built on the transformer encoder architecture, such as BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), can be used as the backbone of such a classification-based reasoner. Figure 2(a) shows an example of using the BERT model to train a classification-based reasoner (CLS-BERT). In particular, given a training example $\mathcal{D}^{(i)} = \{\mathbf{l}^{(i)}, \mathbf{h}^{(i)}, \mathcal{P}^{(i)}\}$, the BERT model is trained to predict the hypothesis label by encoding $[\mathbf{h}^{(i)}; \mathcal{P}^{(i)}]$ and computing $P_\theta(\mathbf{l}^{(i)}|\mathbf{h}^{(i)}, \mathcal{P}^{(i)})$. To do so, the contextualised representation of the '`[CLS]`' token is subsequently projected down to two logits and passed through a softmax layer to form a Bernoulli distribution indicating that a hypothesis is *true* or *false*.

3.2 Prompt-based Reasoning

Deductive reasoning can also be approached as a cloze-completion task by formulating a valid conclusion as a cloze test. Specifically, given a reasoning example, i.e., $\mathcal{D}^{(i)}$ with its premises $\mathcal{P}^{(i)}$, and a cloze prompt $\mathbf{c}^{(i)}$ (e.g. *"A* `[MASK]` *can fly"*), instead of predicting a binary label, this cloze-completion task is to predict the masked token $\mathbf{a}^{(i)}$ (e.g. *raven*) to the cloze question $\mathbf{c}^{(i)}$.

The BERT-based models have been widely used in the prompt-based reasoning tasks (Helwe et al., 2021; Liu et al., 2022), by concatenating the premises and the prompt as input and predicting the masked token based on the bidirectional context. In general, there are two training objectives for the prompt-based reasoning task, i.e., the mask language modelling (MLM) and task-specific (cloze-filling) objectives. For MLM, the given PLMs are trained over the reasoning examples using their original pretraining MLM objective to impose deductive reasoning ability; see Figure 2(b) for an example of the BERT reasoner MLM-BERT. For the cloze-filling objective, the PLMs are trained with a task-specific cloze filling objective. As illustrated in Figure 2(c), Cloze-BERT is trained to predict the masked token in the cloze prompt, by computing the probability $P_\theta(\mathbf{a}^{(i)}|\mathbf{c}^{(i)}, \mathcal{P}^{(i)})$. We note that, unlike the original pretraining MLM objective where 15% tokens of the input are masked randomly, the cloze-filling objective only masks the answer token $\mathbf{a}^{(i)}$ in the cloze prompt $\mathbf{c}^{(i)}$.

This prompt-based reasoning task matches the mask-filling nature of BERT. In this way, we can probe the native reasoning ability of BERT without any further fine-tuning and evaluate the contribution of reasoning training to the PLMs' reasoning ability. Foreshadowing, our experimental results in Section 5 indicate that reasoning training impacts the model both positively and negatively.

4 Experiments and Results

Recent PLMs have shown surprisingly near-perfect performance in deductive reasoning (Zhou et al., 2020). However, we argue that high performance does not mean PLMs have mastered reasoning skills. To validate this, we run controlled experiments to examine whether PLM-based reasoners genuinely understand the natural language context, produce conclusions robustly against lexical and syntactic variance in surface forms, and apply learned rules to unseen cases.

4.1 Datasets

Two datasets are used to examine the PLM-based reasoners, namely, the Leap of Thought (**LoT**) dataset (Talmor et al., 2020) and the WikiData (**WD**) dataset (Vrandecic and Krötzsch, 2014).

LoT was originally proposed for conducting the classification-based reasoning experiments for deductive reasoning (Talmor et al., 2020) and has been used as a standard (and sole) benchmark to probe the deductive reasoning capabilities of PLMs (Tafjord et al., 2021; Helwe et al., 2021). This dataset is automatically generated by prompting knowledge graphs, including ConceptNet (Speer et al., 2017), WordNet (Fellbaum, 1998) and WikiData (Vrandecic and Krötzsch, 2014). LoT contains 30,906 training instances and 1,289 instances for each validation and testing set. Each data point in LoT also contains a set of distractors that are similar but irrelevant to deriving the conclusion.

For the prompt-based reasoning task, we can reformulate the LoT dataset to fit our cloze-completion task. Instead of having a set of premises $\mathcal{P}$, a hypothesis $\mathbf{h}$, and a binary label $\mathbf{l}$, we rewrite the hypothesis in LoT into a cloze $\mathbf{c}$ and the answer $\mathbf{a}$ (e.g. *A raven can fly.* → *A [MASK] can fly.*). Note that we only generate those cloze questions on the positive examples. Consequently, the results across these two tasks are not directly comparable.

The **WD** dataset is an *auxiliary* reasoning dataset which we generated and extracted from Wikidata5m (Wang et al., 2021b). Similar to previous work (Petroni et al., 2019; Talmor et al., 2020), we converted a set of knowledge graph triples into linguistic statements using manually designed prompts. The full description of the dataset construction is provided in Appendix C. The final WD dataset contains 4,124 training instances, 413 validation instances, and 314 test instances. WD only contains positive examples: therefore, we only use this dataset for the cloze-completion task.

4.2 Adversarial Probing

Previous work demonstrates that PLMs can achieve near-perfect empirically results in reasoning tasks. For example, RoBERTa-based models record a near-perfect accuracy of 99.7% in the deductive reasoning task on LoT (Talmor et al., 2020). However, another recent study shows that in some natural language inference benchmarks, PLMs are still not robust to the negation examples (Hossain et al., 2020), while humans can handle negations with

Perturbation	Premises	Conclusion	Valid
Original	A bird can fly. A raven is a bird.	A raven can fly.	✓
Paraphrasing	A bird is able to fly. A raven is a bird species.	A raven can fly.	✓
Synonym Substitution	A fowl can fly. A raven is a fowl.	A raven can fly.	✓
Negation	A bird can fly. A raven is a bird.	A raven cannot fly.	✗
Retained knowledge	A bird can live up to 100 years.	–	✓

Table 1: Examples of different perturbations strategies that were used to create the adversarial dataset (see §4.2).

ease. In order to systematically probe PLMs' deductive reasoning capabilities, we design controlled experiments over three different adversarial test settings by generating different *surface form perturbations*, *negation of the original examples*, and creating additional *retained knowledge anchors*. Table 1 shows some different adversarial examples.

Surface Form Perturbations. The theory of mental models postulates that deductive reasoning is based on manipulations of mental models representing situations. In other words, envisaging the situations and making a deduction can be viewed as a semantic process (Johnson-Laird, 1999; Polk and Newell, 1995). On the other hand, previous works demonstrate that, instead of learning interpretable meaning representations and generalising across different surface forms, PLMs tend to learn artefacts in the training data, e.g., higher-order word co-occurrence statistics (Sinha et al., 2021).

As both LoT and WD datasets are prompted from knowledge graphs, the lexical and syntactical variance of the dataset is minimal, with imaginable artefacts. To examine if the PLM-based reasoner could consistently perform reasoning against linguistic diversity and variability (in terms of both the token-level and the syntactic-level diversity), we employ two types of surface form perturbations to the data items from the original datasets:

- **Synonym Substitution:** In order to investigate to what extent the PLM-based reasoners would be sensitive to the token-level semantic diversity in terms of deriving their conclusions, we employ synonym substitution (Dhole et al., 2021) to the premises $\mathcal{P}$. Synonym substitution does not modify the syntactic structures and the premises' semantics, preserving all the original input's structural information. In our setting, a word is replaced by a uniform-randomly selected synonym based on WordNet (Fellbaum, 1998) with a probability of 50%.
- **Paraphrasing:** To further investigate the PLM-based reasoners' robustness on sentence-level semantic variability, we paraphrase the premises $\mathcal{P}$ with two paraphrasing systems: (i) PEGASUS, an end-to-end model fine-tuned for paraphrasing (Zhang et al., 2020) (ii) Syntactically Diverse Paraphrasing (SD-Paraphrasing), a two-step framework that incorporates neural syntactic preordering for better diversity (Goyal and Durrett, 2020).

Negated Examples. Understanding negation is often considered as the first test case in natural language understanding tasks (Ettinger, 2020; Khemlani et al., 2012; Schon et al., 2021). To examine whether PLMs can handle negation in the deductive reasoning task, we construct a set of negated samples by negating the hypothesis $\mathbf{h}$ or the cloze prompt $\mathbf{c}$ while keeping the premises $\mathcal{P}$ unchanged (Hosseini et al., 2021). For the classification-based reasoning task, the label of the negated hypothesis is then also flipped. For the cloze-completion task, since the answer for the original query will unlikely be the same answer for the negated queries, predicting the original answer would be regarded as a wrong prediction.

Anchors of Retained Knowledge. Prior work has shown that PLMs are prone to forgetting previously learnt knowledge when fine-tuning with new knowledge data (De Cao et al., 2021), the so-called catastrophic forgetting issue (Kirkpatrick et al., 2017; de Masson d'Autume et al., 2019). It is thus natural to also probe whether deductive reasoning training still retains the knowledge already stored in the original PLM. In this work, in order to measure to which extent PLMs retain the knowledge acquired during pretraining, we introduce a set of 'retained knowledge statements' or *anchors* for each dataset. There are two criteria for such *anchors*: (i) they are semantically close to the conclusions in our test data, (ii) they do not meet the conditions of the premises for a reasoning replacement.[4] Ideally, the reasoning training should not affect the prediction of PLMs when reasoning over these anchors.

We create such a set of anchors for both LoT and WD, and investigate the behaviour of the reasoning models over these anchors based on the prompt-based reasoning task. In particular, these anchors should be real-world textual statements that contain the target word (to meet criterion (i) above), but their newly composed sentences (by the reasoning replacement) are unlikely true statements (to meet criterion (ii) above). To this end, we use the BM25 algorithm (Sparck Jones et al., 2000) to retrieve the top 10 sentences for each 'reasoning' target word from the Wikipedia corpus.[5] Then, we construct the anchor sentences based on these top 10 retrieved sentences by replacing their target words with their hyponym/hypernym words. The final anchors are selected from these top 10 sentences only when the newly created sentences do not likely exist in the entire Wikipedia corpus (i.e. their top-1 similar sentence should have less than a BM25 score of 50). Ideally, this set of retrained knowledge statements is relevant but should not be affected by the reasoning training.

4.3 Evaluation

Following previous work (Talmor et al., 2020), the evaluation metric for classification-based reasoning is accuracy. For prompt-based reasoning, we calculate top K recall (R@K) by measuring what fraction of the correct answers are retrieved in the top K predictions. For the negation examples, we report the top K error rate (E@K) because a retrieved answer $\mathbf{a}$ and the negated cloze question $\neg\mathbf{c}$ would compose a fallacy.

In the following, we report our findings and numerical results based on the BERT-based reasoners (in particular `bert-base-uncased`), but we note that other PLMs (such as RoBERTa) of various sizes observe the same performance trends and result in the same findings and conclusions. Appendix B provides results for other PLMs.

Model	R@1	R@5	R@10
Dataset: **LoT**			
Pretrained	13.15	59.18	70.96
MLM-BERT	98.36	98.36	98.36

Cloze-BERT	100	100	100

Table 2: Recall of the correct answer in the top K predictions (R@K) from the BERT model before and after deductive prompt-based reasoning fine-tuning. Both MLM-BERT and Cloze-BERT achieve (near-)perfect R@1 scores after fine-tuning.

5 Results and Discussion

We evaluate the impact of reasoning training on the PLMs and investigate their robustness against three well-known issues of PLMs: utilising artefacts from data, incapability of modelling negation, and catastrophic forgetting. We further conduct qualitative analysis to understand the inference errors introduced by deductive reasoning training.

5.1 Deductive Reasoning Training

Finding 1 *All the deductive reasoning training approaches significantly improve PLMs' reasoning capabilities, achieving near-perfect deductive reasoning performance on both the reasoning test sets.*

Table 2 reveals that the prompt-based reasoners achieve near-perfect performance on both datasets, regardless of the reasoning training method. In particular, on LoT dataset the R@1 score of BERT has increased from 13.15% to 98.36% and 99.73% after the MLM reasoning training (i.e. MLM-BERT) and the cloze reasoning training (i.e. Cloze-BERT) respectively, which are in line with previously reported result (Talmor et al., 2020). The near-perfect trends are observed in the classification-based reasoning models, where CLS-BERT also achieves a high accuracy score of 94.72% after reasoning training (Table 5).[6] In sum, while the off-the-shelf BERT model already demonstrates a decent level of empirical performance, conducting reasoning training on the pretrained BERT achieves strong or even near-perfect performance on both datasets.

---

[4] Taking the premise (a) of Figure 1 as an example, the 'bird' token in the statement 'A bird can fly.' was replaced by its hyponym 'raven' after reasoning training. However, in the anchor statement 'The bird species is decreasing.', the 'bird' token should not be replaced by 'raven'.

Table 5: Accuracy scores on test sets obtained via applying various surface form perturbations from Section 4.2.

5.2 Surface Form Perturbations

Finding 2 *Surface form perturbations drastically decrease PLMs' reasoning performance.*

A natural follow-up question to ask is to what extent the aforementioned near-perfect numbers really reflect the model's reasoning abilities. We thus perform surface form perturbations to add lexical and syntactic variance to the test datasets and probe the model against such variations.

Table 3 demonstrates the performances of the MLM-BERT and Cloze-BERT reasoners, as well as the vanilla pretrained BERT language model, on our controlled test sets generated by different perturbation approaches. We can observe that the scores for both reasoners decrease substantially (>30%) even when applying simple synonym substitution, which only adds lexical variance to the prompt-generated query. In contrast, the pretrained BERT language model is less vulnerable to such an issue. This finding aligns with the hypothesis that PLMs tend to memorise word co-occurrence statistics (Sinha et al., 2021).[7]

We also observe from Table 3 that the R@1 performances of all reasoners decrease strongly when applying either the Pegasus-Paraphrasing or SD-Paraphrasing methods to the premises. In particular, the drops are especially pronounced with the SD-Paraphrasing method, which is designed exactly to generate syntactically very diverse paraphrases. On the other hand, we see from Table 5 that similar performance degradation trends can be observed in the classification-based reasoning task. These results illustrate that current PLMs perform inconsistently against various surface form perturbations, suggesting that future work should look into the creation of more robust reasoners that should be resilient to lexical, syntactic, and semantic variability.

---

[6] Note that we cannot obtain the performance of original BERT since the classification head has not been trained yet.

[7] The comparison of large models (e.g. `bert-large`) can be found in Appendix B, which indicates the similar trends.

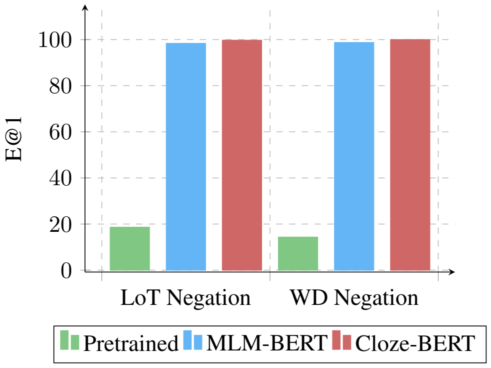

Figure 3: Results (E@1 scores, lower is better) on the test set comprising negated examples; before versus after deductive-reasoning training.

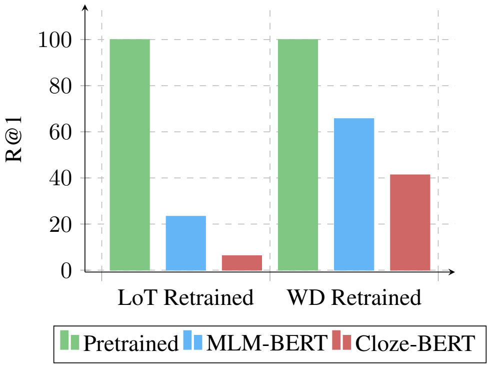

Figure 4: Results (R@1 scores, higher is better) on the test set comprising anchors of retained knowledge; before versus after deductive-reasoning training.

5.3 Negated Examples

Finding 3 *All reasoners cannot distinguish between negated and non-negated examples.*

Figure 3 reveals that the error rate E@1 scores (the lower, the better)[8] for all reasoners on the set of negated examples largely increase after reasoning training. The original off-the-shelf BERT model achieves E@1 of 18.63% on LoT and 14.33% on the WD dataset. However, after reasoning training, the error rate of MLM-BERT significantly increases to 98.36% (LoT) and 98.73% (WD). Cloze-BERT's performance is even worse, with E@1 scores of 99.73% (LoT) and 100% (WD), suggesting a clear case of overfitting to word co-occurrence and other artefacts in the training sets. Moreover, the accuracy score on negated LoT examples is only 9.34%, while a random baseline would score 50%. In sum, these scores indicate that the PLM-based reasoners cannot distinguish between negated and non-negated examples, and their performance on negated examples substantially worsens after reasoning training due to task-specific overfitting.

A quick error analysis, provided in Table 4, further points to the issues with negated examples. The first example shows that the off-the-shelf BERT model makes a reasonable guess, semantically related to an entity mentioned in the premises. This guess is similar to a human guess from the same premises. However, after reasoning training, both MLM-BERT and Cloze-BERT make wrong predictions, and Cloze-BERT is extremely confident in its wrong predictions.

5.4 Anchors of Retained Knowledge

Finding 4 *Previously learnt knowledge is not fully retained after reasoning training, and the trained reasoners (catastrophically) forget it.*

Figure 4 shows that performance on the anchors deteriorates substantially after reasoning training. On LoT, MLM-BERT 'forgets' ∼77% of the previously learnt knowledge, achieving only 23.34% on R@1. Cloze-BERT performs even worse, scoring only 6.27% R@1. The drops are slightly lower but still substantial on WD: MLM-BERT retains 65.7% and Cloze-BERT retains 41.32% of the previously stored knowledge. This result indicates that reasoning training yields the well-known phenomenon of catastrophic forgetting: this effect seems even more pronounced with Cloze-BERT, which relies on a very task-specific objective that might result in overfitting the task data.

Furthermore, Table 6 displays several qualitative examples where the predictions in green refer to the correct predictions based on human judgement. Notice that in the last example, even though the predictions from the two trained reasoners are correct, the probabilities are much lower.

Several strategies might help mitigate catastrophic forgetting. A promising direction is encapsulating lightweight adapter modules (Houlsby et al., 2019; Pfeiffer et al., 2020b; Ansell et al., 2021) within the underlying PLM, where all the 'deductive reasoning capability' will be stored solely in the adapter modules, leaving the original PLM intact (Pfeiffer et al., 2020a). Other similar parameter-efficient and modular methods include prefix tuning (Li and Liang, 2021) or sparse masks (Sung et al., 2021; Ansell et al., 2022). Their main

---

[8] E@1 only denotes a specific type of error: the model makes a wrong prediction due to negation being added, i.e. the negation error. However, many other types of errors that a model can make a wrong prediction, but they are not our focus and thus not measured. In other words, (1 - E@1) is not equivalent to accuracy.

The numbers in the parentheses are the respective probabilities of each prediction after the softmax layer.

premise is to separate knowledge extraction and composition, preserving previously learnt knowledge during reasoning training. We leave reasoning training with such methods for future research.

6 Conclusion

In this paper, we probed into the deductive reasoning capabilities of PLMs and conducted comprehensive controlled experiments to examine and compare various deductive reasoning training approaches. Our experimental results showed that current PLM-based deductive reasoners suffer from several issues: **1)** they rely on artefacts from the training data, **2)** they are incapable of modelling negation in deductive reasoning, and **3)** they forget knowledge acquired during pretraining when they get specialised into deductive reasoners. In particular, our experimental study demonstrated that models are vulnerable to multiple adversarial methods, including simple surface form perturbations such as synonym substitution or paraphrasing. While the PLMs trained for deductive reasoning achieve seemingly perfect empirical results in different reasoning datasets, they cannot yet systematically generalise to other deductive reasoning examples. Consequently, our study also calls for further, more rigorous examinations of future PLM-based models' deductive reasoning abilities.

Limitations

Despite the thorough experiments on standard and popular PLMs of various sizes, this study explores only encoder-based models. Some generation-based models under other Transformer architectures, such as encoder-decoder (T5) or decoder-only (GPT-3), were also deployed in the reasoning tasks (Bostrom et al., 2021; Wei et al., 2022). We do not probe those groups of models here due to the difficult of evaluation and we leave them for future research.

Further, for prompt-based reasoning, the current reasoners only support and have been evaluated on single-token prediction in a single language (i.e. English). Several prior works have demonstrated that conducting multi-token prediction is considerably more difficult (Jiang et al., 2020a), which would pose an additional challenge to the PLMs in deductive reasoning tasks. One avenue of future work should also extend the scope of analyses to multilingual and multi-token prediction.

In addition, we note that better evaluation resources that could address paraphrases and word senses, especially for mask-filling tasks, are still lacking. This limitation is particularly significant in our setting. For example, in addition to the single-token answer in the evaluation datasets we used, there are some other feasible answers (e.g. synonyms) for the same query, which should also be considered a correct prediction. However, such answers are ignored by the current standard evaluation protocols. As a result, there is a certain level of unavoidable noise in the evaluation process.

Finally, introducing a reasoning dataset is highly challenging and appreciated by the community. Leap-of-thought is to our knowledge the only existing dataset that is suitable for our deductive reasoning evaluation. To solidify our conclusions, we further constructed an auxiliary dataset (WD) following a similar procedure to LoT. Although our data construction method is commonly used to extract reasoning examples, such an automatic procedure, unfortunately, inevitably reflects the quality and errors (e.g. nonsensical statements) from our source (WikiData). To reduce such noisy examples, we have conducted multiple rounds of filtering (see

Appendix for the filtering process) and manually removed as many meaningless relations as we can, given that manually verifying each reasoning example is a highly labour-intensive task.

A Experimental Details

Table 7 lists our model hyperparameters. Among these models, MLM-BERT and Cloze-BERT were implemented using the HuggingFace transformers package (Wolf et al., 2020). We implement CLS-BERT via the SBERT repository (Reimers and Gurevych, 2019), which is built on top of the HuggingFace repository (Wolf et al., 2020). Unless mentioned otherwise, all the hyperparameters are set to the default values provided in the HuggingFace and SBERT repositories.

Hyper-parameter	**Value**
MLM-BERT and Cloze-BERT	
batch_size	2
max_sequence_length	512
training_epoch	3
CLS-BERT	
batch_size	64
max_sequence_length	128
training_epoch	20

Table 7: Model hyper-parameters.

B Evaluation Results for PLMs

Table 8 supplements the main paper by providing additional results with classification-based reasoners, where the reasoners start from different PLMs: `distil-bert`, `bert-base`, `bert-large`, `roberta-base`, and `roberta-large`. These results corroborate the main findings presented in the main paper; see Section 5. Larger models do perform slightly better than their smaller variants on average. However, the results also demonstrate that different models, regardless of their size, suffer from exactly the same issues, discussed in the main paper.

Table 9 and Table 10 demonstrate performance over adversarial test sets for prompt-based reasoners (1. MLM-based, 2. Cloze-based). The findings from these tables align with the findings from the main results presented in Section 5.

C WD Dataset Construction Pipeline

We construct the **WD** dataset following the pipeline shown in Figure 5, and outlined in what follows.

Source Data. We choose the Wikidata5m dataset (Wang et al., 2021b) as the knowledge source for **WD**. Wikidata5m is a million-scale knowledge graph dataset created upon Wikidata (Vrandecic and Krötzsch, 2014). This dataset comprises 20 million triples, describing relevant and important knowledge statements about real-world entities.

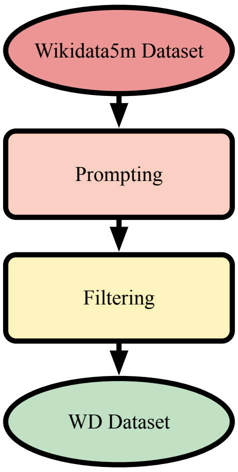

Figure 5: Data construction pipeline for the **WD** dataset. This **WD** dataset is extracted and derived from WikiData5m (Wang et al., 2021b). Following the previous pipeline (Petroni et al., 2019), we convert a set of knowledge graph triples into linguistic statements using manually designed prompts.

Prompting. We manually select a set of relations based on their frequency and design their corresponding prompts shown in Table 11. Given a taxonomic relation, such as is_a with relation ID P31, we sample a relevant taxonomic-knowledge graph triple: $\langle raven, is\_a, bird\rangle$. We then retrieve other relevant triples about the subject and the object, for example, $\langle bird, is\_capable\_of, fly\rangle$ and $\langle raven, is\_capable\_of, fly\rangle$. Next, we use our predefined prompts to convert the knowledge graph triples to textual knowledge statements: *A bird can fly*, *A bird is a raven* and *A raven can fly*. Furthermore, these prompted statements assemble an inference instance in the **WD** dataset: if *A bird can fly* and *A bird is a raven*, then *A raven can fly*. In our cloze-completion task setting, we mask the object of the taxonomic triple (e.g. $raven$) in the conclusion statement to form a cloze question (*A [MASK] can fly*). Therefore, $raven$ is the correct answer to this question.

Filtering. We filter those constructed inference instances with the following properties: (i) We only choose examples with answers being a single masked token, and these answers should be included in the BERT vocabulary. (ii) For all in-

Abstract

This work focuses on in-context data augmentation for intent detection. Having found that augmentation via in-context prompting of large pre-trained language models (PLMs) alone does not improve performance, we introduce a novel approach based on PLMs and pointwise V-information (PVI), a metric that can measure the usefulness of a datapoint for training a model. Our method first fine-tunes a PLM on a small seed of training data and then synthesizes new datapoints – utterances that correspond to given intents. It then employs intent-aware filtering, based on PVI, to remove datapoints that are not helpful to the downstream intent classifier. Our method is thus able to leverage the expressive power of large language models to produce diverse training data. Empirical results demonstrate that our method can produce synthetic training data that achieve state-of-the-art performance on three challenging intent detection datasets under few-shot settings (1.28% absolute improvement in 5-shot and 1.18% absolute in 10-shot, on average) and perform on par with the state-of-the-art in full-shot settings (within 0.01% absolute, on average).

1 Introduction

Intent detection, defined as the identification of a user's intent given an utterance, is a fundamental element in task-oriented dialogue systems, usually occurring within the Natural Language Understanding (NLU) component. One of the practical challenges of training and deploying NLU modules is data scarcity, due to various reasons, such as under-represented languages, privacy and ethical concerns, or simply the cost of collecting and annotating sufficiently large amounts of data for new intents. Consequently, accurately identifying intents in limited-resource scenarios has drawn attention from the community (Papangelis et al., 2021; Mehri and Eric, 2021; Zhang et al., 2021b, for example).

There are three main families of approaches that address the challenge of limited data for intent detection: data augmentation (Peng et al., 2021; Li et al., 2021), focusing on generating high-quality synthetic training and evaluation data; few-shot learning (Zhang et al., 2020, 2021b), focusing on creating learning algorithms that can cope with limited amounts of data; and transfer learning (Namazifar et al., 2021), focusing on learning algorithms that can generalize across domains (therefore not requiring in-domain data). In this work, we follow the data augmentation approach, which is a general method that attempts to augment a human-authored dataset with a large set of synthetically-generated instances. Most recent work has suggested using Pre-trained Language Models (PLMs) for data augmentations under various setups, e.g., (Peng et al., 2021), showing great improvements in performance. However, simply generating a large number of synthetic data points is not enough; we need to consider the quality of each data point, i.e., how beneficial it would be to the model's performance if that synthetic data point is added to the training set. This is an important issue since the model might learn to overfit to synthetic datapoints (which may be low quality, represent specific use cases, etc.) and thus under-perform on real data.

In this work, we propose to apply Pointwise $\mathcal{V}$-Information (PVI) (Ethayarajh et al., 2022) for data augmentation, in a way that leverages a PLM to generate synthetic examples that are relevant and beneficial for training the downstream model, which in our case is an intent classifier. Our contributions are as follows:

- We propose a novel filtering method based on PVI (Ethayarajh et al., 2022) to filter out examples that are not relevant or helpful to the desired intent.
- We conduct experiments on three challenging intent detection datasets and show that our

method achieves state-of-the-art performance.

- We conduct an in-depth study and present a comprehensive analysis of the factors that influence performance, including ablation studies and comparisons with alternative methods.

The rest of the paper is organized as follows: In Section 2 we present relevant work and in Section 3 we introduce our method. In sections 4 and 5 we discuss training details, experiments, and results. In section 6, we present our analysis and discuss alternative approaches we investigated. In section 7 we conclude, and in the following sections we discuss limitations and ethical considerations.

2 Related Work

Intent Detection Intent detection is the task of identifying the user's intent by mapping the user's natural language utterance into one of several predefined classes (Hemphill et al., 1990; Coucke et al., 2018). It is a critical component in the pipeline of task-oriented dialogue systems, as it is used to determine the user's goal and to trigger an appropriate system action (Raux et al., 2005; Young et al., 2013). Several datasets have been proposed to evaluate the performance of intent detection models (Casanueva et al., 2020; Liu et al., 2019a; Larson et al., 2019, for some recent examples). With the availability of such datasets, intent detection has been extensively studied in the literature. Recently, pre-trained language models (e.g., BERT (Devlin et al., 2019)) have been shown to be effective in intent detection (Bunk et al., 2020; Zhang et al., 2020, 2021a,b; Mehri and Eric, 2021).

Data Augmentation Data augmentation is a widely-used technique to address the problem of data scarcity. Paraphrasing the data is one of the ways frequently used for augmentation and can produce more diverse synthetic text with different word choices and sentence structures while preserving the meaning of the original text. Paraphrasing methods have been shown to be effective in many natural language processing tasks (Gupta et al., 2018; Edunov et al., 2018; Iyyer et al., 2018; Wei and Zou, 2019; Cai et al., 2020; Okur et al., 2022; Panda et al., 2021; Jolly et al., 2020). However, such methods often fail to generate more challenging and semantically diverse sentences that are important for the robustness of the downstream models.

Recently, conditional generation – using a PLM to produce text conditioned on some label – has become the dominant paradigm of data augmentation (Bowman et al., 2016; Kumar et al., 2019; Anaby-Tavor et al., 2020; Kumar et al., 2020; Yang et al., 2020a; Lee et al., 2021). This is usually achieved by fine-tuning a language model to produce the original text given the label.

In the field of intent detection, previous work has proposed using data augmentation techniques to generate synthetic training data (Sahu et al., 2022; Papangelis et al., 2021). Sahu et al. (2022) also used PLMs to generate augmented examples, but they require human effort for labeling. This is a challenging task since it is expensive to annotate large amounts of data.

Our approach involves data valuation, similar to the concepts of Ghorbani and Zou (2019); Mindermann et al. (2022). However, our approach differs from such previous work in two key ways. First, Ghorbani and Zou (2019) only evaluated the quality of the training set after training them, whereas we evaluate the synthetic examples before training the task model. Second, Mindermann et al. (2022) selected points that minimize the loss on a holdout set, whereas we select synthetic examples that are reasonably challenging to the task model. Our approach aims to address the problem of data scarcity by evaluating the synthetic examples generated by PLMs and selecting the most valuable examples to augment the training data.

In-context Learning Large language models such as GPT-3 (Brown et al., 2020) and OPT (Zhang et al., 2022) have shown to be able to perform many natural language processing tasks with in-context learning. In this paradigm, the model is provided with a few exemplars based on which it performs the respective task.

In-context learning is a promising solution for few-shot learning. Because of the effectiveness in few-shot performance, in-context learning has been applied to a wide range of NLP tasks. For dialogue tasks, in-context learning has been applied to intent classification (Yu et al., 2021), semantic parsing (Shin and Durme, 2022), and dialogue state tracking (Hu et al., 2022).

However, PLMs require a large amount of computational resources and the limitation on input length restricts the application of PLMs to intent detection tasks with large numbers of intents (e.g., 150 intents in CLINC (Larson et al., 2019)), where

Prompt:

The following sentences belong to the same category as '**Refund not showing up**':

Example 1:I'm supposed to have a refund but it isn't there

Example 2:My refund is not here yet

...

Example 10:When will I be able to see the refund

Example 11:

Example Completions:

- It's been weeks since I ordered my items and I still can't seem to see the funds.
- I am looking for information about when I can expect my refund
- I've submitted a refund request but I haven't seen a change in my account. What's going on?
- Please track my refund!
- the refund has not arrived yet so when will it show?
- Where is my refund? It doesn't appear on my statement.
- There was an error with the refund, when will I receive this amount again

Figure 1: An example of the prompt used to generate synthetic examples. The intent class is *refund not showing up*. Completions are generated by a pre-trained language model via sampling. Note that 5-shot experiments only use 5 examples from the training set.

we cannot fit examples for each intent in the input. One solution would be to call the model multiple times, each time with a subset of the possible intents. This would lead to increased inference time and may also impact performance. Consequently, Yoo et al. (2021); Sahu et al. (2022) leveraged in-context learning and PLMs to generate synthetic examples for intent detection, instead of directly deploying the PLM. However, they did not consider the quality of the generated examples, which may lead to the model overfitting on examples that are not relevant to the desired intent.

3 In-Context Data Augmentation

In the following section, we describe our proposed two-stage method for data augmentation, which we refer to as In-Context Data Augmentation (**ICDA**). The overall procedure is summarized in Algorithm 1. We apply ICDA to the task of few-shot intent detection, which involves classifying a user utterance x into an intent label $y \in Y$. ICDA aims to generate synthetic examples x' such that they would belong to a given intent y.

3.1 Synthesizing Examples

The core idea is to use a large pre-trained language model such as GPT-3 (Brown et al., 2020) or OPT (Zhang et al., 2022) to generate synthetic data in the context of the training set. In particular, for each intent class, we create a natural language context (prompt) that contains the intent class name, a set of real training examples under the same intent class, and an incomplete example. For instance, the prompt for the intent class *refund_not_showing_up* is shown in Figure 1. We feed the prompt to the language model and obtain a set of synthetic examples as outputs. In this work, we use OPT-66B (Zhang et al., 2022) as the language model to generate a set of examples for each intent class. We adopt typical decoding with $\tau = 0.9$ (Meister et al., 2022) and set repetition penalty to 1.1 following Keskar et al. (2019) to generate the synthetic examples.[1] Due to the fine-grained nature of intents, and the sampling-based generation aiming to produce a set of diverse datapoints, we expect some of the generated utterances to not match the given intent.

Note that our method leverages PLMs in a way that is orthogonal to the intent detection model. Unlike other methods that use the same model to directly predict the intent class of a user utterance, we use a PLM to generate synthetic training instances. These instances are then used to augment the actual training data and train a smaller intent detection model. This approach leverages the power of PLMs while preserving the independence of the intent detection model design.

3.2 PVI Filtering

As mentioned above, given the stochastic nature of synthetic data generation, we expect some of the synthetic utterances not to match the given intent. To address this phenomenon, we filter generated instances and retain only those that are relevant and helpful to the desired intent classes.

Specifically, we apply Pointwise V-Information (Ethayarajh et al., 2022) - an idea originally suggested for understanding how difficult a dataset is - as a filter to discard unhelpful datapoints. PVI of an utterance x with respect to its corresponding intent class, y, is defined as:

$$\mathrm{PVI}(x \to y) = -\log_2 g^*[\emptyset](y) + \log_2 g'[x](y)$$

where, in this work, g' and g^* are the intent detection models finetuned with and without the input x, respectively. $\emptyset$ is a special token that is used to indicate the absence of an input utterance.

Intuitively, PVI measures the amount of information that the input x provides to the intent detection

---

[1] Implementation details are available from `https://huggingface.co/docs/transformers/main_classes/text_generation`

Algorithm 1: In-Context Data Augmentation with PVI Filtering

```
Input: Task Model $\mathcal{V}$, Language Model
       $\mathcal{PLM}$, Data Multiplier $m$, PVI
       Threshold Function $\epsilon$

Data: Seed Data $\mathcal{D}_{\text{train}} =$
      $\{(\text{input } x_i, \text{gold label } y_i)\}_{i=1}^{n}$
$g' \leftarrow$ Finetune $\mathcal{V}$ on $\mathcal{D}_{\text{train}}$
$\emptyset \leftarrow$ empty string
$g^* \leftarrow$ Finetune $\mathcal{V}$ on $\{(\emptyset, y_i) | (x_i, y_i) \in \mathcal{D}_{\text{train}}\}$
$\mathcal{D}_{\text{synthetic}} \leftarrow \text{Prompt}(\mathcal{PLM}, \mathcal{D}_{\text{train}})$
for $(x_i, y_i) \in \mathcal{D}_{\text{synthetic}}$ do
    $\text{PVI}(x_i \rightarrow y_i) \leftarrow -\log_2 g^*[\emptyset](y_i) + \log_2 g'[x_i](y_i)$
$\mathcal{D}_{\text{synthetic}} \leftarrow \{(x_i, y_i) | (x_i, y_i) \in \mathcal{D}_{\text{synthetic}} \ \& \ \text{PVI}(x_i \rightarrow y_i) > \epsilon(y_i)\}$
$g \leftarrow$ Finetune $\mathcal{V}$ on $\mathcal{D}_{\text{train}} \bigcup \mathcal{D}_{\text{synthetic}}$
```

model (compared to the absence of meaningful input). A high PVI value indicates that the input x provides a lot of information to the model, and thus is more likely to be helpful when training the model to classify instances of the intent class y. On the contrary, a low PVI value indicates that the input x provides little information to the model, and thus is likely to be irrelevant to the intent class y (Ethayarajh et al., 2022).

We set a threshold ϵ (tunable parameter) to determine which x are retained and conduct experiments to study the effect of the threshold in Section 6. Algorithm 1 defines ϵ as a function of y to allow flexibility in its definition: either a fixed threshold for all intent classes, or a different threshold per intent class.

4 Experimental Setup

4.1 Datasets

To evaluate the effectiveness of our approach in intent detection in cases where we have a large number of often semantically similar intent labels, we chose the BANKING (Casanueva et al., 2020), HWU (Liu et al., 2019a), and CLINC (Larson et al., 2019) datasets and compare with recent state-of-the-art baselines. BANKING comprises 13,083 utterances in a single banking domain and 77 intents. HWU includes 25,716 utterances with 64 intents across 21 domains. CLINC contains 23,700 utterances with 150 intents across 20 domains.

	Full-shot mult.	Few-shot mult.
XS	-	1x
S	1x	4x
M	2x	16x
L	4x	64x
XL	-	128x

Table 1: To assess the impact of the synthetic data size on performance, we experiment with several data multipliers (*synthetic data size = source data size x mult.*).

4.2 Training

In our experiments, we use RoBERTa-LARGE (Liu et al., 2019b) as the intent detection model $\mathcal{V}$ in Algorithm 1. We use OPT-66B[2] (Zhang et al., 2022) as the language model $\mathcal{PLM}$ to generate synthetic examples and set the data multiplier m to be 128[3]. We set the PVI threshold function ϵ to be the average PVI under each intent class in the validation set, where the PVI is computed using the same models as in Algorithm 1. We train RoBERTa-LARGE for 40 epochs with a batch size of 16, a learning rate of $1e-5$, and the AdamW optimizer (Loshchilov and Hutter, 2019). We use the HuggingFace Transformers library (Wolf et al., 2020) for all experiments.

4.3 Baseline Models

We compare our proposed method with the following baselines:

RoBERTa-BASE + Classifier is a baseline that uses RoBERTa-BASE (Liu et al., 2019b) with a linear classifier on top (Zhang et al., 2020).

USE is a universal sentence encoder pre-trained on 16 languages supporting multiple down-stream tasks (Yang et al., 2020b).

CONVERT is an intent detection model finetuned from dual encoder models, which is pre-trained on (input, response) pairs from Reddit (Henderson et al., 2020).

CONVBERT fine-tunes BERT on a large open-domain dialogue corpus with 700 million conversations (Mehri et al., 2020) .

CONVBERT + Combined is an intent detection model based on CONVBERT, with example-driven training based on similarity matching and observers for transformer attentions. It also conducts task-adaptive self-supervised learning with masked language modeling (MLM) on the intent detection

---

[2] We used p3dn.24xlarge AWS EC2 instances for our experiments.

[3] This means that we generate m times the available training data, e.g. (5 x 77) x m in the 5-shot BANKING case.

datasets. Here, “Combined" represents the best MLM+Example+Observers setting in the referenced paper (Mehri and Eric, 2021).

DNNC (Discriminative Nearest-Neighbor Classification) is a discriminative nearest-neighbor model, which finds the best-matched example from the training set through similarity matching. The model conducts data augmentation during training and boosts performance by pre-training on three natural language inference tasks (Zhang et al., 2020).

CPFT (Contrastive Pre-training and Fine-Tuning) is the current state-of-the-art in few-shot intent detection on the selected datasets. It is pre-trained on multiple intent detection datasets in a self-supervised contrastive manner and then fine-tuned with supervised contrastive learning (Zhang et al., 2021b).

5 Experimental Results

We conduct experiments on three benchmark datasets to validate the effectiveness of our proposed method. We first use OPT-66B to generate augmentation examples and then apply our method to enhance a RoBERTa-Large model trained on three datasets. We repeat all experiments with 5 random seeds and report the average performance in Full-shot and Few-shot settings. To investigate the effect of the synthetic data size, we experiment with a variety of multipliers (see Table 1 for notations). Results are shown in Table 2.

Full-shot settings. In this setting, we use the entire training set for each domain. The proposed method achieves the best performance on BANKING and comparable results on HWU and CLINC. In particular, on BANKING, we improve the ConvBERT + Combined baseline (Mehri and Eric, 2021) by 0.59% (absolute) and the RoBERTa-Large baseline by 0.72% (absolute). Compared with the ConvBERT + Combined, which is pre-trained on intent detection datasets in a self-supervised fashion and adds examples-driven training and specific model architectural design, our method achieves similar results with much simpler model design. Furthermore, our method is orthogonal to model architectures and can be integrated with any other approach for further improvement.

We also find that ICDA improves the performance of the RoBERTa-Large model on HWU and CLINC. This highlights the effectiveness of our method for enhancing intent detection models. Moreover, state-of-the-art performance on BANKING with the proposed method and RoBERTa-Large shows that our method is capable of generating high-quality augmentation examples to enhance the RoBERTa-Large model on the most fine-grained intent detection task.

Few-shot settings. In this setting we only use a small number of instances (datapoints) per class. We evaluate our method in both 5-shot and 10-shot settings and compare it with several strong baselines. Our proposed method outperforms all baselines on all datasets in both 5-shot and 10-shot settings. ICDA-M achieves the best performance in 5-shot settings on BANKING dataset and ICDA-XL achieves the best performance on HWU and CLINC datasets in 5-shot settings and on all datasets in 10-shot settings. All configurations of our method significantly improve the performance of a RoBERTa-Large model trained on any of the three datasets. Compared with CPFT (Zhang et al., 2021b), which utilizes contrastive learning for few-shot intent detection with extra data, our method achieves better performance without any additional human-annotated data. This showcases the advantage of our method for few-shot intent detection.

We also observe that our method consistently improves the performance of the baseline model as the number of synthetic datapoints increases from XS to XL. This indicates that the generated instances from our method can gradually cover more and more information of real instances and are capable of providing more useful information for model training.

6 Analysis and Discussion

In this section, we analyze the performance of ICDA and other approaches we tried. We first identify several factors that affect performance, and then present evidence that ICDA works by transferring knowledge from the pretrained generator to the task model. We then discuss a data-relabelling experiment and an experiment using uncertainty measures or data cartography (Swayamdipta et al., 2020) as filters.

6.1 Factors that Affect ICDA Performance

ICDA is effective at various training sizes. Throughout this work, we conduct experiments with different seed data sizes[4] to study the effect of

---

[4] By *seed data*, we mean data taken from each dataset, i.e. not synthetic data produced by ICDA.

Table 2: Intent Detection Accuracy (in %) in few-/full-shot settings with augmented data from OPT-66B. Numbers in bold are the best results and numbers with * are statistically significant by t-test ($p < 0.05$) compared to the baselines (**5** / **10** examples per intent).

	Model	BANKING	HWU	CLINC
	RoBERTa-Large	86.08	84.11	93.56
	All	84.19	84.57	94.24
	All w/ relabeling	87.05	85.22	93.02
PVI	Global Low PVI	73.99	69.61	85.42
	Global High PVI	87.38	86.27	94.27
	Per-Intent Low PVI	76.49	71.84	89.33
	Per-Intent High PVI	**88.64**	**87.36**	**94.71**

Table 3: Intent Detection Accuracy (in %) for RoBERTa-Large model in 10-shot settings with ICDA-M synthetic instances from OPT-66B. Numbers in bold are statistically significant by t-test ($p < 0.05$). "All" represents using all synthetic data without PVI filtering. and "All w/ relabeling" represents using "All" and an oracle intent classifier to relabel the synthetic data.

training size. By looking at the results in Table 2, we observe that our proposed method consistently improves the accuracy of the downstream model in all training sizes. Also, as the training size decreases, we see that the ICDA improvement increases significantly. For example, on BANKING, the improvement goes from 0.72% in the full shot setting to 5.02% as the training size decreases to 5-shot. This indicates that ICDA is more effective when we have few training data available.

PVI filtering threshold. To study the effect of the threshold function ϵ, we conduct experiments with two different threshold functions: *Global*, and *Per-Intent*. *Global* means that the PVI threshold is the same for all intent classes, which is the average PVI value in the validation set. *Per-Intent* means that the PVI threshold is different for each intent class, which is the average PVI value under each intent class in the validation set. As a sanity check, we also conduct experiments using synthetic instances with PVI values lower than the threshold (*Low PVI)* as opposed to the normal (*High PVI)* instances.

We show the results in Table 3 (bottom half), where we see that *Per-Intent High PVI* filtering performs the best. Compared to using all synthetic training data without filtering (referred to as *All*), we see that *High PVI* filtering in general helps in improving accuracy. In BANKING, for example, when PVI filtering is applied with *Per-Intent High PVI*, the accuracy is 88.64% with 10-shot training size, which is significantly better than the result without PVI filtering (84.19%) – the same holds for the other two datasets. For the *Low PVI* conditions, we observe that performance drops significantly. This indicates that the model overfits on those examples that are not relevant to the desired intent. We discuss the *All w/ relabelling* condition in Section 6.3.

In Figure 2, we plot the F1 score against the PVI score of the test set instances grouped by intent, showing that some classes are harder than others, further supporting why we need a threshold per class rather than a global one.

6.2 Why Does ICDA Work?

PVI filtering discards mislabeled examples. We believe that the success of ICDA is because of not only the high diversity of the synthetic instances produced by the generator, but also the fact that PVI filtering effectively discards digressed instances. To verify this hypothesis,

Data	Prompt Label	Generated Sentence	PVI
BANKING	Refund not showing up (PVI Threshold: 5.79)	I didn't see my refund appear on my statement.†	**6.10**
		Where did your refund end up at? Please send it back immediately since I had a return and then refunded your purchase in full and I want it all returned back to my credit card.†	**5.81**
		Can we please cancel my return & resend my goods again	3.97
		Please confirm what is the reason for delay in payment for my purchase?	-3.86
HWU	alarm query (PVI Threshold: 4.28)	show me all the alarms and remind me about them†	**5.69**
		i want to be notified when alarm goes off.†	**4.36**
		how do i delete or disable alarms.	3.18
		list all the events on this date	-5.13
CLINC	accept reservation (PVI Threshold: 6.53)	does hanover steakhouse take reservations†	**6.74**
		are there any restaurants that take reservations for dinner in philadelphia†	**6.58**
		how many days prior is required for making reservations	5.39
		what time does bibiana's in greenwich open	−4.31

Table 4: Synthetic examples generated from OPT-66B. † indicates the sentences that belong to the same intent as the prompt label from our manual assessment; and bold denotes the PVI values over the threshold for given label.

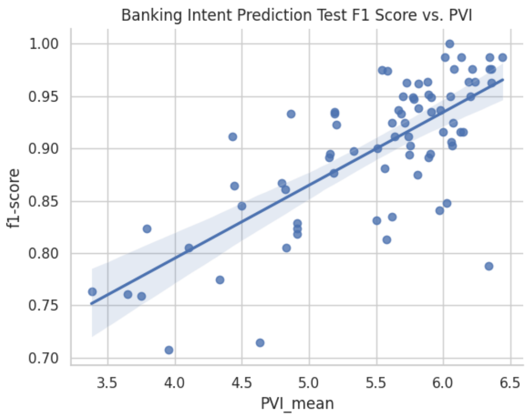

Figure 2: Intent Detection F1 score per intent class (circle) of the BANKING test set, justifying why we need a PVI threshold per intent.

Data	Split	D-1 ↑	D-2 ↑	Self-BLEU ↓	PPL ↓
Bank.	Test	-	-	-	12.14
	10-shot	0.15	0.54	0.24	**17.34**
	ICDA	**0.21**	**0.66**	**0.11**	21.33
HWU	Test	-	-	-	14.84
	10-shot	0.25	0.71	0.07	**26.97**
	ICDA	**0.30**	**0.78**	**0.03**	28.52
CLINC	Test	-	-	-	14.77
	10-shot	0.15	0.49	0.28	**34.23**
	ICDA	**0.20**	**0.60**	**0.17**	37.34

Table 5: Quantitative metrics of fluency and diversity of real and synthetic utterances in 10-shot settings as measured with distinct-1 (D-1), distinct-2 (D-2), self-BLEU, and perplexity.

we randomly sample several synthetic instances from the OPT-66B generator and manually assess if each instance follows the same intent as the prompt label. We show some examples in Table 4. We observe that instances that are relevant to the desired intent are assigned high PVI values, and instances that are not relevant to the desired intent are assigned low PVI values. This further indicates that the per-intent threshold function provides an effective indicator of relevance. For example, in the BANKING dataset, most relevant instances have PVI values greater than 5.79, and most non-relevant instances have PVI values less than 5.79. This indicates that PVI filtering is an effective method for discarding mislabeled data points.

ICDA produces fluent and diverse utterances. We hypothesize that our proposed method is effective because it introduces more fluent and diverse utterances. We therefore compare synthetic data under the 10-shot XS condition (i.e., we generate 10 synthetic datapoints) with the original 10-shot datapoints taken from the training data. Then we use a GPT2 model trained on the test set of each benchmark dataset to calculate the perplexity of the generated utterances. We also use the same synthetic set to calculate the distinct-1, distinct-2, self-BLEU, and perplexity (PPL) metrics. We report the results in Table 5 and observe that our proposed method generates more diverse utterances as shown by distinct-1, distinct-2, and self-BLEU. This indicates that our proposed method harnesses the generation power of the OPT-66B generator. Additionally, the perplexity of synthetic utterances is slightly higher than the human-annotated training set. These results suggest that our proposed method generates more diverse utterances, which can help the task model to learn a better representation.

6.3 Data Relabelling

Following Sahu et al. (2022), we wanted to see if it is effective to use the available data to train an intent classifier and then use it to relabel the synthetic data. Intuitively, such a method would correct mistakes in the generation process. To test the feasibility of this approach, we train an oracle classifier using the entire training data of each dataset and use this as an upper bound. The results are shown in Table 3 (“All w/ relabeling"), where we see that while promising, this approach underperforms ICDA.

7 Conclusion

We introduced **I**n-**C**ontext **D**ata **A**ugmentation, a novel data augmentation framework to generate synthetic training data, preserving quality and diversity. We demonstrate that ICDA is effective on multiple intent detection benchmarks, with state-of-the-art few-shot performance. Our analysis shows that ICDA tends to perform better in low-resource settings and that our PVI filtering strategy is important for performance. Future work includes applying ICDA to other conversational understanding tasks such as slot filling and dialogue state tracking, and incorporating other filtering or data selection strategies for further performance gains.

Limitations

In this section we take BANKING as a case study to motivate PVI and discuss some of the limitations of our approach. Figure 3 shows how much we gain (or lose) in F1 score when we use a custom threshold for each class vs. a fixed threshold. While most classes benefit, there are clearly many that show performance degradation. Another limitation is the size of the model we use to generate synthetic instances (OPT-66B); in general the larger the model is, the better the generated data is.

Ethical Considerations

As with any work involving PLMs (or *foundation models*), due to the data and training methods, there is inherent risk of generating biased, toxic, harmful, or otherwise unwanted output. Regarding our work in particular, as we show in Figure 3, the model's performance on some of the classes can degrade. More analysis needs to be done before deploying our approach, since it is unclear whether it will introduce a bias towards certain types of classes.

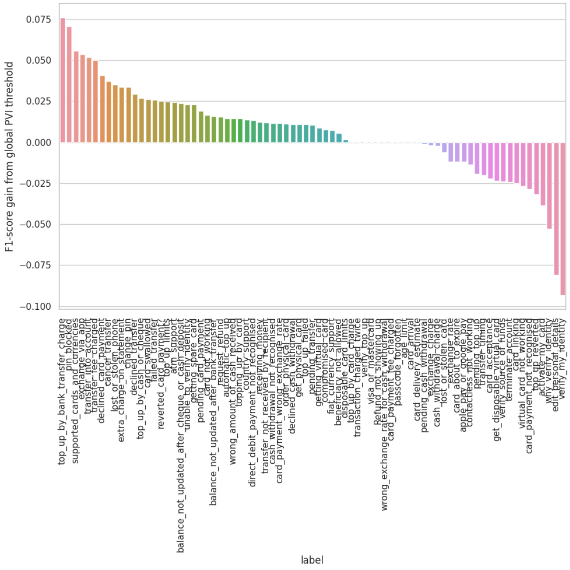

Figure 3: This figure shows the difference in Intent Detection F1 score for each intent, if we have a PVI threshold per-class VS having a fixed PVI threshold. See larger figure in Appendix.
