Therefore, in this work, we propose a novel selection scheme for predicted answers from the conversation history, which filters out predictions that are likely to be incorrect, unlike the existing work that uses all the predicted answers including incorrect ones. The remaining step is then to identify possibly incorrect predictions. To this end, we propose to use the confidence and uncertainty of the model's prediction, which are measured by its likelihood and entropy, respectively. In particular, if the model predicts the previous answer with lower confidence (i.e., lower likelihood) or higher uncertainty (i.e., higher entropy) than a certain threshold, we regard the model's previous answer as probably incorrect, and remove it from the conversation history in answering the current question during evaluation. On the other hand, during training, we soften the sampling process so that, instead of using the hard threshold above, we sample a predicted answer based on its confidence or uncertainty (e.g., the lower the uncertainty, the higher the chance to include the predicted answer in the conversation history), in order to diversify the model's input.

However, when dealing with confidence and uncertainty, we should be careful about a miscalibrated situation (Guo et al., 2017), which happens when uncertainty and confidence do not correspond to the error and accuracy of ground-truth correctness, respectively. In other words, if the model is not calibrated enough and the distribution for confidence and uncertainty is highly skewed over particular ranges, the highly uncertain or low confident yet valid predictions could be removed. Therefore, to prevent such a performance degrading situation, we further calibrate models using a temperature scaling scheme (Guo et al., 2017) before estimating the uncertainty or confidence. We refer to our method as Answer Selection-based realistic Conversational Question Answering (AS-ConvQA).

We validate our method on two standard ConvQA datasets, QuAC (Choi et al., 2018) and CoQA (Reddy et al., 2019), against diverse baselines on a realistic evaluation protocol. The experimental results show that our method significantly outperforms these baselines, and a detailed analysis supports the importance of uncertainty- and confidence-based answer selection schemes.

Our contributions in this work are threefold:

- We propose to remove incorrect predictions in a conversation history, which degenerate ConvQA models' performances during inference.
- We present confidence- and uncertainty-based answer filtering schemes, which are further calibrated to obtain reliable predictions.
- We show that our method achieves outstanding performances on realistic ConvQA tasks.

2 Related Work

Conversational Question Answering ConvQA requires a model to understand the context of questions and paragraphs along with previous conversational questions and answers (Choi et al., 2018; Reddy et al., 2019). While the simplest approach to consider such conversation histories is to embed them along with the given question and paragraph in the representation space, recent work (Huang et al., 2019; Qu et al., 2019b; Chen et al., 2020) proposed to leverage the relevant histories by selectively using them. However, Vakulenko et al. (2021) and Kim et al. (2021) have shown that even a simple concatenation of previous questions and answers outperforms these selection-based methods, thanks to the advances in pre-trained language models (Devlin et al., 2019; Liu et al., 2019) that are designed to attend to the relevant parts. Furthermore, recent methods (Elgohary et al., 2019; Kim et al., 2021; Vakulenko et al., 2021; Raposo et al., 2022) rather focus on the problem of ambiguity in the input question by proposing a question rewriting scheme for its disambiguation, showing remarkable performance improvements.

However, the aforementioned work has a fundamental limitation on the evaluation protocol: They evaluate models based on ground-truth answers working as a conversation history, which are not available in a real-world setting. Li et al. (2022) point out this problem of ground-truth history evaluation but use the ground-truth answers during evaluation as well, since they target at disambiguating pronouns in the question by comparing the predicted and ground-truth answers. Alternatively, Mandya et al. (2020) and Siblini et al. (2021) use the model's predictions instead of the ground-truth answers during evaluation, and further train the model with predicted answers. However, they do not take into account the quality of predicted answers, where low-quality ones are not useful (see Figure 1). Thus, we propose to selectively use the predicted answers that are probably correct, based on their calibrated confidences and uncertainties.

Confidence and Uncertainty As it is nearly impossible for models to always make accurate predictions, unreliable predictions become serious issues when deploying machine learning models to real-world settings. Motivated to prevent such a risk, mechanisms of estimating the reliability of model's predictive probabilities based on confidence and uncertainty are recently proposed (Abdar et al., 2021; Houben et al., 2022). We note that confidence is usually measured by the softmax outputs of models (Guo et al., 2017), and that uncertainty can be quantified by Bayesian models, which can be approximated via Monte Carlo (MC) dropout (Gal and Ghahramani, 2016; Kendall and Gal, 2017). With much work on confidence and uncertainty estimations in computer vision tasks (Guillory et al., 2021), related topics have been recently adopted for NLP tasks as well (Shelmanov et al., 2021; Wu et al., 2021; Malinin and Gales, 2021; Vazhentsev et al., 2022). While confidence and uncertainty estimation should also be considered in ConvQA, we believe that this venue is under-explored so far. In particular, since questions are asked sequentially, it is likely that untrustworthy predictions in the conversation history would negatively affect the performance. To tackle this, we propose to exclude low-confident or uncertain predictions when training and evaluating the ConvQA model.

Calibration Confidence and uncertainty help interpret the validity of the model's prediction. However, it is not safe to rely on them when the model is not calibrated, where the correct likelihood does not match the predicted probability (Guo et al., 2017), or the model error does not match the predicted uncertainty (Laves et al., 2019). Since deep neural networks are prone to miscalibration as the number of parameters has much increased, large pre-trained language models are also not free from this problem (Wang et al., 2021; Zhao et al., 2021; Dan and Roth, 2021). One of the most prevalent approaches to calibrating the model is to rescale a logit vector before the softmax function for regularizing the probability, which is known as temperature scaling (Guo et al., 2017). While there exist lots of calibration schemes, including label smoothing (Szegedy et al., 2016) and confidence penalty (Pereyra et al., 2017), in this work, we use temperature scaling as a calibrator, since it is simple yet effective while not changing the output class of the model prediction (i.e., only scaling logits).

3 Method

We first introduce ConvQA. Then, we describe our answer validating methods based on confidence and uncertainty values with their calibration schemes.

3.1 Conversational Question Answering

We provide general descriptions of a ConvQA task. For the i-th turn of the conversation, we are given a question Q_i and its corresponding context C, as well as its conversation history consisting of previous questions and answers: $\mathcal{H}_i = \{Q_{i-1}, A_{i-1}, ..., Q_1, A_1\}$. Then, the goal of ConvQA is to correctly extract the ground-truth answer A_i from C along with Q_i and $\mathcal{H}_i$, as follows:

$$P(A_i) = M_\theta(C, Q_i, Q_{i-1}, A_{i-1}, ..., Q_1, A_1), \quad (1)$$

where M_θ is a ConvQA model, parameterized by θ, and, for the sake of simplicity, we omit conditional variables C, Q_i, and $\mathcal{H}_i$ on the left side of Equation 1, i.e., $P(A_i) = P(A_i|C, Q_i, \mathcal{H}_i)$. Note that existing work (Elgohary et al., 2019; Kim et al., 2021; Vakulenko et al., 2021; Raposo et al., 2022) has an unrealistic assumption that a set of ground-truth answers $\{A_{i-1}, ..., A_1\}$ is available during evaluation as in Equation 1. However, this evaluation setup is far from reality, since they are not always available when the user's novel questions come in, unlike the training phase which optimizes a model with ground-truth answers. Therefore, we should particularly modify the formulation in Equation 1 to accommodate a realistic evaluation scenario, which we describe in the next subsection.

3.2 Realistic ConvQA

To tackle the problem of accessing ground-truth answers during evaluation in Equation 1, we aim at redefining its formulation to evaluate ConvQA models under real-world situations as shown below.

Evaluation When a user asks a unique question whose ground-truth answers are not accessible, the most naïve approach is to work with the relevant context and previous questions, as follows:

$$P(\bar{A}_i) = M_\theta(C, Q_i, Q_{i-1}, ..., Q_1), \qquad (2)$$

where $\bar{A}_i$ denotes the i^{th} predicted answer $(i > 1)$ during inference time. However, the formulation in Equation 2 may be suboptimal, since it ignores predicted answers $\{\bar{A}_{i-1}, ..., \bar{A}_1\}$ that occurred in the former conversation, which may be beneficial for the current prediction. Thus, we can instead make inference with predicted answers, as follows:

$$P(\bar{A}_i) = M_\theta(C, Q_i, Q_{i-1}, \bar{A}_{i-1}, ..., Q_1, \bar{A}_1). \qquad (3)$$

However, when evaluating with Equation 3 while training with Equation 1, a problematic discrepancy arises, as model M_θ uses gold answers A_i for training but predicted answers $\bar{A}_i$ for inference.

Training To tackle this inconsistency, recent work (Mandya et al., 2020; Siblini et al., 2021) randomly decides whether to use $\bar{A}_i$ or A_i during the training phase, as follows:

$$P(A_i) = \begin{cases} M_\theta(C, Q_i, Q_{i-1}, \bar{A}_{i-1}, ...) \text{ w.p. } \lambda_{rand}, \\ M_\theta(C, Q_i, Q_{i-1}, A_{i-1}, ...) \text{ w.p. } 1 - \lambda_{rand}, \end{cases} \qquad (4)$$

where λ_{rand} is the probability of using $\bar{A}_i$, which is set based on heuristic sampling schemes, either using the random coin flipping or increasing the sampling rate based on the number of steps.

While such an attempt bridges the gap between training and inference in the real-world setting, critical limitations remain. First, as Figure 1 shows, we observe that using all the predicted answers rarely contributes to the model performance, as they include incorrect answers that hinder accurate predictions for the current question. Also, we further point out that there still exists a discrepancy between training and evaluation: The model observes ground-truth answers in Equation 4 which are yet unobservable for evaluation in Equation 3. Therefore, to tackle these challenges, we propose to selectively use the predicted answers based on the predictions' confidences and uncertainties.

3.3 Predicted Answer Selection Scheme

Our key intuition is that confidence and uncertainty are simple yet effective measures to filter out inaccurate predictions. Before going into details, we first define the notations. Let $\boldsymbol{x_i} \in X$ be an i^{th} input (i.e., turn) for ConvQA model M_θ, which consists of current question Q_i, its relevant context C, and conversation history $\mathcal{H}_i$. Then, labels of given input $\boldsymbol{x_i}$ are defined as $y_i^{(start)} \in C$ and $y_i^{(end)} \in C$ with $C \in \{1, ..., K\}$, where K is the number of sequence lengths for context C. In other words, $y_i^{(start)}$ and $y_i^{(end)}$ denote the start and end spans, respectively. Further, to predict labels $y_i^{(start)}$ and $y_i^{(end)}$, we first obtain a logit vector $\boldsymbol{z}_i$ for each label[1], and use it for calculating a probability vector $\boldsymbol{p}_i$ over K spans: $\boldsymbol{p}_i = \texttt{softmax}(\boldsymbol{z}_i)$, where `softmax` is a softmax function.

Confidence We now define the confidence. From the probability $\boldsymbol{p} = \texttt{softmax}(\boldsymbol{z})$, a model likelihood can be interpreted as confidence, as follows[2]:

$$s_{conf} = \max_{y \in C} p(y|\boldsymbol{z}), \qquad (5)$$

where s_{conf} denotes the confidence value.

Uncertainty While confidence can estimate how confident the model is on its prediction, it might be also beneficial to measure the model's certainty with Bayesian deep learning techniques (Kendall and Gal, 2017) to prevent erroneous predictions, which we describe here. At first, to calculate the uncertainty value, we need to obtain N different predictions for approximating the model's distribution. To do so, we first enable dropout (Srivastava

---

[1] We omit superscripts *start* and *end* for simplicity.

[2] For simplicity, we omit a turn index i, which is represented in a subscript, for example, Q_i for the i^{th} conversation.

et al., 2014) in the language model during inference, and then forward input $\boldsymbol{x}$ for N times with N different dropout masks, which is referred to as Monte Carlo (MC) dropout (Gal and Ghahramani, 2016). Then, we can obtain probability vector $\boldsymbol{p}$ via MC integration: $\boldsymbol{p} = \frac{1}{N}\sum_{n=1}^{N} \texttt{softmax}(\boldsymbol{z}^{(n)})$, where $\boldsymbol{z}^{(n)}$ is the logit vector from each forward pass. Then, based on probability $\boldsymbol{p}$, the uncertainty is quantified via its entropy over K classes (Kendall and Gal, 2017; Laves et al., 2019), as follows:

$$s_{uncer} = -\frac{1}{\log K}\sum_{k=1}^{K} p(k)\log p(k), \quad (6)$$

where s_{uncer} denotes the uncertainty value, which we normalize to be on a scale between 0 and 1 with $\frac{1}{\log K}$ in Equation 6, following (Laves et al., 2019).

3.4 Calibrating Confidence and Uncertainty

We then describe the calibration schemes to match the model's predicted confidence and uncertainty to its correct likelihood and error, respectively.

Perfect Calibration In order to calibrate trustworthiness of the confidence and uncertainty, we first describe perfectly calibrated situations. Given the input $\boldsymbol{x}$, the model predicts the most likely class, $\bar{y} = \arg\max \boldsymbol{p}$, from the entire classes with the highest probability, $\bar{p} = \max \boldsymbol{p}$. Each perfect calibration for confidence and uncertainty is then as follows (Guo et al., 2017; Laves et al., 2019):

$$\begin{aligned} &\mathbb{P}(\bar{y} = y | s_{conf} = p) = p, \\ &\mathbb{P}(\bar{y} \neq y | s_{uncer} = p) = p, \end{aligned} \quad (7)$$

where y denotes the true label with $\forall p \in [0, 1]$.

Calibration and Uncertainty Error However, perfect calibration defined in Equation 7 is hardly achievable in practical settings due to noise and prediction errors. Thus, we rather define a calibration error to estimate how much the model's prediction is calibrated. One of the most prevalent methods to quantify calibration error for confidence is to measure the difference in expectation between confidence and accuracy as follows (Guo et al., 2017):

$$\mathbb{E}_{s_{conf}}[\, |\mathbb{P}(\bar{y} = y | s_{conf} = p) - p|\,], \quad (8)$$

where $\forall p \in [0, 1]$. Also, miscalibration of uncertainty is quantified as follows (Laves et al., 2019):

$$\mathbb{E}_{s_{uncer}}[\, |\mathbb{P}(\bar{y} \neq y | s_{uncer} = p) - p|\,]. \quad (9)$$

However, since s_{conf} and s_{uncer} lie in a continuous domain, it is impossible to sample them infinite times for every p when measuring calibration errors. Therefore, we further approximate them in a discrete space, which was in the continuous domain (Equations 8, 9), by dividing the predictions into M bins and then measuring accuracy for each corresponding bin. Formally, accuracy and confidence per bin are as follows (Guo et al., 2017):

$$\begin{aligned} \texttt{acc}(B_m) &= \frac{1}{|B_m|}\sum_{i \in B_m} \mathbf{1}(s_{conf} = y^{(i)}), \\ \texttt{conf}(B_m) &= \frac{1}{|B_m|}\sum_{i \in B_m} s_{conf}, \end{aligned} \quad (10)$$

where B_m is a set of label indices whose values are within the m^{th} bin among M non-overlapping bins. Similarly, error and uncertainty per bin are formally defined as follows:

$$\begin{aligned} \texttt{err}(B_m) &= \frac{1}{|B_m|}\sum_{i \in B_m} \mathbf{1}(s_{uncer} \neq y^{(i)}), \\ \texttt{uncer}(B_m) &= \frac{1}{|B_m|}\sum_{i \in B_m} s_{uncer}. \end{aligned} \quad (11)$$

Using definitions in Equations 10, 11 above, we now measure the approximated calibration errors. Regarding confidence, the Expected Calibration Error (ECE) (Guo et al., 2017) is defined as follows:

$$ECE = \sum_{m=1}^{M} \frac{|B_m|}{n} |\texttt{acc}(B_m) - \texttt{conf}(B_m)|, \quad (12)$$

where n is the number of samples in total. For uncertainty, Expected Uncertainty Calibration Error (UCE) (Laves et al., 2019) is defined as follows:

$$UCE = \sum_{m=1}^{M} \frac{|B_m|}{n} |\texttt{err}(B_m) - \texttt{uncer}(B_m)|. \quad (13)$$

Calibration with Temperature Scaling With the calibration criteria (i.e., ECE and UCE), we now aim at obtaining well-calibrated confidence and uncertainty values having low ECE and UCE. To do so, we apply a temperature scaling scheme, which regulates the scale of the obtained logit vector $\boldsymbol{z}$ with a single scalar, namely temperature $\tau > 0$. Note that temperature scaling does not affect the maximum value of the softmax output; therefore, accuracy is preserved. Formally, the calibrated probability vector $\hat{\boldsymbol{p}}$ is defined as follows:

$$\hat{\boldsymbol{p}} = \texttt{softmax}(\boldsymbol{z}/\tau). \quad (14)$$

We find the τ value based on the low calibration errors, i.e., ECE and UCE, in experiments.

3.5 Overall Pipeline

We now summarize the overall pipeline of our AS-ConvQA framework, which leverages the calibrated confidence and uncertainty values to sample valid predictions for inference, while using them during training as well. Our training pipeline consists of two steps, which we explain below.

Step 1 We start training a model with gold answers A_i following the training protocol in Equation 1, since, if the model cannot observe gold answers, it might fail to capture and generate accurate answers, easily leading to degenerated performances (Mandya et al., 2020). Then, to prepare for Step 2, we make inference with it to obtain prediction $\bar{A}_i$ together with its confidence and uncertainty, for each input $\boldsymbol{x}_i$ in the training set.

Step 2 With the predicted answers and their confidences and uncertainties from Step 1, we further train the model to reflect the predicted answers instead of the ground-truth answers. Note that our objective is to filter out less confident or uncertain predictions in inference. Thus, since filtered ones are not observable during our realistic evaluation phase, we also aim at reflecting such an occurrence during training to narrow the gap between training and evaluation. To do so, instead of training with all predicted answers, we rather sample a predicted answer based on its confidence or uncertainty value:

$$P(A_i) = \begin{cases} M_\theta(C, Q_i, Q_{i-1}, \bar{A}_{i-1}, ...) \text{ w.p. } \lambda_{valid}, \\ M_\theta(C, Q_i, Q_{i-1}, ...) \text{ w.p. } 1 - \lambda_{valid}, \end{cases} \tag{15}$$

where λ_{valid} is obtained by the previous prediction's ($\bar{A}_{i-1}$) confidence or uncertainty: $\lambda_{valid} \in [s_{conf}, 1 - s_{uncer}]$. Note that, in contrast to existing work (Mandya et al., 2020; Siblini et al., 2021) represented in Equation 4, our work does not use previous gold-answers (A_{i-1}) for training as well.

For evaluation, we follow the realistic evaluation protocol described in Equation 3. However, instead of using all predictions (Mandya et al., 2020; Siblini et al., 2021), we rather remove low-confident or uncertain predictions against the threshold.

4 Experimental Setups

We explain datasets, metric, and models. Please see Appendix A for further implementation details.

4.1 Dataset and Metric

QuAC QuAC (Choi et al., 2018) is the benchmark ConvQA dataset, which is known to resemble a realistic information seeking dialogue, where questioners were prevented from reading paragraphs for its collection. QuAC consists of 14K dialogues and 100K pairs of questions and paragraphs. As the test set is not publicly open, we use a development set.

	QuAC		CoQA	
	BERT	**RoBERTa**	**BERT**	**RoBERTa**
Gold	59.86	65.08	72.79	77.62
No Pred.	55.44	61.24	70.83	75.56
All Pred.	55.76	61.53	71.28	75.42
CoQAM	55.83	61.55	71.27	74.29
Robust-P	54.21	60.32	70.17	73.96
Attentive Selection	55.74	61.42	71.05	74.60

AS-ConvQA$_{\texttt{uncer}}$ (Ours)	**57.35**	**62.33**	**72.08**	**76.33**
AS-ConvQA$_{\texttt{combine}}$ (Ours)	**57.06**	**62.18**	**71.99**	**76.76**

Table 1: F1-scores on QuAC and CoQA. Note that Gold model is not a fair baseline as it uses the ground-truth answers during inference, and thus is evaluated in an unrealistic setting.

CoQA CoQA (Reddy et al., 2019) is another ConvQA dataset with 127K pairs of questions and paragraphs; however, unlike QuAC, questioners were allowed to share paragraphs during collection. We also use a development set instead of the test set, which is not publicly available.

F1-score We evaluate models with F1-score, following the standard protocol (Kim et al., 2021).

4.2 Question Answering Models

For question answering models, we use two base-size pre-trained language models widely used in ConvQA tasks: **BERT-base** (Devlin et al., 2019) and **RoBERTa-base** (Liu et al., 2019).

4.3 Baselines and Our Models

We compare AS-ConvQA to other relevant baselines using predicted answers. Gold model, which is an indicator, uses gold answers as the answer history during evaluation, which is not realistic, whereas all the others are evaluated with predicted answers. All models are trained with the same protocol, using gold answers as the conversation history for the first half of training epochs (Step 1).

Gold This model uses the ground-truth answers during training and evaluation, thus unrealistic.

No Prediction (No Pred.) This model does not use the predicted answers as the conversation history in either training or evaluation steps.

All Prediction (All Pred.) In contrast to No Pred., this model uses all the predicted answers during both training and evaluation steps.

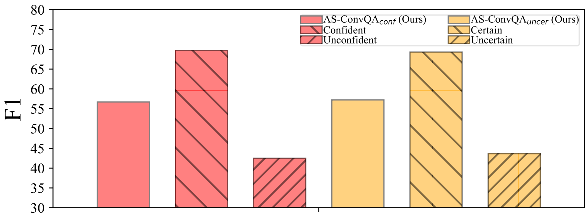

Figure 2: Comparison results of certain (confident) and uncertain (unconfident) predictions on QuAC. Note that a threshold is set as the median of the uncertainty (confidence) values.

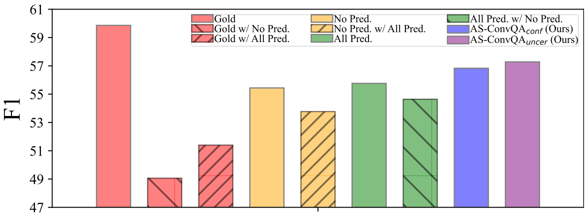

Figure 3: F1-scores on the mismatching evaluation settings for each baseline model on QuAC, either using all of the predictions or none of them as the previous answer history.

CoQAM For training, this model uses the random sampling scheme represented in Equation 4, which samples either predicted or ground-truth answers with coin-flipping (Mandya et al., 2020). For evaluation, it uses all the predictions as the history.

Robust-P Similar to CoQAM, this model uses a heuristic answer sampling scheme in a random manner, but increases the predicted answer sampling rate for training (Siblini et al., 2021). Also, it is evaluated with all predicted answers.

Attentive Selection This model uses the attention mechanism to softly select the relevant answers in the history, following previous work (Qu et al., 2019b; Huang et al., 2019; Chen et al., 2020).

AS-ConvQA$_{\texttt{conf}}$ (Ours) This is our model that filters out unconfident answers via confidence values during training and evaluation, after calibration.

AS-ConvQA$_{\texttt{uncer}}$ (Ours) This is also our model that filters out uncertain answers during training and evaluation, after calibrating uncertainty values.

AS-ConvQA$_{\texttt{combine}}$ (Ours) This model combines our confidence and uncertainty modules, where we use the mean of calibrated confidence and (1-uncertainty) values for filtering out samples.

5 Results and Discussion

In this section, we show overall performances of our proposed method along with detailed analyses.

Main Results As Table 1 shows, the proposed AS-ConvQA models including confidence and uncertainty schemes show significant performance gains over all baselines on two different QA models. Interestingly, No Pred. model, which does not utilize previous answers as the conversation history, shows comparable to or even better performance than the other baseline models based on either exploiting all the predicted answers or randomly sampling them with heuristic ratios. This implies that it is more helpful not to use low-quality predicted answers – unconfident or uncertain – at all than to use them. On the other hand, our models take advantage of filtering out probably invalid predictions, thus achieving improved performance.

Moreover, our AS-ConvQA models outperform the attention-based history selection model (i.e., Attentive Selection). This is because, even though previous answers are all incorrect, the attention scheme should leverage some of them (i.e., the sum of attention scores for previous answers should be 1), which leads the model to answer with an inaccurate history. Meanwhile, AS-ConvQA models can ignore possibly wrong predictions, thus decreasing the risk of being affected by the inaccurate history.

Last, when combining confidence and uncertainty modules, the performance is not much further enhanced. To analyze this, we first measure the number of overlapping questions, where each of the AS-ConvQA$_{\texttt{conf}}$ and AS-ConvQA$_{\texttt{uncer}}$ models predicts with higher confidence or lower uncertainty than its median value. Then, we observe that about 74.82% and 77.12% of the questions overlap on QuAC and CoQA, respectively. This indicates that unconfident and uncertain samples are highly correlated, which are likely to be filtered out by both confidence- and uncertainty-based models. In other words, due to similar effects of AS-ConvQA$_{\texttt{conf}}$ and AS-ConvQA$_{\texttt{uncer}}$ models, the performance of combined models is not much improved.

Unconfident and Uncertain Predictions In order to see whether predictions with low confidence or high uncertainty actually correspond to incorrect answers, we compare the performances between the certain (unconfident) and uncertain (confident) predictions. As Figure 2 shows, low-confident and uncertain samples lead to drastic performance degradation. This result corroborates our hypothesis that a prediction with low confidence or high uncertainty acts as an obstacle in ConvQA tasks.

Impact of Realistic Evaluation Setups To see results in realistic settings – not using ground-truth answers during inference – for the Gold model, we

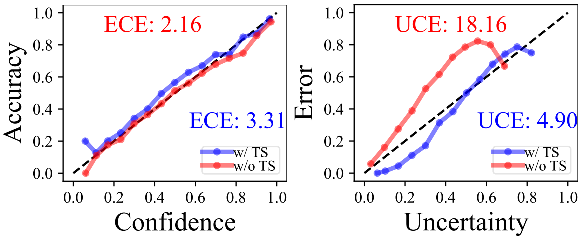

Figure 4: Reliability diagrams with and without temperature scaling (TS), regarding confidence or uncertainty on QuAC.

train it with ground-truth answers, and then test either with predicted answers or without them. Figure 3 shows that performances of the Gold model are drastically dropped, and even lower than both No Pred. and All Pred., even though tested on the same strategies. This can be explained with the term of exposure bias (Bengio et al., 2015; Mandya et al., 2020), where a discrepancy exists between training and evaluation, which hinders the model from performing well on test data that differs from training data. Furthermore, this also explains one of the reasons why CoQAM and Robust-P models perform poorly: Since they observe ground-truth answers for training, which are not observable during evaluation, they underperform ours.

Training & Evaluation Discrepancy We have observed a discrepancy between training and evaluation for the Gold model above. Then, the next possible question is whether this discrepancy also happens for models that are trained on the predicted answers, but evaluated in different settings. To see this, we test No Pred. and All Pred. models in a mismatching evaluation setting. As Figure 3 shows, a discrepancy exists for both models, though the gaps are smaller than the Gold model. This implies that even if a ConvQA model is trained on the predictions, the problem of discrepancy should not be ignored. Meanwhile, our proposed models can alleviate such an issue with a selective sampling scheme based on confidence and uncertainty.

Effectiveness of Calibration We show the effect of calibration on confidence and uncertainty values in Figure 4. Regarding confidence, the QA model already generates calibrated scores; thus there is no reason to scale the logit vector with temperature scaling (i.e., w/ temperature scaling yields more errors in terms of ECE). However, regarding uncertainty, the estimated uncertainty scores from the model have high errors in terms of UCE, i.e., not calibrated. Thus, after applying the temperate scaling scheme, the uncertainties become calibrated.

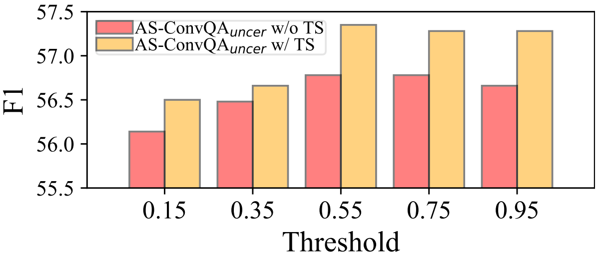

Figure 5: Comparison between the calibrated and not calibrated AS-ConvQA$_{\text{uncer}}$ with varying thresholds on QuAC.

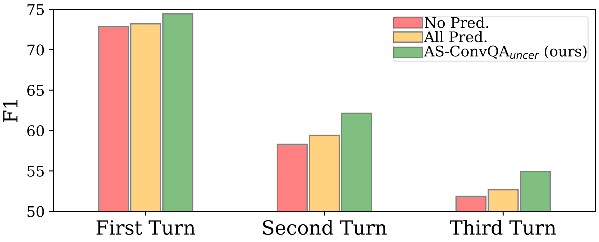

Figure 6: F1-scores for the first, second, and third conversational turns on QuAC with baselines and our AS-ConvQA.

Note that the calibrated uncertainties further contribute to the performance gain, as Figure 5 shows, since the model can observe a broad range of uncertainty values during training, making the model easily capture and reject uncertain predictions.

Effectiveness on Conversational Turns To see how the proposed AS-ConvQA contributes to the quality of the conversation as it proceeds, we further analyze the performances of former and latter conversational turns. As shown in Figure 6, both the former and latter turns benefit from our AS-ConvQA, and the performance improvements are more significant on the latter turn. This result implies that our AS-ConvQA effectively prevents the accumulation of errors, which originate from the incorrect predictions in the previous turns.

Case Study We conduct a case study. As the first example in Table 2 shows, even though both All Pred. and AS-ConvQA$_{\text{uncer}}$ models inaccurately predict $\bar{A}_6$, they handle it differently: All Pred. accepts it, while ours reject it for the subsequent question. In particular, All Pred. model misinterprets 'this' as 'big break' when answering Q_6 as well as Q_7; however, since 'this' actually refers to 'Laputa: Castle in the Sky', All Pred. further propagates the misleading prediction to the next question. By contrast, our model decides not to select $\bar{A}_6$ as a conversational history due to its high uncertainty, thus not repeating the previous mistake when answering Q_7. The proportion of such examples is about 0.52, where our model predicts the previous answer incorrectly but answers the next

question with a high F1-score over 50. This emphasizes the importance of our selection scheme, especially when there exist ambiguous words prone to mispredictions.

In addition to this case of removing the uncertain previous prediction, we further compare our model against the No Pred. model in the case where the model predicts with the previous answer history having a low uncertainty value. As the second example in Table 2 shows, while both No Pred. and AS-ConvQA$_{\text{uncer}}$ correctly predict $\bar{A}_5$, No Pred. does not use $\bar{A}_5$ as the answer history when answering the next question, Q_6. However, as $\bar{A}_5$ contains important information of 'it' in Q_6, No Pred. model gives an inaccurate answer to Q_6, since the model is confused about what 'it' refers to. On the other hand, our model selects $\bar{A}_5$ as the answer history due to its low uncertainty value, thereby correctly predicting $\bar{A}_6$ with the previous prediction $\bar{A}_5$. In a third example of Table 2, we show the potential failure of our model, which is discussed in the Limitations section after Section 6.

6 Conclusion

In this work, in order to tackle the challenge of inaccurately predicted answers in the conversation history, we proposed a novel answer selection scheme based on their confidence and uncertainty values. We further calibrated the output values of the model to match the model's predicted confidence and uncertainty to its correct likelihood and error, which makes our answer selection scheme more reliable. The experimental results and analyses demonstrate that AS-ConvQA significantly improves the ConvQA model performance in a realistic evaluation setting without making any architectural changes.

Limitations

While we show the clear advantages of using our AS-ConvQA in realistic ConvQA tasks with both quantitative and qualitative perspectives, there could be possible failures: estimated confidence and uncertainty of a model's prediction do not match its actual correctness. For instance, the third example in Table 2 shows that AS-ConvQA$_{\texttt{uncer}}$ gives an incorrect answer to Q_4, since it removes the correctly predicted previous answer (i.e., $\bar{A}_3$) due to its incorrectly estimated uncertainty. Specifically, both Q_3 and Q_4 ask the additional information: 'What else did they do?'. However, the erroneous deletion of $\bar{A}_3$ makes our model bound to the previous question, repeatedly giving the same answer as $\bar{A}_3$. This implies that AS-ConvQA$_{\texttt{uncer}}$ sometimes assigns high uncertainty to the correct prediction and filters it, which may mislead the model, especially for the one that requires careful attention to the context with the previous answer. Therefore, as future work, one may improve mechanisms to measure incorrectness of predictions.

Ethics Statement

As the need for fully autonomous conversational agents has been rapidly emerging, it is crucial to consider whether ConvQA models can correctly answer a sequence of questions in a realistic setting, in which gold answers for previous questions are unavailable. We note that, in such a challenging setting, our work contributes to the improved performance by selectively using predicted answers with model confidence and uncertainty instead of using predefined gold answers. However, as ConvQA models predict answers based on the given paragraph, we should further consider a scenario where the paragraph itself is not trustworthy, sometimes having offensive contents. Subsequently, this may lead the entire conversation vulnerable to generating unexpected and undesired texts. While this is not the concern raised from our proposed AS-ConvQA models themselves, we still have to make an effort to prevent such an undesirable behavior.

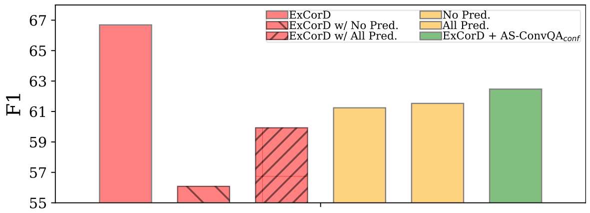

Figure 7: F1-scores on the mismatching evaluation settings for the recent ExCorD model (Kim et al., 2021) on QuAC.

A Experimental Implementation Details

We implement all models using PyTorch (Paszke et al., 2019) and Transformers library (Wolf et al., 2020). For language models, we use BERT-base and RoBERTa-base models with 110M and 125M parameters, respectively. For training, we set the training epoch as 2 with the batch size of 12, where the first epoch is used for Step 1 while the second epoch is used for Step 2. Furthermore, we optimize all models with the Adam optimizer (Kingma and Ba, 2015) with a learning rate of 3e-5. For computiting resources, we use a single GeForce RTX 3090 GPU with 24GB memory, on which each training epoch requires approximately 4 hours.

For hyperparameters, we search the temperature value τ for temperature scaling with a validation set, in the range of $(0, 2]$. Also, we set the filtering threshold for Step 2, in the range of $[\texttt{median} - 0.25, \texttt{median} + 0.25]$, where `median` is the median value of confidence or uncertainty for all samples. For the number of dropout masks (i.e., N for the uncertainty estimation in Section 3.3) for measuring uncertainty, we set it as 10.

We use two benchmark ConvQA datasets, which are QuAC[3] (Choi et al., 2018) and CoQA[4] (Reddy et al., 2019). Note that, while our main focus is on predicting the extractive answers within a given context, CoQA is designed for answering question in a free-form text, which might not appear in a given context. Therefore, following the experimental setting from Reddy et al. (2019), we convert the CoQA dataset to our extractive ConvQA setting. In particular, we assume the gold answer as the provided rationale, and then make prediction on it, except for simple yes or no questions. For the yes or no questions, we additionally augment yes and no tokens at the end of the paragraph.

B Additional Experimental Results

Realistic Evaluation of ExCorD Even though we validate a negative impact of exposure bias in Figure 3, we further explore the performance of the unrealistic state-of-the-art model, ExCorD (Kim et al., 2021), that uses gold answer histories, in Figure 7 with the realistic ConvQA setting that uses predicted answers. We observe that, similar to the mismatching evaluation experiments reported in Figure 3, the F1-scores of ExCorD drastically drop when evaluated with No Pred. and All Pred. settings, which aligns with our motivation. On the other hand, the performance is much improved by further adapting our AS-ConvQA on ExCorD. This result indicates the importance of filtering unnecessary predictions together with the applicability of our AS-ConvQA model in a realistic setting.

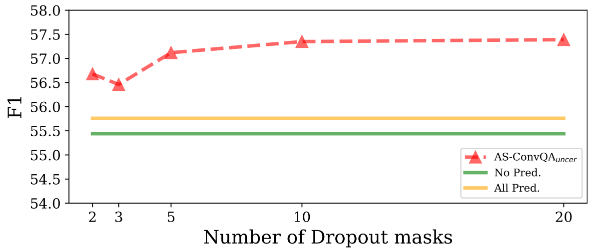

Figure 8: F1 scores with varying dropout numbers on QuAC.

Varying the Number of Dropout Masks In order to understand how the number of dropout masks (i.e., N used for uncertainty estimation in Section 3.3) affects the performance, we vary the number of masks for AS-ConvQA$_{\texttt{uncer}}$. As Figure 8 shows, the performance is stabilized after a certain number of masks (i.e., 5). This indicates the importance of setting an appropriate sampling number, since approximating the uncertainty with a small number of masks is likely to be inaccurate.

Abstract

Tongue twisters are meaningful sentences that are difficult to pronounce. The process of automatically generating tongue twisters is challenging since the generated utterance must satisfy two conditions at once: phonetic difficulty and semantic meaning. Furthermore, phonetic difficulty is itself hard to characterize and is expressed in tongue twisters through a heterogeneous mix of phenomena such as alliteration and homophony. In this paper, we propose **PANCETTA**: **P**honeme **A**ware **N**eural **C**ompletion to **E**licit **T**ongue **T**wisters **A**utomatically. We leverage phoneme representations to capture the notion of phonetic difficulty, and we train language models to generate original tongue twisters on two proposed task settings. To do this, we curate a dataset called *TT-Corp*, consisting of existing English tongue twisters. Through automatic and human evaluation, as well as qualitative analysis, we show that **PANCETTA** generates novel, phonetically difficult, fluent, and semantically meaningful tongue twisters.

1 Introduction

A *tongue twister* is a sentence which is both *articulatorily difficult* (i.e. colloquially speaking, *hard to say* or "twisting") while at the same time being *meaningful and fluent*. Some examples of tongue twisters are shown in Table 1.

Together with riddles, rhymes, fables, and other such creative artifacts, tongue twisters were historically often employed as a vehicle for early transmission of native language diction, grammar, and vocabulary to children, through parent-child interaction, playtime activity, and kindergarten instruction (Akinyemi, 2003; Mcgovern, 2021). Tongue twisters have also been used as experimental aids for research studies of speech production in cognitive science and related disciplines, both among healthy speakers and those with speech and auditory disorders such as dysarthria (Kember et al., 2017). They are also used as pedagogic aids in speech therapy, as well as for treatment of speech disorders and psychological disorders relating to public speaking and elocution (Revathy and Ravindran, 2016). An example of this was in a scene[1] from *The King's Speech (2010)*, where George VI repeats a tongue twister during therapy to reduce his stutter. Lastly, tongue twisters find use as teaching aids for English diction in EFL (English as a Foreign Language) instructional settings (Prošić-Santovac, 2009).

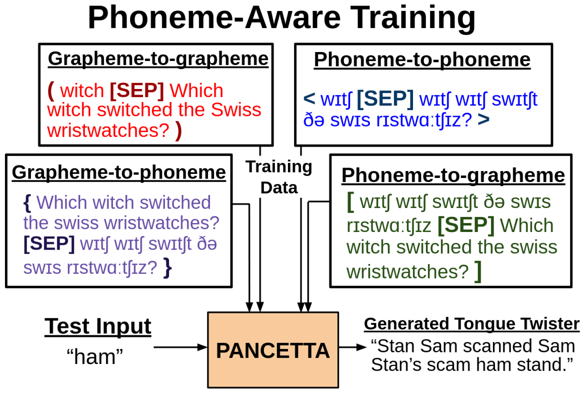

Figure 1: Overview of the phoneme-aware training in the **PANCETTA** model.

The coining of a novel, unique tongue twister which spreads sufficiently to become normative and well-recognized is rare, hence characterizing them as long-tailed linguistic phenomena (Naik, 2022). However, they are not limited to English, and are found across the world's languages, e.g., Persian (*"Shish sikh jigar sikhi shi shezar."*) (Jam, 2018) and French (*"Cinq chiens chassent six chats."*)

Consider the idealized scenario where we have a *"mouth model"* which a) maps different regions of the mouth, palate, and the larynx to the dictio-

	king, art, wall	A truly rural frugal ruler's mural was on the wall.	ə truːli rʊrəl fruːgəl ruːlrz mjʊrəl wɑːz ɑːn ðə wɔl.

Table 1: Example inputs and target outputs for both the TT-Prompt and TT-Keyword task settings, along with the phoneme representations of the tongue twisters.

nary of fundamental sounds, i.e. phones being produced, and b) based on this grounding, can quantify the hardness of producing one sound after another by inducing a distance measure between any phone pair. Assuming access to this idealized model, one could deconstruct the process of generating a tongue twister as sampling a sequence of preferably difficult/distant phone-phone transitions starting with an initial sequence of one or more phones (which could come from a prompt, or be chosen uniformly, based on the task setting).

However, there are several impediments which make realizing such an idealized model considerably intractable. First, the dictionary of fundamental sounds at the granularity we use in practice, i.e. at the level of phonemes, does not neatly map to particular points of the palate (Ladefoged and Johnson, 2014). Rather, each phoneme itself corresponds to a set of actions involving multiple organs and palatal regions. For instance, velar consonants like *k* are produced based on tongue-velum (soft upper palate) interaction. Secondly, a tongue twister as per its definition is not merely a difficult to pronounce sequence of phonemes, but also one that maps to a meaningful and fluent sequence of words. How one can maintain this property in conjunction with the process of sampling difficult transitions from the mouth model's space is unclear.

The automatic generation of tongue twisters has largely been unexplored. This task is challenging because it requires being able to model phonetic difficulty of various syllables and tokens, which is not something that existing language models are trained to do. To achieve this, we have to work in the phoneme space. Phonemes have previously been used to aid in speech recognition (Sundararaman et al., 2021) and rhyme generation (Hopkins and Kiela, 2017). We hypothesize that by working with phonemes, we will be able to model and generate patterns that characterize phonetic difficulty.

Tongue twisters go beyond relatively simpler phonetic phenomena such as alliteration, since they employ a heterogeneous mix of strategies (Jorgensen, 1981) including alliteration itself (*she sells seashells*), use of homophonic words/subwords (*sells*/*-shells*, *she*/*sea-*), and alternating between similar start phonemes for tokens (*s* and *sh*), sometimes even using multiple such phenomena in conjunction within the same example to create the cumulative effect of articulatory difficulty.

Our contributions are as follows: (1) We curate a dataset, *TT-Corp*, of diverse tongue twisters. (2) We present two new task settings (TT-Prompt and TT-Keyword) for automatic tongue twister generation, and we design and evaluate simple baselines for these tasks. (3) We propose a phoneme-aware method called **PANCETTA**, which models and generates coherent and phonetically difficult phrases by taking phonemes into account. We show that **PANCETTA** generates higher-quality tongue twisters through both automatic and human evaluations and qualitative analysis of the outputs.

2 Task Settings and Dataset

2.1 Task Settings

We propose two settings for automatic tongue twister generation. We call these tasks TT-Prompt and TT-Keyword. Examples of these two tasks can be found in Table 1, and they are detailed below:

1. **Generating tongue twisters from prompts (TT-Prompt)**: Given a few words to start a sentence, the goal is to complete the sentence in a coherent way such that the resulting generation is a tongue twister. Prompts can be of varying lengths.

2. **Generating tongue twisters from keywords (TT-Keyword)**: Given a set of keywords, the goal of this task is to generate a coherent tongue twister which incorporates the semantics of the keywords.

Tongue Twister	Non-TT Version
There was a little witch which switched from Chichester to Ipswich. (ex.1)	There was a small enchantress which exchanged from Chichester to Ipswich.
He wanted to desert his dessert in the desert. (ex.2)	He desired to abandon his sweet in the desert.
Tie a tight knot in the shape of a nought. (ex.3)	Bind a taut gnarl in the form of a zero.

Table 2: Examples of the synonym replacement process to generate non-tongue twister versions of the tongue twisters in *TT-Corp*. Different colors are used to indicate which words are replaced by their synonyms.

The set of keywords can be of varying sizes. These keywords do not necessarily have to appear verbatim and do not necessarily have to appear in order.

2.2 *TT-Corp* Dataset

As previously noted, tongue twisters are long-tailed linguistic phenomena, and it is rare to find new unique tongue twisters. Given this, we curate a dataset of 644 unique English tongue twisters into a dataset called *TT-Corp*. These tongue twisters are compiled from various sources, ranging from blog posts to English learning websites. A more detailed list of these sources and data processing details can be found in Appendix A. Despite the seemingly small scale of this dataset, multiple studies have successfully generated creative text even when training data is limited: 511 personifications (Keh et al., 2022), 1400 MadLibs (Hossain et al., 2017), 401 portmanteaus (Deri and Knight, 2015), and 576 clippings (Mattiello, 2013).

We also create a non-tongue twister version of each input in *TT-Corp*, which will later be used to explore style transfer models (§3.1) and to train a phonetic difficulty classifier (§3.2.1). This is done through synonym replacement. First, we determine the parts-of-speech of all the words in the sentence and identify the nouns, verbs, and adjectives.[2] We then use WordNet (Fellbaum, 1998) to generate a list of synonyms for each of these nouns, verbs, and adjectives, and we select the highest ranked replacement which shares the same part-of-speech. Examples of this process are shown in Table 2.

One key advantage of this synonym replacement process is that it can replace a word according to its part-of-speech in the sentence. In the second example in Table 2, the word "desert" appears twice – first as a verb (which is replaced with "abandon"), and again as a noun (which is not replaced). However, this synonym replacement process does not take the context of the words into account. In the third example, while the individual synonym replacements make sense on their own, the final sentence sounds quite unnatural. For our purposes, however, this is not a significant issue: we do not need the replacement sentences to be absolutely perfect, as the quality of the ground-truth tongue twister is more important. This will be explained further when we use this parallel dataset in §3.2.1.

3 Methodology

As this is a new task, there are no existing methods that can easily generate novel tongue twisters. The main challenge is how to incorporate phonetic difficulty into our generations. To do so, we propose two baseline and two phoneme-aware models, which are applicable to both the TT-Prompt and TT-Keyword task settings (see Table 3).

3.1 Models

1. **Grapheme-based Methods (g2g)** – We treat tongue twister generation as a seq2seq task, where the prompt (for TT-Prompt) or keywords (for TT-Keyword) is the input, and the tongue twister is the target output. We fine-tune GPT-2 (Radford et al., 2019) and GPT-J (Wang and Komatsuzaki, 2021) using the input sequences "(X [SEP] Y)", where X represents the prompt/keywords, Y represents the tongue twister, and [SEP] is a separator token.

2. **Style Transfer Methods** – Given a prompt or a set of keywords, we generate a sentence (not necessarily a tongue twister) using GPT-2. This is easy for TT-Prompt since GPT-2 is trained to do causal language modeling. For TT-Keyword, we need to first train a GPT-2 model to perform keyword-to-text. We sample 10,000 sentences from WikiText-103 (Merity et al., 2016) and extract their keywords using KeyBERT (Grootendorst, 2020). We then fine-tune GPT-2 using an "(X [SEP] Y)" template as described in the g2g methods. Here, X represents the keywords, and Y represents the corresponding sentence.

We then attempt to convert these generated natural sentences into tongue twisters. We treat this as a seq2seq task and train a seq2seq model using our parallel dataset. During training, we use the non-TT versions as inputs and the tongue twisters as the ground truth target outputs. We use BART

---

[2] The spaCy library (Honnibal and Montani, 2017) was used to extract the POS tags.

Method Name	Models Used	Description	Phoneme Representation	Leverage Pretraining
Grapheme-based Methods	GPT-2, GPT-J	g2g	✗	✓
Style Transfer Methods	BART, T5	g2g + g2g	✗	✓
PANCETTA-P	GPT-2, BART	g2p + p2p + p2g	✓	✗
PANCETTA-J	GPT-2, GPT-J	g2g, p2p, g2p, p2g (only g2g during test-time)	✓	✓

Method Name	Example
Grapheme-based Methods	She sells → She sells seashells on the seashore.
Style Transfer Methods	She sells → She sells things on the beach. → She sells seashells on the seashore.
PANCETTA-P	She sells → ʃiː sɛlz → ʃiː sɛlz siːʃɛlz ɑːn ðə siːʃɔr → She sells seashells on the seashore.
PANCETTA-J	She sells → She sells seashells on the seashore. She sells seashells on the seashore. → ʃiː sɛlz siːʃɛlz ɑːn ðə siːʃɔr. ʃiː sɛlz siːʃɛlz ɑːn ðə siːʃɔr. → She sells seashells on the seashore. ʃiː sɛlz → ʃiː sɛlz siːʃɛlz ɑːn ðə siːʃɔr.

Table 3: Summary of the models discussed in §3.1, along with some examples.

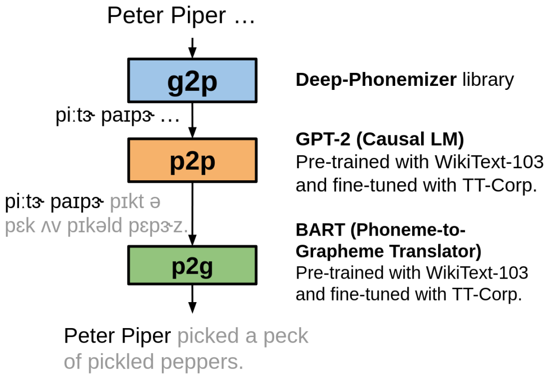

Figure 2: Overview of **PANCETTA-P** pipeline.

(Lewis et al., 2020) and T5 (Raffel et al., 2020) models for this seq2seq task.

3. **PANCETTA-P** (Phoneme) – For the previous g2g models, the fine-tuning was done only using graphemes. Because graphemes are not always representative of pronunciation, we hypothesize that it may be difficult for such models to capture information regarding the pronunciation. If we instead had a generative model which works on the phoneme space, then we could fine-tune this model on the tongue twister phonemes and hope that it can better capture these phonetic cues.

We first pretrain a GPT-2 model to perform causal LM generation for phonemes. Pretraining is done using WikiText: we first convert all the WikiText sentences into their IPA phoneme representations and train a GPT-2 model on it.[3] For TT-Keyword, instead of training a causal phoneme LM, we train to generate from keywords, using the (X [SEP] Y) template previously described. While there are multiple g2p phonemization toolkits, there are no readily available p2g toolkits that work well. Hence, we train our own p2g model. We treat this as a seq2seq translation task, once again using WikiText. We train a BART model with the phonemes as the inputs and the graphemes as the targets. Once both the p2p generation and the p2g translation models are trained, we then fine-tune the p2p models on the tongue twister phonemes (all steps similar to g2g), then use the p2g model to retrieve the grapheme representation of the outputs (see Figure 2). Lastly, since there is no capitalization in the phoneme space, we have to fix the capitalization of the generated outputs. We use the FastPunct library for this.[4] Unlike the previous g2g methods, we only use GPT-2 (and not GPT-J) for **PANCETTA-P** because GPT-J is too large to pretrain in a reasonable fashion.

4. **PANCETTA-J** (Joint) – One drawback of **PANCETTA-P** is that because we do our own pre-training on the phoneme space, we are not able to leverage the existing pre-training of large language models. In order to leverage both the phoneme representations and the pre-training of GPT, we propose **PANCETTA-J**. This is similar to g2g, but instead of only training with the template (X [SEP] Y), we train with 4 different templates, representing 4 different modalities. Specifically, we train with the templates (PK_G [SEP] TT_G), <PK_P [SEP] TT_P>, [TT_G [SEP] TT_P], and {TT_P [SEP] TT_G}, where PK represents the prompts/keywords, TT represents the tongue twisters, G represents the grapheme representation, and P represents the phoneme representation. These 4 modalities represent g2g, p2p, g2p, and p2g respectively. Here, the type of surrounding brackets function similar

---

[3] The `deep-phonemizer` Python package was used for g2p transliteration.

[4] https://github.com/notAI-tech/fastPunct

to custom tokens which indicate the modality for the model.

At test time, the model can be directly decoded using g2g mode without requiring phoneme information. We hypothesize that the phonetic structures learned during training time can serve as an effective "scaffold" — being used explicitly only during finetuning time (Swayamdipta et al., 2018).

3.2 Evaluation Metrics

3.2.1 Automatic Evaluation

As described in §1, a good tongue twister needs to satisfy two criteria: it needs to be both difficult to pronounce, as well as semantically coherent. We consider these two notions separately.

1. **Phonetic Difficulty**: We fine-tune a pretrained BERT-base classifier to differentiate between tongue twisters and regular sentences. To train this model, we use the parallel dataset of (TT, non-TT) pairs as described in §2.2. We specifically use these (TT, non-TT) pairs so that the model learns to classify based on phonetic difficulty rather than semantics. However, as mentioned in §2.2, some replacement sentences may sound unnatural. To ensure that the classifier learns to differentiate tongue twisters instead of picking up on these false signals, we augment our dataset with additional negative examples consisting of 500 sentences randomly sampled from WikiText. Rather than directly training on the sentences, we first convert the sentences to phoneme representations and train a classifier on the phonemes. This trained BERT classifier achieves an 83.4 F1-score on the test set of the parallel dataset, indicating that it is indeed successful at discriminating phonetically easy and difficult sentences. To further verify that this metric successfully measures phonetic difficulty, we show that it correlates well with human-annotated measures of phonetic difficulty (§5.2 and Table 6).

2. **Fluency:** We not only want phonetically difficult sentences; they must also be fluent and coherent. To measure this, we use the generation (log-perplexity) losses from a pretrained GPT-2.

3. **Keyword Relevance** (only for TT-Keyword): In TT-Keyword, we want to ensure that the generated tongue twister is semantically similar to the keywords used. To measure this, we use the BERT embedding of keywords and compare it with the embedding of the target sentence. More specifically, we use the BERTScore (Zhang* et al., 2020) between the generated sentence and the "sentence" consisting of the keywords separated by commas.

3.2.2 Human Evaluation

The human evaluation metrics are very similar to the ones in §3.2.1. These are as follows: (1) **Phonetic Difficulty** ("*How hard is the sentence to pronounce? To get a better sense of the difficulty, try saying the sentence out loud, quickly, and multiple times.*") and (2) **Fluency** ("*Does it sound like good English with good grammar?*") Evaluations were done on a scale of 1-5, with 5 being the highest. Further details about human evaluation are in §4.2.

4 Experimental Setup

4.1 Implementation Settings

Prompt / Keyword Extraction: To extract prompts for TT-Prompt, we simply consider the first three words of each sentence by checking for the whitespace character. To extract keywords for TT-Keyword, we use the KeyBERT library (Grootendorst, 2020), which returns keywords ranked by their cosine similarity scores to the entire sentence itself. For each sentence, we consider the top 5 keywords as our set of keywords. When a sentence has <5 keywords, we simply take all the keywords. In our dataset, 39.56% of the examples had <5 keywords.

Dataset splits: We split *TT-Corp* into a training-validation-test split with a 70-15-15 ratio. We use the same splits across all models and across both TT-Prompt and TT-Keyword task settings, as well as for training the phonetic difficulty classifier.

GPT-2 fine-tuning (g2g, **PANCETTA-P**, **PANCETTA-J**): We use the pretrained GPT2-base (124M params.) and fine-tune for 5 epochs with a learning rate of 5e-5 and 100 warmup steps.

BART pretraining (**PANCETTA-P**): For the p2g model, we pretrain BART-base (139M params.) on WikiText-103 phonemes. We split WikiText into train-validation-test splits of 80-10-10. The final training set has size 523k. Training was done for 20 epochs with batch size of 16, learning rate of 5e-4, and weight decay of 0.1 with a cosine scheduler.

BART & T5 fine-tuning (Style Transfer): We fine-tune BART-large (406M params.) & T5-large (737M params.) for 30 epochs with a batch size of 16, learning rate of 2e-5, and 400 warmup steps.

GPT-J fine-tuning (g2g, **PANCETTA-J**): Because GPT-J is too large (6B parameters), we use

	TT-Prompt		TT-Keyword		
Method	Phon. Difficulty	Fluency ↓	Phon. Difficulty	Fluency ↓	Keyword Relevance
g2g (GPT-2)	0.774	5.433	0.786	5.224	0.795
g2g (GPT-J)	0.848	5.643	0.856	5.593	0.794
Style Transfer (GPT-2+BART)	0.672	4.356	0.472	**3.662**	0.783
Style Transfer (GPT-2+T5)	0.631	**4.256**	0.414	4.309	0.780
PANCETTA-P (GPT-2+BART)	0.794	5.986	0.871	6.596	0.801
PANCETTA-J (GPT-2)	0.785	5.244	0.803	5.058	**0.803**
PANCETTA-J (GPT-J)	**0.866**	5.718	**0.888**	5.169	0.800
Gold Outputs	0.925	5.745	0.925	5.745	0.812

Table 4: Automatic evaluation averages for both TT-Prompt and TT-Keyword. The best-scoring method for each metric is highlighted in **bold**. Higher scores are better for all metrics except for fluency.

a compressed version of GPT-J, [5] which incorporates various techniques such as 8-bit quantization (Dettmers et al., 2021) and low-rank adaptation (Hu et al., 2021). To fine-tune, we use 10 epochs, a batch size of 1, and a learning rate of 1e-5.

For the GPT models (i.e. GPT-2 and GPT-J), generation was done using nucleus sampling (p=1.0, temperature=0.8). Meanwhile, for the BART and T5 models, generation was done using beam search with a beam size of 5. Additional hyperparameters and details on implementation can be found in Appendix C.

4.2 Human Evaluation Settings

Human evaluation was done on Amazon Mechanical Turk (AMT). We selected annotators with >97% HIT approval rate from Anglophone countries. [6] In each HIT, we present the generated outputs for each example in randomized order, and each test example was evaluated by exactly 2 annotators.

We conduct two rounds of annotation, one for TT-Prompt and another for TT-Keyword. Within each round, we further subdivide annotating GPT-2 experiments and GPT-J experiments. This GPT-2/GPT-J split only applies to g2g and **PANCETTA-J** models; for the style-transfer and **PANCETTA-P** models, we keep the same models for both rounds of evaluation. This is done to ensure that we only have one independent variable so that the changes in performance are due to the methodologies rather than the size of the models. Another reason for subdividing GPT-2/GPT-J experiments is so that we do not subject annotators to information overload from having to annotate too many similar examples. Owing to the same consideration, we also decided to omit human evaluation on the Style Transfer T5 baseline because we found it very similar to Style Transfer BART.

5 Results and Analysis

5.1 Automatic Evaluation Results

Table 4 shows the average results for the metrics outlined in §3.2.1. From the phonetic difficulty results, we see that our proposed **PANCETTA** models score higher than the baselines. More specifically, comparing g2g (GPT-2) (0.774) vs **PANCETTA-J** (GPT-2) (0.785) and comparing g2g (GPT-J) (0.848) vs **PANCETTA-J** (GPT-J) (0.866), we see that incorporating phoneme representations indeed aids in producing more phonetically difficult sentences. This pattern also holds true for TT-Keyword, where both GPT-2 and GPT-J see increases in performance after incorporating phonemes. We also observe that **PANCETTA-P** performs reasonably well in phonetic difficulty and has the highest score of the non-GPT-J models for both TT-Prompt and TT-Keyword. In fact, for TT-Keyword, **PANCETTA-P** is able to get very close to **PANCETTA-J** (GPT-J), which is remarkable, considering that it is only using a GPT-2 model.

For fluency, style transfer models score better than the other models. This is likely because style transfer models first generate a regular sentence, then attempt to *"tongue twisterize"* it. However, there is no guarantee that the sentence can even be reasonably converted to a tongue twister, resulting in minimal changes being made to the original GPT-generated sentence, thereby leading to good fluency scores when using perplexity. Meanwhile, we see that **PANCETTA-P** has the worst perplexity score. However, it is important to note that even the ground truth tongue twisters score poorly here (around the same scores as **PANCETTA** models). Tongue twisters do not usually use typical English tokens in standard sequences, thereby resulting in worse perplexity scores. Nonetheless, fluency/perplexity is still important as a sanity check for the basic qualities of the generated text (whether the generation is coherent, if it makes unnecessary

[6] More details about the human eval are in Appendix B.

Method	TT-Prompt		TT-Keyword	
	Phonetic Difficulty	Fluency	Phonetic Difficulty	Fluency
g2g (GPT-2)	3.056	3.736	3.847	**4.139**
Style Transfer (GPT-2+BART)	2.569	3.639	3.500	3.819
PANCETTA-P (GPT-2+BART)	**3.528**	**3.778**	3.722	3.764
PANCETTA-J (GPT-2)	3.153	3.764	**3.889**	3.931
Gold Outputs	3.361	3.931	3.833	4.000
g2g (GPT-J)	3.521	**3.979**	3.791	3.708
Style Transfer (GPT-2+BART)	3.271	3.75	3.25	3.750
PANCETTA-P (GPT-2+BART)	**3.854**	3.708	3.833	**3.896**
PANCETTA-J (GPT-J)	3.708	3.646	**3.979**	3.604
Gold Outputs	3.750	4.000	4.104	3.729

Table 5: Human evaluation averages for TT-Prompt and TT-Keyword. The top half of the table correspond to methods using GPT-2 as the base architecture, while the bottom half of the table correspond to methods using GPT-J as the base architecture. Top method scores for each metric are highlighted in **bold**.

grammatical errors, etc.). To this end, the fluency scores of **PANCETTA** models are adequate.

Lastly, for keyword relevance, most scores are close to each other. The three **PANCETTA** models have the three highest scores, indicating that **PANCETTA** is able to generate difficult tongue twisters without compromising the task at hand.

5.2 Human Evaluation Results

Table 5 shows the average results for the human evaluation. As with the automatic evaluations, we see an increase in phonetic difficulty when we introduce phonemes into the training process. Comparing g2g (GPT-2) and **PANCETTA-J** (GPT-2), we see an increase from 3.056 to 3.153 for TT-Prompt and from 3.847 to 3.889 for TT-Keyword. This trend also occurs for GPT-J models. Despite not being able to leverage existing GPT pretraining, **PANCETTA-P** also works very well, outperforming all non- **PANCETTA** models in all but one setting. These positive results indicate that incorporating phonetic information is indeed helpful.

In terms of phonetic difficulty, we observe that for TT-Prompt, **PANCETTA-P** works best for both GPT-2 and GPT-J, while for TT-Keyword, **PANCETTA-J** works best for both GPT-2 and GPT-J. This may be because generating from keywords is generally more difficult than completing a prompt, so **PANCETTA-J** benefits from existing pretraining. Meanwhile, in terms of fluency, g2g methods work best for 2 settings, and **PANCETTA-P** works best for 2 settings. Tongue twisters usually use words in creative and unnatural-sounding ways, and this may sometimes negatively affect fluency, so the "most fluent" sentence may not necessarily be the best tongue twister. Nevertheless, all the fluency metrics for **PANCETTA** models are around 3.7 to 3.8, indicating good fluency. Overall, we conclude that **PANCETTA** substantially improves phonetic difficulty while maintaining a competitive level of fluency.

Task	Pearson Correlation	Spearman Correlation
TT-Prompt	0.117 (p=0.076)	0.116 (p=0.079)
TT-Keyword	0.102 (p=0.177)	0.134 (p=0.075)

Table 6: Corr. between human annotations and automatic metrics (BERT classifier) for phonetic difficulty.

To verify the validity of using our BERT classifier to automatically measure phonetic difficulty, we compute correlations between the classifier's scores and human-annotated phonetic difficulty scores (Table 6). We observe that the correlations are > 0.1 with relatively low p-values, which is an adequate score when comparing various automatic and human-annotated metrics (Gangal et al., 2022). While this can be further improved and is a limitation of our work, we also note that the automatic phonetic difficulty metric scores the gold outputs the highest (at 0.925) and the style transfer models lowest, which indicates that it is able to decently capture the notion of phonetic difficulty.

5.3 Qualitative Analysis

Table 7 shows sample generations for both TT-Prompt and TT-Keyword. We observe that both PAN-P and PAN-J are able to use a wide variety of tongue twister techniques, such as rhyme (*grape/crepe/crate-* in ex.1 PAN-P), alliteration (*kneadle/knuckle* in ex.3 PAN-J), alternating final sounds (*land/lamb* in ex.2 PAN-P), alternating initial sounds (*six-/sheik* in ex.4 PAN-J), and repetition. They are also able to generate proper nouns to suit the sentence, such as "*Donna*" and "*Needles Nood*" in ex.3 PAN-P. They can also combine multiple such techniques in a single tongue twister, such as *stick/stock* and *land/lamb* in ex.2 PAN-P.

Comparing this with the baseline methods (g2g and Style T.), we see that the generated outputs of the g2g baseline are decent and somewhat tongue

Method	**Text**
Inputs	(ex.1) The pirates pirated ...
Gold out.	The pirates pirated private property.
g2g	The pirates pirated the pepper pot.
Style T.	The pirates pirated more than $50 million in online gambling in 2013.
PAN-P	The pirates pirated a little grape crepe. The pirate dread cratered a little.
PAN-J	The pirates pirated the paired prince with a pair of paired pistols.
Inputs	(ex.2) If you stick ...
Gold out.	If you stick a stock of liquor in your locker, it is slick to stick a lock upon your stock or some joker who is slicker is going to trick you of your liquor if you fail to lock your liquor with a lock?
g2g	If you stick two sticks together, you get two sticks tied together.
Style T.	If you stick with the same line, you have different things going for you.
PAN-P	If you stick a stock of land in a lamb and a lamb in a farm.
PAN-J	If you stick a stock stick on the stock stick you stick, who's going to stick it on the stock stick you stick?

Method	**Text**
Inputs	(ex.3) needles, noodles, kneadle, don, need
Gold out.	I don't need your needles to kneadle noodles.
g2g	One noodle needs a kneeler to lean on
Style T.	Near the end of his reign, Leiblau had to send a delegate to Parliament, to support his friend King Gules of Northumbria.
PAN-P	If Donna Needles Need, who is Needles Nood, and the Need?
PAN-J	Don't kneadle a knuckle with a knuckle needle!
Inputs	(ex.4) thieves, thankful, thanked, thirty, thursday
Gold out.	The thirty-three thankful thieves thought that they thanked the other thirty-three thankful thieves throughout Thursday.
g2g	The thieve thanked the thankful thief on Thursday.
Style T.	Thanked by Thnx for the idea, I thought it was an idea that I wanted to do a spoof of Thankful Thankful and Thnx.
PAN-P	Thankful thieves thought that they thought they thrilled the throne throughout Thursday.
PAN-J	These sixty sheiks sent these thousand and sixty sheiks sixty sheiks thanking them for shouting these sixty sheiks sixty shouts on Thursday.

Table 7: Qualitative examples for both TT-Prompt (first 2 examples) and TT-Keyword (last 2 examples). We report only the best performing model based on phonetic difficulty from automatic evaluations for each type (in brackets): literal input, gold output, g2g (GPT-J), Style Transfer (BART), **PANCETTA-P** (GPT-2+BART), and **PANCETTA-J** (GPT-J). Additional examples can be found in Appendix D.

twister-like but usually are very short and simple, often relying too much on alliterations. Meanwhile, the outputs for the style transfer methods are generally not tongue twisters. As discussed in §5.1, this is likely because it commonly fails at fully converting a regular sentence into a tongue twister.

For TT-Prompt, we observe that even with a non-alliterative prompt such as "If you stick" (ex.2), the **PANCETTA** models can still generate good tongue twisters, whereas the g2g method attempts to use repetition but the generated text is not that difficult to pronounce. Meanwhile, for the TT-Keyword setting, PAN-J is able to incorporate the semantics of the words, rather than just copying the words themselves: in ex.4, PAN-J replaces "thirty/thieves" in the keywords with "sixty/sheiks". Lastly, comparing PAN-P and PAN-J, we see that PAN-J sentences generally sound smoother, while PAN-P sentences sometimes end rather abruptly ("*in a farm.*" in ex.2; "*and the Need?*" in ex.3). In addition, some of the outputs from PAN-P lack coherence (ex.3). This is likely because PAN-P uses a phoneme language model and hence is unable to leverage the large-scale pretraining from GPT models. On the other hand, this lack of large-scale pretraining can potentially free up PAN-P to use more diverse tongue twister techniques, such as rhymes (ex.1) and proper nouns (ex.3) which are less common in PAN-J.

6 Related Work

Automatic tongue twister generation is a largely unexplored task. Existing systems mostly use synonym replacements (Zeng, 2019) on existing tongue twisters, which requires a large list of tongue twisters to begin with and cannot generate novel ones from scratch. Carey (2017) generates tongue twisters using sound vectors, and Joshipura (2020) trains an LSTM on a small tongue twister dataset, but neither are able to produce novel and semantically coherent examples. Furthermore, no methods currently exist for the TT-Keyword task.

There have been multiple studies on creative generation of various figures of speech such as similes (Chakrabarty et al., 2020), metaphors (Chakrabarty et al., 2021), and personifications (Keh et al., 2022). However, these other creative linguistic constructs don't require working with another modality in the same way that tongue twister generation relies on phonemes. Among these creative linguistic constructs, the closest ones to tongue twisters would likely be alliterations (Hopkins and Kiela, 2017), rhymes (Xue et al., 2021), and poetry (Ghazvininejad et al., 2017; Cruys, 2020). Notably, DeepHaiku (Gonsalves, 2022) also explores using phonemes and a multitask objective in order to generate haikus. However, tongue twister generation goes beyond alliterations and rhymes; rather it is a mix of all these various techniques. In addition, it differs from poetry generation because poetry generation focuses on generating rhythmic verses and syllables, whereas the main focus of tongue twister generation is on phonetic difficulty.

Using phonemes in language modeling has been previously explored in the speech domain for automatic speech recognition (Sundararaman et al., 2021; Belinkov et al., 2019; Xu et al., 2021). In this paper, we trained a BART model to do p2g translation. Other existing methods include expectation maximization (Knight et al., 2006), A* search (Corlett and Penn, 2010), and Hidden Markov Models (Hopkins and Kiela, 2017).

There is also work on more general constrained text generation tasks. An example is Feng et al. (2019), who propose Semantic Text Exchange to adjust a text's topic-level semantics. Lin et al.

(2020) introduce a generative commonsense reasoning task using keyword-to-text generation called CommonGen. SAPPHIRE (Feng et al., 2021b) and VisCTG (Feng et al., 2022) investigate approaches to improve performance on CommonGen, the latter using per-example visual grounding.

7 Conclusion and Future Work

In this paper, we proposed the task of automatic tongue twister generation, and explored it under two settings: TT-Prompt and TT-Keyword. We curated a dataset called *TT-Corp* of 600+ English tongue twisters from various sources and proposed **PANCETTA**, a training methodology which incorporates phoneme representations. We implemented two variants: **PANCETTA-P** (Phoneme), which trains a phoneme-based language model, and **PANCETTA-J** (Joint), which jointly incorporates both phoneme-level information and grapheme-level information during training time. Through empirical results and qualitative evaluations, we showed that incorporating phonemes is indeed helpful in producing effective tongue twisters which are harder to pronounce while staying fluent.

While **PANCETTA** works well at generation, the generation process lacks interpretability. This is most notable when looking at the phonetic difficulty classifier. Currently, the classifier does not identify and separately score elements of phonetic difficulty or come up with an explicit decomposition. We believe that such explicit decomposition can be very useful in the future for understanding more about tongue twisters and the "mouth model" discussed in §1. In addition, the procedure of fine-tuning a pretrained model in 4 different modes involving both graphemes and phonemes, devised here to fine-tune **PANCETTA-J**, can also be adopted more generally as a data augmentation (Feng et al., 2021a, 2020) method for LM fine-tuning, creating a (pseudo) count of 4N training examples given N initial ones. Lastly, tongue twisters can potentially be incorporated in dialogue agents, adding creativity and personality (Li et al., 2020).

Limitations

As mentioned in §7, our current model and classifer are deficient in terms of their interpretability on certain aspects, and would greatly benefit from addition to their interpretability on these fronts.

Our models and datasets are limited to English tongue twisters (Bender and Friedman, 2018). In addition, when we convert to the phoneme space, we only use IPA phonemes. We selected IPA because it is the most common and most readily available phonemization method. However, there also exist many other phonemization methods such as the ARPAbet / CMU Pronouncing Dictionary (Weide, 2005), the SAMPA (Wells, 2005), or the Festival phonemization scheme (Black and Lenzo, 2003). We also choose to use deep-phonemizer for g2p transliteration. There are many other available phonemization tools such as Epitran (Mortensen et al., 2018) and the `phonemizer` Python package (Bernard and Titeux, 2021). It would be interesting to explore how the performance will change if we try other phoneme alphabets or phonemization methods.

In addition, we see in §5 that the style transfer models do not really work that well. In this paper, we only tried simple BART and T5 seq2seq models. One possible way to expand on this would be to try other more sophisticated style transfer methods.

Due to computational resources, we were not able to explore larger models and had to use a compressed version of GPT-J, which may have slightly affected the performance.

Ethics

The *TT-Corp* dataset we propose and release herein has undergone a per-example, manual, vetting process during its curation and pre-processing stage, as described further in Appendix A.2, which removes examples which may exhibit offensive words, profanities, racism, gender bias, and other malicious language.

We do collect human evaluation ratings using crowd-sourcing, specifically through AMT. However, we neither solicit, record, nor request any kind of personal or identity information from the annotators. Our AMT annotation was conducted in a manner consistent with terms of use of any sources and intellectual property and privacy rights of AMT crowd workers. Crowdworkers were fairly compensated: $0.56 per fluency and phonetic difficulty HIT, for roughly 2 min tasks. This is at least 2 times the minimum U.S.A. wage of $7.25 per hour ($0.56 per 2 mins is around $16.8 per hour).

NLG models are known to suffer from biases learnable from training or finetuning on data, such as gender bias (Dinan et al., 2020). However, our work and contribution does not present or release any completely new model architectures, and is primarily concerned with more careful adaptation and finetuning of existing pretrained models for a particular class of creative linguistic constructs (i.e. tongue twisters). The frailties, vulnerabilities, and potential dangers of these models have been well researched and documented, and a specific re-investigation would be repetitive and beyond the scope and space constraints of this paper.

We do not foresee any explicit way that malicious actors could specifically misuse finetuned models that could be trained on our data, beyond the well-researched, aforementioned misuse that is possible in general with their instantiation for any transduction task or dataset (e.g. summarization).

A Additional Details — Dataset Collection

A.1 Sources

We curate our tongue twisters from a heterogeneous mix of online sources, including but not limited to the ones listed below:

1. University of Arkansas
2. The r/tonguetwister Subreddit
3. Various AskReddit threads
4. Mondly.com
5. Uebersetzung
6. Marcus Stuart's LOL Tongue Twisters book
7. Language Avenue
8. Bilingual Monkeys
9. Pun.me
10. ESL
11. Sweetrhymes
12. EngVid
13. IvyPanda

A.2 Vetting

We then perform the following filtering steps to retain only a collection of high-quality dataset examples:

- Remove near-repetitive examples to ensure each example is unique
- Remove excessively short or meaningless examples lacking sentence structure, e.g. *blue blood, bad blood*
- Remove poems or rhymes
- Remove examples containing offensive words, racism, gender bias or other harmful and malicious language of any nature, to prevent models learnt from this data from further ingraining or amplifying such phenomena.

B Appendix B: Evaluation Details

To prevent annotator judgements for one attribute from inadvertently influencing the other, we conduct the studies for soliciting Fluency and Phonetic Difficulty scores separately.

Averaging over the 4 settings described in §4.2 (TT-Keyword/TT-Prompt × GPT-2/GPT-J), a total of 20 unique AMT annotators participated in the study for Fluency, each performing 3.6 HITs on average. Annotators were compensated $0.56 per HIT, each of which was designed to take < 2 mins on average.

Averaging over the 4 settings, 16.51 unique AMT annotators participated in the second, separate study for Phonetic Difficulty, each performing 4.36 HITs on average. Annotators were compensated $0.56 per HIT, each of which was designed to take < 2 mins on average.

C Further Implementation Details

In §4.1, we detailed the hyperparameters used for pre-training BART, as well as for fine-tuning GPT-2, GPT-J, BART, and T5. We conduct a hyperparameter search to check which values led to the best performance. For learning rate, we tried {1e-6, 5e-6, 1e-5, 2e-5, 2e-5, 1e-4}; for batch size, we tried {2,4,8,16}; and for number of epochs, we tried {2, 5, 10, 20}. These search bounds were selected based on known commonly-used values for these models. We start with a baseline model of lr=2e-5, bsz=8 and 10 epochs, and individually change each setting to investigate its effect on performance. One trial was conducted per hyperparameter setting. We use a maximum sequence length of 256. In terms of other hyperparameters, we mostly used default values which are known to work for these models. This includes the warmup steps and learning rate decays, which we detail in §4.1. (Note: the above hyperparameter search settings are for fine-tuning. We could not do an extensive hyperparameter search for pre-trainig due to time constraints. We ran pre-training twice to test the effect of learning rate 1e-4 vs. 5e-4, and ultimately selected 5e-4.)

Model selection was done based on the epoch with the best validation loss. We report the best validation losses for each training process below: GPT-2 pre-training=0.77, GPT-2 fine-tuning (TT-Prompt)=1.08, GPT-2 fine-tuning (TT-Keyword) =0.95, GPT-J fine-tuning (TT-Prompt)=1.23, GPT-J fine-tuning (TT-Keyword)=1.19, BART-fine-tuning (TT-Keyword) = 1.31, BART-fine-tuning (TT-Prompt) = 1.30, T5-fine-tuning (TT-Keyword) = 1.45, T5-fine-tuning (TT-Prompt) = 1.52.

All training was done on Google Colaboratory environments using V100 GPUs with 16GB memory. Pre-training GPT-2 for the p2p model took 90 minutes per epoch, and pre-training BART for the p2g model took 70 minutes per epoch. In terms of fine-tuning on *TT-Corp*, GPT-2 takes around 1 minute per epoch, GPT-J around 2 minutes per epoch, BART around 1 minute per epoch, and T5 around 1 minute per epoch.

D Additional Qualitative Examples

In §5.3, we only report the best performing models for each of the methods. In Table 8, we extend this to all models for all the methods. We also provide a few more examples for both TT-Prompt and TT-Keyword.

Method	**Text**
Inputs	(ex.1) The pirates pirated ...
Gold out.	The pirates pirated private property.
g2g (GPT2)	The pirates pirated the property.
g2g (GPTJ)	The pirates pirated the pepper pot.
Style T. (BART)	The pirates pirated more than $50 million in online gambling in 2013.
Style T. (T5)	The pirates pirated more than $50 million in online gambling in 2013, according to a government-backed study.
PAN-P	The pirates pirated a little grape crepe. The pirate dread cratered a little.
PAN-J (GPT2)	The pirates pirated the music and the Roman river carried the criminals off.
PAN-J (GPTJ)	The pirates pirated the paired prince with a pair of paired pistols.
Inputs	(ex.2) If you stick ...
Gold out.	If you stick a stock of liquor in your locker, it is slick to stick a lock upon your stock or some joker who is slicker is going to trick you of your liquor if you fail to lock your liquor with a lock?
g2g (GPT2)	If you stick a weight silky liquor on your wrist, you should stick a weight silky liquor on your inner wrist.
g2g (GPTJ)	If you stick two sticks together, you get two sticks tied together.
Style T. (BART)	If you stick with the same line, you have different things going for you.
Style T. (T5)	If you stick with the same line, you have different things going for yout.
PAN-P	If you stick a stock of land in a lamb and a lamb in a farm.
PAN-J (GPT2)	If you stick a stock of liquor in your locker it is slick to put a lock on your stock.
PAN-J (GPTJ)	If you stick a stock stick on the stock stick you stick, who's going to stick it on the stock stick you stick?
Inputs	(ex.3) I saw Susie ...
Gold out.	I saw Susie sitting in a shoe shine shop.
g2g (GPT2)	I saw Susie sitting on the sofa with a big black basket of biscuits.
g2g (GPTJ)	I saw Susie sitting on a buttercup.
Style T. (BART)	I saw Susie and then she came and took me to the kitchen where we cleaned.
Style T. (T5)	I saw Susie and then she came and took me to the kitchen where we cleaned up and we started talking about the new dog," she recalled.
PAN-P	I saw Susie sitting on a seasawe horse. and I saw haunted houses.
PAN-J (GPT2)	I saw Susie sitting in a speck of sheared sheep's sheep's sheep's sheep skin.
PAN-J (GPTJ)	I saw Susie sitting on a butter bucket with a black butter bucket sat on her butter bucket.

Method	**Text**
Inputs	(ex.4) needles, noodles, kneadle, don, need
Gold out.	I don't need your needles to kneadle noodles.
g2g (GPT2)	Don's dirt feet meet your earrings at the bottom of the dirt cany bore trail.
g2g (GPTJ)	One noodle needs a kneeler to lean on
Style T. (BART)	Near the end of his reign, Leiblau had to send a delegate to Parliament, to support his friend King Gules of Northumbria.
Style T. (T5)	Near the end of his reign, Leiblau had to send a delegate to Parliament, to support his friend King Gules of Northumbria.
PAN-P	If Donna Needles Need, who is Needles Nood, and the Need?
PAN-J (GPT2)	If you crave a soft chew toy, buy a chew toy that needs to chew.
PAN-J (GPTJ)	Don't kneadle a knuckle with a knuckle needle!
Inputs	(ex.5) thieves, thankful, thanked, thirty, thursday
Gold out.	The thirty-three thankful thieves thought that they thanked the other thirty-three thankful thieves throughout Thursday.
g2g (GPT2)	Twelve thieves today took sixty dollars from Thies' birthday party.
g2g (GPTJ)	The thieve thanked the thankful thief on Thursday.
Style T. (BART)	Thanked by Thnx for the idea, I thought it was an idea that I wanted to do a spoof of Thankful Thankful and Thnx.
Style T. (T5)	Thanked by Thnx for the idea, I thought it was an idea that I wanted to do a spoof of Thankful Thankful and Thnx, so it went to the video website, Twitter, and did some research on a T shirt.
PAN-P	Thankful thieves thought that they thought they thrilled the throne throughout Thursday.
PAN-J (GPT2)	I'm grateful tonight for thanking the valiant brave thieves.
PAN-J (GPTJ)	These sixty sheiks sent these thousand and sixty sheiks sixty sheiks thanking them for shouting these sixty sheiks sixty shouts on Thursday.
Inputs	(ex.6) snails, silently, sailed, slimy
Gold out.	Six slimy snails sailed silently.
g2g (GPT2)	Six silently sullen sullen snails slid silently across the sea.
g2g (GPTJ)	Slimy snails sailed silently.
Style T. (BART)	The ship was spotted by U.S. Coast Guard helicopter from a distance of four thousand, seven hundred nautical miles.
Style T. (T5)	The ship was spotted by Uas was was was was by by by by by by by.
PAN-P	Sailed from static line seven and all silently from Trondheim at seven on Sunday night.
PAN-J (GPT2)	Sailing silently on the sleigh.
PAN-J (GPTJ)	Six squandered snails silently sailed in a slivy ship.

Table 8: Additional qualitative examples for both TT-Prompt (first 3) and TT-Keyword (last 3): literal input, gold output, g2g (GPT-2), g2g (GPT-J), Style Transfer (BART), Style Transfer (T5), **PANCETTA-P** (GPT-2+BART), **PANCETTA-J** (GPT-2), and **PANCETTA-J** (GPT-J).

A User-Centered, Interactive, Human-in-the-Loop Topic Modelling System

Abstract

Human-in-the-loop topic modelling incorporates users' knowledge into the modelling process, enabling them to refine the model iteratively. Recent research has demonstrated the value of user feedback, but there are still issues to consider, such as the difficulty in tracking changes, comparing different models and the lack of evaluation based on real-world examples of use. We developed a novel, interactive human-in-the-loop topic modeling system with a user-friendly interface that enables users compare and record every step they take, and a novel topic words suggestion feature to help users provide feedback that is faithful to the ground truth. Our system also supports not only what traditional topic models can do, i.e., learning the topics from the whole corpus, but also targeted topic modelling, i.e., learning topics for specific aspects of the corpus. In this article, we provide an overview of the system and present the results of a series of user studies designed to assess the value of the system in progressively more realistic applications of topic modelling.

1 Introduction

Huge amounts of unstructured, textual data are generated daily. As more data becomes available, it becomes more difficult to search, understand and discover the knowledge within it. Because of the human effort it requires, conventional qualitative approaches, such as Grounded Theory, (Glaser et al., 1968) are no longer feasible with such large volumes of data. Topic modelling is a potential solution that has received increasing attention in recent research (Heidenreich et al., 2019; Curiskis et al., 2020; Dantu et al., 2021; Goyal and Howlett, 2021) to help users organize, search, and understand large amounts of information. It is an unsupervised machine learning technique for identifying hidden topics in large, unstructured text corpora, in which a hidden topic is represented by a group of words describing a common theme. Users can easily identify the topics in each document and search for documents closely associated with a specific topic for a more in-depth study. However, the topics generated by conventional topic models are often incoherent and contain many unrelated words (Chang et al., 2009; Mimno et al., 2011; Boyd-Graber et al., 2014). Although these issues can be addressed by pre-processing the target data source, for example, by removing irrelevant words from the vocabulary list and adjusting the hyper-parameters of the model, such as the number of topics, this requires familiarity with the algorithm. Hence, it is difficult for anyone who does not have some knowledge of topic modelling.

Human-in-the-loop topic modelling (HL-TM) incorporates human knowledge into the topic modelling process to address the aforementioned issues. It allows users who are not experts in topic modelling to refine the model through a set of refinement operations, such as adding words to a topic, removing words from a topic, splitting topics, or merging topics (Jagarlamudi et al., 2012; Wang et al., 2012; Choo et al., 2013; Hoque and Carenini, 2015; Lund et al., 2017; Smith et al., 2018). While most of these studies did not feed the refinement operations into an iterative retraining process, Smith et al. (2018) implemented a fully interactive, user-centered HL-TM system, and examined how the user experience is affected by issues arising in interactive systems, such as unpredictability, trust and lack of control. However, there are still limitations to their work. First, their system only allows users to refine the model sequentially, meaning that once a user updates the model, a new model overrides the previous model. This prevents users from comparing the effects of applying different refinement operations to the same model, making it difficult to find the most appropriate ones. Furthermore, because the previous model is no longer accessible, users may find it challenging to decide whether

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 505–522
May 2-6, 2023 ©2023 Association for Computational Linguistics

the new version is really an improvement. Second, their system does not allow users to retract the changes they made after the underlying model was updated. This becomes a problem when users make inappropriate changes that lead to unexpected results. It is especially frustrating when a user has spent a lot of time refining the model and the whole effect is ruined by one inappropriate change. Third, they use Latent Dirichlet Allocation (LDA) (Blei et al., 2003) as their underlying model.

Since LDA is a full-analysis model that can only learn topics from the whole corpus, its application is limited to when users have no *apriori* assumptions about the topics of the corpus. While users can refine the model by adding prior knowledge in an attempt to turn an unrelated topic into one that focuses on the aspect of interest, the phenomenon of higher order co-occurrence in LDA (Heinrich, 2009) may prevent any infrequent words related to the aspect of interest being assigned to the unrelated topic. For instance, given a set of posts about health, researchers may wish specifically to analyze the impact of food on health. Researchers would add food-related words such as “food”, “eat” to an unrelated topic. If these words have a relatively low frequency of occurrence in the posts, then the system may not turn the unrelated topic into a food-related topic. Fourth, an important question that has not yet been explored is how to signal to users when their assumptions do not match reality (Kumar et al., 2019), which may bias the refinement process. For instance, a user may think that a technology-related topic should contain words like “apple, google", while the input corpus has the word “apple" related to fruit. By adding “apple" to the topic, the topic will be contaminated with fruit-related words. Such incorrect refinements would result in poor results.

To address these issues, we implemented a novel HL-TM system that supports six refinement operations, including *add words, remove words, swap word order, remove documents, merge topics*, and *split topic* (Lund et al., 2017; Smith et al., 2018). Unlike Smith et al. (2018), where users can only refine the model sequentially and cannot retract the changes they made, in our system, users can make different attempts at refinement to the same model node and compare the resulting models. A complete refinement history is also presented, allowing users to track their changes from the first step. These also ensure that users can revert to the previous model node when an inappropriate refinement operation is applied. Instead of using LDA as the underlying model, our system uses the query-driven topic model (QD-TM) from (Fang et al., 2021) as the underlying model. The advantage is that the QD-TM not only supports the full-analysis capabilities from LDA, i.e., learning the overall topics from the whole corpus, but also supports users in performing targeted analysis, i.e., learning topics focused on specific aspects of the corpus by mitigating the effects of higher order co-occurrence phenomenon in LDA (Fang et al., 2021).

Moreover, we also implemented a novel automatic topic words suggestion feature to guide users in adding appropriate words to the selected topic. This feature extracts a list of candidate words related to the topic from which users can select words to add to the topic. Our evaluation results demonstrate the usefulness of this feature, where the suggested words are closely related to the selected topic and align better with the ground truth. We also conducted a series of user studies designed to assess the value of the system on real world application scenarios.

This work makes the following contributions: (1) a novel interactive HL-TM system with an advanced user interface that allows users to train different models from the same model node and retract inappropriate changes applied; (2) the use of QD-TM as the underlying model to support both the full-analysis and targeted-analysis topic modelling capabilities; (3) a novel and efficient topic words suggestion feature to guild users add appropriate words to the selected topics; and (4) a small scale user study and two detailed studies designed to replicate real-world application scenarios.

2 Background

Query-driven topic model is a semi-supervised topic modelling algorithm developed by Fang et al. (2021). It allows users to specify a simple query in words or phrases and return query-related topics. The original model involves a two-stage modelling process; in the first stage, the model infers one topic for each concept as well as other unrelated topics, while in the second stage, the model extends the topic of each concept into a set of subtopics. In our work, we are only interested in the first stage of the model. If there is no query input, the model works as a conventional topic model.

The model is based on a variant of a Hierarchical

Dirichlet Process (HDP) (Teh et al., 2006), which is a nonparametric Bayesian model that assumes that a restaurant (i.e., a document) has a set of tables and serves dishes (i.e., topics) from a global menu. A single dish is only served at a single table for all customers (i.e., words) who sit at that table. We developed our version of the algorithm based on the Gibbs sampling technique. For a word w_{ji} at document j and position i, the probability for sampling an existing table t is:

$$p(t_{ji} = t \mid t^{-ji}, k) \propto \mathbb{1}(w_{ji}, k_{jt}) n_{jt}^{-ji} f_{k_{jt}}^{-w_{ji}}(w_{ji}) \tag{1}$$

and the probability for sampling a new table t^{new} is:

$$p(t_{ji} = t^{new} \mid t^{-ji}, k) \propto \alpha p(w_{ji} \mid t^{-ji}, t^{new}, \mathbf{k}) \tag{2}$$

Here, t^{-ji} are the table assignments of all other words. k_{jt} is the topic assignment of table t at document j. n_{jt}^{-ji} is the number of words in document j at table t and $f_{k_{jt}}^{-w_{ji}}(w_{ji})$ is the probability of w_{ji} assigned to topic k_{jt}. $\mathbb{1}(w_{ji}, k_{jt})$ is an indicator function, which takes on value 0 if w_{ji} is a pre-defined word associated to a topic z that $z \neq k_{jt}$, and 1 otherwise. α is a hyperparamenter of the model. The probability for sampling a topic $k_{jt^{new}}$ for the new table is:

$$p(k_{jt^{new}} \mid t, k^{-jt^{new}}) \propto \mathbb{1}(w_{ji}, k_{jt}) m_k f_k^{-w_{ji}}(w_{ji}) \tag{3}$$

Human-in-the-Loop topic modelling has received a lot of attention in recent years. Boyer et al. (2017) created a Human–Machine methodology for identifying Systems Thinking topics in a large corpus of text. Users are required to subjectively identify and provide seed documents describing the topic to guide the topic model's training. The methodology, however, did not incorporate any prior knowledge into the modelling process, instead it simply modified the training corpora. Various refinement operations, such as adding words, removing words, adding documents, removing documents, creating topics, merging topics, or removing topics, were implemented to better utilize human knowledge in the topic modelling process (Hoque and Carenini, 2015; Lund et al., 2017; Smith et al., 2018). During the model sampling process, the refinements change the prior knowledge of the underlying model. To understand the usefulness of different refinement operations, Lee et al. (2017) conducted a user-centered approach to find out how non-expert users interpret topic models and what refinement operations they want most, but they only implemented a basic system without full interaction, so the refinement operations they applied did not update the underlying topic model.

Smith et al. (2018) took one step forward from Lee's work by implementing a fully interactive, user-centered HL-TM system and further examined how common interactive machine learning challenges, such as unpredictability, latency and trust, affect the user experience. Kumar et al. (2019) were the first to comparatively evaluate different refinement operations, as well as two feedback injection frameworks, namely informed priors and constraints. They not only suggested that future research should test the system with end users, since their experiments only used simulated user behavior, but also mentioned that it's important to signal to users when their assumptions do not match reality. Though other HL-TM systems exist such as UTOPIAN (Choo et al., 2013) and ConVisIT (Hoque and Carenini, 2015), they use alternative approaches such as non-negative matrix factorization and fragment quotation, and do not provide the complete set of refinement operations that users need (Lee et al., 2017).

Our work can be seen as an extension of the work of Smith et al. (2018). Compared to these studies, it not only provides a fully interactive HL-TM system incorporating various refinement operations but also provides a more user-centered design, such as a complete refinement history and a topic words suggestion feature to enhance the user experience.

3 Proposed System

We introduce our implementation and the interface design in this section.

3.1 Refinement Implementations

Our system uses Gibbs sampling as the inference technique and adopts the constraint method described in Kumar et al. (2019) to inject new information. Every time a user provides a feedback to the system, it first forgets table-word assignment t_{ji} and then injects new information into the system using a potential function $f(k, w, j)$ (Yang et al., 2015) of the hidden topic k of word w in document j. The equation (1) then becomes:

$$p(t_{ji} = t \mid t^{-ji}, k) \propto \mathbb{1}(w_{ji}, k_{jt}) n_{jt}^{-ji} f_{k_{jt}}^{-w_{ji}}(w_{ji}) f(k_{jt}, w_{ji}, j) \tag{4}$$

Prior work (Lee et al., 2017; Smith et al., 2018) discovered that users typically prefer simple refinement operations, therefore, we implemented the following six refinement operations that are commonly used by users in previous studies:

Add word x to topic z. We update the potential function $f(k, w, j)$ such that $f(k, w, j) = 1$ if $k = z$ and $w = x$, otherwise it is assigned a value of 0.

Remove word x from topic z. We update the potential function $f(k, w, j)$ such that $f(k, w, j) = 0$ if $k = z$ and $w = x$, otherwise it is assigned a value of 1.

Swap word order of w_1 and w_2 in topic z so that w_2 has higher order than w_1. We first compute the ratio r between the difference $n_{w_1,z} - n_{w_2,z}$ and n_{w_2}, where $n_{w_1,z}$ and $n_{w_2,z}$ are the counts of w_1 and w_2 in topic z, respectively, and n_{w_2} is the counts of w_2 in all topics except z. We then update the potential function $f(k, w, j)$, such that $f(k, w, j) = 1$ if $k = z$ and $w = w_2$, otherwise it is assigned δ, where $\delta = 0$ if $r > 1$, otherwise $\delta = 1.0 - r$.

Remove document d from topic z. We update the potential function $f(k, w, j)$ such that $f(k, w, j) = 0$ if $k = z$ and $j = d$, otherwise it is assigned a value of 1.

Merge topic t_2 into t_1. In the next Gibbs sampling iteration, we only sample topics for words assigned to t_2 in the previous Gibbs sampling iteration. We update the potential function $f(k, w, j)$ such that $f(k, w, j) = 1$ if $k = t_1$ and $w \in t_2$, otherwise it is assigned a value of 0.

Split topic t into two topics using seed words s, i.e., s need to be moved from t to a new topic t_n. To do this, we first create a new topic using the nonparametric model. Then, we apply the *add word* operation to add all the words in s to t_n.

3.2 Topic words suggestion

We developed a novel topic words suggestion feature in QD-TM to let users decide which words should appear or not appear in the topic words. Using only subjective input may result in topic words that are spurious, but combining the suggested words can help users to steer the model in the right direction. The topic words suggestion feature is integrated into the Gibbs samplings process of the model. It has two stages. First, it samples an indicator of whether a document is relevant to a topic or not. Second, it updates the suggested words from the relevant documents.

Document relevance sampling For each topic k, if a document contains any of the suggested words and is sampled to be relevant to the topic in the previous Gibbs sampling iteration, then it is assumed to be relevant to the topic in the current Gibbs sampling iteration. Otherwise, we use the following equation modified from Wang et al. (2016) to decide if the document is relevant to the topic:

$$p(r_k = c \mid \mathbf{r}, \pi, \beta, \gamma_{\mathbf{r}}, \gamma_{\mathbf{ir}}) \propto \begin{cases} (C_c^{R(-m)} + \gamma_r) \times \frac{\prod_v^V \Gamma(n_{k,v}^{-m} + \beta)}{\Gamma(\sum_v^V (n_{k,v}^{-m} + f_{c,m,v}) + V\beta)} \\ \text{if } c = 1 \\ (C_c^{R(-m)} + \gamma_{ir}) \times \frac{\prod_v^V \Gamma(n_{\tilde{k},v}^{-m} + \beta)}{\Gamma(\sum_v^V (n_{\tilde{k},v}^{-m} + f_{c,m,v}) + V\beta)} \\ \text{if } c = 0 \end{cases} \tag{5}$$

where $C_c^{R(-m)}$ is the number of documents under relevance status c excluding the current document m, $n_{k,v}^{(-m)}$ is the counts of term v in target topic k excluding the words from the current document m, $f_{c,m,v}$ is the frequency of term v in document m under relevance status c, and π indicates the Bernoulli distribution over relevance status. β, γ_r, and γ_{ir} are hyperparameters, and V is the vocabulary size of the dataset.

Automatic keywords expansion To get suggested words for a topic in each Gibbs sampling iteration, we first calculate the score of term v in the relevant documents of the topic:

$$Score(v) = P_R(v) log \frac{P_R(v)}{P_C(v)}, \tag{6}$$

where $P_R(v)$ is the probability of term v in the relevant documents and $P_C(v)$ is the probability of term v in the whole corpus. We extract terms with high scores as the candidate terms. We then calculate the cosine similarity between each candidate term and the embedding of the topic, and only add terms to the suggested words list when the similarity is greater than 0.5. The embedding of a topic k can be obtained by:

$$emb(k) = \sum_m^M P^i(k, m) emb(m), \tag{7}$$

where $p^i(k, m)$ is the probability of m^{th} word of topic k in i^{th} iteration, M is the total number of representative words in the topic, which is usually set to 10, and $emb(m)$ is the pretrained word embedding of the m^{th} word.

3.3 Interface Design

The user interface of the system consists of two windows (Appendix A). In the first window (Figure A1), users can define the hyper-parameters of a topic model, such as the initial number of topics. If users are interested in topics describing specific concepts or aspects of the corpus, they can also define the prior knowledge of a topic model in this window. If no prior knowledge is provided, then the model behaves as a conventional topic model without any prior knowledge.

The second window (Figure A2) displays the detailed information of the trained model. Users can view the model as a list of topics. Users can also refine the model using the refinement operations implemented and track model change histories. Different from previous systems where users can only refine a model sequentially and cannot retract the changes they made, we include a model history panel with a novel model tree structure so users can make different attempts at refinement to the same model node and compare the resulting models. To help users interpret each topic, we also show a set of topic labels from the automatic topic labeling algorithm (Mei et al., 2007), where a topic label is a phrase that summarises the main idea of the topic. A detailed description of the interface can be found in Appendix A.

4 Evaluation

The evaluation is divided into two parts. In the first part, we evaluated the performance of the topic words suggestion feature in a controlled, laboratory experiment, where we compared two versions of our system. In the second part, we evaluated the HT-LM system by applying it in two realistic topic modelling use cases.

4.1 Topic words suggestion evaluation

Datasets Three commonly used datasets for topic modelling were chosen: the 20newsgroup [1] dataset containing 18k news posts from 20 categories; the TagMyNews [2] dataset containing 32k short English news from 7 categories; and the SearchSnippets (Xu et al., 2017) dataset containing 12k short English news from 8 categories.

Baselines Our HL-TM system uses QD-TM as the underlying model. To test whether the *topic words suggestion* feature can improve the original model, we used only this feature to refine the QD-TM and compared the refined model with the original QD-TM.

Parameterisation We focused on the targeted topic modelling capabilities of QD-TM. To make fair comparisons, we adopted the same experimental settings described in Fang et al. (2021). We used query phrases to represent the main concept of each category in a dataset, following the same setup as in Fang et al. (2021). Categories that do not have meaningful names were removed from the datasets, e.g., `talk.politics.misc` in the 20Newsgroup dataset. The query phrases were integrated into the model using the first window of our HL-TM interface.

We used our HL-TM system to refine the original QD-TM and only used the *add word* refinement operation. In each Gibbs sampling iteration, for each topic, we added all suggested words to the topic. For the hyper-parameters in equation (5), β is set to 0.5, and both γ_r and γ_{ir} are set to 1. We ran 2000 Gibbs sampling iterations.

Results We evaluated the quality of the final models in terms of topic coherence and document retrieval performance as in Fang et al. (2021). Better precision@K scores indicate that the learnt topics are more discriminative and representative. Higher coherence scores indicate better topic interpretability. Table 1 shows the performance of adding suggested topic words to the model. We observed that the refined model achieves higher coherence scores compared with the original model. It indicates that the suggested words are semantically related to each topic and can help produce more coherent topics. The better precision@K scores also show that the suggested topic words are highly relevant to the predefined categories of the dataset. This is expected as the word suggestion feature in our system tends to identify more important words related to the category of the corresponding topic. Instead of blindly adding the suggested words to the model, our system allows users to decide which suggested words should be added. This allows them to use their domain knowledge to further filter out noise.

4.2 Laboratory evaluation

Description To compare our system with the state-of-the-art human-in-the-loop topic modelling system (Smith et al., 2018), we recruited 20 participants via a university campus email list to run

[2] http://acube.di.unipi.it/tmn-dataset/

Model	20news		TagMyNews		SearchSnippets	
	Coherence	Precision@K	Coherence	Precision@K	Coherence	Precision@K
QD-TM	0.445	0.612	0.413	0.736	0.475	0.741
QD-TM + words suggestion	**0.482**	**0.634**	**0.477**	**0.763**	**0.481**	**0.825**

Table 1: Average results for adding suggested topic words for model refinement. We ran each model five times. We used the topic coherence metric C_V from Röder et al. (2015)

a small-scale user study, with one subject group working with an equivalent of Smith et al. (2018) – our system with no model history, no words suggestion, and no topic labeling (old system) – and one group working with our full-featured system (new system). In a factorial design with two independent variables, we used two corpora of Reddit posts focusing on online teaching platforms (corpus A) and Twitter tweets discussing the 2021 United Nations Climate Change Conference (corpus B). Participants were randomly allocated into two groups. The first group did corpus A with the old system and corpus B with the new system, and the second group did corpus B with the old system and corpus A with the new system. The task was to conduct a qualitative analysis of the datasets.

Participants randomly started with either the old system or the new system to eliminate the influence of training effects. We then evaluated the average topic quality of the two system conditions. In addition to comparing topic quality across systems, we also asked participants questions about how much they like the new features. All participants were fluent English speakers and non-experts in topic modelling. Each participant received a £20 Amazon gift card as payment for the experiment.

Dataset and Topic Model We used two datasets for the experiments. The Reddit dataset contains 9,651 posts focusing on online teaching platforms. These posts were randomly sampled from the original dataset taken from Alqazlan et al. (2021). The Twitter dataset contains 8,990 tweets related to the 2021 United Nations Climate Change Conference. We used keywords related to the conference to search for tweets between 31 October 2021 and 17 November 2021. These keywords (see Table B1) were checked and provided by social scientists researching COP26 climate change tweets through a few rounds of manual inspection of the tweets. We used QD-TM as the underlying model, and used a standard stop words list and 2000 Gibbs sampling iterations to initialize the topics. We set the initial topic number to 10 and 13 respectively for the Reddit and Twitter datasets, respectively, based on our previous experience with these datasets. For each subsequent update during the task, 10 Gibbs sampling iterations were run.

Procedure Sessions took around 60 minutes on average, and they were conducted face-to-face. We began by introducing participants to topic modelling and how to use the tools to refine topics. For both systems, we asked them to first read the top five posts of each topic to interpret the underlying theme and then read the corresponding top 10 topic words and use the provided refinement operations to refine the topic until the top 10 topic words and the top 5 posts are consistent with the interpreted theme. For the new system, participants could also access the new features – model history, word suggestions, and topic labelling to assist their in refinements. We asked participants to click the *apply refinements* button to update the underlying model after they have added all the necessary refinements to a topic. They were allowed to undo any operations that have not been applied to the underlying model. After they finished the refining tasks, we asked them to rate how much they are satisfied with the resulting topics and how much they like the new features. Due to time limitations, we only asked participants to refine the first five topics of each system. The first five topics of the starting model for each corpus can be found in Table B2 and Table B3.

Findings We recorded user interactions with the tools. Users performed a total of 1,284 refinements using the two systems. Among the top four most used operations were the *delete words* operation (used 554 times), the *swap words* operation (used 512 times), the *add words* operation (used 171 times), and the *delete document* operation (used 81 times). This is consistent with the findings of Smith et al. (2018), who also observed that these operations were the four most used operations (excluding the add to stop words operation since our system didn't implement this). For the new system, the *add words* operation was applied 115 times in total, among which 56 times were adding suggested words, which indicates that the suggested words operation had high usage. We report the usage of refinements for each subject group in Table B4.

To evaluate whether using the new system can result in better topics than the old system, participants were asked to rate their satisfaction with the final topics of the two systems on a five point scale (1 not very satisfied, 5 very satisfied). For the Reddit dataset, the average satisfaction score for the new system was 4.2 (SD=0.67), while the score for the old system was 3.89 (SD=0.78). Although a Mann-Whitney U test (U=30.5, z=0.83887, p=.200) showed this difference was not statistically significant, 8 out of 10 participants were satisfied with final topics of the new system. For the Twitter dataset, the score for the new system was 4.0 (SD=0.71), while the score for the old system was 3.2 (SD=0.67). A Mann-Whitney U test (U=18.5, z=1.8985, p=.029) showed that the difference was statistically significant, suggesting that the new system can help improve topic quality.

To evaluate whether the model tree feature can help users track changes, we asked participants to rate their agreement with the statement, "I was able to remember what the model looked like before my updates", on a five point scale (1 strongly disagree satisfied, 5 strongly agree), for both the old and new systems. The average agreement was 3.1 (SD=1.07) for the old system and 3.9 (SD=0.85) for the new system. A Mann-Whitney U test (U=116, z=2.25868, p=.012) showed the difference to be statistically significant. Participants were also asked to rate their agreement with the statement, "the model tree feature of the new system can help me track my updates". The average agreements for the statement was 4.35 (SD=1.04). This strongly suggests that the model tree feature of the new system can help users track their changes. To evaluate the usefulness of the words suggestion feature, we asked participants to rate their agreement with the statement, "the suggested words feature of the new system can help me identify relevant words of the topics". The average agreements for the statement was 4.1 (SD=0.64). 17 out of 20 participants stated that the feature is very useful, suggesting that the feature is a good supplement for adding words to topics. The finding is consistent with the observation of user interactions with the new system that around 50% (56 out of 115) of added words were from the suggested words list. For the topic labelling feature, participants were asked if they agreed with the statement, "the topic labels from the full-featured system can help me interpret the meaning of the topics". The average score for the statement was 3.25, and 11 out of 20 mentioned that the provided labels for some topics are totally irrelevant. This suggests that the algorithm (Mei et al., 2007) doesn't fit the datasets well and suggests the needs for a more accurate topic labelling algorithm in the future.

Suggestions Though the user studies show promising results, participants also had suggestions for improving the new system. Six mentioned that the swap words operation didn't fit their needs well. Instead of swapping the order of the two selected words, they prefer to allow the selected words to be inserted in new positions, which provides more flexibility when ranking topic words. One participant suggested allowing the undo any of the previously added operations directly, rather than starting with the most recently operation.

4.3 Use case one: Tutors' experiences in the Gig Economy

Description To evaluate our system on real-world document analysis tasks, we invited a researcher who is investigating the Gig Economy to use our model. In previous work, Alqazlan et al. (2021) applied LDA to identify topics that are related to tutors' experiences in the Gig Economy from a Reddit dataset where tutors posted about their experiences of working on online teaching platforms. We asked the researcher to use our system to identify the relevant topics in the dataset and assess whether using our system can produce better results than LDA. As Alqazlan et al. (2021) has previously found that a 17-topic LDA extracted the most number of relevant topics, for a fair comparison, the initial number of topics for our system was also set to 17. The researcher was encouraged to use any refinement operations provided by the system until she felt that the top 5 relevant posts of each detected topic revolved around one main theme.

Results A total of 16 models were trained and two branches were created during the refinement process, with models 11, 12 and 13 constituting one branch and models 14, 15 and 16 constituting the other branch. Both of these branches were extended from model 10, which was trained sequentially from the initial model. By using the model tree panel to compare these models, it was found that Model 16 produced the most satisfactory results. Of all the refinement operations, *remove document* was used the most and *swap word order* was used the least. The researcher commented that the *swap word order* could be more useful if it only adjusts the position of a word in the topic, rather than swapping a word with another one.

We compare LDA with Model 16 and present the qualitative results here. For both models, the researcher was asked to manually assign a label to each topic. For the LDA model, 11 topics were found to be relevant to tutors' experience in the Gig Economy, two of which (Table C1) were missed by Model 16, while for Model 16, 16 topics were found to be relevant, of which seven topics (Table C2) were not identified by the LDA. This indicates that our HL-TM system is able to assist the researcher to identify more relevant topics.

To determine whether using our system can help produce better quality topics, we measured the topic coherence score for the 9 relevant topics identified by both LDA and Model 16 (Table C3). We used the best performing topic coherence measure CV based on the external corpus (Wikipedia) (Röder et al., 2015). We found that our system produced better topic coherence scores for six topics, while the LDA produced better scores for only three topics. This finding is consistent with the researcher's view that only two topics from the LDA were of better quality than Model 16. We present the relevant topics from both LDA and Model 16 in Appendix C.

4.4 Use case two: Patenting strategies for pre-determined patent value categories

Description We invited a second researcher, who is working on patenting strategies, to evaluate our system. In a previous study, Ribeiro and Shapira (2020) has identified a set of patent value categorises (Table D1) for synthetic biology patents. However, their work was based entirely on human evaluation and was, therefore, time-consuming, and biased evaluations could occur, so only 102 patent documents were analysed. In this use case, the researcher aimed to use our system to categorise a larger patent sample to the pre-defined categories and reduce human selection bias. 2607 related patents in the United States Patent and Trademark Office (USPTO) dataset were used. The predefined categorises are presented in Appendix D.

To identify documents in their predefined categories in the dataset, the researcher used the first window of the interface to incorporate prior knowledge. A list of final concept words of each category is presented in Table D2 in Appendix D. The initial number of topics is set to 20.

Results By using the first window of the user interface to incorporate priori knowledge, the initial model was able to roughly infer topics for the predefined categories, although the topics were not yet of high quality. We then asked the researcher to examine the top 10 relevant documents of these topics to assess the categorisation quality. The average precision is 0.3. The researcher then refined these topics using the system until she felt that it best categorised the top 5 relevant documents into each category and was satisfied with the resulting topic words. In total 23 models were trained and five branches were created, with Model 23 being the best one. After the refinements, we asked the researcher to further examine the top 10 relevant documents of the refined topics to compare with the initial model. The average precision for the refined topics is 0.96, which is much higher than the result from the initial model. This verifies that the use of the system can help identify a larger sample of documents in pre-defined categories than the previous manual evaluation method. In total, the *add word* operation was applied 62 times, among which 41 times were related to adding suggested words from the system. This shows that our topic words suggestion feature can indeed identify words that are highly relevant to specific topics.

We also compared the topic coherence scores for the focused topics from the initial model (Table D2) and from Model 23 (Table D3). The scores are 0.404 and 0.434, respectively. It shows that using the system can help produce better quality topics.

5 Conclusions and Future work

We have developed a novel user-centered, interactive, HL-TM system to address the limitations of the prior work (Smith et al., 2018). An advanced user interface with a model history panel is presented to allow users compare different models and retract inappropriate changes. The use of the QD-TM as the underlying model supports both the full-analysis and targeted-analysis capabilities. A novel topic words suggestion feature is also integrated into the system and the evaluation shows that the feature is promising for suggesting reasonable and coherent words for topics. A small scale experimental user study and two detailed use cases further verified the usefulness of the system on real-world tasks. From the use cases, we observed that both researchers trained many different models with multiple branches created (use case one has 16 models trained and two branches created, while use case two has 23 models trained and five branches created). This shows that researchers are very likely to change their mind when refining a topic model, so allowing researchers to compare different models and retract their changes is helpful. In the future, we plan to improve the system based on the results from the user evaluations and conduct more extensive evaluations to gather feedback on deploying the system in a wide variety of applications.

Limitations

We used two small datasets in the user evaluations, so participants were not affected by latency issues, where the user would have to wait while the algorithm performs updates. Since QD-TM is more complex than LDA, and the words suggestion feature further increased the complexity of the computation, a large dataset could lead to latency problems. The time complexity of our system is O(DLK + KV), where D is the number of documents used, L is the average document length, K is the number of topics and V is the vocabulary size. We tested the system with two different dataset sizes (20,000 tweets vs. 8,990 tweets). By using 20,000 tweets, the average wait time for model updates during user interaction (10 Gibbs sampling iterations) was 34 seconds, compared to 14 seconds using 8,990 tweets.

According to Smith et al. (2018), longer wait times can negatively affect users when using interactive systems, suggesting that latency could be an issue in our system as the size of the dataset increases. However, as is well known, these effects can be mitigated through the provision of time affordances (Conn, 1995). We will address this in the future.

In addition to the latency issue, the laboratory evaluation we conducted also has limitations. Not all the participants were familiar with qualitative analysis. It is likely that participants with extensive experience in qualitative analysis identify more valuable refinements to the models, resulting in better quality topics.

Appendix A: Interface Design

The user interface of the system consists of two windows. If users are interested in topics describing specific concepts or aspects of the corpus, they can define the prior knowledge of a topic model in the first window (Figure A1). They can use a query phrase to define the concept of interest. The input query phrase is expanded to a set of candidate concept words using the concept words extractor from Fang et al. (2021). Users can use their knowledge to determine which words should be included in a topic and click the "+" buttons next to them to add to the final concept words list of a topic. They can also add words that are not in the candidate words list to the final list based on their knowledge. The words in the final list can be removed by clicking the corresponding “-” buttons. It also supports viewing the top relevant documents of the input query by changing the viewing options from "By keywords" to "By documents".

If users have no preferred interest in the topics of the corpus, they can leave the final concept words list of each topic empty, and the model behaves as a conventional topic model without any prior knowledge. Users can click the "apply" button to apply the settings to the underlying model. Users can view the resulting topics by clicking the "View" button in the bottom, which takes them to the second window of the user interface.

The second window of the interface (Figure A2) has three panels: *model history* panel (left panel), *model detail* panel (middle panel), and *inter-topic distance map* (right panel). The *model history* panel consists of two subpanels: the *model tree* panel (top panel), which displays the refined models in a tree structure, and the *refinements history* panel (bottom panel). Every time a user refines a selected model, a new model is added to the tree. As shown in Figure A2, users can also create new branches from the same model node. For example, model 5, model 6 and model 7 are all refined from model 4. The *refinements history* panel allows users to view the refinements history between two connected models by clicking on the edge between them. Users can also view the pending refinements of the selected model as shown in Figure A2.

The pending refinements will not be applied to the underlying model until users click the "Apply Refinement" button. We also include an "undo" button to allow users to undo previously added refinements. The *model history* panel allows users to compare previously refined models and keep track of their previous changes to further assist the refinement process. By clicking the "Download models" button, users can download the entire model tree to their local machine, and by clicking the "Load models" button, users can load a previously downloaded model tree to continue the refinements.

The *model detail* panel, shown in the middle of Figure A2, provides an overview of the selected model’s topics, as well as the top words in each one. Weight represents the prevalence of the topic in the whole corpus. Users can rename a topic by typing a new name in the “Topic” column. Users can also merge or split topics in this panel. The right side of Figure A2 is the *inter-topic distance map*. Each circle represents a topic, with its size representing the topic weight in the corpus. The *inter-topic distance map* is an intuitive way to reveal the quality of a topic model where a larger distance between topics indicates a better model (Sievert and Shirley, 2014). By clicking the “view” button on the window, the selected topic’s specifics will then be presented as shown in Figure A3.

The top left side of Figure A3 shows a set of topic labels from the automatic topic labeling algorithm (Mei et al., 2007), where a topic label is a phrase that summarises the main idea of the topic. The aim of the topic label is to help users interpret the topic. We also present the top words of the topic with corresponding topic-word weights. Weights indicate the prevalence of the words in the topic. Users can apply *add, delete* or *swap word order* refinement operations here. The right side of Figure A3 displays the top documents associated with the topic and ranks them based on their weight, representing the document’s prevalence of the topic. Users can apply the *remove document* refinement operation here. By clicking the "view" button, users can view the details of the selected document.

When users click the "add" button in Figure A3, an "add words" sub-panel (Figure A4) appears. A list of words suggested by the topic words suggestion feature is displayed in the panel. Users can select from the suggested words or from their own knowledge to add words to the selected topic.

A Survey of Methods for Addressing Class Imbalance in Deep-Learning Based Natural Language Processing

Abstract

Many natural language processing (NLP) tasks are naturally imbalanced, as some target categories occur much more frequently than others in the real world. In such scenarios, current NLP models tend to perform poorly on less frequent classes. Addressing class imbalance in NLP is an active research topic, yet, finding a good approach for a particular task and imbalance scenario is difficult.

In this survey, the first overview on class imbalance in deep-learning based NLP, we first discuss various types of controlled and real-world class imbalance. Our survey then covers approaches that have been explicitly proposed for class-imbalanced NLP tasks or, originating in the computer vision community, have been evaluated on them. We organize the methods by whether they are based on sampling, data augmentation, choice of loss function, staged learning, or model design. Finally, we discuss open problems and how to move forward.

1 Introduction

Class imbalance is a major problem in natural language processing (NLP), because target category distributions are almost always skewed in NLP tasks. As illustrated by Figure 1, this often leads to poor performance on minority classes. Which categories matter is highly task-specific and may even depend on the intended downstream use. Developing methods that improve model performance in imbalanced data settings has been an active area for decades (e.g., Bruzzone and Serpico, 1997; Japkowicz et al., 2000; Estabrooks and Japkowicz, 2001; Park and Zhang, 2002; Tan, 2005), and is recently gaining momentum in the context of maturing neural approaches (e.g., Buda et al., 2018; Kang et al., 2020; Li et al., 2020; Yang et al., 2020; Jiang et al., 2021; Spangher et al., 2021). The problem is exacerbated when classes overlap in the feature space (Lin et al., 2019; Tian et al., 2020). For example, in patent classification, technical categories differ largely in frequency, and the concepts mentioned in the different categories can be very similar.

Figure 1: **Class imbalance** has a negative effect on **performance** especially for minority classes in a variety of NLP tasks. Upper charts show label count distributions, lower part show test/dev F1 by training instance count (lighter colors indicate fewer test/dev instances). All models are based on transformers.

On a large variety of NLP tasks, transformer models such as BERT (Vaswani et al., 2017; Devlin et al., 2019) outperform both their neural predecessors and traditional models (Liu et al., 2019; Xie et al., 2020; Mathew et al., 2021). Performance for minority classes is also often higher when using self-supervised pre-trained models (e.g., Li and Scarton, 2020; Niklaus et al., 2021), which parallels findings from computer vision (Liu et al., 2022). However, the advent of BERT has not solved the class imbalance problem in NLP, as illustrated by Figure 1. Tänzer et al. (2022) find that on synthetically imbalanced named entity datasets with

majority classes having thousands of examples, at least 25 instances are required to predict a class at all, and 100 examples to learn to predict it with some accuracy.

Despite the relevance of class imbalance to NLP, related surveys only exist in the computer vision domain (Johnson and Khoshgoftaar, 2019b; Zhang et al., 2021b). Incorporating methods addressing class imbalance can lead to performance gains of up to 20%. Yet, NLP research often overlooks how important this is in practical applications, where minority classes may be of special interest.

Our contribution is to draw a clear landscape of approaches applicable to deep-learning (DL) based NLP. We set out with a problem definition (Sec. 2), and then organize approaches by whether they are based on sampling, data augmentation, choice of loss function, staged learning, or model design (Sec. 3). Our extensive survey finds that re-sampling, data augmentation, and changing the loss function can be relatively simple ways to increase performance in class-imbalanced settings and are thus straightforward choices for NLP practitioners.[1] While promising research directions, staged learning or model modifications often are implementation-wise and/or computationally costlier. Moreover, we discuss particular challenges of non-standard classification settings, e.g., imbalanced multi-label classification and catch-all classes, and provide useful connections to related computer vision work. Finally, we outline promising directions for future research (Sec. 4).

Scope of this survey. We focus on approaches evaluated on or developed for neural methods. Work from "traditional" NLP (e.g., Tomanek and Hahn, 2009; Li et al., 2011; Li and Nenkova, 2014; Kunchukuttan and Bhattacharyya, 2015) as well as Natural Language Generation (e.g., Nishino et al., 2020) and Automatic Speech Recognition (e.g., Winata et al., 2020; Deng et al., 2022) are not addressed in this survey. Other types of imbalances such as differently sized data sets of subtasks in continual learning (Ahrens et al., 2021) or imbalanced regression (Yang et al., 2021) are also beyond the scope of this survey. In Sec. 3.5, we briefly touch upon the related area of few-shot learning (Wang et al., 2020c).

Related surveys. We review imbalance-specific data augmentation approaches in Sec. 3.2. Feng et al. (2021) give a broader overview of data augmentation in NLP, Hedderich et al. (2021) provide an overview of low-resource NLP, and Ramponi and Plank (2020) discuss neural domain adaptation.

2 Problem Definition

Class imbalance refers to a classification setting in which one or multiple classes (**minority classes**) are considerably less frequent than others (**majority classes**). More concrete definitions, e.g., regarding the relative share up to which a class is seen as a minority class, depend on the task, dataset and labelset size. Much research focuses on improving all minority classes equally while maintaining or at least monitoring majority class performance (e.g., Huang et al., 2021; Yang et al., 2020; Spangher et al., 2021). We next discuss prototypical types of imbalance (Sec. 2.1) and then compare controlled and real-world settings (Sec. 2.2).

2.1 Types of Imbalance

To systematically investigate the effect of imbalance, Buda et al. (2018) define two prototypical types of label distributions, which we explain next.

Step imbalance is characterized by the fraction of minority classes, μ, and the size ratio between majority and minority classes, ρ. Larger ρ values indicate more imbalanced data sets. In prototypical step imbalance, if there are multiple minority classes, all of them are equally sized; if there are several majority classes, they also have equal size. Figure 2a shows a step-imbalanced distribution with 40% of the classes being minority classes

---

[1] We provide practical advice on identifying potentially applicable class imbalance methods in the Appendix (Figure 3).

and an imbalance ratio of $\rho = 10$. NLP datasets with a large catch-all class as they often arise in sequence tagging (see Sec. 2.2) or in relevance judgments in retrieval models frequently resemble step-imbalanced distributions. The ρ ratio has also been reported in NLP, e.g., by Li et al. (2020), although more task-specific imbalance measures have been proposed, e.g., for single-label text classification (Tian et al., 2020). In **linear imbalance**, class size grows linearly with imbalance ratio ρ (see Figure 2b), as, e.g., in the naturally imbalanced SICK dataset for natural language inference (Marelli et al., 2014).

Long-tailed label distributions (Figure 2c) are conceptually similar to linear imbalance. They contain many data points for a small number of classes (*head classes*), but only very few for the rest of the classes (*tail classes*). These distributions are common in computer vision tasks like instance segmentation (e.g., Gupta et al., 2019a), but also in multi-label text classification, for example with the goal of assigning clinical codes (Mullenbach et al., 2018), patent categories (Pujari et al., 2021), or news and research topics (Huang et al., 2021).

2.2 Controlled vs. Real-World Class Imbalance

Most real-world label distributions in NLP tasks do not perfectly match the prototypical distributions proposed by Buda et al. (2018). Yet, awareness of these settings helps practitioners to select appropriate methods for their data set or problem by comparing distribution plots. Using synthetically imbalanced data sets, researchers can control for more experimental factors and investigate several scenarios at once. However, evaluating on naturally imbalanced data provides evidence of a method's real-world effectiveness. Some recent studies combine both types of evaluation (e.g., Tian et al., 2021; Subramanian et al., 2021; Jang et al., 2021).

Many NLP tasks require treating a large, often heterogenous **catch-all class** that contains all instances that are not of interest to the task, while the remaining (minority) classes are approximately same-sized. Examples include the "Outside" label in IOB sequence tagging, or tweets that mention products in contexts that are irrelevant to the annotated categories (Adel et al., 2017). Such real-world settings often roughly follow a step imbalance distribution, with the additional difficulty of the catch-all class.

2.3 Evaluation

As *accuracy* and *micro*-averages mostly reflect majority class performance, choosing a good evaluation setting and metric is non-trivial. It is also highly task-dependent: in many NLP tasks, recognizing one or all minority classes well is at least equally important as majority class performance. For instance, non-hateful tweets are much more frequent in Twitter (Waseem and Hovy, 2016), but recognizing hateful content is the key motivation of hate speech detection. Which classes matter may even depend on downstream considerations, i.e., the same named entity tagger might be used in one application where a majority class matters, and another where minority classes matter more. Several evaluation metrics exist that have been designed to account for class-imbalanced settings, but no de facto standard exists. For example, *balanced accuracy* (Brodersen et al., 2010) corresponds to the average of per-class recall scores. It is often useful to record performance on *all* classes and to report *macro*-averages, which treat all classes equally.

3 Methods for Addressing Class Imbalance in NLP

In this section, we survey methods that either have been explicitly proposed to address class-imbalance issues in NLP or that have been empirically shown to be applicable for NLP problems. We provide an overview of which methods are applicable to a selection of NLP tasks in Appendix A.

3.1 Re-Sampling

To increase the importance of minority instances in training, the label distribution can be changed by various sampling strategies. Sampling can either be executed once or repeatedly during training (Pouyanfar et al., 2018). In *random oversampling* (**ROS**), a random choice of minority instances are duplicated, whereas in *random undersampling* (**RUS**), a random choice of majority instances are removed from the dataset. ROS can lead to overfitting and increases training times. RUS, however, discards potentially valuable data, but has been shown to work well in language-modeling objectives (Mikolov et al., 2013).

When applied in DL, ROS outperforms RUS both in synthetic step and linear imbalance (Buda et al., 2018) and in binary and multi-class English and Korean text classification (Juuti et al., 2020; Akhbardeh et al., 2021; Jang et al., 2021). More flexible variants, e.g., re-sampling only a tunable share of classes (Tepper et al., 2020) or interpolating between the (imbalanced) data distribution and an almost perfectly balanced distribution (Arivazhagan et al., 2019), can also further improve results. *Class-aware sampling* (**CAS**, Shen et al., 2016), also referred to as *class-balanced sampling*, first chooses a class, and then an instance from this class. Performance-based re-sampling during training, following the idea of Pouyanfar et al. (2018), works well in multi-class text classification (Akhbardeh et al., 2021).

Issues in multi-label classification. In multi-label classification, label dependencies between majority and minority classes complicate sampling approaches, as over-sampling an instance with a minority label may simultaneously amplify the majority class count (Charte et al., 2015; Huang et al., 2021). CAS also suffers from this issue, and additionally introduces within-class imbalance, as instances of one class are selected with different probabilities depending on the co-assigned labels (Wu et al., 2020). Effective sampling in such settings is still an open issue. Existing approaches monitor the class distributions during sampling (Charte et al., 2015) or assign instance-based sampling probabilities (Gupta et al., 2019b; Wu et al., 2020).

3.2 Data Augmentation

Increasing the amount of minority class data during corpus construction, e.g., by writing additional examples or selecting examples to be labeled using Active Learning, can mitigate the class imbalance problem to some extent (Cho et al., 2020; Ein-Dor et al., 2020). However, this is particularly laborious in naturally imbalanced settings as it may require finding “the needle in the haystack,” or may lead to biased minority class examples, e.g., due to collection via keyword queries. Synthetically generating additional minority instances thus is a promising direction. In this section, we survey data augmentation methods that have been explicitly proposed to mitigate class imbalance and that have been evaluated in combination with DL.

Text augmentation generates new natural language instances of minority classes, ranging from simple string-based manipulations such as synonym replacements to Transformer-based generation. *Easy Data Augmentation* (**EDA**, Wei and Zou, 2019), which uses dictionary-based synonym replacements, random insertion, random swap, and random deletion, has been shown to work well in class-imbalanced settings (Jiang et al., 2021; Jang et al., 2021; Juuti et al., 2020). Juuti et al. (2020) generate new minority class instances for English binary text classification using EDA and embedding-based synonym replacements, and by adding a random majority class sentence to a minority class document. They also prompt the pre-trained language model GPT-2 (Radford et al., 2019) with a minority class instance to generate new minority class samples. Tepper et al. (2020) evaluate generation with GPT-2 on English multi-class text classification datasets, coupled with a flexible balancing policy (see Sec. 3.1).

Similarly, Gaspers et al. (2020) combine machine-translation based text augmentation with dataset balancing to build a multi-task model. Both the main and auxiliary tasks are German intent classification. Only the training data for the latter is balanced and enriched with synthetic minority instances. In a long-tailed multi-label setting, Zhang et al. (2022) learn an attention-based text augmentation that augments instances with text segments that are relevant to tail classes, leading to small improvements. In general, transferring methods such as EDA or backtranslation to multi-label settings is difficult (Zhang et al., 2022, 2020; Tang et al., 2020).

Hidden space augmentation generates new instance vectors that are not directly associated with a particular natural language string, leveraging the representations of real examples. Using representation-based augmentations to tackle class imbalance is not tied to DL. SMOTE (Chawla et al., 2002), which interpolates minority instances with randomly chosen examples from their K-nearest neighbours, is popular in traditional machine learning (Fernández et al., 2018), but leads to mixed results in DL-based NLP (Ek and Ghanimifard, 2019; Tran and Litman, 2021; Wei et al., 2022). Inspired by CutMix (Yun et al., 2019), which cuts and pastes a single pixel region in an image, **TextCut** (Jiang et al., 2021) randomly replaces small parts of the BERT representation of one instance with those of the other. In binary and multi-class text classification experiments, TextCut improves over non-augmented BERT and EDA.

Good-enough example extrapolation (**GE3**, Wei, 2021) and **REPRINT** (Wei et al., 2022) also operate in the original representation space. To synthesize a new minority instance, GE3 adds the vector representing the difference between a majority class instance and the centroid of the respective majority class to the mean of a minority class. Evaluations on synthetically step-imbalanced English multi-class text classification datasets show improvements over oversampling and hidden space augmentation baselines. GE3 assumes that the distribution of data points of a class around its mean can be extrapolated to other classes, an assumption potentially hurting performance if the minority class distribution differs. To account for this when subtracting out majority characteristics, REPRINT performs a principal component analysis (PCA) for each class, leveraging the information on relevant dimensions during sample generation. This method usually outperforms GE3, with the cost of an additional hyperparameter (subspace dimensionality).

MISO (Tian et al., 2021) generates new instances by transforming the representations of minority class instances that are located nearby majority class instances. They learn a mapping from minority instance vectors to "disentangled" representations, making use of mutual information estimators (Belghazi et al., 2018) to push these representations away from the majority class and closer to the minority class. An adversarially-trained generator then generates minority instances using these disentangled representations. Tian et al. apply MISO in naturally and synthetically imbalanced English and Chinese binary and multi-class text classification with a single minority class.

ECRT (Chen et al., 2021) learns to map encoder representations (feature space) to a new space (source space) whose components are independent of each other given the class, assuming an invariant causal mechanism from source to feature space. The independence enables them to generate new meaningful minority examples by permuting or sampling components in the source space, resulting in medium improvements on a large multi-label text classification dataset with many labels.

Further related work exists in the area of **transfer learning** (Ruder et al., 2019), e.g., from additional datasets that provide complementary information on minority classes. For instance, Spangher et al. (2021) achieve small gains by manually selecting auxiliary datasets to improve imbalanced sentence-based discourse classification. However, complementary datasets have to be retrieved for each application, and task loss coefficients have to be tuned. Adapting methods to predict useful transfer sources (Lange et al., 2021) might help alleviate these problems.

3.3 Loss Functions

Standard *cross-entropy loss* (**CE**) is composed from the predictions for instances that carry the label in the gold standard, which is why the resulting classifiers fit the minority classes less well. In this section, we summarize loss functions designed for imbalanced scenarios. They either re-weight instances by class membership or prediction difficulty, or explicitly model class margins to change the decision boundary. Throughout this section, we use the variables and terms as shown in Table 1.

Losses for Single-Label Scenarios. *Weighted cross-entropy* (**WCE**) uses class-specific weights α_j that are tuned as hyperparameters or set to the inverse class frequency (e.g., Adel et al., 2017; Tayyar Madabushi et al., 2019; Li and Xiao, 2020). While WCE treats all instances of one class in the same way, *focal loss* (**FL**, Lin et al., 2017) down-weights instances for which the model is already confident (implemented with the $(1-p_j)^\beta$ coefficient). FL can of course also be used with class weights. Instead of mimicking accuracy like CE, *dice loss* (**Dice**, Milletari et al., 2016) tries to capture class-wise F1 score, with the predicted probability p_j proxying precision and the ground truth indicator y_j proxying recall. *Self-adjusting dice loss* (**ADL**, Li et al., 2020) combines confidence-based down-weighting via $1-p_j$ with Dice loss. For sequence labeling, QA and matching on English and Chinese datasets, Dice performs better than FL and ADL.

Rather than re-weighting instances, *label-distribution-aware margin loss* (**LDAM**, Cao et al., 2019), essentially a smooth hinge loss with label-dependent margins Δ_j, aims to increase the distance of the minority class instances to the decision boundary with the aim of better generalization for these classes. Cao et al.'s evaluation largely focuses on computer vision, but they also report results for LDAM on a synthetically imbalanced version of the IMDB review dataset (Maas et al., 2011), achieving a much lower error on the minority class than vanilla CE or CE with re-sampling or re-weighting. Subramanian et al. (2021) propose LDAM variants that consider bias related to socially salient groups (e.g., gender-based bias) in addition to class imbalance, evaluating them on binary text classification.

Single-label	**CE**	$-\sum_{j=1}^{C} y_j \log p_j$	**WCE**	$-\sum_{j=1}^{C} \alpha_j y_j \log p_j$
	FL	$-\sum_{j=1}^{C} y_j (1-p_j)^{\beta} \log p_j$		
	Dice	$\sum_{j=1}^{C} 1 - \frac{2p_j y_j + \gamma}{p_j^2 + y_j^2 + \gamma}$	**ADL**	$\sum_{j=1}^{C} 1 - \frac{2(1-p_j)p_j y_j + \gamma}{(1-p_j)p_j + y_j + \gamma}$
	LDAM	$-\sum_{j=1}^{C} y_j \log \frac{\exp(z_j - \Delta_j)}{\exp(z_j - \Delta_j) + \sum_{l \neq j} \exp(z_l)}$ with $\Delta_j = K/n_j^{1/4}$		
	RL	$\mathbb{1}(gt \neq A) \log(1 + \exp(\rho(m^+ - z_{gt}))) + \log(1 + \exp(\rho(m^- - z_{c^-})))$		
Multi-label	**BCE**	$-\sum_{j=1}^{C} [y_j \log p_j + (1-y_j) \log(1-p_j)]$		
	WBCE	$-\sum_{j=1}^{C} \alpha_j [y_j \log p_j + (1-y_j) \log(1-p_j)]$		
	FL	$-\sum_{j=1}^{C} [y_j (1-p_j)^{\beta} \log p_j + (1-y_j) p_j^{\beta} \log(1-p_j)]$		
	DB	$-\sum_{j=1}^{C} [y_j \hat{\alpha}_j (1-q_j)^{\beta} \log q_j + (1-y_j) \hat{\alpha}_j \frac{1}{\lambda} q_j^{\beta} \log(1-q_j)]$ with $q_j = y_j \sigma(z_j - v_j) + (1-y_j)\sigma(\lambda(z_j - v_j))$		

C	number of classes
y	target vector
p	model prediction vector
α	class weights
β	tunable focusing parameter
z	model logits vector
γ	smoothing constant
n_j	size of class j
K	label-independent constant
gt	index of ground-truth class
m^+	margin to correct class
m^-	... to most competitive incorrect class
A	special catch-all class
c^-	index of largest non-gt logit
λ	scaling factor
$\hat{\alpha}_j$	instance-specific class weights
v_j	class-specific bias

Table 1: Overview of **loss functions** formulated for one instance. See Appendix A for references/implementations.

In settings with a large artificial and potentially heterogeneous **catch-all class** (see Sec. 2.2), many areas of the space contain representations of the catch-all class. Here, vanilla LDAM might be an appropriate loss function as it encourages larger margins for minority classes. In such cases, *ranking losses* (**RL**) can also be effective to incentivize the model to only pay attention to "real" classes. On an imbalanced English multi-class dataset with a large catch-all class, Adel et al. (2017) find a ranking loss introduced by dos Santos et al. (2015) improves over CE and WCE. For minority classes, this loss function maximizes the score of the correct label z_{gt} while at the same time minimizing the score of the highest-scoring incorrect label z_{c^-}. For the catch-all class A, only z_{c^-} is minimized; z_{gt} is ignored. Similarly, Hu et al. (2022) apply class weights only to non-catch-all classes.

Losses for Multi-Label Scenarios. In multi-label classification, each label assignment can be viewed as a binary decision, hence *binary cross-entropy* (**BCE**) is often used here. Under imbalance, two issues arise. First, although class-specific weights have been used with BCE (e.g., Yang et al., 2020), their effect on minority classes is less clear than in the single-label case. For each instance, all classes contribute to BCE, with the labels *not* assigned to the instance (called *negative classes*) included via $(1-y_j)\log(1-p_j)$. Thus, if *weighted binary cross-entropy* (**WBCE**) uses a high weight for a class, it also increases the importance of negative instances for a minority class, which may further encourage the model to *not* predict this minority class.

To leverage class weights more effectively in BCE, one option is to only apply them to the loss of positive instances as proposed for multi-label image classification (Kumar et al., 2018). Related work includes uniformly upweighting positive instances of *all* classes in hierarchical multi-label text classification (e.g., Rathnayaka et al., 2019). An approach to multi-label emotion classification by Yilmaz et al. (2021) performs training time balancing by adapting FL such that for a given mini-batch the loss over all instances in this mini-batch has exactly the same value for every class.

If a classifier already correctly predicts a negative class for an instance, the loss can be further decreased by reducing the respective label's logits. In CE, due to the softmax that uses the logits of all classes, the impact of this effect becomes minor once the logit for the correct class is much larger than those of the other classes. However, the problem is more severe in BCE (Wu et al., 2020), as logits are treated independently. As minority labels mostly occur as negative classes, this logit suppression leads to a bias in the decision boundary, making it less likely for minority classes to be predicted. To tackle this issue and based on a multi-label version of FL, Wu et al. (2020) propose *distribution-balanced loss* (**DB**) for object detection, adding *Negative Tolerant Regularization* for the loss for negative classes by transforming the logits of positive and negative classes differently (see q_j in Table 1). This regularization imposes a sharp drop in the loss function for negative classes once the respective logit is below a threshold. Moreover, DB introduces instance-specific class weights $\hat{\alpha}$ to account for imbalances caused by class-aware sampling (see Sec. 3.1) in multi-label scenarios. These weights reflect the frequency of a class and the quantity and frequency of the positive labels of the instance. Huang et al. (2021) have shown large improvements of DB over BCE even when using uniform sampling on two long-tailed multi-label English text classification datasets.

While Cao et al. (2019) propose and theoretically justify LDAM for single-label classification only, it has been successfully applied to multi-label text classification as well (Biswas et al., 2021). Ferreira and Vlachos (2019) show that applying a cross-label dependency loss (Yeh et al., 2017; Zhang and Zhou, 2006) can be helpful for multi-label stance classification. Similarly, Lin et al. (2019) introduce a label-confusion aware cost factor into their loss function. The adaptive loss of Suresh and Ong (2021) integrates inter-label relationships into a contrastive loss (Khosla et al., 2020), which compares the score of a positive example with the distance to that of other positive and negative examples in order to push its representation closer to the correct class and further away from the wrong class(es). The resulting loss function learns how to increase the weight of confusable negative labels relative to other negative labels. Combining label-confusion aware loss functions with class weighting techniques is a promising research direction.

Re-Sampling vs. Loss Functions. Re-sampling and loss functions that are specifically designed for class-imbalanced settings are based on the same idea of increasing the importance of minority instances. Re-sampling is conceptually simpler and has a direct impact on training time, e.g., oversampling may cause a considerable increase. By contrast, the loss functions explained above are more flexible, e.g., by modeling desirable properties of margins, but also mostly harder to interpret.

3.4 Staged Learning

One approach to finding a good trade-off between learning features that are representative of the underlying data distribution and reducing the classifier's bias towards the majority class(es) is to perform the training in several stages. *Two-staged training* is common in imbalanced or data-scarce computer vision tasks (e.g., Wang et al., 2020b,a; Zhang et al., 2021a). The first stage usually performs standard training in order to train or fine-tune the feature extraction network. Later stages may freeze the feature extractor and re-train the classifier layers using special methods to address class imbalance, e.g., using more balanced data distributions or specific losses. For example, Cao et al. (2019) find their LDAM loss to be most effective when the training happens in two stages. In NLP, deep-learning models are usually based on pre-trained neural text encoders or word embeddings. Further domain-specific pre-training before starting the fine-tuning stage(s) can also be effective (Gururangan et al., 2020).

Several NLP approaches that fall under *staged learning* are directly inspired by computer vision research. In the context of long-tailed image classification, Kang et al. (2020) find that class-balanced sampling (see Sec. 3.1) helps when performing single-stage training, but that in their two-stage *classifier re-training* (**cRT**) method, using the original distribution in the first stage is more effective than class-balanced sampling. cRT employs the latter only in the second stage after freezing the representation weights. Yu et al. (2020) perform a similar decoupling analysis on long-tailed relation classification, essentially confirming Kang et al. (2020)'s results on this NLP task with respect to the re-sampling strategies. Additionally, they find that loss re-weighting under this analysis behaves similar to re-sampling, i.e., it leads to worse performance when applied during representation learning, but boosts performance when re-training the classifier. Hu et al. (2022) successfully leverage Kang et al.'s ideas for event detection, where both trigger detection and trigger classification suffer from class imbalance.

Jang et al. (2021) model imbalanced classification as a continual learning task with k stages where the data gradually becomes more balanced (*sequential targeting*, **ST**). The first stage contains the most imbalanced subset, and then the degree of imbalance decreases, with the last stage presenting the most balanced subset. The training objective encourages both good performance on the current stage and keeping information learnt in previous stages. Their experiments include binary and ternary English and Korean text classification. Active Learning (AL), which contains several stages by definition, has also been shown to boost performance of BERT models for minority classes (Ein-Dor et al., 2020). For a discussion about AL and deep learning, see Schröder and Niekler (2020).

3.5 Model Design

The methods described so far are largely independent of model architecture. This section describes model modifications that aim at improving performance in imbalanced settings.

Observing that the weight vectors for smaller classes have smaller norms in standard joint training compared to staged-learning based cRT (see Sec. 3.4), Kang et al. (2020) normalize the classifier weights directly in one-staged training using a hyperparameter τ to control the normalization "temperature" (**τ-norm**). τ-norm achieves similar or better performance than cRT in long-tailed image classification and outperforms cRT in relation extraction, but cRT works better for named entity recognition and event detection (Nan et al., 2021).

SetConv (Gao et al., 2020) and **ProtoBERT** (Tänzer et al., 2022) learn representatives for each class using *support sets* and classify an input (the *query*) based on its similarity to these representatives. SetConv applies convolution kernels that capture intra- and inter-class correlations to extract class representatives. ProtoBERT uses class centroids in a learned BERT-based feature space, treating the distance of any instance to the catch-all class as just another learnable parameter. At each training step, SetConv uses only one instance per class in the query set, but preserves the original class imbalance in the support set, whereas ProtoBERT uses fixed ratios. In the respective experimental studies, ProtoBERT performs better than using a standard classification layer on top of BERT for minority classes in NER if less than 100 examples are seen by the model, while SetConv excels in binary text classification with higher degrees of imbalance and in multi-class text classification.

The **HSCNN** model (Yang et al., 2020) uses class representatives only for the classification of tail classes, while head classes are assigned using a standard text CNN (Kim, 2014). HSCNN learns label-specific similarity functions, extracting instance representations from the pre-final layers of two copies of the original CNN, and assigns a tail class if the similarity to the class representative (computed as the mean of 5 random support instances) exceeds 0.5. On tail classes, HSCNN consistently improves over the vanilla CNN.

In addition, there exist a number of **task-specific solutions**. Prange et al. (2021) propose to construct CCG supertags from predicted tree structures rather than treating the problem as a standard classification task. In order to recognize implicit positive interpretations in negated statements in a class-imbalanced dataset, van Son et al. (2018) argue that leveraging information structure could be one way to improve inference. *Structural causal models* (**SCM**s) have been applied to imbalanced NLP tasks, encoding task-specific causal graphs (e.g., Nan et al., 2021). Similarly, Wu et al. (2021) causally model how bias in long-tailed corpora affects topic modeling (Blei et al., 2003) and use this to improve training of a variational autoencoder.

A research area closely related to class imbalance is **few-shot learning** (FSL, Wang et al., 2020c), which aims to learn classes based on only very few training examples. Model ideas from FSL can be leveraged for long-tailed settings, e.g., by making use of relational information about class labels in the form of knowledge graph embeddings or other forms of embedding hierarchical relationships between labels (Han et al., 2018; Zhang et al., 2019), or computing label-specific representations (Mullenbach et al., 2018).

4 Insights and Future Directions

We have provided a comprehensive, concise and structured overview of current approaches to dealing with class imbalance in DL-based NLP.

What works (best)? As there is no established benchmark for class-imbalanced settings, evaluation results are hard to compare across papers. In general, re-sampling or changing the loss function may lead to small to moderate gains. For data augmentation approaches, the reported performance increases tend to be larger than for re-sampling or new loss functions. The effects of staged training or modifications of the model vary drastically, ranging from detrimental to very large performance gains.

Hence, re-sampling, data augmentation, and changing the loss function are straightforward choices in class-imbalanced settings. Approaches based on staged learning or model design may sometimes outperform them, but often come with a higher implementation or computational cost. For a practical decision aid and potential application settings of some class imbalance methods, see Figure 3 in Appendix B and Table 3 in Appendix A.

How should we report results? Much NLP research only reports aggregate statistics (Harbecke et al., 2022), making it hard to judge the impact on improvements by class, which is often important in practice. We thus argue that NLP researchers should *always* report per-class statistics, e.g., as in Figure 1. Open-sourcing spreadsheets with the exact numbers would enable the community to compare systems more flexibly from multiple angles, i.e., with respect to whichever class(es) matter in a particular application scenario, and to re-use this data in research on class imbalance. Reviewers should also value works that analyze performance for relevant minority classes rather than focusing largely only on overall accuracy improvements.

A main hindrance to making progress on class imbalance in computer vision and NLP alike is that experimental results are often hard to compare (Johnson and Khoshgoftaar, 2019a, 2020). A first important step would be to not restrict baselines to methods of the same type, e.g., a new data augmentation approach should not only compare to other data augmentation methods, but also to using loss functions for class imbalance. Establishing a shared and systematic benchmark of a diverse set of class-imbalanced NLP tasks would be highly beneficial for both researchers and practitioners.

How can we move forward? Most work on class-imbalanced NLP has focused on single-label text classification. Finding good solutions for multi-label settings is still an open research challenge. Class imbalance also poses problems in NLP tasks such as sequence labeling or parsing, and we believe that the interaction of structured prediction models with methods to address class imbalance is a promising area for future research. Moreover, we need to study how class imbalance methods affect prediction calibration in order to provide reliable confidence estimates.

In general, inspiration for new model architectures could for example be drawn from approaches developed for few-shot learning (Wang et al., 2020c). Recently, prompting (Radford et al., 2019) has emerged as a new paradigm in NLP, which performs strongly in real-world few-shot settings (Schick and Schütze, 2022). Methods that improve worst-case performance under distribution shift (e.g., Sagawa et al., 2020) might also be applied to improve minority-class performance.

Acknowledgements

We thank the anonymous reviewers for their valuable comments, and Heike Adel, Stefan Grünewald, Subhash Pujari, and Timo Schrader for providing data for our teaser image. We thank them and Talita Anthonio, Mohamed Gad-Elrab, Lukas Lange, Stefan Ott, Robert Schmier, Hendrik Schuff, Daria Stepanova, Jannik Strötgen, Thang Vu, and Dan Zhang for helpful discussions and feedback on the writing. We also thank Jason Wei and Jiaqi Zeng for answering questions about their work.

Limitations

This paper is a survey, structuring, organizing and describing works and concepts to address *class imbalance* including *long-tailed learning*. While we touch upon *data augmentation* and *few-shot learning*, we do not comprehensively review those areas. Details on the scope of this review have also been described in Sec. 1.

The search process for the survey included searching for the keywords *class imbalance* and *long tail* in Google Scholar and the ACL Anthology, as well as carefully checking the papers that cite relevant papers.

Finally, the paper only constitutes a literature review, it does not yet provide a comprehensive empirical study which is much needed in this research area, but it will be of use in carrying out such a study.

Abstract

In this paper, we seek to improve the faithfulness of TempRel extraction models from two perspectives. The *first* perspective is to extract genuinely based on contextual description. To achieve this, we propose to conduct counterfactual analysis to attenuate the effects of two significant types of training biases: the *event trigger bias* and the *frequent label bias*. We also add tense information into event representations to explicitly place an emphasis on the contextual description. The *second* perspective is to provide proper uncertainty estimation and abstain from extraction when no relation is described in the text. By parameterization of Dirichlet Prior over the model-predicted categorical distribution, we improve the model estimates of the correctness likelihood and make TempRel predictions more selective. We also employ temperature scaling to recalibrate the model confidence measure after bias mitigation. Through experimental analysis on MATRES, MATRES-DS, and TDDiscourse, we demonstrate that our model extracts TempRel and timelines more faithfully compared to SOTA methods, especially under distribution shifts.

1 Introduction

Event temporal relation (TempRel) extraction is an essential step towards understanding narrative text, such as stories, novels, news, and guideline articles. With a robust temporal relation extractor, one can easily construct a storyline from text and capture the trend of temporally connected event mentions. TempRel extraction is also broadly beneficial to various downstream tasks including clinical narrative processing (Jindal and Roth, 2013; Bethard et al., 2016), question answering (Llorens et al., 2015; Meng et al., 2017; Stricker, 2021), and schema induction (Chambers and Jurafsky, 2009; Wen et al., 2021; Li et al., 2021).

Most existing TempRel extraction models are developed with data-driven machine learning approaches, for which recent studies also incorporate advanced learning and inference techniques such as structured prediction (Ning et al., 2017, 2018b; Han et al., 2019; Wang et al., 2020; Tan et al., 2021), graph representation (Mathur et al., 2021; Zhang et al., 2022), data augmentation (Ballesteros et al., 2020; Trong et al., 2022), and indirect supervision (Zhao et al., 2021; Zhou et al., 2021). These models are prevalently built upon pretrained language models (PLMs) and fine-tuned on a small set of annotated documents, e.g., TimeBank-Dense (Cassidy et al., 2014), MATRES (Ning et al., 2018c), and TDDiscourse (Naik et al., 2019).

A) I went to e_1:SEE the doctor. However, I was more seriously e_2:SICK. $\Longrightarrow$ e_1 After e_2

B) Microsoft said it has e_3:IDENTIFIED three companies for *the China program* to run through June. The company also e_4:GIVES each participating startup in *the Seattle program* $20,000 to create software. $\Longrightarrow$ e_3 Before e_4

Figure 1: Examples of unfaithful extractions. Before and After that follow the arrows denote the extracted TempRel's from the sentences by (Zhou et al., 2021).

Though these recent approaches have achieved promising evaluation results on benchmarks, whether they provide *faithful* extraction is an unexplored problem. The *faithfulness* of a relation extraction system is not simply about how much accuracy a system can offer. Instead, a faithful extractor should concern the validity and reliability of its extraction process. Specifically, when there is a TempRel to extract, a faithful extractor should genuinely obtain what is described in the context but not give *trivial guesses* from surface names of events or most frequent labels. Besides, when there is no relation described in the context, the system should selectively abstain from prediction.

We observe that in recent models, biases from prior knowledge in PLMs and statistically skewed training data often lead to unfaithful extractions

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 541–553
May 2-6, 2023 ©2023 Association for Computational Linguistics

(see Fig. 1). Example A thereof exhibits a case where the model adheres to the prior knowledge where people usually **see the doctor** *after* **getting sick**, but in this context **getting sick** is obviously a consequent of **seeing the doctor**. In Example B, BEFORE is extracted due to statistical biases learned from training data that BEFORE is not only the most frequent TEMPREL between ***identify*** and ***give***, but is also the most frequent TEMPREL between the first and second event in narrative order (Gee and Grosjean, 1984). However, with a closer inspection, it can be noticed that the two events in Example B are involved in different programs, one in *the China program*, the other in *the Seattle program*. Therefore, the system should abstain from prediction and give VAGUE as output.

In this paper, we seek to improve the faithfulness of TEMPREL extraction models from two perspectives. The *first* perspective is to guide the model to genuinely extract the described TEMPREL based on a relation-mentioning context. To achieve this goal, we conduct counterfactual analysis (Niu et al., 2021) to capture and attenuate the effects of two typical types of training biases: *event bias* caused by treating event trigger names as shortcuts for TEMPREL prediction, and *label bias* that causes the model prediction to lean towards more frequent training labels. We also propose to affix tense information to event mentions to explicitly place an emphasis on the contextual description.

The *second* perspective is to teach the model to abstain from extraction when no relation is described in the text. To know when to abstain, the models need to have a good estimate of the correctness likelihood. By incorporating Dirichlet Prior (Malinin and Gales, 2018, 2019) in the training phase of current TEMPREL extraction models, we improve the predictive uncertainty estimation of the models and make the TEMPREL predictions more selective. Furthermore, since the counterfactual analysis component (from the *first* perspective) may shift the model-predicted categorical distribution, we also employ temperature scaling (Guo et al., 2017) in inference to allow for recalibrated confidence measure of the model.

The technical contributions of our work are two-folds. First, to the best of our knowledge, this is the first study on the faithfulness issue of event-centric information extraction. Evidently, the development of a faithful TEMPREL extraction system contributes to more robust and reliable machine comprehension of events and narratives. Second, we propose training and inference techniques that can be easily plugged into existing neural TEMPREL extractors and effectively improve model faithfulness by mitigating prediction shortcuts and enhancing the capability of selective prediction.

Our contributions are verified with TEMPREL extraction experiments conducted on MATRES (Ning et al., 2018c), TDDiscourse (Naik et al., 2019) and distribution-shifted version of MATRES (MATRES-DS). Particularly, we evaluate on how precise and selective our TEMPREL extraction method is on in-distribution data, and how well it generalizes under distribution shift. Experimental results demonstrate that the techniques explored within the two aforementioned perspectives bring about promising results in improving faithfulness of current models. In addition, we also apply our method to the task of timeline construction (Do et al., 2012), showing that faithful TEMPREL extraction greatly benefits the accurate construction of timelines.

2 Related Work

Event TEMPREL Extraction. Recent event TEMPREL extraction approaches are mainly built on PLMs to obtain representations of event mentions and are improved with various learning and inference methodologies. To improve the quality of event representations, Mathur et al. (2021) embrace rhetorical discourse features and temporal arguments; Trong et al. (2022) select optimal context sentences via reinforcement learning to achieve SOTA performances; while Liu et al. (2021b); Mathur et al. (2021); Zhang et al. (2022) employ graph neural networks to avoid complex feature engineering. From the learning perspective, Ning et al. (2018a), Ballesteros et al. (2020), and Wang et al. (2020) enrich the models with auxiliary training tasks to provide complementary supervision signals, while Ning et al. (2018b), Zhao et al. (2021) and Zhou et al. (2021) bring into play distant supervision from heuristic cues and patterns. Nevertheless, recent data-driven models risk amplifying bias by exacerbating biases present in the pretraining and task training data when making predictions (Zhao et al., 2017). To rectify the models' biases towards prior knowledge in PLMs and shortcuts learned from biased training examples, our work proposes several training and inference techniques, seeking to improve the faithfulness of neural TEMPREL extractors as described in §1.

Bias Mitigation in NLP. Methods for mitigating prediction biases can be categorized as retraining and inference (Sun et al., 2019). Retraining methods address the bias in early stages or at its source. For instance, Zhang et al. (2017) masks the entities with special tokens to prevent relation extraction models from learning shortcuts from entity names, whereas several works conduct data augmentation (Park et al., 2018; Alzantot et al., 2018; Jin et al., 2020; Wu et al., 2022) or sample reweighting techniques (Lin et al., 2017; Liu et al., 2021a) to reduce biases in training. However, masking would result in the loss of semantic information and performance degradation, and it is costly to manipulate data or find proper unbiased data in temporal reasoning. Directly debiasing the training process may also hinder the model generalization on out-of-distribution (OOD) data (Wang et al., 2022). Therefore, inspired by several recent studies on debiasing text classification or entity-centric information extraction (Qian et al., 2021; Nan et al., 2021), our work adopts counterfactual inference to measure and control prediction biases based on automatically generated counterfactual examples.

Selective Prediction. Neural models have become increasingly accurate with the advances of deep learning. In the meantime, however, they should also indicate when their predictions are likely to be inaccurate in real-world scenarios. A series of recent studies have focused on resolving model miscalibration by measuring how closely the model confidences match empirical likelihoods. Among them, computationally expensive Bayesian (Gal and Ghahramani, 2016; Küppers et al., 2021) and non-Bayesian ensemble (Lakshminarayanan et al., 2017; Beluch et al., 2018) methods have been adopted to yield high quality predictive uncertainty estimates. Other methods have been proposed to use uncertainty reflected from model parameters to assess the confidence, including sharpness (Kuleshov et al., 2018) and softmax response (Hendrycks and Gimpel, 2017; Xin et al., 2021). Another class of methods adjust the models' output probability distribution by altering loss function in training via label smoothing (Szegedy et al., 2016) and Dirichlet Prior (Malinin and Gales, 2018, 2019). Besides, temperature scaling (Guo et al., 2017) also serves as a simple yet effective post-hoc calibration technique. In this paper, we model TEMPREL's with Dirichlet Prior in learning, and during inference we employ temperature scaling to recalibrate confidence measure of the model after bias mitigation.

3 Preliminaries

A document D is represented as a sequence of tokens $D = [w_1, \cdots, e_1, \cdots, e_2, \cdots, w_m]$, where some tokens belong to the set of annotated event triggers, i.e., $\mathcal{E}_D = \{e_1, e_2, \cdots, e_n\}$, and the rest are other lexemes. For a pair of events (e_i, e_j), the task of TEMPREL extraction is to predict a relation r from $\mathcal{R} \cup \{\text{VAGUE}\}$, where $\mathcal{R}$ denotes the set of TEMPREL's. An event pair is labeled VAGUE if the text does not express any determinable relation that belongs to $\mathcal{R}$. Let $\mathbf{y}^{(i,j)}$ denote the *model-predicted categorical distribution* over $\mathcal{R}$.

In order to provide a confidence estimate $\mathbf{y}$ that is as close as possible to the true probability, we first describe three separate factors (Malinin and Gales, 2018) that attribute to the predictive uncertainty for an AI system, namely epistemic uncertainty, aleatoric uncertainty, and distributional uncertainty. Epistemic uncertainty refers to the degree of uncertainty in estimating model parameters based on training data, whereas aleatoric uncertainty results from data's innate complexity. Distributional uncertainty arises when the model cannot make accurate predictions due to the lack of familiarity with the test data.

We argue that the way of handling VAGUE relations in existing TEMPREL extractors is problematic since they typically merge VAGUE into $\mathcal{R}$. In fact, VAGUE relations are complicated exception cases in the IE task, yet the annotation of such exceptions are never close to exhaustive in benchmarks, or even not given (Naik et al., 2019). In this work, we consider VAGUE relations as a source of **distributional uncertainty** and separately model them. Details are introduced in §4.2.

4 Methods

In this section, we first present how we obtain event representations and categorical distribution $\mathbf{y}$ in a local classifier for TEMPREL (§4.1). Then we introduce proposed learning and inference techniques to improve model faithfulness from the perspectives of selective prediction (§4.2) and prediction bias mitigation (§4.3), before we combine these two techniques with temperature scaling and introduce the OOD detection method in §4.4.

4.1 Local Classifier

Given that the context around an event pair (e_i, e_j)[1] has linguistic signals and temporal cues that are beneficial to TEMPREL prediction, the context of (e_i, e_j) considered in our model starts from the sentence before e_i and ends at the sentence after e_j. Inspired by Zhou and Chen (2021) for improving entity representation by prepending entity type information to entity mention spans, we add tense information of events into event trigger representations in this work. Accordingly, we enclose e_i and e_j with "@" and "#" respectively[2] and prepend their tense information to their spans with "$*$" and "$\wedge$". We provide a detailed example for affixing tense information in Appx. §A.1.

To characterize event pair (e_i, e_j), we obtain the two events' contextual representations and attention heads from PLMs. The classifer is trained to uncover the context that is critical to both events by multiplying their attentions before we send the concatenation of token embeddings and attention multiplication to a multi-layer perceptron (MLP) with $|\mathcal{R}|$ outputs. In this fashion, we obtain the $|\mathcal{R}|$-dimensional logits vector $\mathbf{z}^{(i,j)}$ and categorical distribution $\mathbf{y}^{(i,j)}$, where the probability of a label $r \in \mathcal{R}$ is given by the softmax function $\sigma(\cdot)$:

$$y_r = \sigma(\mathbf{z})_r = \frac{e^{z_r}}{\sum_{k=1}^{|\mathcal{R}|} e^{z_k}} . \quad (1)$$

4.2 Parameterization of Dirichlet Prior

As discussed in preliminaries (§3), VAGUE corresponds to complicated exception cases in inference. We model them as out-of-distribution (OOD) cases which are different from in-distribution (ID) data describing the relations in $\mathcal{R}$. The goal of providing high-quality confidence estimate $\mathbf{y}$ requires the model to yield a sharp predicted distribution centered on one of the labels in $\mathcal{R}$ when it is confident and yield a flat distribution over $\mathcal{R}$ for OOD inputs, as is shown in Fig. 2. To achieve this goal, we explicitly **parameterize a prior distribution** over categorical distributions. Because of the tractable analytic properties[3] of Dirichlet distribution (Eq. 2), we choose to parameterize a *sharp* and a *flat* Dirichlet prior over the model-predicted categorical distribution for ID and OOD inputs, respectively. The Dirichlet distribution is parameterized by its concentration parameters $\boldsymbol{\alpha}$, where α_0 is the precision of Dirichlet distribution. Higher values of α_0 lead to sharper, more confident predicted distributions.

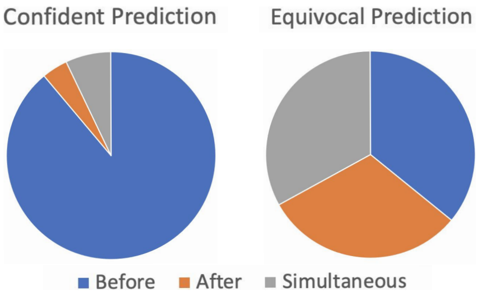

Figure 2: An illustration for desired behaviors of model predicted categorical distribution.

$$\begin{gathered}\texttt{Dir}(\mathbf{y};\boldsymbol{\alpha}) = \frac{\Gamma(\alpha_0)}{\prod_{k=1}^{|\mathcal{R}|}\Gamma(\alpha_k)} \prod_{k=1}^{|\mathcal{R}|} y_k^{\alpha_k - 1}, \\ \alpha_k > 0,\ \alpha_0 = \sum_{k=1}^{|\mathcal{R}|} \alpha_k .\end{gathered} \quad (2)$$

To attain the aforementioned behaviors, on ID data the model is trained to minimize the KL divergence between a sharp Dirichlet distribution and the model-predicted categorical distribution:

$$\mathcal{L}_{ID} = \mathbb{E}_{\mathrm{p}_{\mathrm{ID}}(\boldsymbol{x})}[KL[\mathrm{p}(\mathbf{y}) \parallel \texttt{Dir}(\mathbf{y};\boldsymbol{\alpha}_s)]], \quad (3)$$

where $\mathrm{p}_{\mathrm{ID}}(\boldsymbol{x})$ denotes ID data and $\boldsymbol{\alpha}_s$ denotes concentration parameters of the sharp Dirichlet distribution. On OOD data, the model minimizes the KL divergence between a flat Dirichlet distribution and the model-predicted categorical distribution:

$$\mathcal{L}_{OOD} = \mathbb{E}_{\mathrm{p}_{\mathrm{OOD}}(\boldsymbol{x})}[KL[\mathrm{p}(\mathbf{y}) \parallel \texttt{Dir}(\mathbf{y};\boldsymbol{\alpha}_f)]], \quad (4)$$

where $\mathrm{p}_{\mathrm{OOD}}(\boldsymbol{x})$ denotes OOD data and $\boldsymbol{\alpha}_f$ denotes the concentration parameters of the flat Dirichlet distribution. And the total loss of the model is

$$\mathcal{L} = \lambda_1 \mathcal{L}_{ID} + \lambda_2 \mathcal{L}_{OOD}, \quad (5)$$

where the λ's are hyperparameters to balance the influence of each loss. With the parameterization of Dirichlet prior, the learning process seeks to partly enhance the model's faithfulness by outputting confident estimates when it encounters ID inputs, and outputting equivocal estimates when the context does not express any TEMPREL in the meantime.

4.3 Counterfactual Analysis

After looking into the selective prediction perspective of faithfulness, we now address the other perspective: to mitigate biases from pre-trained knowledge and the task training data during the inference

---

[1] For event pair (e_i, e_j) we assume e_i is the first event in narrative order if $i < j$.

[2] Note that similar to *typed entity marker (punct)* by Zhou and Chen (2021), such enclosing has the benefit of highlighting mention spans without introducing new special tokens.

[3] $\Gamma(\cdot)$ in Eq. 2 denotes the gamma function.

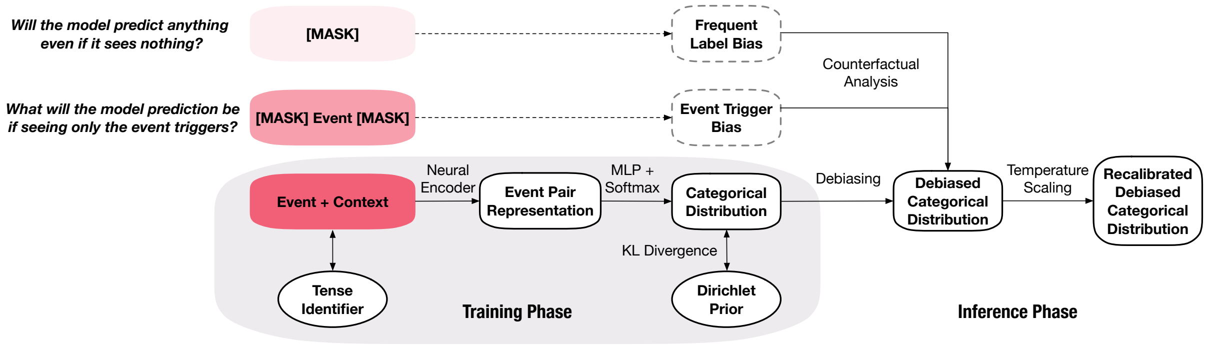

Figure 3: An overview of our approach to improving model faithfulness. In the training phase we obtain the model-predicted categorical distribution $\mathbf{y}$ with a neural encoder and parameterize a Dirichlet Prior over $\mathbf{y}$. And then we conduct counterfactual analysis to distill and mitigate biases during inference before leveraging temperature scaling to obtain recalibrated and debiased $\mathbf{y}$.

stage. Given that we have observed two types of biases in existing models, namely the event trigger bias and the frequent label bias, we ask the following questions:

- *What will the model prediction be if seeing the full context?*
- *What will the model prediction be if seeing only the event tiggers?*
- *Will the model predict anything even if it sees nothing?*

Inasmuch as we have described the learning process of the model, we know how to obtain model prediction given full context and can easily answer the first question. The second and third one, however, are hypothetical questions whose answers reflect the confounding biases that we would like to mitigate. With *attention masks* in recent PLMs (Devlin et al., 2019; Liu et al., 2019; Joshi et al., 2020; Lan et al., 2019), our model can be endowed with *imagination ability* effortlessly. By inputting a counterfactual instance with the context masked while maintaining the spans of event triggers to the model, we can obtain the model prediction given event trigger names only, which we denote by $\check{\mathbf{y}}$. And by sending an empty (counterfactual) instance, we obtain the model prediction where no textual information is given, which we denote by $\bar{\mathbf{y}}$. Intuitively, the two terms $\check{\mathbf{y}}$ and $\bar{\mathbf{y}}$ thereof provide measurements for the trigger bias and label bias.

Our goal is to use the biases assessed from model prediction (on counterfactual instances) to generate debiased categorical distribution. We remove the event trigger bias and the frequent label bias via element-wise subtraction, which is proved to be simple yet empirically effective (Qian et al., 2021):

$$\mathbf{y}' = \mathbf{y} - \beta_1 \check{\mathbf{y}} - \beta_2 \bar{\mathbf{y}}, \tag{6}$$

where $\mathbf{y}'$ denotes the debiased categorical distribution and the β's are independent parameters for balancing the terms that represent biases. We find the optimal values for β_1 and β_2 on different datasets[4] via grid beam search (Hokamp and Liu, 2017):

$$\hat{\beta}_1, \hat{\beta}_2 = \arg\max_{\beta_1, \beta_2} \psi(\beta_1, \beta_2), \quad \beta_1, \beta_2 \in [a, b], \tag{7}$$

where ψ is a metric function (e.g., F_1 scores) for evaluation, and a, b are the search boundaries.

In a nutshell, we obtain debiased categorical distribution by removing biases distilled via counterfactual inputs, thus encouraging the model to extract genuinely based on the contextual content. Nevertheless, the debiased model is not yet perfect. A minor drawback lies in that its confidence estimates might have been shifted by element-wise subtraction in Eq. 6 though it provides predictions with good evaluation results. Therefore we employ temperature scaling as our last step to allow for recalibrated confidence measure of the model.

4.4 Temperature Scaling and OOD Detection

The subtraction operation in Eq. 6 might result in negative values in $\mathbf{y}'$. To provide a proper estimate of the correctness likelihood, we first normalize the probabilities in $\mathbf{y}'$, where we replace the negative values with a small positive value and clips the values that are greater than 1:

$$\mathrm{norm}(y'_r) = \begin{cases} \epsilon, & if\ y'_r < 0 \\ 1 - \epsilon, & if\ y'_r > 1 \\ y'_r, & \text{otherwise} \end{cases} \tag{8}$$

---

[4] Using the development splits of datasets.

where ϵ denotes a small positive number, $r \in \mathcal{R}$. And then we use the inverse function of softmax to obtain the debiased logits vector $\mathbf{z}'$:

$$\mathbf{z}' = \sigma^{-1}(\text{norm}(\mathbf{y}')), \tag{9}$$

In this way we are able to apply temperature scaling (Guo et al., 2017) over $\mathbf{z}'$ and get the recalibrated and debiased categorical distribution $\hat{\mathbf{y}}$:

$$\hat{\mathbf{y}} = \sigma(\mathbf{z}'/T), \tag{10}$$

where $T > 0$ denotes the temperature[5].

To detect OOD inputs, we need to measure the uncertainty of the model predictions. We use the *entropy* (Eq. 11) of the final categorical distribution $\hat{\mathbf{y}}$, which captures the uncertainty encapsulated in the entire distribution. On the dev set with VAGUE examples, we find the optimal threshold of $\mathcal{H}[\hat{\mathbf{y}}]$ below which the model predictions are considered equivoques and the inputs are OOD.

$$\mathcal{H}[\hat{\mathbf{y}}] = -\sum_{k=1}^{|\mathcal{R}|} \hat{y}_k \ln(\hat{y}_k) \ . \tag{11}$$

To sum up, we improve the model faithfulness in both training and inference phase with robust event presentations, Dirichlet Prior parameterization, counterfactual analysis and temperature scaling. The entire workflow is shown in Fig. 3.

5 Experiments

In this section, we describe the experiments[6] on two tasks: TEMPREL extraction and timeline construction. We first introduce the datasets that we adopt or create for evaluation (§5.1), followed by the evaluation protocols (§5.2). Evaluation results are discussed in §5.3 before we provide a detailed ablation study and case study in §5.4 and §5.5.

5.1 Datasets

We evaluate using the following datasets, for which statistics are given in Appx. §A.4.

MATRES (Ning et al., 2018c) is a TEMPREL benchmark annotated with the multi-axis scheme that helps achieve higher inter-annotator agreements (IAA) than previous benchmark datasets (Cassidy et al., 2014; Styler et al., 2014; O'Gorman et al., 2016). Four relations are annotated for the start time comparison of event pairs in 275 documents, namely BEFORE, AFTER, SIMUTANEOUS, and VAGUE. We train our model on the training set of MATRES, and evaluate our model on the dev and test sets of MATRES, MATRES-DS and TDDiscourse, which we introduce next.

MATRES-DS is an evaluation dataset that we created with distribution shifts (DS) compared to MATRES. Since one of our goals is to mitigate the bias of event triggers in the training data, we examine whether our proposed model stays uninfluenced when the distribution of event triggers is altered. We replace frequent triggers in the MATRES dev and test sets that appear within the top 5K frequent lemmas[7] with their uncommon synonyms, and replace infrequent triggers with their frequent synonyms from the list of frequent lemmas. MATRES-DS also presents a mismatch between the training and test distributions, or dataset shift (Quinonero-Candela et al., 2008), where distributional uncertainty often arises.

TDDiscourse (Naik et al., 2019) is a dataset for discourse-level event temporal ordering, in which TEMPREL's between global long-distance event pairs are annotated. As another data source with distribution shifts compared to MATRES, we adopt the manually annotated subset of TDDiscourse, namely TDD-man, in our experiments. The TEMPREL set $\mathcal{R}_T$[8] annotated in TDDiscourse is a superset of the TEMPREL set $\mathcal{R}_M$ defined in MATRES. Given that TDD-man serves as evaluation data on which we do not train our model, a relation in $\mathcal{R}_M \cup \{\text{VAGUE}\}$ is predicted for each pair of events in the test set of TDD-man.

5.2 Evaluation Protocols

For **event TEMPREL extraction**, we compare our model with the current and previous SOTA models (Trong et al., 2022; Mathur et al., 2021) trained on MATRES. The models are evaluated on not only how precise and selective their extraction is on ID data (MATRES), but are also examined for their generalizability under distribution shifts (MATRES-DS and TDD-man). We report micro-F_1 score as an evaluation metric following previous papers. We also report macro-F_1, which reflects the fairness of model prediction, and expected calibra-

---

[5] T is obtained by minimizing the negative log likelihood on the dev set. We refer readers to Appx. §A.3 for details.

[6] We refer readers to Appx. §A.5 for the discussion of experimental setup.

Table 2: Model performance on MATRES, MATRES-DS, and TDD-man for timeline construction. The metrics are exact match accuracy (Acc) and minimum edit distance (MED) between prediction and ground truth.

tion error (ECE) that approximates the *difference in expectation between confidence and accuracy*. The definition of ECE is provided in Appx. §A.2.

We also apply our model to the **timeline construction** task, where the goal is to sort a list of events in a document in chronological order. To construct the timeline, the model first constructs a directed graph G with predicted non-VAGUE TEMPREL's between every event pairs. Then, edges in G with lowest confidence scores are removed until G becomes a directed acyclic graph (DAG). Finally, the timeline is generated as the linear ordering of the vertices in the DAG by topological sorting. In this way, we circumvent the possible conflicts in model predictions for timeline construction and the *faithful removal* of least confident edges serves as an examination on the quality of model-predicted confidence. On the three datasets, we report the accuracy of exact match and the average minimum edit distance between predicted and ground truth timelines as evaluation metrics.

5.3 Results

In Tab. 1, we report the TEMPREL extraction results. On MATRES, the SOTA model (Trong et al., 2022) still offers the best performance in terms of micro-F_1 whereas our model achieves comparable macro-F_1 score and lower calibration error. In contrast, our proposed *faithful* TEMPREL extractor outperforms baseline methods in terms of all evaluation metrics under the dataset shifts caused by replacement of event triggers in MATRES-DS and longer context distances between global event pairs in TDD-man. Specifically, our model shows a significant gain of 2.0% macro-F_1 and 0.8% micro-F_1 over the SOTA model on MATRES-DS and surpasses the previous SOTA model on TDD-man by 1.0% micro F_1, not to mention the improvements on confidence calibration. We attribute this superior performance under dataset shifts to the mitigation of biases from prior knowledge and training set statistics as well as the techniques we employ to improve predictive uncertainty estimation. For a visual illustration of model calibration, we present the reliability diagram that plots the expected sample accuracy as a function of confidence in Fig. 4.

Tab. 2 exhibits similar observations: our model outperforms both baselines on timeline construction by a large margin in terms of both metrics. Specifically, under dataset shifts within MATRES-DS and TDD-man, our model surpasses the best baseline by 11.4% and 14.4% in accuracy, while drastically reducing the minimum edit distance by relatively 11.4% and 28.9%. Evidently, the capabilities of selective prediction and bias mitigation make our model stand out in complex scenarios like timeline construction, whereas the bias and inferior calibration of existing models exacerbate unfaithful extractions when multiple decisions have to be made simultaneously.

5.4 Ablation Study

To analyze the effect of each model component, we conduct an ablation study of our model where we

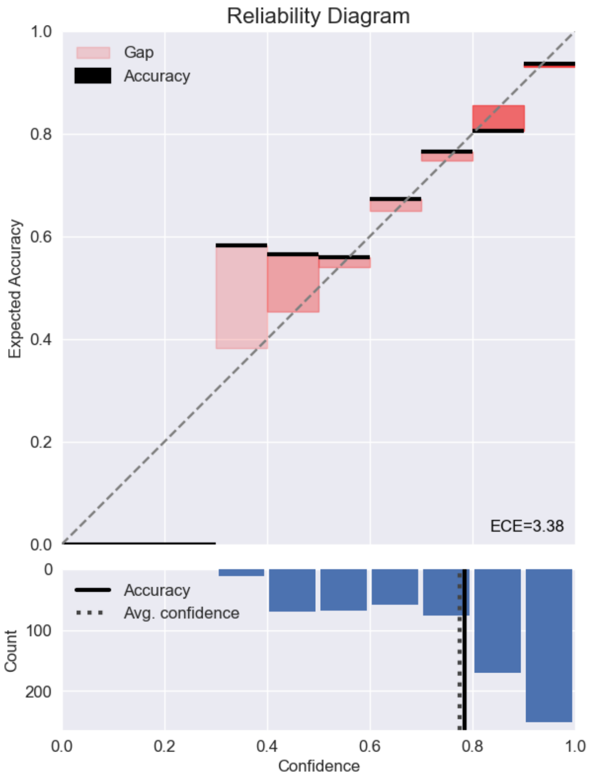

Figure 4: Reliability diagram and confidence histogram of our model predictions on test set of MATRES.

remove one component at a time (see Tab. 1)[9]. We observe on MATRES that, without the counterfactual analysis component, the model performance becomes worse by 2.4% in micro-F_1 and 1.6% in macro-F_1. Under dataset shifts, the model performance is reduced by 3.8% in micro-F_1 and 2.4% in macro-F_1 on TDD-man without the parameterization of Dirichlet Prior. The model performance in terms of F_1 scores is slightly influenced by taking away the temperature scaling component while the model calibration severely degrades.

From the ablation results in Tab. 2, we notice that temperature scaling has modest effects on the model performances, while Dirichlet Prior plays the most important role towards faithful timeline construction. It is also noteworthy that tense information considerably benefits the model to generalize well under distribution shifts in that it provides a useful feature applicable to all domains.

5.5 Case Study

As shown in Fig. 5, we provide a case study on timeline construction for three events. The reason why our model predicts AFTER for the third pair is probably due to the misleading temporal cues in text, Thursday and Tuesday, while the long distance between events undermines the confidence for this prediction. When our model builds a directed graph with three relations, a cycle is identified and the edge with lowest confidence is removed from the graph, and thus our model constructs the correct timeline. Without tense information, the model makes wrong prediction concerning the second event whose trigger is an adjective. And without Dirichlet Prior or temperature scaling, the model calibration becomes noticeably worse.

> A new Essex County task force began delving Thursday into the e_1:SLAYINGS of 14 people ... officials have been e_2:CAREFUL not to draw any firm conclusions, leaving open the possibility of a serial killer ... "I haven't e_3:SEEN a pattern yet," said Patricia Hurt, the Essex County prosecutor, who created the task force on Tuesday.

Model	(e_1, e_2)	(e_2, e_3)	(e_1, e_3)	Timeline
Gold	B	B	B	(e_1, e_2, e_3)

Figure 5: Case study on timeline construction for one of the documents in TDD-man. The table shows predicted TEMPREL's and confidence for three event pairs, where B stands for BEFORE and A stands for AFTER. The cells in light red and light blue are wrong predictions and relations removed in timeline construction, respectively.

6 Conclusion

In this paper, we investigate on improving faithfulness for event TEMPREL extraction from two perspectives. To enhance the selectiveness of model predictions, we parameterize a Dirichlet Prior over the model-predicted categorical distribution to regularize the model to behave differently with ID and OOD data. To mitigate two types of biases from PLMs and training data, we add tense information to obtain robust event representations and conduct a counterfactual analysis to reduce the risk of carrying prediction shortcuts into inference. We also employ temperature scaling to combine the two faithful perspectives, which recalibrates the confidence measure of the model after bias mitigation. Through experimental analysis on MATRES, MATRES-DS, and TDDiscourse, we demonstrate that our model faithfully extracts event temporal relations and timelines from text, so as to generalize well under distribution shifts.

---

[9] We leverage cross-entropy as the training loss when we remove Dirichlet Prior in the training phase.

7 Acknowledgments

The authors would like to thank the anonymous ACL ARR reviewers for their insightful feedback on our work. This work was supported by Contract FA8750-19-2-1004 with the US Defense Advanced Research Projects Agency (DARPA). Approved for Public Release, Distribution Unlimited. This research is also based upon work supported in part by the Office of the Director of National Intelligence (ODNI), Intelligence Advanced Research Projects Activity (IARPA), via IARPA Contract No. 2019-19051600006 under the BETTER Program. The views and conclusions contained herein are those of the authors and should not be interpreted as necessarily representing the official policies, either expressed or implied, of ODNI, IARPA, the Department of Defense, or the U.S. Government. In addition, this work is supported in part by the NSF Grant IIS 2105329, an Amazon Research Award and a Cisco Research Award.

Limitations

As the event representation introduced in our method is augmented with tense information, it potentially leads to limitations when applying to languages other than English, especially tenseless languages and languages having fewer tenses. The training of our models also requires considerable GPU resources which might produce environmental impacts, though the inference stage does not take up much computational resources.

Ethics Statement

There are no direct societal implications of this work. The proposed method attempts to provide high-quality and faithful event TEMPREL extraction and timeline construction. We believe that the intellectual merits of developing robust event-centric information extraction methods are demonstrated by this work. For any information extraction methods, real-world open source articles used to extract information may contain societal biases. Extracting event-event relations from articles with such biases may spread the bias into the acquired knowledge. Yet we believe that the proposed method can benefit various downstream NLP/NLU tasks like event prediction, task-oriented dialogue systems and risk detection.

A.1 Example of event context affixed tense information

Original context: [CLS] For his part, Fidel Castro is the ultimate political survivor.[SEP] People have PREDICTED his demise so many times, and the US has TRIED to hasten it on several occasions.[SEP] Time and again, he endures.[SEP]

Context with affixed tense information: [CLS] For his part, Fidel Castro is the ultimate political survivor.[SEP] People have @ * *Present Perfect Simple* * PREDICTED @ his demise so many times, and the US has # ∧ *Present Perfect Simple* ∧ TRIED # to hasten it on several occasions.[SEP] Time and again, he endures.[SEP]

Figure 6: An example of the original context of event pair (PREDICTED, TRIED) and the context after affixing tense information to corresponding event spans.

A.2 Definition of ECE

Expected Calibration Error (ECE) metric (Guo et al., 2017) measures exactly the difference in expectation between confidence and accuracy. Empirically it is approximated by dividing the data into M confidence based bins, i.e., B_m (where $m \in \{1, 2, ..., M\}$) contains all datapoints i for which predicted confidence p_i lies in $(\frac{m-1}{M}, \frac{m}{M}]$. If acc$(B_m)$ and conf(B_m) denotes the average accuracy and prediction confidence for the points in B_m, ECE is defined as:

$$\mathrm{ECE} = \sum_{m=1}^{M} \frac{|B_m|}{n} \left| \mathrm{acc}(B_m) - \mathrm{conf}(B_m) \right|, \quad (12)$$

where n is the number of samples. The difference between acc and conf for a given bin represents the calibration gap (red bars in reliability diagrams – e.g. Fig. 4). We use ECE as the primary empirical metric to measure model calibration.

A.3 Negative Log Likelihood

Negative log likelihood is a standard measure of a probabilistic model's quality. It is also referred to as the cross entropy loss in the context of deep learning. Given a probabilistic model $\hat{\pi}(Y|X)$ and n samples, NLL is defined as:

$$\mathcal{L} = -\sum_{i=1}^{n} \log(\hat{\pi}(y_i|\bar{X}_i)) \quad (13)$$

It is a standard result that, in expectation, NLL is minimized if and only if $\hat{\pi}(Y|X)$ recovers the ground truth conditional distribution $\pi(Y|X)$. The temperature T in temperature scaling is optimized with respect to NLL on the dev sets.

A.4 Dataset Statistics

MATRES is composed of 275 news documents and the train/dev/test split is 183/72/20 documents where 6336/6404/818 event pairs are annotated respectively. The same statistics hold for MATRES-DS since we only change the event triggers in the inputs instead of the labels. In TD-Discourse, 4,000/650/1,500 and 32609/1435/4258 TEMPREL's are annotated in the train/dev/test sets of TDD-man and TDD-Auto, respectively.

A.5 Experimental Setup and Hyperparameter Setting

In the training phase, we fine-tune the pre-trained 1024-dimensional Big Bird (Zaheer et al., 2020) to encode the context of event triggers. We obtain the tense information of event triggers with an off-the-shelf tense identifier[10]. The parameters of the model are optimized using AMSGrad (Reddi et al., 2018) with the learning rate set to 5×10^{-6}, batch size set to 20, and the training process is limited to 40 epochs on a server with Nvidia A6000 GPU. All experiments are repeated with five different random seeds and the results reported are their average. To obtain $\boldsymbol{\alpha}_s$ in Eq. 3, we smooth the target means to redistribute a small amount of probability density to the other corners of the Dirichlet. In our experiments, we set $\lambda_1 = \lambda_2 = 1$ in Eq. 5. On the dev set of TDD-man the optimal β's of the model in Eq. 6 are $\beta_1 = -0.4, \beta_2 = 0.6$, where the search bounds, a and b equal to -1 and 1.

LoFT: Enhancing Faithfulness and Diversity for Table-to-Text Generation via Logic Form Control

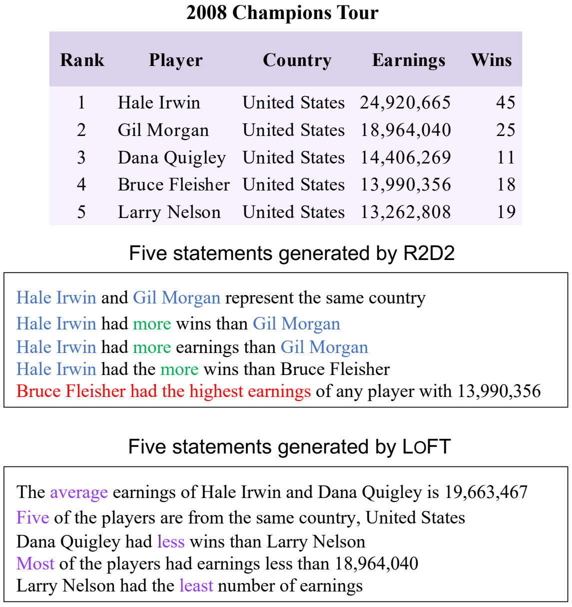
Yilun Zhao[*1] **Zhenting Qi**[*2] **Linyong Nan**[1]
Lorenzo Jaime Yu Flores[1] **Dragomir Radev**[1]
[1]Yale University [2] Zhejiang University
`yilun.zhao@yale.edu` `zhenting.19@intl.zju.edu.cn`

Abstract

Logical Table-to-Text (LT2T) generation is tasked with generating logically faithful sentences from tables. There currently exists two challenges in the field: 1) *Faithfulness*: how to generate sentences that are factually correct given the table content; 2) *Diversity*: how to generate multiple sentences that offer different perspectives on the table. This work proposes LoFT, which utilizes logic forms as fact verifiers and content planners to control LT2T generation. Experimental results on the LogicNLG dataset demonstrate that LoFT is the first model that addresses unfaithfulness and lack of diversity issues simultaneously. Our code is publicly available at `https://github.com/Yale-LILY/LoFT`.

1 Introduction

Table-to-Text (T2T) generation aims to produce natural language descriptions from structured tables. A statement generated from tabular data can be inferred based on different levels of information (e.g., value of a specific cell, logical operation result across multiple cells). Although current T2T models (Lebret et al., 2016; Wiseman et al., 2017; Puduppully et al., 2019; Parikh et al., 2020) have shown remarkable progress in fluency and coherence, they mainly focus on surface-level realizations without much logical inference.



2008 Champions Tour

Rank	Player	Country	Earnings	Wins
1	Hale Irwin	United States	24,920,665	45
2	Gil Morgan	United States	18,964,040	25
3	Dana Quigley	United States	14,406,269	11
4	Bruce Fleisher	United States	13,990,356	18
5	Larry Nelson	United States	13,262,808	19

Five statements generated by R2D2

Hale Irwin and Gil Morgan represent the same country
Hale Irwin had more wins than Gil Morgan
Hale Irwin had more earnings than Gil Morgan
Hale Irwin had the more wins than Bruce Fleisher
Bruce Fleisher had the highest earnings of any player with 13,990,356

Five statements generated by LoFT

The average earnings of Hale Irwin and Dana Quigley is 19,663,467
Five of the players are from the same country, United States
Dana Quigley had less wins than Larry Nelson
Most of the players had earnings less than 18,964,040
Larry Nelson had the least number of earnings

Figure 1: An example of logical table-to-text generation. (a) Statements generated by previous models (Nan et al., 2022): the generation suffers from 1) *Lack of diversity*, as three of the generated statements are focused on the same table regions (i.e., "Hale Irwin" and "Gil Morgan"), and three of them use the similar reasoning operations (i.e., comparative); 2) *Unfaithfulness*, as one of the generated statements is factually incorrect given the table content. (b) Statements generated by LoFT: By utilizing logic forms to *control* the generation, our method can generate multiple factually correct sentences that each use a different reasoning operation to offer various perspectives on the tabular data.

Recently, Chen et al. (2020a) proposed LogicNLG, which is tasked with generating textual descriptions that require logical reasoning over tabular data (i.e., LT2T generation). LT2T generation is challenging as it requires a model to learn the logical inference knowledge from table-text pairs and generate multiple *factually correct* sentences. Another challenge for LT2T generation is the *diversity* of generated text. Natural Language Generation (NLG) encourages the diverse output of statements over a single input, as it provides various perspectives on the data and offers users more choices. In LT2T generation, requirements for diversity naturally emerge from the need to apply different logical operations to extract different levels of table information. However, current methods (Chen et al., 2021; Nan et al., 2022; Liu et al., 2022a; Zhao et al., 2022b) that address issues of unfaithfulness have overlooked the importance of diversity. As shown in Figure 1, multiple statements generated using current methods (Nan et al., 2022) might only cover information from the same

---

table region or logical operation. Such issues related to lack of diversity could limit the deployment of LT2T models in the real world.

In this work, we attribute *unfaithfulness* and lack of *diversity* to the absence of *controllability* over generation. Specifically, due to the large number of combinations of different logical operations and table regions, the space of factually correct statements is exponentially large. However, LOGICNLG uses the whole table as the input, without providing annotations related to any other explicit control attribute. As a result, it is hard and uncontrollable for neural models to decide a favorable choice of logical selections solely based on the table input. We believe such *uncontrollability* leads to unfaithfulness and lack of diversity issues.

This work proposes LOFT, a framework that utilizes logic forms as mediators to enable *controllable* LT2T generation. Logic forms (Chen et al., 2020d,b) are widely used to retrieve evidence and explain the reasons behind table fact verification (Yang et al., 2020; Yang and Zhu, 2021; Ou and Liu, 2022). In this work, logic forms are used as: 1) fact verifiers to ensure the factual correctness of each generated sentence; and 2) content planners to control which logical operation and table region to use during the generation. Experimental results show that LOFT surpasses previous methods in faithfulness and diversity simultaneously.

2 Related Work

Logical Table-to-Text (LT2T) Generation LOGICNLG (Chen et al., 2020a) is tasked with generating logically faithful sentences from tables. To improve the faithfulness of generated statements, Nan et al. (2022) trained a system both as a generator and a faithfulness discriminator with additional replacement detection and unlikelihood learning tasks. Liu et al. (2022a) pre-trained a model on a synthetic corpus of table-to-logic-form generation. Zhao et al. (2022b) demonstrated that faithfulness of LT2T can be improved by pre-training a generative language model over synthetic Table QA examples. However, these methods overlook the importance of diversity in T2T generation, and might generate multiple statements that cover the same table regions or reasoning operations. Previous methods in NLG proposed to improve diversity by modifying the decoding techniques (Li et al., 2016). However, these approaches degrade faithfulness as measured against baselines (Perlitz et al., 2022). To enable controllable generation and improve diversity, Perlitz et al. (2022) used logical types of statements as a control. However, such methods still suffer from problems related to unfaithfulness, and may generate statements covering limited table regions. This work proposes to leverage the logic form as a fact checker and content planner to control LT2T generation, which tackles the challenges about faithfulness and diversity at the same time.

Table Fact Verification via Logic Form Logic forms are widely used in Table Fact Verification (Chen et al., 2020b). Specifically, given an input statement, the model (Yang et al., 2020; Yang and Zhu, 2021; Ou and Liu, 2022) will first translate it into logic form. Then the logic form will be executed over the table, and return `true/false` as the entailment label for a given statement. While several works (Chen et al., 2020d; Shu et al., 2021; Liu et al., 2021) focused on generating fluent statements from logic forms, the utilization of logic forms to benefit LT2T generation is still unexplored.

3 LOFT

This section first introduces the logic form utilized, and then delves into the training and inference process of LOFT. We also explain how the use of logic forms can enhance both faithfulness and text-diversity in LT2T generation.

3.1 Logic Form Implementation

Logic forms are widely used to retrieve evidence and explain the reasons behind table fact verification. We use the same implementation as Chen et al. (2020d), which covers 8 types of the most common logical operations (e.g., count, aggregation) to describe a structured table. Each logical operation corresponds to several Python-based functions. For example, the definition of function `all_greater(view, header, value)` under "majority" category is: checking whether all the values under `header` column are greater than `value`, with the scope (i.e., `view`) of all or a subset of table rows. The complete list of logical operation types and corresponding function definitions are shown in Table 4 in Appendix.

3.2 LOFT Training

Training Task Formulation Given the serialized tabular data with selected columns as T, the train-

(a) LoFT training stage.

(b) LoFT inference stage.

Figure 2: The illustration of LoFT. (a) During the training stage, the SASP model is first applied to translate each statement in the LogicNLG training set into the logic form. Then LoFT is trained to generate the reference statement given the translated logic form and serialized table data. (b) During the inference stage, given each table, the logic form synthesis pipeline was first applied to synthesize candidate logic forms that cover different table regions and logical operations. LoFT is applied to generate statements for each candidate logic form. Then a statement verifier is used to filter out those potentially unfaithful statements. As a result, LoFT can generate a diverse set of faithful statements covering different table regions and reasoning operations. For each table in the LogicNLG test set, we randomly sampled five candidate statements for evaluation.

ing objective of LoFT is to generate a sentence $\boldsymbol{y} = (y_1, y_2, \ldots, y_n)$ that is both fluent and faithful, with the translated logic form l as control.

$$\boldsymbol{y} = \text{argmax} \prod_{i=1}^{n} P(y_i | y_{<i}, T,\, l;\, \theta) \qquad (1)$$

where θ denotes the parameters of a seq2seq LM.

Training Dataset Collection Since the LogicNLG dataset does not contain logic form annotations, we had to augment each statement in the training set with its corresponding logic forms. To construct *{statement, logic form}* parallel data for the LogicNLG training set, we adapted SASP (Ou and Liu, 2022), the state-of-the-art model for TabFact dataset, which leverages structure-aware semantic parsing over tables to translate the given statement into logic form. In this work, given an example in the LogicNLG training set, SASP was applied to generate its logic form, resulting in a total of 15,637 examples for LoFT training.

3.3 LoFT Inference

During the inference stage, for each given table, we first applied the logic form synthesis pipeline to synthesize multiple candidate logic forms (Liu et al., 2022a). For each of these logic forms, the system generates its corresponding statement. The faithfulness of these statements were further checked by a verifier.

Logic Form Synthesis Pipeline To synthesize a candidate set of logic forms paired with each supporting table, we applied a similar logic form synthesis pipeline as Liu et al. (2022a).

We extracted templates of logic forms from the collected LoFT training dataset. Specifically, we categorized functions with similar definitions (e.g., `max/min`, `greater/less`) into smaller groups to obtain a more abstract template. Each function category corresponded to one unique table reasoning skill. For each template, we masked specific entities in the logic forms as typed placeholders (i.e., `col` to denote a column header, `obj` to denote an object). Finally, we obtained 45 different templates, covering 8 table logical operations. Table 4 shows the complete list of reasoning operations and corresponding function definitions.

Given the table and each set of selected columns, the pipeline would synthesize a total of 20 candidate logic forms whose execution result over the table is `True`. To generate a candidate logic form, the pipeline first sampled a logic form using a weighted-sampling technique with the weight equal to the template distribution in the LoFT training dataset (Section 3.2). The weighted sampling is to ensure that the generated candidate logic forms follow a similar distribution as LogicNLG. To instantiate the sampled template, a bottom-up sampling strategy is adopted to fill in each placeholder of the template and finally generate the logic form.

Statement Generation & Verification Through the logic form synthesis pipeline, we obtained a large number of candidate logic forms. For each logic form, we used LoFT to generate the corresponding statement. The candidate statements might still contain some factually incorrectness, thus we applied an NLI-based verifier to filter out those potentially unfaithful generations. Specifically, we used the TABFACT (Chen et al., 2020b) dataset to train a classifier, which adopts RoBERTa-base as the backbone. We fed each generated statement and its corresponding table into the classifier, and only kept those statements that were predicted as entailed. Then we randomly sampled five statements as the output for each table in LOGICNLG.

3.4 Enhancing LT2T via Logic Form Control

This subsection provides two perspectives to explain why logic forms can help improve both faithfulness and diversity of LT2T generation.

Logic Form as Content Planner Logic forms pass column or cell values as arguments, guiding the model to focus on relevant table regions. The function category of the logic form, such as `count`, helps the model better organize logical-level content planning.

Logic Form as Fact Verifier Logic forms are defined with unambiguous semantics, hence are reliable mediators to achieve faithful and controllable logical generations. During the inference stage, we synthesize candidate logic forms with 100% execution correctness. The sampled logic form serves as a fact verifier and conveys accurate logical-level facts for controllable LT2T generation.

4 Experimental Setup

We next discuss the evaluation metrics, baselines, and implementation details for the experiments.

4.1 Evaluation Metrics

We applied various automated evaluation metrics at different levels to evaluate the model performance from multiple perspectives.

Surface-level Following Chen et al. (2020a), we used BLEU-1/2/3 to measure the consistency of generated statements with the reference.

Diversity-level We used Distinct-n (Li et al., 2016) and self-BLEU-n (Zhu et al., 2018) to measure the diversity of five generated statements for each table. Distinct-n is defined as the total number of distinct n-grams divided by the total number of tokens in the five generated statements; Self-BLEU-n measures the average n-gram BLEU score between generated statements. We measured Distinct-2 and Self-BLEU-4 in our experiment.

Faithfulness-level Similar as the previous works (Chen et al., 2020a; Nan et al., 2022; Liu et al., 2022a), we used a parsing-based evaluation metric (i.e., SP-Acc) and two NLI-based evaluation metrics (i.e., NLI-Acc and TAPEX-Acc) to measure the faithfulness of generation. SP-Acc directly extracts the meaning representation from the generated sentence and executes it against the table to verify the correctness. NLI-Acc and TAPEX-Acc use TableBERT (Chen et al., 2020b) and TAPEX (Liu et al., 2022b) respectively as their backbones, and were finetuned on the TABFACT dataset (Chen et al., 2020b). Liu et al. (2022a) found that NLI-Acc is overly positive about the predictions, while TAPEX-Acc is more reliable to evaluate the faithfulness of generated sentences.

4.2 Baseline Systems

We implemented following baseline systems for the performance comparison: **GPT2-TabGen** (Chen et al., 2020a) directly fine-tunes GPT-2 over the LOGICNLG dataset; **GPT2-C2F** (Chen et al., 2020a) first produces a template which determines the global logical structure, and then generates the statement conditioned on the template; **DCVED** (Chen et al., 2021) applies a deconfounded variational encoder-decoder to reduce the spurious correlations during LT2T generation training; **DEVTC** (Perlitz et al., 2022) utilized reasoning operation types as an explicit control to increase the diversity of LT2T generation; and **R2D2** (Nan et al., 2022) trains a generative language model both as a generator and a faithfulness discriminator with additional replacement detection and unlikelihood learning tasks, to enhance the faithfulness of LT2T generation.

4.3 Implementation Details

Following Shu et al. (2021), we converted each logic form into a more human-readable form for both LOFT training and inference data. LOFT was implemented using fairseq library (Ott et al., 2019), with BART-Large (Lewis et al., 2020) as the backbones. All experiments were conducted on an 8 NVIDIA RTX-A5000 24GB cluster. Both LOFT and the statement verifier was trained for 5,000 steps with a batch size of 128. The best checkpoints were selected by the validation loss.

Model	Surface-level	Diversity-level		Faithfulness-level		
	BLEU-1/2/3↑	Distinct-2↑	s-BLUE-4↓	SP-Acc↑	NLI-Acc↑	TAPEX-Acc↑
GPT2-TabGen (Chen et al., 2020a)	48.8/27.1/12.6	59.0	55.3	42.1	68.7	45.0
GPT2-C2F (Chen et al., 2020a)	46.6/26.8/13.3	60.3	52.8	42.7	72.2	44.1
DCVED* (Chen et al., 2021)	49.5/28.6/15.3	–	–	43.9	76.9	–
DEVTC‡ (Perlitz et al., 2022)	51.3/30.6/16.3	73.7	21.3	44.3	77.9	55.6
R2D2 (Nan et al., 2022)	51.8/32.4/18.6	60.1	51.5	50.8	85.6	60.2
LoFT	48.1/27.7/14.9	**79.5**	**17.7**	**57.7**	**86.9**	**61.8**

Table 1: Performance on the LogicNLG test set. ‡: results from our own implementation; ∗: code not released and we used the results reported in original papers. LoFT achieves great improvement on faithfulness and diversity.

Diversity Criteria	DEVTC		R2D2		LoFT	
	Best↑	Worst↓	Best↑	Worst↓	Best↑	Worst↓
Table Coverage	8	16	5	20	29	5
Reasoning Op	19	1	2	37	24	2

Table 2: Number of times the system was selected as best or worst by majority vote (including ties). LoFT outperforms other baselines in terms of diversity for both table coverage and reasoning operations.

Model	Faithfulness ↑ Agreement / κ	Fluency ↑ Agreement / κ
DEVTC	63.5 / 0.69	86.5 / 0.80
R2D2	71.5 / 0.73	**90.0** / 0.84
LoFT	**75.0** / 0.76	88.0 / 0.81

Table 3: Human evaluation results on the criteria of faithfulness and fluency, with the total agreement by Fleiss' Kappa (κ) (Fleiss, 1971). LoFT has the best performance in terms of faithfulness, while achieving comparable performance in fluency.

5 Experimental Results

This section discusses automated and human evaluation results of different systems.

5.1 Main Results

Table 1 presents the results on LogicNLG. LoFT outperforms all the baselines on the criteria of diversity and faithfulness, and is the first model that achieves state-of-the-art results on both faithfulness- and diversity-level. It is worth noting that in the LogicNLG setting, a generated statement is allowed to cover a different table region or reasoning operations from the references, as long as it is fluent and factually correct. However, in such cases, the reference-based metrics will be low, explaining why the BLEU-1/2/3 scores of LoFT are lower than other models.

5.2 Human Evaluation

We conducted the human evaluation with four expert annotators using the following three criteria: (1) *Faithfulness* (scoring 0 or 1): if all facts contained in the generated statement are entailed by the table content; (2) *Diversity* (voting the best & worst): if the five generated statements cover information from different table regions, and use different reasoning operations; (3) *Fluency* (scoring 0 or 1): if the five generated statements are fluent and without any grammar mistakes.

We chose R2D2 (Nan et al., 2022) and DEVTC (Perlitz et al., 2022) for comparison, as they achieved best-performance results in faithfulness and diversity, respectively. We sampled 50 tables from the LogicNLG test set. For each table, we selected all five generated statements from each model's output. To ensure fairness, the model names were hidden to the annotators, and the display order between three models was randomly shuffled. Human evaluation results show that LoFT delivers improvements in both faithfulness (Table 3) and diversity (Table 2), while achieving comparable performance in fluency (Table 3).

6 Conclusions

This work proposes LoFT, which utilizes logic forms as fact verifiers and content planners to enable controllable LT2T generation. Experimental results on LogicNLG demonstrate that LoFT delivers a great improvement in both diversity and faithfulness of LT2T generation.

Limitations

The first limitation of our approach is that LoFT does not explore long text generation (Moosavi et al., 2021). LoFT only supports the generation of multiple single sentences. To enable long text generation (i.e., generate a long paragraph that delivers various perspectives on the table data), a global content planner (Su et al., 2021) needs to be designed to highlight which candidate sentences should be mentioned and in which order. Additionally, we believe that LoFT can also be applied to text generation over hybrid context with both textual and tabular data (Chen et al., 2020c; Zhao et al., 2022a; Nakamura et al., 2022).

The second limitation of our work is that the statement verifier discussed in Section 3.3 was trained using the same data as NLI-Acc and TAPEX-Acc. This might bring some bias for NLI-based metrics on faithulness-level evaluation. In the future, we will exploit a more robust automated evaluation system (Fabbri et al., 2021; Liu et al., 2022c) to comprehensively evaluate the LT2T model performances from different perspectives.

Moreover, we applied the SASP model (Ou and Liu, 2022) to convert statements into logic forms (Section 3.2). Some converted logic forms may be inconsistent with the original statement. We believe that future work could incorporate the Logic2Text (Chen et al., 2020d) dataset into training data to further improve the LoFT performance.

Ethical Consideration

We used the LogicNLG (Chen et al., 2020a) dataset for training and inference. LogicNLG is publicly available under MIT license[1] and widely used in NLP research and industry.

PROMPTDA : Label-guided Data Augmentation for Prompt-based Few Shot Learners

kshu@iit.edu

Abstract

Recent advances in large pre-trained language models (PLMs) lead to impressive gains on natural language understanding (NLU) tasks with task-specific fine-tuning. However, directly fine-tuning PLMs heavily relies on sufficient labeled training instances, which are usually hard to obtain. Prompt-based tuning on PLMs has shown to be powerful for various downstream few-shot tasks. Existing works studying prompt-based tuning for few-shot NLU tasks mainly focus on deriving proper label words with a verbalizer or generating prompt templates to elicit semantics from PLMs. In addition, conventional data augmentation strategies such as synonym substitution are also widely adopted in low-resource scenarios. However, the improvements they bring to prompt-based few-shot learning have been demonstrated to be marginal. Thus, an important research question arises as follows: *how to design effective data augmentation methods for prompt-based few-shot tuning?* To this end, considering the label semantics are essential in prompt-based tuning, we propose a novel *label-guided data augmentation* framework **PROMPTDA**, which exploits the enriched label semantic information for data augmentation. Extensive experiment results on few-shot text classification tasks show that our proposed framework achieves superior performances by effectively leveraging label semantics and data augmentation for natural language understanding.

1 Introduction

Pre-trained language models (PLMs) have shown promising performances in various applications such as text classification (Yang et al., 2019), document summarization (Zhang et al., 2020a), question answering (Mirzaee et al., 2021). The recent advancement of *prompt-based tuning* has shown a significant improvement over normal fine-tuning on various few-shot tasks (Brown et al., 2020). Typically, the prompt-based tuning paradigm transforms a NLU task into a masked language modeling (MLM) problem. For example, in sentiment analysis, an original sentence "`nice movie to watch.`" can be augmented with a *template* "`It is [MASK]`" as the input x. Each class (e.g., POSITIVE) is represented by a *label word* (e.g., `good`) selected by a *verbalizer* from the vocabulary (Schick and Schütze, 2021). The prediction of the class POSITIVE is based on the probability of the `[MASK]` being filled with the token `good`.

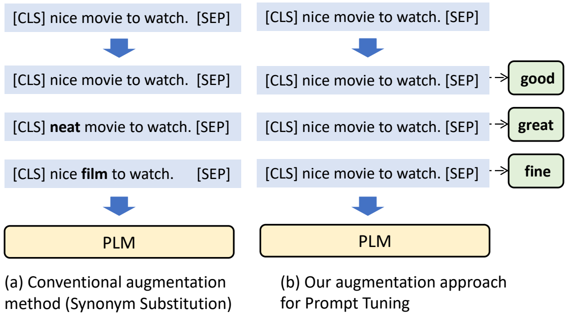

Figure 1: The basic comparison of conventional data augmentation methods and our proposed augmentation framework **PROMPTDA**. `{good, great, fine}` are the label words for prompt tuning. Conventional DA constructs ***instances*** for augmentation. But PROMPTDA conducts ***instance-label pairs*** for augmentation.

In addition, conventional data augmentation (DA) methods such as synonym substitution are also widely applied when the training data is limited (Chen et al., 2021). However, it has been shown in previous works that they can only bring marginal improvements for prompt-based few-shot learning (Zhou et al., 2021). We argue that one of the reasons could be that these DA methods mainly focus on transforming the *instances* while not incorporating the *label semantics*, which have great potential to improve the performances of few-shot tasks (Luo et al., 2021) and are essential for prompt-based few-shot learners (Liu et al., 2021). Therefore, we focus on a new problem of designing augmentation strategies for the prompt tuning paradigm and explore fusing label semantics into

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 562–574
May 2-6, 2023 ©2023 Association for Computational Linguistics

augmentation for prompt-based few-shot learners.

Specifically, different from most prompt-based tuning methods that adopt an *one-to-one verbalizer* (Schick and Schütze, 2021; Gao et al., 2021), we propose to incorporate the rich label semantic information contained in the label words derived from an *one-to-multiple verbalizer* into a new data augmentation paradigm. As shown in Figure 1, compared with previous data augmentation methods that mainly focus on constructing more ***instances***, our method PROMPTDA proposes to construct ***instance-label pairs*** for augmentation, which opens a new dimension for conducting augmentation. For example, with the one-to-multiple verbalizer mapping from the class POSITIVE to a set of label words {`good, great, fine`}, we aim to generate a set of synthetic data points $\{(x, \texttt{good}), (x, \texttt{great}), (x, \texttt{fine})\}$ based on the original instance x and leverage them to enhance the performances of the prompt-based few-shot learners. Furthermore, extensive experiment results in section § 5.5 also show that our proposed PROMPTDA can be regarded *orthogonal* to the conventional DA methods (e.g., synonym substitution) to some extent. Thus, PROMPTDA can complement with conventional augmentation approaches to further improve the performances.

To this end, we propose a new label-guided data augmentation framework for prompt-based few-shot learners named PROMPTDA, which contains three coherent modules including *Label Augmentation*, *Augmented Prompt-based Tuning*, and *Prediction Transformation*. First, we utilize a PLM to automatically search for an one-to-multiple verbalizer on a specific training set and derive a set of semantically similar tokens for each class as the label words. Second, in the training stage, we construct the instance-label pairs from the original data with regards to each label word for augmentation in prompt tuning. Third, in the inference stage, we utilize the trained language model to predict the label by aggregating the probability scores on the derived label words.

The contributions of this paper are summarized as follows: (1) we study a new problem of designing data augmentation strategies for prompt-based few-shot learners; (2) we propose a novel label-guided data augmentation framework PROMPTDA that exploits the rich label semantic information of one-to-multiple verbalizer for improving prompt tuning; (3) we conduct extensive experiments on real-world few-shot classification tasks and demonstrate the effectiveness of the proposed framework.

2 Related Work

Prompt-based Tuning has attracted increasing attention recently for various natural language processing tasks including text classification (Gao et al., 2021), question answering (Jiang et al., 2020), language generation (Li and Liang, 2021), etc. The prompt-based learning framework has shown promising performances especially in zero shot or few shot classification tasks when limited or no labels are available (Liu et al., 2021). For example, Gao *et al.* propose a prompt-based fine-tuning framework that automatically generates prompt templates and incorporates demonstrations to improve few-shot classification performances (Gao et al., 2021). Shin *et al.* proposes the AutoPrompt method to automatically generate prompts and verbalizers for eliciting the knowledge from language models (Shin et al., 2020). Other works on improving prompt-based model performances also mainly focus on constructing various types of prompt templates and verbalizers (Liu et al., 2021).

Few-shot Text Classification aims to build text classification model when few labeled data is available. Existing works mainly follow the following categories. First, semi-supervised learning where unlabeled data, alongside usually a small amount of labeled data, is used for learning (Mukherjee and Awadallah, 2020; Lee et al., 2021). For example, Subhabrata *et al.* propose to jointly learn from a small set of labeled data and a large amount of unlabeled data with uncertainty using self-training (Mukherjee and Awadallah, 2020). Second, meta-learning frameworks such as metric-based (Sui et al., 2020) and optimization-based approaches (Bansal et al., 2019). Third, weakly supervised learning to derive weak labels (Shu et al., 2020; Meng et al., 2020) in addition to the limited clean labels to improve text classification. Other approaches include transfer learning via learning to adapt transferable information from the source domain to the target domain (Gupta et al., 2020), or leveraging auxiliary tasks to improve the target tasks (Xia et al., 2021; Yin, 2020).

Data Augmentation is to construct synthetic data from an available dataset to enlarge the data size, which can help supervised training with enriched training data (Chen et al., 2021; Guo, 2020;

Shu et al., 2018), or self-supervised learning for constructing samples in pretext tasks (Zhang et al., 2017; Yoon et al., 2020), etc. Data augmentation techniques for natural language generally fall into data space and feature space (Bayer et al., 2021). In the data space, augmentation methods transform the data in character-level, word-level, phrase-level or document-level. In the feature space, representations in the latent space are manipulated by adding noise or interpolation (Schwartz et al., 2018; Verma et al., 2019). However, conventional data augmentation methods bring marginal improvements under prompt tuning paradigm (Zhou et al., 2021). It is under exploring about how to design effective data augmentation methods for prompt-based few-shot scenarios. Therefore, we propose a novel label-guided data augmentation mechanism in prompt-based tuning for few shot tasks.

3 Problem Definition

The goal of few-shot classification task is to learn a classifier to predict the label of unseen instances with limited labeled samples during the training. Following the widely-used few-shot setting (Gao et al., 2021; Liu et al., 2021), we assume that a large pre-trained language model (e.g., BERT) $\mathcal{M}$ can be utilized to fine-tune on a downstream task with the dataset $\mathcal{D} = \{\mathcal{X}, \mathcal{Y}\}$, where $\mathcal{X}$ denotes the instances and $\mathcal{Y}$ indicates the corresponding labels. For each task, the number of training instances for each class is K, which is usually small (e.g., 8 or 16). The goal is to design a prompt learning strategy that generalizes well on unseen samples in the test set $\mathcal{D}_{\text{test}}$ with few labeled training data in $\mathcal{D}_{\text{train}}$. To ensure a fair parameter setting, we assume that a validation set $\mathcal{D}_{val}$ is available, and $|\mathcal{D}_{\text{val}}| = |\mathcal{D}_{\text{train}}|$. The test set $\mathcal{D}_{\text{test}}$ is the same as the full-data training setting.

4 Label-guided Data Augmentation for Prompt-based Tuning

In this section, we detail the proposed framework PROMPTDA, which is illustrated in Figure 2. It mainly consists of three modules: (1) a Label Augmentation module to derive multiple label words for each class to enrich the label space; (2) an Augmented Prompt-based Tuning module for augmenting the training data guided by label words; (3) a Prediction Transformation module to transform the prediction from the label words to original classes.

4.1 Label Augmentation

Due to the limited available labels in few-shot learning, recent works are generating label words to help prediction (Schick and Schütze, 2021; Gao et al., 2021). The goal is to extend the label space by incorporating the rich semantics in the vocabulary. While existing works mainly focus on selecting one label word for each class manually or automatically in prompt-tuning, the resultant label words often have a large variance and the semantics in other candidate label words are ignored. Therefore, we explore automatically searching for multiple label words for each class to better enrich the label space. Let $\mathcal{F} : \mathcal{Y} \to \mathcal{V}_{\mathcal{Y}}$ denote the one-to-multiple verbalizer that maps each label category $y \in \mathcal{Y}$ to a set of label words $\mathcal{V}_y = \{v_y^1, v_y^2, ..., v_y^{k_y}\} \subset \mathcal{V}$, where $k_y = |\mathcal{V}_y|$ denotes the number of selected label words for each class.

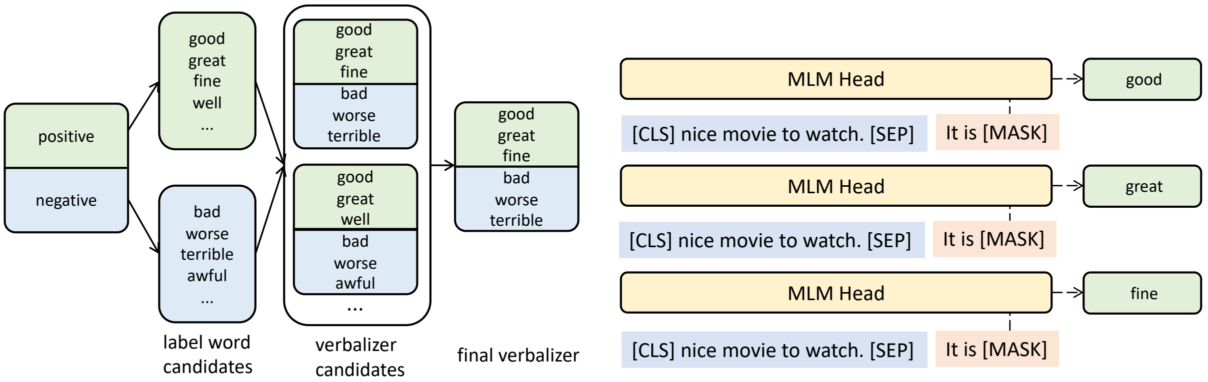
Firstly, we aim to search for a candidate set of label word $\tilde{\mathcal{V}}_y \subset \mathcal{V}$ that is semantically similar to each class $y \in \mathcal{Y}$. Let $\mathcal{D}^y_{\text{train}}$ denote the subset of training data with the class y. $\mathcal{T}(x)$ denotes the input x with a fixed template $\mathcal{T}$. `Po([mask])` denotes the position of `[mask]` in the input x. We propose to select the Top-m label words from vocabulary as $\tilde{\mathcal{V}}_y$ based on the conditional likelihood over $\mathcal{D}^y_{\text{train}}$ for each class y:

$$\tilde{\mathcal{V}}_y = \underset{v \in \mathcal{V}}{\text{Top-}m} \left\{ \sum_{(x,y) \in \mathcal{D}^y_{\text{train}}} \Pr(v, \mathcal{T}(x)) \right\} \tag{1}$$

where $\Pr(v, \mathcal{T}(x))$ denotes the corresponding probability score of each token in the vocabulary filling in `Po([mask])` in PLM inference as:

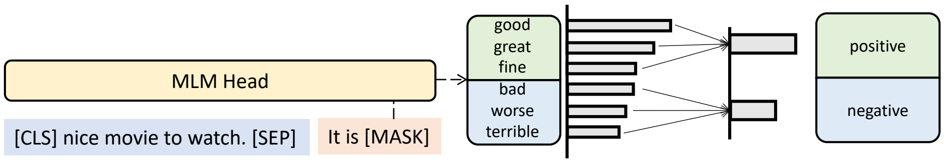
$$\Pr(v, \mathcal{T}(x)) = \Pr(\texttt{Po([mask])} = v \mid \mathcal{T}(x)) \tag{2}$$

Secondly, we construct a verbalizer candidate set F for the whole dataset. It is a combinatorial problem to select k_y label words from $\tilde{\mathcal{V}}_y$ to construct $\mathcal{V}_y$ for each class y. The number of possible candidates of $\mathcal{V}_y$ is $\binom{|\tilde{\mathcal{V}}_y|}{k_y}$. Then the element number of the verbalizer candidate set F is $|F| = \binom{|\tilde{\mathcal{V}}_y|}{k_y}^{|\mathcal{Y}|}$. We utilize each one-to-multiple verbalizer candidate in F to infer and calculate the prediction accuracy on $\mathcal{D}_{\text{train}}$ via the same *prediction transformation* method in section § 4.3. Then we select the Top-n candidates from F based on the prediction accuracy. If there exist multiple candidates with the same accuracy score, we randomly select one as the



(a) Label Augmentation

(b) Augmented Prompt-based Tuning



(c) Prediction Transformation

Figure 2: The proposed **PROMPTDA** for few-shot learning (with sentiment classification task as an example): (a) **Label Augmentation**: deriving multiple label words for each class to enrich the label semantic space; (b) **Augmented Prompt-based Tuning**: training with the augmented instance-label pairs via masked language modeling; (c) **Prediction Transformation**: aggregating the probability scores on the derived label words for the final prediction.

final one-to-multiple verbalizer. Otherwise, we select the verbalizer candidate with highest accuracy score. Note that m and n are both hyperparameters picked by pilot study on the specific datasets.

4.2 Augmented Prompt-based Tuning

To enrich the training data for the few-shot text classification task, it is natural to utilize data augmentation methods such as token-level or sentence-level augmentation for fine-tuning (Chen et al., 2021). Most of the existing data augmentation methods focus on enlarging training data conditioned on the original label space. Orthogonal to previous augmentation methods, our method incorporates label semantic information into prompt-tuning via augmenting sample-label pairs rather than only augmenting samples. For $(x, y) \in \mathcal{D}_{\text{train}}$, we have obtained the corresponding label word set $\mathcal{V}_y = \{v_y^1, v_y^2, ..., v_y^{k_y}\}$. Then we can include $\{(x, v_y^1), (x, v_y^2), ..., (x, v_y^{k_y})\}$ for augmentation. Let $\tilde{\mathcal{D}}_{\text{train}}$ denote the augmented dataset. The resultant dataset can be denoted as follows:

$$\tilde{\mathcal{D}}_{\text{train}} = \cup_{(x,y)\in\mathcal{D}_{\text{train}}}\{(x, v_y^1), (x, v_y^2), ..., (x, v_y^{k_y})\} \tag{3}$$

In the training process, we follow the MLM training paradigm and minimize the negative log-likelihood on the whole augmented training set $\tilde{\mathcal{D}}_{\text{train}}$. The optimization objective is:

$$\mathcal{L} = \sum_{(x,v)\in\tilde{\mathcal{D}}_{\text{train}}} - \log \Pr(v \mid x) \tag{4}$$

For $(x, v) \in \tilde{\mathcal{D}}_{\text{train}}$, the conditional probability of filling the position of `[mask]` with v is:

$$\begin{aligned} \Pr(v \mid x) &= \Pr(\texttt{Po([mask])} = v \mid x) \\ &= \frac{\exp\left(\mathbf{w}_v \cdot \mathbf{h}_{\texttt{[MASK]}}\right)}{\sum_{v' \in \mathcal{V}} \exp\left(\mathbf{w}_{v'} \cdot \mathbf{h}_{\texttt{[MASK]}}\right)} \end{aligned} \tag{5}$$

where $\mathbf{w}_v$ denotes the pre-softmax output vector for each token v in the vocabulary, and $\mathbf{h}_{\texttt{[MASK]}}$ denotes the corresponding hidden state of the `[MASK]` position. Note that we completely reuse the PLM and do not introduce new parameters in the training process, which is important for prompt-based tuning to be effective in few-shot scenarios.

4.3 Prediction Transformation

We have demonstrated the process of training the MLM classifier head with the augmented data in the prompt-based tuning paradigm. Next, we describe how to perform the inference for the target class. Let h denote the function that transforms the probability scores on the label word set $\mathcal{V}_y = \{v_y^1, v_y^2, ..., v_y^{k_y}\}$ into the probability score of each class y. Since the label word with the highest probability score in set $\mathcal{V}_y$ can represent the class y, we use $h = max()$ to calculate the final probability score of each class. Then the probability score of each class y can be calculated as:

$$\Pr(y \mid x) = h(\mathrm{P}(v_y^1, x), \mathrm{P}(v_y^2, x), ..., \mathrm{P}(v_y^{k_y}, x)) \tag{6}$$

where for (x, v_y^i) that satisfies $(x, v_y^i) \in \tilde{\mathcal{D}}_{\text{train}}$ and $v_y^i \in \mathcal{V}_y, (i = 1, 2, ..., k_y)$, $\mathrm{P}(v_y^i, x)$ is denoted as the conditional probability of filling the position of `[mask]` with v_y^i:

$$\mathrm{P}(v_y^i, x) = \Pr(\texttt{Po([mask])} = v_y^i \mid x) \tag{7}$$

After we obtain the probability score over each class, the final predicted class $\hat{y}$ is calculated as:

$$\hat{y} = \mathrm{argmax}_{y \in \mathcal{Y}} \Pr(y \mid x) \tag{8}$$

5 Experiments

In this section, we present the experiments to evaluate the effectiveness of the proposed PROMPTDA. Specifically, we aim to answer the following research questions:

- **RQ1** Can PROMPTDA improve the performance of few-shot prompt-based tuning?
- **RQ2** Can the proposed Label Augmentation strategy help the target label prediction?
- **RQ3** Can the PROMPTDA make the prompt-based tuning method more stable?

5.1 Experimental Settings

Datasets. We evaluate the proposed framework on few shot text classification datasets from the widely-used NLU benchmark GLUE (Wang et al., 2018) including SST-2 (Socher et al., 2013), CoLA (Warstadt et al., 2019) and other common datasets including MR (Pang and Lee, 2005), CR (Hu and Liu, 2004), Subj (Pang and Lee, 2004), MPQA (Wiebe et al., 2005), SST-5 (Socher et al., 2013). These datasets covers different tasks such as sentiment analysis, topic classification and opinion classification from various domains including movie reviews, news pieces, etc. The statistics of the datasets are shown in Table 4 in Appendix.

Baselines. We compare the proposed approach with various representative methods including **Majority**, **Fine-Tuning**, **GPT-3** (Brown et al., 2020), **EFL** (Wang et al., 2021), **LM-BFF** (Gao et al., 2021) and **Prompt Tuning**. More details are described in the Appendix A.3.

Evaluation setting. Evaluation is critical in few-shot scenarios because small changes of the training set can result in a large variance in the performance of the test set. Following the few-shot setting in (Perez et al., 2021), (Zhang et al., 2020b), (Gu et al., 2021) and (Gao et al., 2021), we randomly select K-shot samples from original dataset for each class to construct the training set $\mathcal{D}_{\text{train}}$ and select another K-shot samples to construct the development set $\mathcal{D}_{\text{val}}$. For enhancing the stability of evaluation, we utilize the whole test set of original dataset as out test set $\mathcal{D}_{\text{test}}$ and change the random seed of sampling $\mathcal{D}_{\text{train}}$ and $\mathcal{D}_{\text{val}}$ for five times. We select RoBERTa-large as our backbone model to make fair comparison with baseline LM-BFF.

5.2 Experimental Results

In this section, we present our main results, and address the aforementioned research questions pertaining to our PROMPTDA approach.

In addition to comparing with baselines such as Majority, normal fine tuning and prompt-based method GPT-3, EFL, LM-BFF, we conduct more experiments to verify the effectiveness of our proposed method PROMPTDA as a plug-in module. Because different template choices can result in a large variance of performance (Gao et al., 2021), we design two groups of experiments, namely template-free and template-augmented, to investigate whether or not our method can improve over standard prompt-based tuning method regardless of template design. For the template-augmented group of experiments, we manually choose "`It is [MASK]`" as the template, following (Wang et al., 2021). For the template-free group of experiments, we only append "`[MASK]`" in the input. We report the results of PROMPTDA in Table 1 when the size of data augmentation is ×3 (i.e., $k_y = 3$). We also consider two scenarios where the label words are derived manually or with our automatic label augmentation mechanism. We choose 8 samples ($K = 8$) per class as the few-shot setting of our main experiments. For fair comparison, we choose the same random seed of training set sampling as LM-BFF. We train for 10 epochs on each dataset following (Wang et al., 2021). We report the average performance and standard variance of our results over five runs of sampling on each dataset. The main results can be seen in Table 1.

Performance analysis We analyze the performance from three perspectives to answer the afore-

Method	**SST-2** (Acc)	**MR** (Acc)	**CR** (Acc)	**Subj** (Acc)	**CoLA** (Acc)	**MPQA** (Acc)	**SST-5** (Acc)
Majority (full)	50.9	50.0	50.0	50.0	69.1	50.0	23.1
Fine-Tuning (full)	95.0	90.8	89.4	97.0	86.2	89.4	58.7
Fine-Tuning	60.5 (3.1)	60.3 (7.5)	61.9 (5.1)	78.3 (8.2)	51.1 (8.4)	59.0 (3.4)	31.5 (7.5)
GPT-3 (Brown et al., 2020)	82.9 (3.4)	81.2 (2.5)	86.8 (1.5)	53.2 (1.5)	52.1 (6.2)	62.9 (3.5)	31.5 (4.3)
EFL (Wang et al., 2021)	67.5 (8.5)	69.8 (7.5)	75.3 (4.8)	78.9 (7.8)	54.3 (8.9)	68.4 (5.7)	35.2 (6.3)
LM-BFF (Gao et al., 2021)	89.1 (4.1)	83.6 (3.4)	87.8 (4.3)	81.6 (6.1)	53.5 (4.5)	73.9 (8.9)	41.2 (3.1)
Prompt Tuning‡	85.5 (5.2)	83.0 (3.7)	86.5 (3.0)	81.8 (5.6)	50.5 (10.3)	71.5 (9.8)	37.5 (5.5)
PT + PromptDA(m.)‡	87.3 (4.4)	82.5 (1.4)	88.1 (2.7)	81.3 (4.9)	51.2 (7.5)	72.9 (9.1)	39.4 (4.3)
PT + PromptDA(au.)‡	87.6 (4.1)	83.1 (3.1)	87.8 (1.2)	83.4 (2.5)	52.8 (8.1)	74.5 (7.8)	41.8 (3.9)
Prompt Tuning†	85.8 (5.8)	79.3 (8.2)	86.1 (8.0)	81.2 (5.7)	52.7 (6.6)	75.1 (13.7)	38.4 (4.7)
PT + PromptDA(m.)†	88.9 (3.9)	**83.8 (1.9)**	84.9 (5.7)	82.4 (9.9)	51.3 (15.5)	78.1 (8.9)	42.7 (7.1)
PT + PromptDA(au.)†	**89.5 (2.9)**	83.7 (2.6)	**88.3 (4.1)**	**86.8 (3.1)**	**55.9 (7.1)**	**78.4 (9.2)**	**43.3 (1.6)**

Table 1: The main results using RoBERTa-large on representative NLU tasks. All the results are evaluated on full test sets and averaged over 5 runs. $K = 8$: 8 samples per class for all the experiments; †: template augmented; ‡: template-free; (m.): manual label augmentation; (au.): automatic label augmentation; PT: Prompt Tuning.

mentioned research questions.

To answer **RQ1**, we compare the proposed method with existing baselines. First, in general, we can observe that the standard prompt-based tuning method with PromptDA consistently perform better than or is comparable with baselines such as GPT-3, EFL, LM-BFF and normal fine tuning (results of "PT + PromptDA(au.)†" in Table 1). Compared with LM-BFF, standard prompt-based tuning with PromptDA performs better on all the datasets. For example, our method achieves a 6% gain over LM-BFF on Subj and MPQA datasets. Compared with normal fine tuning, our method achieves superior performance by a large margin. For example, our method obtains a 47.9% improvement over normal fine tuning on SST-2 dataset.

Second, we can see that PromptDA can improve over standard prompt-based tuning method regardless of template design (results of "PT + PromptDA(au.)†" and "PT + PromptDA(au.)‡" in Table 1). Compared with standard prompt tuning, PromptDA can achieve a better performance over the seven datasets regardless of being template-free or template-augmented, which suggests that PromptDA has no relation with template design and can be used as a plug-in module for improving performance of prompt tuning.

Third, PromptDA generally improves over standard prompt-based tuning method regardless of automatic label word selection or manual label word selection (results of "PT + PromptDA(au.)†" and "PT + PromptDA(m.)†" in Table 1). Compared with standard prompt tuning, prompt tuning with automatic label word selection achieves improvements over all the datasets. For prompt tuning with manual label word selection, it also has performance gains over SST-2, MR, Subj, MPQA and SST-5 datasets.

To answer **RQ2**, we perform an ablation study of PromptDA, and compare the results of "PT + PromptDA(au.)†" and "PT + PromptDA(m.)†" in Table 1. We can see that regardless of template design, our proposed automatically searched label words generally perform better than manually searched label words. For example, "PT + PromptDA(au.)†" achieves a 5.3% improvement over "PT + PromptDA(m.)†" on Subj dataset.

We analyze the reason from three perspectives. First, we hypothesize that human bias may hinder selecting optimal label words and our proposed automatic method relies on language model itself and can minimize human bias. Second, it may be easier for human to select similar words as label words for sentiment-related datasets with the label name "`positive, negative`", but it is hard to select semantically similar words as label words for tasks in other domains. For example, it is hard to manually identify semantically similar words as label words for Subj dataset with the label name "`subjective, objective`", which illustrates the necessity of our proposed automatic method for searching label words. Third, our proposed Label Augmentation method can search for different label words on different training data, but it is hard for the manual label word selection method to adapt to different specific datasets.

To answer **RQ3**, we analyze the stability of performances of PromptDA. In general, we observe that PromptDA reduces the variance of prompt-tuning. (Standard variance of "PT +

SST-2	label name	`positive	negative`
	label words (m.)	`positive, great, good	negative terrible bad`
	label words (au.)	`wonderful brilliant fantastic	terrible done disappointing`
Subj	label name	`objective	subjective`
	label words (m.)	`good neutral fair	bad emotional personal`
	label words (au.)	`disturbing terrifying key	bad not nonsense`
SST-5	label name	`very positive	positive	neutral	negative	very negative`
	label words (m.)	`great perfect excellent	good, pretty, wonderful	neutral normal fine	bad worse not	terrible awful ridiculous`
	label words (au.)	`great brilliant fantastic	extraordinary remarkable fascinating	enough terrible funny	awful bad worse	boring done unnecessary`

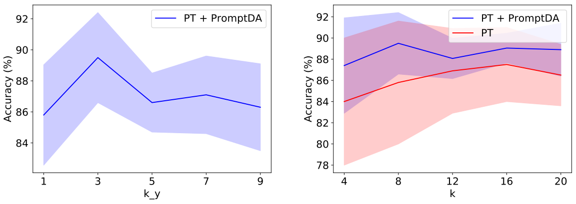
Table 2: An illustration of the label words searched automatically or manually on SST-2, Subj and SST-5 datasets.

PROMPTDA(au.)†” in Table 1). The uncertainty of prompt-based tuning methods mainly comes from different distribution of small training set, different designs of the template and various selections of label words for each class. Compared with LM-BFF and normal fine tuning methods, our method generally reduces the variance of prediction. For example, the standard variance of prediction over five runs for “PT + PROMPTDA(au.)†” has decreased around 48.4% on Subj compared to LM-BFF and has decreased 78.7% on SST-5 compared with normal fine tuning. Compared with standard prompt-based tuning method, PROMPTDA can improve the stability of tuning on most of the datasets.

5.3 Analysis of Label Word Selection

Without loss of generosity, we take the dataset SST-2, Subj and SST-5 for example to analyze the quality of Label Augmentation (the label word results are shown in Table 2 and the complete label word results over five runs on SST-2, CR, MR, Subj, CoLA, MPQA, SST-5 datasets are shown in Appendix Table 6). *The goal of label augmentation is to find semantically similar words to enrich the label space.* With regards to the manual way, we find the synonyms of label name from dictionary as the label words and ensure these words are in the vocabulary. And we select the same label words for different seeds. With regards to our proposed automatic method, we only rely on the training set and language model (e.g., RoBERTa-large) to find the semantically similar words from vocabulary and do not rely on label name itself.

The Table 2 shows the label words automatically or manually searched on datasets SST-2, Subj and SST-5 respectively. For sentiment related datasets such as SST-2 with the label name {`positive/negative`}, the label words automatically searched are literally similar to the manually selected label words, which probably means the way language models (e.g., RoBERTa-large) reasons about what are similar words is close to the human way in sentiment domain. Nonetheless, for other datasets such as Subj with the label name {`objective/subjective`}, it is interesting to observe that the label words automatically searched are not literally similar to label name or manually selected label words, which may infer that the way language models (e.g., RoBERTa-large) reason about what are similar words is different from the human way in other domains. We argue that *how to define word similarity in label semantic space* needs more research in the future. For dataset such as SST-5, we can see that it is much harder to select appropriate label words when the number of classes is larger, which also verifies the importance of automatic label word selection.



(a) # size of augmentation (b) # samples per class

Figure 3: The impact analysis of the size of label words and training samples per class on SST-2 dataset.

5.4 Assessment of Data Augmentation

We analyze data augmentation from two perspectives including the size of data augmentation and the size of training set.

The size of data augmentation We choose to study the effect of the size of PROMPTDA on template-augmented prompt-based tuning on SST-2 dataset. The results over five runs for 10 epochs are presented in Figure 2 (a). We can observe that PROMPTDA can generally improve over prompt-based tuning regardless of the size of augmentation. However, larger augmentation may result in more

Method	SST-2 (Acc)	MR (Acc)	CR (Acc)	Subj (Acc)	SST-5 (Acc)
PT	85.8 (5.8)	79.3 (8.2)	86.1 (8.0)	81.2 (5.7)	38.4 (4.7)
PT with Conventional DA	89.2 (1.3)	80.3 (3.1)	86.5 (4.5)	82.3 (8.0)	39.1 (4.5)
PT with PROMPTDA	89.5 (2.9)	83.7 (2.6)	88.3 (4.1)	86.8 (3.1)	43.3 (1.6)
PT with PROMPTDA & Conventional DA	**89.7 (1.6)**	**84.8 (1.5)**	**89.2 (1.3)**	**87.0 (3.1)**	**44.7 (1.1)**

Table 3: The main results of evaluating Prompt Tuning (PT) with PROMPTDA and conventional DA method on NLU tasks. All the results are evaluated on full dev sets and averaged across 5 different training sets. $K = 8$: 8 samples per class for the experiments. Conventional DA refers to *synonym substitution*.

unstable final prediction. We analyze the reason from two perspectives. First, larger data augmentation may contain more label noise. Since we utilize an one-to-multiple verbalizer to guide data augmentation, the size of data augmentation is equal to the number of label words per class, which may cause more noisy label words. Unsuitable label word selections may worsen the performance and increase the variance of final prediction. Second, more label words per class may cause the model harder to converge on small training sets. When training for the same epochs, prompt tuning with more label words per class may perform more unstable.

The size of the training set We study the effect of the size of training set on template-augmented prompt-based tuning with and without PROMPTDA. The size of data augmentation is ×3. The results over five runs for 10 epochs are presented in Figure 2 (b). We have several observations from the results. First, our method PROMPTDA consistently improves over standard prompt-based tuning regardless of the size of training sets. Second, our proposed method generally decreases the variance of prompt-based tuning. Third, the improvement space of PROMPTDA over prompt-based tuning decreases as the number of samples per class increases.

5.5 Combination with Conventional DA

Although conventional data augmentation methods are still effective when training data is limited (Chen et al., 2021), previous works verified that they can bring marginal improvement for the prompt tuning paradigm (Zhou et al., 2021). It is worth exploring whether or not PROMPTDA can complement with conventional DA for further enhancing the performance of prompt tuning.

We follow the same setting as the main experiments and test conventional DA, PROMPTDA and the combination on standard prompt-based tuning paradigm with template. With regards to conventional DA, we select *synonym substitution* method from nlpaug toolkit (Ma, 2019) and enlarge the training set by ×2. With regards to our proposed PROMPTDA, we enlarge the training set by ×3. The experiment results over five different sampling seeds for 10 epochs are shown in Table 3.

We can observe that the combination of PROMPTDA and Conventional DA method consistently outperforms only using PROMPTDA or Conventional DA method. Conventional DA methods mostly focus on exploiting the semantic information of the instance itself. Our method proposes to utilize label semantic information to guide data augmentation and does not change instances. PROMPTDA conducts the augmentation from a different perspective compared with conventional augmentation methods. Therefore, our proposed method PROMPTDA can be regarded *orthogonal* to conventional DA methods to some extent and complement with each other.

6 Conclusion and Future Work

In this paper, we study a new problem of data augmentation in prompt-based tuning for few shot learners. To leverage the label semantic information, we propose a novel label-guided data augmentation approach PROMPTDA, which can derive multiple label words and exploit the rich semantic information of the label words. We conduct extensive experiments on various datasets and demonstrate the effectiveness of PROMPTDA for few-shot learning. We also conduct detailed analysis on the effects of manual/automatic label augmentation, the size of augmentation, the size of label words, and combination with conventional DA.

There are several interesting directions for future work. First, we will extend PROMPTDA to multi-label few shot tasks and leverage multi-aspect label space. Second, we will explore prompt-based data augmentation for token-level tasks such as few-shot name entity recognition (NER). Third, we will explore prompt-based tuning to enhance the interpretability capacity for various NLP tasks.

Limitations

Our work is the first step for designing data augmentation strategies for prompt tuning paradigm. In this work, we focus on the natural language understanding (NLU) tasks. The prompt tuning paradigm is applied in various tasks including language generation, question answering, dialog system, etc. Designing augmentation strategies for prompt-based few-shot learners in more applications is under exploration.

Ethics Statement

This paper focuses on the task of few-shot natural language understanding and conducts experiments on open datasets. The implementation details are described in Appendix for reproduction.

A Appendix

A.1 Implementation Details

We implemented our model and all baselines with PyTorch and run each experiment on a single NVIDIA GeForce RTX 3090 GPU. The hyperparameters are the same for all methods based on RoBERTa-large (the learning rate is 3e-6, the batch size is 4, the number of training epochs is 10). Following (Gao et al., 2021), we select the random seeds for sampling the training set and validation set as $\{13, 21, 42, 87, 100\}$.

A.2 Dataset Details

In general, we follow the experiment setting of (Gao et al., 2021). For datasets from GLUE (Wang et al., 2018) including SST-2 (Socher et al., 2013) and CoLA (Warstadt et al., 2019), we use the original development sets for testing. For datasets requiring cross-validation evaluation like MR (Pang and Lee, 2005), CR (Hu and Liu, 2004), MPQA (Wiebe et al., 2005) and Subj (Pang and Lee, 2004), we randomly sample 2,000 instances as the testing set and remove them from the training set. For the dataset SST-5 (Socher et al., 2013), we use the official test sets. The dataset statistics are shown in Table 4.

A.3 Baseline Details

The details of the baselines are as follows:

- **Majority**: The label is predicted by taking the majority class in the training set. We run this baseline on the full-data setting.
- **Fine-Tuning**: The prediction is based on the pre-trained language model that is fine-tuned with the specific training data. We run this baseline in the full-data and few-shot setting.
- **GPT-3** (Brown et al., 2020): GPT-3 in-context tuning in the zero-shot setting. We pack the training samples into the input together and directly conduct inference.
- **EFL** (Wang et al., 2021): An entailment-based prompt tuning framework. For fair comparison, we do not pretrain the language model on MNLI task but directly tune the language model as the prompt tuning paradigm.
- **LM-BFF** (Gao et al., 2021): A prompt tuning model that automatically searches for demonstrations, templates and label words. Note that LM-BFF utilizes one-to-one verbalizer for label word selection.
- **Prompt Tuning**: The standard Prompt-based Tuning augmented by a simple template or template-free.

A.4 Comparison of RoBERTa vs BERT

We conduct experiments to investigate the impact of the backbone model. Table 5 shows the results of using BERT-large(uncased) and RoBERTa-large. The experiment setting is the same as the main experiments. We can observe that our proposed PROMPTDA improves the performance of prompt tuning regardless of the backbone model.

A.5 The Verbalizer and Template Design

For each random seed of $\{13, 21, 42, 87, 100\}$, we can construct different training sets and validation sets. Thus, the verbalizers searched automatically for each run are different, which are shown as "label words (au.)" in Table 6. The verbalizers manually designed for each run are the same, which are shown as "label words (m.)" in Table 6. We follow previous works (Gao et al., 2021; Wang et al., 2021) and design a simple template "`It is [MASK]`" for each input.

Dataset	# Classes	# Length	# Train	# Test	Type	Labels
SST-2	2	19	6,920	872	sentiment	positive, negative
MR	2	20	8,662	2,000	sentiment	positive, negative
CR	2	19	1,775	2,000	sentiment	positive, negative
Subj	2	23	8,000	2,000	subjectivity	subjective, objective
CoLA	2	8	8,551	1,042	acceptability	grammatical, not_grammatical
MPQA	2	3	8,606	2,000	opinion polarity	positive, negative
SST-5	5	18	8,544	2,210	sentiment	v. pos., positive, neutral, negative, v. neg.

Table 4: Statistics of the datasets.

BERT-large	**SST-2**	**Subj**	**SST-5**
PT	82.3 (4.6)	80.3 (6.2)	34.5 (3.8)
PT + PROMPTDA	87.1 (3.1)	82.9 (3.3)	37.5 (2.8)
RoBERTa-large	**SST-2**	**Subj**	**SST-5**

Incorporating Question Answering-Based Signals into Abstractive Summarization via Salient Span Selection

Abstract

In this work, we propose a method for incorporating question-answering (QA) signals into a summarization model. Our method identifies salient noun phrases (NPs) in the input document by automatically generating wh-questions that are answered by the NPs and automatically determining whether those questions are answered in the gold summaries. This QA-based signal is incorporated into a two-stage summarization model which first marks salient NPs in the input document using a classification model, then conditionally generates a summary. Our experiments demonstrate that the models trained using QA-based supervision generate higher-quality summaries than baseline methods of identifying salient spans on benchmark summarization datasets. Further, we show that the content of the generated summaries can be controlled based on which NPs are marked in the input document. Finally, we propose a method of augmenting the training data so the gold summaries are more consistent with the marked input spans used during training and show how this results in models which learn to better exclude unmarked document content.[1]

1 Introduction

Abstractive sequence-to-sequence summarization models have become very effective methods of easily generating summaries of input documents (Rush et al., 2015; Nallapati et al., 2016; Lewis et al., 2020).

Previous work has demonstrated that conditioning the summary generation on salient document sentences results in higher-quality summaries and more controllable summarization models (Chen and Bansal, 2018; Dou et al., 2021). Salient sentences are typically identified during training by lexical overlap with the gold summaries (Nallapati et al., 2017) and predicted during inference.

Input Document

Incumbent Goodluck Jonathan phoned former military leader Muhammadu Buhari on Tuesday to concede defeat in Nigeria's presidential elections, Buhari's party says. Jonathan acknowledged the phone call and his defeat in a written statement to his countrymen. "I thank all Nigerians once again for the great opportunity… I promised the country free and fair elections. I have kept my word…" Buhari ruled Nigeria from late 1983 until August 1985… **The 72-year-old retired major general's experience…**

Gold Summary

Incumbent President Goodluck Jonathan acknowledges defeat, says he delivered on promise of fair elections. Muhammadu Buhari 's party says Jonathan called to concede even before final results are announced. Buhari is a 72-year-old retired major general who ruled in Nigeria in the 1980s.

Figure 1: Salient spans identified by QA-based signals (shown in color) more precisely identify salient document content than those that identify salient sentences based on lexical overlap (shown in bold). Our method classifies the salient spans, marks them in the input document, and then generates a summary.

Although marking different sentences as salient allows for some controllability over the content of the summary, desired summary content cannot be specified at the sub-sentence level. Further, labeling sentences as salient via n-gram overlap does not directly take the predicate-argument structure of the text into account, which could result in a lower-quality supervision signal that misidentifies which particular instance of an n-gram is salient.

In this work, we propose to condition the summary generation on salient sub-sentence level spans which are identified by reasoning about the predicate-argument relations in the text.

We mark noun phrases (NPs) in the input document as salient if the predicate-argument relation

---

they participate in is present in the gold summary (§2). This idea is implemented using automatic question generation (QG) and answering (QA). For each NP, a wh-question that is answered by the NP is generated from the text. Then, the NP is marked as salient if the generated wh-question is correctly answered in the gold summary according to a learned QA model, resulting in a more precise, sub-sentence level supervision signal (see Fig. 1).

The QA-based salience signal is incorporated into a two-stage summarization model (§3). First, a phrase salience classifier is trained to identify which NPs in the document are salient. Then, the predicted salient spans are marked in the input document with special tokens and used to conditionally generate a summary of the document with a fine-tuned BART model (Lewis et al., 2020).

While we show that marking NPs as salient controls the summary content, the model often outputs extra, undesired information. To that extent, we propose a data augmentation procedure that removes sentences unsupported by any salient span and generates new training examples based on what content should be able to be generated by subsets of the salient spans (§4).

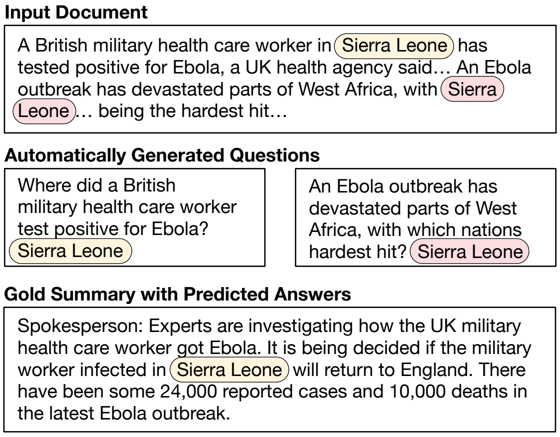
Our experiments on three different summarization datasets show that the two-stage model trained with QA-based salient span supervision generates higher-quality summaries than lexical baseline methods of identifying salient spans on more extractive datasets according to several automatic evaluation metrics (§6.1). Further, our data augmentation procedure results in summaries that are significantly shorter with only a small reduction in the percent of target content covered, demonstrating it successfully eliminates undesired summary content (§6.2).

The contributions of our work include: (1) a novel method of including QA-based signals into summarization generation; (2) a two-stage model for incorporating phrase-level supervision into a summarization system; and (3) a data-augmentation procedure which results in more controllable summarization models.

2 Question-Based Salience

We begin by describing how QA is used to identify salient spans of text in the input document and discuss the advantages of this approach.

We define a document NP as salient if its corresponding predicate-argument relation also appears in the gold summary. To identify such NPs automatically, we employ question-generation and question-answering models as follows.



A British military health care worker in Sierra Leone has tested positive for Ebola, a UK health agency said… An Ebola outbreak has devastated parts of West Africa, with Sierra Leone… being the hardest hit…

Where did a British military health care worker test positive for Ebola? Sierra Leone

An Ebola outbreak has devastated parts of West Africa, with which nations hardest hit? Sierra Leone

Spokesperson: Experts are investigating how the UK military health care worker got Ebola. It is being decided if the military worker infected in Sierra Leone will return to England. There have been some 24,000 reported cases and 10,000 deaths in the latest Ebola outbreak.

Figure 2: We define a document noun phrase as salient if the wh-question it answers is also answered in the gold summary. Here, the first (yellow) instance of "Sierra Leone" is salient and the second (red) is not because the gold summary answers the automatically generated question for the first instance but not the second.

For each NP in the source document, we use the sentence it appears in to automatically generate a wh-question for which the NP is the answer. This QA pair represents the predicate-argument relation that the NP participates in. Then, we assume if a second text can be used to correctly answer that question, it contains the same predicate-argument relation. Thus, we use a QA model to automatically answer the question against the gold summary and mark the NP as salient if the QA model predicts the question is answerable and the predicted answer is correct. In practice, we assume a predicted answer is correct if it shares at least one token in common with the NP which was used to generate the question.

An example of this procedure is illustrated in Fig. 2 for two occurrences of the NP "Sierra Leone." Questions for each phrase are automatically generated from the input document and answered against the gold summary. Since the QA model correctly answered the first question but predicted the second question is not answerable, only the first occurrence of "Sierra Leone" is marked as salient.

We refer to the NPs identified by this procedure as "silver spans."[2] Specific implementation details

---

[2] The term "silver" refers to the fact that the salient spans are not perfect because they were identified by sequence of learned models rather than humans ("gold" spans; §6.1).

of the generation and answering models can be found in §5.

2.1 Advantages of a QA-Based Approach

Using QA to identify salient spans of text has several advantages. First, because our QA approach operates at the phrase-level, it is able to be more precise about what specifically is salient in the document in contrast to sentence-level approaches. For example, in the second sentence of Fig. 1, the QA-based salience signal identifies “Jonathan” and “his defeat” as salient but not “written statement.” A sentence-level approach would mark the entire sentence as salient and thus cannot make that distinction.

Second, because the QA-based approach reasons about the predicate-argument structure of the text, it is able to distinguish between which specific instances of the same NP are salient and which are not. This is illustrated in Fig. 2 in which the first occurrence of “Sierra Leone” is marked as salient but the second is not because the gold summary does say the health care worker was infected in Sierra Leone, but it does not say it is one of the hardest hit countries. A salience signal that uses a bag-of-n-grams approach (e.g., ROUGE-based methods) cannot easily decide which instance “Sierra Leone” is salient.

3 A Two-Stage, Span-Based Model

Next, we propose a two-stage, span-based model that can incorporate the QA-based salience signals into the learning procedure. The first of the two stages, the span selection component, classifies salient spans within the text. The second stage, the generation component, generates the summary given the document and the salient spans. The details of each component are detailed next.

3.1 Salient Span Classifier

Given an input document $d = [x_1, \ldots, x_n]$ and a set of spans S, in which each span $s_{i,j}$ represents a sequence of tokens $x_i, \ldots, x_j$ in d, the span classifier outputs a score for each span based on how salient it is in the document. Our definition of salience is discussed in §2.

Concretely, the input tokens are first encoded using BART. Then, the representation of a span is created by concatenating the BART encodings of the first and last tokens in the span. Finally, a linear classifier is trained using this encoding to predict the salience of each span.

A set of silver spans $S^* \subseteq S$ is used to train the model using a binary cross-entropy loss. When using the QA-based approach, S is the set of NPs in the document and S^* is the subset that our QG-QA algorithm identified as salient. We reweight the loss term of each span such that positive and negative spans contribute equally. During inference, a score is predicted for each span in S and the top-k sorted by highest score are passed to the generation component. We choose the k spans independently, although they could also be selected jointly.

3.2 Generation Component

Given an input document and set of salient spans, the generation component produces a summary of the document. The salient spans are represented by inserting special tokens directly into the document’s sequence of tokens before and after the spans. For example, if span $s_{4,5}$ was marked as salient, the document’s tokens would be represented as

```
... x3 [SS] x4 x5 [SE] x6 ...
```

where `[SS]` and `[SE]` mark the start and end of the span.

Since the salient spans are represented in the document tokens, we are able to directly train a sequence-to-sequence model to generate the gold summary from the modified document representation without any changes to the model’s architecture.

During training, we use silver spans and the ground-truth summary to fine-tune BART using a standard cross-entropy loss function. The ground-truth summary does not have any marking of salient spans. For inference, the predicted salient spans from the span classifier are used instead of the silver spans.

4 Improving Controllability via Data Augmentation

Although there is nothing to directly force the generation model to learn to include content based on the supervision provided by the salient spans, if the supervision is of high enough quality, we expect the model will learn to do so. Indeed, we later show in §6.2 that this is true, thus the content of the summary can be controlled by which spans are marked as salient. However, it is also desirable for a controllable summarization model to also not include

Figure 3: An example of our data augmentation procedure. The colors represent the mapping between document and summary spans. The document spans are given to the generation model during training. In this example, no span maps to the third summary sentence, so it is removed entirely. Then, new training instances are generated using the first summary sentence and first two summary sentences with their corresponding salient document spans.

content which is not marked as salient. The generation models may learn to include extra information for at least two reasons.

First, the gold summaries may include content which cannot be generated based on only the silver salient spans that were used to train the generation model, so it may learn to output extra, unmarked information. This could happen if the QG/QA models are imperfect (resulting in a noisy supervision signal) or if the gold summary contains information that cannot be mapped to the document. Second, if the model is trained to generate summaries of a certain length and the length of the summary necessary to include all of the information marked by the spans is smaller than those used for training — for example, because the number of marked spans is small — the model could generate additional information simply to increase the summary length.

An artifact of our silver span annotation procedure enables us to address these controllability issues. If a document span is marked as salient, that means it has a corresponding phrase in the gold summary which expresses the same content. Therefore, the QG-QA procedure creates a mapping between which parts of the gold summary should be able to be generated by marking different parts of the input document.

We propose to leverage this mapping to augment the training data in two ways. First, we remove any gold summary sentence which has no phrase mapped to the document. These sentences would encourage the model to generate additional content based on unmarked spans.

Second, we generate new pairs of salient spans and gold summaries for training by selecting the first k remaining gold summary sentences and the subset of salient document spans which map to them. For instance, if $k = 2$, only the salient spans which are mapped to the first two summary sentences are marked in the input document, and the model is trained to generate only those sentences. We generate new examples for each original training instance using all possible values of k. By training on these new pairs, the model should learn to better control the length of the output summary based on the number of marked salient spans. An example of these augmentations is included in Fig. 3.

Although this procedure is described within the context of the QA-based supervision, it can be implemented with any such mapping between the document and gold summaries.

5 Experimental Setup

Datasets Our experiments use three popular English single-document summarization datasets: CNN/DailyMail (Nallapati et al., 2016), XSum (Narayan et al., 2018), and NYTimes (Sandhaus, 2008). Specific details on the sizes of the datasets can be found in Appendix A.

Baselines & Other Work We compare the salient spans selected by our QA-based method against three baseline span selection methods. The first marks salient sentences by greedily selecting k sentences that maximize the ROUGE-2 score calculated against the gold summary, a popular method that is frequently used to train extractive summarization models (Nallapati et al., 2017) as well as other two-step abstractive systems (Chen and Bansal, 2018; Dou et al., 2021). The other two mark entities and NPs as salient if they appear in the gold summaries as determined by lexical matching. We only mark the first occurrence of the phrases as salient since we found that worked better than marking all occurrences.

Additionally, we compare our results to BART (the original implementation and our own; Lewis et al., 2020) since our models are built on top of it. We also compare to GSum (Dou et al., 2021), which uses salient sentence guidance that is similar to our baseline salient sentence method. GSum encodes the additional guidance signal separately from the input document and uses the document and guidance encodings to generate the summary.

Summarization Evaluation Metrics The models are automatically evaluated using three metrics which calculate a similarity score between the generated and gold summaries. ROUGE (Lin, 2004) compares the two summaries based on their lexical overlap. BERTScore (Zhang et al., 2020) calculates a similarity score between the summaries based on their tokens' BERT embeddings (Devlin et al., 2019). QAEval (Deutsch et al., 2021) is a QA-based evaluation metric which generates questions from the gold summaries and answers them against the generated summaries. Its similarity score is equal to the average token F_1 score calculated between the predicted and expected answers.

We additionally perform a human evaluation of summary quality on Mechanical Turk. We ask 3 Turkers to rate the quality of 50 summaries per model from the CNN/DailyMail dataset on a scale from 1 to 5 based on the importance of the information, faithfulness, fluency, and coherence. Details on the manual evaluation can be found in Appendix G.

Controllability Evaluation Metrics The controllability of our model is evaluated using the *question recall*. Given k marked spans, we define the question recall to be equal to the percent of the corresponding k wh-questions that are answered by the summary according to the QA model. This approximates the recall on the desired predicate-argument structures in the summary. We additionally report the ratio between k and the length of the generated summary in tokens to measure the precision of the generated information. A larger value means the summary is more concise.

Implementation Details The QG/QA models are the same as used by QAEval. The generation model is initialized with BART-Large and fine-tuned on data collected by Demszky et al. (2018). The answering model is initialized with ELECTRA-Large (Clark et al., 2020) and fine-tuned on SQuAD 2.0 (Rajpurkar et al., 2018).

The span classification and generation models are both initialized with BART-Large and fine-tuned on the respective datasets. They were trained for three and five epochs, respectively, and the model with the best precision@1 and ROUGE-2 F_1, respectively, on the validation set were selected as the final models. See Appendix B for more specific implementation details.

6 Results

6.1 Summarization Evaluation

Automatic Evaluation Table 1 contains the models' performances as evaluated by automatic metrics, both using the spans predicted by the classifier ("end-to-end") and the silver spans (i.e., assuming a "perfect" classifier).

Interestingly, we find a somewhat surprising result. On CNN/DailyMail and NYTimes, the end-to-end QA-based model performs the best among the different span labeling methods and the baseline BART. On NYTimes, it is also better than GSum. However, if the silver span labels are used, the lexical NP-based model out-performs the rest by a somewhat large margin. It is surprising that a seemingly better generation model would result in worse end-to-end performance.

To better understand this result, we manually labeled all of the NPs in 50 CNN/DailyMail documents as salient or not salient based on whether the corresponding predicate-argument relation was present in the reference summary (see Appendix E for details). These spans, which we call the gold spans, can be used to evaluate the precision and recall of the silver spans as well as the output from the salient span classifiers.

Table 2 shows that the QA-based labels are more precise but have lower recall than the lexical NP labels. Because the lexical NP method aggressively marks the first occurrence of any NP in the document which is present in the reference as salient, it is unsurprising that its recall would be high. Since it cannot distinguish between instances of the same NP due to its bag-of-words representation, its precision is low. In contrast, the QA-based approach can reason about which occurrence of an NP is salient (resulting in higher precision), but the recall is lower likely due to noise in the QG/QA models. This same pattern appears in Table 2 with the outputs from the salient span classifiers, although the precisions and recalls are notably lower than the silver span labels'.

We believe that the discrepancy between the end-to-end and silver span-based models' performances can be explained by these results. The lexical NP generation model was trained with a high recall silver supervision at 66.3, allowing the generation

Table 3: The ablated lexical NP supervision shows as the noise increases, the silver span performance decreases but end-to-end performance improves.

model to achieve good performance when the silver spans are provided. Yet during inference the model is provided with spans that only have around 54.4 recall, 12 points lower. We suspect the generation model learned to rely heavily on the marked salient spans — and empirically we observed that it copied very heavily from them — thus when the quality of the span signal was reduced, the resulting summaries similarly got worse. In contrast, the difference between the QA-based model's recall during training and inference is only estimated to be around 2.4, so this issue is less severe, resulting in better end-to-end summaries.

To test this hypothesis, we artificially ablated the lexical NP-based generation model's silver span supervision's recall by removing $k\%$ of the salient spans uniformly at random — thus making the training spans look more similar to the spans during inference — and retrained the model. We would expect the silver span-based model's performance to decrease while the end-to-end model's increases. Indeed, in Table 3 we find that this does happen. These results suggest that the relationship between the classifier's performance and generation model's supervision is important for good end-to-end results and could be explored in future work.

Although the end-to-end lexical NP results begin

	BART	Sentences	QA

to approach the QA-based model's performance, they do not quite reach it. Further, the QA-based silver spans maintain an F_1 advantage over the lexical NP method (Table 2). While the QA-based approach can be improved with better question generation and answering models, the lexical NP labeling method is inherently limited. Therefore, the QA-based method does appear to be the best method of incorporating additional supervision into the summarization models based on the automatic metrics.

Human Evaluation Table 4 contains the results of evaluating BART and the sentence- and QA-based models on CNN/DailyMail (the best performing) using human summary quality annotations from Mechanical Turk. On average, our span-based methods have higher quality summaries than the baseline method of BART. After collecting annotations for 50 summaries on CNN/DailyMail, we were unable to obtain statistical significance between the two span-based models, however, doing so may be prohibitively difficult (Wei and Jia, 2021).

6.2 Controllability Evaluation

Automatic Evaluation The controllability of the QA-based generation model is evaluated in Fig. 4 using the original training data as well as the augmented data described in §4. We plot the question recall and the ratio between k and the length of the generated summaries for the top k most salient spans output by the QA-based salient span classifier for various values of k on CNN/DailyMail. The data augmentation procedure is split into only removing sentences that do not answer a question ("+Rm Sents") plus also generating new training examples ("+New Examples"). We also include the results for BART (for which the summary is constant for all k) for relative comparisons.

Although BART's question recall is initially higher than the QA models' recalls, as k increases it falls lower. We suspect this is because BART has learned to include the same content that the span classifier also identifies as salient when k is small and the length of its summaries allows it to cover more content. However, when k increases, the span classifier potentially predicts different spans as salient than what BART learned, resulting in divergent content and a lower recall for BART. The higher recall of the QA models demonstrates that their summary content is indeed being controlled via the input spans. Further, the QA models have far better k-to-length ratios, meaning their summaries are shorter than BART's even when their recalls are higher, suggesting they generate far less content which is unrelated to the marked spans.

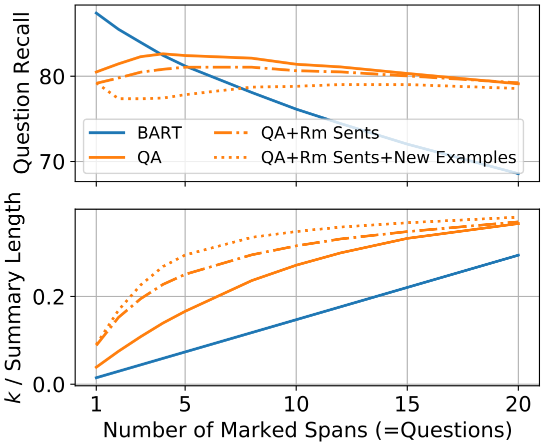

Figure 4: The percent of questions which correspond to the marked spans answered by the generated summaries (top) and the summary lengths in tokens (bottom). The QA methods have higher question recall than BART and are far more concise, demonstrating that marking input spans controls the summary content.

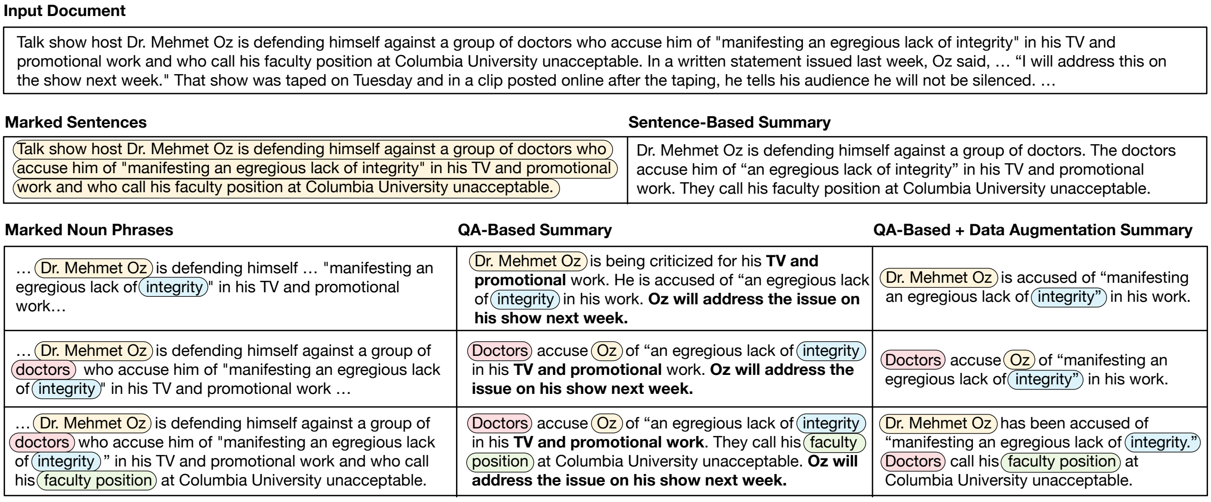
Among the QA-based models, we do observe a small drop in recall when the model is trained with data augmentation. However, the data-augmented summaries express that information far more concisely (because the ratio between k and the summary length is higher). For example, when 10 input spans are marked, there is a relative 0.9% and 3.2% drop in recall for removing sentences and the full data augmentation procedure, respectively, but the summary lengths are 14% and 22% shorter. Therefore, the data augmentation procedures do result in models which have learned to not generate extra content.

Controllability Example Example summaries from the QA models and sentence-based model with different marked input spans are shown in Fig. 5. Because the sentence-based model is limited to marking full sentences, the content which is taken from the marked sentence cannot be further



Input Document

Talk show host Dr. Mehmet Oz is defending himself against a group of doctors who accuse him of "manifesting an egregious lack of integrity" in his TV and promotional work and who call his faculty position at Columbia University unacceptable. In a written statement issued last week, Oz said, … "I will address this on the show next week." That show was taped on Tuesday and in a clip posted online after the taping, he tells his audience he will not be silenced. …

Marked Sentences	Sentence-Based Summary
Talk show host Dr. Mehmet Oz is defending himself against a group of doctors who accuse him of "manifesting an egregious lack of integrity" in his TV and promotional work and who call his faculty position at Columbia University unacceptable.	Dr. Mehmet Oz is defending himself against a group of doctors. The doctors accuse him of "an egregious lack of integrity" in his TV and promotional work. They call his faculty position at Columbia University unacceptable.

Marked Noun Phrases	QA-Based Summary	QA-Based + Data Augmentation Summary
… Dr. Mehmet Oz is defending himself … "manifesting an egregious lack of integrity" in his TV and promotional work…	Dr. Mehmet Oz is being criticized for his **TV and promotional** work. He is accused of "an egregious lack of integrity in his work. **Oz will address the issue on his show next week.**	Dr. Mehmet Oz is accused of "manifesting an egregious lack of integrity" in his work.
… Dr. Mehmet Oz is defending himself against a group of doctors who accuse him of "manifesting an egregious lack of integrity" in his TV and promotional work …	Doctors accuse Oz of "an egregious lack of integrity in his **TV and promotional** work. **Oz will address the issue on his show next week.**	Doctors accuse Oz of "manifesting an egregious lack of integrity" in his work.
… Dr. Mehmet Oz is defending himself against a group of doctors who accuse him of "manifesting an egregious lack of integrity" in his TV and promotional work and who call his faculty position at Columbia University unacceptable.	Doctors accuse Oz of "an egregious lack of integrity in his **TV and promotional work**. They call his faculty position at Columbia University unacceptable. **Oz will address the issue on his show next week.**	Dr. Mehmet Oz has been accused of "manifesting an egregious lack of integrity." Doctors call his faculty position at Columbia University unacceptable.

Figure 5: Example summaries generated by the sentence-based model (middle), QA-based model (bottom center) and QA-based model trained on the augmented data (bottom right). The QA-based models allow for much more control over the summary content than the sentence model by marking different combinations of phrases. The augmented-data summaries better eliminate unmarked content from the input than the standard model (extra information generated by the standard model shown in bold).

controlled. In contrast, the figure shows how the QA models' summaries can be altered by marking different NPs within the sentence, thus demonstrating the benefits of phrase-level controllability.

The example in Fig. 5 also shows how the data augmentation procedure improves controllability. The phrases which the standard model includes but the augmented model does not are marked in bold. The augmented model does a better job at excluding content which was not marked in the input document.

7 Related Work

QA-Based Signals QA-based signals have been used for evaluating summaries (Eyal et al., 2019; Durmus et al., 2020; Wang et al., 2020; Deutsch et al., 2021), including Scialom et al. (2021), who explore a similar notion of document salience. They have also been used to align content across documents (Weiss et al., 2021) as well as train summarization models (Arumae and Liu, 2018, 2019; Scialom et al., 2019). The models which incorporate QA-based signals typically do so using reinforcement learning. In contrast, our approach is simpler. We incorporate the QA-based signal by marking spans in the document, and our models are trained using easier-to-optimize cross-entropy objective functions.

Incorporating Additional Supervision Recent work by Dou et al. (2021) proposes a framework for incorporating additional guidance into summarization models, called GSum. They separately encode the input document and the supervision signal, whereas we directly mark spans in the text. This allows for our generation component to have a simpler architecture than theirs. While they are able to encode any natural language string, our model provides more direct supervision by identifying which specific tokens are salient.

Other work has included predicate-argument structure into summarization to generate more faithful summaries (Cao et al., 2018; Jin et al., 2020; Zhu et al., 2021). They represent the predicate-arguments either using dependency trees or OpenIE tuples, whereas we represent them via QA pairs. These works include that information to try and generate faithful summaries, whereas our goal is to identify salient document content.

Controllable Summarization Work on controllable summarization has focused on aspects such as the length of the summary (Fan et al., 2018) and the content in an interactive setting (Shapira et al., 2017) or via prompting (He et al., 2020). Incorporating our QA-based signal via prompting may be difficult given the number of questions which would need to be concatenated onto the input.

Other approaches control content via planning as in entity templates (Narayan et al., 2021), marking records in a data-to-text approach (Puduppully et al., 2019), or using aspect controllers (Amplayo et al., 2021). The marked salient spans in our work could be viewed as a content plan as well.

Data Augmentation Previous work has proposed methods for removing sentences or full summaries from the training data in order to discourage the summarization model from learning to generate unfaithful information (Matsumaru et al., 2020; Nan et al., 2021; Narayan et al., 2021). In addition to removing sentences, we generate new training instances in order to learn to exclude content which is not marked as salient in the input, resulting in more controllable models.

8 Conclusion

In this work, we proposed a method for incorporating QA-based signals into a summarization model by automatically marking document NPs as salient based on whether a NP's corresponding wh-question is answered correctly in the summary. We showed that incorporating this signal into our two-stage summarization model results in higher quality summaries than baseline methods of identifying salient spans. Finally, we demonstrated that our data augmentation algorithm, which attempts to ensure the span supervision is consistent with the gold summaries, improves controllability by eliminating unmarked content from the output summaries.

Limitations

The summarization model proposed in this work relies on the existence of question generation and question answering models, which are used to preprocess the data for training. It is likely that such models only exist or are of high-enough quality for high resource languages, such as English, which limits the languages that our model can be trained on in practice. However, we do not see a reason why our model could not be applied to another language as long as those additional resources are available.

Further, because the question generation model produces simple wh-questions and the question answering model is only able to reason about the predicate-argument structure of the text (due to it being trained on SQuAD 2.0), our procedure for identifying salient document phrases requires that the same information across the document and reference summary must be expressed in relatively similar ways (e.g., up to rephrasing and synonyms). If the reference summary does contain the answer to the generated question but identifying that answer requires a level of reasoning beyond reasoning about the predicate-argument structure (e.g., does it require multi-hop reasoning?), the specific models proposed in this work may fail to identify those salient phrases. This limits the types of datasets for which we expect our proposal to do well on (discussed more in Appendix D). However, if matching document and reference summary information requires a level of reasoning that is supported by the generation and answering models, then we suspect our proposal will work, in theory, but we have not experimented with this in practice.

Our methods out-perform the baseline systems the most when evaluated by QAEval, and we leverage the same QG/QA technology as this metric. While this commonality may bias our system toward summaries that are favored by QAEval, we argue this is not necessarily a bad thing. Previous work has incorporated ROUGE-based signals into their models, either indirectly by selecting extractive labels based on ROUGE or directly by optimizing ROUGE via reinforcement learning. Our approach is analogous to these modeling approaches, and QAEval has been demonstrated to be a better evaluation metric than ROUGE, so it is likely a better metric to optimize for.

A Dataset Statistics

The sizes of the CNN/DailyMail, XSum, and NYTimes datasets are included in Table 5. The Table

Dataset	#Train	#Valid	#Test	Span Type	#Spans
CNN/DM	287,113	13,368	11,490	Sentences	3
				Entities	10
				Lex. NPs	25
				QA	20
XSum	204,045	11,332	11,334	Sentences	1
				Entities	1
				NPs	5
				QA	1
NYTimes	44,382	5,523	6,495	Sentences	4
				Entities	15
				Lex. NPs	45
				QA	27

Table 5: The number of instances in the training, validation, and test splits of the three datasets used in our experiments as well as the number of spans selected by the classification component that were passed as input to the generation component.

also includes the number of spans per span type that were selected from the classification component and passed to the generation component during inference. The values were selected based on a parameter sweep on the validation set. The number of spans with the highest ROUGE-2 F_1 score was selected.

B Implementation Details

All of the models were trained with the same hyperparameters for across datasets and span types which were based on those used by BART (Lewis et al., 2020).

The classification component was a BART-Large model that was fine-tuned with a binary cross-entropy classification loss. We selected the model based on which had the best precision@1 on the validation dataset. The generation models were also fine-tuned BART-Large models, but they instead use a cross-entropy loss function.

Both the components were trained using Adam (Loshchilov and Hutter, 2019) with weight decay and learning rate 3e-5. The classification component was trained for 3 epochs, and the final model was selected based on the precision@1 on the validation set. The generation component was trained for 5 epochs, and the final model was selected based on the ROUGE-2 F_1 score on the validation set.

C Salient Span Classifier Evaluation

Fig. 6 contains the precision@k and recall@k of the span based classifiers calculated against the corresponding silver spans. These plots should be interpreted as how well the span classifiers were able to learn from their respective supervision, not necessarily the true quality of the output span labels (which would require evaluating against human-annotated gold labels, as in Table 2). The "x" symbols denote the operating points used in the end-to-end model, which were chosen based on the number of spans that resulted in the highest ROUGE-2 F_1 score on the validation data.

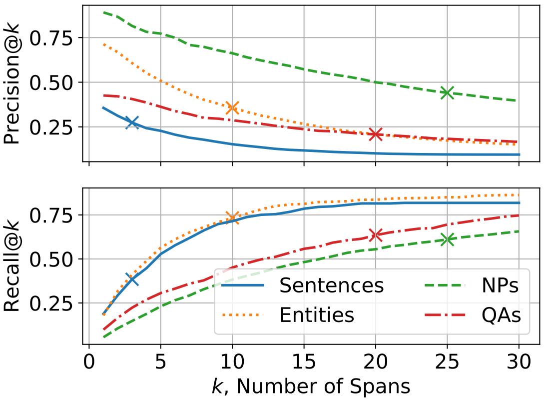

Figure 6: The performances of the salient span classifiers using the different types of salient phrase labeling evaluated against the silver spans. The "x" marks the operating points used in the end-to-end models.

D XSum Results

Table 6 contains the automatic summarization evaluation results on the XSum dataset. These results are included in the Appendix because incorporating the span-based supervision does not improve end-to-end results over the baseline BART model, which is a conclusion also reached by GSum, a model closely related to ours.

We suspect this is due to the abstractive nature of XSum compared to the more extractive CNN/DailyMail and NYTimes. Since the methods for identifying salient spans rely on the document and gold summary explicitly stating the salient content, we suspect the abstractiveness of XSum would result in this happening less frequently and thus be less beneficial to a summarization model trained on XSum.

E Gold Span Annotation Protocol

We selected 50 test instances from the CNN/DailyMail dataset uniformly at random and labeled each of the document NPs as salient or

Method	XSum

Table 6: The results of the models trained on the XSum dataset as evaluated with the automatic evaluation metrics. The span-based models do not improve over the baseline BART, potentially due to the abstractive nature of the XSum dataset.

not salient based on whether the corresponding predicate-argument relation also appears in the gold summary. We did not mark instances in which the NP's predicate-argument relation could be inferred from the gold summary via entailment as salient since our silver span labeling methods aim to mark phrases as salient if the content is explicilty included in the gold summary.

In general, this procedure was straightforward due to the extractive nature of the dataset in which the gold summaries copy heavily from the input document. If information was repeated in the input document, we tried to label the occurrence which contained the most predicate-argument relations which also matched the gold summary. That is, we selected the "best match." Otherwise, the first occurrence was selected.

Although our labeling procedure may be noisy, we do not have reason to believe that the labels may be biased in favor of either the lexical NP or QA labeling methods. Therefore, the statistics calculated from these labels should only be used as diagnostic tools to make relative comparisons between the different labeling methods rather than precise estimates of their exact values. 50 documents were sufficient to achieve statistically different results.

Our annotations will be released after publication.

Model	R1	R2	RL	BSc	QAE
Silver Spans					
QAs	55.3	31.4	51.9	90.0	33.7
QAs + Data Aug.	55.2	31.3	51.7	89.9	33.4
End-to-End					
QAs	45.5	21.9	42.4	88.5	24.4
QAs + Data Aug.	45.3	21.8	42.1	88.4	24.3

Table 7: The automatic evaluation metrics for summary quality are nearly the same for the QA-based model and the QA-based model trained on the augmented data.

F Data-Augmentation Automatic Evaluation

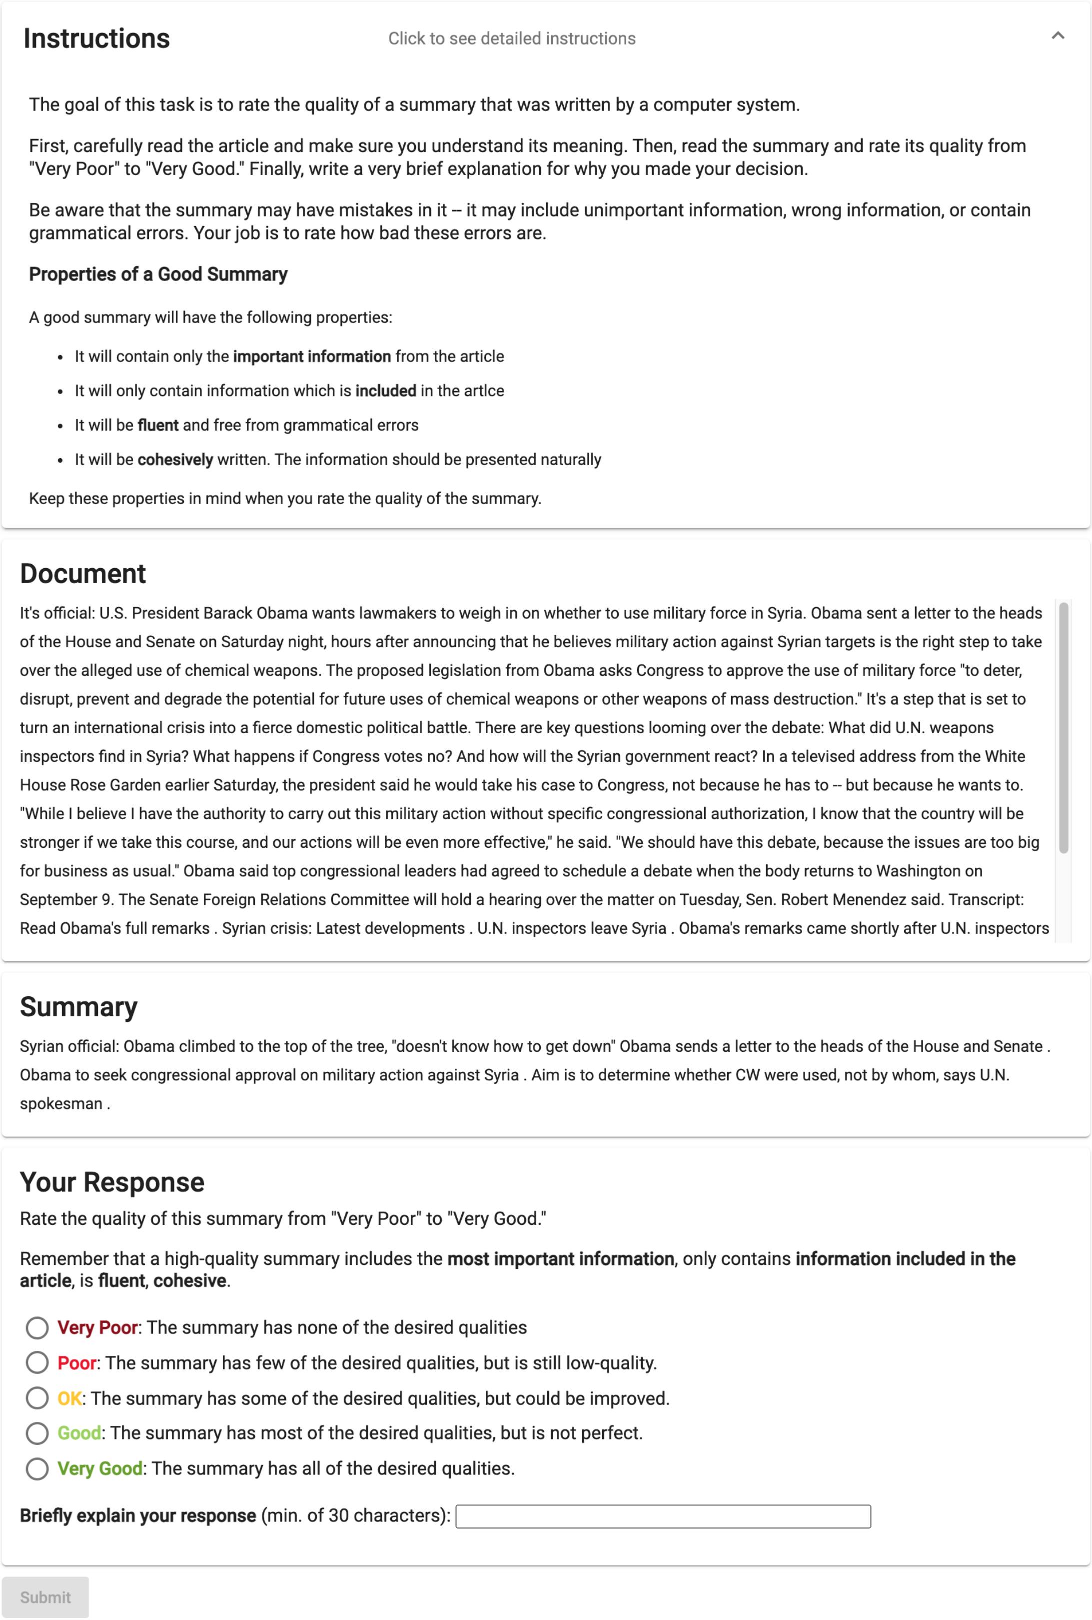
Table 7 contains the comparison between the standard and data-augmented training procedures based on the automatic metrics. The scores are nearly the same. The benefit of the model trained on the augmented data is in its controllability, which is not captured by this evaluation because the models trained with the standard and augmented training data receive the same spans as input supervision.

G Human Evaluation Details

Fig. 7 contains a screenshot of the tool we used for annotating summary quality on MTurk. The annotators were instructed to rate the summaries from "Very Poor" to "Very Good" based on whether the summary contained important information, was faithful to the input document, was fluent, and was cohesive. The ratings were converted to a Likert scale from 1-5 and averaged across all of the ratings for a system.

In order to encourage the annotators to pay attention to the task, we also required that they write a very brief explanation of how they made their decision, inspired by Narayan et al. (2021).

The MTurk annotators were paid at a rate of around $15 USD per hour.



Instructions

The goal of this task is to rate the quality of a summary that was written by a computer system.

First, carefully read the article and make sure you understand its meaning. Then, read the summary and rate its quality from "Very Poor" to "Very Good." Finally, write a very brief explanation for why you made your decision.

Be aware that the summary may have mistakes in it -- it may include unimportant information, wrong information, or contain grammatical errors. Your job is to rate how bad these errors are.

Properties of a Good Summary

A good summary will have the following properties:

- It will contain only the **important information** from the article
- It will only contain information which is **included** in the artlce
- It will be **fluent** and free from grammatical errors
- It will be **cohesively** written. The information should be presented naturally

Keep these properties in mind when you rate the quality of the summary.

Document

It's official: U.S. President Barack Obama wants lawmakers to weigh in on whether to use military force in Syria. Obama sent a letter to the heads of the House and Senate on Saturday night, hours after announcing that he believes military action against Syrian targets is the right step to take over the alleged use of chemical weapons. The proposed legislation from Obama asks Congress to approve the use of military force "to deter, disrupt, prevent and degrade the potential for future uses of chemical weapons or other weapons of mass destruction." It's a step that is set to turn an international crisis into a fierce domestic political battle. There are key questions looming over the debate: What did U.N. weapons inspectors find in Syria? What happens if Congress votes no? And how will the Syrian government react? In a televised address from the White House Rose Garden earlier Saturday, the president said he would take his case to Congress, not because he has to -- but because he wants to. "While I believe I have the authority to carry out this military action without specific congressional authorization, I know that the country will be stronger if we take this course, and our actions will be even more effective," he said. "We should have this debate, because the issues are too big for business as usual." Obama said top congressional leaders had agreed to schedule a debate when the body returns to Washington on September 9. The Senate Foreign Relations Committee will hold a hearing over the matter on Tuesday, Sen. Robert Menendez said. Transcript: Read Obama's full remarks . Syrian crisis: Latest developments . U.N. inspectors leave Syria . Obama's remarks came shortly after U.N. inspectors

Summary

Syrian official: Obama climbed to the top of the tree, "doesn't know how to get down" Obama sends a letter to the heads of the House and Senate . Obama to seek congressional approval on military action against Syria . Aim is to determine whether CW were used, not by whom, says U.N. spokesman .

Your Response

Rate the quality of this summary from "Very Poor" to "Very Good."

Remember that a high-quality summary includes the **most important information**, only contains **information included in the article**, is **fluent**, **cohesive**.

○ Very Poor: The summary has none of the desired qualities
○ Poor: The summary has few of the desired qualities, but is still low-quality.
○ OK: The summary has some of the desired qualities, but could be improved.
○ Good: The summary has most of the desired qualities, but is not perfect.
○ Very Good: The summary has all of the desired qualities.

Briefly explain your response (min. of 30 characters): ______

Figure 7: A screenshot of the tool we used for annotating summary quality on MTurk.

Patient Outcome and Zero-shot Diagnosis Prediction with Hypernetwork-guided Multitask Learning

Shaoxiong Ji and Pekka Marttinen
Aalto University, Finland
`{shaoxiong.ji; pekka.marttinen}@aalto.fi`

Abstract

Multitask deep learning has been applied to patient outcome prediction from text, taking clinical notes as input and training deep neural networks with a joint loss function of multiple tasks. However, the joint training scheme of multitask learning suffers from inter-task interference, and diagnosis prediction among the multiple tasks has the generalizability issue due to rare diseases or unseen diagnoses. To solve these challenges, we propose a hypernetwork-based approach that generates task-conditioned parameters and coefficients of multitask prediction heads to learn task-specific prediction and balance the multitask learning. We also incorporate semantic task information to improve the generalizability of our task-conditioned multitask model. Experiments on early and discharge notes extracted from the real-world MIMIC database show our method can achieve better performance on multitask patient outcome prediction than strong baselines in most cases. Besides, our method can effectively handle the scenario with limited information and improve zero-shot prediction on unseen diagnosis categories.

1 Introduction

Recent advances apply artificial intelligence to predict clinical events or infer the probable diagnosis for clinical decision support (Shickel et al., 2017; Li et al., 2021). Those works extensively study clinical data from Electronic Health Records (EHRs). For example, the Doctor AI model for predictive modeling on EHRs (Choi et al., 2016) and the Deep Patient model for unsupervised patient record representation learning (Miotto et al., 2016) is proposed by leveraging longitudinal medical data. Within the patient records, we can also find various clinical notes written by general practitioners or physicians and annotated with specific diagnosis results, medical codes, and other clues of patient outcome. Those clinical notes consist of meaningful health information, including health profile, clinical synopsis, diagnostic investigations, and medications, which can empower the clinical decision making (Li et al., 2021). Clinical text mining has demonstrated its feasibility in diverse healthcare applications, including medical code prediction (Ji et al., 2021), readmission prediction (Huang et al., 2019) and diagnosis prediction (van Aken et al., 2021). Readmission and length-of-stay prediction can help with utility management, especially when healthcare service is in high demand. Diagnostic prediction can support clinicians in making decisions based on many clinical reports. This study focuses on multitask patient outcome prediction from clinical notes, which classifies patients' diagnostic results and predicts clinical outcomes to empower expert clinicians and improve healthcare services' efficiency.

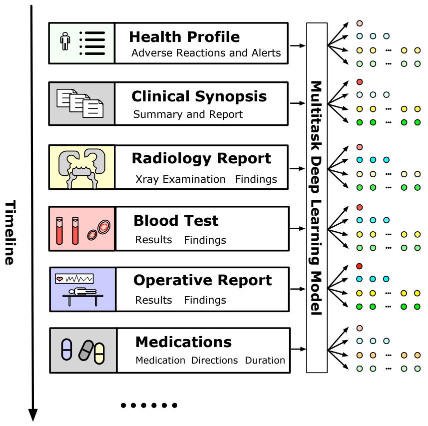


Figure 1: An example of multitask patient outcome prediction based on sequential inputs of clinical notes in the electronic health record. The multitask deep learning model dynamically predicts the probabilities of several patient outcomes at different stages during hospital admission.

Existing work on clinical note representation learning and multitask clinical outcome prediction focuses on building neural architectures for feature learning (Huang et al., 2019) or considers differ-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 589–598
May 2-6, 2023 ©2023 Association for Computational Linguistics

ent prediction tasks under the joint learning framework (Harutyunyan et al., 2019). However, there remain some unsolved challenges. First, the joint learning scheme for multiple tasks cannot effectively deal with inter-task interference, in which the predictors of different tasks compete with each other. Second, the task context information is usually underused, making multitask learning task-ignorant. Third, current learning algorithms are easy to overfit on seen training examples but fail to generalize on rare diseases or unseen diagnoses.

We propose a novel multitask learning method for patient outcome and zero-shot diagnosis prediction from clinical notes to solve the aforementioned challenges. We propose to incorporate task information to enable task-specific prediction in multitask learning. Inspired by the hypernetworks (Ha et al., 2017) that use a small neural network to generate parameters for a larger neural network, we encode the semantic task information as the task context and use the encoded task embeddings as shared meta knowledge to generate the task-specific parameters of prediction heads for multiple tasks. Our proposed method effectively utilizes the task information and produces task-aware multitask prediction heads. Our method is also generalizable on unseen diagnoses by maintaining the shared meta knowledge encoded as semantic task embeddings. Furthermore, we propose to dynamically update the weight coefficients of the multitask learning objective using another random hypernetwork, inspired by random projections (Wójcik and Kurdziel, 2019), to balance the learning from multiple clinical tasks.

Our contributions include:

- We propose to utilize task information via task embeddings for multitask patient outcome prediction spanning readmission, diagnosis, and length-of-stay prediction from clinical text and develop a hypernetwork for task-specific parameter generation to share information among different tasks.
- We propose to regularize the objective function via a randomly parameterized task weighting scheme that effectively balances the learning process among multiple tasks, taking their relationships into account.
- Experiments on two datasets extracted from a real-world clinical database show that our proposed method outperforms strong multitask learning baselines and achieves more robust performance in zero-shot diagnosis prediction.

2 Method

2.1 Problem Setup and Overall Architecture

The clinical document in patient health records is denoted as $\mathbf{d}_{1:n} = x_1, \ldots, x_n$, where each x_i is the i-th token. Patient outcome prediction predicts clinical results by mapping the input text into prediction scores with a function $\mathcal{F} : \mathcal{X}^n \rightarrow \mathcal{Y}^m$ such that $y = \mathcal{F}(x_1, \ldots, x_n; \boldsymbol{\theta})$, where $y \in \mathbb{R}^m$ is the patient outcome, m is the number of classes, and $\boldsymbol{\theta}$ are the model parameters. Under the multitask task setting, we have k learning tasks $\{\mathcal{T}_t\}_{t=1}^{k}$ that are related to the outcome of clinical intervention. Multitask learning algorithm captures the relatedness of multiple tasks and improves the modeling (Zhang and Yang, 2021). In this study, we predict multiple clinical outcomes. Thus, the goal of the learning process is to fit a single-input multi-output function $y_t = \mathcal{F}(x_1, \ldots, x_n; \boldsymbol{\theta}_{shared}, \boldsymbol{\theta}_t)$, where $y_t \in \mathbb{R}^{m_t}$ is the ground truth label and m_t is the number of classes of the t-th task, $\boldsymbol{\theta}_{shared}$ are the shared model parameters, and $\boldsymbol{\theta}_t$ the task-specific parameters. The learning objective is to minimize the weighted sum of loss functions of multiple tasks, denoted as

$$\mathcal{L}(\boldsymbol{\theta}) = \sum_{t=1}^{k} \alpha_t \mathcal{L}_t \left(y_t, \hat{p}_t; \boldsymbol{\theta}_{shared}, \boldsymbol{\theta}_t\right), \qquad (1)$$

where α_t is the weight coefficient of t-th task.

The progress of a clinical intervention comes with multiple records, as illustrated in Fig. 1, leading to lengthy clinical notes. Following Huang et al. (2019), we segment long clinical documents into several chunks, i.e., the document segmented to r chunks becomes $\mathbf{d}_{1:r} = c_1, \ldots, c_i, \ldots, c_r$, where the i-th chunk c_i contains s tokens. The segmentation has two advantages: 1) it enables progressive prediction from chunks of clinical notes calculated from the predictions of individual chunks (see details in Experiments); 2) it makes the input text length suitable for standard transformer-based pretrained models (described in the next section).

We propose a hypernetwork-guided multitask learning framework to predict multiple patient outcomes. Fig. 2 illustrates the overall framework, where the generation flow generates parameters.

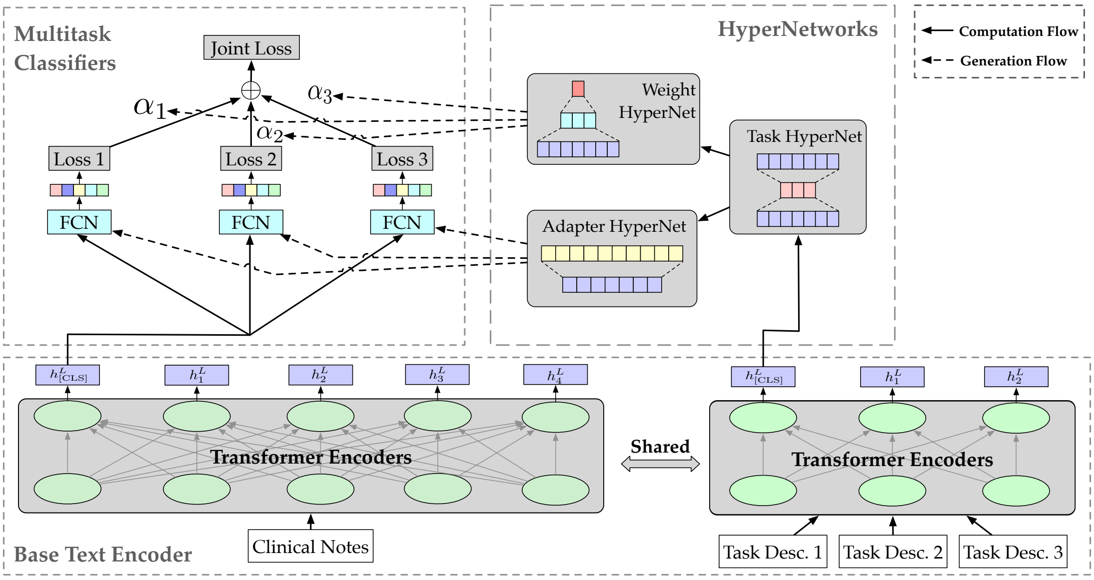

Figure 2: The illustration of our proposed hypernetwork-guided multitask learning framework

Specifically, we use a shared transformer-based text encoder to obtain hidden representations of clinical notes and task information. We develop a hypernetwork-based module, called Adapter HyperNet, to generate task-specific parameters for classification heads based on the task embeddings trained by a bottleneck network. The generated task-specific parameters then become the parameters of classification heads. To balance the learning of the joint objective function, we deploy the weight hypernetwork to generate weight coefficients conditioned on the task embeddings.

2.2 Base Text Encoder

We deploy the Bidirectional Encoder Representations from Transformers (BERT) model (Devlin et al., 2019) as our base text encoder to learn rich text features. The BERT text encoder pre-trains a language model with masked language modeling and next sentence prediction objectives in an unsupervised manner. Then, a downstream fine-tuning is followed by tuning the pre-trained model checkpoint with suitable learning objectives for downstream applications. The pre-training and fine-tuning paradigm can effectively exploit semantic knowledge from large training corpora and achieve superior performance in many downstream applications. Due to the discrepancy of vocabularies in general and specific domains, many efforts have been made to pre-train a transformer language model in various specific domains. To benefit the most from unsupervised representation learning for clinical application, we adopt the ClinicalBERT that starts from the standard BERT checkpoint and continues pre-training on clinical notes (Huang et al., 2019). Given text chunks c_i as inputs, we use the last layer's hidden representation of BERT-based text encoder to represent the encoded clinical note, i.e.,

$$\mathbf{H} = [\mathrm{BERT}(c_1,\ \boldsymbol{\theta_0}),\ \ldots, \mathrm{BERT}(c_r,\ \boldsymbol{\theta_0})] \quad (2)$$

where $\mathbf{H} \in \mathbb{R}^{s \times d_h}$, s is the sequence length, c_i is the i-th chunked text, and $\boldsymbol{\theta_0}$ is the model parameter of BERT encoder initialized from self-supervised pretraining. We can use the pooled embedding of the hidden representations to represent the clinical note, which is denoted as $\mathbf{h} \in \mathbb{R}^{d_h}$. Similarly, we input the textual label of each task to obtain the task description embeddings with a shared BERT-based text encoder parameterized with $\boldsymbol{\theta_0}$. Specifically, for the t-th task with m_t classes, the initial task embeddings are $\mathbf{T_t} \in \mathbb{R}^{m_t \times d_t}$, where d_t is the embedding dimension. The obtained task embeddings capture the task information and preserve the semantic meaning of classes in each task.

2.3 Task-Conditioned Hypernetworks

Our goal is to utilize task side-information to enable robust patient outcome prediction, especially for those classes with very few instances or that were unseen in the training set. In the joint training of multitask learning, it is easy to suffer from intertask interference. Inspired by the hypernetworks (Ha et al., 2017) that generate model parameters to enable weight-sharing across neural layers, we propose the task-conditioned hypernetworks with semantic task label embeddings to generate the parameters of multitask classification heads for clinical outcomes. The task-conditioned parameter generation can enable task context-aware learning from multiple tasks and share knowledge across different tasks.

Task Embeddings To facilitate the parameter generation conditioned on task information, we further use a bottleneck network to train the task embeddings obtained from the contextualized embeddings of the BERT-based text encoder. The bottleneck network contains two fully-connected layers with ReLU as the activation function (Nair and Hinton, 2010), denoted as:

$$\mathbf{Z_t} = \big(\mathrm{ReLU}(\mathbf{T_t W_1})\big)\mathbf{W_2}, \tag{3}$$

where $\mathbf{W_1} \in \mathbb{R}^{d_t \times d_b}$ and $\mathbf{W_2} \in \mathbb{R}^{d_b \times d_t}$ are weight matrices of linear layers, $\mathbf{Z_t} \in \mathbb{R}^{m_t \times d_t}$ are the output task embeddings, d_b is the hidden dimension that restricts the bottleneck with fewer neurons, and the bias terms are omitted for simplicity. The bottleneck network has been applied in many fields, such as image noise reduction. We use this structure to reduce the potential noise in task classes because the assignment of diagnosis in MIMIC-III does not use a systematic ontology.

Adapter Hypernetwork Inspired by the hypernetwork-generated adapters (Mahabadi et al., 2021) that fine-tune transformer layers, we equip the multitask classification heads with adapter hypernetworks that generate the parameters. Furthermore, we inject the contextual information in the task labels into parameter generation, which provides task-specific classification heads capable of task context-aware learning.

The adapter hypernetwork takes task embeddings of each task as input and generates model parameters written as

$$\mathbf{W_t} = \mathcal{H}(\mathbf{Z_t}),\ \forall\, t = 1, \ldots, k \tag{4}$$

where $\mathbf{W_t} \in \mathbb{R}^{d_h \times m_t}$ is the generated weight parameters for the classification head of the t-th task. We instantiate hypernetworks with simple linear layers. Specifically, the matrices of task embeddings $\mathbf{Z_t}$ are flattened into vectors $\mathbf{v_t} \in \mathbb{R}^{m_t * d_t \times 1}$, projected into the hidden representation space $\mathbb{R}^{m_t * d_h \times 1}$ with nonlinear activation, and reshaped to the size of weight matrices $\mathbb{R}^{m_t \times d_h}$ to act as the parameters of classification heads. The bias parameters are also generated similarly. The adapter hypernetwork conditioned on the task context shares the meta knowledge of tasks and enables task-specific prediction. Thus, the inter-task interference in the multitask setting can be effectively mitigated. Furthermore, the semantic embeddings of task context provide the adapter hypernetwork a good initialization of task classes to generate task-specific parameters, facilitating the meta-learning from limited information for zero- or few-shot scenarios.

2.4 Task-Conditioned Learning Objective

In the joint training framework of multitask learning, the standard method corresponds to manually tuning the weight coefficient α_t. However, this requires human efforts to configure additional hyperparameters when tuning the multitask learning algorithms manually. To avoid this, we propose to use another *random* hypernetwork $\mathcal{G}$ to generate the weight coefficients and make the weighted objective function of the joint multitask learning conditioned on task context. The weight coefficient hypernetwork $\mathcal{G}$ is defined as

$$\beta_t = \mathcal{G}(\mathbf{Z_t}),\ \forall\, t = 1, \ldots, k. \tag{5}$$

This hypernetwork is a multilayer perceptron (MLP), and it takes the task embeddings $\mathbf{Z_t}$ as input and outputs a one-dimensional scalar. Then we apply the softmax function to generate normalized weight probability, i.e.,

$$\alpha_t = \frac{\exp(\beta_t)}{\sum_{t=1}^{k} \exp \beta_t}. \tag{6}$$

In practice, we initialize the weight hypernetwork randomly and freeze the weights during optimization. Hence this approach can be seen as analogous to the technique of random projection (Wójcik and Kurdziel, 2019), which projects high-dimensional points to a lower dimension using a random weight matrix, and which is known to preserve the relationships of the points. Here, however, the role of the projection weight matrix is taken by the weight hypernetwork. In this way, the weight coefficients learned from the task context can preserve the semantic task information and reweigh the joint loss dynamically when the contexts change. We hypothesize that this also adds flexibility to training and regularization of the model, which contributes to the improved performance (see Section 3.5).

3 Experiments

3.1 Datasets and Setup

3.1.1 Datasets

We use the admission-level patient records in the MIMIC-III dataset for experiments. From the vast information in this database, we select the free-text patient notes as the testbed for natural language processing research. We release the source code [1].

Table 1: A statistical summary of datasets and tasks

Dataset	# Samples			# Classes			
	Train	Val.	Test	Readm.	Adm. Type	Diag.	LoS
Discharge	26,245	3,037	3,063	2	3	2,624	10
Early Notes	6,656	743	608	2	3	2,637	10

This study considers four classification tasks, i.e., readmission prediction, diagnosis classification, length-of-stay prediction, and admission type classification. Following the prior work (Huang et al., 2019), we build two datasets, i.e., one extracted from discharge summaries (denoted as `Discharge`) and one with early notes that were created within three days after admission (denoted as `Early Notes`), according to the period of patient admission date and the date when the notes are charted. Table 1 summarizes the number of instances and classes in our extracted datasets. In-hospital death prediction is also an essential task of patient outcome. However, we focus more on readmission, and mortality precludes the possibility of readmission. Thus, we filter out all the in-hospital death cases, which also aligns with the prior work (Huang et al., 2019). We also consider a proxy task of admission type classification that categorizes the clinical notes into "emergency", "elective" and "urgent" (studied in Sec. 3.4).

3.1.2 Tasks

Readmission Prediction The goal of this binary classification task is to predict whether the patient will be readmitted within 30 days of discharge.

Diagnosis Prediction The MIMIC-III dataset has a total of 15,691 classes of diagnoses in the "ADMISSIONS" table. We extract the clinical notes from the "NOTEEVENTS" table and get a total of 2,715 diagnoses in the extracted datasets of discharge and early notes, where frequent diagnoses include pneumonia, congestive heart failure, and sepsis. In our train/val/test split of discharge notes, 2,209 diagnoses appear in the training set, which allows us to test the performance of zero-shot prediction.

Length-of-Stay (LoS) Prediction Following the setting of Harutyunyan et al. (2019), we define the length-of-stay prediction as a 10-class classification problem. Specifically, the duration of stay is divided into ten buckets, i.e., one class for stays less than a day, seven classes for one-to-seven-day stays, one for stays longer than a week but shorter than two, and the last one class for stays over two weeks. A slight difference is that the duration of stay in our definition is calculated during the span between when the patient was admitted to the hospital and when discharged from the hospital.

3.1.3 Baselines

We compare our method, dubbed MT-Hyper, with several multitask learning algorithms on electronic health records and clinical natural language processing. **MT-LSTM (Harutyunyan et al., 2019)** adopts a basic LSTM-based neural network and is jointly trained with several patient outcome prediction tasks. This method is initially designed for modeling time series. We modify it with a word embedding module for modeling clinical text in patients' health records. **MT-BERT (Mulyar and McInnes, 2020)** is a unified clinical NLP model that utilizes the BERT model architecture for text encoding and learns features with multiple clinical task prediction heads simultaneously. It originally consists of eight task heads, while our implementation uses fewer clinical prediction tasks. **MT-RAM (Sun et al., 2021)** proposes a neural module with feature recalibration and aggregation for multitask learning that mitigates the mutual interference of different tasks and refines the feature learning from noisy clinical text.

3.1.4 Settings and Evaluation

We use the Adam optimizer (Kingma and Ba, 2014) to optimize the model and set different learning rates for different text encoders and classification heads. The learning rates of LSTM-based methods range from $5\mathrm{e}^{-5}$ to $1\mathrm{e}^{-3}$. As to BERT-based methods, we use a lower learning rate for both base text encoder and classification heads, ranging from $1\mathrm{e}^{-5}$ to $5\mathrm{e}^{-5}$. Because clinical BERT only has pretrained checkpoints with the BERT base model and the limitation of computing resources, we adopt the BERT base architecture as our text encoder. We use 300D word embedding, and the dimension of

	MT-BERT	31.18 ± 4.36	64.49 ± 2.22	31.69 ± 4.48	65.93 ± 1.86
	MT-RAM	32.09 ± 2.46	66.33 ± 2.33	32.66 ± 2.34	68.22 ± 2.11
	MT-Hyper	**36.37** ± 1.51	**67.47** ± 1.23	**37.14** ± 1.54	**69.28** ± 1.41

LSTM hidden states is also set to 300. We run each algorithm ten times and report the average score and standard deviation. We monitor the validation loss in each trial and set the number of epochs that triggers the early stop mechanism to be 3 for the BERT encoder and 10 for the LSTM encoder.

Our problem definition considers readmission as a binary classification problem, while the rest of the tasks are defined as multi-class classification problems. For readmission prediction, we use weighted F1 and AUC-ROC. For multi-class classification problems, we report micro averaged scores. As we segment lengthy clinical notes into shorter chunks for progressive prediction, we report the results of two types of evaluation scheme, i.e., *progressive* scores that are calculated with the prediction probabilities of note chunks and the *ultimate* scores of a complete admission that are measured by aggregating every prediction on segmented notes. The ultimate scores can also be viewed as a similar strategy to the bagging-based ensemble, in which each single prediction is based on different chunks of an instance and the final prediction is an ensemble of different predictions.

3.2 Main Results

This section presents the main results on prediction at discharge and early prediction. As admission type classification has limited usage in real-world scenarios, we do not include it in the comparison of main results but use it in the discussion of task conditioning.

Early Prediction Table 2 shows the results of patient outcome prediction from early notes. In both progressive and ultimate prediction, our proposed method outperforms three baselines in most cases. The baseline models are relatively stronger in tasks with fewer classes. For example, MT-BERT and MT-RAM produce a relatively good prediction on readmission, while their performance for multi-class diagnosis prediction is much worse than our proposed method. Furthermore, our proposed method can make more stable predictions in most cases according to the standard deviation. Our method outperforms the baselines by a relatively large margin in terms of the average scores of three prediction tasks.

Prediction at Discharge Next, we consider prediction at discharge, while keeping the setup otherwise similar to the early prediction. Discharge notes provide relatively complete information about patient hospital visits. Table 3 shows the prediction results. Our method has comparable readmission prediction performance, superior diagnosis prediction, inferior performance in the length-of-stay prediction, and relatively better overall performance measured by average score than other baselines. Besides, our method has smaller values of standard deviation in most cases when making a prediction at discharge.

3.3 Zero-shot Diagnosis Prediction

We study a more challenging scenario of zero-shot diagnosis prediction. In the extracted datasets, among the total 2,624 diagnoses of discharge, 2,209 diagnoses appear in the training set, i.e., 415 types of diagnoses are unseen in the evaluation data. We adopt this sampled setting to test the performance of zero-shot diagnosis prediction. Table 4 shows the AUC-ROC scores of progressive and ul-

Table 3: Results of patient outcome prediction at discharge with average score ± standard deviation reported. Bold values indicate the cases when our model obtain the best performance.

timate diagnosis prediction on zero-shot diagnosis categories. The results indicate that the baseline models make terribly incorrect predictions with AUC-ROC scores lower than the random guess. These baselines cannot learn meta-knowledge of diagnoses, making them overfitting on seen diagnoses in the training set. In contrast, our proposed MT-Hyper can capture the task context and semantic diagnosis information. Therefore, our method is more generalizable on unseen diagnoses and achieves satisfactory performance under the challenging zero-shot setting.

Table 4: Results (AUC-ROC) of zero-shot diagnosis prediction on unseen diagnosis results with average score ± standard deviation reported. Bold values indicate the cases when our model obtain the best performance.

3.4 Semantic Relation of Task Embeddings

We study the semantic relation of task embeddings to verify if task conditioning uses task information. We include the admission type classification as an auxiliary task and train four tasks jointly to achieve this goal. We filter out “newborn" and “death" and define the admission type classification as a three-way classification task with admission types of “emergency", “elective" and “urgent". The classification task categorizes the type of admission for each clinical note. It may have no practical usage in clinical support. However, it is a useful auxiliary task for clinical note understanding. Thus, we choose this task as an auxiliary task to help study the semantic relation of task embeddings. We obtain the task embeddings from the trained model and aggregate embeddings of each task into a vector via mean pooling. To visualize task vectors in low dimensional space, we apply principal component analysis to reduce the dimension of task vectors. Firstly, we plot task label embeddings of readmission, admission type and length-of-stay and together with the first 50 diagnoses. Figure 3a shows that different label embeddings are relatively far apart from each other, and the two tasks that are similar to each other, readmission prediction and admission type prediction, appear close to each other. We further zoom in to the embeddings of length-of-stay task labels in Figure 3b. However, here we cannot find any clear interpretable pattern. We hypothesize that the prediction of length-of-stay would benefit from clinical document understanding and numerical reasoning over the ordinal categories, and the hypernetwork-based architecture with semantic task embeddings does not effectively capture this ordinal relation of different lengths of stay. This may partially explain why our method did not provide advantage over other methods on the length-of-stay prediction.

3.5 Ablation Study

Our proposed method consists of two hypernetworks, i.e., adapter hypernetwork for task-specific parameter generation and weight hypernetwork (WH) for task weight coefficient generation. We conduct an ablation study on the usage of weight

hypernetwork. Table 5 and Table 6 show the results of patient outcome prediction from early notes and prediction at discharge respectively. The weight hypernetwork dynamically adjusts the weight coefficients of joint loss and contributes to the performance improvement in most cases. MT-Hyper with weight hypernetwork has better predictive scores in 10 out of 16 evaluation metrics on patient outcome prediction from early notes. As for patient outcome prediction at discharge, MT-Hyper with weight hypernetwork outperforms its counterpart without weight hypernetwork.

4 Related Work

Patient outcome prediction, including automatic coding (Friedman et al., 2004; Yan et al., 2010), patient severity (Naemi et al., 2020), in-hospital mortality, decompensation, length of stay and phenotyping (Harutyunyan et al., 2019), can empower health practitioners to make better clinical decision. Many studies have been conducted to investigate the usability of deep learning for accurate prediction using time-series, clinical text, or multimodal data. Zufferey et al. (2015) compared different multi-label learning algorithms. Che et al. (2015) proposed a deep phenotyping model regularized on the categorical structure of the medical ontology. Zhang et al. (2019) proposed an attention-based LSTM network to model the disease progression in a time-aware fashion. Similarly, Men et al. (2021) extended the LSTM model to be attention- and time-aware for multi-disease prediction. Convolutional neural networks have also been deployed in this field. For example, (Bardak and Tan, 2021) developed CNN-based networks for multimodal learning from patient records. Clinical notes as an essential modality of EHRs have also been studied intensively. Ghassemi et al. (2014) extracted topic features from free-text patient data for mortality prediction. Mulyar and McInnes (2020) extracted clinical information from clinical documents via fine-tuning large-scale pretrained language models.

Multitask learning learns multiple tasks simultaneously with a shared representation and transfers the domain knowledge in related tasks to improve the learning capacity (Caruana, 1997). It has also attracted much attention from the research community of machine learning and natural language processing for healthcare. Mahajan et al. (2020) studied semantic similarity degrees of clinical notes by a multitask learning method with iterative data selection. Sun et al. (2021) proposed a multitask learning framework with feature calibration for medical coding. Several multitask learning schemes have also been developed for learning from clinical time-series (Harutyunyan et al., 2019). Hypernetworks (Ha et al., 2017) that generate weights for other networks have also been adopted to solve the learning problem with multiple tasks, for example, the Hyperformer that generates the parameters of adapter modules for fine-tuning NLP task streams (Mahabadi et al., 2021). Inspired by this work, our work starts from a different setting that learns different tasks simultaneously, utilizes the semantic information of clinical predication tasks, and balances the learning objective via task conditioning.

5 Conclusion

Patient hospitalization is a complex process, which needs the learning algorithm to model multiple risk indicators. Multitask learning can jointly learn from patient records to empower clinical decision-making. To address the challenges of inter-task interference and poor generalizability to unseen labels in recent multitask learning frameworks for healthcare, we propose a hypernetwork-guided multitask learning method that learns from the task context and generates task-specific parameters for effective multitask prediction on patient outcomes. The proposed method incorporates contextualized language representations to encode clinical notes and capture the task context via the semantic embeddings of tasks. The hypernetwork-guided multitask learning framework enables task-conditioned learning and balances the joint learning objective across different tasks. Experimental studies on the real-world MIMIC-III dataset show our proposed method achieves better performance on early prediction and more robust performance on zero-shot diagnosis prediction.

Limitations

The proposed task-conditioned multitask learning method requires to obtain task embeddings from the semantic description.

Abstract

Aspectual meaning refers to how the internal temporal structure of situations is presented. This includes whether a situation is described as a state or as an event, whether the situation is finished or ongoing, and whether it is viewed as a whole or with a focus on a particular phase. This survey gives an overview of computational approaches to modeling lexical and grammatical aspect along with intuitive explanations of the necessary linguistic concepts and terminology. In particular, we describe the concepts of stativity, telicity, habituality, perfective and imperfective, as well as influential inventories of eventuality and situation types. Aspect is a crucial component of semantics, especially for precise reporting of the temporal structure of situations, and future NLP approaches need to be able to handle and evaluate it systematically.

1 Introduction

Lexical and grammatical aspect play essential roles in semantic interpretation (Smith, 2003), and yet even state-of-the-art natural language understanding (NLU) systems do not address these linguistic phenomena systematically (Metheniti, 2022). Consider this example: an NLU-based personal assistant, noticing the boarding time of a flight, tells a passenger (who is still shopping at the airport) "You miss flights" (i.e. on a regular basis) instead of "You are missing the flight" (now!). The traveler might misinterpret this utterance as chit-chat and indeed miss the flight. Aspectual encoding errors impair fluid and correct communication.

While there has been a notable amount of work on modeling lexical and grammatical aspect in the computational linguistics community (Moens and Steedman, 1988; Siegel and McKeown, 2000b; Friedrich et al., 2016; Kober et al., 2020), this area is still a niche in natural language processing (NLP). In this paper, we survey the state of research in this area and argue that a good computational understanding of lexical and grammatical aspect is paramount for capturing temporal information signaled by linguistic encoding. We thereby add to the on-going discussion in the NLP community about what is required to achieve true natural language understanding (Bender and Koller, 2020; Dunietz et al., 2020; Trott et al., 2020).

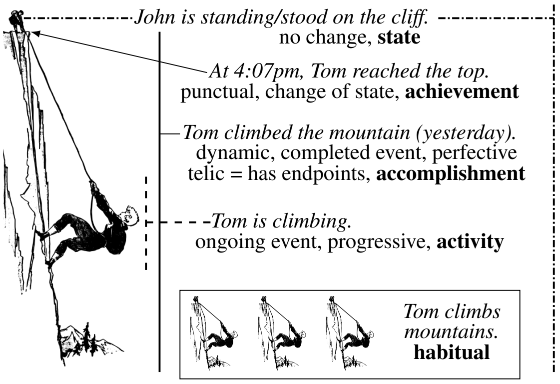

Figure 1: **Aspect** is like the camera lens of language, the device by which we focus on particular phases of a situation (Vendler, 1957; Smith, 1997).

When describing a situation, as exemplified in Figure 1, producers of language have options for how to depict the situation and which subparts of it to highlight. Just as a cinematographer uses focus to highlight certain elements of a scene and thus bring them to the attention of the viewer, different aspectual choices focus on different subparts of the situation at hand, leaving the rest as background (analogy due to Smith, 2003). For example, many situations can be construed as either *foregrounded* events ("Tom climbed the mountain"), moving narrative time forward, or as states ("John stood on the cliff"), which often function as the *background* in a narrative or explanation. Aspectual choices may trigger hard inferences, softer implicatures, or simply expectations, having a non-negligible impact on the reader or listener. One aim of this survey is to clarify the sometimes complex linguistic work on aspect, giving NLP researchers and practitioners a

Table 1: Available **Datasets** labeled with aspectual information.

conceptual toolkit, plus a glossary of aspect-related terminology (Appendix A). The second aim is to survey computational work on modeling aspect.

Aspectual categories are *semantic* notions that are conveyed through a variety of mechanisms (Section 2). Fundamental aspectual distinctions (Section 3) may be part of the lexical meaning of a verb and are also influenced by context. These distinctions drive some influential inventories of eventuality types (Section 3.3). Grammatical aspect (Section 4) is marked morphologically in some (e.g., Slavic) languages, or via the choice or absence of tense-aspect features in languages such as English. Section 5 explains the idea of situation types, aspectual distinctions at the clause level.

As a consequence of the often distributed or even implicit encoding of aspect, computational models need to consider a variety of lexical and grammatical features as well as discourse and pragmatic information. While some NLP systems trained on end-to-end datasets may get some of these cases right, we are not aware of a system treating such problems in a principled manner. A recent study finds that transformer-based embeddings are useful for classifying clausal aspect (Metheniti, 2022), but it remains unclear just how these models learn or incorporate aspectual information. This survey focuses on modeling aspectual information as it is annotated in the datasets listed in Table 1.

In Section 6, we discuss potential ways of moving the field forward. We argue that explicit modeling or evaluation of aspectual categories should become a routine perspective in future NLP: getting aspect right has high stakes for applications such as temporal question answering, machine translation, or computer-aided language learning.

2 Where Does Aspect Live?

Comrie (1976) notes that there is a terminological and conceptual confusion around tense and aspect. This is at least partially because the expression of temporal location is intertwined morphologically with aspect in many languages of the world (Smith, 1997), so the traditional grammatical terminologies of individual languages often introduce tense/aspect combinations simply as tenses. Tense is *deictic* and locates the time of a situation relative to the utterance or relative to another situation. Aspect, in contrast, refers to situation-internal time.

Aspectual distinctions are *covert* categories (Whorf, 1945; Smith, 1997), expressing particular temporal semantic concepts in a way that does not have a one-to-one mapping to lexical, grammatical or syntactic categories (Fillmore, 1969). For example, the English Progressive[1] often indicates an ongoing situation without focusing on its endpoints ("I am eating an apple"), but it also signals future events ("I am going to Paris"). The grammatical form of such tense-aspect combinations can often be automatically detected with high accuracy (Ramm et al., 2017; Myers and Palmer, 2019). This type of aspect, encoded in the tense system of a language, is different from *semantic* concepts which refer to how the internal structure of a situation is presented; this survey focuses on the latter.

So where does *covert, semantic* aspect live? Aspectual meaning is compositional, composed by the verb's inherent meaning, its arguments, its tense, any morphological aspect markers, some prepositional phrases, and the adverbs of the sentence (Verkuyl, 1972; Mourelatos, 1978; Smith, 1997). Eventuality and situation type inventories make use of several dimensions of aspect to distinguish between different types of temporal structures. *Lexical aspect* refers to information contained in the meaning of verbs (or verb senses), with the consequence that their values often can be determined

---

[1] Following Comrie (1976), we use initial capitals for the names of language-particular categories and lower case for language-independent semantic distinctions.

only when observing how the verb interacts with its clausal context. A second dimension, *grammatical* or *viewpoint* aspect, refers to whether there is a focus on part of the situation or whether the situation is viewed as a whole or even as repeating. Grammatical aspect and situation types are both semantic categorizations at the sentence/clause level (e.g., Vendler, 1957; Verkuyl, 2005; Smith, 2003).

3 Inherent Lexical Aspect

Here we explain two fundamental notions related to inherent *lexical aspect*: *stativity* refers to whether a situation is viewed as an event or state, and *telicity* refers to whether an endpoint is visible in a clause.

3.1 Stativity

The most fundamental distinction made in the hierarchies of eventuality types is that between *states* ("love," "own") and *events* ("run," "buy"). In contrast to *dynamic* predicates, *stative* verbs entail no change (Filip, 2012). States obtain in time but they do not take time; events occur, happen, or take place (Smith, 1997). Events may have a beginning and/or an end (Comrie, 1976), and they are often *durative*, i.e., conceived as lasting for a certain period of time. Some events are dynamic situations describing a change of state such as "John reached the goal"; these are perceived as *punctual*. For punctual, single-stage events which cause no change of state, Smith (1997) adds the situation type *semelfactives*, for verbs like "knock," "flash," or "blink." While dynamic in nature, semelfactives return to their initial state at their end and often occur as *iteratives* (Filip, 2012). The stativity distinction pertains to verb senses, not verb types. For example, the verb type "make" has both a dynamic (1a) and a stative (1b) sense.

(1) (a) She is **making** a cake. (*dynamic*)
(b) She **makes** a great host. (*stative*)

In theory, the analysis of stativity could be applied to inventories of verb senses such as WordNet (Fellbaum, 2010). In practice, most computational works focus on classifying verbs in context.

Early computational approaches. The dynamic-stative distinction is at the heart of early approaches to computational modeling of tense and aspect. In the PUNDIT system for temporal information processing (Passonneau, 1988a), the lexical aspect of verbs in tensed clauses can be read from the system's output: transition events use `become`, processes use `do`; other cases signal states. In the context of lexicon induction, Klavans and Chodorow (1992a) suggest representing event structure of a verb as its *degree of stativity*, which is estimated by the proportion of occurrences in a corpus that are in the Progressive. Brent (1991a) also presents a program for identifying stativity using syntactic indicators: verbs that occur frequently with the Progressive or that combine with rate adverbs (e.g. "quickly", "slowly") are usually dynamic. Both works evaluate by manually inspecting system output.

Datasets. Siegel (1999) presents a manually annotated dataset of 739 training and 739 test clauses taken from medical discharge summaries, covering 222 different verb types. With the aim of reproducing and extending their work, Friedrich and Palmer (2014a) have three annotators label 7,875 clauses from MASC (Ide et al., 2008), marking the clause's main verb as *stative* or *dynamic*.If annotators see both readings, they may select both. The dataset has later been extended to cover 30,333 clauses from MASC and 10,607 clauses from Wikipedia (Friedrich et al., 2016). Kober et al. (2020) introduce the DIASPORA dataset, in which 927 utterances from a corpus of human-human phone conversations (Brennan et al., 2013) are labeled with whether the first verb phrase of each utterance is stative or dynamic. The dataset spans 69 different verb types. Chen and Palmer (2022) produce 292 contrast sets for stativity in English and outline strategies for converting between stative and dynamic expressions of the same situation. For more datasets that annotate stativity as one feature among others, see Section 3.3.

Modeling.[2] Siegel (1999, 1997) and Siegel and McKeown (2000b) propose a machine-learning approach to classifying stativity that describes each verb occurrence exclusively using corpus-based statistics of the corresponding verb type. The verb-type based indicators are normalized counts that reflect, for instance, how often the verb co-occurs with the past tense, in the perfect, or in negated form (for a full list, see Appendix D.1). Using these features, they train logistic regression models, decision trees, and genetic programming algorithms.

Friedrich and Palmer (2014a) compare these corpus-based *linguistic indicators* to instance-based syntactic-semantic features representing the clausal context, e.g., the part-of-speech tag of the

---

[2] Appendix B summarizes computational systems and approaches to modeling aspect.

verb, tense, voice, and WordNet information (Fellbaum, 2010) for the verb's arguments. Using the LCS database (Dorr, 2001) and a procedure described by Dorr and Olsen (1997), they also construct three seed sets with verb types that either occur exclusively as *dynamic*, only as *stative*, or can take both aspects. Based on these seed sets and a pre-trained syntactic distributional model (Thater et al., 2010), similarity values are computed and used as additional features. Kober et al. (2020) input sums of non-contextualized word embeddings (Mikolov et al., 2013) for the clause's main verb as well as selected context words to a logistic regression classifier. Overall, they find that using the local context in the form of a word window outperforms the verb-type only classifier, but that feeding in the entire sentence hurts. Metheniti (2022) also classify stativity (called "duration" in their work) by fine-tuning various transformer models and classification layers. They find BERT (Devlin et al., 2019) models work better than RoBERTA (Liu et al., 2019), AlBERT (Lan et al., 2019) and XLNet (Yang et al., 2019).

3.2 Telicity

The second important distinction related to inherent lexical aspect is that of *telicity*. The term *telic*, derived from Greek *télos* (goal) was introduced by Garey (1957). In his definition, telic verb senses have a built-in goal: when that goal is reached, a change of state occurs and the event is complete (Smith, 1997). Telicity is also sometimes referred to as *boundedness* (e.g., by Loáiciga and Grisot, 2016). As illustrated by (2), telicity is a feature of the entire clause (Verkuyl, 2005).

(2) (a) He was swimming in the lake. *(atelic)*
(b) He was swimming across the lake. *(telic)*

When a telic verb is used in the *imperfective* as in (3a), the arrival or nonarrival at the goal is hidden (Garey, 1957). If the same verb is applied in the *perfective* as in (3b), it means that the goal has been reached at the time of reference. Hence, if (3a) is true at some particular point in time, it cannot be the case that (3b) is true at the same point in time.

(3) (a) John was recovering. *(telic, imperfective)*
(b) John has recovered. *(telic, perfective)*

In contrast, *atelic* verbs do not have to wait for a goal for their realization; they are realized as soon as they begin. If an atelic verb is used in imperfective form as in (4a), we can infer that the sentence in perfective form (4b) is also true.

(4) (a) Sue was singing. *(atelic, imperfective)*
(b) Sue has sung. *(atelic, perfective)*

Datasets. Siegel and McKeown (2000b) describe a small dataset annotated for *completedness*, i.e, telicity. Their training and test sets each consist of approximately 300 clauses taken from 10 novels and covering 204 different dynamic verbs. Friedrich and Gateva (2017) manually annotate 1863 clauses taken from MASC (Ide et al., 2008) for telicity. The Captions dataset (Alikhani and Stone, 2019) marks telicity in several image caption corpora. They find that the proportion of telic verbs ranges from 6% to 59% across corpora, with atelic descriptions prevailing in almost all corpora. In the DIASPORA dataset (Kober et al., 2020), in each utterance, the first VP is annotated with its *predicational* aspect (stative, telic, or atelic).

Modeling. Siegel and McKeown (1996, 2000b) propose a machine-learning approach to classifying telicity of verb occurrences using their above-described corpus-based linguistic indicators. For example, verbs frequently occurring in the Progressive are likely atelic. Leveraging these corpus-based *linguistic indicators*, Friedrich and Gateva (2017) integrate syntactic-semantic contextual features into their logistic regression model. They also leverage additional silver standard training data in the form of projected annotations from the English-Czech InterCorp (Čermák and Rosen, 2012; Rosen and Vavřín, 2012). Their approach, using the machine-readable Czech dictionary Vallex (Žabokrtský and Lopatková, 2007), is based on the assumption that most perfective Czech verbs are translated using telic verb constructions, and that most imperfective verbs correspond to atelic constructions. Loáiciga and Grisot (2016) create an automatic classifier similar to that of Friedrich and Gateva (2017) to classify *boundedness* of French verbs, i.e., whether the endpoint of an event has occurred or not. They show that this is useful for picking the correct tense in French translations of the English Simple Past. Several more recent studies have shown that distributional and neural models can be trained to predict telicity as annotated in available datasets (Kober et al., 2020; Metheniti et al., 2021; Metheniti, 2022). BERT-style models perform well on existing telicity datasets (with larger models outperforming smaller models), yet it is still unclear how or whether they actually capture aspect. Metheniti (2022) observe that models are always highly confident in their predictions, re-

Type	*dynamic*	*durative*	*telic*	**Examples**
state	-	+	-	know the answer, love Mary
activity	+	+	-	laugh, stroll in the park, swim
accomplishment	+	+	+	build a house, walk to school
achievement	+	-	+	win a race, recognize
semelfactive	+	-	-	tap, knock, hiccup, tap, wink

Table 2: Eventuality types (Vendler, 1957; Smith, 1997).

gardless of their accuracy (a common phenomenon for neural models). We are not aware of any probing or explainability studies in this area yet, and how to obtain better calibrated models is an open research question.

3.3 Eventuality Types

We now explain some influential inventories of *eventuality types*, which are ontologies of the temporal structures of events and/or states. Table 2 shows the set of situation types introduced by Vendler (1957): *state*, *activity*, *accomplishment*, and *achievement*. There are other similar schemata (Kenny, 1963; Mourelatos, 1978, more details in Appendix C.1); we use Vendler's terminology here.

States are inherently stative and atelic. They are *durative* as they usually extend in time, though this time period may be very short as in (5).

(5) He was very quiet for two seconds.

The other three Vendler classes are all dynamic. They differ in whether they have a built-in endpoint, and in whether a clearly defined process leads up to this endpoint. *Activities* as in (6), consisting entirely of a process, use atelic verbs. *Accomplishments* as in (7) consist of a process that leads up to a built-in terminal point. Similarly, *achievements* as in (8) have an endpoint including a change of state, but the verb meaning does not include a process leading up to this point. Smith (1997) adds the *semelfactive type* (see Section 3.1).

(6) Mary was laughing. *(activity)*

(7) Mary wrote a letter. *(accomplishment)*

(8) He arrived at the station. *(achievement)*

Moens and Steedman (1988) work with aspectual profiles of sentences (for details see Appendix C.1) that are classified by making reference to a so-called *nucleus*. For example, "John built a house" consists of the *preparatory phase* (the house is being built), a *culmination point* (the moment at which it is completed), and a *consequent state* (the house is complete). The process of **aspectual coercion** shifts aspectual verb types based on their arguments or other aspectual operators such as adverbials. When used with a predicate whose lexical entry corresponds to a culminated process, the English Progressive strips off the culmination point and makes visible only the preparatory process as in "John was running a mile."[3]

Datasets. Zarcone and Lenci (2008) create a dataset of 3129 occurrences of 28 Italian verbs manually annotated for Vendler-style event types. Keelan (2012) works on an eight-way classification task for categories based on Leech's (1971) classes (see Appendix C.2). More recently, in the context of the Richer Event Description (RED) annotation scheme (Ikuta et al., 2014; O'Gorman et al., 2016; O'Gorman et al., 2021), the annotation of events with finer-grained Vendler-style situation types has been proposed (Croft et al., 2016). Falk and Martin (2016) select 167 frequent French verbs from a lexical resource (François et al., 2007), and label the corresponding 1199 entries ("readings") with eight aspectual classes similar to those of Mourelatos (1978) as listed in Appendix C.1. Their classification task is finer-grained than labeling verb types, but coarser-grained than clause-level labeling. Egg et al. (2019) annotate 4200 clauses from the German SdeWac (Faaß and Eckart, 2013) with the features stative, durative vs. punctual, and boundedness. With the aim of improving zero-shot image to verb recognition, Zellers and Choi (2017) crowdsource a dataset of 1710 verb templates (such as "put up") for 1203 different verbs annotated with the four Vendler categories. The Caption dataset (Alikhani and Stone, 2019) annotates image captions with the features stative, durative, punctual, telic, and atelic.

Modeling. Zarcone and Lenci (2008) train a maximum entropy classifier that uses adverbial, morphological, and syntactic features, as well as features capturing argument structure. Keelan (2012) uses an SVM (Cortes and Vapnik, 1995) with features similar to the linguistic indicators of Siegel and McKeown (2000b). Zellers and Choi (2017) use GloVe embeddings (Pennington et al., 2014) to represent the input verb. They concatenate this embedding with a phrase embedding of the verb's dictionary definition computed using a recurrent neural network, and add a linear layer on top. Hermes et al. (2015) induce Vendler classes for German verb types, using Siegel-style distributional

---

[3] Thus offering an elegant solution to the *imperfective paradox* (Dowty, 1979; Lascarides, 1991).

features extracted from dependency-parsed corpus data (3000 sentences per verb type) and SVMs for type-level classification. Hermes et al. (2018) compare the above framework to shallow distributional vectors considering only co-occurring word types for each verb. Finally, Gantt et al. (2022) propose a generative model for event types (and other information) fitted from English data annotated with a range of aspectual and other properties. The resulting 4-class event type inventory closely resembles Vendler classes in the distinctions it draws.

The main obstacle to systematically comparing the works mentioned in this section is that their authors make differing choices for the granularity of both the annotation scheme and the computational modeling, and conclusions drawn from the studies depend on these choices. For better comparability, we need better benchmarking.

4 Grammatical Aspect / Viewpoint

Phenomena treated as *grammatical aspect* or *viewpoint* (Smith, 1997) take different views (the entire situation vs. a part of it), or signal recurrence.

4.1 Perfective vs. Imperfective

The *perfective* viewpoint presents situations as complete with both an initial and a final endpoint, while the *imperfective* viewpoint makes only certain parts of the situation visible to the receiver (Smith, 1997). The situation in (9a) is presented imperfectively, focusing on the middle phase of John's eating. In contrast, (9b) is viewed in the perfective. Here, the interpretation is that (b) happens during the interval at which (a) is true.

(9) (a) John was eating a sandwich *(imperfective)*
(b) when Susan entered. *(perfective)*

The perfective/imperfective distinction is observed cross-linguistically, although some languages make even finer distinctions. For example, Chinese has two perfective aspect markers and two imperfective aspect markers. The two perfective markers *le* (10a) and *guo* (10b) differ in the present relevance, with the former indicating completion of a situation while the latter emphasizes the experience of having been through a situation. The two imperfective aspect markers *zhèngzài* and *zhe* both indicate a situation is on-going at the reference time, but the latter emphasizes the resulting state of a situation (Chao, 1968; Li and Thompson, 1989; Ljungqvist, 2007).

(10) (a) tā jìn le fángjiān "*He has entered the room (and is still in the room)"*
(b) tā jìn guò fángjiān "*He entered the room (at some point but is no longer in the room)"*
(c) tā zhèngzài jìn fángjiān "*He is entering the room"*
(d) fángjiān de mén kái zhe "*The door of the room is open."*

While also referring to endpoints, the concept of viewpoint differs from telicity: telicity describes types of situations independent of which phase is focused (e.g., "eating a sandwich" in (9a) is an (inherently-telic) accomplishment); viewpoint adds the focus (in this case on the phase during which the eating happens and the endpoint has not yet been reached; more details in Appendix C.3). It is the perfective-imperfective distinction that has traditionally been referred to as *aspect* in Slavic linguistics (Filip 1999). Computational work leverages parallel corpora to map the distinction, which is partially *overt* (i.e., explicit in the morphosyntax) in Slavic languages, to English text (Stambolieva, 2011; Friedrich and Gateva, 2017). Despite overall high accuracy, the models still struggle to reach high scores for the minority class *atelic*. In addition, such annotation projection approaches are not easily scalable, as they require strong knowledge of the languages involved.

4.2 Habituality

Habituals such as (11b) are sentences that "express regularities about the world which constitute generalizations over events and activities" (Carlson, 2005); on a sentence-level, they can be regarded as "derived statives" (Smith, 1997). In contrast, the term *episodic* refers to particular events. Habituals allow exceptions, e.g., (11b) is still true if Mary sometimes takes the train.

(11) (a) Mary cycled to work. *(episodic)*
(b) Mary cycles to work. *(habitual)*

Habitual sentences may also use stative predicates as in (12), generalizing over situations in which some state applies (Smith, 2005).

(12) Sloths sometimes rest on trees. *(habitual)*

Habituals are not restricted to what one would usually consider a matter of habit (Carlson, 2005); they can also have inanimate subjects as in (13).

(13) Glass breaks easily. *(habitual)*

Habituality is not to be confused with *iterativity*, which states that a situation occurs repeatedly, but not regularly, as in "the light flashed." Borderline cases are discussed in Appendix C.4.

Data and Modeling. Mathew and Katz (2009) randomly select 1052 sentences for 57 verbs from the Penn TreeBank (Marcus et al., 1993) and manually mark them as habitual or episodic. They train both a decision tree and a Naive Bayes classifier on syntactic features extracted from gold parses. Friedrich and Pinkal (2015a) argue that in order to be able to apply such a model on free text, a third category, which they call *static*, needs to be taken into consideration, which covers lexically stative, negated, and modalized clauses. They experiment with Random Forest classifiers (Breiman, 2001) using syntactic-semantic features and linguistic indicators (see Section 3.1). Govindarajan et al. (2019) label UD-EWT (Silveira et al., 2014) with real-valued properties indicating e.g., the "degree" of habituality. Their multi-layer perceptron uses features from verb databases such as LCS and GLoVe embeddings. Results for predicting habituality are overall promising, although there is a need for experiments with careful consideration of and controls over the verb types involved.

Other recent related work (Williams, 2012; Williams and Katz, 2012; Vempala et al., 2018) extracts typical durations (in terms of actual time measures) for verb lemmas from Twitter. They distinguish episodic and habitual uses of the verbs, using the method of Mathew and Katz (2009), and collect typical durations (e.g., "seconds" or "weeks") for episodic and habitual uses separately for each verb. The problem has further been studied in the context of acquiring common sense knowledge (e.g., Zhou et al., 2019; Yang et al., 2020).

4.3 Grammatical Aspect in Recent Syntactic-Semantic Frameworks

The **Universal Dependencies** (UD) guidelines[4] define six aspectual *features* for verbs: Hab, Imp, Iter, Perf, Prog, and Prosp (prospective, for relative future). The categories are assumed to be language-specific and close to the respective morphologies, and the exact definition of each feature is left to the individual languages. UD parsers frequently treat the identification of these features as a tagging task (e.g., Kondratyuk and Straka, 2019).

In the context of a pilot study on integrating aspect into Abstract Meaning Representations (Banarescu et al., 2013, **AMR**), Donatelli et al. (2018) propose to indicate whether a clause is habitual or ongoing (in addition to marking stativity and telicity). Tense and aspect annotation has been incorporated into Dialogue-AMR and used to annotate a corpus of human-robot interactions (Bonial et al., 2019, 2020). The Uniform Meaning Representations (**UMR**) framework (Van Gysel et al., 2021) uses a lattice for typologically-motivated annotation of aspect. The lattice begins by making the distinction between three categories: HABITUAL, which covers recurring states and events; PROCESS, which covers all non-recurring dynamic situations; and IMPERFECTIVE, designated for non-recurring states and atelic processes. The PROCESS category is further divided into ongoing ACTIVITIES, ENDEAVORS which have begun but not finished, and PERFORMANCES, which are completed dynamic processes. See Appendix D.2 for the full lattice.

Chen et al. (2021) build a rule-based system leveraging syntactic and semantic cues to annotate English sentences according to the UMR aspect lattice. Due to the recency of these frameworks, so far there is only very limited computational work.

5 Situation Entities

In this section, we review work on automatically classifying *situation entity* (SE) types (see inventory in Appendix D.3). SEs are "semantic concepts organized according to their internal temporal properties" (Smith, 2003). They are introduced to the discourse by a clause's verb constellation, i.e., the clause's main verb and its arguments and modifiers. Deciding on the type of an SE thus involves the combination of lexical and syntactic factors. In contrast to eventuality types (Section 3.3), situation entities capture the linguistic nature of the clause (Friedrich and Palmer, 2014b). EVENTS include all dynamic verb constructions referring to particular non-recurring situations, no matter whether there is a pre-defined endpoint or not. They may occur in the perfective or imperfective. GENERALIZING SENTENCES correspond to habituals as described in Section 4.2, with the exception of GENERIC SENTENCES that comprise all sentences making statements about kinds (Krifka et al., 1995).

Datasets. Palmer et al. (2007) present 6065 clauses taken from the Brown corpus (Francis and Kučera, 1979) and MUC-6 (Grishman and Sundheim, 1996), manually annotated with SE types. The SitEnt dataset (Friedrich et al., 2016; Friedrich, 2017) consists of 40,000 clauses from 13 genres annotated for SE types with substantial agreement (Friedrich and Palmer, 2014b). Govindarajan et al.

---

[4] https://universaldependencies.org/u/feat/Aspect.html

(2019) crowdsource UDW-G, a dataset of 37,146 arguments and 33,114 predicates in 16,222 sentences with continuous judgments on a scale from 1 to 5 with distinctions essentially following the schema of Friedrich et al. (2016).

Modeling. Palmer et al. (2007) use a maximum entropy sequence tagger with part-of-speech and CCG-based (Steedman, 2000) syntactic features to predict labels for each sentence separately. In an oracle experiment, they show that including the label of the previous sentence(s) as a feature improves performance. Friedrich et al. (2016) present the first true sequence labeling approach to SE types classification using conditional random fields (Lafferty et al., 2001) with distributional features in the form of Brown cluster IDs (Brown et al., 1992) and syntactic-semantic features. Kober et al. (2020) propose to classify predicational aspect with distributional semantics, using non-contextualized word embeddings and sums of the word vectors of the target words and their context words. Several works (Palmer et al., 2007; Palmer and Friedrich, 2014; Friedrich et al., 2016) find that sequence information mostly helps when training in-domain and has the biggest impact on identifying GENERIC SENTENCES, which often require discourse context for classification, even by human annotators (Friedrich and Pinkal, 2015b).

SE types have also been modeled using a variety of neural approaches. Becker et al. (2017) employ a GRU-based (Cho et al., 2014) RNN with an attention mechanism. Dai and Huang (2018) dynamically build context-aware clause representations, informed by their paragraph-wide contexts. They propose a hierarchical recurrent neural network that reads entire paragraphs at once, learning interdependencies for clauses. Their model uses word2vec (Mikolov et al., 2013) embeddings for words, and first computes contextualized word embeddings using a BiLSTM over the entire paragraph. Clause embeddings are formed by max pooling over the word embeddings of each clause, and then clause embeddings are further contextualized via another BiLSTM. For further improving SE classification, they add a CRF layer on top, and finally predict SE labels via softmax. Recently, BERT (Devlin et al., 2019) and GPT-2 (Radford et al., 2019) have been employed for the classification task by Rezaee et al. (2021), who also compare to using ParBERT (Cohan et al., 2019). While BERT only considers one clause at a time, ParBERT reads several sentences at once, separated by [SEP] tokens, and then uses the embeddings of the [SEP] tokens to predict a label for the corresponding clause. Comparing a variety of neural models based on non-contextualized word embeddings on their situation-entity related regression tasks, Govindarajan et al. (2019) reach levels similar to human agreement.

The computational problem of identifying SE types has recently been studied extensively. Overall, SE patterns are specific to the domain, genre or *discourse mode* (Smith, 2003). Future research could use SE-style analysis for NLP tasks like temporal processing or information extraction.

6 How Can We Move Forward?

In this section, we discuss potential steps that could lead to more successful modeling of aspectual information, as well as how to leverage that information in NLP applications.

6.1 Dataset Construction

To date, there is no consensus or standard across languages regarding where aspect lives. Ongoing efforts in the UMR community aim to develop typologically-informed aspectual representations that work across languages, but so far very few UMR datasets exist. Whether achieving a standard for aspectual representation is a necessary step or not, in order to make more rapid progress on the computational modeling of aspect, first the various models need to be **benchmarked** on the same tasks and datasets. **Dataset construction** in this area is challenging. Annotators not only need to have extensive linguistic training but also often domain expertise. Formulating the problem as a crowdsourcing task is a possible direction (Govindarajan et al., 2019), but obtaining consistently high agreement is (as for most tasks) difficult in this setup. **Multilingual** datasets and models are still under-researched, yet they are of particular relevance due to applications in computer-aided language learning or the evaluation of machine translation (see examples in Appendix E).

6.2 Modeling

More research is also needed on whether recent **embeddings** or text encoders capture or abstract away from aspectual features. Recent experimental findings on the SitEnt dataset show that, when training data within the same domain and genre is available, performance of pre-trained transformers is in the range of human agreement (Metheniti, 2022; Dai and Huang, 2018). The current state-of-the-art model based on BERT-GPT achieves a macro-average F1 of 79.1 compared to an estimate of human performance (78.6). Yet, most verbs are either not ambiguous or have a strongly predominant majority class that the models memorize (Friedrich and Palmer, 2014a; Kober et al., 2020). We expect much insight to come from further studying verb types that behave differently depending on the context. Moreover, results on cross-genre classification of SE types are yet inconclusive. Dai and Huang (2018) report high cross-genre scores for BERT, ParBERT, and BERT+GPT, but out of these models, there is no clear winner across all genres. Overall, when only using out-of-genre training data, performance of the BERT+GPT model still drops to an F1 of 70.7.

Investigating aspectual information in the context of **document-level models** (e.g., Beltagy et al., 2020) is another opportunity: cues for aspectual interpretion may occur earlier in the discourse than the sentence being interpreted (see App. E).

Linguistic indicators (Siegel and McKeown, 2000a) have been shown to be useful for predicting aspectual features in the absence of training data. Another research direction should hence look at how aspectual information can be **induced from raw data** or parallel corpora on a larger scale and for a broader set of distinctions. Future work should also investigate the interaction with other elements of semantics such as argument structure.

In sum, systems for predicting aspectual information encounter several challenges: (a) many verb types are ambiguous, (b) datasets for the task show significant class imbalance, and (c) for many verb types, no training data at all is available. Initial experiments with careful controls for different groups of verbs were highly promising (Friedrich and Palmer, 2014a; Kober et al., 2020), but available annotated data is sparse, especially for ambiguous verb types. More research is required to disentangle the effects of potentially lexically biased datasets, class imbalance, and sparsity.

6.3 Applications

Automatic classifiers for aspectual distinctions clearly have **applications** in the **digital humanities** and quantitative linguistics, where research questions may directly target the use of aspect. Recent highly fluent (but not necessarily always accurate) language generation models such as GPT-3 (Brown et al., 2020) and ChatGPT[5] open up a new level of writing assistance or language learning systems. We believe that a fruitful direction for future research is to make such systems explainable, also in the sense that they are able to give linguistically founded qualitative feedback to the user about why an aspectual form is correct or wrong in a particular context. Benchmarking on datasets explicitly annotated for aspectual information will let us estimate the degree to which text generated by the models is in line with the author's intentions. In Appendix F, we provide some chat logs of conversations with ChatGPT that illustrate how far it is from being an adequate tool for teaching the linguistic concepts described in this survey.

However, we argue that paying attention to aspect is necessary to arrive at fluent human-level NLP systems as motivated by our "miss the flight" example in Section 1. In Appendix E, we discuss two potential application areas: temporal processing and machine translation. In a nutshell, some works suggest that embedding spaces still struggle to capture the nature of tense and aspect, with consequences for commonsense reasoning driven by temporal properties, and can hence lead to wrong conclusions. Similarly, machine translation systems may (and still do) go wrong when cues for the correct temporal form occur much earlier in the document then the sentence being translated. More research is needed on how to **incorporate features** explicitly or **guide systems** implicitly towards the right output with regard to aspectual information, and also on how to convincingly evaluate generated output with regard to aspectual plausibility.

7 Conclusion

This paper provides an overview of the linguistic concepts and terminology associated with aspect, and also surveys existing datasets and prior work in computational modeling of aspect. Because the expression of aspect varies across languages, the proper incorporation of aspect into downstream NLP tasks requires language-dependent research rooted in the language-independent categories surveyed here. The semantic concepts expressed by lexical and grammatical aspect play essential roles in semantic interpretation, and their proper coding and evaluation must not be neglected if we are to one day develop human-level NLU systems.

---

Limitations

This survey reviews linguistic and computational work on lexical and grammatical aspect. While we believe that we covered the vast majority of relevant computational works, we of course only scratch the surface of the body of theoretical linguistic work and need to simplify at times.

As the term *aspect* is highly ambiguous and used in NLP primarily within sentiment analysis, it is difficult to search for relevant papers. Our search hence relied mainly on following citation networks.

Ethical Considerations

We did not identify any potential ethical issues with this survey.

Acknowledgements

We thank the anonymous reviewers for their extremely valuable comments. This survey incorporates insights from countless extremely valuable discussions with many researchers and students. In particular, we thank Manfred Pinkal, Josef van Genabith, Bonnie Webber, Mark Steedman, Mike Lewis, Omri Abend, Melissa Peate Sorensen, Michaela Regneri, Andrea Horbach, Stefan Thater, Vera Demberg, Ines Rehbein, Caroline Sporleder, Fatemeh Torabi Asr, Asad Sayeed, Alessandra Zarcone, Hanna Kermes, Damyana Gateva, Anna Nedoluzhko, Michal Novák, Martha Palmer, and Laura Michaelis.

APPENDIX

A Glossary

This glossary intends to provide a concise alphabetically ordered overview of the linguistic terminology used in this paper.

accomplishment eventive / dynamic situation type according to (Vendler, 1957; Smith, 1997), consisting of a preparatory phase and an endpoint, e.g., “build a house.”

achievement eventive / dynamic situation type according to (Vendler, 1957; Smith, 1997) consisting only of the *punctual* event that changes a state, e.g., “win the race.”

activity eventive / dynamic situation type according to (Vendler, 1957; Smith, 1997), describes a process that does not have a pre-defined endpoint, e.g., “swim.”

atelic describes situations or verbs that do not have a built-in endpoint, e.g., “draw.”

bounded see *telic*.

covert describes linguistic categories that are not directly inferrable from the lexicon or from grammatical/syntactic structure (Whorf, 1945). They usually consist of *semantic* concepts that require taking into account the context or pragmatic factors.

durative describes states that extend in time.

dynamic describes a type of situation / verb that has a part to its meaning that applies a force or changes a state.

episodic describes particular events that “happen” or “have happened” (opposite of *habituals*).

eventive see *dynamic*.

habitual clause that expresses a situation that repeats regularly and expresses a characteristic, e.g., “John drives to work” or “Bishops move diagonally” (Krifka et al., 1995).

imperfective describes a perspective on a situation focusing one or none of the potential endpoints, but not both

iteratives clauses (usually with *semelfactive* verbs) that signal that the event expressed by the verb is executed a number of times, e.g., “the light flashed.”

overt describes linguistic categories that are directly inferrable from the lexicon or from grammatical/syntactic structures.

state a situation that is not changing, e.g., “John owns a house.”

stative describes verbs or situations that express a state.

perfective describes constructions that show a situation with its endpoint(s), e.g., “John traveled to the US (last week).”

progressive describes constructions that focus on a particular phase of a situation that is currently ongoing, e.g., “John is traveling to the US (at the moment).”

punctual event that occurs at a single point in time, e.g., “hiccup.” – *dynamic* by definition.

semelfactive *punctual* situation or event type (Smith, 1997).

telic describes situations or verbs that have a built-in endpoint, e.g., “capture.”

B Overview of Modeling Approaches

Table 3 gives a concise overview of existing modeling approaches.

C Further Linguistic Background

C.1 Eventuality Types

In Section 3.3, we explain a taxonomy of eventuality types according to Vendler (1957). As shown in Figure 2, Kenny (1963) adds *performances*, which are “actions that tend towards a goal.” Mourelatos (1978) criticizes that these earlier analyses focus too much on predicates that require human agency, and suggests the terminology in Figure 2.

As explained in Section 3.3, Moens and Steedman (1988) introduce an inventory of eventuality types similar to those of Vendler (1957), but referring to the characteristics of whether an event is *atomic*, *extended* (*durative*) and whether it has a *consequent state*. The definitions of the types along with examples are given in Table 4.

Type of Model	Reference(s)	Categories Targeted / Task
Rule-based	Passonneau (1988b) (PUNDIT)	stativity
	Chen et al. (2021)	UMR aspect features
Progressive as indicator	Klavans and Chodorow (1992b)	stativity
Linguistic indicators	Brent (1991b)	stativity
	Siegel and McKeown (1996, 2000b)	stativity, boundedness
Naive Bayes + Decision Tree	Mathew and Katz (2009)	habituality
Random Forest Classifiers	Friedrich and Pinkal (2015a)	habituality
Logistic regression	Friedrich and Palmer (2014a)	lexical aspect
	Loáiciga and Grisot (2016)	boundedness
	Friedrich and Gateva (2017)	telicity
	Zarcone and Lenci (2008)	Vendler types
Distributional models	Kober et al. (2020)	telicity
SVM	Keelan (2012)	Leech's classes
	Hermes et al. (2015, 2018)	Vendler classes
Max Ent Sequence Tagger	Palmer et al. (2007)	situation entity types
CRF	Friedrich and Pinkal (2015b)	genericity
	Friedrich et al. (2016)	situation entities
word2vec + GRU	Becker et al. (2017)	situation entity types
GloVe + GRU	Zellers and Choi (2017)	verb-level Vendler classes
Paragraph-level neural model	Dai and Huang (2018)	situation entity types
ELMO + MLP	Govindarajan et al. (2019)	habituality (continuous features, UDS-G)
BERT + classifiers	Metheniti et al. (2021); Metheniti (2022)	telicity
BERT + tagger	e.g., Kondratyuk and Straka (2019)	UD aspectual features
BERT, GPT, ParBERT	Rezaee et al. (2021)	situation entity types
Generative model	Gantt et al. (2022)	event types

Table 3: **Computational systems and approaches** to modeling aspect.

Vendler (1957)	*dynamic*	*durative*	*telic*	Moens and Steedman (1988)	*atomic event*	*extended event*	*consequent state*	**Examples**
State	-	+	-	state	NA	NA	NA	know the answer, love Mary, understand
Activity	+	+	-	process	-	+	-	laugh, stroll in the park, run, swim
Accomplishment	+	+	+	culminated process	-	+	+	build a house, walk to school
Achievement	+	-	+	culmination	+	-	+	win a race, reach the top, recognize
Semelfactive	+	-	-	point event	+	-	-	tap, knock, hiccup, wink

Table 4: **Eventuality** types (Vendler, 1957; Smith, 1997) / **Temporal Ontology** (Moens and Steedman, 1988).

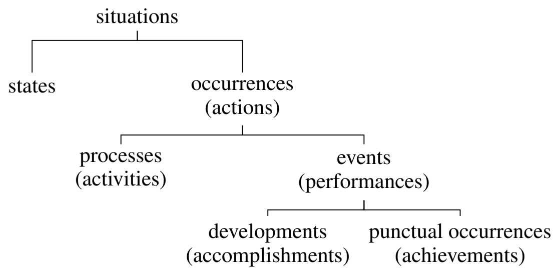

Figure 2: Classification of aspectual oppositions according to Mourelatos (1978), terms used by Vendler (1957) and Kenny (1963) in parentheses.

C.2 Leech's Classes

In addition to categories corresponding to those of Figure 2, Leech (1971) distinguishes between *Attitude* states ("hate," "hope") and *Relationship* states ("own," "resemble"). There are also two categories for *Perception* and *Cognition* verbs such as "hear," "see," or "feel," which are generally hard to classify along the stative-dynamic dimension (Comrie, 1976).

C.3 Details on Viewpoint Aspect

In some cases, viewpoint aspect (Section 4) and situation type interact. The perfective viewpoint is naturally available for the situation types (Section 3.3) activity, accomplishment, semelfactive and achievement; the imperfective viewpoint is available for states, activities and accomplishments (Smith, 1997). The usage of the perfective viewpoint with stative predicates indicates aspectual coercion as introduced in Section 3.3. For example, in Chinese the stative predicate "gāo" means to be tall. When used with the perfective marker "le," an ingressive meaning is implied, i.e., "tā gāo-le" translates as "he became tall."

C.4 Habituals: Borderline cases

Habitual sentences (Section 4.2) describe situations that are characteristic of an extended period of time (Comrie, 1976), a decision that is of conceptual rather than of linguistic nature. In fact, Filip and Carlson (1997) even argue that *sentential genericity*, which corresponds to habituality, is independent from tense and aspect, and that habitual sentences such as (14) can occur in the perfective.

(14) In the eighties, John went to work by bus.

The interaction of habituality and modality is by no means trivial (Hacquard, 2009) as illustrated by (15a), and negated sentences are another unclear case (15b-c).

(15) (a) I had to swim every day. *(habitual?)*
(b) John smokes. *(habitual)*
(c) John does not smoke. *(habitual?)*

The concept of habituality does not include *dispositional sentences* such as "John can swim," which denote abilities or preferences.

D Further Computational Background

D.1 Linguistic Indicators

Table 5 reports the full set of linguistic indicator features as proposed by Siegel and McKeown (2000b) and related works.

Feature	Example
frequency	-
past	*said*
perfect	*had won*
progressive	*is winning*
negated	*not/never*
particle	*up/in/...*
no subject	-
continuous adverb	*continually, endlessly*
evaluation adverb	*better, horribly*
manner adverb	*furiously, patiently*
temporal adverb	*again, finally*
in-PP	*in an hour*
for-PP	*for an hour*

Table 5: **Linguistic indicators** computed over large syntactically parsed text corpora (Siegel and McKeown, 2000b).

D.2 Aspect in UMR

As briefly described in Section 4.3, the UMR (Uniform Meaning Representation) (Van Gysel et al., 2021) framework approaches annotation of aspect from a typological perspective. Aspect is represented as an attribute for events in UMR, and since cross-linguistically languages mark aspect in different ways, both grammatically and lexically, the UMR aspect categories are arranged in a lattice. This allows UMRs to be annotated at the level of granularity that is most appropriate for a particular language.

SE type	Example
Eventualities	
STATE	The colonel owns the farm.
EVENT	John won the race.
REPORT	"...", said Obama.
General Statives	
GENERIC SENT.	The lion has a bushy tail.
GENERALIZING SENTENCE	Mary often fed the cat last year.
Abstract Entities	
FACT	(I know) that she refused the offer.
PROPOSITION	(I believe) that she refused the offer.
QUESTION	Who wants to come?
IMPERATIVE	Hand me the pen!

Table 6: Situation entity types (Smith, 2003).

The resulting lattice (Van Gysel et al., 2022) appears in Figure 3. The top-level of the lattice represents broad distinctions between aspect categories across languages, while the bottom level represents the finer distinctions.

D.3 Situation entity inventory

Table 6 provides the complete inventory of situation entity types. Section 5 offers a partial inventory, focusing on those categories for which aspect is a key determining property.

D.4 Event Classes in TimeBank

TimeML (Pustejovsky et al., 2003, 2010) events are "situations that occur or happen," but also include "states or circumstances in which something obtains or holds true." Thus, the usage of the term *event* denotes a *situation* in the sense of Smith (1997). In TimeML, tensed verbs, stative adjectives and event nominals that describe situations temporally located in the text can be marked with the categories shown in Table 7.

TimeML event classification corresponds to a word-sense level task. Saurí et al. (2005), in their event recognition system, simply assign the class that was most frequently observed for each verb type in the training data to events and reach an accuracy of 82.3% on TimeBank 1.2. The top-performing systems (Jung and Stent, 2013; Bethard, 2013; Chambers, 2013) of the 2013 TempEval challenge (UzZaman et al., 2013) use corpus-based features, WordNet synsets, parse paths and fea-

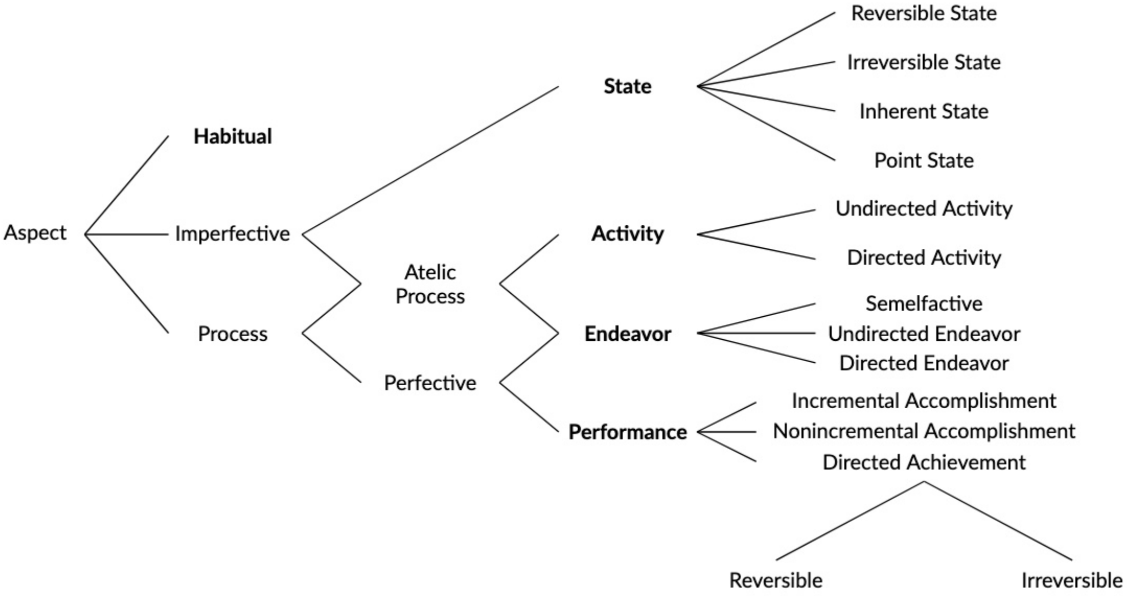

Figure 3: UMR annotation lattice for aspect (Van Gysel et al., 2022).

tures from typed dependencies to classify events as a joint task with determining the event's span. Bethard and Martin (2006) phrase the recognition of EVENTs and their semantic class as a chunking task using syntactic-semantic features such as part-of-speech, morphological information, word clusters and WordNet hypernyms. Llorens et al. (2010) extend this idea by using a conditional random field (Lafferty et al., 2001) enhanced with semantic role information. Costa and Branco (2012) explore the usefulness of a wider range of explicitly aspectual features, including linguistic indicators, for temporal relation classification in Portuguese.

More recent TempEval challenges (Bethard et al., 2016, 2017) did not offer a task for classifying event classes.

E (Potential) Applications

Despite its importance for understanding, few NLP tasks explicitly incorporate aspectual information. Here we discuss the potential uses in two application areas; many other areas could also benefit, including argumentation mining, computer-aided language learning, and information extraction.

Temporal Processing. Together with tense, aspect is essential to the linguistic system encoding temporal information (Smith, 1997, 2003). Yet there is little work systematically leveraging aspectual information in temporal relation extraction systems, possibly because TimeML event classes (Pustejovsky et al., 2003, 2010, Appendix D.4) are not strictly rooted in linguistic theory. We believe that recognizing the mode of discourse and the type of temporal progression (which is different e.g., in a narrative, an encyclopedia entry, or a news article) is key to recognizing temporal structure in text.

Event Class	Explanation and Examples
OCCURRENCE	situations that happen: *die, crash, merge*
STATE	circumstances in which sth. holds: *like, own, the kidnapped girl, on board*
I_ACTION	intensional actions: *try, persuade*
I_STATE	intensional states: *love, believe, enjoy*
ASPECTUAL	predicates that pick out a phase of the event: *begin, start, continue*
I_REPORTING	capture attribution: *said*
PERECPTION	physical perception of another event: *see, hear, feel*

Table 7: TimeML event classes (Pustejovsky et al., 2003).

With the help of templates, Vashishtha et al. (2020) re-cast existing temporal relation and temporal duration datasets as natural language inference (NLI) datasets. Existing models perform well on classifying English sentence-internal relations this way, indicating that the number of tense pair patterns is somewhat limited. However, using large-pretrained transformer based models with a paradigm shift (Sun et al., 2021) is unlikely to be the solution to temporal reasoning, as shown by Kober et al. (2021). They create a dataset consisting of 11,138 pairs of short sentences labeled with a binary annotation scheme (*entailment* vs. *non-entailment*), addressing tense and the perfect vs. progressive distinction in English. For example, "John is visiting London" entails "John has arrived in London," but "John will visit London" does not. They evaluate a range of models including non-contextualized and contextualized embeddings pre-trained on SNLI (Bowman et al., 2015) and DNC (Poliak et al., 2018) and find that none of these models outperforms a majority class baseline on the new dataset. This suggests that embedding spaces struggle to capture the more latent nature of tense and aspect.

In our view, a first step towards leveraging the knowledge about tense and aspect provided by linguistic theory could be to systematically study how recent language models and NLP systems succeed or fail with regard to these categories, as pioneered in the pre-neural age for example by Zhang and Xue (2014); Reichart and Rappoport (2010).

Machine Translation. While recent MT systems often perform well, they do not systematically treat aspectual notions (Vanmassenhove et al., 2017), but rather rely on common translations for a particular domain. Consider the following example. In contrast to English, the German simple present may or may not indicate habituality. When translating to English, a choice must be made based on the context. The translation[6] in (16b) wrongly indicates habitual viewpoint, while the context suggests an ongoing event (the correct translation would be "is riding").

(16) (a) Tim ist schon weg. Er fährt gerade mit dem Fahrrad zur Arbeit. *(ongoing event)*
(b) Tim is already gone. He just rides his bike to work. *(habitual, wrong)*

The cue need not be in the immediately preceding sentence, but could occur much earlier in the discourse. In (17), "fährt" should be translated as "is riding," but the cue is in the first sentence.

(17) (a) Tim ist schon weg. Er arbeitet an der Universität. Er fährt gerade mit dem Fahrrad zur Arbeit. *(ongoing event)*
(b) Tim is already gone. He works at the university. He just rides his bike to work. *(habitual, wrong[7])*

Aspect is a crucial component of semantic interpretation, and special care is needed to make sure translations correctly capture it.

F ChatGPT Logs

Accessed January 26 and 27, 2023.

In this section we provide logs from our interactions with ChatGPT on some of the main topics covered by this survey. Our aim is to investigate the extent to which a system like ChatGPT could serve as a tool for teaching about aspect; in other words, what does ChatGPT know about aspect?

Note that some of ChatGPT's analyses are surprisingly accurate, however, it also presents several completely wrong analyses and only produces correct analyses if guided to them by the user during the generation process.

Each subsection contains one or more segments from a chat log about a particular aspectual notion. We use the formatting shown below:

- *Prompt*
- Text generated by ChatGPT (with interesting parts highlighted in **bold**)
- *[Comments]*

F.1 Talking about Stativity

Consider the following text. "Alice was beginning to get very tired of sitting by her sister on the bank, and of having nothing to do: once or twice she had peeped into the book her sister was reading, but it had no pictures or conversations in it, and 'what is the use of a book,' thought Alice, 'without pictures or conversation?'" Which verb phrases refer to states, which verb phrases refer to events in this passage?

In this passage, "was beginning to get very tired" and "having nothing to do" are verb phrases that refer to states. "She had peeped" and **"had no pictures or conversations in it" are verb phrases that refer to events**.

[The verb phrases "have nothing to do" and "had no pictures or conversations in it" are states; "had peeped" is an event; "was beginning" is a special case at it signals the beginning of a state

---

[6] Google Translate, October 5, 2022

[7] Google Translate, October 19, 2022

(inchoative aspect). ChatGPT's response is simplistic and in some cases completely wrong.]

Why is "had no pictures or conversations in it" an event?

The phrase "had no pictures or conversations in it" is an event because it describes something that happened in the past, specifically that the book did not contain pictures or conversations. The verb "had" is in the past tense which indicates that **the action of the book not having pictures or conversations** is completed, and it happened in the past. An event can be a completed past action or something that is happening currently or in the future.

[...]

Could you interpret the phrase as a state as well?

It could be interpreted as a state in the sense that the book currently lacks pictures or conversations, however, in the context of the passage **it is clear that the author is describing a past event** where Alice had looked into the book and found that it did not contain pictures or conversations, **as opposed to the book being in a state of lacking pictures or conversations**. The past tense of the verb "had" and the context of Alice peeping into the book suggest it's an event that happened in the past. Additionally, the phrase "'what is the use of a book,' thought Alice, 'without pictures or conversation?'" also suggest that it's an event that happened in the past. So, it can be interpreted as a state, but in this context, it is more likely an event.

[*Even in this context, the verb phrase describes a state (a property of the book).*]

I agree that "peeped into the book" is an event. But what about "the book had no pictures in it"?

In the sentence "the book had no pictures in it", the phrase "had no pictures in it" describes the state of the book, specifically that it did not contain any pictures. The verb "had" is in the past tense, which indicates that this is a statement about the book's state at a specific point in the past. The phrase describes a state that existed at a certain point in the past. Even though "had" is in past tense, it is used to describe a state, not an event. Additionally, the phrase is not describing something that just happened, but a characteristic of the book, which implies a state.

[*This explanation is correct. However, the above conversation clearly illustrates that ChatGPT generates text explaining the aspectual nature of the various verb phrases without having a deeper understanding of their semantics and hence without being consistent in its relatively random interpretations.*]

Telicity is a property of an event type expressed by verbs, i.e., referring to events that have an endpoint. Atelic verbs refer to event types that do not have a built-in endpoint. Can you give me examples for each case?

Sure, here are some examples of telic verbs and the events they describe:

"She finished the book." (finish)

"He graduated from college." (graduate)

"They completed the project." (complete)

And here are some examples of atelic verbs and the events they describe:

"She is reading a book." (read)

"He is studying for the exam." (study)

"They are working on the project." (work)

[*These examples are correctly classified except for "read a book."*]

Why is the event type "read a book" atelic?

The event type "read a book" is considered atelic because it does not have a built-in endpoint. In other words, when someone says "She is reading a book," it does not necessarily imply that the act of reading will come to a definite conclusion. Reading a book can be an ongoing activity that may or may not be completed. **It does not have an inherent endpoint.**

[*Here, the analysis confuses between progressive aspect and analysing telicity at the event type (predicate) level. (Admittedly, this is a very fine-grained notion that humans also need to think carefully about.) In "She was reading a book", the event type "read a book" is telic, while the sentence in the progressive presents the ongoing situation of reading a book, hiding the end points.*]

Wouldn't the endpoint mean she finished reading the entire book?

Yes, in the sentence "She finished the book" the endpoint would mean she finished reading the entire book. The verb "finish" implies that an action has come to completion, so when it is used in the context of reading a book, it implies that the book has been read in its entirety. However, it's worth noting that some verbs can have multiple meanings and context can affect the interpretation of a sentence.

In contrast, when someone says "She is reading a book" it doesn't necessarily imply that the act of reading will come to a definite conclusion or that she will finish reading the entire book, she could stop reading at any time. And that's why the event is atelic.

I think the event is still telic, but the sentence focuses on a phase of it.

You are correct that the event of reading a book, in general, is telic, as it does have a natural endpoint, which is when the person finishes reading the book. However, when we use the verb "read" in the present progressive form "is reading," it describes the action as being ongoing and does not imply a definite conclusion. It describes the event as a phase or a state of being rather than a completed action.

So in the sentence "She is reading a book," the emphasis is on the current state of reading and not on the endpoint of finishing the book. The sentence "She finished the book" implies that the action of reading is completed and the verb "finish" implies that an action has come to completion.

So, in summary, while the overall event of reading a book is telic, in certain sentence constructions, such as "She is reading a book," the focus is on the ongoing state of the event, making it atelic.

[*The last part of the analysis is correct, except that the event of reading a book is always telic, and the progressive focuses on part of the situation. This does not make the event type atelic. The explanations given in this section focus more on the progressive vs. non-progressive distinction, not on the telic vs. atelic distinction.*]

F.2 Eventuality Types

(Prompted with the first two paragraphs of Section 3.3 of this paper including examples.)

Can you please analyse: "Tom held a meeting"

The sentence **"Tom held a meeting" is an example of an achievement** according to Vendler's (1957) classification of situation types. The sentence describes an event that has an endpoint, the meeting, and it is also a change of state. The verb "held" is also telic, meaning it has a specific endpoint and it does not include a process leading up to this point, which fits with the definition of an achievement. The phrase "held a meeting" implies that there was a start and an end to the meeting and it implies that it has been completed.

Can you please analyse: "Tom was holding a meeting"?

The sentence **"Tom was holding a meeting" is an example of an activity** according to Vendler's (1957) classification of situation types. The sentence describes an ongoing process of holding a meeting without any specific endpoint. The verb "was holding" is also atelic, meaning it does not have a specific endpoint, which fits with the definition of an activity. The phrase "holding a meeting" implies that there is a meeting in progress, but it does not specify when or if the meeting is completed.

[...]

[*The predicate "hold a meeting" is in fact an accomplishment, as it is dynamic, durative, and telic. The change in grammatical aspect from perfect to progressive does not change the underlying eventuality type. Again, the system seems to be misled by the progressive aspect.*]

Can you please analyse: "Anna was swimming across the lake"?

The sentence "Anna was swimming across the lake" is an example of an activity according to Vendler's (1957) classification of situation types. The sentence describes an ongoing process of swimming without any specific endpoint. The verb "was swimming" is also atelic, meaning it does not have a specific endpoint, which fits with the definition of an activity. **The phrase "across the lake" indicates that Anna is swimming over a significant distance, covering a large geographical area,** but the sentence does not specify when or if the journey is completed.

[*The default interpretation for this sentence is as an accomplishment, with the goal of reaching the other side of the lake. There is a second plausible, though less likely, interpretation in which Anna is engaged in the activity of swimming in a location that is across the lake from the speaker. ChatGPT proposes a third, highly-unlikely interpretation, akin to describing something as happening "all across the world."*]

Can you please analyse "Tim swam across the pool three times".

The sentence **"Tim swam across the pool three times" is an example of an accomplishment** according to Vendler's (1957) classification of situation types. The sentence describes a process (swimming) that leads to a built-in terminal point, the completion of swimming across the pool. The verb "swam" is telic, meaning it has a specific endpoint, which fits with the definition of an accomplishment. Additionally, the phrase "across the pool" indicates that Tim is swimming over a significant distance, covering a large geographical area and the sentence implies that the journey has been completed. The number "three times" indicates that the process was repeated a specific number of times, and it gives the sense that the accomplishment has been reached multiple times.

[*When substituting “pool” for “lake” and adding the frequency adverb “three times”, GPT’s interpretation of the event type of "swim across X" is correct, again hinting at the randomness of the generated explanations.*]

Incorporating Context into Subword Vocabularies

Abstract

Most current popular subword tokenizers are trained based on word frequency statistics over a corpus, without considering information about co-occurrence or context. Nevertheless, the resulting vocabularies are used in language models' highly contextualized settings. We present SAGE, a tokenizer that tailors subwords for their downstream use by baking in the contextualized signal at the vocabulary creation phase. We show that SAGE does a better job than current widespread tokenizers in keeping token contexts cohesive, while not incurring a large price in terms of encoding efficiency or domain robustness. SAGE improves performance on English GLUE classification tasks as well as on NER, and on Inference and NER in Turkish, demonstrating its robustness to language properties such as morphological exponence and agglutination.

BPE	_His _son _Raj ash ri _Sud h ak ar _has _p enn ed **_dial og ues** _and _songs _for _some _films _that _were _dubbed _into _Telugu .

Table 1: The token *og* is selected by BPE (vocabulary of size 16,000) for achieving the frequency objective, but is discarded by SAGE for failing to be contextually coherent. These examples from the corpus demonstrate some different contexts.

1 Introduction

Much of the research space in current NLP is focused on advancing models: modifying pre-training objectives, improving network architectures, adding tasks and schemes for downstream evaluation. Limited work is dedicated to a crucial step underlying all modern large language models (LLMs), namely the **tokenization** phase. In order to process a given string of text, an LLM must first obtain a vector representation of the input by segmenting it into tokens. Since out-of-vocabulary (OOV) items inhibit the performance of models, current tokenizers produce tokens which are possibly proper subsegments of input words, known as **subwords**. This method, popularized by systems such as WordPiece (Schuster and Nakajima, 2012), Byte-Pair Encoding (BPE; Sennrich et al., 2016) and UNIGRAMLM (Kudo, 2018), allows any word to be represented by one or more tokens, removing the OOV problem while allowing more flexibility in determining the token vocabulary size, which ultimately affects model speed (mostly through the softmax generation targets) and performance (through better ability to represent less-frequent words).

One potential pitfall of both BPE and UNIGRAMLM, as well as their proposed variants (He et al., 2020; Provilkov et al., 2020), is that they are trained on word frequency statistics alone, without considering information about word co-occurrence or contexts. At the same time, the resulting vocabularies are used in highly contextualized settings, the LLMs, where a single subword such as *og* might appear in very different contexts derived from words like *dial og ues* and *pseud og ene*. We propose a system which prepares subwords for their downstream use by baking in the contextualized signal **at the vocabulary creation step**. Our model, SAGE, uses the SKIPGRAM objective (Mikolov et al., 2013) over a corpus as the basis for iteratively eliminating candidate subwords from an initial large vocabulary until the desired vocabulary size has been reached. As Table 1 shows, SAGE succeeds in removing the ambiguous *og* token, facilitating distinct contextualization procedures for the example sentences

(taken from Wikipedia).

We present our algorithm, SaGe, which is predicated on iterative pruning of contextually noisy tokens from the vocabulary, and compare its effects on token properties and context cohesion with BPE both in- and out-of-domain, in English and Turkish. We then evaluate its performance on downstream tasks by training a BERT-based LLM (Devlin et al., 2019) on a vocabulary produced by both tokenizers in both languages, demonstrating substantial improvements on most English GLUE tasks and on NER, as well as Turkish NLI and NER. We emphasize that as opposed to most current tokenizer variants, our model is a "plug and play" substitution for any subword token vocabulary, requiring no modification in the inference protocol (or code) when pre-training or applying an applicable LLM from a popular shared library.[1]

2 Subword Vocabulary Creation

The methods used to tokenize corpus in order to later assign tokens with continuous vectors, or *embeddings*, have evolved over the years. Initially, each word in the corpus was assigned its own embedding (Collobert and Weston, 2008; Mikolov et al., 2013). OOVs, i.e. words not appearing in the original training corpus or below a certain frequency threshold, would receive a special (but identical) "UNK" vector. Subword tokenizers (Schuster and Nakajima, 2012; Wu et al., 2016) were introduced to alleviate this issue, allowing segmentation of all text into embeddable units (assuming no unseen characters, a much more relaxed constraint for languages using alphabetical scripts). The training process used to create a subword vocabulary from which the model then decodes text input involves optimizing an encoding objective over a large corpus. To date, all tokenizers used in practice in large models focus on efficiency and information-theoretic objectives, and reduce the corpus to a unigram frequency count of space-delimited words, reducing calculation time but losing all contextual signal. SaGe reintroduces the contextual dependencies between words into vocabulary creation via a two-stage process, namely over-application of BPE followed by iterative pruning using ideas inspired by UnigramLM and SkipGram. We briefly present these algorithms before tying them together into SaGe.

Algorithm 1 Byte-pair encoding vocabulary creation (Gage, 1994; Sennrich et al., 2016)

```
Input: Corpus $C$, Vocabulary final size $V$.
Output: Vocabulary $\mathcal{V}$ of size $V$ (ordered).
procedure BPE($C, V$)
    $\mathcal{V} \leftarrow$ All unique characters in $C$
    while $|\mathcal{V}| < V$ do                              ▷ Merge tokens
        $\langle t_L, t_R \rangle \leftarrow$ Most frequent bigram in $C$
        $t_{NEW} \leftarrow t_L \oplus t_R$                    ▷ Make new token
        $\mathcal{V} \leftarrow \mathcal{V} \oplus [t_{NEW}]$
        $C$.ReplaceAll($\langle t_L, t_R \rangle, t_{NEW}$)
    end while
return $\mathcal{V}$
end procedure
```

Byte-Pair Encoding. The BPE algorithm creates a vocabulary "bottom-up", starting with all single characters from the alphabet, iteratively adding tokens until reaching the desired vocabulary size. In each iteration, the added token is the concatenation of the most frequent adjacent pair of existing tokens (see Algorithm 1). The default setting of the algorithm's most popular implementation (Kudo and Richardson, 2018) restricts token addition within word boundaries, facilitating training from unigram frequencies. In addition, LLM tokenizers using BPE (Liu et al., 2019; Radford et al., 2019; Wolf et al., 2020) decode sequences not by applying merges by order of the vocabulary, as originally dictated by the algorithm, but through greedy largest-subsequence left-to-right inference.

Unigram Language Model. UnigramLM offers a top-down vocabulary creation process, starting with an initial vocabulary of all substrings in the input corpus and pruning tokens iteratively until reaching the desired vocabulary size. The pruning procedure involves calculating the overall unigram likelihood of the corpus with the current vocabulary versus a vocabulary lacking the candidate pruning token (see Algorithm 2 for details), which we refer to as the **ablation objective**. Under this system, decoding is ideally performed by considering probabilities of all possible segmentations using, e.g., the Viterbi algorithm; again, common practice is to use left-to-right greedy decoding.

Skipgram Objective. The SkipGram objective (Mikolov et al., 2013) formalizes the relation between a target token t and its context, asking whether context tokens c within a window W_t of pre-defined size can be predicted from t. These predictions are done via sigmoid activation over the inner product of embeddings trained for targets ($\boldsymbol{E}^{(T)}$) and contexts ($\boldsymbol{E}^{(C)}$). When aggregated over

Algorithm 2 UnigramLM vocabulary creation (Kudo, 2018). $n \arg\min_X$ denotes the n bottom-ranked elements in X.

```
Input: Corpus $C$, Vocabulary final size $V$, pruning batch size $k$.
Output: Vocabulary $\mathcal{V}$ of size $V$.
procedure UnigramLM($C, V$)
    $\mathcal{V} \leftarrow$ All substrings occurring more than once in $C$
    while $|\mathcal{V}| > V$ do                          ▷ Prune tokens
        $X^{(j)} \leftarrow$ tokenize($C$, $\mathcal{V}$)
        $\mathcal{L}(\mathcal{V}) \leftarrow \sum_{j=1}^{|C|} \log\left(P(X^{(j)})\right)$
        for all $t \in \mathcal{V}$ do:      ▷ Calculate ablation objective
            $loss_t \leftarrow \mathcal{L}(\mathcal{V} \setminus \{t\}) - \mathcal{L}(\mathcal{V})$
        end for
        $\mathcal{P} \leftarrow \min(k, |\mathcal{V}| - V) \arg\min_{t \in \mathcal{V}}(loss_t)$
        $\mathcal{V} \leftarrow \mathcal{V} \setminus \mathcal{P}$                          ▷ Prune
    end while
return $\mathcal{V}$
end procedure
```

Algorithm 3 SaGe vocabulary creation. $n \arg\min_X$ denotes the n bottom-ranked elements in X.

```
Input: Corpus $C$, Vocabulary final size $V$, basic tokenizer $\mathcal{T}$, overshoot factor $n$, pruning batch size $k$, likelihood recalculation frequency $m$, size of pruning candidate set $M$, embedding recalculation frequency $l$.
Output: Vocabulary $\mathcal{V}$ of size $V$.
procedure SaGe($C, V$)
    $\mathcal{V} \leftarrow \mathcal{T}(C, n \cdot V)$
    $i \leftarrow 0$
    while $|\mathcal{V}| > V$ do
        if $i \equiv 0 \pmod{l \times m}$ then
            $\boldsymbol{E}^{\mathcal{V}} \leftarrow$Word2Vec($\mathcal{V}$)          ▷ Embedding table
        end if
        $\mathcal{L}(\mathcal{V}, \mathcal{C}) \leftarrow$ SGObj($\boldsymbol{E}^{\mathcal{V}}, \mathcal{C}$) ▷ Total likelihood (1)
        if $i \equiv 0 \pmod{m}$ then              ▷ Update bottom set
            for all $t \in \mathcal{V}$ do:
                $loss_t \leftarrow \mathcal{L}(\mathcal{V} \setminus \{t\}, \mathcal{C}) - \mathcal{L}(\mathcal{V}, \mathcal{C})$
            end for
            $\mathcal{V}_{bot} \leftarrow M \arg\min_{t \in \mathcal{V}}(loss_t)$
        else                           ▷ Update losses for bottom set
            for all $t \in \mathcal{V}_{bot}$ do:
                $loss_t \leftarrow \mathcal{L}(\mathcal{V} \setminus \{t\}, \mathcal{C}) - \mathcal{L}(\mathcal{V}, \mathcal{C})$
            end for
        end if
        $\mathcal{P} \leftarrow \min(k, |\mathcal{V}| - V) \arg\min_{t \in \mathcal{V}_{bot}}(loss_t)$
        $\mathcal{V}_{bot} \leftarrow \mathcal{V}_{bot} \setminus \mathcal{P}$                         ▷ Prune
        $\mathcal{V} \leftarrow \mathcal{V} \setminus \mathcal{P}$
        $i \leftarrow i + 1$
    end while
return $\mathcal{V}$
end procedure
```

all tokens in a corpus, SkipGram can be used as a total likelihood measure, approximating its overall contextual cohesion:

$$\mathcal{L}(\mathcal{V}, \mathcal{C}) = -\sum_{t \in \mathrm{tok}(\mathcal{C}, \mathcal{V})} \sum_{c_j \in W_t} \log\left(\sigma(\boldsymbol{E}_t^{(T)} \cdot \boldsymbol{E}_{c_j}^{(C)})\right). \tag{1}$$

As token vocabularies or their inference methods change, so do the target sequences and their contexts, resulting in differences in aggregated likelihood which can then act as scores comparing one tokenization to another. We use this behavior as the ablation objective for SaGe.

3 SaGe Vocabulary Creation

SaGe[2] is a top-down tokenizer, following UnigramLM's general procedure, incorporating a SkipGram objective as its vocabulary trimming rule. Given an initial vocabulary $\mathcal{V}$ and a corpus $\mathcal{C}$, SaGe computes a SkipGram embedding space over $\mathcal{V}$ which provides it with an overall likelihood over $\mathcal{C}$ as in (1). It then proceeds to calculate the *loss* of each token in the vocabulary were it to be removed, eliminating the tokens incurring minimal loss and re-tokenizing the corpus according to the updated vocabulary, repeating this procedure until reaching the desired vocabulary size V. Having learned this vocabulary, downstream inference proceeds exactly as in the other segmentation-based methods, in a greedy left-to-right manner. SaGe can also be adapted to anticipate other decoding algorithms, by changing the re-tokenization steps accordingly.

In practice, applying the full process described above introduces multiple sources of considerable computational complexity: for example, calculating the ablation objective for each token in each iteration produces a quadratic amount of calculations over the entire corpus; recalculating embeddings for an updated vocabulary is similarly unreasonable to perform at each iteration. We ameliorate these and other sources of complexity using a series of heuristics found in preliminary experiments to be minimally disruptive to precision of likelihood calculations. We will now describe these heuristics, all depicted in Algorithm 3. First, instead of initializing the vocabulary as the full set of possible character sequences in the corpus, as in UnigramLM, we use any existing noncontextual tokenizer such as BPE to learn a vocabulary larger than V by a factor of n, and begin the pruning process from there. Next, instead of removing a single token from the bottom of the loss-ranked vocabulary, we remove a batch of the k bottom tokens

---

[2] The name is not an acronym; it is intended to evoke SkipGram while maintaining the “suffix” of *BPE*.

Sentence fragment	. . . use of an include directive is when referring to . . .

Tokenization using $\mathcal{V} \setminus \{\_\texttt{includ}\}$	_use _of _an _inc l u [de _direct **ive** _is _when] _ref er r ing _to

Table 2: The effect of retokenization on a context window of width 2 (in brackets) surrounding a target token (in bold). A left-side context token has been replaced as a result of an out-of-window vocabulary ablation.

each time, as does UNIGRAMLM.[3] To avoid frequent loss recalculation, we recompute the entire likelihood set once every m ablation steps, and only keep the bottom M tokens as pruning candidates for the next m steps. Our preliminary experiments support this decision, as we found the ranked list of losses tends to stay relatively stable over dozens of batch-pruning iterations. Lastly, to avoid the costly re-training of the embedding matrix for all tokens given the updated corpus, which only results in minor changes in likelihood during subsequent iterations, we only perform it every l iteration batches, i.e. after the ablation of $k \times m \times l$ tokens. n, k, l, m and M are all algorithm hyperparameters tuned empirically based on desired runtime, corpus size and vocabulary size.

Contextual Loss. In order to calculate the per-token SKIPGRAM likelihood loss, all sentences where a token t occurs need to be re-segmented according to $\mathcal{V} \setminus \{t\}$, and their new likelihoods recorded. To support performing this calculation on a large scale, we maintain a mapping of tokens to sentences containing them, as well as these sentences' current likelihoods. This must be done at the sentence level rather than the window level, since a remaining suffix from an out-of-window re-tokenization may combine with in-window characters and form different token sequence replacements at a given stage. Consider the example in Table 2, where re-tokenization results in the replacement of a context token for a distant target.

Negative Sampling. The original SKIPGRAM objective uses negative samples to estimate context probabilities. Since our application of SKIPGRAM within the vocabulary creation algorithm (independent of the embeddings training procedure) includes only likelihood estimation with no parameter updates, we do not sample negative tokens, a process which would introduce substantial noise and complexity.

4 SAGE Vocabulary Properties

For an analysis of our modified algorithm's advantages, we trained vocabularies of a pre-determined size using both BPE and SAGE. We selected $|\mathcal{V}| = 16,000$, and obtained corpora for English (750,000 lines from the August 2022 Wikipedia dump) and Turkish (the entire text of the September 2022 Wikipedia dump), opting for languages that share the Latin alphabet but differ in family (Indo-European vs. Turkic) and, crucially, in morphological properties: English is a low-exponence, low-synthesis language, while Turkish features multiple inflectional exponence and high verbal synthesis, as well as highly agglutinative morphology (Bickel and Nichols, 2013a,b). We used the following hyperparameter settings to compute the vocabularies: Initial vocab size $20,000$ (or $n = 1.25$), $l = 4$, $k = 100$, $M = 1500$, $m = 10$. We used the Gensim package to train the SKIPGRAM models (Rehurek and Sojka, 2011), and Sentencepiece (Kudo and Richardson, 2018) to obtain the initial BPE vocabularies.[4] More hyperparameters are detailed in Appendix A.

We present an analysis of the resulting vocabularies, highlighting the advantages and trade-offs exhibited by context-based subword tokenization. Generally speaking, most of the tokens discarded from SAGE's initial vocabulary appear in the baseline BPE's final vocabulary. Among the differences between the vocabularies are many short tokens that appear in BPE's but not SAGE's, proper substrings of longer tokens also appearing in the BPE vocabulary. This is due to BPE's bottom-up merge table construction, which forces retention of the entire chain of tokens created: if *the* is part of the vocabulary, either *th* or *he* must also be there. While essential for the original intended decoding process, actual implementations of greedy decoding have no need for this property. SAGE's initial vocabulary shares this characteristic, but the trimming process allows any token to be ablated,

---

[3] As in UNIGRAMLM and other ablation-based vocabularies, single-character tokens are never removed from the vocabulary, in order to allow for all in-alphabet words to be tokenized.

[4] Since BPE augments its vocabulary iteratively, the baseline BPE vocabulary is a proper subset of that used to initialize SAGE.

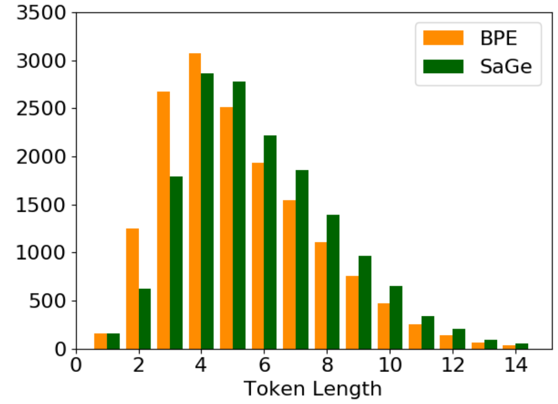

Figure 1: Token length distribution of BPE's vocabulary vs. SAGE's on English.

More frequent in

ing	ist	ings	ff
ation	ate	ations	ates

Table 3: Tokens with high difference in frequency between tokenizations (English models).

including those in the middle of merge chains. Another difference found between the vocabularies is the strong preference of SAGE for word-initial tokens. 83% of the tokens that appear in SAGE's vocabulary but not in BPE's are word-initial, compared to only 22% of the BPE-only tokens. This is reasonable, since a token surviving SAGE's ablation steps exhibits high loss for the condition of its removal, which is arguably the case when a nearby target word needs to predict a word-initial context.

Token Length. Figure 1 shows a histogram of token lengths (in characters) for the 16,000-token SAGE and BPE vocabularies in English (results on Turkish are similar). SAGE clearly selects longer tokens for its vocabulary, again a sensible outcome given their higher chance of being contextually coherent. The difference is most stark with tokens of length 2 and 3; when considering only tokens appearing in exactly one of the final vocabularies, we find that 56% of BPE-only tokens are of length 2 and 3, while 55% of SAGE-only tokens are of length 5 and above.

Token Frequency. We compute the frequency of tokens in the encoding form of the English training corpus, once using SAGE vocabulary and once using BPE's. In Table 3 we show some of the tokens with the biggest difference in frequency between SAGE and BPE tokenizations. We can see SAGE reverts to single-character tokens considerably more often than BPE (also demonstrated in the last example in Table 1). We view this as a feature of context-based tokenization—its vocabulary is partitioned between (mostly short) tokens that are highly ambiguous in context and (mostly long) tokens that have coherent contexts. At the same time, BPE is rife with tokens that are medially ambiguous contextually, whose resulting embeddings can be neither useful nor completely ignorable, adding noise to the representation sequences. As a result, SAGE breaks down complex suffixes, which in English are compositional, into their constituent morphology. The suffix *ings* is thus dismantled to *ing s*, whereas BPE reserves a token for it, mostly unhelpful in itself.

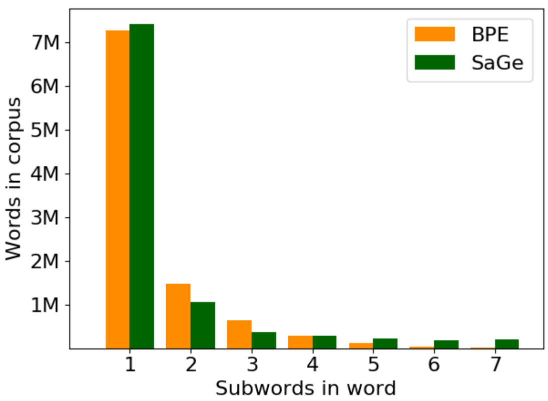

Figure 2: Number of subwords required to tokenize a word, collected over the original English training corpus.

Subword Fertility. Fertility, as defined in the statistical machine translation literature, refers to the average number of subwords produced per tokenized word. Figure 2 exhibits a histogram of all English corpus words by their subword length, using the BPE vocabulary and the SAGE vocabulary. Although SAGE retains more words as single tokens, it trades them off with more words having five subwords or more, compared with BPE's abundance of words with 2 and 3 subwords. This follows the trend described so far, of SAGE's preference for dismantling unknown words into meaningless single-character tokens rather than confusing, ambiguous length-2 and length-3 tokens. We believe that BPE's behavior harms text understand-

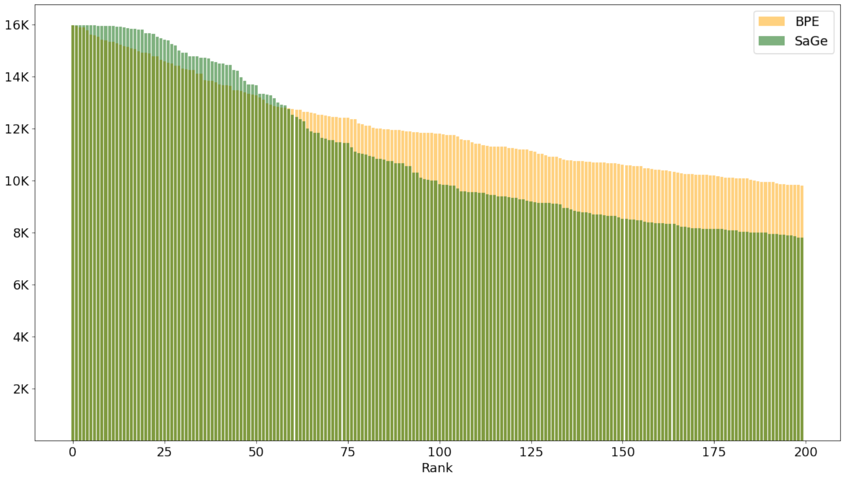

Figure 3: Number of distinct neighbors each token encounters in a width-5 window, top 200, Turkish.

ing in suggesting that these ambiguous fragments (consider "og") have some meaning that an LLM can try and learn, whereas SAGE's single-character breakdown indicates a word that's truly unknown and cannot be inferred by composing constituent in-vocab subwords.

Fertility translates to a trade-off in **encoding efficiency** to SAGE's contextual advantage: a sample of 150K lines from English Wikipedia is encoded by 4 million BPE tokens, optimizing only an information-theoretic objective, whereas SAGE produces 4.5 million. Having said that, this inefficiency might be further offset during LLM pretraining: we propose that contextually coherent tokens will require fewer update steps in order to achieve useful embedding parameters, helping the model converge faster compared to BPE tokens. We leave testing this hypothesis to future work.

Contextual Exponence. To determine the degree to which SAGE effectively optimizes tokens' contextual soundness, which is its ultimate goal, we plot the number of distinct neighbors each token encounters throughout the training corpus, ranked from high to low, in Figure 3. The very top of the ranking is occupied by single-character tokens which are context-null by design, which SAGE makes the most of by placing in almost all contexts. After a few dozen tokens, SAGE's context counts dip below BPE's, a trend which continues all the way through the vocabulary, making up a more contextually coherent set. These findings hold for English as well as Turkish, and replicate when taking a context window of size 2, different from that used during SAGE construction.

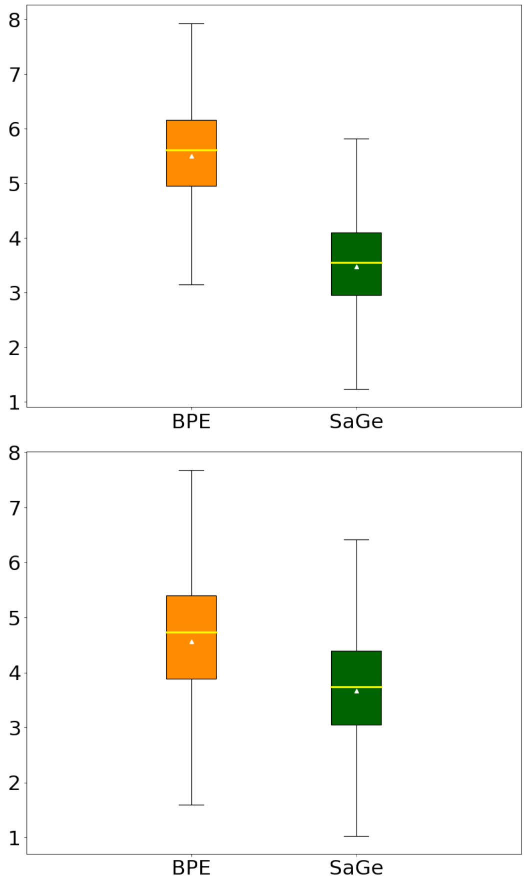

Figure 4: Distribution of token neighbors/frequency ratio for a width-5 window in English (top) and Turkish (bottom); BPE (left) and SAGE (right)

These findings can arguably be attributed to a frequency artifact, where SAGE simply outputs more tokens with lower frequency in order to provide them with fewer contexts. We thus present a normalized analysis in Figure 4, depicting the ratio between each token's number of unique neighbors and its frequency, distributed over the entire vocabulary. SAGE provides substantially lower ratios in both languages, supporting our original claim.

4.1 Robustness to Domain Change

One possible limitation of the SAGE objective is that it increases the reliance on the original training corpus compared to word-count-only algorithms. In and of itself, this should not necessarily be viewed as a problem, assuming the collected corpus is a faithful representative of an LLM's use case.[5] To this end, we collected comparable corpora from non-Wikipedia domains and ran our analysis on the SAGE and BPE vocabularies trained on Wikipedia. Our findings suggest that while SAGE loses its relative advantage in context-dependence over BPE, it does not fall behind it (i.e. it has not overfit to the Wikipedia domain). We present a fertility chart for an English corpus of 7.5M words from Quora questions[6] in Figure 5, depicting similar trends to that on Wikipedia (Figure 2) but with smaller differences between SAGE and BPE; the neighbor-to-frequency ratio aggregation chart in Figure 6 differs from Figure 4 (top) substantially but shows that SAGE and BPE tokens do not diverge significantly on this measure. We repeated the experiment on English legal text centered on US congress bills (Henderson et al., 2022) and on a 2.6M-word Turkish corpus of online reviews,[7] and observed similar trends.

These results indicate that while a considerable amount of the longer tokens preferred by SAGE were selected to optimize contextuality in the source domain, as it was designed to do, there is no "short blanket" effect for text originating in different domains. This could either be due to wide-scope advantages of some of the tokens selected by SAGE, or due to an intrinsic deficiency in BPE's long-tail tokens, or a combination of both.

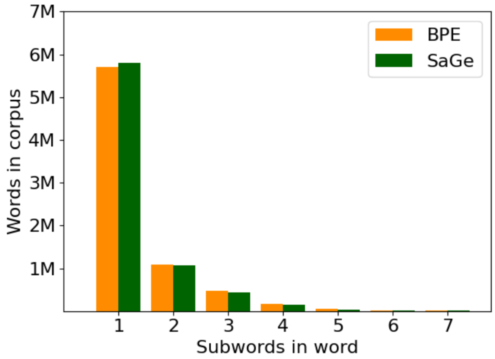

Figure 5: Number of subwords required to tokenize a word using the original Wikipedia-trained vocabularies, collected over a English Quora questions corpus.

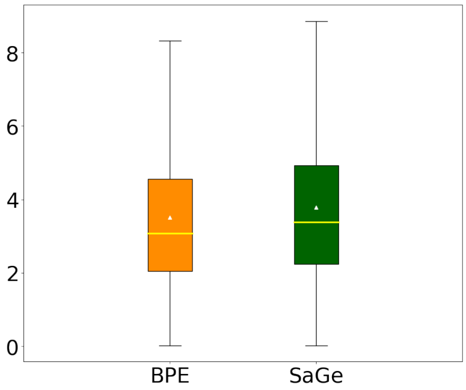

Figure 6: Distribution of token neighbors/frequency ratio for a width-5 window in English, based on a Wikipedia-trained vocabulary and collected over a English Quora questions corpus.

5 Downstream Evaluation

In order to evaluate the utility of our tokenization algorithm for major NLP tasks, we compare SAGE to a BPE vocabulary of the same size by means of pre-training a BERT-parameterized model (Devlin et al., 2019) using an expedited training scheme (Izsak et al., 2021). We then evaluate the LLM's performance both on sequence classification via the English GLUE benchmark (Wang et al., 2018) and the Turkish partition of XNLI (Conneau et al., 2018), and on named entity recognition in English (Wang et al., 2019) and Turkish (Al-Rfou et al., 2015). We use the default settings from Huggingface's library implementations of the fine-tuning processes (Wolf et al., 2020) and do not perform hyperparameter tuning for either model.

We present our results on sequence-level tasks in Table 4. SAGE tokenization improves performance on nearly all tasks with particularly sub-

---

[5] Indeed, existing literature recommends adding pre-training steps on new domains before fine-tuning models for them (e.g., Han and Eisenstein, 2019).

stantial improvements (1.3–8 accuracy points) on NLI datasets. Results on NER are presented in Table 5, again showing SAGE's dominance over BPE. Due to the length of the training pipeline leading from vocabulary creation through pre-training to fine-tuning, it is difficult to find individual examples where difference in tokenization leads to direct changes in prediction; we attribute the consistent overall gains in downstream performance mostly to the LLM pre-training step, where the design of SAGE's context-friendly vocabulary enables a more coherent contextual signal to flow through the transformer layers during backpropagation. We note that in general, our models fare worse on GLUE tasks compared to Izsak et al. (2021). We attribute this in part to the smaller token vocabulary size, and more substantially to the smaller pre-training corpus we used in our experiments.

6 Related Work

In recent years, a growing body of research has demonstrated the shortcomings of existing tokenization algorithms in the context of representing linguistic phenomena in different languages across different tasks (Banerjee and Bhattacharyya, 2018; Klein and Tsarfaty, 2020; Hakimi Parizi and Cook, 2020; Rust et al., 2021; Maronikolakis et al., 2021; Mielke et al., 2021; Hofmann et al., 2021), as well as the statistical properties affecting their downstream performance (Bostrom and Durrett, 2020). Our work addresses the concerns raised in this line of work by introducing an improved subword vocabulary creation method which leverages the contextual aspects of the main intended use case, namely LLMs. Previous work towards this goal includes algorithms which offer robustness within an existing subword vocabulary (Provilkov et al., 2020; He et al., 2020; Hiraoka, 2022), necessitating modification of either training, inference, or both procedures in the context of LLMs. Others have considered tuning the *size* of a subword vocabulary (Salesky et al., 2020), or selecting from an enlarged set of possible segmentations (Asgari et al., 2020), for optimizing performance on downstream tasks.

Some alternative tokenization methods focus on the application of a model which considers the expected downstream tasks together with the pretraining corpus (Hiraoka et al., 2020), to the degree of jointly optimizing the tokenizer with the downstream model (Hiraoka et al., 2021). In addition to the massive changes in training and inference procedures this approach incurs, we note that it is difficult to apply to large contextualized models due to the long path from tokenization to prediction; SAGE overcomes this problem by "nudging" only the LLM vocabulary itself towards a contextualization-friendly segmentation.

The concept of subword tokenization made its rise alongside that of contextualized representations, meaning that little work exists where SKIP-GRAM or other static models are trained over proper subword segmentations. Recently, Kaushal and Mahowald (2022) did so for a proof-of-concept of a spelling prediction model, in lieu of training full LLMs. To our knowledge, no work to date has used a static embedding-based objective to score token sequence likelihood for a separate task (as we do for vocabulary trimming).

Finally, we acknowledge the recent efforts to do away with tokenization altogether, be it through character-only (Clark et al., 2022) or byte-only (Xue et al., 2022) models, or through encoding characters visually and passing them through a vision model (Salesky et al., 2021; Rust et al., 2022).

These represent an even more radical departure from the established application of LLMs, and we look forward to testing their abilities against our improved contextual subword tokenization methods. We note that while these models have been facing issues regarding scaling, mostly on the decoding side, SAGE vocabularies are ready to be used immediately within existing popular LLM implementations. Furthermore, recent work has shown the limited utility of character-level transformers in semantic tasks, even for morphologically rich languages with nontrivial orthography-morphology relations (Keren et al., 2022).

7 Conclusion

In this work, we introduced SAGE, a context-aware tokenizer built using insights from BPE, UNIGRAMLM, and SKIPGRAM, and showed that it achieves better results when used in an LLM-pre-train-then-fine-tune schema on two typologically distant languages on both the sequence and token levels. We believe that further investigation into incorporating context in tokenization models can improve results even further, and intend to also extend our efforts toward other languages and writing systems, as well as to multilingual tokenizers. For example, we plan to apply SAGE in the context of Abjads like Hebrew and Arabic, as well as languages written in alphasyllabaries such as Devanagari.

Within SAGE itself, there is room for improvement. The algorithm is still relatively slow, taking roughly a day to run on a strong CPU, making it difficult to apply to a truly large corpus, to start from a larger initial vocabulary, or to conduct exhaustive search over the hyperparameters. We intend to keep optimizing it, and continue evaluation against other subword and character-only schemas.

Limitations

We acknowledge several limitations of SAGE, a novel algorithm still in its development stages. First, scaling the vocabulary creation framework up from corpus-level unigram statistics to context dependence incurs many points where linear factors turn into quadratic, and worse. We introduced several heuristics to alleviate this issue in §3, however SAGE still takes longer to train compared to BPE and other tokenizers, by roughly a factor of ten. While having no effect on downstream pre-training and fine-tuning steps, it does mean hyperparameters are more difficult to tune. Second, the prohibitive resources required to implement a full LLM pipeline has limited our downstream evaluation setup to ten individual tasks on two languages. Ideally, as more languages with more diverse scripts and typological properties are examined, better generalizations can be made about the utility of integrating context into subword tokenizer vocabularies. Finally, we still do not have a well-formed theory of integrating multiple domains, languages, or scripts together into a single vocabulary. This question has interested researchers in recent years (e.g., Chung et al., 2020; Rust et al., 2021; Zhang et al., 2022), yet a tokenizer-internal solution (as opposed to data balance manipulation) still seems to have eluded the community. This question affects SAGE more than other tokenizers, given its reliance on context, which changes starkly when considering multiple sources of text in unison.

Acknowledgments

We thank Jacob Eisenstein and Cassandra Jacobs for work on earlier versions of the high-level idea, and Timo Schick and Lütfi Kerem Senel for fruitful conversations in early stages of the project. We thank Marco Cognetta, Michael Elhadad, Omer Levy, and attendees of ISCOL 2022 for comments and suggestions on more recent versions of the work. We thank the reviewers for their helpful comments. We thank Kaj Bostrom, Peter Izsak, and Tamar Levy for helping us obtain and operate resources for training our models.

Abstract

Text Summarization is a popular task and an active area of research for the Natural Language Processing community. It requires accounting for long input texts, a characteristic which poses computational challenges for neural models. Moreover, real-world documents come in a variety of complex, visually-rich, layouts. This information is of great relevance, whether to highlight salient content or to encode long-range interactions between textual passages. Yet, all publicly available summarization datasets only provide plain text content. To facilitate research on how to exploit visual/layout information to better capture long-range dependencies in summarization models, we present *LoRaLay*, a collection of datasets for long-range summarization with accompanying visual/layout information. We extend existing and popular English datasets (arXiv and PubMed) with visual/layout information and propose four novel datasets – consistently built from scholar resources – covering French, Spanish, Portuguese, and Korean languages. Further, we propose new baselines merging layout-aware and long-range models – two orthogonal approaches – and obtain state-of-the-art results, showing the importance of combining both lines of research.

1 Introduction

Deep learning techniques have enabled remarkable progress in Natural Language Processing (NLP) in recent years (Devlin et al., 2018; Raffel et al., 2019; Brown et al., 2020). However, the majority of models, benchmarks, and tasks have been designed for unimodal approaches, i.e. focusing exclusively on a single source of information, namely plain text. While it can be argued that for specific NLP tasks, such as textual entailment or machine translation, plain text is all that is needed, there exist several tasks for which disregarding the visual appearance of text is clearly sub-optimal: in a real-world context (business documentation, scientific articles, etc.), text does not naturally come as a sequence of characters, but is rather displayed in a bi-dimensional space containing rich visual information. The layout of e.g. this very paper provides valuable semantics to the reader: in which section are we right now? At the blink of an eye, this information is readily accessible via the salient section title (formatted differently and placed to highlight its role) preceding these words. Just to emphasize this point, *imagine having to scroll this content in plain text to access such information.*

In the last couple of years, the research community has shown a growing interest in addressing these limitations. Several approaches have been proposed to deal with visually-rich documents and integrate layout information into language models, with direct applications to Document Understanding tasks. Joint multi-modal pretraining (Xu et al., 2021; Powalski et al., 2021; Appalaraju et al., 2021) has been key to reach state-of-the-art performance on several benchmarks (Jaume et al., 2019; Graliński et al., 2020; Mathew et al., 2021). Nonetheless, a remaining limitation is that these (transformer-based) approaches are not suitable for processing long documents, the quadratic complexity of self-attention constraining their use to short sequences. Such models are hence unable to encode global context (e.g. long-range dependencies among text blocks).

Focusing on compressing the most relevant information from long texts to short summaries, the Text Summarization task naturally lends itself to benefit from such global context. Notice that, in practice, the limitations linked to sequence length are also amplified by the lack of visual/layout information in the existing datasets. Therefore, in this work, we aim at spurring further research on how to incorporate multimodal information to better capture long-range dependencies.

Our contributions can be summarized as follows:

---

[*] Work partially done while at reciTAL.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 636–651
May 2-6, 2023 ©2023 Association for Computational Linguistics

- We extend two popular datasets for long-range summarization, arXiv and PubMed (Cohan et al., 2018), by including visual and layout information – thus allowing direct comparison with previous works;

- We release 4 additional layout-aware summarization datasets (128K documents), covering French, Spanish, Portuguese, and Korean languages;

- We provide baselines including adapted architectures for multi-modal long-range summarization, and report results showing that (1) performance is far from being optimal; and (2) layout provides valuable information.

All the datasets are available on HuggingFace.[1]

2 Related Work

2.1 Layout/Visually-rich Datasets

Document Understanding covers problems that involve reading and interpreting visually-rich documents (in contrast to plain texts), requiring comprehending the conveyed multimodal information. Hence, several tasks with a central layout aspect have been proposed by the document understanding community. *Key Information Extraction* tasks consist in extracting the values of a given set of keys, e.g., the *total amount* in a receipt or the *date* in a form. In such tasks, documents have a layout structure that is crucial for their interpretation. Notable datasets include FUNSD (Jaume et al., 2019) for form understanding in scanned documents, and SROIE (Huang et al., 2019), as well as CORD (Park et al., 2019), for information extraction from receipts. Graliński et al. (2020) elicit progress on deeper and more complex Key Information Extraction by introducing the Kleister datasets, a collection of business documents with varying lengths, released as PDF files. However, the documents in Kleister often contain single-column layouts, which are simpler than the various multi-column layouts considered in LoRaLay. *Document VQA* is another popular document understanding task that requires processing multimodal information (e.g., text, layout, font style, images) conveyed by a document to be able to answer questions about a visually rich document (e.g., *What is the date given at the top left of the form?*, *Whose picture is given in this figure?*). The DocVQA dataset (Mathew et al., 2021) and InfographicsVQA (Mathew et al., 2022) are commonly-used VQA datasets that respectively provide industry documents and infographic images, encouraging research on understanding documents with complex interplay of text, layout and graphical elements. Finally, to foster research on visually-rich document understanding, Borchmann et al. (2021) introduce the Document Understanding Evaluation (DUE) benchmark, a unified benchmark for end-to-end document understanding, created by combining several datasets. DUE includes several available and transformed datasets for VQA, Key Information Extraction and Machine Reading Comprehension tasks.

2.2 Existing Summarization Datasets

Several large-scale summarization datasets have been proposed to boost research on text summarization systems. Hermann et al. (2015) proposed the CNN/DailyMail dataset, a collection of English articles extracted from the CNN and The Daily Mail portals. Each news article is associated with multi-sentence highlights which serve as reference summaries. Scialom et al. (2020) bridge the gap between English and non-English resources for text summarization by introducing MLSum, a large-scale multilingual summarization corpus providing news articles written in French, German, Spanish, Turkish and Russian. Going toward more challenging scenarios involving significantly longer documents, the arXiv and PubMed datasets (Cohan et al., 2018) consist of scientific articles collected from academic repositories, wherein the paper abstracts are used as summaries. To encourage a shift towards building more abstractive summarization models with global content understanding, Sharma et al. (2019) introduce BIGPATENT, a large-scale dataset made of U.S. patent filings. Here, invention descriptions serve as reference summaries.

The vast majority of summarization datasets only deal with plain text documents. As opposed to other Document Understanding tasks (e.g., form understanding, visual QA) in which the placement of text on the page and/or visual components are the main source of information needed to find the desired data (Borchmann et al., 2021), text plays a predominant role in document summarization. However, guidelines for summarizing texts – espe-

---

[1] `https://hf.co/datasets/nglaura/arxivlay-summarization`, `https://hf.co/datasets/nglaura/pubmedlay-summarization`, `https://hf.co/datasets/nglaura/hal-summarization`, `https://hf.co/datasets/nglaura/scielo-summarization`, `https://hf.co/datasets/nglaura/koreascience-summarization`

cially long ones – often recommend roughly previewing them to break them down into their major sections (Toprak and Almacioğlu, 2009; Luo et al., 2019). This suggests that NLP systems might leverage multimodal information in documents. Miculicich and Han (2022) propose a two-stage method which detects text segments and incorporates this information in an extractive summarization model. Cao and Wang (2022) collect a new dataset for long and structure-aware document summarization, consisting of 21k documents written in English and extracted from WikiProject Biography.

Although not all documents are explicitly organized into clearly defined sections, the great majority contains layout and visual clues (e.g., a physical organization into paragraphs, bigger headings/subheadings) which help structure their textual contents and facilitate reading. Thus, we argue that layout is crucial to summarize long documents. We propose a corpus of more than 345K long documents with layout information. Furthermore, to address the need for multilingual training data (Chi et al., 2020), we include not only English documents, but also French, Spanish, Portuguese and Korean ones.

3 Datasets Construction

Inspired by the way the arXiv and PubMed datasets were built (Cohan et al., 2018), we construct our corpus from research papers, with abstracts as ground-truth summaries. As the PDF format allows simultaneous access to textual, visual and layout information, we collect PDF files to construct our datasets, and provide their URLs.[2]

For each language, we select a repository that contains a high number of academic articles (in the order of hundreds of thousands) and provides easy access to abstracts. More precisely, we chose the following repositories:

- Archives Ouverte HAL (French),[3] an open archive of scholarly documents from all academic fields. As HAL is primarily directed towards French academics, a great proportion of articles are written in French;
- SciELO (Spanish and Portuguese),[4] an open access database of academic articles published in journal collections from Latin America, Iberian Peninsula and South Africa, and covering a broad range of topics (e.g. agricultural sciences, engineering, health sciences, letters and arts). Languages include English, Spanish, and Portuguese.
- KoreaScience (Korean),[5] an open archive of Korean scholarly publications in the fields of natural sciences, life sciences, engineering, and humanities and social sciences. Articles are written in English or Korean.

Further, we provide enhanced versions of the arXiv and PubMed datasets, respectively denoted as arXiv-Lay and PubMed-Lay, for which layout information is provided.

3.1 Collecting the Data

Extended Datasets The arXiv and PubMed datasets (Cohan et al., 2018) contain long scientific research papers extracted from the arXiv and PubMed repositories. We augment them by providing their PDFs, allowing access to layout and visual information. As the abstracts contained in the original datasets are all lowercased, we do not reuse them, but rather extract the raw abstracts using the corresponding APIs.

Note that we were unable to retrieve all the original documents. For the most part, we failed to retrieve the corresponding abstracts, as they did not necessarily match the ones contained in the PDF files (due to *e.g.* PDF-parsing errors). We also found that some PDF files were unavailable, while others were corrupted or scanned documents.[6] In total, about 39% (35%) of the original documents in arXiv (PubMed) were lost.

arXiv-Lay The original arXiv dataset (Cohan et al., 2018) was constructed by converting the LaTeX files to plain text. To be consistent with the other datasets – for which LaTeX files are not available – we instead use the PDF files to extract both text and layout elements. For each document contained in the original dataset, we fetch (when possible) the corresponding PDF file using Google Cloud Storage buckets. As opposed to the original procedure, we do not remove tables nor discard sections that follow the conclusion. We retrieve the corresponding abstracts from a metadata file provided by Kaggle.[7]

[5] http://www.koreascience.or.kr

[6] For more details on this, see Section A.1 in the Appendix.

[7] https://www.kaggle.com/Cornell-University/arxiv

PubMed-Lay For PubMed, we use the PMC OAI Service[8] to retrieve abstracts and PDF files.

HAL We use the HAL API[9] to download research papers written in French. To avoid excessively long (e.g. theses) or short (e.g. posters) documents, extraction is restricted to journal and conference papers.

SciELO Using Scrapy,[10] we crawl the following SciELO collections: Ecuador, Colombia, Paraguay, Uruguay, Bolivia, Peru, Portugal, Spain and Brazil. We download documents written either in Spanish or Portuguese, according to the metadata, obtaining two distinct datasets: SciELO-ES (Spanish) and SciELO-PT (Portuguese).

KoreaScience Similarly, we scrape the KoreaScience website to extract research papers. We limit search results to documents whose publishers' names contain the word *Korean*. This rule was designed after sampling documents in the repository, and is the simplest way to get a good proportion of papers written in Korean.[11] Further, search is restricted to papers published between 2012 and 2021, as recent publications are more likely to have digital-born, searchable PDFs. Finally, we download the PDF files of documents that contain an abstract written in Korean.

3.2 Data Pre-processing

For each corpus, we use the 95th percentile of the page distribution as an upper bound to filter out documents with too many pages, while the 5th (1st for HAL and SciELO) percentile of the summary length distribution is used as a minimum threshold to remove documents whose abstracts are too short. As our baselines do not consider visual information, we only extract text and layout from the PDF files. Layout is incorporated by providing the spatial position of each word in a document page image, represented by its bounding box (x_0, y_0, x_1, y_1), where (x_0, y_0) and (x_1, y_1) respectively denote the coordinates of the top-left and bottom-right corners. Using the PDF rendering library Poppler[12], text and word bounding boxes are extracted from each PDF, and the sequence order is recovered based on heuristics around the document layout (e.g., tables, columns). Abstracts are then removed by searching for exact matches; when no exact match is found, we use `fuzzysearch`[13] and `regex`[14] to find near matches.[15] For the non-English datasets, documents might contain several abstracts, written in different languages. To avoid information leakage, we retrieve the abstract of each document in every language available – according to the API for HAL or the websites for SciELO and KoreaScience – and remove them using the same strategy as for the main language. In the case an abstract cannot be found, we discard the document to prevent any unforeseen leakage. The dataset construction process is illustrated in Section A in the Appendix.

3.3 Datasets Statistics

The statistics of our proposed datasets, along with those computed on existing summarization datasets of long documents (Cohan et al., 2018; Sharma et al., 2019) are reported in Table 1. We see that document lengths are comparable or greater than for the arXiv, PubMed and BigPatent datasets.

For arXiv-Lay and PubMed-Lay, we retain the original train/validation/splits and try to reconstruct them as faithfully to the originals as possible. For the new datasets, we order documents based on their publication dates and provide splits following a chronological ordering. For HAL and KoreaScience, we retain 3% of the articles as validation data, 3% as test, and the remaining as training data. To match the number of validation/test documents in HAL and KoreaScience, we split the data into 90% for training, 5% for validation and 5% for test, for both SciELO datasets.

4 Experiments

4.1 Models

For reproducibility purposes, we make the models' implementation, along with the fine-tuning and evaluation scripts, publicly available.[16]

We do not explore the use of visual information in long document summarization, as the focus is on evaluating baseline performance using state-of-the-art summarization models augmented with layout information. While visual features might provide a better understanding of structures such as tables and figures, we do not expect substantial gains with

KoreaScience	37,498	3,192	95

Table 1: Datasets statistics. Article and summary lengths are computed in words. For KoreaScience, words are obtained via white-space tokenization. Difference between arXiv and arXiv-Lay is due to the fact that we retain the whole document, while Cohan et al. (2018) truncate it after the conclusion.

respect to layout-aware models. Indeed, the information provided in figures (i.e., information that cannot be captured by layout or text) are commonly described in the caption or related paragraphs.

Text-only models with standard input size We use Pegasus (Zhang et al., 2020) as a text-only baseline for arXiv-Lay and PubMed-Lay. Pegasus is an encoder-decoder model pre-trained using gap-sentences generation, making it a state-of-the-art model for abstractive summarization. For the non-English datasets, we rely on a finetuned MBART as our baseline. MBART (Liu et al., 2020) is a multilingual sequence-to-sequence model pretrained on large-scale monolingual corpora in many languages using the BART objective (Lewis et al., 2019). We use its extension, MBART-50 (Tang et al., 2020),[17] which is created from the original MBART by extending its embeddings layers and pre-training it on a total of 50 languages. Both Pegasus and MBART are limited to a maximum sequence length of 1,024 tokens, which is well below the median length of each dataset.

Layout-aware models with standard input size We introduce layout-aware extensions of Pegasus and MBART, respectively denoted as Pegasus+Layout and MBART+Layout. Following LayoutLM (Xu et al., 2020), which is state-of-the-art on several document understanding tasks (Jaume et al., 2019; Huang et al., 2019; Harley et al., 2015), each token bounding box coordinates (x_0, y_0, x_1, y_1) is normalized into an integer in the range [0, 1000]. Spatial positions are encoded using four embedding tables, namely two for the coordinate axes (x and y), and the other two for the bounding box size (width and height). The layout representation of a token is formed by summing the resulting embedding representations The final representation of a token is then obtained through point-wise summation of its textual, 1D-positional and layout embeddings.

Long-range, text-only models To process longer sequences, we leverage BigBird (Zaheer et al., 2020), a sparse-attention based Transformer which reduces the quadratic dependency to a linear one. For arXiv-Lay and PubMed-Lay, we initialize BigBird from Pegasus (Zaheer et al., 2020) and for the non-English datasets, we use the weights of MBART. The resulting models are referred to as BigBird-Pegasus and BigBird-MBART. For both models, BigBird sparse attention is used only in the encoder. Both models can handle up to 4,096 inputs tokens, which is greater than the median length in PubMed-Lay, HAL and KoreaScience.

Long-range, layout-aware models We also include layout information in long-range text-only models. Similarly to layout-aware models with standard input size, we integrate layout information into our long-range models by encoding each token's spatial position in the page. The resulting models are denoted as BigBird-Pegasus+Layout and BigBird-MBART+Layout.

Additional State-of-the-Art Baselines We further consider additional state-of-the-art baselines for summarization: i) the text-only T5 (Raffel et al., 2019) with standard input size, ii) the long-range Longformer-Encoder-Decoder (LED) (Beltagy et al., 2020), and iii) the layout-aware, long-range LED+Layout, which we implement similarly to the previous layout-aware models.

4.2 Implementation Details

We initialize our Pegasus-based and MBART-based models with, respectively, the google/pegasus-large and facebook/mbart-large-50 checkpoints shared through the Hugging Face Model Hub. As for T5 and LED, we use the weights from t5-base and allenai/led-base-16384, respectively.[18]

Following Zhang et al. (2020) and Zaheer et al. (2020), we fine-tune our models up to 74k (100k) steps on arXiv-Lay (PubMed-Lay). On HAL, the total number of steps is set to 100k, while it is de-

---

[17] For the sake of clarity, we refer to MBART-50 as MBART.

[18] The large versions of T5 and LED did not fit into GPU due to their size.

Dataset	Instances			Input Length		Output Length	
	Train	Dev	Test	Median	90%-ile	Median	90%-ile
arXiv (Cohan et al., 2018)	203,037	6,436	6,440	6,151	14,405	171	352
PubMed (Cohan et al., 2018)	119,924	6,633	6,658	2,715	6,101	212	318
arXiv-Lay	122,189	4,374	4,356	6,225	12,541	150	249
PubMed-Lay	78,234	4,084	4,350	3,761	7,109	182	296
HAL	43,379	1,384	1,385	4,074	8,761	179	351

KoreaScience	35,248	1,125	1,125	2,916	5,094	219	340

Table 2: Datasets splits and statistics. Input and output lengths are computed in tokens, obtained using Pegasus and MBART-50's tokenizers for the English and non-English datasets, respectively.

creased to 50k for the other non-English datasets.[19] For each model, we select the checkpoint with the best validation loss. For Pegasus and MBART models, inputs are truncated at 1,024 tokens. For BigBird-Pegasus models, we follow Zaheer et al. (2020) and set the maximum input length at 3,072 tokens. As the median input length is much greater in almost every non-English dataset, we increase the maximum input length to 4,096 tokens for BigBird-MBART models. Output length is restricted to 256 tokens for all models, which is enough to fully capture at least 50% of the summaries in each dataset.

For evaluation, we use beam search and report a single run for each model and dataset. Following Zhang et al. (2020); Zaheer et al. (2020), we set the number of beams to 8 for Pegasus-based models, and 5 for BigBird-Pegasus-based models. For the non-English datasets, we set it to 5 for all models, for fair comparison. For all experiments, we use a length penalty of 0.8. For more implementation details, see Section B.1 in the Appendix.

5 Results and Discussion

5.1 General Results

In Table 3, we report the ROUGE-L scores obtained on arXiv and PubMed datasets (reported by Zaheer et al. (2020)), as well as on the corresponding layout-augmented counterparts we release. [20] On arXiv-Lay and PubMed-Lay, we observe that, while the addition of layout to Pegasus does not improve the ROUGE-L scores, there are gains in integrating layout information into BigBird-Pegasus. To assess whether these gains are significant, we perform significance analysis at the 0.05 level using bootstrap, and estimate a ROUGE-L threshold that predicts when improvements are significant. ROUGE-L improvements between each pair of models are reported in Table 11 in the appendix. On arXiv-Lay, we compute a threshold of 1.48 ROUGE-L, showing that BigBird-Pegasus+Layout significantly outperforms all Pegasus-based models. In particular, we find a 1.56 ROUGE-L improvement between BigBird-Pegasus and its layout-augmented counterpart, demonstrating that the addition of layout to long-range modeling significantly improves summarization. On PubMed-Lay, we compute a threshold of 1.77. Hence, the 0.96 ROUGE-L improvement from BigBird-Pegasus to its layout-augmented counterpart is not significant. However, the variance in font sizes in PubMed-Lay is much smaller compared to arXiv-Lay (see Table 12 in the appendix), reflecting an overall more simplistic layout. Therefore, we argue that layout integration has a lesser impact in PubMed-Lay, which can explain the non-significance of results. In addition, we find that BigBird-Pegasus significantly outperforms Pegasus and Pegasus+Layout only when augmented with layout, with an improvement of, respectively, 2.3 and 2.2 points. This demonstrates the importance of combining layout and long-range modeling.

While T5 and LED obtain competitive results, we find that the gain in adding layout to LED is minor. However, the models we consider have all been pre-trained only on plain text. As a result, the layout representations are learnt from scratch during fine-tuning. Similarly to us, Borchmann et al. (2021) show that their layout-augmented T5 does not necessarily improve the scores, and that performance is significantly enhanced only when the model has been pre-trained on layout-rich data.

Further, we observe, for both Pegasus and BigBird-Pegasus, a drop in performance w.r.t. the scores obtained on the original datasets. This can be explained by two factors. First, our extended

---

[19] We tested different values for the number of steps (10k, 25k, 50k, 100k) and chose the one that gave the best validation scores for MBART.

[20] For detailed results, please refer to Section C.1 in the Appendix.

Model	# Params	arXiv/ arXiv-Lay	PubMed/ PubMed-Lay
Pegasus (Zhang et al., 2020)	568M	38.83	41.34
BigBird-Pegasus (Zaheer et al., 2020)	576M	41.77	42.33

KoreaScience (ko)	73.53	70.26	68.78

Table 5: Percent confidence obtained for the main language, for each dataset split.

datasets contain less training data due to the inability to process all original documents. Secondly, the settings are different: while the original arXiv and PubMed datasets contain clear discourse information (e.g., each section is delimited by markers) obtained from LaTeX files, documents in our extended versions are built by parsing raw PDF files. Therefore, the task is more challenging for text-only baselines, as they have no access to the discourse structure of documents, which further underlines the importance of taking the structural information, brought by visual cues, into account.

Table 4 presents the ROUGE-L scores reported on the non-English datasets. On HAL, we note that BigBird-MBART does not benefit from layout. After investigation, we hypothesize that this is due to the larger presence of single-column and simple layouts, which makes layout integration less needed. On both SciELO datasets, we notice that combining layout with long-range modeling brings substantial improvements over MBART. Further, we find that the plain-text BigBird models do not improve over the layout-aware Pegasus and MBART on arXiv-Lay and SciELO-ES, demonstrating that simply capturing more context does not always suffice. Regarding performance on KoreaScience, we can see a significant drop in performance for every model w.r.t the other non-English datasets. At first glance, we notice a high amount of English segments (e.g., tables, figure captions, scientific concepts) in documents in KoreaScience. To investigate this, we use the cld2 library[21] to detect the language in each non-English document. We consider the percent confidence of the top-1 matching language as an indicator of the presence of the main language (i.e., French, Spanish, Portuguese or Korean) in a document, and average the results to obtain a score for the whole dataset. Table 5 reports the average percent confidence obtained on each split, for each dataset. We find that the percentage of text written in the main language in KoreaScience (i.e., Korean) is smaller than in other datasets. As the MBART-based models expect only one language in a document (the information is encoded using a special token), we claim the strong presence of non-Korean segments in KoreaScience causes them to suffer from interference problems. Therefore, we highlight that KoreaScience is a more challenging dataset, and

(a) Article length (b) Summary length (c) σ of bounding box height

Figure 1: Benefit of using layout on arXiv-Lay (blue) and PubMed-Lay (red), defined as the difference in ROUGE-L scores between BigBird-Pegasus+Layout and BigBird-Pegasus. For each dataset, quartiles are calculated from the distributions of article lengths (a), summary lengths (b) and variance in the height of the bounding boxes (c). ROUGE-L scores are then computed per quartile range, and averaged over each range.

we hope our work will boost research on better long-range, multimodal *and* multilingual models.

Overall, results show a clear benefit of integrating layout information for long document summarization.

5.2 Human Evaluation

Metric	**BigBird**	**BigBird+Layout**
Precision %	35.15 (0.81)	37.51 (0.70)
Recall %	28.07 (0.73)	33.59 (0.86)
Coherence	3.80 (0.38)	3.75 (0.62)
Fluency	4.48 (0.03)	4.34 (0.16)
Overlap %	8.77 (0.24)	7.49 (0.36)
Flow %	30.75 (0.68)	33.02 (0.71)

Table 6: Average human judgement scores obtained by comparing gold-truth abstracts and summaries generated by BigBird and BigBird+Layout from 50 documents sampled from arXiv-Lay and HAL. Inter-rater agreement is computed using Krippendorff's alpha coefficient, and enclosed between parentheses.

To gain more insight into the effect of document layout for summarizing long textual content, we conduct a human evaluation of summaries generated by BigBird-Pegasus/BigBird-MBART and their layout-aware counterparts. We choose the BigBird-based models over the LED ones, as the gain in augmenting BigBird with layout is much more apparent. We evenly sample 50 documents from arXiv-Lay and HAL test sets, filtering documents by their topics (computer science) to match the judgment capabilities of the three human annotators. We design an evaluation interface (see Section C.2 in the appendix). For each sentence s_i in the generated summary, we ask the annotators to highlight the relevant tokens in s_i, along with the equivalent parts in the ground-truth abstract (denoted h_i). Further, we ask them to rate the summary in terms of coherence and fluency, on a scale of 0 to 5, following the DUC quality guidelines (Dang, 2005). Finally, annotators are asked to penalize summaries with hallucinated facts. The highlighting process allows us to compute precision and recall as the percentage of highlighted information in the generated summary and the ground-truth abstract, respectively. Moreover, we can compute an overlap ratio as the percentage of highlighted information that appears several times in the generated summary. Lastly, we calculate a flow percentage that evaluates how well the order of the ground-truth information is preserved by computing the percentage of times where the highlighted text h_i in the gold summary for one generated sentence s_i follows the highlighted text h_{i-1} for the previous sentence s_{i-1} (i.e. where any token from h_i occurs after a token in h_{i-1}). Table 6 reports the scores for each metric and model, averaged over all 50 documents, along with inter-rater agreements, computed using Krippendorff's alpha coefficient. We find that adding layout to the models significantly improves precision and recall, results in less overlap (repetition), and is more in line with the ground truth order. Further, annotators did not encounter any hallucinated fact in the 50 generated summaries. To conclude, reported results show that human annotators strongly agree that adding layout generates better summaries, further validating our claim that layout provides vital information for summarization tasks.

5.3 Case Studies

To have a better understanding of the previous results, we focus on uncovering the cases in which layout is most helpful. To this end, we identify features that relate to the necessity of having layout: 1) article length, as longer texts are intuitively easier to understand with layout, 2) summary length, as longer summaries are likely to cover more salient information, and 3) variance in font sizes (using the height of the bounding boxes), and, as such, the complexity of the layout. The benefit of using layout is measured as the difference in ROUGE-L scores between BigBird-Pegasus+Layout and its purely textual counterpart, on arXiv-Lay and PubMed-Lay. We compute quartiles from the distributions of article lengths, ground-truth summary lengths, and variance in the height of bounding boxes.[22] Based on the aforementioned factors, the scores obtained by each model are then grouped by quartile range, and averaged over each range, see Figure 1. On arXiv-Lay, we find that layout brings most improvement when dealing with the 25% longest documents and summaries, while, for both datasets, layout is least beneficial for the shortest documents and summaries. These results corroborate our claim that layout can bring important information about long-range context. Concerning the third factor, we see, on PubMed-Lay, that layout is most helpful for documents that have the widest ranges of font sizes, showcasing the advantage of using layout to capture salient information.

6 Conclusion

We have presented LoRaLay, a set of large-scale datasets for long-range and layout-aware text summarization. LoRaLay provides the research community with 4 novel multimodal corpora covering French, Spanish, Portuguese, and Korean languages, built from scientific articles. Furthermore, it includes additional layout and visual information for existing long-range summarization datasets (arXiv and PubMed). We provide adapted architectures merging layout-aware and long-range models, and show the importance of layout information in capturing long-range dependencies.

7 Limitations

The proposed corpus is limited to a single domain, that of scientific literature. Such limitation arguably extends to the layout diversity of documents. In terms of risks, we acknowledge the presence of Personally Identifiable Information such as author names and affiliations; nonetheless, such information is already voluntarily made public by the authors themselves.

LoRaLay: A Multilingual and Multimodal Dataset for *Long Range* and *Layout*-Aware Summarization – Appendix

A Datasets Construction

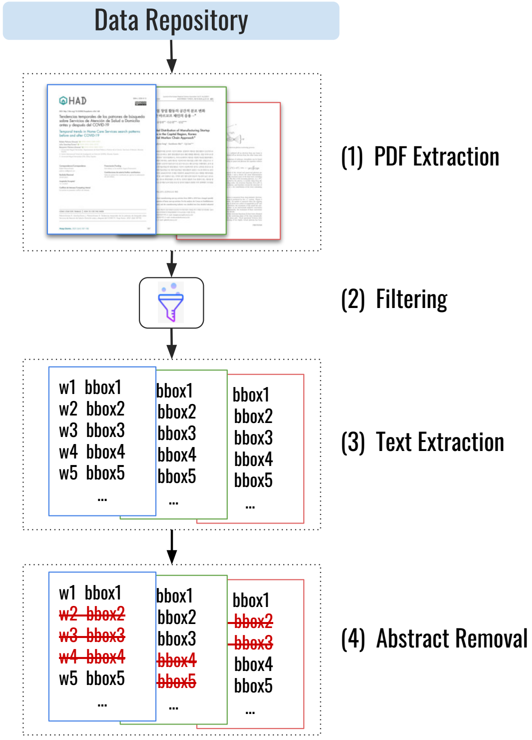

Figure 2: Dataset Construction Process.

A.1 Extended Datasets – Lost Documents

Figure 3 provides details on the amount of original documents lost in the process of augmenting arXiv and PubMed with layout/visual information. We observe four types of failures, and provide numbers for each type:

- The link to the document's PDF file is not provided (*Unavailable PDF*);
- The PDF file is corrupted (i.e., cannot be opened) (*Corrupted PDF*);
- The document is not digital-born, making it impossible to parse it with PDF parsing tools (*Scanned PDF*);
- The document's abstract cannot be found in the PDF (*Irretrievable Abstract*).

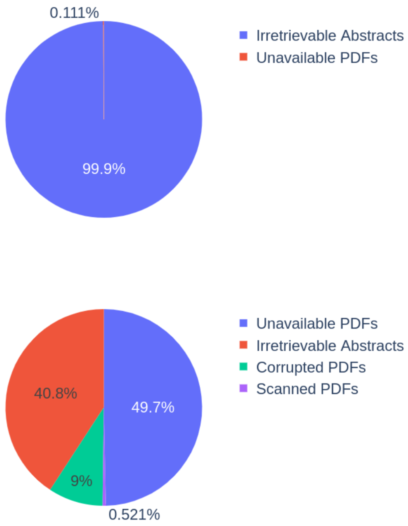

Figure 3: Distribution of failure types in arXiv-Lay (top) and PubMed-Lay (bottom).

A.2 KoreaScience – Extraction Rule

Korean documents in KoreaScience are extracted by restricting search results to documents containing the word "Korean" in the publisher's name. We show that this rule does not bias the sample towards a specific research area. We compute the distribution of topics covered by all publishers, and compare it to the distribution of topics covered by publishers whose name contains the word *Korean*. Figure 4 shows that the distribution obtained using our rule remains roughly the same as the original.

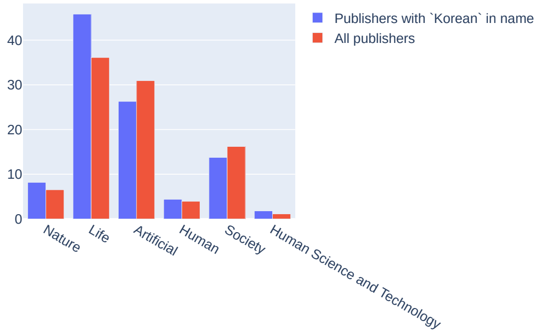

Figure 4: Distribution of topics covered by all publishers (red) vs distribution of topics covered by publishers whose name contains the word *Korean* (blue).

A.3 Samples

We provide samples of documents from each dataset in Figure 5.

A.4 Datasets Statistics

The distribution of research areas in arXiv-Lay and HAL are provided in Figures 6 and 7, respectively. Such distributions are not available for the other datasets, as we did not have access to topic information during extraction.

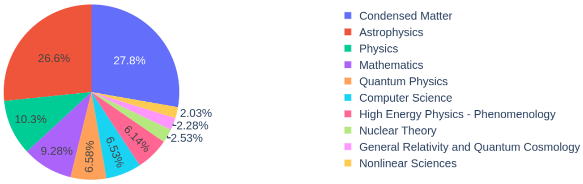

Figure 6: Distribution of research areas in arXiv-Lay.

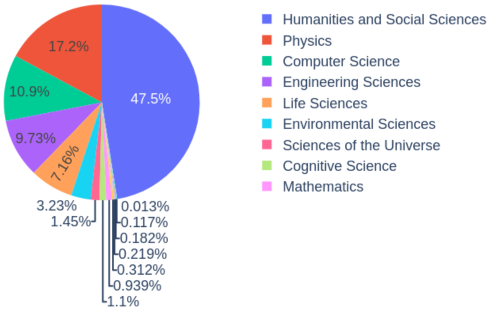

Figure 7: Distribution of research areas in HAL.

B Experiments

B.1 Implementation Details

Models were implemented in Python using PyTorch (Paszke et al., 2017) and Hugging Face (Wolf et al., 2019) librairies. In all experiments, we use Adafactor (Shazeer and Stern, 2018), a stochastic optimization method based on Adam (Kingma and Ba, 2014) that reduces memory usage while retaining the empirical benefits of adaptivity. We set a learning rate warmup over the first 10% steps – except on arXiv-Lay where it is set to 10k consistently with Zaheer et al. (2020), and use a square root decay of the learning rate. All our experiments have been run on four Nvidia V100 with 32GB each.

Statistical Learning of Arbitrary Computable Classifiers

Ground-truth abstract

Statistical learning theory chiefly studies restricted hypothesis classes, particularly those with finite Vapnik-Chervonenkis (VC) dimension. The fundamental quantity of interest is the **sample** complexity: the **number** of **samples** required to **learn** to a **specified level** of **accuracy.** Here we consider **learning** over the set of all computable labeling functions. Since the VC-dimension is infinite and a priori (uniform) **bounds** on the **number** of **samples** are impossible, we let the **learning** algorithm decide when it has seen sufficient **samples** to have learned. We first show that **learning** in this setting is indeed possible, and develop a **learning** algorithm. We then show, however, that bounding **sample** complexity independently of the distribution is impossible. Notably, this impossibility is entirely due to the requirement that the **learning** algorithm be computable, and not due to the **statistical** nature of the problem.

You selected the following sentence generated by Model B. Highlight the parts in the sentence that can be found in the ground-truth abstract.

Conventional statistical learning theory attempts to bound the number of samples needed to learn to a specified level of accuracy for each of the above models (e.g. neural networks, support vector machines).

Summary generated by Model B

	Sentence	Precision (%)
☑	Conventional statistical learning theory attempts to bound the number of samples needed to learn to a specified level of accuracy for each of the above models (e.g. neural networks, support vector machines).	40.62
☐	However, if we allow ourselves to change the model, then the VC-dimension of the overall learning algorithm is not finite, and much of statistical learning theory does not directly apply.	16.67
☐	In contrast, we prove that distribution-independent bounds do not exist altogether for computable learning algorithms in our setting.	72.22
☐	Our results imply that computable learning algorithms in the universal setting must "waste samples" in the sense of requiring more samples than is necessary for statistical reasons alone.	0.0

Abstract

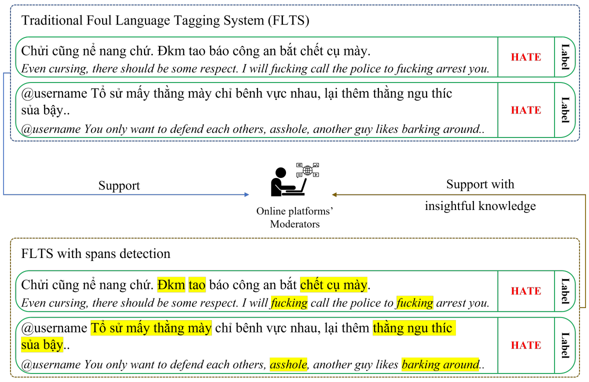
The rise in hateful and offensive language directed at other users is one of the adverse side effects of the increased use of social networking platforms. This could make it difficult for human moderators to review tagged comments filtered by classification systems. To help address this issue, we present the ViHOS (**Vi**etnamese **H**ate and **O**ffensive **S**pans) dataset, the first human-annotated corpus containing 26k spans on 11k comments. We also provide definitions of hateful and offensive spans in Vietnamese comments as well as detailed annotation guidelines. Besides, we conduct experiments with various state-of-the-art models. Specifically, XLM-R$_{Large}$ achieved the best F1-scores in Single span detection and All spans detection, while PhoBERT$_{Large}$ obtained the highest in Multiple spans detection. Finally, our error analysis demonstrates the difficulties in detecting specific types of spans in our data for future research. Our dataset is released on GitHub[1].

Disclaimer: This paper contains real comments that could be considered profane, offensive, or abusive.

1 Introduction

Social networking sites have been widely used all over the world. Here, users can easily share their thoughts, connect with others, or earn money by selling items, creating content, and so on. Since these sites are universally accepted, many extreme users misuse comment functions to abuse other individuals or parties with hate and offensive language. Consequently, it has been proved that these types of speech could harm other users' health (Mohan et al., 2017; Anjum et al., 2018). Sometimes these behaviors can be considered cyberbullying, cyber threats, or online harassment.

However, current studies are mainly about classifying comments as a whole with binary labels (Zampieri et al., 2019; Nguyen et al., 2021b) or multiple labeling schemes of abusive behaviors (Davidson et al., 2017; Founta et al., 2018; Mathur et al., 2018). These efforts are made to aid human moderators, who need to review a massive number of online tagged comments that violate their community standards. However, a system that can highlight the spans that make a comment hateful or offensive can be more advantageous to human moderators who frequently deal with long and tedious comments and prefer explanations over a system-generated unexplained tag per comment. Furthermore, in some cases, using highlighted spans and moderators' context knowledge, they can take some actions to stop cyberbullying or online harassment. Nevertheless, there is only a study on toxic spans, SemEval-2021 Task 5: Toxic Spans Detection (Pavlopoulos et al., 2021). On the other hand, in a study of Mathew et al. (2020), hate and offensive spans worked as a rationale to support models in classifying the whole comments.



Chửi cũng nể nang chứ. Đkm tao báo công an bắt chết cụ mày.
Even cursing, there should be some respect. I will fucking call the police to fucking arrest you.

@username Tổ sử mấy thằng mày chỉ bênh vực nhau, lại thêm thằng ngu thíc sủa bậy..
@username You only want to defend each others, asshole, another guy likes barking around..

Figure 1: An example of the aid of spans detection for traditional foul language tagging system can provide additional insightful knowledge about tagged comments for human moderators.

In Vietnamese, the resources about hate and offensive language are limited, namely ViHSD (Luu et al., 2021), HSD-VLSP (Vu et al., 2020), and UIT-ViCTSD (Nguyen et al., 2021b). Indeed, there

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 652–669
May 2-6, 2023

is no study about hate and offensive spans in Vietnamese. This motivated us to (i) develop a new task of extracting hate and offensive spans from Vietnamese social media texts that conceivably impact research and downstream applications and (ii) provide the Natural Language Processing (NLP) research community with a new dataset for recognizing hate and offensive spans in Vietnamese social media texts.

Our two main contributions are summarized:

1. We created the first human-annotated dataset for Vietnamese Hate and Offensive Spans (ViHOS) comprising 26,467 human-annotated spans on 11,056 comments. Our dataset is annotated with a clear definition of hate and offensive spans, along with detailed and specialized guidelines for a less-studied language like Vietnamese. Compared to the toxic spans dataset at SemEval-2021 Task 5 (Pavlopoulos et al., 2021), which is built to detect toxic spans from toxic comments, or the HateXplain dataset (Mathew et al., 2020), which has spans working as a rationale for classifying the whole sentence, ours includes not only a large number of texts with annotated hate and offensive spans but also clean texts without any spans. This effort is made to serve a new task of detecting hate and offensive spans from Vietnamese online social media comments.

2. To evaluate the efficacy of our dataset, strong baselines are empirically investigated on ViHOS, including BiLSTM-CRF (Lample et al., 2016), XLM-R (Conneau et al., 2019), and PhoBERT (Nguyen and Nguyen, 2020). We conducted various experiment schemas, including comparing the full dataset having additional clean comments with the dataset that does not have; Single span detection, Multiple spans detection, and All spans detection. We obtain that: (i) Additional clean comments help the baselines have better performance than the dataset without them for 10±2% (ii) After fine-tuning the deep learning model and pre-trained language models, results show that the pre-trained language models outperform the deep learning models.

2 Related work

To the best of our knowledge, much of the research in the field of hate speech detection has been conducted in English due to the abundance of corpora and the robust pre-trained models. Many benchmark datasets for hate and offensive speech in other languages have also been published in recent years, including Arabic (Mubarak et al., 2020), Dutch (Tulkens et al., 2016), and French (Chiril et al., 2019). Novel models are introduced to improve the efficiency of hate and offensive speech detection. Initial approaches were based on typical machine learning and deep neural networks with word embeddings. Transformer-based models such as BERT (Devlin et al., 2018), BERTology (Rogers et al., 2020), and BERT-based transfer learning (Ruder et al., 2019) have recently been used to detect hate and offensiveness that achieved competitive results in major SemEval shared tasks such as SemEval-2020 Task 12 (Zampieri et al., 2020), and SemEval-2021 Task 5 (Pavlopoulos et al., 2021). However, research in Vietnamese is still limited in terms of the dataset and experimental methods. Only a few outstanding research exist, such as ViHSD (Luu et al., 2021), HSD-VLSP (Vu et al., 2020), and UIT-ViCTSD (Nguyen et al., 2021b).

For the topic of detecting foul spans, there are only a few case studies in English that are closely related, namely the SemEval-2021 Task 5: Toxic Spans Detection dataset (Pavlopoulos et al., 2021) and the HateXplain dataset (Mathew et al., 2020). The toxic spans, defined in the SemEval-2021 Task 5 dataset, are the sequences of words that make a text toxic. There are a total of 10,629 posts in this dataset, which stems from the Civil Comments dataset (Borkan et al., 2019). Another dataset with hate and offensive spans at the word level is HateXplain. The HateXplain contains 20,148 Gab and Twitter posts. Each post is manually classified into one of three labels: hateful, offensive, and normal.

In this study, we focus on Vietnamese to close the gap and **develop the first Vietnamese hate and offensive spans detecting benchmark**.

3 Dataset Creation

3.1 Dataset Source

ViHOS consists of 11,056 comments derived from the ViHSD dataset (Luu et al., 2021). The Vietnamese Hate Speech Detection dataset (ViHSD) is one of the few large and credible social media text datasets in a low-resource language like Vietnamese. ViHSD contains 27,624, 3,514, and 2,262 of CLEAN, HATE, and OFFENSIVE comments, respectively. Comments in ViHSD are public and collected from social media platforms.

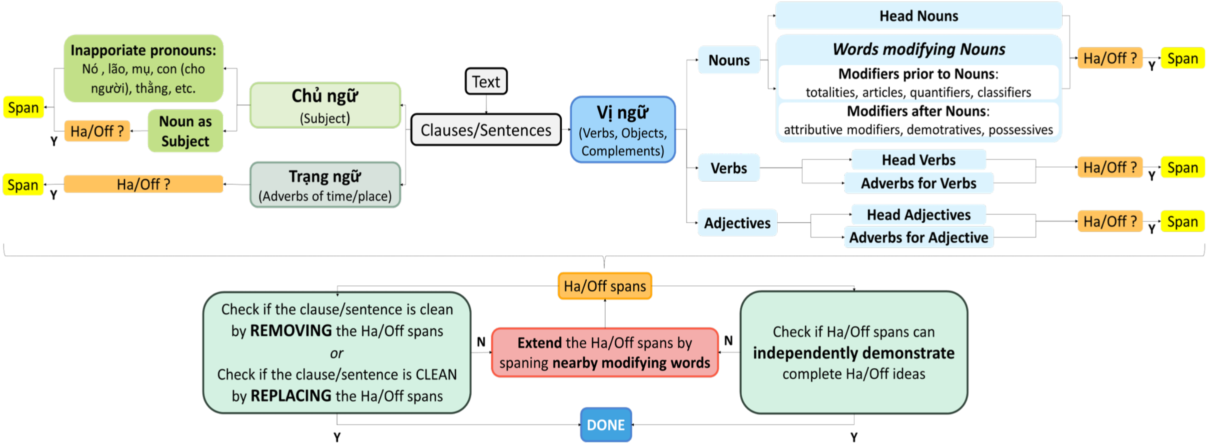

Figure 2: Detailed annotation guidelines for annotating comments for annotators. In which, *Ha/Off?* stands for a requirement for annotators to check whether the associated components are hate (Ha) or offensive (Off) or not.

Thus, metaphors, idioms, proverbs, and other tricky characteristics of online comments abound.

All of the HATE, OFFENSIVE comments from ViHSD after removing duplicates (5,528 comments left) are used to annotate the hate and offensive spans. Otherwise, 5,528 CLEAN comments, which also come from ViHSD and do not violate any hate or offensive definition defined in Section 3.2, are manually annotated for our dataset. We append the 5,528 CLEAN comments because: (*) We aim to detect the hate and offensive spans directly in online comments; (**) With an equal number of span and non-span (clean) comments helps models not be biased towards any type.

3.2 Annotation Guidelines

Our goal is to create a dataset that contains comprehensive hate and offensive thoughts, meanings, or opinions within the comments rather than just a lexicon of hate and offensive terms. We define the hate or offensive spans as follows to help annotators understand our goals:

- Harassing, cursing, insulting, disrespecting others.
- Sexual or verbal abuse towards one or a group of individuals based on their sensitive characteristics such as region, religion, politics, body, gender, etc.
- Insinuations, metaphors, metonymy used for hate, offensive or controversial purposes on sensitive issues such as region, gender, religion, politics, human rights, etc.
- Disuniting any factions or parties based on their politics, religion, ideologies, genders, etc.
- Causing verbal disrespect by using inappropriate pronouns.
- If replaced or removed, the sentence will no longer be hateful or offensive.

However, the hate or offensiveness in Vietnamese comments might cover one or even many components of a sentence. For instance: "thằng ad thở ra cái tư duy như trẻ lớp mầm" (**Eng:** *the admin speaks as his mind just like a kindergarten boy.)* This comment consists of three nouns/nouns phrases: "thằng ad"$_{\textit{the admin}}$ (it is offensive when calling a guy as a "thằng") as subject; "cái tư duy"$_{\textit{mind}}$ (the appearance of the word "cái" causes this noun phase become offensive) and "trẻ lớp mầm"$_{\textit{kindergarten boy}}$ as objects; one verb: "thở" (it usually means *breathe*, but in this context, we could consider it as *speak* but in a hate manner). As defined above, we must annotate a part of the subject, "thằng," and the whole phrase of the verb with its objects, "thở ra cái tư duy như trẻ lớp mầm" (**Eng:** *speaks as his mind just like a kindergarten boy*) in order to capture the whole hate or offensive ideas.

Therefore, we provided detailed guidelines (Figure 2) to assist annotators in determining when to annotate one or multiple components in a hateful and offensive sentence. As we observed, most of the comments in our dataset are colloquial. These comments are written freely and lack many grammatical rules. As a result, we frequently witness comments that lack subject(s), verb(s), conjunc-

	Phase 1				**Phase 2**	**Phase 3**
	1^{st}	**2^{nd}**	**3^{rd}**	**4^{th}**		
Kappa score	0.4161	0.4568	0.4936	0.6402	0.7239	0.7215
F1-score	0.7085	0.7186	0.7534	0.8219	0.8219	0.8585

Table 1: Inner-annotator agreement scores in three phases of annotation. In which, 1^{st}, 2^{nd}, 3^{rd}, 4^{th} are corresponding with four rounds of training annotators in Phase 1.

tions, punctuation marks, and so on. To deal with this, the comments were split into clauses/sentences (units). The smallest subdivided unit must have at least a cluster of "Chủ ngữ"-"Vị ngữ" ("Subject"-"Verb, objects, complements"), which is considered as a simple sentence or clause, or a cluster of "Chủ ngữ"-"Vị ngữ" nesting in another "Chủ ngữ"-"Vị ngữ" as a complex sentence or clause. From this, annotators can recognize components in clauses or sentences before annotating them.

Furthermore, in Appendix A and Appendix B, we also provided notices for annotators in Table 9 and ways to help them deal with nine online foul linguistic phenomena in Table 8 while annotating the data.

3.3 Dataset Construction Process

For dataset construction, we conducted three phases in which Phases 2 and 3 were inspired by Truong et al. (2021) and used metrics as bellow to calculate Inter-Annotator Agreement (IAA) among annotators. LightTag (Perry, 2021) is the tool we used for annotating data.

Assessment of Inter-Annotator Agreement Cohen's Kappa is widely used to measure inter-annotator agreement (IAA) in most tasks and is accepted as the standard measure (McHugh, 2012). However, numerous studies indicated that Kappa is not the most proper measure for the NLP sequence tagging task like NER (Hripcsak and Rothschild, 2005; Grouin et al., 2011). The reason is that the definite number of negative cases required to calculate the Kappa does not exist for named entity spans. Spans in our task are the sequences of characters rather than sequences of tokens since hate and offensive spans could be icon(s), word(s), or distinct character set(s) (see Table 8 for more details). Therefore, the pre-existing fixed number of characters to consider in the process of annotating is not existent.

A solution to deal with this is to calculate a character-level-based Kappa. Still, it has two associated problems: (1) annotators need to look at sequences of one or more characters instead of characters alone, causing the Kappa not to reflect the annotation task well; and (2) the "O"-labeled characters (the negative cases) outnumber the hate and offensive ones (the positive cases), provoking the Kappa to be computed on highly imbalanced data. For these reasons, the F1-score calculated without the negative cases is usually the measure for calculating IAA for the NLP tagging tasks like NER (Deleger et al., 2012). In this paper, IAA based on both F1-score (macro average) and character-level-based Kappa are calculated, while the former is the primary measure.

Phase 1: Pilot Annotation

Six undergraduate students were hired for our annotation tasks. The primary purpose of this pilot annotation phase was to familiarize our annotators with this task before entering the Main Annotation phase. We then developed an initial version of annotation guidelines with examples and distributed them to annotators. All annotators were required to carefully study the guidelines and give feedback before annotating the same 100 random samples from the 5,528 HATE, OFFENSIVE comments from ViHSD. This process was conducted four times with the F1-score and the Kappa for measuring IAA, which was calculated by averaging the results of pairwise comparisons across all annotators, shown in Table 1. All annotators were qualified as there was no F1-score of pairwise comparisons below 0.8.

Phase 2: Ground Truth Annotation

We randomly sampled a Ground Truth set of 600 comments from the 5,528 HATE, OFFENSIVE comments for this phase. Two guideline developers annotated the Ground Truth set separately using the well-developed guidelines from the former phase, resulting in an F1-score of 0.86 and Kappa (Cohen's Kappa) of 0.72. Afterward, we hosted a discussion to deal with annotation conflicts and update the annotation guidelines.

Phase 3: Main Annotation

We split the remaining HATE and OFFENSIVE

	Train	Dev	Test
Number of clean comments	4,552	569	575
Number of Ha/Off comments	4,422	553	553
Average clean comments length	8.69	8.50	9.04
Average Ha/Off comments length	16.81	17.68	16.13
Clean comments vocabulary size	4,234	1,423	1,400
Ha/Off comments vocabulary size	5,162	2,089	2,013
Number of multi-span comments (%)	2,322 (26.26)	308 (27.85)	296 (26.76)
Number of single-span comments (%)	1,970 (22.27)	229 (20.70)	235 (21.25)
Number of non-span comments (%)	4,552 (51.47)	569 (51.45)	575 (51.99)
Average number of spans	2.10	2.09	2.00

Table 2: ViHOS statistics. Vocabularies size and comments length are calculated at the syllable level.

comments (Luu et al., 2021) (4,928 comments left) into six non-overlapping and equal subsets. We also divided the 600-sample Ground Truth set from Phase 2 into six equal 100-sample smaller sets to insert into each subset. Each well-trained annotator from Phase 1 received a subset to annotate. Their annotation performance was assessed by calculating the F1 score and the Kappa score of the 100-sample Ground Truth sets in their subset. If any score is below 0.81 in terms of the F1 score, its corresponding annotator has to annotate again until it meets the requirement. This process was completed with an F1-score of 0.86 in the mean.

Furthermore, our annotators manually annotated CLEAN comments from ViHSD to spot any hate and offensive spans before being added to our dataset. This process collected 5,528 additional clean comments that met our requirements of having no hate and offensive spans.

3.4 Dataset Statistics

Before conducting dataset analysis and experiments, ViHOS has a total of 11,056 comments after the annotation process and is divided into three subsets: train, development, and test, with an 8:1:1 ratio. In detail, ViHOS has 5,360 comments with hate and offensive spans and 5,696 clean comments without in which 5,528 comments were additionally added and 168 comments have no hate and offensive spans after Phase 3 in the annotation process. Table 2 contains more information on the ViHOS statistics. It is apparent that the vocabulary of ViHOS is medium-sized, which is due to the small number of words in comments and comments in our dataset. In addition, more statistics about spans in ViHOS are shown in Table 3.

		Train	Dev	Test

4 Experiments and Results

4.1 Baseline Models

We treat the task of detecting hate and offensive spans as a task of sequence tagging. As a result, we make use of IOB format (Ramshaw and Marcus, 1995) to tag characters for model training, and testing. We conduct experiments on a set of solid baseline models, including BiLSTM-CRF and two pretrained language models, XLM-R and PhoBERT, to assess the difficulty of our dataset.

BiLSTM-CRF: We use BiLSTM-CRF (Lample et al., 2016), a model that achieves high performance in the span detection tasks (Pavlopoulos et al., 2021; Nguyen et al., 2021a). We implemented this model with three main layers: (1) The word embedding layer using pre-trained PhoW2V (Nguyen et al., 2020), (2) The BiLSTM layer, and (3) the Conditional Random Field (CRF).

XLM-R: XLM-RoBERTa (Conneau et al., 2019) is a multilingual language model and a variant of RoBERTa, pre-trained on 2.5T of data across 100 languages containing 137GB of Vietnamese texts. On several cross-lingual benchmarks, XLM-R outperforms mBERT.

	BiLSTM-CRF + Pho2W$_{syllable}$	**BiLSTM-CRF + Pho2W$_{word}$**	**XLM-R$_{Base}$**	**XLM-R$_{Large}$**	**PhoBERT$_{Base}$**	**PhoBERT$_{Large}$**
Full Data	0.7453	0.7036	0.7467	**0.7770**	0.7569	0.7716
W/o additional clean comments	0.6241	0.6244	0.6479	0.6756	0.6738	**0.6867**

Table 5: Experimental results on Single span, Multiple spans, and All spans subsets.

PhoBERT: PhoBERT (Nguyen and Nguyen, 2020) is a monolingual language model which is pre-trained on a 20GB Vietnamese dataset and has the same architecture and approach as RoBERTa. PhoBERT is proven as a state-of-the-art method in multiple Vietnamese-specific NLP tasks such as Part-Of-Speech Tagging, Dependency Parsing, and NER (Truong et al., 2021; Nguyen and Nguyen, 2020).

4.2 Experimental Settings

We empirically fine-tuned all pre-trained language models using *simpletransformers*[2]. For the tokenizer, each comment was tokenized using VnCoreNLP (Vu et al., 2018) in word-level and syllable-level for fine-tuning the PhoBERT and the XLM-R, respectively. In addition, we used Adam optimizer with a learning rate of 2e-5, a batch size of 8, and trained with 10 epochs.

We utilized a pre-trained word embedding - PhoW2V both syllable-level and word-level settings (Nguyen et al., 2020) with 100 dims to implement the BiLSTM-CRF model. The optimal hyper-parameters of BiLSTM-CRF are described in Table 6. All baseline models were trained on a system having 26GB RAM and an NVIDIA Tesla P100 GPU.

4.3 Evaluation Metrics

The macro-average F1-score (F1) is used to evaluate our models. For each pair of gold-predicted spans, we compute F1 and then calculate the arithmetic mean of F1 for each of these cases. It should be noted that the final F1-score, Accuracy, and Precision reported are an average of more than ten runs with various random seeds.

Hyper-parameters	**Values**
Optimizer	Adam
Learning rate	0.001
Mini-batch size	64
LSTM hidden state size	60
Embedding size	100
Dropout	[0.1, 0.1]
Epochs	10

Table 6: Hyper-parameters of the BiLSTM-CRF.

4.4 Experiments and Results

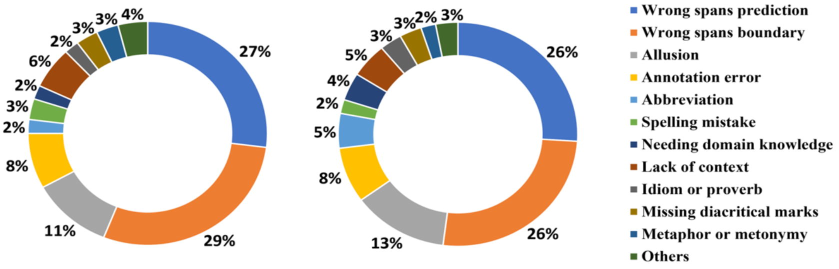
Table 4 reports the baseline results before and after adding the 5,528 additional clean comments. We discover that after the addition, the performances improve 0.1002±0.0210. Specifically, PhoBERT$_{Large}$ considerably outperforms other models in the dataset without additional clean data, achieving 0.6867 in F1-score. In addition, the best model trained on Full data is XLM-R$_{Large}$, which has an F1-score of 0.7770. We find that XLM-R$_{Large}$ increased by 0.1014 and PhoBERT$_{Large}$ increased by 0.0849. These results demonstrate that the appearance of the additional clean comments successfully reduces model bias and improves performance.

Table 5 reports our results in three subsets corresponding to Single, Multiple, and All spans. Both Single and Multiple spans subsets are made by the process of splitting the All spans, which also known as the test set, based on the number of spans in each comment. Their results are described as follows:

Single span: We experimented with both

---

[2] https://simpletransformers.ai/ (ver.0.63.3)



(a) Error Analysis on PhoBERT$_{\text{Large}}$

(b) Error Analysis on XLM-R$_{\text{Large}}$

Figure 3: Error analysis conducted on prediction on dev set made by PhoBERT$_{Large}$ and XLM-R$_{Large}$. We divide error cases into 12 categories including wrong spans detection, wrong spans boundary, allusion, annotation error, abbreviation, spelling mistake, needing domain knowledge, lack of context, idiom or proverb, missing diacritical marks, metaphor or metonymy, and others (rare characters, mixing other languages, all words stick together, etc.). These error cases are defined in Appendix C.

syllable-level and word-level language models. We discover that the pre-trained language models outperform the BiLSTM-CRF model by 0.3521±0.0099 in F1. This significant gap proves the fact that word embedding and features extraction of the pre-trained language models on the social media texts are superior to the BiLSTM-CRF. The XLM-R$_{Large}$ model achieves the best performance with a 0.7214 in F1-score. On the other hand, PhoBERT$_{Large}$ achieves a 0.7067 in F1-score. These results show no significant difference in performances among the multilingual and monolingual pre-trained models in the Single span.

Multiple spans: We experimented with the syllable-level and word-level and found that the pre-trained language models beat the BiLSTM-CRF model by 0.3212±0.0132. In addition, the performance of XLM-R$_{Large}$ is slightly better than the PhoBERT$_{Large}$ by 0.0036 in F1-score. The results on the Multiple spans are always better than the Single span, which might be explained by the fact that data in Multiple spans comprise more hate and offensive spans that can assist the models in learning more features of the data.

All spans: The results of the experiments on the All data are higher than the Single span and the Multiple spans. Specifically, in terms of F1-score, results of the XLM-R$_{Large}$ model are higher by 0.0556 and 0.0413 than the highest in the Single span and the Multiple spans, respectively while the figures for the PhoBERT$_{Large}$ are 0.0649 and 0.0395, respectively.

4.5 Results Analysis

We choose two best models: PhoBERT$_{Large}$ and XLM-R$_{Large}$ to conduct error analysis. As shown in Figure 3, we report the statistics of the ratio of various types of error cases[3] of 100 random samples in the dev set. We notice that *wrong spans prediction*[4], *wrong spans boundary*[5], *allusion*[6], *annotation error*[7], and *lack of context*[8] are major types of prediction failure of the PhoBERT$_{Large}$ and the XLM-R$_{Large}$.

We show some cases from the ViHOS development set in Table 7. In the first case of "Ns vậy lại xúc phạm cái đầu b**i *neutral face emoji*" (**Eng**: *If you said so, you insult the d**k head *neutral face emoji**), we notice that the PhoBERT$_{Large}$ could only predict "đầu"$_{head}$ as a hate and offensive span, whereas XLM-R$_{Large}$ predicts "b**i"$_{b**i}$. Both fail to predict the full boundary of "đầu b**i"$_{d**k\ head}$. The reason is that asterisks exist in the text ("b**i"). As defined in Subsection 4.2, the PhoBERT$_{Large}$, which was fine-tuned on the word-level data, cannot identify these tokens, but the XLM-R$_{Large}$, which was fine-tuned on the syllable-level data, can somewhat predict more accurate hate and offensive span even if it has asterisks.

Furthermore, in the second sampled comment, both best models failed to predict "đám cờ vàng" (**Eng**: *those yellow flag ones*) as a hate and offensive span, owing to the fact that this phase is an offensive metaphor for a rival party to Vietnamese

---

[3] Definition of errors are explained in the Appendix C.

[4] The model predicts clean spans as hateful and offensive.

[5] The model predicts inadequate boundary or fails to predict correctly.

[6] The comment refers to another person or subject indirectly and disrespectfully.

[7] The annotated span is wrong in terms of our guidelines. There is no later annotation modification in ViHOS.

[8] The comment has multiple meanings in different contexts, which mislead the prediction.

Ground truth spans	Models	
	PhoBERT$_{Large}$	XLM-R$_{Large}$
Ns vậy lại xúc phạm cái đầu b**i *neutral face emoji* (**Eng**: _If you said so, you insult the d**k head *neutral face emoji*_)	["xúc", "đầu"]	["b**i"]
@username nhân dân VN tức là cờ đỏ. Còn đám cờ vàng là lũ súc vật lưu vong. Hiểu hông? (**Eng**: _@username Vietnamese people are red flag. The yellow flag ones are animals and exiled. Understand?_)	["đỏ.", "đám", "lũ", "súc"]	["đám", "lũ", "súc", "vật", "vong."]
Cướp đêm là giặc, cướp ngày là quan. 24/7 lúc nào cũng phải nơm nớp. Than ôi cái đất nước hạnh phúc (**Eng**: _Night thieves are enemies, day thieves are bureaucrats. 24/7, we are in a perpetual state of fear and anxiety. What a happy country_)	["Cướp", "cướp", "nớp."]	["Cướp", "giặc,", "cướp"]
Đúng rồi đéo thể tin được. Đáng lẽ phải cào bằng ra mới đúng. Thật không thể tin nổi. Phải cào bằng ra mới được (**Eng**: _Yes, fucking unbelievable. They should dig until it comes out. Unbelievable. Should dig till it comes out_)	["đéo", "cào", "cào"]	["đéo"]

Table 7: Case studies in the dev set from ViHOS that are complicated for the PhoBERT$_{Large}$ and XLM-R$_{Large}$. The highlighted spans in first column are Ground truth spans associated with their comments. **Eng** refers to the English meaning of associated comments.

people. In the third instance, the phrase "cướp đêm là giặc, cướp ngày là quan," (**Eng**: *night thieves are enemies, day thieves are bureaucrats*) which is an idiom that originated from folk poetry, also misleads the prediction. In the final example, the verb "cào"$_{dig}$ has no object and must be comprehended in context. These intriguing and challenging linguistic phenomena encourage more research into more robust models and methods in this field.

5 Conclusion and Future Work

We presented ViHOS, a new Vietnamese dataset for evaluating hate and offensive spans detection models. ViHOS includes 26,467 human-annotated spans on 11,056 comments. In addition, state-of-the-art models are conducted as the first baseline models, including BiLSTM-CRF and pre-trained language models such as XLM-R$_{Base}$, XLM-R$_{Large}$, PhoBERT$_{Base}$, and PhoBERT$_{Large}$. As a result, the XLM-R$_{Large}$ model achieves the best performance, with an F1-score of 0.7770. Furthermore, we discover that the performance when detecting multiple spans is better than the performance in detecting single spans in Vietnamese hate and offensive spans detection. Our dataset is available publicly at the GitHub link[9].

Despite the study's many promising contributions, the proposed research work still has several potential concerns, especially since the performance is still modest, and incorrect predictions could harm users' reputations if they rely heavily on our method. We intend to expand the dataset size and diversity of hate and offensive context for Vietnamese in the future to address this shortcoming. Furthermore, pre-and post-processing techniques will be used to standardize social networking texts (Clark and Araki, 2011) and deal with complex cases (as discussed in Subsection 4.5) to improve model performance(Suman and Jain, 2021; Kotyushev et al., 2021; Chhablani et al., 2021), particularly for Vietnamese pre-trained language models.

---

Limitations, Social Impacts, and Ethical Considerations

Limitations and Social Impacts

There are numerous incomprehensible comments in our dataset due to the lack of context. Consequently, our annotators had to place themselves in imaginary contexts in order to annotate those comments (see Table 9 for more details about our solution). This shortcoming combined with the limitations of the neural networks in terms of understanding various linguistic phenomena (see Table 8 for more details about nine different linguistic phenomena) caused their performances of this task still insufficient to become practical.

We also acknowledge the risk associated with publicizing a dataset of hate and offensive spans (e.g. utilizing ours as a source for building abusive chatbots). However, we firmly believe that our proposed benchmark creates more value than risks.

Ethical Considerations

The undergraduate students in the annotation process are Vietnamese native speakers; have at least 12 years of studying Vietnamese with average scores on the Vietnam National Exam on Literature of 6.5; have at least three years of using social network platforms. They were explicitly warned that their tasks will display hateful and offensive content and if they became overwhelmed, they were also urged to stop labeling. These undergraduate students were paid $0.1 per comment, which takes an average of 6.44 seconds to complete (excluding the time used by workers who took exceptionally lengthy comments).

All the comments in ViHOS originated in the study of Luu et al., 2021, which preserved users' anonymity by removing all of them when creating the ViHSD. As a result, the comments in our dataset do NOT reflect our thoughts or viewpoints. ViHOS is available to the public under a usage agreement for research and related purposes only.

A Abusive Language Characteristics

Table 8: Characteristics of abusive language in ViHOS with examples, explanations, and solutions for annotators.

Abusive language characteristics	**Examples**	**Explanations and Solutions**
Non-diacritical marks comments	(1) Dit me cai quy trinh,vao cap cuu deo co tien,deo bao hiem thi nam do di. (**Eng:** *Fuck the procedure, without money or insurance, you could just lay there and no one cares about your emergency* (2) Dung la con linh dien dien vua thoi chang qua nt goi de choc my dien thoi "con ng" nhu linh dien thi ai them (**Eng:** *That must be the Crazy Linh, so crazy! I just call to tease the Crazy My. No one gonna love Crazy/The person like Crazy Linh!*	**Explanation:** some of these non-diacritical marks comments might trick annotators a little bit. (1): this is a non-diacritical marks comment but still able to understand. (2): there are some problems causing annotators to re-read multiple times as no punctuation, diacritic, and the text "con ng" could be considered as "crazy girl" or "the type (of human)" and both of these meanings is inappropriate. **Solution:** Non-diacritical marks comments are annotated as others. Annotators have to re-read until they fully understand the texts if needed. Those examples are annotated as follows: (1): ["Dit me", "deo", "deo"] (**Eng:** ["*Fuck*", "*fuck*", "*fuck*"]) (2): ["con", "dien", "dien", "con ng", "dien", "ai them"] (**Eng:** ["*con*", "*crazy*", "*crazy*", "*crazy/the person like*", "*crazy*", "*No one gonna love*"] in which the word "con" is an inappropriate way to call a woman.)

Table 8 continued from the previous page.

Metaphors, metonymies	(1) cái miệng rộng quá đẻ con ra còn lọt (**Eng:** *The mouth is too big that a baby could even be born through it*) (2) Dm! qua đợt dịch này thì thằng sống ích kỷ này chắc sớm gia nhập juventuts (**Eng:** *Fuck it! After the pandemic, this selfish boy will soon join Juventuts*)	**Explanation:** in our dataset, many comments use metaphors or metonymy to convey their hate or offensiveness in another way. (1): this is a metaphor of a mouth as a vagina. (2): this is a metonymy of Juventus' jersey as prison shirts (a common metonymy in Vietnamese). **Solution:** Annotators are required to annotate the whole ideas of metaphors, metonymy. (1): ["cái miệng rộng quá đẻ con ra còn lọt"] (2): ["Dm", "thằng sống ích kỷ này chắc sớm gia nhập juventuts"] (**Eng:** ["*Fuck*", "*this selfish boy will soon join Juventuts*"])
Puns	(1) Ad đăng bài này cũng là Bồn Kỳ Lắc nè nè nè :) (**Eng:** *The admin, who posts this, is also a "Bồn Kỳ Lắc")*	**Explanation:** Some comments use phrases that only read them backwards, they make sense. As in the example, "Bồn Kỳ Lắc", if this phrase is read backwards, it is "Bắc Kỳ Lồn" (pussy north). **Solution:** Annotators are required to annotate these puns too. (1): ["Bồn Kỳ Lắc"]
Using non-words characters to form hieroglyphs	(1) có tin t lấy *knife symbol* xiên chết cụ m ko :))) (**Eng:** *Do you belive that I could get a *knife symbol* to fucking kill you?*) (2) Đâm vào () (**Eng:** *stab in the ()*	**Explanation:** (1): the *knife symbol* is used instead of the word knife. (2): the existence of "()" can be considered as pussy in this context. **Solution:** Annotating the non-words only if they can convey a full meaning of hate or offensiveness, and the whole phase if they can not. (1): ["t", "*knife symbol*", "xiên chết cụ m""] (**Eng:** ["*t*", "**knife symbol**", "*fucking kill you*"]) in which "t", "m" are inappropriate pronouns.) (2): ["Đâm vào ()"]

Table 8 continued from the previous page.

Spelling mistakes	(1) Tôi đeo hiểu bạn noi cai gì luôn a :))) (**Eng:** *I have no fucking idea about what you saying*) (2) Mà dx cái chữi ngta nghe hài vcl bù lại củng đở (**Eng:** *Those fucking curses is so funny that can even refill that*) (3)Khi bạn xai trính tã nhưng cá ghén vít đún trính tã :)) (**Eng:** *When you make spelling mistakes but trying to fix it :))*)	**Explanation:** (1): the words "đeo," "noi," "cai," "a" are spelling mistakes. The words can be understood as "đéo," "nói," "á". As that, these words are the same in accidentally missing acute marks. (2): the words: "chữi," "củng," "đở" are spelling mistakes is a phenomenon of mistaking tilde mark for hook above mark, and this often happens in some parts of Vietnam (Nguyen Hoai Nguyen, 2010). There are also familiar phenomena of mistaking marks such as tilde mark for underdot mark, acute mark for hook above mark, and so on (Nguyen Hoai Nguyen, 2010). (3): the phases: "xai trính tã," "cá ghén," "vít đúng trính tã" are spelling mistakes but on purpose. This comment utilizes spelling mistakes to attack opponents who also have spelling mistakes. Furthermore, these spelling mistakes also abuse opponents based on regional distinctions in accent, which cause some phenomenon of mistaking diacritical marks as in Example (2). **Solution:** The same as dealing with non-diacritical marks comments, annotators work as usual. (1): ["deo"] (**Eng:** ["*fuck*"]) (2): ["chữi", "vcl"] (**Eng:** ["*curse*", "*fuck*"]) (3): ["bạn xai trính tã nhưng cá ghén vít đún trính tã :))"]

Table 8 continued from the previous page.

Allusive language	(1) ra gì thì toi rồi, nó khác gì cách đảng CS chọn người, hồng hơn chuyên. Suy nghĩ kĩ đi. Giải độc cộng sản đã khó, giải độc tư tưởng cánh tả còn khó hơn. (**Eng:** *If it had something, it was done! It is just like the way CS (stands for Communism) chooses people, beauty over the profession. Detoxifying Communism is hard; detoxifying the left-wing political ideologies is even harder.*) (2) Rút kinh nghiệm lại được xài nghìn tỷ (**Eng:** *Just say learned and then can use trillion VND*)	**Solution:** Annotators are required to annotate the whole profound abuse. (1): ["toi", "hồng hơn chuyên", "Giải độc cộng sản đã khó, giải độc tư tưởng cánh tả còn khó hơn"] (**Eng:** ["*die*", "*beauty over the profession*", "*Detoxifying Communism is hard; detoxify the left-wing political ideologies even harder*"]) (2): ["Rút kinh nghiệm lại được xài nghìn tỷ"]
Homonym	(1) coin card ("coin card" is a homonym of "con cặc", which means *dick*)	**Solution:** annotate the whole abusive homonym. (1): ["coin card"]
Mixing languages	(1) Vl fake **Eng:** Fuck! Fake) (2) phe *X* compat tổng *Y* =)) (**Eng:** *X's side combats Y's side*) (3) Tối Thầy stream đá phò đi thầy ơi (**Eng:** *You should stream fucking some whores tonight, please!*)	**Solution:** treat foreign words as others and annotate if they meet the definition of hate and offensive spans. (1): ["Vl", "fake"] (**Eng:** ["*fuck*", "*fake*"]) (2): ["compat"] (**Eng:** ["*combat*"]) (3): ["đá phò"] (**Eng:** ["*fuck some whores*"])

Table 8 continued from the previous page.

Trick hate speech detecting systems on purpose	(1) Đấy Ông già xạo l*n của các bạn được tắm bồn Thái Lan đấy=))) (**Eng:** *See, your fucking old liar is Thai bathing again =))))*) (2) thằng c h.ó ngu (**Eng:** *Fucking stupid guy*) (3) vualonemlabaonhieu cm (**Eng:** *How long in cm to fit your pussy?*)	**Explanation**: some hate or offensive comments use punctuation to censor their inappropriate words (as in (1), asterisk is used in the word l*n (pussy)) or to disunite characters in words (as in (2), dot and space are used to disunite the words chó (dog) into c h.ó). These efforts actually can trick many hate speech detecting systems, or to put all words together (as in (3), vualonemlabaonhieu cm should be "vừa lồn em là bao nhiêu cm"). **Solution:** we annotate all characters which can be form into hate or offensive phase. (1): ["xạo l*n"] (**Eng:** ["*fucking lie*"]) (2): ["thằng c h.ó", "ngu"] (3): ["lon"] (**Eng:** ["*pussy*"])

B Notices for annotators

Table 9: Additional notices for annotators.

Notices	Example	Explanation
Try to figure out and consider as in the original context of the comments.		This could help annotators understand complex and non-context hate, offensive comments.
Do not let emotion affect the annotating process.		Annotators exposed in a long time to toxic comments are reported to get used to the frequently appearing hate, offensiveness.
Check the provided Vietnamese Dictionary if there is any uncertainty in being sure a word is hate or offensive.		We use the most reputable Vietnamese dictionary (Hoang Phe, 1983) to provide to annotators.
Should span the object is compared to in an inappropriate comparison.	"Ăn cơm nhìn như chó" (**Eng:** *You eat like a dog*) **Spans:** ["nhìn như chó"]	We consider this is an inappropriate comparison in which annotators must span "chó"$_{dog}$.

Table 9 continued from the previous page.

However, we should span the whole comparison if spanning only the object is compared to might not convey the complete hate or offensive idea	"ý thức như trẻ lớp mầm" **Spans:** ["ý thức như trẻ lớp mầm"] (**Eng:** *Your awareness is just like a kindergarten kid*)	If we only span "trẻ lớp mầm" (kindergarten kid), it will not convey the complete offensive idea. As that, annotators are encouraged to span the whole text instead.
Do not span conjunctions; exceptional Vietnamese cases; standard ways to call LGBTQ+.	(1) Vì thế, nên, nhưng, mà, etc. (**Eng:** *so, so, but, but, etc.*) (2) Gay, les, etc (3) Bóng, bê đê, ái nam ái nữ, etc.	(1) Some conjunctions in Vietnamese. (2) Appropriate ways to specify LGBTQ+. (3) Inappropriate ways to specify LGBTQ+ that need to be spanned in comments.
Blatant hate and offensive words prioritize being spanned over the others, especially in sentences without diacritics and could not be understanded.	May Cha H O an Tro. Cap. Ranh c. Di ngoi le. Nhieu chuyen. Do Cai Thu , do tam than **Spans:** ["Cap", "ngoi le", "Nhieu chuyen", "do tam than"] (**Eng:** ["*steal*", "*gossip*", "*talkative*", "*psycho*"])	Similar to this non-diacritical and incomprehensible comment, words as highlighted ones are more straightforward to be spanned.
Span the whole phase violating human rights.	"Về nước anh nên vào tù ở trước thay vì đi cách ly." (**Eng:** *When you return to Vietnam, you should go to jail first instead of going to isolation*) **Spans:** ["Về nước anh nên vào tù ở trước thay vì đi cách ly"]	Comments violate human rights, usually complex to specify hate, offensive words to span. As in this example, a Vietnamese citizen comes back from a foreign country has a right to have isolated healthcare firstly.
Span the whole obscene acronyms.	(1) clgv (**Eng:** *wtf is that?*) (2) clmn (**Eng:** *your mom's pussy*) (3) cmn (**Eng:** *your mother*).	
Follow the rule with words that do not have diacritics and conjoin to span out the hate, offensive spans.	cailongithe (**Eng:** *wtf is that?*)	Some comments have strings being constructed by many words missing diacritical marks, but still able to understand. The annotators should only span the hate and offensive characters set out of the string as in the example.
Span hate, offensiveness separately.	"Cả đám dlv là nhóm ngu dốt, trẻ trâu potay vcl luôn." (**Eng:** *The whole dlv crew are stupid, bull-headed kids (so I have) no fucking thing to say.*) **Spans:** ["đám", "ngu dốt", "trẻ trâu"] (**Eng:** ["*crew*", "*stupid*", "*bull-headed kids*"])	This comment must be spanned as in the example, but not as "đám," "ngu dốt, trẻ trâu," "vcl," "NGU."

C Definition of Error Cases for Error Analysis

We introduce 12 error definitions as follows:

1. **Wrong spans prediction**: The model predicts clean spans as hateful and offensive.
2. **Wrong spans boundary**: The model predicts inadequate boundary or fails to predict correctly.
3. **Allusion**: The comment refers to another person or subject in an indirect and disrespectful way.
4. **Annotation error**: Annotators have improperly annotated the span. The reason might be that they somehow do not follow the provided guidelines. However, there is no modification in the final dataset.
5. **Abbreviation**: The comment contain short forms of words.
6. **Spelling mistake**: The comment is spelling mistake.
7. **Needing domain knowledge**: Dialect and professional expertise are required to detect span in comments.
8. **Lack of context**: In different contexts, the comment could be understand in multiple meaning.
9. **Idiom or proverb**: The comment contains idiom or proverb.
10. **Missing diacritical marks**: Words in the comment do not have diacritical marks.
11. **Metaphor or metonymy**: The comment contains metaphor or metonymy.
12. **Others**: The comment contains rare characters, other languages, words in it are stick together, etc.

VOTE'N'RANK: Revision of Benchmarking with Social Choice Theory

Abstract

The development of state-of-the-art systems in different applied areas of machine learning (ML) is driven by benchmarks, which have shaped the paradigm of evaluating generalisation capabilities from multiple perspectives. Although the paradigm is shifting towards more fine-grained evaluation across diverse tasks, the delicate question of how to aggregate the performances has received particular interest in the community. In general, benchmarks follow the unspoken *utilitarian* principles, where the systems are ranked based on their mean average score over task-specific metrics. Such aggregation procedure has been viewed as a sub-optimal evaluation protocol, which may have created the illusion of progress. This paper proposes VOTE'N'RANK, a framework for ranking systems in multi-task benchmarks under the principles of the social choice theory. We demonstrate that our approach can be efficiently utilised to draw new insights on benchmarking in several ML sub-fields and identify the best-performing systems in research and development case studies. The VOTE'N'RANK's procedures are more robust than the mean average whilst being able to handle missing performance scores and specify conditions under which the system becomes the winner.

1 Introduction

Benchmarking has evolved as a conventional practice for accelerating the development of generalisable systems in different applied areas of machine learning (ML). Benchmarks are typically designed as a collection of datasets, corresponding task-specific evaluation metrics, and a criterion for summarising the overall performance on the tasks (Ruder, 2021). The benchmark holders provide public leaderboards, which are utilised by ML researchers and practitioners for comparing novel systems against one another, and, if applicable, human baselines, as well as selecting the best-performing ones for practical purposes. According to the benchmark sharing platform PAPERSWITHCODE[1], the community has put much effort into creating more than $10,000$ influential benchmarks in natural language processing (NLP), computer vision, and knowledge graphs, to name a few.

Criticism of the benchmark pillars. The benchmark methodological foundations have received wide criticism from academic and industrial communities (Bowman and Dahl, 2021). The criticism covers various aspects of benchmarking, raising concerns about the construct validity (Raji et al., 2021), fragility of the design and task choices (Dehghani et al., 2021), data leakage and annotation artifacts (Elangovan et al., 2021), SoTA-chasing tendencies at the cost of large carbon footprints (Bender et al., 2021), and low reproducibility of the reported results (Belz et al., 2021), inter alia. Recommendations proposed in these studies are of utmost importance to benchmark holders, system users, and developers. However, little attention has been paid to a more nuanced methodological question: *how to aggregate performance scores in multi-task benchmarks?*

Limits of canonical aggregation. The appropriateness of mean aggregation in multi-task ML problems is an ongoing debate in the community. The mean aggregation procedure implies that all task metrics are homogeneous (Colombo et al., 2022). Otherwise, it is recommended to evaluate the statistical significance of differences between models with non-parametric tests (Demšar, 2006; Benavoli et al., 2016). In practice, the NLP GLUE-style benchmarks (Wang et al., 2018, 2019a, 2021; Liang et al., 2020) use arithmetic average to rank models over heterogeneous metrics, which may lead to

---

*Equal contribution.

May 2-6, 2023

biased evaluation and subjective outcomes (Nießl et al., 2022; Waseem et al., 2021). The top-leading systems may dominate the others only on the outlier tasks (Agarwal et al., 2021), and their ranking is inconsistent with other Pythagorean means (Shavrina and Malykh, 2021). At the same time, the mean aggregation ignores the relative ordering and relies on the absolute score difference (Peyrard et al., 2017), equally treating tasks of different complexity (Mishra and Arunkumar, 2021) and from different domains (Webb, 2000).

Novel aggregation principles. Recent research has addressed these limitations, introducing novel aggregation methods and principles. One of the directions frames benchmarking in terms of microeconomics, highlighting the importance of the user utility (Ethayarajh and Jurafsky, 2020). The other studies urge evaluation of technical system properties in real-world scenarios (Zhou et al., 2021; Ma et al., 2021) and reliability of system rankings (Rodriguez et al., 2021). The benchmarking paradigm is also shifting towards adopting evaluation principles from other fields, such as non-parametric statistics and social choice theory (Choudhury and Deshpande, 2021; Min et al., 2021; Varshney et al., 2022; Colombo et al.).

Contributions. Drawing inspiration from the social choice theory, we make two application-oriented contributions and introduce an alternative tool for benchmark evaluation. First, this paper proposes VOTE'N'RANK, a flexible framework to rank systems in multi-task/multi-criteria benchmarks and aggregate the performances based on end-user preferences. VOTE'N'RANK includes 8 aggregation procedures that rely on rankings in each criterion and allow to aggregate homogeneous and heterogeneous information. The framework is easy-to-use and allows the users to plug in their own data. Second, we analyse the framework's application in four case studies: *(i)* re-ranking three NLP and multimodal benchmarks; *(ii)* exploring under which circumstances a system becomes *a Condorcet winner*; *(iii)* evaluating robustness to omitted task scores; and *(iv)* ranking systems in accordance with user preferences.

We publicly release the VOTE'N'RANK framework[2] to foster further development of reliable and interpretable benchmark evaluation practices for both academic and industrial communities.

2 VOTE'N'RANK

2.1 Background

The study of how individual preferences can be combined to reach a collective decision is the focus of *social choice theory* (Arrow, 2012). There are two main approaches to deal with preferences: *utilitarian* and *ordinal*. The first approach relies on the so-called cardinal utility, which implies that there exists some unique utility function for each individual that defines their preferences. Here, we can work with utilities as numerical values, and collective decision making aims to maximise the *social welfare utility*. Examples of such utilities are *utilitarian and egalitarian social welfare* measures, where the sum of utilities of individual agents and the utility of the worst agent get maximised, respectively.

The *utilitarian* approach has its drawbacks. First, it implies that kind of utility exists, which is not always true: individuals can compare two systems and prefer one to another but cannot say how many "utils" they got. Second, it assumes that individual utilities can be compared. The latter is a solid requirement for benchmarking problems, e.g. when we need to aggregate heterogeneous criteria such as performance and computational efficiency. In order to sum them up, one needs a transformation function that puts the metrics in the same measurement scheme. For example, DYNASCORE (Ma et al., 2021) utilises Marginal Rate of Substitution (MRS) from economics as such transformation function. Third, the utilitarian compensatory principle is questionable. Can low performance in one task/criterion be compensated by high performance in the others? (Munda, 2012)

The *ordinal* approach has a weaker requirement, where individuals have preferences (x is preferred to y, $x \succ y$, i.e. binary relations over objects), which should be aggregated in social preference (also called social rankings). This approach allows us to aggregate rankings from different tasks and criteria without worrying about measurement schemes.

2.2 Aggregation Procedures

Definitions. We adopt the conceptual definitions from the social choice theory to the objectives of selecting the best-performing system and ranking a set of systems as follows: *(i) a voter* or a *criterion* is a task in a given benchmark, and *(ii) an alternative* is a system candidate.

---

[2] `github.com/PragmaticsLab/vote_and_rank`

Objectives. Suppose we have a set M of systems $m \in \{m_1, \dots, m_{|M|}\}$ from the benchmark including a set T of voters $t \in \{t_1, \dots, t_{|T|}\}$ and the corresponding criteria $S = \{s_{mt}\}_{m=1,t=1}^{m=|M|,t=|T|}$, where s_{mt} is the score of system m in task t. Given that, we pursue two main objectives of the aggregation procedure σ, $\sigma : S \mapsto (M, \succ_\sigma)$: *(i)* to select the best performing alternative m^*, so that there is no alternative $\hat{m}, \hat{m} \succ_\sigma m^*$, and *(ii)* to rank the alternatives in the descending order according to σ values, so that $m_i \succ_\sigma m_j$. Here $\succ_\sigma$ denotes the preference resulting from the aggregation procedure σ.

Procedures. We propose 8 rules from 3 different classes: *scoring rules*, *iterative scoring rules*, and *majority-relation based rules*. We provide more details and examples in Appendix A.1.

2.2.1 Scoring rules

The total score of each system is calculated as the sum of corresponding scores in each task $Sc(m) = \sum_{i=1}^{|M|} c_i p_i(m)$, where $p_i(m)$ is the number of tasks having model m in the i^{th} place, and c_i is the i^{th} element of the scoring vector c. The systems with the highest scores constitute the final decision. We study the following rules that differ in their scoring vectors.

- *Plurality rule* applies $c = (1, 0, \dots, 0)$.
- *Borda rule* operates on $c = (|M| - 1, |M| - 2, \dots, 1, 0)$.
- *Dowdall rule* applies the scoring vector $c = (1, 1/2, \dots, 1/|M|)$.

The scoring vectors are designed to satisfy the voting rules' properties mentioned in Table 8 in Appendix A.2. The scoring vectors' design is based on the mathematical foundations of the social choice theory and is generally accepted in the community (Aizerman and Aleskerov, 1995).

Interpretation. The *Plurality* rule is one of the most widely used in everyday life. It only requires information about the best alternative for each voter. The *Borda* rule takes into account information about all alternatives. It assumes that differences in positions should be treated the same, whether it is between the first and the second alternatives or the second and the third ones. At the same time, the *Dowdall* rule is in some way in-between *Plurality* and *Borda*. It considers information about all alternatives but gives more weight to the difference in the preferences. A similar approach is used in the Eurovision song contest: they use $c = (12, 10, 8, 7, \dots, 1)$ making the difference in top positions more important to the outcome.

2.2.2 Iterative scoring rules

- The *Threshold rule* applies $c = (1, 1, .., 1, 1, 0)$. In case of ties scoring vectors $(1, 1, ..., 1, 0, 0)$, ..., $(1, 0, ..., 0, 0)$ are iteratively applied and used only to compare systems with the maximum sum of scores.
- The *Baldwin rule* iteratively applies scoring vectors $(|M|-1, |M|-2, ..., 1, 0)$, $(|M|-2, |M|-3, ..., 1, 0, 0)$,..., $(1, 0, ..., 0, 0)$, and at each iteration discards systems with the minimum sum of scores.

Both rules stop the procedure when it is impossible to break ties or there is only one alternative left.

Interpretation. The rules are similar in their iterative nature but different in terms of the intuition behind them. The *Threshold* rule is based on the idea that the worst position is what matters the most. When we start with $c = (1, 1, .., 1, 1, 0)$, we choose the alternatives declared worst in the least amount of cases. Since there can be ties, additional iterations are used to break them with $c = (1, 1, ..., 1, 0, 0)$ and so on; in other words, by looking at the least-k positions until we have one alternative left or can not break ties.

The *Baldwin* rule has two main differences from *Threshold*. First, it is based on the *Borda* score and considers information from all positions in the ranking, not only the worst one. Second, whilst the *Threshold* rule applies a new vector to the original profile and compares only tied alternatives, the *Baldwin* rule iteratively eliminates the least scored systems and moves the remaining up in rankings. For example, if system m_A is in the fifth place, but alternatives from the first four places are eliminated in the first rounds, m_A will be the first until it is eliminated or is among alternatives in the outcome.

2.2.3 Majority-relation based rules

Let us define a majority relation μ over the set of alternatives as the following binary relation: $m_A \mu m_B$ iff m_A is ranked higher than m_B by more criteria.

- *Condorcet rule*. m_C is the Condorcet winner (CW) iff $m_C \mu m$ for any $m \in M$.
- *Copeland rule*. Define the lower counter set of systems m_A as a set of systems dominated by m_A via μ: $L(m_A) = \{m \in M, m_A \mu m\}$. In a similar way, define the upper counter set of systems m_A as a set of systems that dominate m_A

via μ: $U(m_A) = \{m \in M, m\mu m_A\}$. Define $u(m) = |L(m)| - |U(m)|$. The final decision is provided by the alternatives with the highest $u(m)$.

- *Minimax rule*. Let $s(m_A, m_B)$ be the number of criteria for which system m_A is ranked higher than system m_B if $m_A \mu m_B$ or $s(m_A, m_B) = 0$ otherwise. The systems are ranked according to the formula $\text{rank}(m_A) = -\max_B s(m_B, m_A)$.

Interpretation. CW is the alternative that beats all the others in pairwise comparison. However, the *Condorcet* rule does not declare any winner if the CW does not exist. The *Copeland* and *Minimax* rules select the CW whenever it exists and solve the drawback as follows. The *Copeland rule* selects an alternative that dominates more alternatives and is dominated by less (the difference between the numbers is maximised). The *Minimax rule* chooses the alternative with the minimum number of defeats.

2.3 Properties of the Aggregation Procedures

There is a multitude of voting rules in the social choice theory (Nurmi, 1983; Levin and Nalebuff, 1995; De Almeida et al., 2019; Aleskerov et al., 2010). The motivation behind our rules[3] is that they generally overcome the mean aggregation limitations and vary in their *properties*, allowing the user to be more flexible in choosing the rule for their purposes. The outcomes can be interpreted in terms of the properties followed or violated by the rules. We discuss our rules' properties in Appendix A.2.

2.4 Framework

Figure 1 describes three supported settings of performing the aggregation objectives. The toy benchmark has three evaluated alternatives and consists of seven voters grouped by the task, e.g. natural language inference, text classification, and question answering (QA).

A Basic aggregation: the aggregation procedure is applied to the leaderboard as is.

B Weighted aggregation: each voter in the group is assigned a group weight equal to $1/|T_{group}|$. The blue group weights are $1/3$, and the orange and the violet group weights are $1/2$. Each group contributes equally to the final ranking, regardless of the number of voters.

C Two-step aggregation: each voter group is treated as a standalone leaderboard. We independently apply a procedure to each voter group and compute an interim ranking shown as "elector". Next, we aggregate the groupwise rankings by applying the same procedure one more time and compute the final ranking.

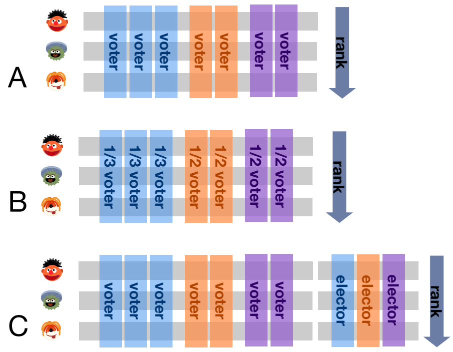

Figure 1: Three ways to run the aggregation procedures. A: Basic aggregation. B: Weighted aggregation. C: Two-step aggregation.

3 Case Studies

This section describes four case studies on three NLP and multimodal benchmarks. Our main objective here is to re-interpret the benchmarking trends under the social choice theory. We provide a brief description of the benchmarks below.

- GLUE (General Language Understanding Evaluation; Wang et al., 2018) combines nine datasets on QA, sentiment analysis, and textual entailment. GLUE also includes a linguistic diagnostic test set. $|M|$=30.
- SGLUE (Wang et al., 2019a) is the GLUE follow-up consisting of two diagnostic and eight more complex NLU tasks, ranging from causal reasoning to multi-hop and cloze-style QA. $|M|$=22.
- VALUE (Video-and-Language Understanding Evaluation; Li et al.) covers 11 video-and-language datasets on text-to-video retrieval, video QA, and video captioning. $|M|$=7.

The leaderboards present the results of evaluating various neural models, such as BERT (Devlin et al., 2019), STRUCTBERT (Wang et al., 2019b), ALBERT (Lan et al., 2019), ROBERTA (Liu et al., 2019), T5 (Raffel et al., 2020), DEBERTA (He et al., 2020), ERNIE (Zhang et al., 2019), and their ensembles and other model configurations.

---

[3] We do not consider more complex rules like *Kemeny* since it is NP-hard to find the Kemeny winner (Bartholdi et al., 1989), and it is often implemented as the *Borda* rule approximation (Colombo et al.).

Benchmark	k	σ^{gm}	σ^{og}	**Copeland**	**Minimax**	**Plurality**	**Dowdall**	**Borda**
GLUE	top-1	1.0	1.0	1.0	1.0	1.0	1.0	1.0

Borda	0	7.96 $\pm$3.8	1	5.38 $\pm$1.8

Table 2: Discriminative power (DP) and independence of irrelevant alternatives (IIA) values. The lower, the better for both DP and IIA.

3.1 Re-interpreting Benchmarks

Method. We begin with a case study on re-ranking systems on the publicly available leaderboards using the scoring and majority-relation based rules[4]: *Plurality*, *Dowdall*, *Borda*, *Copeland*, and *Minimax* as the baselines. σ^{og} is an aggregation metric that identifies the amount by which the system fails to get a minimum score of $\gamma = 0.95$ (lower is better). The comparison is run by computing *(i)* the agreement rate (AR; in %), i.e. the proportion of the top/least-k systems between the given procedure and σ^{am}, *(ii)* the Kendall Tau correlation (τ) between the total rankings, *(iii)* the discriminative power (DP) or the number of tied alternatives. i.e. alternatives with the same score (Brandt and Seedig, 2016), and *(iv)* the independence of irrelevant alternatives (IIA), i.e. how often the *new* systems change the ranking (see Appendix A.2 for details). IIA is computed iteratively in two steps. First, we initialise a leaderboard with two random systems m_A and m_B. Second, we add a new random system m_C to the leaderboard and check if the rankings of m_A and m_B have changed. We repeat the procedure by adding up to $|M|$ systems and counting how often the new system affects the ranking. The experiment is run 50 times to account for randomness.

Results. Table 1 and Table 2 present the results except for the VALUE benchmark which is discussed in Appendix B. We find that methods tend to agree on the top systems, but *Minimax* and *Plurality* disagree on which ones are the worst. Despite high ARs on particular top/least-k systems, the order of the systems on GLUE and SGLUE is different, which is indicated by the low correlation coefficients. The Pythagorean mean results are consistent with one another on the top-7 systems and may lead to different worst systems. σ^{og} generally disagrees with σ^{am} for the top and worst systems on GLUE but has higher ARs and correlation on SGLUE.

At the same time, the DP results demonstrate that *Dowdall* and *Borda* produce only one pair of alternatives with the same score, whilst *Minimax* and *Plurality* treat a significantly larger number of systems as equivalent. The reason is that the rules initially intend to define the best alternative, and they are indecisive between the alternatives when utilised to rank. The IIA experiment shows that introducing a new system influences the *Dowdall* and *Borda* rankings. However, this tendency is less common for *Copeland*, *Minimax*, and *Plurality* and is observed only up to 2 times on SGLUE.

Overall, we observe that the GLUE and SGLUE benchmark rankings depend on the aggregation procedure. The human baseline (HUMAN) rank has risen by up to 13 positions on GLUE (see Table 3). The *Copeland* method takes HUMAN, DEBERTA+CLEVER, and T5 equal, meaning that the difference between the number of candidates they dominate and are dominated by is the same. The *Minimax* ranking suggests that HUMAN, T5, and the ALBERT+DAAF+NAS ensemble are equivalent, meaning that minimal maximum defeats against other models are the same. In their turn, the *Plurality* and *Dowdall* procedures rank HUMAN as the second-best solution, since HUMAN receives the best performance in several tasks, such as RTE (Wang et al., 2018) and MNLI (Williams et al., 2018). The tendency is also observed on the SGLUE benchmark (see Table 9 in Appendix B), with the exception that HUMAN is selected as the winner by the *Copeland*, *Plurality*, and *Dowdall*

---

[4] We omit the iterative rules here for the sake of space.

Table 3: Results of re-ranking the GLUE benchmark. Changes in the system ranks are depicted with arrows, whilst the superscripts denote scores assigned by the aggregation procedure. Notations: 🙋🏽‍♀️=HUMAN; 😃=ERNIE; 🗑️=STRUCTBERT+CLEVER; 😐=DEBERTA+CLEVER; 🧚=DEBERTA/TURINGNLRV4; 🟦=MACALBERT+DKM; 🐛=T5; 🦁=ALBERT+DAAF+NAS; 🔵=FUNNEL. The superscript values stand for the voting rules' scores, whilst the subscript values indicate changes in the ranking positions. $\uparrow x$ means up x positions, $\downarrow x$ means down x positions, $\updownarrow$ means no changes.

procedures and is equal to the ERNIE system according to *Minimax*. The results for *Borda* are similar to σ^{am} and σ^{gm} on the top-4 and top-6 ranks on GLUE and SGLUE, respectively.

Selecting the winner. Another application of the voting rules includes selecting the winner from the set of alternatives. Here, we also utilise the *Threshold*, *Baldwin*, and *Condorcet* rules. Note that we run the VALUE experiment over missing and non-missing scores since the HUMAN results are presented for only 6 out of 11 tasks.

Results. Table 4 presents the results of selecting the winner for each benchmark. ✗ denotes that *(i)* the given method does not support missing values, or *(ii)* there is no *Condorcet* winner (CW). We observe that different SoTAs are selected by 2/7/3 (on GLUE/SGLUE/VALUE) procedures as opposed to σ^{am}, σ^{gm}, and σ^{og}. The *Threshold* rule selects T5+UDG and STRUCTBERT+CLEVER as winners because their performance is the worst the least amount of times. The *Baldwin* rule agrees with the *Plurality* and *Minimax* results. When considering VALUE missing scores, we find that HUMAN is declared SoTA by the *Copeland*, *Minimax*, and *Condorcet* procedures. It means that HUMAN beats any other model in pairwise comparison and is declared the CW, whilst significantly outperforming the systems on specific tasks.

Case study discussion. Benchmarks can suffer from *saturation*, which is characterised by surpassing estimates of the human performance followed by stagnation in SoTA improvements (Ott et al., 2022). The NLP community has discussed saturation of the GLUE benchmark over time (Kiela et al., 2021; Ruder, 2021) and minor performance gains of the upcoming top-leading systems on SGLUE (Rogers, 2019). However, the discussion relies on the mean aggregation. Let us take a step away from the *utilitarian* approach. We observe that HUMAN may still take leading positions, and system ranking varies on these benchmarks under the social choice theory principles. VALUE demonstrates more stable results in terms of the AR and the system order, which we attribute to its novelty and minor performance differences between the systems. Overall, our rules provide interpretable results and cope with the missing leaderboard values in contrast to the *utilitarian* methods.

3.2 The Condorcet Winner

One of the most natural ways to choose the best system given a set of weights defined by the user is the Condorcet method, which declares a system the winner if it dominates all other alternatives in pairwise comparison (Black et al., 1958). The Condorcet method is hard to destabilise (Edelman, 2015) and easy to interpret in practice, indicating that the CW best matches the preferences. Given the weights vector, finding the CW, if it exists, is trivial. We can also find the weights that make a given alternative the CW or determine that no weights with that property exist.

Method. Let us define an operator $R(m_1, m_2, i)$:

$$R(m_1, m_2, i) = \begin{cases} 1, & \text{if } \exists s_{m_1 i} \wedge \exists s_{m_2 i} \wedge s_{m_1 i} > s_{m_2 i}, \\ -1, & \text{if } \exists s_{m_1 i} \wedge \exists s_{m_2 i} \wedge s_{m_1 i} < s_{m_2 i}, \\ 0, & \text{otherwise} \end{cases} \quad (1)$$

A system m is declared a CW if the following property is satisfied:

$$\forall m' \in M \setminus \{m\} \quad \sum_{k=1}^{|T|} R(m, m', k) w_k \geq 0 \quad (2)$$

Let $G_m \in \{-1, 0, 1\}^{|M|-1 \times |T|}$ be a matrix such that $G_{ij} = R(m, m'_i, j)$, where $\{m'_1, .., m'_{|M|-1}\} = M \setminus \{m\}$.

Equation 2 can be re-written as: $G_m \cdot w \succcurlyeq 0$, which results in defining a space W^* in $\mathbb{R}^{|T|}$, whose each point is a weight vector making m a CW. Any linear algorithm can be applied to find a point in W^* or determine that W^* is empty. Furthermore, any other linear conditions can be added, such as upper/lower bounds of the w components and a linear function that needs to be optimised, e.g. $w_i \longrightarrow \min$. Let us call a system for which there exists a vector of weights making it a CW *prospective*. By definition, the system is *prospective* if W^* is not empty.

Example. Let us illustrate the method on the SGLUE benchmark (see Table 4). There is no CW if the task weights are assigned uniformly. Nevertheless, T5 may become the CW when the BOOLQ accuracy (Clark et al., 2019) and MULTIRC exact match scores (Khashabi et al., 2018) have equal weights of 0.5, and the other criteria weights are zeroed. In this scenario, T5 has been found to be a *prospective* system on SGLUE, whiste ROBERTA is declared *non-prospective*.

Results. There are 9/88, 10/12, and 3/3 prospective/non-prospective systems on GLUE, SGLUE, and VALUE, respectively. The results indicate that it is possible to find specific evaluation scenarios in which a given system is the best. In contrast, the non-prospective system always has an alternative that performs neither worse nor better.

Case study discussion. The CW criterion presents another perspective of selecting the best systems. Notably, the existence of the CW weights assumes that practitioners can simulate a set of real-world scenarios where the system is the best across the given axes. Specifying if the system can be the CW on the leaderboard would help diagnosing the systems without additional heavy experiments. The developers also can document this information on model sharing platforms, e.g. HUGGINGFACE (Wolf et al., 2020).

3.3 Robustness to Missing Scores

This case study considers a more detailed analysis of the majority-relation based voting rules that can be efficiently utilised for ranking systems and selecting the winner over missing scores. Here, we evaluate the robustness of the rules to omitted performance scores and analyse how the rankings change under such perturbation.

Method. *Copeland* and *Minimax* take as input the majority graph in which each vertex corresponds to a candidate and an edge from the candidate m_1 to m_2 exists iff $m_1 \mu m_2$, i.e. m_1 is ranked higher than m_2 by more criteria. Let us say there are T criteria $t \in \{t_1, \dots, t_T\}$ and $w \in \{w_1, \dots, w_n\}$ are the weights assigned to them.

$$m_1 \mu m_2 \iff \sum_{i=1}^{|T|} w_i R(m_1, m_2, i) > 0 \quad (3)$$

When evaluating $R(m_1, m_2, i)$, this approach can handle missing values, ignoring the pairs where either of the scores is missing. We can apply the majority-relation based rules using relation μ to rank alternatives with missing scores without losing any information whilst accounting for the available criteria.

We analyse the robustness of the *Copeland* and *Minimax* rules as follows. First, we compute the rankings using both methods on each benchmark without omitting scores and use them as references. Next, we randomly replace N scores with empty values and find top-7 systems over the corrupted leaderboards. We calculate the Spearman correlation (ρ) between the final rankings and the references. Note that we use the median values when omitting scores for σ^{am} and σ^{og} as the baselines.

Results. Figure 2 shows that σ^{am} and σ^{og} display lower stability and *Copeland* performs the best on GLUE and SGLUE. However, we observe that *Minimax* is the least stable on VALUE, whilst *Copeland*, σ^{am}, and σ^{og} perform on par.

Case study discussion. We attribute the low stability of *Minimax* on VALUE to its limitations. Recall that there are minor differences between the systems on VALUE, which cause *Minimax* to score them very similar (see Table 10 in Appendix B). In this case any missing value can influence the rankings, which results in the low ρ coefficients.

3.4 Ranking Based on User Preferences

This case study aims at system ranking based on the user utility. We rank systems in a simulated scenario that considers preferences on *performance*, *computational efficiency*, and *fairness*.

Method. We use the HUGGINGFACE library to fine-tune and evaluate systems on GLUE. Each system is initialised with a fixed set of five random seeds and fine-tuned for five epochs with default hyper-parameters and a batch size of 16. The development set performance is averaged across all runs. We consider the following systems: BERT-base, RoBERTa-base, ALBERT-base, DeBERTa-base, DistilBERT-base (Sanh et al., 2019), DistilRoBERTa-base (Sanh et al., 2019), and GPT2-medium (Radford et al., 2019). The experiments are run on a single GPU unit, NVIDIA A100 80 GB SXM (NVLink), 4-CPU cores, AMD EPYC 7702 2-3.35 GHz, and 1 TB RAM.

The *efficiency* is computed during fine-tuning via the Impact tracker toolkit (Henderson et al., 2020): the total power, run time in hours, GPU usage in hours, and estimated carbon footprint. To maximise these, we inverse the computational efficiency features through multiplying them by -1.

To measure *fairness*, we choose three social bias evaluation datasets: CROWS-PAIRS (Nangia et al., 2020), STEREOSET (Nadeem et al., 2021), and WINOBIAS (Zhao et al., 2018). In these datasets, one sentence is always more stereotyping than the other. Following Nangia et al. (2020), we use MLM scoring (Salazar et al., 2020) to score the pairs. The final metrics account for cases (%) in which a less stereotyping sentence is the most probable.

For the sake of space, we present the results on the *Borda* procedure in the basic, weighted, and two-step aggregation settings (§2.4). We assign the weights vector as $(0.4, 0.3, 0.3)$ to performance, efficiency, and fairness. The weights are introduced to increase the impact of performance. We use σ^{am} as the baseline and interim rankings by each criterion individually as references.

Results. Table 5 shows that DEBERTA is the winner according to σ^{am} and *Borda*. However, it requires more computational resources than the other systems and is mediocre in detecting social biases. As a result, it is not the best system in any user-oriented ranking. In this scenario, *Borda* tends to favour the distilled systems (DISTILROBERTA and DISTILBERT) due to their computational efficiency, which has the highest impact on the ranking with four criteria assigned per task. The weighted *Borda* ranks DISTILBERT, ALBERT, and BERT as the top-3 systems. In its turn, the weighted 2-step *Borda* prefers ALBERT first, followed by BERT and DISTILBERT. ALBERT is selected as the winner by the fairness ranking only and occupies the middle positions in the two other rankings. ROBERTA drops down drastically from the second rank (σ^{am}), whilst GPT2 remains in the least-3 systems.

Case study discussion. Overall, our setup follows DYNASCORE (Ma et al., 2021), where the microe-

Rank	$\sigma^{am}_{\text{Performance}}$	**Borda**	**Weighted Borda**	**Weighted 2-step Borda**	**Borda Performance**	**Borda Efficiency**	**Borda Fairness**

conomic concept of MRS is used to compare performance, efficiency, and fairness metrics, followed by the weighted average score as the final ranking. Unlike the DYNASCORE results, we find that the average performance ranking is not preserved when using our voting rules. The most notable difference is with DEBERTA and ROBERTA systems, which may become penalised for low efficiency in our case. The reason is that in DYNASCORE, the weight of 0.5 is assigned to performance which blocks substantial changes in re-ranking.

4 Recommendations for Rules Choice

The information about the voting rules' properties can be used to choose the most suitable one to the user's preferences (Felsenthal and Machover, 2012). We also provide the following recommendations.

- The *Plurality* rule is a good choice if the user wants only the best systems in *each* criterion.
- If *all* ranking positions matter, use the *Borda* or *Dowdall* rules. Note that *Dowdall* assigns higher weights to the top positions.
- The *Threshold* rule is helpful in cases when the user wants to minimise the number of the low-performance criteria: the rule assigns the highest rank to the system that is considered the worst in the least amount of criteria.
- If the goal is to select the system that beats all the others in pairwise comparison, use the *Baldwin*, *Condorcet*, *Copeland*, or *Minimax* rules. These rules are Condorcet consistent; i.e. choose the CW if it exists. The main difference is how the rules behave when there is no CW. In particular, *Baldwin* selects the system that is left after elimination according to the *Borda* scores. *Copeland* chooses the system that dominates the others in more cases and is dominated by the least. In turn, *Minimax* selects the system with minimum defeat in pairwise comparison.
- The outcomes *may* contain equivalent alternatives (§3.1). Depending on the scenario, the user can select the rule that produces ties with a lower probability or *Dowdall* and *Borda* if their properties meet the preferences.

5 Conclusion and Future Work

This paper introduces novel aggregation procedures to rank and select the best-performing systems under the social choice theory principles. Our approach provides an alternative perspective of system evaluation in benchmarking and overcomes the standard mean aggregation limitations.

Our case studies show that VOTE'N'RANK provides interpretable decisions on the best and worst systems whilst accounting for missing performance scores and potential user preferences. The framework allows for finding scenarios in which a given system dominates the others. At the same time, the rule choice may depend on the particular research and development purpose. We provide recommendations based on the rules' properties and scenarios of the intended framework's application.

The application scope of VOTE'N'RANK is not limited and may be easily extended to other applied ML areas. In our future work we hope to explore applications of the social choice theory in the *multilingual* and *multimodal* benchmarking.

6 Limitations

Robustness. In the robustness experiments, the *Copeland* and *Minimax* rules are less sensitive to performance score drops than σ^{am} and σ^{og}. However, in certain circumstances *Minimax* may display low resistance to such corruption due to its nature, which is analysed in §3.3. Other robustness evaluation settings can be considered, such as sensitivity to removing and adding new tasks (Procaccia et al., 2007; Colombo et al.), which are out of scope of this work.

Ambiguity. Almost all rules in our study allow ties or the recognition of systems as equivalent. This may result in non-resoluteness: the selection of multiple winning systems or the presence of many equivalencies in ranking. However, we empirically observe no or a few ties using the *Dowdall*, *Borda*, and *Copeland* rules, whilst *Minimax* and *Plurality* treat a significant number of systems as equivalent due to their properties (§3.1). VOTE'N'RANK does not currently support any additional tie-breaking rules to be applied in this case. The only exception here is the *Threshold rule* that gives only one winner in almost all cases due to the built-in tie-breaking procedure.

Independence of irrelevant alternatives. The violation of the IIA axiom in applications is a well-known fundamental aspect in the social choice theory, and the voting rules can violate the IIA with different probabilities (Dougherty and Heckelman, 2020). IIA violation may imply undesirable behavior: submitting a new system to the leaderboard affects the relative ranking of the other systems. However, we empirically show that *Copeland* and *Minimax* are less likely to violate IIA than *Plurality* and *Borda* rules (§3.1). The IIA assumption may be unrealistic in practice as it takes no account of perfect or near-perfect substitutes (Suppes, 1965).

Lack of ground truth. Comparison of the aggregation procedures is hindered by the absence of the correct ranking, especially when votes are noisy and incomplete. There is no universal answer to the question of how the systems on the multi-task benchmarks should be preferred. However, we hope to contribute from a practical standpoint, offering an alternative approach to the mean aggregation procedure.

7 Ethical Considerations

Stereotypes and discrimination in LMs' pre-training data can lead to representation biases against race, religion, and social minorities. Our framework allows ranking systems to account for sensitive attributes (Celis et al., 2018), e.g. gender and nationality, or to find the trade-off between multiple criteria, e.g. performance and fairness (Baldini et al., 2022). The rank aggregation rules have been widely adopted to information retrieval and recommendation systems (Dwork et al., 2001; Masthoff, 2011). We assume that translation of the social choice theory into the system evaluation problems may improve the user experience by selecting systems that best satisfy evaluative criteria and individual or group preferences in downstream applications.

A Aggregation Procedures

A.1 Examples

Rank	Task 1	Task 2	Task 3	Task 4	Task 5
1	m_A	m_A	m_B	m_C	m_D
2	m_B	m_C	m_D	m_B	m_B
3	m_C	m_D	m_C	m_D	m_C
4	m_D	m_B	m_A	m_A	m_A

Table 6: A toy leaderboard for illustration purposes.

Rank	Task 1	Task 2	Task 3	Task 4	Task 5
1	m_B	m_C	m_B	m_C	m_D
2	m_C	m_D	m_D	m_B	m_B
3	m_D	m_B	m_C	m_D	m_C

Table 7: The leaderboard based on Table 6 used for describing the *Baldwin* rule.

This appendix provides illustrative examples on how our voting rules work. Here, suppose we have a toy leaderboard with five tasks and four systems as shown in Table 6. The systems are ranked within each task by their performance score. We now compute the rankings using each voting rule.

Scoring rules.

- *Plurality rule* assigns the score of 2 to m_A and scores of 1 to m_B, m_C, and m_D.
- According to the *Borda rule*, the systems that take the first position get 3 points for each task, 2 points are awarded for the second position, etc. As a result, the systems receive the following *Borda* scores: $m_A = 6$, $m_B = 9$, $m_C = 8$, and $m_D = 7$. The system m_B has the highest score and is chosen as the best one.
- For the *Dowdall* rule scoring vector, we get the following scores: $S_{m_A} = 2.75$, $S_{m_B} = 2.75$, $S_{m_C} = 2.5$, and $S_{m_D} = 1.75 + 2/3$. There is a tie between the systems m_A and m_B, and both of them are considered the best models.

Iterative scoring rules.

- For the *Threshold* rule scoring vector (1,1,1,0), we get the following scores: $S_{m_A} = 2$, $S_{m_B} = 4$, $S_{m_C} = 5$, and $S_{m_D} = 4$. The system m_C is the winner. If there is a tie, the scoring vector (1,1,0,0) is further applied for only tied systems.
- The *Baldwin* rule: first, we calculate the *Borda* scores as mentioned above. Second, we eliminate the system m_A since it has the lowest score (see Table 7). Next, we re-calculate the *Borda* scores for a new scoring vector (2,1,0) and get the following results: $S_{m_B} = 6$, $S_{m_C} = 5$, and $S_{m_D} = 4$. At this step, the system m_D is eliminated. Finally, we re-calculate the results for the scoring vector (1,0). The results are $S_{m_B} = 3$ and $S_{m_C} = 2$, and the system m_B is declared the winner.

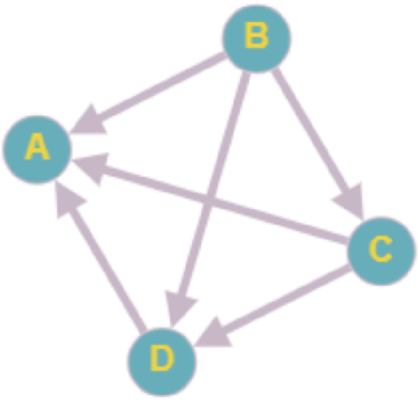

Figure 3: A toy graph example of the majority relation μ based on Table 6.

Majority-relation based rules. The majority relation in this example is illustrated in Figure 3.

- The system m_B is the *Condorcet* winner as it beats each of the alternatives. Note that since all majority-relation based rules (*Copeland* and *Minimax*) are *Condorcet consistent*, they declare the system m_B the winner as well. Let us illustrate it in more detail.
- The *Copeland* rule scores are $u(m_A) = -3$, $u(m_B) = 3$, $u(m_C) = 1$, $u(m_D) = -1$. The system m_B is the winner as it has the highest $u(x)$.
- The *Minimax* rule scores are $rank(m_A) = -3$, $rank(m_B) = 0$, $rank(m_C) = -3$, $rank(m_D) = -3$. Here, the system m_B has the highest rank.

A.2 Properties

We consider the following properties to describe our voting rules and summarise them in Table 8.

- **Transitivity.** There are no cycles in the final ranking. An example of the cycle is a situation, where m_A is better than m_B, m_B is better than m_C, and m_C is better than m_A.

	Plurality	*Borda*	*Dowdall*	*Threshold*	*Baldwin*	*Copeland*	*Minmax*
Transitivity	✓	✓	✓	✓	✓	✓	✓
Anonymity	✓	✓	✓	✓	✓	✓	✓
Unanimity	✓*	✓	✓	✓	✓	✓	✓
IIA	✗	✗	✗	✗	✗	✗	✗
Monotonicity	✓	✓	✓	✓	✗	✓	✓
Majority	✓	✗	✓	✗	✓	✓	✓
CW	✗	✗	✗	✗	✓	✓	✓
Condorcet loser	✗	✓	✗	✗	✓	✓	✗
Sum	5	5	5	4	6	7	6

Table 8: Rules and their properties. *The non-winning Pareto-dominated systems can be tied.

- **Unanimity (Pareto efficacy).** If the system m_A is ranked higher than m_B according to all criteria, then m_A should be ranked higher.
- **Non-dictatorship (Anonymity).** There is no single criterion that defines the final ranking.
- **Independence of irrelevant alternatives (IIA).** For any two systems, the information about other systems should not influence their ranking.
- **Monotonicity.** If the system m_A is the winner and it started to rank higher according to one of the criteria, then it should still be the winner.
- **Majority criterion.** If the system m_A is considered the best by more than 50% criteria, then it should be the winner.
- **Condorcet winner criterion**. This criterion is a stronger version of the Majority criterion. If the system m_A is the Condorcet winner (CW), it should be the winner according to the rule.
- **Condorcet loser criterion.** If the system m_A is the Condorcet loser ($a \mu M^L$ for any $a \in A$), it should never be the winner according to the rule.

Recall that the *Condorcet* rule by definition complies with the Condorcet winner and loser criteria. The other properties can not be checked in application to benchmarking since the rule is defined on a restricted domain: it does not provide the results on any possible combination of rankings.

There is no single best voting rule since none of them satisfies properties of the Arrow's impossibility theorem (Arrow, 2012; Geanakoplos, 2005): transitivity, unanimity, non-dictatorship, and independence of irrelevant alternatives (IIA).

B Case Studies

We do not report the agreement rate, the Kendall Tau (τ) correlation, and the IIA results for VALUE since we are given only up to 7 evaluated alternatives: CRAIG.STARR (Shin et al., 2021), DUKG (Li et al., 2021), HUMAN, and four HERO-based configurations (Li et al., 2020). The HERO-based baselines are trained in the following settings: single-task training (ST), multi-task training (MT) by tasks or domains, all-task training (AT) and AT first then ST (AT -> ST). We refer to the configurations as follows:

- HERO$_1$: AT->ST, PT+FT;
- HERO$_2$: AT->ST, FT-only;
- HERO$_3$: ST, PT+FT;
- HERO$_4$: ST, FT-only.

The VALUE results. Table 10 and Table 11 show the VALUE re-ranking results over missing/non-missing scores. ✗ means that the given aggregation method does not operate over missing values. In the first case, we observe that the *Copeland* and *Minimax* rules generally agree on the final outcomes except for the fifth and sixth positions. The rules select HUMAN as the winner. At the same time DUKG and HERO$_1$ have the same *Minimax* values, and the *Minimax* values of the least-3 systems are also equal. In the second case, we omit HUMAN due to missing scores on 6 out of 11 tasks for comparable interpretation. However, there are 3 tied alternatives in the *Minimax* and *Dowdall* outcomes. Interestingly, all methods are consistent in conclusions on the top-3 systems, with the *Minimax* treating DUKG and HERO$_1$ as equal alternatives. The σ^{og}, *Minimax*, *Plurality*, *Dowdall*, and *Borda* rules make equal decisions on the final outcomes.

Abstract

A modular design encourages neural models to disentangle and recombine different facets of knowledge to generalise more systematically to new tasks. In this work, we assume that each task is associated with a subset of latent skills from an (arbitrary size) inventory. In turn, each skill corresponds to a parameter-efficient (sparse / low-rank) model adapter. By jointly learning adapters and a routing function that allocates skills to each task, the full network is instantiated as the average of the parameters of active skills. We propose several inductive biases that encourage re-usage and composition of the skills, including variable-size skill allocation and a dual-speed learning rate. We evaluate our latent-skill model in two main settings: 1) multitask reinforcement learning for instruction following on 8 levels of the BabyAI platform; and 2) few-shot fine-tuning of language models on 160 NLP tasks of the CrossFit benchmark. We find that the modular design of our network enhances sample efficiency in reinforcement learning and few-shot generalisation in supervised learning, compared to a series of baselines. These include models where parameters are fully shared, task-specific, or conditionally generated (HyperFormer), as well as sparse mixture-of-experts (Task-MoE).

1 Introduction

Task-level generalisation involves training a model on multiple tasks (in parallel or sequentially) and then performing zero-shot inference or few-shot adaptation on new tasks (Caruana, 1997; Ye et al., 2021). However, the training signals from different tasks may interfere with each other (McCloskey and Cohen, 1989) or lead to catastrophic forgetting of previous knowledge (French, 1999). Moreover, when the nature of the tasks varies between training and evaluation, models often struggle to generalise systematically (Hupkes et al., 2020).

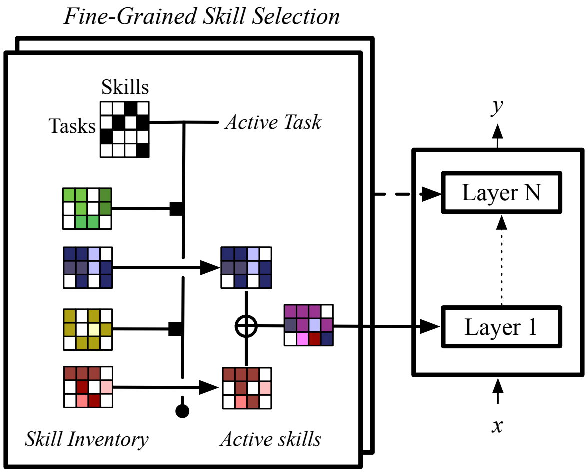

Figure 1: A diagram of our latent-skill model: 1) a row of the task–skill binary matrix is selected according to the active task; 2) the sparse (SFT) or low-rank (LoRA) adapters corresponding to active skills from a layer-specific inventory are combined; 3) the resulting combination is applied to the weights of a neural network, e.g. BART in our multi-task experiments.

A potential solution to these challenges consists in a modular design of neural architectures. In fact, these are endowed with an inductive bias towards updating and activating modules locally and asynchronously, thus preventing negative interference (Jacobs et al., 1991b). Additionally, by disentangling autonomous facets of knowledge (also known as *skills*) that are re-used and recombined in original ways for new tasks, modularity facilitates systematic generalisation (Alet et al., 2018; Ponti, 2021; Kingetsu et al., 2021, *inter alia*).

Previous work on task-level generalisation focused on settings where the skills relevant for new tasks are already known *a priori* (Pfeiffer et al., 2020; Ansell et al., 2022). However, this requires expert knowledge, possibly with sub-optimal granularity and limited to a few domains. In alternative, mixture-of-expert (MoE) methods such as Task-MoE (Kudugunta et al., 2021a) learn a routing function that allocates modules to tasks end-to-end. However, MoEs mostly focus on scaling large lan-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 687–702

guage models trained from scratch, and their effectiveness for out-of-domain generalisation is a moot point (Artetxe et al., 2021; Fedus et al., 2022).

In this work, we introduce a modular architecture that can efficiently adapt to new tasks, by virtue of a series of inductive biases that facilitate generalisation. The full model is shown in Figure 1. For each task, we learn a binary vector that specifies which skills (from a fixed inventory) are used to solve it. In the example, skills 2 and 4 are active. We implement each skill as a parameter-efficient adapter, either sparse (Ansell et al., 2022, SFT) or low-rank (Hu et al., 2021, LoRA). The parameters corresponding to every active skill (red and blue in the example) are then combined, by simple averaging. The resulting combination adapts a pretrained model, such as BART (Lewis et al., 2020), towards a specific task during multitask learning. The variable-size allocation of skills encourages their re-usage and re-combination in new tasks. To promote a coarse-to-fine dynamic where skill allocation is determined before skill-specific parameters, we explore a dual-speed learning rate for these two components (see Section 2.3).

We evaluate our model on reinforcement learning on BabyAI (Chevalier-Boisvert et al., 2019), a platform for instruction following in a simulated environment, and supervised learning on CrossFit (Ye et al., 2021), a benchmark recasting 160 NLP tasks as text-to-text generation problems. Compared to a series of competitive baselines, we obtain higher sample efficiency and higher performance in few-shot adaptation to held-out tasks. In particular, our latent-skill model surpasses non-modular methods for multi-task adaptation, such as HyperFormers (Karimi Mahabadi et al., 2021) and CA-MTL (Pilault et al., 2021), and mixture-of-experts methods such as Task-MoE (Kudugunta et al., 2021a).

Finally, we probe the learnt task–skill allocation matrix and illustrate how our method also enhances interpretability, as it discovers which pairs of tasks require common skills. The code is made available at `https://github.com/McGill-NLP/polytropon`.

2 A Latent-Skill Multitask Model

The goal of multitask learning in modelling a set of tasks $\mathcal{T} = (\mathcal{T}_1, \dots, \mathcal{T}_{|\mathcal{T}|})$ is two-fold: 1) increasing sample efficiency on each seen task by borrowing statistical strength from the others; and 2) attaining systematic generalisation, the ability to adapt robustly to new tasks, possibly based on a few target-domain examples. In particular, in supervised learning, each task $\mathcal{T}_i$ is associated with a dataset $\mathcal{D}_i \triangleq \{(\mathbf{x}_1, \mathbf{y}_1), \dots, (\mathbf{x}_n, \mathbf{y}_n)\}$ and a loss function $\mathcal{L}(\hat{\mathbf{y}}, \mathbf{y})$, where $\mathbf{x}$ is an input and $\mathbf{y}$ is an output. In reinforcement learning, each task is characterised by an initial state distribution $q(\mathbf{x}_1)$, a transition distribution $q(\mathbf{x}_{t+1} \mid \mathbf{x}_t, a_t)$, and a loss function $\mathcal{L}(\mathbf{x}_1, a_1, \dots, \mathbf{x}_h, a_h) \to \mathbb{R}$,[1] where $\mathbf{x}$ is a state, a is an action, and h is the temporal horizon of each episode. Thus, each task defines a Markov Decision Process (MDP).

Fully sharing the parameters of a model across tasks (Stickland and Murray, 2019) may exhaust its capacity or create interference among the gradients from task-specific losses (Wang et al., 2021). These limitations can be countered by instead composing task-specific adapters (Pfeiffer et al., 2021) or softly sharing parameters (Ponti et al., 2021a; Karimi Mahabadi et al., 2021; Ansell et al., 2021). The first method leads to an explosion in parameter count, which grows with the number of tasks. Moreover, the second method suffers during few-shot adaptation to new tasks as the entangled (i.e., non-modular) knowledge may overfit the training distribution.

Instead, we posit that there exists a (possibly small) fixed inventory of skills $\mathcal{S} = (\mathcal{S}_1, \dots, \mathcal{S}_{|\mathcal{S}|})$, where $|\mathcal{S}| \ll |\mathcal{T}|$. Each skill is an independent facet of knowledge that is reused across a subset of tasks. These assumptions guarantee both scalability and modularity. In particular, we seek to create a model that jointly learns which skills are active for which task, aggregates the corresponding skill parameters according to some deterministic function, and maximises the multitask log-likelihood:

$$\begin{gathered}\operatorname*{arg\,max}_{Z,\Phi} \sum_{\mathcal{T}_i} \sum_{(\mathbf{x},y)\in\mathcal{T}_i} \log p(y \mid \mathbf{x}, \boldsymbol{\vartheta}_i)\, p(Z)\, p(\Phi), \\ \text{where } \boldsymbol{\vartheta}_i = \delta(Z_i, \Phi, \boldsymbol{\vartheta}_0)\end{gathered} \tag{1}$$

The learnable parameters, as shown in Figure 1, are: i) Z, which denotes the task–skill allocation matrix, representing a soft partition of skills across tasks; ii) Φ, a tensor containing the parameters of each skill. As we explain in Section 2.4, these consist in either sparse or low-rank linear adapters. δ is a deterministic combination function that takes as input the task–skill allocation vector Z_i for task $\mathcal{T}_i$,

---

[1] This is the negative of the reward: $\mathcal{L}(\cdot) = -\mathcal{R}(\cdot)$.

the skill parameters Φ and some shared parameters across tasks $\boldsymbol{\vartheta}_0$ and creates a task-dependent set of parameters $\boldsymbol{\vartheta}_i$, i.e. in our model, we use simple averaging of the active skills (see Figure 1). $\boldsymbol{\vartheta}_i$ is then used to predict the task label y given the input $\mathbf{x}$. In what follows, we illustrate each component separately.

2.1 Soft Partitions

What is the best strategy to determine which skills are active for which task? The cognitively inspired notion of modularity at the level of structured inputs assumes that modules compete with each other for activation and updating (Bengio, 2017; Goyal et al., 2021). This intuition is translated in practice into a softmax across modules and top-k selection, such as in mixtures of experts (MoEs; Kudugunta et al., 2021a; Fedus et al., 2022). Nevertheless, we argue, modularity at the task level should reflect the fact that tasks fall into a hierarchy: more complex ones subsume simpler ones as sub-tasks. This idea has a long history, harking back to early works on MoEs (Jacobs et al., 1991b) and neural programme induction (Rosenbaum et al., 2019). Hence, we allow for variable-size subsets of skills.

As a consequence, we assume that the matrix $Z \in \{0,1\}^{|\mathcal{T}| \times |\mathcal{S}|}$ representing task–skill allocations is a soft partition: each cell z_{ij} is a binary scalar indicating if skill-specific parameters Φ_j are active for a certain task $\mathcal{T}_i$. However, being discrete, such a binary matrix is not differentiable and therefore cannot be learned end-to-end via gradient descent. Instead, we implement it as a collection of Bernoulli distributions continuously relaxed through a Gumbel-sigmoid (Maddison et al., 2017; Jang et al., 2017), which ensures stochasticity while allowing for differentiable sampling:

$$\hat{z}_{i,j} = \sigma\left[\log \frac{\sigma(z_{i,j})\, u}{(1-\sigma(z_{i,j}))\,(1-u)}^{1/\tau}\right] \\ u \sim \text{Uniform}(0,1). \tag{2}$$

In principle, either a coarse-grained soft partition can be learned globally for the entire neural network, or different fine-grained soft partitions can be assigned to each layer. We opt for the second alternative as it affords the model more flexibility and, foreshadowing, yields superior performance. Therefore, Z and Φ are henceforth assumed to be layer-specific, although we will omit layer indexes in the notation for simplicity's sake.

2.2 Skill-specific Parameters

Given the matrix row $\hat{Z}_i$ for task $\mathcal{T}_i$ from Equation (2) and a matrix of skill-specific parameters $\Phi \in \mathbb{R}^{|\mathcal{S}| \times d}$, where d is the dimension of the layer parameters, the aggregate of the parameters of active skills is superimposed to a base parameterisation $\boldsymbol{\vartheta}_0 \in \mathbb{R}^d$ shared across tasks. For instance, $\boldsymbol{\vartheta}_0$ may be either the initialisation from a pre-trained model or learned from scratch:

$$\boldsymbol{\vartheta}_i = \delta(Z_i, \Phi, \boldsymbol{\vartheta}_0) \triangleq \boldsymbol{\vartheta}_0 + \sum_{\mathcal{S}_j} \Phi_j \frac{\hat{z}_{i,j}}{\sum_{\mathcal{S}_j} \hat{z}_{i,j}}, \tag{3}$$

where $\boldsymbol{\vartheta}_i$ denote the parameters obtained by combining the active skills for the specific task $\mathcal{T}_i$. Note that we normalise the rows of the task–skill allocation matrix $\hat{Z}$ prior to composition because the variable number of active skills per task would otherwise affect the norm of the combined parameters $\boldsymbol{\vartheta}_i$, thus making training unstable.

2.3 Inductive Biases

A possible failure mode during training is a collapse into a highly entropic or non-sparse allocation matrix $\hat{Z}$, e.g., where all skills are active and skill-specific parameters remain general-purpose rather than specialising. Thus, we also provide an inductive bias to encourage the model to learn a low-entropy, highly-sparse allocation matrix.

In particular, we experiment with a dual-speed learning rate, setting its value for Z higher than for Φ. Intuitively, by accelerating learning of the soft partition matrix, to minimise the loss it becomes more convenient to discover better task–skill allocations over settling for general-purpose parameters that are agnostic with respect to the subset of active skills. This is reminiscent of the hypothesis that different kinds of knowledge require faster or slower rates of learning (Kahneman, 2011).

2.4 Parameter Efficiency

In order to keep the skills modular, each of them must correspond to a separate layer parameterisation. Nevertheless, this may lead to a significant increase in both time and space complexity. Thus, we explore parameter-efficient implementations of Φ that only add a negligible amount of parameters to the base model. In particular, we contemplate both sparse and low-rank approximations.

Sparse Fine-Tuning (SFT; Ansell et al., 2022) learns a highly sparse vector of differences Φ with respect to a base model ϑ_0. Its non-zero entries are identified by a binary matrix $M \in \{0,1\}^{|\mathcal{S}| \times d}$. For simplicity, we randomly draw M, as this was shown to perform almost on par with more sophisticated criteria without requiring a separate selection phase (Ansell et al., 2022). SFT is agnostic with respect to the underlying neural architecture.

Low-Rank Adapters (LoRA; Hu et al., 2021) is another method for parameter-efficient fine-tuning designed specifically for Transformer architectures. It factorises each weight of the linear projections inside self-attention as a batched matrix multiplication between two low-rank tensors $A \in \mathbb{R}^{|\mathcal{S}| \times o \times r}$ and $B \in \mathbb{R}^{|\mathcal{S}| \times r \times i}$, where r stands for the rank. In our model, each linear projection $f : \mathbb{R}^i \to \mathbb{R}^o$ is implemented as:

$$\mathbf{x}' = [W_0 + (\mathbf{z}^\top AB)]\mathbf{x} + \mathbf{b}_0 \qquad (4)$$

where $\Phi \triangleq \text{flatten}(AB)$.

We employed sparse adapters (LT-SFT) for the reinforcement learning experiments and low-rank adapters (LoRA) for the NLP experiments. The rationale behind this choice is showing that our method is effective independent of the choice of adapters.

2.5 Baselines

We measure the performance of our SKILLED model, where we learn the skill–task allocation matrix Z end-to-end, against these baselines, which derive from a certain configuration of Z:

- PRIVATE: each task has a separate model parameterisation. During few-shot adaptation, given that $\mathcal{T}_{train} \cap \mathcal{T}_{eval} = \emptyset$, this model cannot benefit from any transfer of information between training and evaluation tasks. This is equivalent to the special case where the task–skill allocation matrix is an identity matrix $Z = I$ of size $|\mathcal{T}| \times |\mathcal{T}|$ and $|\mathcal{S}| = |\mathcal{T}|$.
- SHARED: a shared skill is learnt on the training tasks and then fine-tuned for each evaluation task separately. This is equivalent to the special case where the task–skill allocation matrix is a matrix of ones $Z = \mathbf{1}$ of size $|\mathcal{T}| \times 1$ and $|\mathcal{S}| = 1$.
- EXPERT, where the task–skill allocation is contingent on expert knowledge about task relationships. Crucially, Z is fixed *a priori* rather than being learned.

In addition, for the NLP experiments, we compare our SKILLED method to two state-of-the-art baselines for multitask learning. In the first baseline, HYPER, parameters are softly shared (Karimi Mahabadi et al., 2021; Pilault et al., 2021). These methods generate adapters for the pre-trained model parameters with hyper-networks conditioned on task embeddings. Note that HYPER has a hidden connection with SKILLED, despite their apparent difference. In fact, we can draw an equivalence between i) binary skill vectors $\mathbf{z}$ and task embeddings; ii) the matrix of skill-specific parameters Φ and linear hyper-network weights. Crucially, in our case $\mathbf{z}$ is binary and modular, rather than continuous and entangled.

Secondly, we compare SKILLED with TASK-MOE (Kudugunta et al., 2021a). MoEs were originally conceived for scaling large language models trained from scratch, rather than model adaptation. Moreover, their modules consist of multiple feed-forward networks after the attention layer inside Transformers. The routing function to allocate modules to tasks is based on softmax and top-k selection. This, however, does not favour module re-usage, contrary to variable-size allocation, and instead creates a rich-gets-richer mechanism.

Contrary to their original formulation, we implement the modules of HYPER and TASK-MOE through LoRA adapters rather than Adapter layers and FFNs, respectively. This ensures that the number of updated parameters is similar to SKILLED as implemented in Equation (4) and thus their results are comparable. On top of this, LoRA was shown to offer a better trade-off between performance and efficiency (Liu et al., 2022).

3 Reinforcement Learning Experiments

3.1 Dataset

As a proof-of-concept experiment, we perform multitask reinforcement learning on the BabyAI platform (Chevalier-Boisvert et al., 2019). This benchmark consists in a series of increasingly complex levels, where an agent must execute a linguistic command by navigating a two-dimensional grid world and manipulating objects. Crucially, levels are procedurally generated to reflect different subsets of skills (e.g., PICKUP, UNLOCK, *et cetera*). This enables us to test our model in a controlled setting where performance based on learned skills can be compared with 'ground truth' skills. In particular, we focus on a similar subset of 8 levels as

Hui et al. (2020).

3.2 Experimental Setup

The neural architecture adheres to the best model reported in Hui et al. (2020), BOW_ENDPOOL_RES. It encodes the linguistic input through a Gated Recurrent Unit (GRU; Cho et al., 2014) and the visual input through a convolutional network (CNN). These two streams from different modalities are then merged into a single representation through FiLM (Perez et al., 2018). This component performs a feature-wise affine transformation of the CNN output conditioned on the GRU output.

Afterwards, a Long Short-Term Memory network (LSTM; Hochreiter and Schmidhuber, 1997), a recurrent module keeping track of the agent state trajectory, receives the multimodal representation and returns the current hidden state. This in turn is fed into two distinct MLPs, an actor and a critic (Sutton, 1984). The actor yields a distribution over actions, whereas the critic a reward baseline for the current state. In our experiments, each row of the matrix Φ corresponds to a possible parameterisation for all these components.

To determine *a priori* a skill–task allocation for the EXPERT baseline, we harness the information about the skills employed to procedurally generate each level by Chevalier-Boisvert et al. (2019, p. 6). For the SKILLED model, we set $|\mathcal{S}| = 9$ similarly to EXPERT. This allows us to compare learned skills and 'ground-truth' skills from an inventory of identical size. As a parameter-efficient implementation of Φ, we employ SFT (Ansell et al., 2022) with a sparsity of 90%. For all model variants, $\boldsymbol{\vartheta}_0$ and Φ are both initialised from a Kaiming uniform (He et al., 2015) and learnable. During training, we sample levels uniformly. The full specification of hyper-parameters is available in Appendix A.

3.3 Results

We now measure if our latent-skill model facilitates sample efficiency, which following Chevalier-Boisvert et al. (2019) is defined as the number of episodes required for an agent to reach a success rate greater than 0.99.[2] Success in turn is defined as executing an instruction in a number of steps $n < n_{\max}$, where the threshold again depends on the level complexity.

We plot our results in Figure 2. Firstly, models sharing information across tasks (either fully or mediated by skills) enjoy higher sample efficiency than assigning disjoint parameters for each task (PRIVATE), as they can borrow statistical strength from each other. Crucially, among information-sharing models, dual-speed SKILLED (where knowledge is modular) surpasses SHARED (where knowledge is entangled among tasks). Thus, considering a task as a collection of fine-grained skills that can be separated and reused is the most effective way of sharing information. Finally, results surprisingly show that learning a task–skill allocation matrix end-to-end (SKILLED) is more beneficial than leveraging the ground-truth task–skill decomposition used to create the BabyAI levels (EXPERT). This highlights the fact that different tasks might mutually benefit in ways that go beyond what is posited *a priori* by experts, and that our proposed approach can successfully uncover and exploit such task synergies.

Moreover, we run ablations to study the impact of the inductive biases and the parameter-efficient implementation. We compare the SKILLED model in the standard setup (with dual-speed learning rates and sparse skill-specific parameters) with other variants (with a single learning rate or with fully dense skill-specific parameters) in terms of sample efficiency in Table 3 in Appendix B. We find that assigning the same learning rate to every model component drastically slows convergence to an almost-perfect success rate. In addition, employing fully dense skill-specific parameters increases sample efficiency only to a limited degree (~1.9M). Thus, we can verify that parameter sparsification offers an effective trade-off between performance and space complexity.

4 Supervised Learning Experiments

4.1 Dataset

In order to measure the benefits of a modular design for systematic generalisation to new tasks, we run a second set of experiments on CrossFit (Ye et al., 2021), a benchmark including 160 diverse natural language processing tasks in English sourced from Huggingface Datasets (Lhoest et al., 2021). The tasks in CrossFit are all converted into a unified text-to-text format inspired by Raffel et al. (2020). Moreover, they are partitioned into three disjoint subsets. First, a model is pre-trained in a multitask fashion on training tasks $\mathcal{T}_{train}$. Afterwards, it is adapted to each evaluation task from $\mathcal{T}_{eval}$ in a few-shot learning setting. Hyper-parameter are tuned

---

[2] Success rate alone is insufficient as a performance metric as most models can solve all the levels if given enough time.

Table 1: Few-shot adaptation results of SKILLED and five baselines, including the original model from Ye et al. (2021), on 20 evaluation tasks of CrossFit (Ye et al., 2021). For the full name of the metrics, refer to Section 4.1.

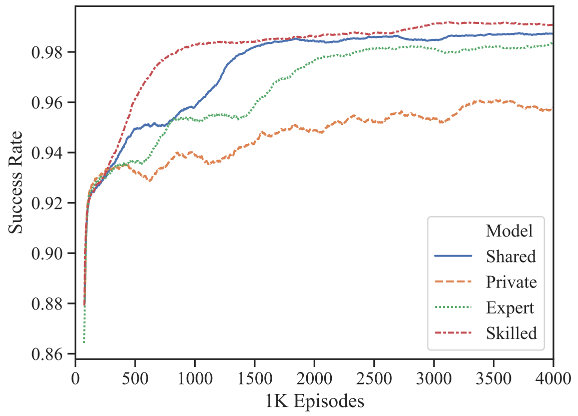

Figure 2: Sample efficiency (success rate vs. number of episodes) for different multitask models across 8 levels of BabyAI. Moving average with window of 100.

on the held-out set $\mathcal{T}_{dev}$.

We adopt the partition 1 (called RANDOM) from Ye et al. (2021), where $|\mathcal{T}_{train}| = 120$, $|\mathcal{T}_{dev}| = |\mathcal{T}_{eval}| = 20$, and tasks are split randomly. This is the most comprehensive partition and most suited for general-purpose models, as it includes all types of tasks. Every task is associated with 5 different few-shot data splits for train $\mathcal{D}_{train}$ and development $\mathcal{D}_{dev}$ and 1 larger data split for evaluation $\mathcal{D}_{eval}$. During multitask pre-training, we concatenate all $\mathcal{D}_{train}$ and $\mathcal{D}_{dev}$ from $\mathcal{T}_{train}$. During few-shot adaptation, for each task in $\mathcal{T}_{eval}$ we use each $\mathcal{D}_{train}$ and $\mathcal{D}_{dev}$ separately in 5 distinct runs and evaluate on $\mathcal{D}_{eval}$. We measure the performance of a model with 7 evaluation metrics according to the type of task: C[lassification]-F1, Acc[uracy], QA-F1, E[xact] M[atch], Rouge-L, M[atthew]-Corr[elation], and P[earson]-Corr[elation].

4.2 Experimental Setup

As pre-trained weights ϑ_0 and architecture for conditional text generation, we choose BART Large (Lewis et al., 2020), a 24-layer Transformer-based encoder–decoder. We use LoRA (Hu et al., 2021) to implement skill-specific parameters efficiently, as it was explicitly designed for the Transformer architecture (cf. Section 2.4). While ϑ_0 remains frozen, A matrices in Φ are initialised to zero matrices following Hu et al. (2021).

As a source of expert knowledge for the EXPERT baseline, we associate each task to a unique skill corresponding to one of the 4 task types of Ye et al. (2021, p. 20)'s taxonomy: question answering, conditional text generation, classification, or other (e.g., regression). The skill inventory size of 8 for SKILLED was chosen among $\{2, 4, 8, 16, 32\}$ based on validation. We set the embedding size e and hidden size h of HYPER to an identical value to ensure a fair comparison. Both SKILLED and HYPER therefore increase the parameter count by $\sim 0.78\%$ per skill and task embedding dimension, respectively. We provide more information on the hyper-parameter configuration in Appendix A.

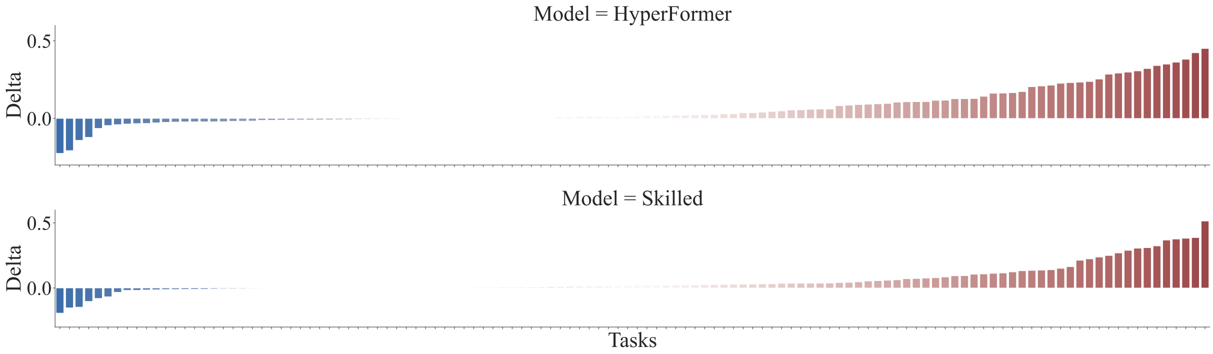

Figure 3: Delta in performance in terms of task-specific metrics between SKILLED (bottom) and HYPER (top) on the one hand and SHARED on the other, across 120 CrossFit tasks seen during multitask pre-training.

4.3 Results

Few-shot Adaptation to New Tasks In the few-shot adaptation setting, our goal is to evaluate the capability of the model to quickly generalise to new tasks unseen during training. This is the most realistic setting as tasks encountered by models deployed 'in the wild' will be characterised by different distributions or involve different input / output spaces. Performance in terms of task-specific metrics is reported in Table 1 for the 20 evaluation tasks individually and on average.

Crucially, results show that SKILLED outperforms alternative formulations of the task–skill allocation matrix, such as SHARED, PRIVATE and EXPERT. Importantly, we note that SKILLED also surpasses HYPER by a sizeable margin despite the two models having comparable parameter counts. This points to the fact that explicitly modularising knowledge learnt during multitask training is important for systematic adaptation to unseen tasks, whereas entangled knowledge is more brittle to distribution shifts in cross-task transfer. Similarly, the average performance of SKILLED is significantly higher that TASK-MOE, which illustrates the importance of variable-size module allocation. Also, it demonstrates that modularity holds promise not only for scaling large language models, but also as a strategy to favour generalisation. Finally, we corroborate the soundness of our experiment setup by reproducing the results of Ye et al. (2021).[3]

Multitask Evaluation on Seen Tasks Moreover, to ensure that modularity does not adversely affect in-domain performance, we evaluate models on the test sets of seen tasks after multitask training. In Figure 3, we report the delta in performance in terms of task-specific metrics between two models (SKILLED on top, HYPER on the bottom) and a baseline (SHARED) for the 120 training tasks. Both models yield positive gains for most tasks over SHARED. Most importantly, SKILLED achieves a performance (48.95 on average) comparable to HYPER (49.37 on average), therefore confirming that explicit modularisation can be as effective as conditional parameter generation when evaluated on seen tasks, but also engenders vast improvements on held-out tasks.

In-Depth Analysis of Learned Skills Finally, we run an in-depth analysis of the task–skill allocation matrices Z learned by SKILLED. We visualise its posterior for $|\mathcal{S}| = 4$ in Figure 5. Specifically, we measure:

1. *Discreteness*. How close is the continuous relaxation to a binary matrix? To this end, we report the average normalised entropy across all probabilities in the cells of the matrix:

$$\text{Discrete}(Z) = \frac{1}{|\mathcal{T}| \cdot |\mathcal{S}|} \sum_{\mathcal{T}_i} \sum_{\mathcal{S}_j} \frac{\mathcal{H}(z_{ij})}{\log 2} \quad (5)$$

   For instance, a binary matrix yields a score of 1, a matrix where every cell is 0.5 yields a score of 0.

2. *Sparsity*. How many skills are active per task on average? We count the rate of non-zero cells in the values rounded to the closest integer:

$$\text{Sparsity}(Z) = \frac{1}{|\mathcal{T}| \cdot |\mathcal{S}|} \sum_{\mathcal{T}_i} \sum_{\mathcal{S}_j} \lfloor z_{ij} \rceil \quad (6)$$

3. *Usage*. Is the allocation of skills across tasks balanced or are some preferred over others? We

---

[3] Note that in Ye et al. (2021) the pre-trained model is BART Small and all parameters are fine-tuned. Hence, these results are not directly comparable.

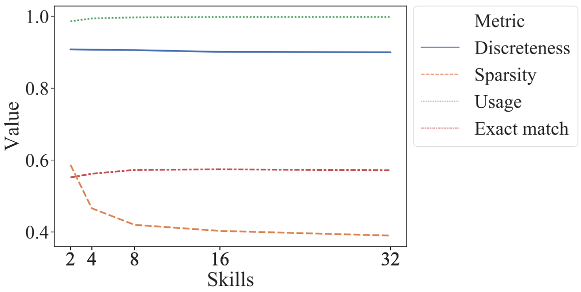

Figure 4: Statistics of the task–skill matrices for different choices of skill inventory size, including: discreteness, sparsity, usage, and the average exact match on the development set of 120 CrossFit tasks.

provide the normalised entropy of a categorical distribution parameterised by $\sum_j Z_{\star,j}$, the sum of the columns of Z:

$$\text{Usage}(Z) = \frac{\mathcal{H}\left[\sum_{\mathcal{T}_i} z_{i,\star}\right]}{\log |\mathcal{S}|} \tag{7}$$

Note that the entropy values are normalised into the range $[0, 1]$ to make them invariant to the number of skills: this quantity is known as 'efficiency'.

We plot these metrics—as well as the performance on in-domain train tasks in terms of exact match—as a function of the skill inventory size in Figure 4. We find that, whilst a continuous relaxation, the learned matrices are highly discretised and all their values are extremely close to either 0 or 1. Moreover, the level of sparsity decreases as the number of skills increases. This means that relatively smaller subsets of skills are required. Instead, usage stays consistently near the maximum value, which implies that there is uniformity in how frequently each skill is active across tasks. Finally, exact match is consistently high for sufficiently large ($|\mathcal{S}| \geq 8$) skill inventories.

Overall, these results demonstrate that a quasi-binary, highly-sparse, and non-trivial allocation matrix can be successfully learned in an end-to-end fashion even with simple inductive biases such as a dual-speed learning rate.

Crucially, learning a skill allocation also facilitates interpreting black-box multitask models. In fact, the structure of Z corresponds to an explicit hierarchy of tasks, where simpler ones are subsumed by more complex ones, and similar tasks can be grouped into the same category if they share the same subset of skills. We plot this hierarchy as a dendrogram in Figure 6. For instance, most GLUE tasks (Wang et al., 2018) are grouped together as they are all focused on natural language understanding: for instance, they require skill 1 (COLA), 2 (MRPC, RTE, SST2, WNLI), or both 1 and 2 (MNLI, QQP).

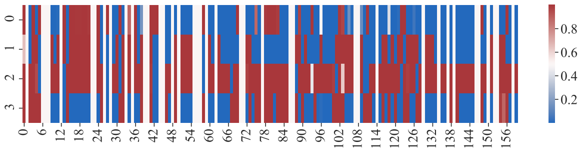

Figure 5: Posterior over Z in SKILLED for $|\mathcal{S}| = 4$.

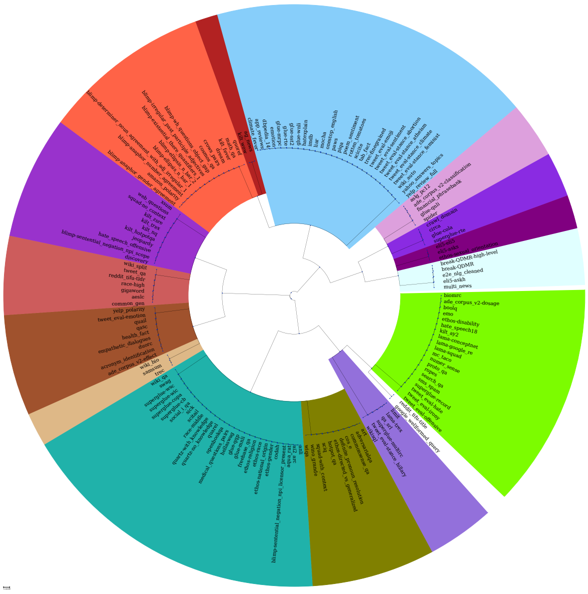

Figure 6: Task partitions for $|\mathcal{S}| = 4$, which corresponds to $2^{|\mathcal{S}|} = 16$ possible subsets of skills.

5 Related Work

Modular Networks Modularising neural networks has long been sought as a way to achieve better generalisation to unseen inputs (Jacobs et al., 1991b; Andreas et al., 2016; Kirsch et al., 2018), tasks (Jacobs et al., 1991a; Alet et al., 2018), and recently to improve continual learning (Ostapenko et al., 2021), to be more robust to changes in the environment (Goyal et al., 2021) and for sequence generation (Zhang et al., 2022).

In routing networks (Rosenbaum et al., 2019), a learnable router decides the order in which modules are applied to the input. Learning the structure of this composition has been achieved using an external parser (Andreas et al., 2016) or by sampling structures with simulated annealing (Alet et al., 2018). In mixture of experts (MoE), the system selects a soft subset of modules depending on the input to be processed (Jacobs et al., 1991b; Shazeer et al., 2017). MoEs can be interpreted invoking the theory of independent mechanisms (Parascandolo et al., 2018) that Goyal et al. (2021) further extend to handle sequential problems. Sun et al. (2020) share subsets of parameters among sparse subnetworks corresponding to different tasks. Within NLP, Fedus et al. (2021) uses a MoE architecture to scale large language model pre-training to trillions of parameters.

Our model conditions the computation on the task rather than on task inputs. Attempts to enforce parameter reuse and modularity for multitask learning include (Rajendran et al., 2017; Ponti et al., 2021a; Kingetsu et al., 2021; Kudugunta et al., 2021b). Rajendran et al. (2017) learn separate modules for each task and then learn how to reuse those modules for a new task. Kudugunta et al. (2021b) uses a set of modules for each task in a multi-lingual translation setting. Our approach does not assume a set of modules for each task but instead decomposes a task into a set of skills themselves reusable across tasks.

Multitask NLP Joint multitask learning in NLP proved an effective strategy for improving model performance in low-resource tasks and for quickly adapting to new tasks (Ruder et al., 2019; Min et al., 2021; Wei et al., 2021; Aribandi et al., 2021; Sanh et al., 2022), languages (Ponti et al., 2019), and modalities (Bugliarello et al., 2022). Liu et al. (2019) trained a shared model for all GLUE tasks and achieved impressive performance on GLUE. Pfeiffer et al. (2021) share information across task-specific parameters while alleviating negative task interference.

In our experiments we parameterise each skill with two kinds of adapters: either SFT (Ansell et al., 2022) or LoRA (Hu et al., 2021). Recently, Karimi Mahabadi et al. (2021) and Pilault et al. (2021) ensure cross-task information sharing by using a hyper-network to generate adapters from task embeddings. Differently, our task-specific parameters are composed of a set of skills from a shared inventory, which makes our approach modular and more scalable.

Several multitask approaches specifically target adaptation to new tasks, such as meta-learning approaches (Alet et al., 2018; Rusu et al., 2019; Ponti et al., 2021b; Garcia et al., 2021; Ostapenko et al., 2021). In our paper, we efficiently achieve few-shot task adaptation by inferring the skill allocation for new tasks and fine-tuning skill parameters initialised from multitask learning.

6 Conclusions

We argued that a modular design is crucial to ensure that neural networks can learn from a few examples and generalise robustly across tasks by recombining autonomous facets of knowledge. To this end, we proposed a model where a subset of latent, discrete skills from a fixed inventory is allocated to each task in an end-to-end fashion. The task-specific instantiation of a neural network is then obtained by combining efficient parameterisations of the active skills, such as sparse or low-rank adapters. We evaluate the sample efficiency of our model on multitask instruction following through reinforcement learning and its few-shot adaptability on multitask text-to-text generation through supervised learning. In both experiments, we surpass competitive baselines such as conditional parameter generation (HyperFormer) and mixture of experts (Task-MoE). Finally, we show that modularity helps interpret multi-task models by inferring explicit relationships between tasks according to the skills they share.

Limitations

Firstly, the kind of knowledge captured by individual skills is not fully interpretable. In terms of task–skill allocation, while some patterns based on task type and textual domain emerge from the clusters of Figure 6, it remains unclear how to systematically probe this information. Moreover, in terms of skill-specific parameters, it is hard to measure the diversity among learned skills. In fact, due to the under-specification of neural networks, different configurations in the parameter space may in fact correspond to the same function.

Secondly, few-shot adaptation in our experiments is based on the assumption that the skill inventory is fixed. Therefore, the model is compelled to recombine and possibly fine-tune old skills. Instead, each unseen task should involve a combination of newly discovered and previously honed skills. In the future, a possible extension of our method for continuous learning should adopt this more natural assumption.

Finally, we explore only a subset of the problems where different skills can be combined. In addition to instruction following and conditional text generation, our results should be replicated also in multilingual and multimodal benchmarks (Bugliarello et al., 2022, *inter alia*).

A Hyper-parameters

A.1 BabyAI

We follow closely the best hyper-parameter setup of Hui et al. (2020). Tiles in the visual input are encoded into embeddings of size 128 via a look-up table. The CNN has 2 layers, filter size 3, stride 1, and padding 1; whereas the FiLM module has 2 layers. A residual layer is added between the CNN output and each of the FiLM layers. The output of FiLM is max-pooled with a layer of size 7 and stride 2. Both the LSTM and the GRU have a hidden size of 128.

A learning rate of 1e-4 is adopted for Adam (Kingma and Ba, 2015). We optimise the model with Proximal Policy Optimisation (PPO; Schulman et al., 2017) and Back-Propagation Through Time (BPTT; Werbos, 1990). Additionally, we use an Advantage Actor–Critic (A2C; Wu et al., 2017) with Generalised Advantage Estimation (GAE; Schulman et al., 2015). The reward is calculated as $(1 - 0.9\, n/n_{\max})$ if the agent completes a task—where n is the number of steps required and $n_{\max}$ is a threshold set according to the level difficulty, 0 otherwise. Returns are discounted by $\gamma = 0.99$.

A.2 CrossFit

During both multitask pre-training and few-shot adaptation, we use the Adam optimiser (Kingma and Ba, 2015) and select a learning rate for Φ among $\{1e-2, 1e-3, 1e-4\}$ based on performance on the development sets of $\mathcal{T}_{train}$ and $\mathcal{T}_{dev}$, respectively. As a more aggressive learning rate for Z in Skilled instead we search in the range $[1e-1, 1e-2]$. We run multitask pre-training for 30 epochs with an effective batch size of 32, with a warm-up of 6% of the total steps. Instead, during few-shot adaptation, the effective batch size is 8 for 1000 training steps, with a warm-up rate of 10% and a weight decay of 1e-2. For each held-out task, a newly added row in Z (initialised with a vector of 0.5) and Φ (initialised from pre-training) are fine-tuned, but not ϑ_0.

For a comparison of parameter counts, LoRA adds $4l(2hr + |\mathcal{T}|) \cdot |\mathcal{S}|$ parameters to the pre-trained model, where l is the number of layers in the encoder and decoder, h is the hidden size, and 4 is the number of linear projections in self-attention (query, key, value, output). We use $r = 16$, $l = 24$ and $h = 1024$ for BART Large, so we add $\sim 3 \cdot 10^6$ parameters per skill. Given that the pre-trained model has $\sim 4 \cdot 10^8$ parameters, this implies an increase of $\sim 0.78\%$ per skill. Hyper adds $4l(2he + 2e) \cdot e$ parameters, an increase of $\sim 0.78\%$ per task embedding dimension.

Abstract

In this work, we study reinforcement learning (RL) in solving text-based games. We address the challenge of combinatorial action space, by proposing a confidence-based self-imitation model to generate action candidates for the RL agent. Firstly, we leverage the self-imitation learning to rank and exploit past valuable trajectories to adapt a pre-trained language model (LM) towards a target game. Then, we devise a confidence-based strategy to measure the LM's confidence with respect to a state, thus adaptively pruning the generated actions to yield a more compact set of action candidates. In multiple challenging games, our model demonstrates promising performance in comparison to the baselines.

1 Introduction

Text-based games are situated systems where the game agents observe textual descriptions, and generate textual commands to interact with the environment. These games have proven to be suitable test-beds for studying various natural language processing (NLP) tasks, such as question answering (Yuan et al., 2019; Xu et al., 2022), dialogue systems (Ammanabrolu et al., 2022), situated language learning (Shridhar et al., 2020) and commonsense reasoning (Murugesan et al., 2021; Ryu et al., 2022). Recent years have witnessed the thriveness of designing reinforcement learning (RL) agents in solving these games (Narasimhan et al., 2015; Hausknecht et al., 2020; Ammanabrolu and Riedl, 2019; Xu et al., 2020b), while the combinatorial action space remains as a challenging issue, preventing RL agents from being deployed in real world applications.

In general, text-based games accept free-form actions, resulting in a large combinatorial action space. Fig. 1 shows a raw excerpt from the classic game "Zork1". A 4-word action has to be selected from $|\mathcal{V}|^4$ candidates, where $\mathcal{V}$ denotes the vocabulary set (Xu et al., 2020a). Given that only 130 actions are required to solve this game, the agent wastes both training data and time in attempting irrelevant actions (Dulac-Arnold et al., 2015). To handle the combinatorial action space, early efforts either heavily rely on hand-crafted rules, or simply assume the availability of the action candidate set. For example, some works consider a set of currently admissible actions (He et al., 2016), or a template-based action space (Hausknecht et al., 2020). Alternatively, some other works alleviated this challenge by filtering inadmissible actions through methods such as action affordance (Jain et al., 2020), bandit-based elimination (Zahavy et al., 2018) and rule-based scoring (Ammanabrolu and Riedl, 2019).

Observation: The door reluctantly opens to reveal a rickety staircase descending into darkness.

Action: go down

Observation: The trap door crashes shut, and you hear someone barring it.

Action: go north

Observation: This is a small room with passages to the east and south and a forbidding hole leading west. A nasty-looking troll, brandishing a bloody axe, blocks all passages out of the room. Your sword has begun to glow very brightly.

Action: kill troll with sword

Observation: Almost as soon as the troll breathes his last breath, a cloud of sinister black fog envelops him, and when the fog lifts, the carcass has disappeared. Your sword is no longer glowing.

Figure 1: Excerpt from the game "Zork1". With a vocabulary size of 697, there are around $697^4 \approx 200$ billion potential 4-word actions in the game.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 703–726
May 2-6, 2023

In handling the combinatorial action space for text-based games, recent pre-trained language models (PLMs) (Devlin et al., 2019; Radford et al., 2019; Brown et al., 2020; Andreas and Klein, 2016) can help generate actions. However, the potential of LM is still less effectively explored. As one of the pioneer works, Yao et al. (2020) proposed the CALM, which is a GPT-2 model pre-trained on human gameplay trajectories, to generate the action candidate set for the RL agent. However, when solving a previously unseen game, CALM tends to generate actions with less satisfying qualities, leading to two consequences that may affect RL training: 1) the action set may contain a large proportion of inadmissible actions, and 2) the useful actions may not be generated. As a mitigation, the CALM model is set to generate a relatively huge action candidate set, followed by ad-hoc operations to filter out the inadmissible actions, which requires prior knowledge. Micheli and Fleuret (2021) extended the LM-based agent to goal-conditioned tasks to follow instructions. Besides the offline pre-training data, the LM is further improved with the successful trajectories collected during online interaction. However, text-based games do not have well-defined goals. Furthermore, some games are so challenging that it is impossible to collect successful trajectories (Tuyls et al., 2022).

In this work, we address the crux of combinatorial action space in solving text-based games. We propose the Confidence-based Self-imitation Model (CSM) to generate the action candidates for the RL agent.[*] Firstly, we leverage the self-imitation learning method (Oh et al., 2018) to rank and exploit past trajectories of high values to adapt a pre-trained LM towards the target game. Then, we propose a confidence-based strategy to measure the LM's confidence (Gandrabur et al., 2006) with respect to a state, thus adaptively pruning the action candidates based on the confidence value. Our model achieves promising performance in six challenging man-made games. Apart from significantly outperforming an action generation-based baseline, our strategy helps the RL agent to even achieve comparable performance to a baseline armed with the oracle action candidate set.

Our main contributions are summarized as follows: Firstly, we develop a LM-based framework to handle the issue of combinatorial action space in solving text-based games. Secondly, we propose a strategy to further improve the LM via self-imitation learning during the RL training. Thirdly, our experiments demonstrate that, the proposed method significantly improve the performance on multiple games compared with the strong contemporary method.

2 Related Work

2.1 RL Agents for Text-based Games

Inspired by the success of RL in playing games (Silver et al., 2016) and various NLP tasks (Fang et al., 2017; Yuan et al., 2019; Ammanabrolu et al., 2022), Narasimhan et al. (2015) and He et al. (2016) introduce RL to solve text-based games. Compared with non-learning-based agents (Hausknecht et al., 2019; Atkinson et al., 2019), the RL-based agents reduce the demand for extensive expert knowledge to develop gameplay strategies, and become the predominant modelling paradigm for solving text-based games. Subsequently, many variants of RL-based agents with different architectures and learning schemes have been proposed (Yuan et al., 2018; Jain et al., 2020; Guo et al., 2020; Xu et al., 2021; Tuyls et al., 2022; Shi et al., 2023). Innovations include modeling state space utilising knowledge graphs (Adhikari et al., 2020; Xu et al., 2020b), integrating question-answering and reading comprehension modules (Ammanabrolu et al., 2020; Xu et al., 2022). While these approaches focus on the problems of partial observability and language semantics, they still face the challenge of the combinatorial action space.

2.2 Combinatorial Action Space in TBGs

The combinatorial language-based action space is one primary challenge in solving text-based games. Early efforts mainly utilise hand-crafted rules or assume the agent has a predefined set of actions to choose from. For instance, the Jericho benchmark provides a valid action handicap that filters out inadmissible actions (i.e. actions that are either unrecognized by the game engine or do not change the underlying game state) at each game state (Hausknecht et al., 2020). This handicap has been widely used as the reduced action space by approaches like DRRN (He et al., 2016). In addition, the template-based action space is introduced where the agent selects first a template, and then a verb-object pair either individually (Hausknecht et al., 2020) or conditioned on the selected template (Ammanabrolu and Hausknecht, 2020). Even

---

[*] Code is available at https://github.com/winni18/CSM.

using the reduced action space, approaches filtering unnecessary actions can further improve the computational tractability and speed up the learning convergence (Zahavy et al., 2018; Jain et al., 2020).

2.3 Pre-training Methods for TBGs

Recent studies focus on enhancing the language understanding capability of agents by introducing pre-trained language processing modules. For instance, Singh et al. (2021) utilise the DistilBERT (Sanh et al., 2019) fine-tuned on human gameplay trajectories to represent game states. Ammanabrolu et al. (2020) employ the pre-trained ALBERT (Lan et al., 2019) to extract information from the textual observation by answering questions, and then update the knowledge graph during training. Adolphs and Hofmann (2020) use a pre-trained task-specific module to predict what is left to complete the tasks. In general, RL-based agents are initialised with knowledge using pre-trained modules before exploring game environments.

Some studies leverage pre-trained language models for action generation (Hausknecht et al., 2020) or word embeddings for affordance detection (Fulda et al., 2017). The approach closest to our work is Yao et al. (2020), which is state-of-the-art without requiring access to admissible actions. In their study, a GPT-2 language model trained on human gameplay trajectories is used to generate action candidates for the RL agent to select. To ensure that the correct actions are provided, the GPT-2 model is set to generate a relatively huge action candidate set, followed by ad-hoc operations to predict the admissibility of an action based on environmental feedback. In contrast, our work intends to narrow down the action space via self-imitation learning and make learning tractable.

3 Preliminaries

Text-based Games as POMDPs The text-based game can be formally formulated as a partially observable Markov Decision Process (POMDP) $(\mathcal{S}, T, \mathcal{A}, \mathcal{O}, R, \gamma)$. At each step t, the agent receives a textual observation $o_t \in \mathcal{O}$ from the game environment, while the latent state $s_t \in S$, which contains the complete internal information of the environment, could not be observed. By executing an action $a_t \in \mathcal{A}$, the environment will transit to the next state according to the latent transition function T, and the agent will receive the reward signal $r_t = R(s_t, a_t)$ and the next observation o_{t+1}. The objective of the agent is to take actions to maximize the expected cumulative discounted rewards $R_t = \mathbb{E}[\sum_{t=0}^{\infty} \gamma^t r_t]$, where $\gamma \in [0, 1]$ is the discount factor.

Trajectory and Episode We define the trajectory τ as the sequence of observation-action pairs collected in an RL episode, i.e., $\tau = (o_1, a_1, o_2, a_2, \ldots, o_l, a_l)$, where l_τ is the length of τ. An RL episode is the process of an agent interacting with the environment from the beginning of a game to a termination state (e.g., the agent dies) or the step exceeding the pre-defined limit.

DRRN Existing RL methods for solving text-based games use game rewards to learn a value function. For instance, the Deep Reinforcement Relevance Network (DRRN) (He et al., 2016) is a choice-based game agent, where each action candidate a is paired with the state o to check its relevance. The agent then passes each pair through a deep neural network with parameters ϕ to estimate the Q-values $Q_\phi(o, a)$. The parameters ϕ of DRRN are trained using tuples (o, a, r, o') sampled from a prioritized experience replay buffer with the temporal difference (TD) loss:

$$\mathcal{L}_{\mathrm{TD}}(\phi) = \left(r + \gamma \max_{a' \in A} Q_\phi\left(o', a'\right) - Q_\phi(o, a)\right)^2 \tag{1}$$

where r is the game reward and γ is the discount factor. The next action is then selected by softmax sampling the predicted Q-values:

$$\pi_\phi(a|o) = \frac{\exp\left(Q_\phi(o, a)\right)}{\sum_{a' \in A} \exp\left(Q_\phi\left(o, a'\right)\right)} \tag{2}$$

To circumvent the challenge of combinatorial action space, DRRN assumes access to the valid action handicap provided by the environment at each game state.

4 Methodology

4.1 Overview

To address the combinatorial action space, we propose the Confidence-based Self-imitation Model (CSM), which leverages the advantages of pre-trained LM and Self-imitation Learning (SiL) for adaptive action generation. Fig.2 shows an overview of CSM. At time step t, the LM is provided with the context $c_t = (o_{t-1}, a_{t-1}, o_t)$ as the input, and generates a set of action candidates $\mathcal{A}_t$

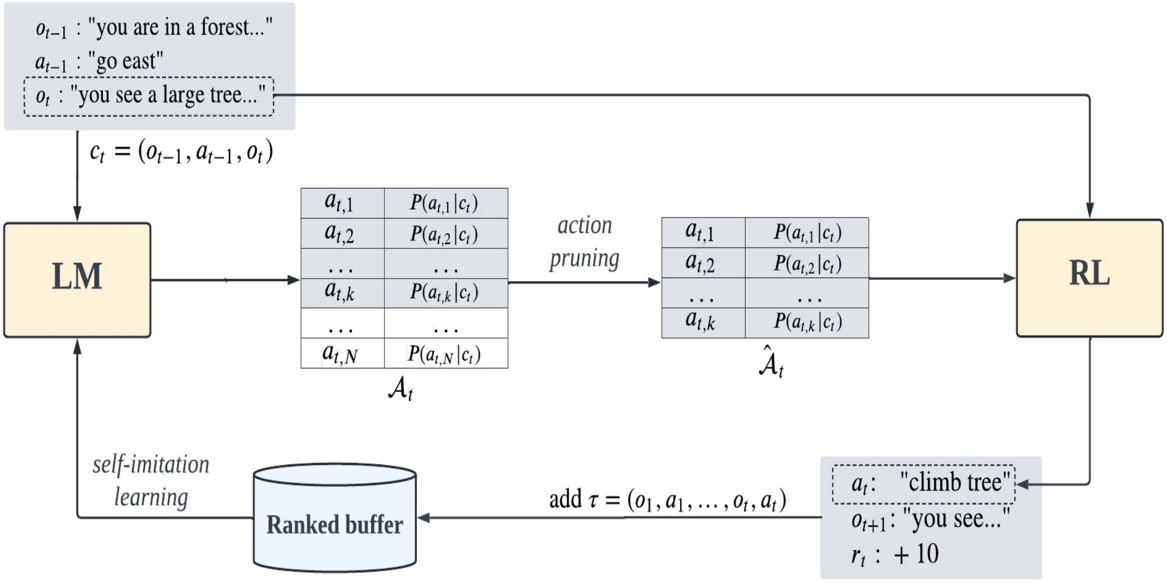

Figure 2: An overview of CSM. The LM takes the context c_t and generates action candidates $\mathcal{A}_t$, and conducts action pruning to further reduce the action space. The RL agent takes the observation o_t, and selects an action $a_t \in \hat{\mathcal{A}}_t$. The valuable trajectories τ are collected to further improve the LM through self-imitation learning.

as well as their probabilities using beam search decoding. Based on the probabilities, we conduct Action Pruning (AP) to obtain a more compact subset of action candidates $\hat{\mathcal{A}}_t \subseteq \mathcal{A}_t$ for the RL agent. Then the RL agent considers the observation o_t and selects an action $a_t \in \hat{\mathcal{A}}_t$. To generate high-quality actions which are more context-relevant, we adapt the LM towards the target game during the RL training. Specifically, we collect and then select the past valuable trajectories τ in an additional replay buffer, to further improve the LM through a self-imitation learning manner.

4.2 Self-imitation Learning

We follow the work of Yao et al. (2020) to utilize the LM for action generation. During pre-training, given human gameplay trajectories τ, we first build the context c_t, then train the LM to minimize the expected cross-entropy loss: $\mathcal{L}_{\text{LM}} = -\mathbb{E}[\log p(a|c)]$, where $\log p(a|c) = \sum_{i=1}^{m} p(a^i|a^{<i}, c)$ for an action with m tokens. During RL, the LM will serve as a “rough” action selector to generate the top-k actions. Then the RL agent will select one action to interact with the environment.

One drawback of the previous work Yao et al. (2020) is that when facing an unseen context, the LM may generate actions with poor performance. A straightforward solution is to continuously improve the LM during RL, thus making it adapted to the target game. Since no external trajectories (e.g., from human players) are available in the RL stage, we consider resorting to the self-imitation learning (Gangwani et al., 2019), i.e., letting the LM learn from the trajectories collected during the RL interaction. One thing we should pay attention to is the quality of the trajectories – sub-optimal trajectories may adversely affect imitation learning (Hu et al., 2019; Xu et al., 2022). Text-based games, especially games originally designed for human players, may be too challenging for agents to walk through. Thus, we cannot directly obtain successful trajectories during interacting with the environment. To alleviate this problem, we build a heap-like replay buffer to store past high-quality trajectories. We regard those obtaining higher scores with fewer steps as high-quality trajectories. Specifically, we rank trajectories within the replay buffer by their game scores (i.e., the sum of collected rewards) and lengths. In addition, we also take into account the novelty, by periodically replacing the old trajectories with new ones of equivalent qualities (e.g., the same scores and lengths).

4.3 Confidence-based Action Pruning

Through the aforementioned SiL, the LM is expected to generate a more reliable action candidate set $\mathcal{A}_t$ of size N. For each action $a_{t,i} \in \mathcal{A}_t$, we then calculate its normalized probability $P(a_{t,i}|c_t)$

Table 1: Game statistics.

Game	Avg.Action Number	Avg.Action Length	Avg.Steps Per Reward	Walkthough Length	Max Score
Balances	23.29	2.99	12	122	51
Inhumane	6.96	2.36	14	123	90
Ludicorp	14.52	2.76	4	364	150
Snacktime	5.68	2.14	8	34	50
Zork1	15.96	2.75	9	400	350
Ztuu	33.93	2.96	5	84	100

according to the beam search score. The probabilities exhibit two characteristics: 1) the long-tail phenomenon in linguistics (Zhan et al., 2021), where only a few probabilities produce lots of actions; 2) the probability distribution varies greatly under different states. Given these findings, we adopt a confidence-based strategy to further prune action candidates of low values, aiming to obtain a further reduced action candidate set $\hat{\mathcal{A}}_t \subseteq \mathcal{A}_t$. Specifically, we accumulate the probabilities of top-k action candidates as the confidence value: $Conf_t(k) = \sum_{i=1}^{k} P(a_{t,i}|c_t)$. We then conduct action pruning (i.e., constraining the action space k) by bonding the confidence value to a fixed, manually determined threshold ξ: $\hat{\mathcal{A}}_t = \{a_{t,i}|Conf_t(k) \leq \xi\}$. In this way, top-$k$ action candidates are selected adaptively. For a more "familiar" context c_t (e.g., it is similar to a context that LM has encountered before), the LM is supposed to be able to obtain correct actions from the training data, and the probability distribution will be centralised to top-ranked actions. In contrast, for an "unfamiliar" c_t, the actions' probabilities might be more uniformly-distributed. In this case, the size of action candidates (e.g., k) will be expanded to ensure a high confidence value.

5 Experiments

5.1 Experimental Setup

We conduct experiments upon six games provided by the Jericho Game Suite (Hausknecht et al., 2020). These games have diverse themes and genres, and each of them can represent a type of task. Different from those generated through pre-defined simple rules (Côté et al., 2018), the games we use are more complex, making them even challenging for human players. Some games contain nonstandard actions (e.g., the spells), which are unlikely to be understood by the language model pre-trained with commonsense knowledge. Table 1 shows the game statistics calculated from the walkthrough of each game.

5.2 Baselines

Our work focus on the challenge of combinatorial action space in text-based games. Thus, we compare CSM with two baselines:

- **CALM** (Yao et al., 2020), which is a pioneer work in LM-guided action generation.
- **DRRN** (He et al., 2016), which assumes access to the "oracle" action set (i.e., the valid action handicap provided by the environment).

Of these methods, CALM is the previous state-of-the-art model without the availability of "oracle" action sets, while the DRRN agent with "oracle" action sets can be regarded as our "upper bound".

5.3 Implementation Details

Training We implement CSM upon CALM's released code, including a pre-trained GPT-2 LM [†]. Both CSM and CALM adopt DRRN as the RL agent, except that $\mathcal{A}_t$ is obtained by LM. We set the step limit of an RL episode as 100, and train the RL agent on 8 parallel running environments for 100k steps. For each step, we train the RL agent with a batch size of 64, using an Adam optimizer with a learning rate of 1e-4. We set the first 20k steps as the warm-up phase, and start self-imitation learning as well as action pruning after this phase. For SiL, we use a trajectory buffer with a size of 50. For every 500 steps, we update the LM for 1 epoch with a batch size of 8, using an Adam optimizer with a learning rate of 2e-5. If there are no fresh trajectories as the training progresses, we conduct SiL using existing trajectories within the buffer. For AP, we use beam search decoding with a beam size of 40 to generate actions and choose

---

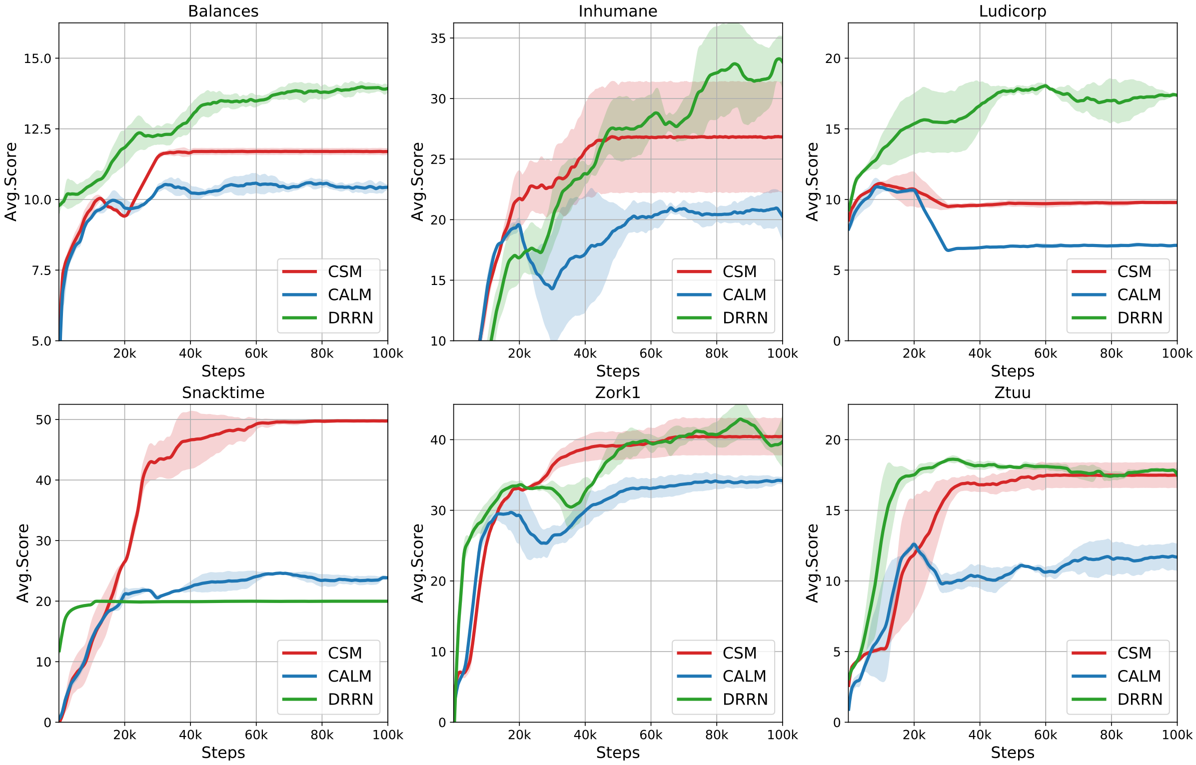

Figure 3: The performance of CSM compared to baselines (CALM and DRRN) throughout training. Shaded areas indicate one standard deviation. Our CSM outperforms CALM while getting much closer to DRRN. Besides, it successfully solves the game "Snacktime".

Table 2: The performance of CSM compared to baselines (CALM and DRRN) after training. The result with † is from Hausknecht et al. (2020). In six environments, our method obtains significant improvement compared to the CALM model, with an average normalized game score of 31.4%.

Game	*Generated $\mathcal{A}_t$*		*Oracle $\mathcal{A}_t$*	**Max**
	CSM	**CALM**	**DRRN**	
Balances	**11.7**	10.5	14.0	51
Inhumane	**27.0**	20.6	33.6	90
Ludicorp	**9.8**	6.8	17.5	150
Snacktime	**49.8**	24.0	20.0	50
Zork1	**40.6**	34.3	40.0	350
Ztuu	**17.5**	11.7	21.6†	100
Avg.Norm	**31.4%**	19.6%	24.9%	

the top 30 actions, i.e., $N = 30$. Then, we use the proposed confidence-based strategy to keep top-k highest-scoring action candidates (k<30). We set ξ as 0.6, and bound k to be no lower than 10. Following previous works, we define the score as the sum of rewards collected within an episode, and report the score averaged over the last 100 finished episodes.

LM For both CSM and CALM, we use the pre-trained GPT-2 model provided by Yao et al. (2020) as the LM module. The LM consists of 12 layers, 768 hidden sizes, and 12 attention heads. This module is first pre-trained on the WebText corpus (Radford et al., 2019), then re-trained on the ClubFloyd dataset (Yao et al., 2020), which consists of 426 human game playing transcripts on 590 games (note that the Jericho-supported games that we experiment with are not included).

RL Both CSM and CALM adopt the DRRN as the RL agent, except that the action candidate set is generated by the LM module. Given the current observation o_t, and a set of currently admissible actions $\mathcal{A}_t$, the RL agent first encodes o_t to build the state representation, then pairs it with each ac-

tion candidate $a_{t,i} \in \mathcal{A}_t$ to compute the Q-value, which will be used as the probability for sampling the action a_t.

Warm-up Since this work does not address the RL exploration problem, we equip both CSM and CALM with a warm-up phase to facilitate training at the very beginning. During this phase, we follow Yao et al. (2020) to filter inadmissible actions from $\mathcal{A}_t$ through a pre-trained fast-text module, without applying SiL or AP. Then after this phase, the fast-text module will be discarded, and the LM has to generate the reliable $\mathcal{A}_t$ by itself. Note that this module is not essential, and could be replaced by other exploration strategies such as Zha et al. (2021); Yao et al. (2021). We leave such integration as a future direction.

5.4 Results

Fig. 3 shows the average episode score throughout training for the baselines, and Table 2 shows the average episode score after training for the baselines. Our CSM demonstrates its effectiveness by significantly outperforming the backbone CALM in all of the six games, with an average normalized game score of 31.4%. Given that DRRN has access to the "oracle" action set $\mathcal{A}_t$, its performance can be regarded as our "upper bound". We observe that the performance of CSM is much closer to DRRN, and even surpasses DRRN in two games. In particular, while DRRN gets stuck in the game "Snacktime", CSM solves this game, making its average normalized score among the highest of all. In Sec. 5.6, we further discuss this case by analyzing

Context: [CLS] scratch man [SEP] You scratch your pet, just gently, not to hurt him or anything. Hmm, your pet seems to have turned that into part of his dream or something, because he sure didn't move this time when you scratched him.right now you aren't carrying anything. (it's not like you need a lot of stuff, anyway.) [SEP]
CSM: **jump on man**, kiss pet, lick pet, kiss man, lick man, push pet, move arm, pull pet, pull arm, push man
CALM: pull man, push man, **jump on man**, push arm, pull pet, push pet, pull arm, lick man, kiss man, kiss pet, lick pet, smell, smell man, sniff, south, smell pet, wait, listen, east, northwest, southwest, get pet, down, jump, hug man, lick it, pet pet pet, up, hug pet, in, take pet, take all, eat pet, talk to pet, sleep, search pet, drop all, stand, open chest, open door, pet dog, pet pet dog, out, pull up on stool, west, north
DRRN: kiss on pet, **jump on him**, north, west

Context: [CLS] push wand [SEP] Once again you chomp down to change what's inside the box. This time there are these guys poking at each other, kinda fighting and joking around and all. This is the sort of thing your pet seems to enjoy watching sometimes, people getting hit with food and slipping and falling down and stuff. Everybody is laughing and nobody ever seems to really get hurt, so you guess it's OK.held carefully between your teeth is a magic wand. [SEP]
CSM: use wand on box, bite wand, push wand, **chew wand**, jump on man, take wand, get wand, read wand, pull wand, lick wand
CALM: push wand, **chew wand**, wait, northeast, south, southwest, northwest, east, rub wand, down, give wand to pet, pull wand, open box, take magic wand, put wand in box, get wand, pull lever, give wand to guy, take all, get magic wand, west, take wand, up, out, eat wand, give book to pet, enter box, read book, use wand on wand, drop wand, north
DRRN: examine legged, **push wand**, take inventory, get in all, take off legged, north, west

Figure 5: Sample gameplay from the game "Snacktime" along with the generated action candidates, and the action chosen by the RL agent (coloured with blue).

the underlying reasons.

5.5 Ablation Studies

In order to evaluate the contribution of the two components in CSM, we compare our model with two variants with either SiL ("w.o. AP") or AP ("w.o. SiL"). In order to demonstrate the effectiveness of confidence-based AP, we also employ constant AP. We set k to 12, which is the average number of actions selected by the confidence-based strategy. Fig. 4 shows the average episode score for the ablation models throughout training, and Table 3 shows the average episode score for the ablation models after training.

In general, adapting the LM with respect to the target game helps ("w.o. AP" v.s., "CALM"), while reducing the action space upon it further boosts the performance ("CSM" v.s., "w.o. AP"). Solely reducing the action space $\mathcal{A}_t$, in contrast, leads to poor performance ("CSM" v.s., "w.o. SiL" v.s., "CALM"). Also, simply utilizing the constant AP together with SiL results in a considerable performance drop. ("CSM" v.s., "constant AP"). Without SiL, the LM has a greater chance of incorrectly filtering actions that are essential to go through the target game.

5.6 Qualitative Analysis

To demonstrate the efficacy of the proposed framework, we present two gameplay examples from the game "Snacktime". Fig.5 shows the generated action candidates and the action chosen by the RL agent, where "Context" denotes c_t, "CSM" and "CALM" denote the actions generated by CSM and CALM respectively, "DRRN" denotes the "oracle" action set used by DRRN. In the first example, all models generate and select the correct action "jump on him", which leads to a +10 reward. Compared with CALM, CSM successfully reduces the action set from 30 to 10, relieving the burden for the RL agent. In the second example, both CSM and CALM generate action sets with the correct action "chew wand" being included. We found that the "oracle" action set provided by the environment is not always perfect, which explains why DRRN gets stuck here[‡]. It shows that our model is capable of generating high-quality, context-relevant actions, and further limits the action space while keeping key actions that may lead to higher scores in the games. Appendix B provides the detail interaction log of CSM on the game "Snacktime".

6 Conclusion

In this work, we studied reinforcement learning in solving the text-based game. We proposed the CSM framework to generate a set of action candidates for the RL agent, which alleviates the issue of combinatorial action space. During RL training, we

---

[‡] Similar phenomenon has also been reported in some other games (Tuyls et al., 2022)

collected and exploited past high-quality trajectories and utilised self-imitation learning to improve the language model. In addition, a confidence-based action pruning strategy was proposed to further restrict the action space. We evaluate our method using the Jericho benchmark. In a variety of text-based games, our method significantly improves the performance compared with the strong contemporary method, and even overcomes the challenging bottleneck in the game "Snacktime".

Limitations

In terms of limitations, text-based games are still far from being solved. Even if the agent has access to admissible actions, sparse rewards, language semantics and partial observability remain challenging obstacles for the existing game agent. In this study, we develop an effective framework to solve the issue of combinatorial action space. Future work can integrate our framework with methods that better leverage linguistic signals in order to make further progress in solving text-based games.

Appendix

The appendix is organized as follows: Sec. A shows more experiment results. Sec. B provides the interaction log of CSM on the game "Snacktime".

A More Results

Reproduction of DRRN Fig. 6 shows the reproducing result of the DRRN baseline, where "DRRN - Ours" denotes the "DRRN" used in the main paper. The dashed lines "DRRN - Official" denote the results reported in Hausknecht et al. (2020) and Yao et al. (2020). According to Tuyls et al. (2022), the action candidate set $\mathcal{A}_t$ provided by the environment is not always perfect, so that they manually augmented the environment-provided $\mathcal{A}_t$ with actions from the game walkthrough which are required for making progress[§]. We follow their setting to modify the environment and rerun the DRRN baseline, yielding much better performance than the official results except one game "Ztuu", which we use the official result in Table 2.

Reproduction of CALM Fig. 7 shows the reproducing result of the CALM baseline, where "CALM 20% WU - Ours" denotes the "CALM" used in the main paper. The dashed lines "CALM 100% WU - Official" denote the results reported in Yao et al. (2020). In terms of the original CALM, our replication results are comparable with or better than the official results ("CALM 100% WU" v.s., "CALM 100% WU - Official"). The original CALM adopts a fast-text model to filter out the inadmissible actions from $\mathcal{A}_t$ throughout the RL training process (i.e., they conduct warm-up for 100k steps), heavily alleviating the problem of generating inadmissible actions ("CALM 100% WU" v.s., "CALM w.o. WU"). However, obtaining this fast-text model requires prior knowledge, such as the additional training data and annotations. In our work, we would like to reduce the requirement of such external knowledge, and let the LM to conduct action pruning by itself. For all LM-based models, we only conduct warm-up for the first 20k steps, and discard the fast-text model afterwards ("CALM 20% WU"). As a future direction, we would like to consider more advanced warm-up strategies (Zha et al., 2021), thus eliminating the need for pre-training the fast-text model.

More results Besides the episode score, we provide more results for further analyzing self-imitation learning and action pruning. Regarding SiL, Fig. 8 and Fig. 9 show the average score and length of the trajectories collected in the ranked buffer, respectively. There's no doubt that the average score grows higher as the agent makes progress. Diverse trends could be observed in terms of the average length, since a newly-added trajectory might have both high score and more steps. Regarding AP, Fig. 10 shows the number of LM generated actions k, i.e., $|\hat{\mathcal{A}}_t|$, where it could be observed k gets close to the lower bound after pruning. Fig. 11 shows the LM probability of the top-1 generated action, and Fig. 12 shows the LM probability sum of the top-5 generated actions. After self-imitation learning, the top actions account for a larger proportion of the probability, making it safer for filtering those with low probabilities.

Abstract

Text generation from Abstract Meaning Representation (AMR) has substantially benefited from the popularized Pretrained Language Models (PLMs). Myriad approaches have linearized the input graph as a sequence of tokens to fit the PLM tokenization requirements. Nevertheless, this transformation jeopardizes the structural integrity of the graph and is therefore detrimental to its resulting representation. To overcome this issue, Ribeiro et al. (2021b) have recently proposed StructAdapt, a structure-aware adapter which injects the input graph connectivity within PLMs using Graph Neural Networks (GNNs). In this paper, we investigate the influence of Relative Position Embeddings (RPE) on AMR-to-Text, and, in parallel, we examine the robustness of StructAdapt. Through ablation studies, graph attack and link prediction, we reveal that RPE might be partially encoding input graphs. We suggest further research regarding the role of RPE will provide valuable insights for Graph-to-Text generation.

1 Introduction

Earliest works on AMR-to-Text generation were mostly based on statistical methods. A common practice was to convert AMR-to-Text task into an already studied problems such as Tree-to-Text (Flanigan et al., 2016; Lampouras and Vlachos, 2017), aligned text-to-text (Pourdamghani et al., 2016), Travel Sales Problems (Song et al., 2016) or Grammatical Framework (Ranta, 2011). Recently, most methods are neural-centered with an encoder-decoder architecture (Sutskever et al., 2014) as a backbone (Konstas et al., 2017; Takase et al., 2016; Cao and Clark, 2019). Unfortunately, this architecture coerces the AMR to be linearized as a sequence of tokens. This ends up in structural information loss. To tackle this issue, several strategies have attempted to integrate structure using message propagation (Song et al., 2018; Guo et al., 2019; Damonte and Cohen, 2019; Ribeiro et al., 2019; Zhang et al., 2020b; Zhao et al., 2020). A limitation of those is the absence of pretraining, as demonstrated by Ribeiro et al. (2021a). To this end, Ribeiro et al. (2021b) introduced StructAdapt for lightweight AMR-to-Text with structural adapters. As linearization and tokenization of the input graph are mandatory steps for PLMs, StructAdapt first defines a new graph where nodes are the resulting subwords from the tokenization. As a result, adapter can henceforth include GNN layers operating on the subsequent graph while leveraging pretrained representations.

However, although studies have been made to probe position embeddings (Wang and Chen, 2020; Wang et al., 2021; Dufter et al., 2022), their role on graph encoding has remained unanswered. In this

paper, we are particularly interested in measuring the saliency of RPE with StructAdapt for AMR-to-Text generation. Our novelty is not in proposing a new method to encode graphs such as (Schmitt et al., 2021) but rather in revealing the interesting behaviours of RPE along with StructAdapt.

2 STRUCTADAPT: A Structural Adapter

A major issue in AMR-to-Text, and more generally Graph-to-Text with Transformers (Vaswani et al., 2017), is the linearization of the input structure. The linearization of the graph returns a sequence of node and edge labels according to a certain traversal of the graph. Nonetheless, adjacent nodes in the graph may be at multiple positions away from one another in the final serialization. To counteract this, Ribeiro et al. (2021b) introduced StructAdapt, a structure-aware (encoder) adapter. It solves the problem of segmented nodes labels by reconstructing a new graph from the resulting subwords. More specifically, the relations are primary reified as new nodes in the AMR graph. Furthermore, labels of those reified relations will be added in the vocabulary as new tokens and therefore will not be decomposed into subwords. However, the labels of the original nodes can still be chunked. To deal with this, each subword node will be connected independently to the reified relation of the initial (non-chunked) node. An example is outlined in Figure 1. As a consequence, the vanilla Adapter can now integrate any GNN-based neural network which operates on the new constructed graph (Figure 1), where nodes are the input tokens. Concretely, StructAdapt replaces the first stacked MLP of vanilla adapter with a GNN-based model as shown in Figure 2. For AMR-to-Text, only the encoder is equipped with StructAdapt in order to encode AMR structure. The decoder layers adopt vanilla adapters. In our study, we consider three different GNN-based models which are Graph Convolutional Network (GCN) (Kipf and Welling, 2017), Graph Attention network (GAT) (Veličković et al., 2017) and Relational Graph Convolutional Network (RGCN) (Schlichtkrull et al., 2018). GCN computes a representation for each node a which is a (normalized) aggregation function of representation of its neighbor nodes noted $\mathcal{N}(a)$. GAT is akin to GCN but differs in that aggregation of neighbors embeddings are weighted using an attention mechanism. Unlike GAT and GCN, RGCN further captures the type of the relation between two nodes. In our case, as AMR relations are reified and stand for new nodes of the graphs, our new relations can either be of *direct* ($a \xrightarrow{d} b$) or *reverse* ($a \xleftarrow{r} b$) connections type as in (Ribeiro et al., 2021b). The details of the representations computation for each model can be found in Appendix A. The returned nodes embeddings will then be given as input features to the following MLP.

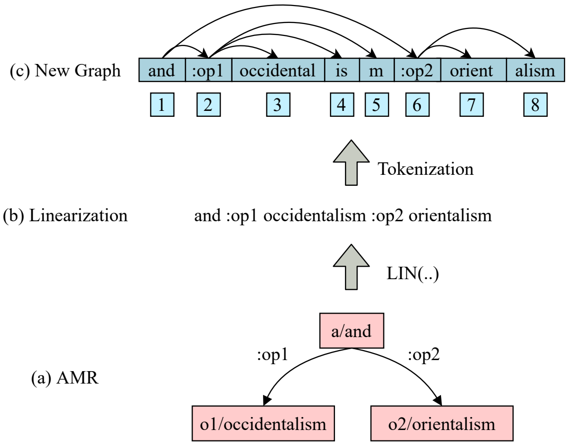

Figure 1: Examples of AMR tokenization for the sentence *"Occidentalism and Orientialism."*. The resulting input graph in (c) contains 8 nodes.

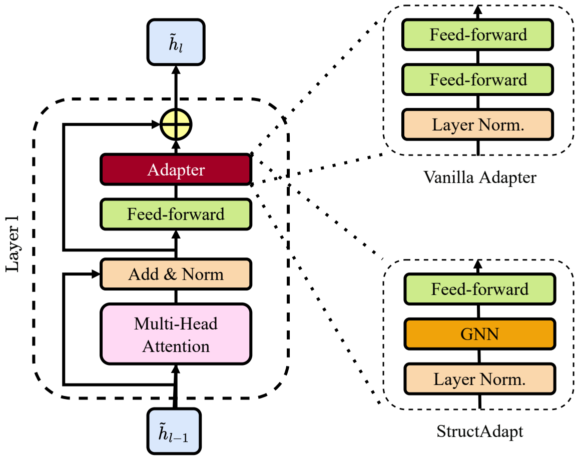

Figure 2: Vanilla Adapter vs StructAdapt

3 Relative Position Embeddings

Instead of adding Absolute Position Embeddings (APE) directly to the token embedding as in standard Transformer model, some models such as T5 make use of relative position embeddings inspired from Shaw et al. (2018). As an alternative to APE, RPE offer interesting features. A noteworthy limitation of APE is the need to set a limit of available positions. Therefore, long sequences may have

to be segmented. Furthermore, APE are directly added to the token representation leading to information inconsistency, i.e. position versus semantic information. To this extent, Shaw et al. (2018) came up with relative position encodings which are supplied to the self-attention mechanism by simply adding a scalar to the logits encoding the supposed relation between a current token i and a token j.

4 Experiments

Throughout our experiments, we make use of the LDC2020T02 dataset (AMR 3.0 release)[1] and use the T5$_{\text{base}}$ model which employs RPE. The training and evaluation details can be found in Appendix B and C, respectively.

4.1 Exploring the Salience of RPE

In this section, we investigate the influence of RPE on the generation quality using structural adapter. RPE are computed in each Transformer head. Position information is then forwarded to the adapter module on top (Figure 2). However, since connections between input nodes (i.e. tokens) are already given to structural adapters in encoder, it is legitimate to question the necessity for RPE on the encoder part but also how would the generation quality vary without such information. Hence, we propose to remove the RPE from the encoder heads to gauge their salience to structure encoding for downstream language generation. Since decoder is not encoding any graph structure, we leave RPE in decoder untouched. For better readability, MLP, GCN, GAT, and RGCN respectively denote: the vanilla adapter, StructAdapt with a GCN layer, StructAdapt with a GAT layer and StructAdapt with a RGCN layer. MLP-based adapter with RPE is our baseline. Results are given in Table 1. A human evaluation is also provided for some encoder adapters in Table 2. First, it is apparent that using RPE systematically yields better generation performances. For the vanilla adapter (i.e. our baseline), we note a 25.3% absolute drop in BLEU when removing RPE. This can also be seen on human evaluation. More than one point is lost toward meaning preservation. The downturn for linguistic correctness is less important since T5 is pretrained and thus rarely prone to syntax errors. Such a result is not surprising for MLP-based adapter since it solely relies on RPE to differentiate tokens at different positions in the linearized AMR. However, a striking observation is that getting rid of RPE for GNN-based adapters leads to lower performances than our baseline. Indeed, when removing RPE when using structural adapter, we would have expected GNN-based approaches to be as competitive as a MLP-based adapter with RPE. We report a relative drop of 12.5 points in BLEU from the baseline. The same conclusion can be drawn from Table 2. This indicates that RPE are capturing relevant information for final generation. To further assess the impact and the role of RPE, we conduct a *graph attack* experiment. Instead of conveying the correct adjacency matrix, we propose to corrupt connectivity information. We randomly generate an adjacency matrix such that generated matrix does not contain any actual connection. We suppose that without RPE, structure-aware adapter will lead to a significant decrease in generated text due to the absence of information about the graph nor the position of nodes in the input sequence. We are especially interested to measure to which extent RPE might be able to take over the encoding of the graph for generation.

Table 4: *Graph Attack* - Human Evaluation. Mean scores (±s.d.)

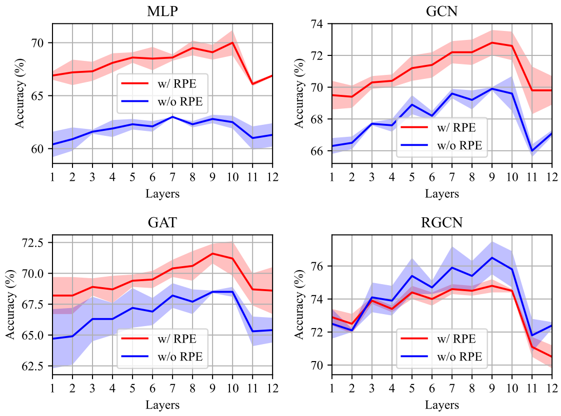

Figure 3: *Probing* - Link Prediction Results using hidden representations $\tilde{h}_i$ at different layers i.

Results are shown in Table 3. Human evaluation for *attacked* GCN and RGCN adapters is given in Table 4. As hypothesized, providing erroneous connectivity without any position embeddings makes structural adapters no longer compelling. We observe that StructAdapt with RGCN is significantly more affected compared to GAT and GCN based adapters. Since RGCN adds direction information for each edge (*direct* and *reverse*), we conjecture that RGCN is much more bewildered. Interestingly, using RPE with corrupted graph (Table 3) leads to similar performance than using graph information without RPE (Table 1). This strongly demonstrates the usefulness of RPE to carry out the generation. We additionally provide a *position attack* experiment in Appendix E where RPE are shuffled randomly. Accordingly, we can further identify the saliency of RPE despite the available GNN. This raises the question of RPE encoding the input graph.

4.2 Can the Graphs Be Reconstructed ?

As shown in Section 4.1, RPE seem to be as competitive as applying GNNs alone. If claiming that RPE also encode graphs is tempting, no strong evidence has been revealed. Indeed, better generation quality is not necessarily a consequence of better graph encoding. Therefore, we probe whether graphs can indeed be reconstructed from the learned hidden representations. To do so, we train a logistic regression, i.e. our probe, to perform link prediction as a binary classification. More specifically, given two nodes representations at a given layer l, our probe returns the probability that nodes are connected. To train our logistic regression model, we sample k positive connections, i.e. two connected nodes, and k negative connections, i.e. two non-connected nodes, for each sample of training and test sets.[2] For our experiment, we choose $k = 2$ which leads to 109,490 and 3,770 samples for each class for training and testing respectively. We plot results in Figure 3. Firstly, we observe very high accuracy for the vanilla adapter without RPE. Accuracies over 60% are easily reached while no structure encoding nor positions information are supplied. This might be a side effect of our probe training. Nevertheless, this gives a lower bound for our experiment. We can see that adding RPE increases the link prediction performance for MLP, GCN and GAT-based adapters. We observe a constant gap of about 3.5% on average. However, we remark that RGCN is able to reconstruct edges on its own with best accuracy. We report a maximum accuracy about 76% while other models are not reaching 73%. This strengthens the idea that giving information of reverse connection may add robustness to graph encoding as shown in (Beck et al., 2018). Generally, we observe that the deeper the representation, the better the link prediction. We notice however that after the 10^{th} layer, significant drops in link prediction arise regardless

---

[2] If k samples cannot be extracted for both positive and negative classes, the sample is discarded.

of adapter type. We assume representations should lose some information about the structure to perform language generation. This may indicate that encoded representation for Graph-to-Text is not just graph-centered. Although counter-intuitive, encoder representations given to the decoder part may not have to encode input graph efficiently in order to verbalize it. We leave this research question for future work. We further provide an analysis on self-attention matrices in Appendix F.

5 Conclusion

In this paper, we have explored the effect of relative position embeddings on AMR-to-Text generation using structural adapters. We have shown that the generation process could be enabled by relative position embeddings when structure is erroneous or missing. In addition, we have demonstrated the capacity of those representations to encode the input graph to some extent. We have further revealed interesting robustness of RGCN model in graph reconstruction ability. For future work, we believe further experiments on other pretrained models and Graph-to-Text tasks may shed more light on the role of position embeddings.

Limitations

A limitation of our study is that we focus on the T5 model only. Since adapters are additional modules to add, it is required to manually implement and directly modify the original code of the pretrained model which is not easily scalable. In addition, we only evaluate on the LDC2020T02 dataset which is the cleanest AMR dataset available.

A Graph Neural Networks

A.1 Graph Convolutional Network (GCN)

To compute the node representation $g_u^l \in \mathbb{R}^{d_g}$ of the node u at layer l, GCN computes an aggregation of neighbors nodes embeddings as:

$$g_u^l = \sigma\left(\sum_{v \in \mathcal{N}(u)} \frac{1}{\deg(u) \times \deg(v)} W^l g_v^l\right) \quad (1)$$

with σ an activation function and $\deg(x)$ the degree of the node x.

A.2 Graph Attention Network (GAT)

GAT applies an attention mechanism to determine importance of neighboors nodes regarding current node u. We have:

$$\begin{aligned} g_u^l &= \sigma\left(\sum_{v \in \mathcal{N}(u)} \mathrm{softmax}(e_{u,v}) W^l g_v^l\right) \\ e_{u,v} &= \mathrm{LeakyReLu}\left(a_{u,v} \Big\Vert_{i=u}^{v} g_i^l\right) \end{aligned} \quad (2)$$

with both σ and LeakyReLu non-linear activation functions and $a_{u,v} \in \mathbb{R}^{2 \times d_g}$ a learnable vector.

A.3 Relational Graph Convolutional Network (RGCN)

RGCN takes into consideration the nature of the relation $r \in \mathcal{R}$ between nodes u and v. It performs

Adapter	Runtime (in hours)
MLP	21.5
GCN	15.6
GAT	22.0
RGCN	16.2

Table 5: *Runtime* - Runs are executed on a single NVIDIA GeForce RTX 3090 GPU.

convolution as the following:

$$g_u^l = \sigma\left(\sum_{r\in\mathcal{R}}\sum_{v\in\mathcal{N}_r(u)} c_{u,r}W_r^l g_v^l\right) \qquad (3)$$

with $\mathcal{N}_r(u)$ the direct neighbors of node u under the relation r, $c_{u,r}$ a normalization term and $W_r^l \in \mathbb{R}^{d_g\times d_g}$ a learnable relation-dependent parameter.

B Training Setting

We used the version 3.3.1 of the HuggingFace's Transformers library (Wolf et al., 2020). We use Adam optimizer with a linearly decreasing learning rate, without warm-up. The initial learning rate is set to 1×10^{-4}. Batch size is set to 8. For decoding, a beam search of 5 is selected. A maximum length of 384 is used in case the *end-of-sentence* token is not encountered. We didn't use gradient clipping nor label smoothing. For GNNs, we make use of the version 1.7.2 of the PyTorch Geometric library (Fey and Lenssen, 2019). We only use a single layer for our GNNs networks, similarly to the vanilla adatper. For GAT, a single attention head was applied. The bottleneck dimension is set to 256 for all of our adapters. This is equivalent to about 4% only of the whole T5$_{base}$ model's parameters to train. The training time for MLP, GCN, GAT and RGCN adapters are given in Table 5. Note that the total runtime depends on the convergence as we are using early stopping.

C Automatic Evaluation

For evaluation, we consider multiple automated metrics. We employ popular n-gram-based metrics which are SacreBLEU (Post, 2018), METEOR (Banerjee and Lavie, 2005), chrf++ (Popović, 2017), TER (Och, 2003) and the semantic-based BertScore metric (Zhang et al., 2020a). In addition, we also report both $\mathcal{M}$ and $\mathcal{F}$ pillars of the decomposable $\mathcal{MF}$ score recently proposed by Opitz and Frank (2021). The meaning preservation, noted $\mathcal{M}$, measures how close the AMR of the generated sentence is to the reference sentence. To do so, both the generated sentence and target sentence are parsed with a pretrained Text-to-AMR model from Cai and Lam (2020). Then, their AMRs are compared using graph-based similarity measures such as Smatch (Cai and Knight, 2013). In contrast, the grammatical form, noted $\mathcal{F}$, measures the linguistic quality of the generated text using state-of-the-art language model (Radford et al., 2019). We also report human evaluation in Section 4.1 to accurately assess the quality of the generated outputs. We ask annotators to evaluate the meaning preservation and linguistic correctness of our generated outputs compared to the references. Details of human evaluation are given in Appendix D.

D Human Evaluation

Since handcrafted annotation is extremely costly, we limited the number of samples and models to assess. We randomly selected 30 test samples per model to evaluate manually. We further limited evaluation to 8 configurations of adapters. This led us with 240 samples to score by multiple annotators. We asked 22 annotators to answer to these following questions with a rate on a 1-6 Likert scale, with 6 the best score:

- Is the generated sentence semantically close to the reference ?
- Is the generated sentence grammatically correct ?

Each annotator was given 50 samples to annotate. We adopted FlexEval (Fayet et al., 2020) to implement a flexible evaluation environment. This allows a streaming evaluation were annotators can stop at any moment and come back to the evaluation later, at one's will. Furthermore, different samples from different models are given to annotators in an balanced manner such that each sample of each model is exposed to at least 2 annotators. Note that one annotator is given some samples from multiple configuration. This avoids evaluation bias toward a single annotator. In our case, each sample from each configuration has been annotated by 4 distinct annotators.

E Position Attack

For a given graph, we also propose to corrupt RPE with a random shuffle. Since the model may learn the generated order through training, we *systematically* shuffle RPE for each epoch for all graphs. Results are given in Table 6.

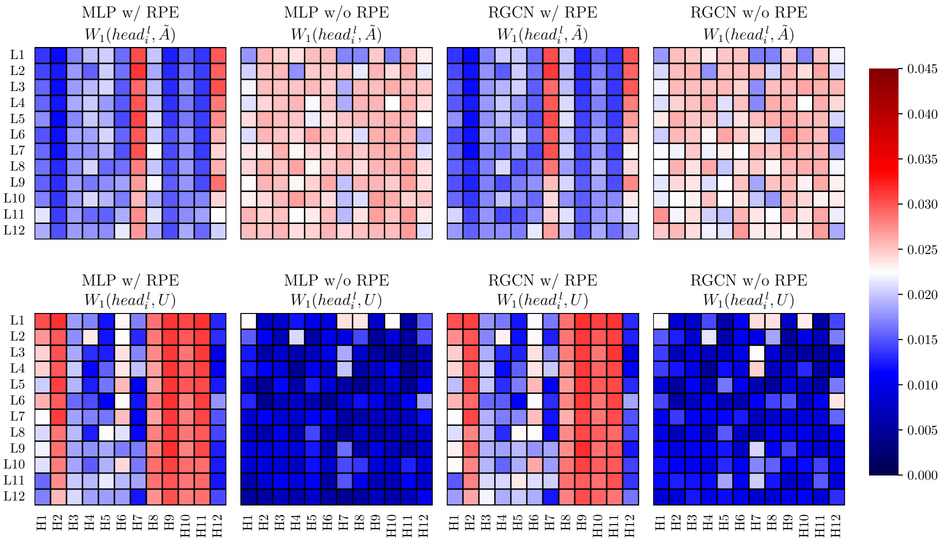

Figure 4: 1-Wasserstein distances of attention distributions for each head (columns) at each layer (rows) from both normalized adjacency matrices (top) and uniform distribution (down). The bluer, the lower the distance.

Adapter	**BLEU**
MLP	19.0±0.6
GCN	28.1±0.6
GAT	28.9±2.3
RGCN	**35.4**±1.2

Table 6: *Position Attack* - Relative Position Embeddings are shuffled.

F Analysis of Attention Matrices

The self-attention matrix gives information about how much weight should be assigned to other tokens (i.e. nodes). Thus, attention matrix can be seen as a pseudo-adjacency matrix. We further propose to inspect the similarity between the attention matrix of each head at each layer with the adjacency matrix of the input graph. Since the input is considered as a sequence of nodes, the shape of the attention matrix and adjacency matrix are equal. However, a limitation of the similarity comparison lies in the respective type of those mathematical objects. Attention matrices are probabilities whereas adjacency matrices are not. To deal with this issue, we convert the adjacency matrix A^s of a sample s to a normalized form $\tilde{A}^s$ such that each row $\tilde{A}^s_n$ is normalized and sums up to one, as described in Eq. 4.

$$A^s = \begin{bmatrix} 0 & 1 & 1 \\ 1 & 1 & 1 \\ 0 & 0 & 1 \end{bmatrix} \quad \tilde{A}^s = \begin{bmatrix} 0 & \frac{1}{2} & \frac{1}{2} \\ \frac{1}{3} & \frac{1}{3} & \frac{1}{3} \\ 0 & 0 & 1 \end{bmatrix} \tag{4}$$

This enables the rows of both attention and adjacency matrices to be probabilities distributions over input nodes. We can therefore measure the distance between those distributions to find out whether attention matrices are somehow close to the (normalized) adjacency matrix, and thus encoding graph connections. To do so, we compute the 1-Wasserstein distance W_1 [3] between the attention distribution of each token n and its corresponding normalized n^{th} row of $\tilde{A}$. We average distances over tokens, and then over samples (Eq. 5). We note $\tilde{A}$, S, and N_s the adjacency matrices, the total number of AMR samples and the length of sequence s, respectively.

$$W_1(\text{head}_i^l, \tilde{A}) = \frac{1}{S}\sum_{s=1}^{S}\frac{1}{N_s}\sum_{n=1}^{N_s} W_1(\text{head}_{i,n}^{l,s}, \tilde{A}^s_n) \tag{5}$$

For fair comparison, we also provide the distance between attention distribution head_i^l and the uniform distribution U which assigns a probability of $\frac{1}{N}$ to each token for a graph with N nodes. We plot distances as heatmaps on Figure 4 where each square indicates either $W_1(\text{head}_i^l, \tilde{A})$ or $W_1(\text{head}_i^l, U)$. When using RPE, we can see that, for both MLP and RGCN-based adapters, the distribution of the attention scores are close to the normalized adjacency matrices of our graphs. Meanwhile, when removing them, we can witness

---

[3] Equivalent to earth mover's distance.

that attention scores are much closer to the uniform distribution and thus smoother. This is in line with our previous results suggesting that RPE might partially encode graphs. Since RPE are shared across layers, we can easily detect similar distances across layers for same heads (visible vertical lines). We also find similar behavior we have previously noted where last layers tend to lose graph information as attention scores slightly move away from the normalized adjacency matrix distribution.

On the Intersection of Context-Free and Regular Languages

Abstract

The Bar-Hillel construction is a classic result in formal language theory. It shows, by a simple construction, that the intersection of a context-free language and a regular language is itself context-free. In the construction, the regular language is specified by a finite-state automaton. However, neither the original construction (Bar-Hillel et al., 1961) nor its weighted extension (Nederhof and Satta, 2003) can handle finite-state automata with ε-arcs. While it is possible to remove ε-arcs from a finite-state automaton efficiently without modifying the language, such an operation modifies the automaton's set of paths. We give a construction that generalizes the Bar-Hillel in the case where the desired automaton has ε-arcs, and further prove that our generalized construction leads to a grammar that encodes the structure of both the input automaton and grammar while retaining the asymptotic size of the original construction.

https://github.com/rycolab/bar-hillel

1 Introduction

Bar-Hillel et al.'s (1961) construction—together with its weighted generalization (Nederhof and Satta, 2003)—is a fundamental result in formal language theory. Given a weighted context-free grammar (WCFG) $\mathcal{G}$ and a weighted finite-state automaton (WSFA) $\mathcal{A}$, the Bar-Hillel construction yields another WCFG $\mathcal{G}_\cap$ whose language $L(\mathcal{G}_\cap)$ is equal to the intersection of $L(\mathcal{G})$ with $L(\mathcal{A})$. Importantly, the Bar-Hillel construction directly proves that weighted context-free languages are closed under intersection with weighted regular languages. The construction was later extended to other formalisms, e.g., tree automata (Maletti and Satta, 2009), synchronous tree substitution grammars (Maletti, 2010) and linear context-free re-writing systems (Seki et al., 1991; Nederhof and Satta, 2011b). Furthermore, the Bar-Hillel construction has seen applications in the computation of infix probabilities (Nederhof and Satta, 2011a) and human sentence comprehension (Levy, 2008, 2011).

Unfortunately, Bar-Hillel et al.'s construction, as well as its weighted generalization by Nederhof and Satta, requires the input automaton to be ε-free.[1] Although any WFSA can be converted to a weakly equivalent[2] ε-free WFSA using well-known techniques (Mohri, 2001, 2002; Hanneforth and de la Higuera, 2010), such an approach adds an additional step of computation, typically increases the size of the output grammar $\mathcal{G}_\cap$, and does not, in general, maintain a bijection between derivations in $\mathcal{G}_\cap$ and the Cartesian product of the derivations in $\mathcal{G}$ and paths in $\mathcal{A}$. In other words, $\mathcal{G}_\cap$ is *not* strongly equivalent to the product of $\mathcal{G}$ and $\mathcal{A}$.[3]

In this note, we generalize the classical Bar-Hillel construction to the case where the automaton we seek to intersect with the grammar has ε-arcs. Our new construction produces a WCFG $\mathcal{G}_\cap$ that is strongly equivalent to the product of $\mathcal{G}$ and $\mathcal{A}$. We further generalize the Bar-Hillel construction to work with arbitrary commutative semirings. Finally, we give an asymptotic bound on the size of the resulting grammar and a detailed proof of correctness in the appendix.

2 Languages, Automata, and Grammars

As background, we now give formal definitions of semirings, weighted formal languages, finite-state automata, and context-free grammars.

2.1 Semirings

Semirings are useful algebraic structures for describing weighted languages (Droste et al., 2009, Chapter 1). In order to define semirings we must first give the definition of a monoid. A **monoid** is a 3-tuple $\mathcal{M} = (A, \bullet, \mathbf{1})$, where A is a set,

---

[1] But they do not require the input grammar to be ε-free.

[2] Two WFSAs are said to be weakly equivalent if they represent the same weighted formal language.

[3] Strong equivalence is formally defined in Definition 6 and Theorem 1.

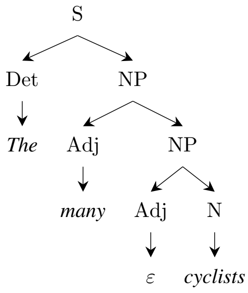
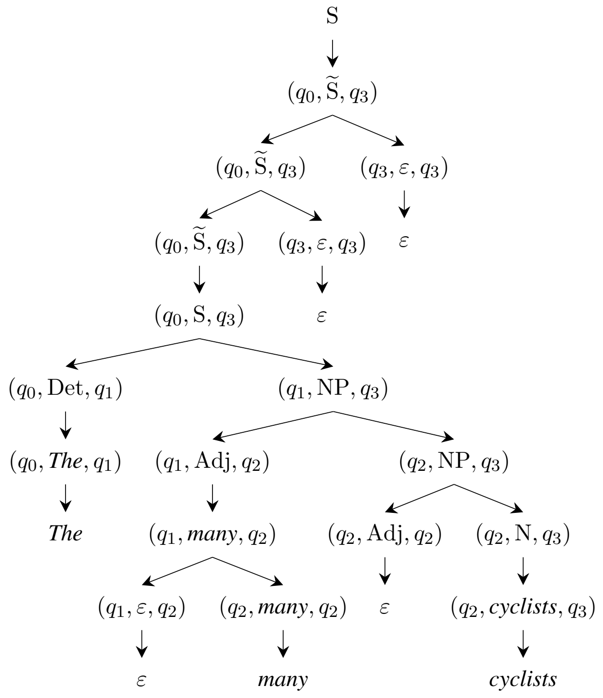
(b) Weighted context-free grammar



(c) Original derivation



(d) Derivation in the intersection grammar

Figure 1: Example of a derivation in the grammar obtained as the intersection of the finite-state automaton (a) and the context-free grammar (b). The derivation tree (d) encodes the derivation tree (c) in the original grammar, and path $q_0 \xrightarrow{\textit{The}/2} q_1 \xrightarrow{\varepsilon/0.3} q_2 \xrightarrow{\textit{many}/0.75} q_2 \xrightarrow{\textit{cyclists}/1} q_3 \xrightarrow{\varepsilon/0.6} q_3 \xrightarrow{\varepsilon/0.6} q_3$. We use rules from Eq. (5g) for ε-arcs appearing before an input symbol, and rules from Eq. (5b) for ε-arcs appearing at the end of the input.

$\bullet : A \times A \to A$ is an associative operator, and $\mathbf{1} \in A$ is a distinguished identity element such that $\mathbf{1} \bullet w = w \bullet \mathbf{1} = w$ for any $w \in A$. We say that a monoid is *commutative* if $\bullet$ commutes, i.e., $w_1 \bullet w_2 = w_2 \bullet w_1$ for any $w_1, w_2 \in A$. We can now give the definition of a semiring.

Definition 1. *A* ***semiring*** $\mathcal{W} = (A, \oplus, \otimes, \mathbf{0}, \mathbf{1})$ *is a 5-tuple where* $(A, \oplus, \mathbf{0})$ *is a commutative monoid,* $(A, \otimes, \mathbf{1})$ *is a monoid,* $\otimes$ *distributes over* $\oplus$*, and* $\mathbf{0}$ *is an* annihilator *for* $\otimes$*, meaning that* $\mathbf{0} \otimes w = w \otimes \mathbf{0} = \mathbf{0}$ *for any* $w \in A$.

We say that $\mathcal{W}$ is commutative if $\otimes$ commutes. In this work, we assume commutative semirings.

2.2 Weighted Formal Languages

This paper concerns itself with transforms between devices that generate weighted formal languages.

Definition 2. *Let* Σ *be an alphabet and* $\mathcal{W} = (A, \oplus, \otimes, \mathbf{0}, \mathbf{1})$ *be a semiring. Then a* ***weighted formal language*** $L : \Sigma^* \to A$ *is a mapping from the Kleene closure of* Σ *to the set of weights* A*. Furthermore, the set* $\operatorname{supp}(L) = \{\boldsymbol{s} \in \Sigma^* \mid L(\boldsymbol{s}) \neq \mathbf{0}\}$ *is called the language's* ***support****.*

Unweighted formal languages (e.g., Sipser, 2006; Hopcroft et al., 2006) are simply the special case of Definition 2 where $\mathcal{W}$ is the boolean semiring. In this note, we discuss algorithms for computing the intersection of two weighted formal languages.[4]

Definition 3. *Let* L_1 *and* L_2 *be two weighted formal languages over the same alphabet* Σ *and the same semiring* $\mathcal{W}$*. The* ***intersection*** *of* L_1 *with* L_2 *is defined as the weighted language*

$$(L_1 \cap L_2)(\boldsymbol{s}) \overset{\text{def}}{=} L_1(\boldsymbol{s}) \otimes L_2(\boldsymbol{s}), \quad \forall \boldsymbol{s} \in \Sigma^* \quad (1)$$

Specifically, this paper concerns itself with the special case of Definition 3 when L_1 is a weighted context-free language (represented by a WCFG), and L_2 is a weighted regular language (represented by a WFSA); we define these two formalisms in the subsequent sections.

In the following, the symbol ε always represents the empty string.

---

[4] The intersection of two weighted languages is also called their Hadamard product (Droste et al., 2009, Chapter 1).

2.3 Weighted Finite-State Automata

We now review the basics of weighted finite-state automata (WFSA), which provide a formalism to represent weighted regular languages.

Definition 4. *A* ***weighted finite-state automaton*** *$\mathcal{A}$ over a semiring $\mathcal{W} = (A, \oplus, \otimes, \boldsymbol{0}, \boldsymbol{1})$ is a 6-tuple $(\Sigma, Q, \delta, \lambda, \rho, \mathcal{W})$. In this tuple, Σ is an alphabet, Q is a finite set of states, and $\delta \subseteq Q \times Q \times (\Sigma \cup \{\varepsilon\}) \times A$ is a finite multi-set of weighted arcs. Further, $\lambda : Q \to A$ and $\rho : Q \to A$ are the initial and final weight functions, respectively. We also define the sets $Q_I = \{q \mid q \in Q,\ \lambda(q) \neq \boldsymbol{0}\}$ and $Q_F = \{q \mid q \in Q,\ \rho(q) \neq \boldsymbol{0}\}$ for convenience.*

We will represent an arc in δ with the notation $q_0 \xrightarrow{a/w} q_1$ where $a \in \Sigma \cup \{\varepsilon\}$ and $w \in A$. A **path** $\boldsymbol{\pi}$ (of length $N > 0$) is a sequence of arcs in δ^* where the states of adjacent arcs are matched, i.e.,

$$q_0 \xrightarrow{a_1/w_1} \cdots q_{n-1} \xrightarrow{a_n/w_n} q_n \cdots \xrightarrow{a_N/w_N} q_N \qquad (2)$$

and where $q_0 \in Q_I$ and $q_N \in Q_F$, i.e., the path starts at an initial state and ends at a final state. The path's **yield**, denoted $\texttt{yield}(\boldsymbol{\pi})$, is the concatenation $a_1 a_2 \cdots a_N$ of all its arc labels (strings of length ≤ 1). The path's **weight**, denoted $w(\boldsymbol{\pi})$, is the product

$$w(\boldsymbol{\pi}) = \lambda(q_0) \otimes \left(\bigotimes_{n=1}^{N} w_n \right) \otimes \rho(q_N) \qquad (3)$$

We denote the set of all paths in $\mathcal{A}$ as $\mathcal{D}_{\mathcal{A}}$, and the set of all paths with yield $\boldsymbol{s}$ as $\mathcal{D}_{\mathcal{A}}(\boldsymbol{s})$. Finally, we define the **language of an automaton** as the mapping $L_{\mathcal{A}} : \Sigma^* \to A$ where we have[5] $L_{\mathcal{A}}(\boldsymbol{s}) = \bigoplus_{\boldsymbol{\pi} \in \mathcal{D}_{\mathcal{A}}(\boldsymbol{s})} w(\boldsymbol{\pi})$. The set of languages that can be encoded by a WFSA forms the class of **weighted regular languages**.

2.4 Weighted Context-Free Grammars

We now go over the necessary background on weighted context-free grammars (WCFGs).

Definition 5. *A* ***weighted context-free grammar*** *is a tuple $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{W}, \mathrm{S}, \mathcal{P})$, where $\mathcal{N}$ is a non-empty set of nonterminal symbols, Σ is an alphabet of terminal symbols, $\mathcal{W} = (A, \oplus, \otimes, \boldsymbol{0}, \boldsymbol{1})$ is a semiring, $\mathrm{S} \in \mathcal{N}$ is a distinguished start symbol, and $\mathcal{P}$ is a set of production rules. Each rule $p \in \mathcal{P}$ is of the form $\mathrm{X} \xrightarrow{w} \boldsymbol{\alpha}$, with $\mathrm{X} \in \mathcal{N}$, $w \in A$, and $\boldsymbol{\alpha} \in (\Sigma \cup \mathcal{N})^*$.*

Given two strings $\boldsymbol{\alpha}, \boldsymbol{\beta} \in (\Sigma \cup \mathcal{N})^*$, we write $\boldsymbol{\alpha} \overset{p}{\Rightarrow}_L \boldsymbol{\beta}$ if and only if we can express $\boldsymbol{\alpha} = \boldsymbol{z}\,\mathrm{X}\,\boldsymbol{\delta}$ and $\boldsymbol{\beta} = \boldsymbol{z}\,\boldsymbol{\gamma}\,\boldsymbol{\delta}$ where $\boldsymbol{z} \in \Sigma^*$ and $p \in \mathcal{P}$ is the rule $\mathrm{X} \xrightarrow{w} \boldsymbol{\gamma}$. A **derivation** $\boldsymbol{d}$ (more precisely, a leftmost derivation) is a sequence $\boldsymbol{\alpha}_0, \ldots, \boldsymbol{\alpha}_N$ with $N > 0$, $\boldsymbol{\alpha}_0 = \mathrm{S}$, and $\boldsymbol{\alpha}_N \in \Sigma^*$, such that for all $0 < n \leq N$, we have $\boldsymbol{\alpha}_{n-1} \overset{p_n}{\Rightarrow}_L \boldsymbol{\alpha}_n$ for some (necessarily unique) $p_n \in \mathcal{P}$. The derivation's **yield**, $\texttt{yield}(\boldsymbol{d})$, is $\boldsymbol{\alpha}_N$, and its weight, $w(\boldsymbol{d})$, is $w(p_1) \otimes \cdots \otimes w(p_N)$. We denote the set of derivations under a grammar $\mathcal{G}$ as $\mathcal{D}_{\mathcal{G}}$ and the set of all derivations with yield $\boldsymbol{s}$ as $\mathcal{D}_{\mathcal{G}}(\boldsymbol{s})$. Finally, we define the **language of a grammar** as $L_{\mathcal{G}}$ where[5] $L_{\mathcal{G}}(\boldsymbol{s}) \overset{\text{def}}{=} \bigoplus_{\boldsymbol{d} \in \mathcal{D}_{\mathcal{G}}(\boldsymbol{s})} w(\boldsymbol{d}), \forall \boldsymbol{s} \in \Sigma^*$. The languages that can be encoded by a WCFG are known as **weighted context-free languages**.

3 Generalizing Bar-Hillel

Given any context-free grammar (CFG) $\mathcal{G}$ and finite-state automaton (FSA) $\mathcal{A}$, Bar-Hillel et al. (1961) showed how to construct a CFG $\mathcal{G}_\cap$ such that $L_{\mathcal{G}_\cap} = L_{\mathcal{G}} \cap L_{\mathcal{A}}$. Later, Nederhof and Satta (2003) generalized Bar-Hillel's construction to work on a *weighted* context-free grammar and a *weighted* finite-state automaton. While they focused on the real semiring, their construction actually works for any commutative semiring. However, neither of these versions correctly computes the intersection when the WFSA (or FSA) contains ε-arcs. Yet, in several applications—such as modeling noisy inputs for human sentence comprehension (Levy, 2008, 2011)—we may be interested in using a WFSA $\mathcal{A}$ that contains ε-arcs. A naïve application of the construction would ignore paths in $\mathcal{A}$ that contain ε-arcs. The problem may be sidestepped by transforming $\mathcal{A}$ into a weakly equivalent ε-free WFSA[6] before applying the construction;[7] this, however, might increase the size of the WFSA and of the intersection grammar, and it would not allow us to identify the paths in the input WFSA that yield a target string in the

---

[5] In the main paper we gloss over the question of how $\bigoplus$-summations over *infinite* sets are to be defined (or left undefined), but we treat this issue in App. B.2.

[6] See footnote 2 for the definition of weak equivalence.

[7] Levy (2008, 2011) uses WFSAs to model the degree of uncertainty under which a human comprehends a particular sentence, in which ε-arcs are used to represent word deletion. He applies the Bar-Hillel construction to compute the intersection of the language represented by the WFSA and the language encoded by a WCFG that represents the comprehender's grammatical knowledge, in order to obtain a joint posterior distribution over parses and words. While he transforms $\mathcal{A}$ to eliminate ε-arcs prior to applying the Bar-Hillel construction (Levy, p.c.), the solution we propose here is an alternative.

intersection grammar.[8]

3.1 The problem with ε-arcs

Before proposing our solution, we explain how the original construction works, and how it fails in the case of ε-arcs. Given a WFSA $\mathcal{A} = (\Sigma, Q, \delta, \lambda, \rho, \mathcal{W})$ and a WCFG $\mathcal{G} = (\mathcal{N}, \Sigma, \mathcal{W}, \mathrm{S}, \mathcal{P})$ over the same alphabet Σ and commutative semiring $\mathcal{W}$, their intersection $\mathcal{G}_\cap$ is defined by the tuple $(\mathcal{N}_\cap, \Sigma, \mathcal{W}, \mathrm{S}, \mathcal{P}_\cap)$, where:

- The set of nonterminal symbols $\mathcal{N}_\cap = \{\mathrm{S}\} \cup Q \times (\mathcal{N} \cup \Sigma) \times Q$ contains the triplets (q_i, X, q_j) plus the start symbol S.[9]
- The set of production rules $\mathcal{P}_\cap$ is given by the equations in Construction 1 of Fig. 2.[10]
- Σ, $\mathcal{W}$, S are the same as in the input grammar.

The intuition behind this construction is that a derivation in the intersection grammar encodes both a path in the input WFSA and a derivation in the input WCFG with matching yield. Specifically, rules (4f) encode arcs in the WFSA and rules (4d) encode production rules in the WCFG. Rules (4e) handle the special case of ε-productions in the input WCFG and rules (4a) are designed to take into account the initial and final weight of a path. These rules may combine through matching nonterminals to permit derivations in the intersection grammar $\mathcal{G}_\cap$.

Unfortunately, this mechanism breaks in the presence of ε-arcs. Although the rules (4f) do construct nonterminals for ε-arcs (when $a = \varepsilon$), the rules (4d) never generate those nonterminals (since the X_m on the right-hand side of a rule are never ε). We show this with an example. Consider the automaton and the grammar in Fig. 1, both of which assign non-zero weight to the string *The many cyclists*. However, their intersection computed with the Bar-Hillel construction is empty. To see this, note that all the paths from q_0 to q_3 contain the arc $q_1 \xrightarrow{\varepsilon/0.3} q_2$. Eq. (4f) will create a rule $(q_1, \varepsilon, q_2) \xrightarrow{0.3} \varepsilon$, but none of the rules produced by Eqs. (4d) and (4e) has the triplet (q_1, ε, q_2) on the right hand side. This misalignment results in an empty set of derivations in $\mathcal{G}_\cap$. In App. A we describe more failure cases in a detailed manner.

3.2 Our generalized construction

We now describe an improved version of the Bar-Hillel construction that handles ε-arcs in the WFSA. In comparison to the original construction, our version of $\mathcal{G}_\cap = (\mathcal{N}_\cap, \Sigma, \mathcal{W}, \mathrm{S}, \mathcal{P}_\cap)$ has

- $\mathcal{N}_\cap = \{\mathrm{S}\} \cup Q \times (\mathcal{N} \cup \{\widetilde{\mathrm{S}}\} \cup \Sigma) \times Q$ as the set of nonterminals, where $\widetilde{\mathrm{S}}$ is a new symbol;
- $\mathcal{P}_\cap$ as the augmented set of production rules given in Construction 2 of Fig. 2.

Our generalized construction adds additional production rules that traverse the ε-arcs. Rules (5g) can traverse a WFSA subpath labeled with $\varepsilon^* a$ to yield a terminal symbol $a \in \Sigma$. At the end of the yielded string, rules (5b) can traverse a WFSA subpath labeled with ε^* that ends at a final state q_F. Our construction carefully avoids overcounting[11] by ensuring that each matching pair of an $\mathcal{A}$-path and a $\mathcal{G}$-derivation of its string corresponds to *exactly one* $\mathcal{G}_\cap$-derivation of that string, as illustrated in Fig. 1. Note that rules (5d) to (5f) are identical to their counterparts in the original construction. Rules (5a) are a modified version of rules (4a) with the special start symbol $\widetilde{\mathrm{S}}$; this allows our construction to handle ε-arcs immediately before the final state—by repeated applications of rule (5b)—before switching $\widetilde{\mathrm{S}}$ back to S with rule (5c). In App. A we illustrate the mechanism with examples.

We now state the theorem of correctness.

Definition 6. *Let Σ be an alphabet and $\mathcal{W}$ be a commutative semiring. Let $\mathcal{G}$ be a WCFG and $\mathcal{A}$ be a WFSA—both over Σ and $\mathcal{W}$. The* ***weighted join*** *of the derivations in $\mathcal{D}_\mathcal{G}$ with the paths in $\mathcal{D}_\mathcal{A}$ is defined as:*

$$(\mathcal{D}_\mathcal{G} \bowtie \mathcal{D}_\mathcal{A}) \overset{\text{def}}{=} \Big\{ \langle \boldsymbol{d}, \boldsymbol{\pi} \rangle \mid \boldsymbol{d} \in \mathcal{D}_\mathcal{G}, \boldsymbol{\pi} \in \mathcal{D}_\mathcal{A} \quad \textit{s.t.}\ \texttt{yield}(\boldsymbol{d}) = \texttt{yield}(\boldsymbol{\pi}) \Big\} \tag{6}$$

with $w(\langle \boldsymbol{d}, \boldsymbol{\pi} \rangle) = w(\boldsymbol{d}) \otimes w(\boldsymbol{\pi})$.

---

[8] In contrast, this is easy under our construction. Each derivation of the target string under $\mathcal{G}_\cap$ uses a particular path in $\mathcal{A}$. To reconstruct that path, ε-arcs and all, simply traverse from left to right the leaves of the derivation tree (e.g., Fig. 1d) and list the states on the triplets where rule (5f) is applied.

[9] Many of the nonterminals will turn out to be **useless** in that they do not participate in any derivation in $\mathcal{D}_{\mathcal{G}_\cap}$. These can be pruned from the grammar along with all rules that mention them (Hopcroft et al., 2006).

[10] Note that this construction can handle multiple initial and final states, whereas Nederhof and Satta's (2003) construction assumes a WFSA with a single initial and a single final state. A path's initial and final weights are taken into account by the weight of rules (4a) of Construction 1 in Fig. 2.

[11] As Fig. 1d illustrates, we do this by introducing a single, right-branching subderivation for each $\mathcal{A}$-subpath $\varepsilon^* a$ that matches an input symbol a. A nonterminal of the form (q_0, ε, q_1) is never used as a right child, nor does it ever combine with a nonterminal of the form (q_0, X, q_1), except at the end of the input, which is specially handled by rules (5b). Similarly, Allauzen et al. (2010) avoid overcounting when intersecting or composing finite-state machines that have ε-arcs.

Construction 1

$$\mathrm{S} \xrightarrow{\lambda(q_I)\otimes\rho(q_F)} (q_I, \mathrm{S}, q_F) \tag{4a}$$
$$\forall q_I \in I, \forall q_F \in F$$

$$(q_0, \mathrm{X}, q_M) \xrightarrow{w} (q_0, \mathrm{X}_1, q_1) \cdots (q_{M-1}, \mathrm{X}_M, q_M)$$
$$\forall(\mathrm{X} \xrightarrow{w} \mathrm{X}_1 \cdots \mathrm{X}_M) \in \mathcal{P}, M > 0 \tag{4d}$$
$$\forall q_0, \ldots, q_M \in Q$$

$$(q_0, \mathrm{X}, q_0) \xrightarrow{w} \varepsilon \tag{4e}$$
$$\forall(\mathrm{X} \xrightarrow{w} \varepsilon) \in \mathcal{P}, \forall q_0 \in Q$$

$$(q_0, a, q_1) \xrightarrow{w} a \tag{4f}$$
$$\forall(q_0 \xrightarrow{a/w} q_1) \in \delta$$

Construction 2

$$\mathrm{S} \xrightarrow{\lambda(q_I)\otimes\rho(q_F)} (q_I, \widetilde{\mathrm{S}}, q_F) \tag{5a}$$
$$\forall q_I \in I, \forall q_F \in F$$

$$(q_I, \widetilde{\mathrm{S}}, q_1) \xrightarrow{\mathbf{1}} (q_I, \widetilde{\mathrm{S}}, q_0)(q_0, \varepsilon, q_1) \tag{5b}$$
$$\forall q_I \in I, \forall q_0, q_1 \in Q$$

$$(q_I, \widetilde{\mathrm{S}}, q_0) \xrightarrow{\mathbf{1}} (q_I, \mathrm{S}, q_0) \tag{5c}$$
$$\forall q_I \in I, \forall q_0 \in Q$$

$$(q_0, \mathrm{X}, q_M) \xrightarrow{w} (q_0, \mathrm{X}_1, q_1) \cdots (q_{M-1}, \mathrm{X}_M, q_M)$$
$$\forall(\mathrm{X} \xrightarrow{w} \mathrm{X}_1 \cdots \mathrm{X}_M) \in \mathcal{P}, M > 0 \tag{5d}$$
$$\forall q_0, \ldots, q_M \in Q$$

$$(q_0, \mathrm{X}, q_0) \xrightarrow{w} \varepsilon \tag{5e}$$
$$\forall(\mathrm{X} \xrightarrow{w} \varepsilon) \in \mathcal{P}, \forall q_0 \in Q$$

$$(q_0, a, q_1) \xrightarrow{w} a \tag{5f}$$
$$\forall(q_0 \xrightarrow{a/w} q_1) \in \delta, a \in \Sigma \cup \{\varepsilon\}$$

$$(q_0, a, q_2) \xrightarrow{\mathbf{1}} (q_0, \varepsilon, q_1)(q_1, a, q_2) \tag{5g}$$
$$\forall a \in \Sigma, \forall q_0, q_1, q_2 \in Q$$

Figure 2: The original Bar-Hillel construction (left) and our generalized version (right) that covers ε-arcs. We highlight the differences from the original construction in red. Note that the weights of rules (4a) and (4f) (respectively (5a) and (5f)) encode the weights of the WFSA, while the weights of rules (4d) and (4e) (respectively (5d) and (5e)) encode weights of the WCFG. All other rules in the generalized construction ((5b), (5c) and (5g)) are assigned weight **1**, and, thus, they do not change the weight of a derivation.

Theorem 1. *Let $\mathcal{G}$ be a WCFG and $\mathcal{A}$ a WFSA over the same alphabet Σ and commutative semiring $\mathcal{W}$. Let $\mathcal{G}_\cap$ be the grammar obtained with our generalized construction. Then we have strong equivalence between $\mathcal{G}_\cap$ and $\langle \mathcal{G}, \mathcal{A} \rangle$; meaning that there is a weight-preserving, yield-preserving bijection between $\mathcal{D}_{\mathcal{G}_\cap}$ and $(\mathcal{D}_\mathcal{G} \bowtie \mathcal{D}_\mathcal{A})$.*

Corollary 1. *$\mathcal{G}_\cap$ and $\langle \mathcal{G}, \mathcal{A} \rangle$ are weakly equivalent, meaning that $L_{\mathcal{G}_\cap}(\boldsymbol{s}) = L_\mathcal{G}(\boldsymbol{s}) \otimes L_\mathcal{A}(\boldsymbol{s})$ whenever the values on the right-hand side are defined.*

See App. B for proofs. Theorem 1 may be seen as a generalization of Theorem 8.1 by Bar-Hillel et al. (1961) and Theorem 12 by Nederhof and Satta (2003). Indeed, the set of derivations produced by Construction 1 is equivalent to the set of derivations produced by Construction 2, modulo an unfold transform (Tamaki and Sato, 1984) to remove rules containing $\widetilde{\mathrm{S}}$. Among the groups of rules listed in Fig. 2, the set of rules with maximum cardinality is the one defined by Eq. (5d). This set has cardinality $\mathcal{O}\left(|\mathcal{P}||Q|^{M_\star}\right)$, where $M_\star$ is 1 plus the length of the longest right-hand side among all the rules $\mathcal{P}$. All other equations in this construction lead to smaller sets of added rules. Since Eq. (5d) is unchanged from Eq. (4d) in the original construction, the asymptotic bound on the number of rules in our output grammar remains unchanged.

4 Conclusion

We generalized the weighted Bar-Hillel intersection construction so that the given WFSA may contain ε-arcs. Our construction is strongly equivalent to the product of the original WCFG and WFSA, i.e., every derivation tree in the resulting grammar represents a pairing of a derivation tree in the input WCFG and a path in the WFSA with the same yield. We gave a full proof of correctness for our construction. By adding output strings to the WFSA arcs and having rule (5f) rewrite to the arc's output string, our method can also be used to compose a WCFG with a weighted finite-state *transducer* (WFST) that could usefully model morphological post-processing or speaker errors.

5 Acknowledgements

The authors acknowledge Roger Levy for correspondence about Levy (2008) and Levy (2011).

6 Limitations

In this note, we generalize a fundamental theoretical result in formal language theory, which has seen a variety of practical applications, including human sentence comprehension under uncertain input (Levy, 2008, 2011) and infix probability computation (Nederhof and Satta, 2003). Although we motivate our paper by discussing the necessity of performing intersections on automata with ε-arcs, we do not explore any such practical applications. Further, while we show that the asymptotic bound on the size of our intersection grammar matches the original Bar-Hillel construction's, we do not discuss multiplicative or added constants introduced in our grammar's size.

Ethical Statement

We do not foresee any ethical issues with our work.

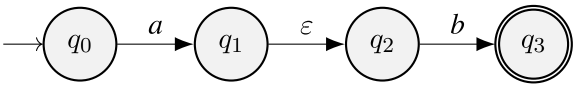
A Failure Cases of Original Construction

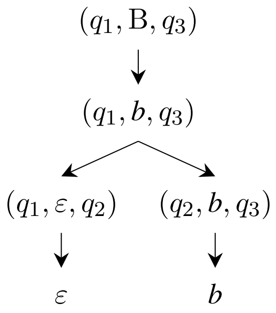
We distinguish two types of failure cases: (i) $\mathtt{supp}(L_{\mathcal{G}_\cap}) \neq \mathtt{supp}(L_{\mathcal{A}}) \cap \mathtt{supp}(L_{\mathcal{G}})$ and (ii) $L_{\mathcal{G}_\cap} \neq L_{\mathcal{A}} \cap L_{\mathcal{G}}$, both of which we will exemplify now. Notably, the case (ii) follows from (i), but—to be comprehensible—we will nonetheless give an example where (ii) fails without (i). For case (i), consider the following unweighted FSA:



and the following unweighted CFG:

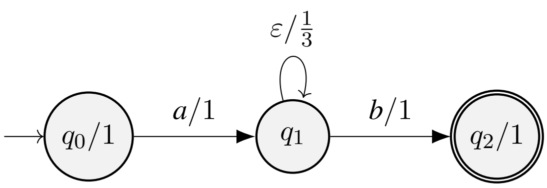
$$\begin{aligned} &\mathrm{S} \rightarrow \mathrm{A}\,\mathrm{B} \\ &\mathrm{A} \rightarrow a \\ &\mathrm{B} \rightarrow b \end{aligned}$$

It is easy to see that the intersection of the language accepted by the FSA and the language generated by the CFG is $\{ab\}$. Construction 1, however, outputs an empty grammar (after pruning useless rules as in footnote 9) and, hence, an empty language. To see this, consider Eq. (4d) and Eq. (4f). First, Eq. (4f) will create a rule $(q_1, \varepsilon, q_2) \rightarrow \varepsilon$, but (q_1, ε, q_2) will be useless because it cannot be reached from any of the rules produced by Eq. (4d). Second, Eq. (4d) will produce reachable nonterminals (q_0, A, q_i) and (q_i, B, q_3), with $i \in \{1, 2\}$. The case of $i = 1$ will reach a but not b, and $i = 2$ will reach b but not a. Let us now show how our generalized construction fixes this failure case. Eq. (5g) generates the rule $(q_1, b, q_3) \rightarrow (q_1, \varepsilon, q_2)(q_2, b, q_3)$ which then combines with rule $(q_1, \mathrm{B}, q_3) \rightarrow (q_1, b, q_3)$ to form a subderivation[12] that covers the substring εb, as shown in the picture below.



Note that rules generated by Eq. (5g) can only mention symbol ε in the left child, not in the right child, as discussed in footnote 11.

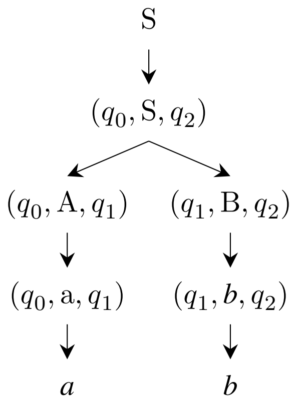
As stated above, to be comprehensive, we also show a case where only case (ii) fails, without (i). Take the following WFSA over the Inside semiring (Huang, 2008):



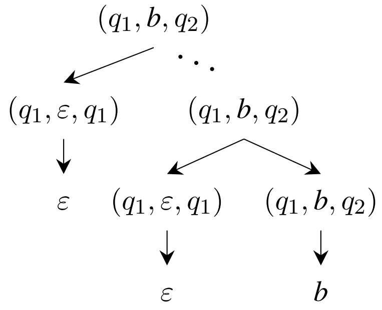
and the same grammar as above with weight 1 for all rules. It is easy to see that the language's weight for $\boldsymbol{s} = ab$ in the WFSA is a geometric series $L_{\mathcal{A}}(\boldsymbol{s}) = \sum_{i=0}^{\infty} \left(\frac{1}{3}\right)^i = \frac{3}{2}$, while in the WCFG, $L_{\mathcal{G}}(\boldsymbol{s}) = 1$. However, the output grammar $\mathcal{G}_\cap$ of Construction 1 will contain one single derivation $\boldsymbol{d}$:

---

[12] In App. B we give a formal definition of subderivation.



with $w(\boldsymbol{d}) = 1$, as all rules either stem from $\mathcal{G}$ or from the arcs $q_0 \xrightarrow{a/1} q_1$ and $q_1 \xrightarrow{b/1} q_2$.This will result in $L_{\mathcal{G}_\cap} = 1$, but $L_\mathcal{A} \cap L_\mathcal{G} = \frac{3}{2}$. This is because there are no derivations rooted at S in $\mathcal{G}_\cap$ that match with the ε-arcs in $\mathcal{A}$: Similarly to the example above, (q_1, ε, q_1) will not be reachable. We will now briefly show how our construction fixes this failure case as well. Note that there are infinitely many paths in the WFSA with yield $\boldsymbol{s} = ab$; but there is also only a single derivation in $\mathcal{D}_\mathcal{G}$ with this yield. Our construction thus ensures that there is exactly one derivation in $\mathcal{D}_{\mathcal{G}_\cap}$ for every *ab* path in $\mathcal{D}_\mathcal{A}$. As the ε-loop allows unboundedly long subpaths from q_1 to q_2 that are labeled with $\varepsilon^* b$, the rules generated by Eq. (5g) will build corresponding unboundedly deep subderivations of the following form:



Finally we observe that a similar argument holds for rules generated by Eq. (5b), and ε-arcs that occur immediately before a final state.

B Proofs

B.1 Proof of Theorem 1

Theorem 1 gives a result for derivations (which are always rooted at S) and paths (which always connect an initial state with a final state). However, in order to prove this theorem we must also consider subderivations and subpaths. We define subderivations as follows: a **subderivation** $\widetilde{\boldsymbol{d}}$ is a sequence $\boldsymbol{\alpha}_0, \ldots, \boldsymbol{\alpha}_N$ with $N \geq 0$, where (i) in the case of $N > 0$, $\boldsymbol{\alpha}_0 = \mathrm{X}$, $\mathrm{X} \in \mathcal{N}$, and $\boldsymbol{\alpha}_N \in (\varepsilon \cup \Sigma^*)$, such that for all $0 < n \leq N$, we have $\boldsymbol{\alpha}_{n-1} \overset{p_n}{\Rightarrow}_L \boldsymbol{\alpha}_n$ for some $p_n \in \mathcal{P}$, and (ii) in the case of $N = 0$, $\boldsymbol{\alpha}_0 \in \Sigma \cup \{\varepsilon\}$. The weight and yield of subderivations are defined analogously to that of derivations. In the extended case of $N = 0$, the yield is equal to $\boldsymbol{\alpha}_0$ and the weight is set to $\mathbf{1}$. We will say that a subderivation is **rooted** at X if $\boldsymbol{\alpha}_0 = \mathrm{X}$. We denote the set of subderivations rooted at X with $\mathcal{D}_\mathcal{G}(\mathrm{X})$. Moreover, a subpath is defined as follows: A **subpath** $\widetilde{\boldsymbol{\pi}}$ (of length $N \geq 0$), is (i) in the case of $N > 0$, a sequence of arcs in δ^* where the states of adjacent arcs are matched, and (ii) in the case of $N = 0$ a single state $q \in Q$.[13] The subpath's weight, denoted $\widetilde{w}(\widetilde{\boldsymbol{\pi}})$, is the product $\widetilde{w}(\widetilde{\boldsymbol{\pi}}) = \bigotimes_{n=1}^{N} w_n$ of the weights of the arcs along the subpath. In the extended case $N = 0$ we set the weight to $\mathbf{1}$ and the yield to ε. Note that, in contrast to the

---

[13] We note the difference to paths defined in §2.3: a subpath does not need to start in an initial state and end in a final state.

weight of a path, the weight of a subpath does not account for initial and final weights. The yield is defined identically to that of paths. We denote the set of all paths starting at q_i and ending at q_j with $\mathcal{D}_{\mathcal{A}}(\{q_i, q_j\})$. Note that the definitions of subderivation and subpath encapsulate the definitions of derivation and path respectively. Furthermore, we will denote with $p\left(\boldsymbol{\pi}\right)$ and $n\left(\boldsymbol{\pi}\right)$, respectively, the first and the last state encountered along a path.

We will now prove two lemmas that will be necessary for the proof of Theorem 1.

Lemma 1. *For any triplet* $(q_0, \mathrm{X}, q_m) \in \mathcal{N}_\cap$, *with* $\mathrm{X} \neq \widetilde{\mathrm{S}}$ *and* $q_0, q_m \in Q$, *there is a bijection* $\psi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$ *from* $\mathcal{D}_{\mathcal{G}_\cap}((q_0, \mathrm{X}, q_m))$ *to the weighted join* $(\mathcal{D}_{\mathcal{G}}(\mathrm{X}) \bowtie \mathcal{D}_{\mathcal{A}}(\{q_0, q_m\}))$, *restricted to tuples in which the path does not have an* ε*-arc immediately before a final state. Moreover, it holds that:*

$$w\left(\widetilde{\boldsymbol{d}}_\cap\right) = w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) \tag{7}$$

$$\texttt{yield}\left(\widetilde{\boldsymbol{d}}_\cap\right) = \texttt{yield}\left(\widetilde{\boldsymbol{d}}\right) = \texttt{yield}\left(\widetilde{\boldsymbol{\pi}}\right) \tag{8}$$

Proof. We begin by showing that ψ is well defined, that it is injective and that it satisfies the properties in Eqs. (7) and (8). We prove this by induction on subderivations.

Lemma 1's Base Case. We begin by observing that the only terminal rules from $\mathcal{P}_\cap$ are defined by Eq. (5f) and Eq. (5e).

Lemma 1's Base Case, Part #1. $\widetilde{\boldsymbol{d}}_\cap$ is obtained by the application of a single production rule $(q_0, a, q_1) \xrightarrow{w} a$ from Eq. (5f). We define $\psi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, where $\widetilde{\boldsymbol{\pi}} = q_0 \xrightarrow{a/w} q_1$ and $\widetilde{\boldsymbol{d}} = a$ is the subderivation that contains just the string a with weight $\mathbf{1}$. It is easy to see that the yield is preserved. Moreover:

$$\begin{aligned} w\left(\widetilde{\boldsymbol{d}}_\cap\right) &= w && \text{(by Eq. (5f))} \quad \tag{9a} \\ &= w \otimes \mathbf{1} \tag{9b} \\ &= \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) \otimes w\left(\widetilde{\boldsymbol{d}}\right) \tag{9c} \end{aligned}$$

Lemma 1's Base Case, Part #2. $\widetilde{\boldsymbol{d}}_\cap$ is obtained by the application of a single production rule $(q_0, \mathrm{X}, q_0) \xrightarrow{w} \varepsilon$ from Eq. (5e). We construct ψ as follows: $\psi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, where $\widetilde{\boldsymbol{d}} = \mathrm{X} \overset{p}{\Rightarrow}_L \varepsilon$ with $p = \mathrm{X} \xrightarrow{w} \varepsilon$, and $\widetilde{\boldsymbol{\pi}}$ is the subpath q_0 with weight $\mathbf{1}$. Clearly the yield is preserved and:

$$\begin{aligned} w\left(\widetilde{\boldsymbol{d}}_\cap\right) &= w && \text{(by Eq. (5e))} \quad \tag{10a} \\ &= w \otimes \mathbf{1} \tag{10b} \\ &= w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) \tag{10c} \end{aligned}$$

Lemma 1's Induction Step. In the induction step, we show that the properties that we have shown for the base case propagate upwards along the derivation. In general, we will show that for any $\widetilde{\boldsymbol{d}}_\cap = (q_0, \mathrm{X}, q_M) \overset{p}{\Rightarrow}_L (q_0, \mathrm{X}_1, q_1), \ldots, (q_{M-1}, \mathrm{X}_\mathrm{M}, q_M) \Rightarrow_L \ldots$, we can construct $\psi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$ such that the mapping is injective and that the properties in Eqs. (7) and (8) hold. Additionally, as for the base case, we will show that $\widetilde{\boldsymbol{\pi}}$ connects q_0 with q_M and that $\widetilde{\boldsymbol{d}}$ is rooted at X. As our inductive hypothesis, we will assume that each of these hypotheses hold for the subderivations rooted at each of the child nonterminals $(q_0, \mathrm{X}_1, q_1), \ldots, (q_{M-1}, \mathrm{X}_\mathrm{M}, q_M)$. We note that the rules from $\mathcal{P}_\cap$ which apply to a nonterminal of form (q_0, X, q_M) with $\mathrm{X} \in \Sigma$ are discussed in base case #1, if instead $\mathrm{X} \in \mathcal{N}$, we either have base case #2 or one of the rules defined by Eq. (5d) and Eq. (5g); we discuss each now.

Lemma 1's Induction Step, Part #1. The topmost rule applied in $\widetilde{\boldsymbol{d}}_\cap$ is $p = (q_0, \mathrm{a}, q_2) \xrightarrow{\mathbf{1}} (q_0, \varepsilon, q_1)(q_1, \mathrm{a}, q_2)$ defined by Eq. (5g). We denote with $\widetilde{\boldsymbol{d}}_{\cap,1}$ the subderivation rooted at (q_0, ε, q_1), and we observe that the only possible form for this derivation is $(q_0, \varepsilon, q_1) \overset{p}{\Rightarrow}_L \varepsilon$ for some $p = (q_0, \varepsilon, q_1) \xrightarrow{w} \varepsilon$. We denote with $\widetilde{\boldsymbol{d}}_{\cap,2}$ the subderivation rooted at (q_1, a, q_2), then by inductive hypothesis, we know that there is a mapping $\psi(\widetilde{\boldsymbol{d}}_{\cap,2}) = \langle \widetilde{\boldsymbol{d}}_2, \widetilde{\boldsymbol{\pi}}_2 \rangle$ such that Eqs. (7) and (8) are satisfied.

Then we construct $\psi(\widetilde{\boldsymbol{d}}_{\cap}) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, so that $\widetilde{\boldsymbol{d}} = \widetilde{\boldsymbol{d}}_2$ and $\widetilde{\boldsymbol{\pi}} = q_0 \xrightarrow{\varepsilon/w} q_1 \circ \widetilde{\boldsymbol{\pi}}_2$. As the yield of the subderivation rooted at (q_0, ε, q_1) is ε, the yield of $\widetilde{\boldsymbol{d}}_{\cap}$ is the same as that of $\widetilde{\boldsymbol{d}}_{\cap,2}$. Further, the yield of $\widetilde{\boldsymbol{\pi}}$ is the same as $\widetilde{\boldsymbol{\pi}}_2$. We thus have that:

$$\texttt{yield}\left(\widetilde{\boldsymbol{d}}_{\cap}\right) = \texttt{yield}\left(\widetilde{\boldsymbol{d}}_{\cap,2}\right), \qquad \texttt{yield}\left(\widetilde{\boldsymbol{d}}\right) = \texttt{yield}\left(\widetilde{\boldsymbol{d}}_2\right), \qquad \texttt{yield}\left(\widetilde{\boldsymbol{\pi}}\right) = \texttt{yield}\left(\widetilde{\boldsymbol{\pi}}_2\right) \quad (11)$$

By induction, we have that the yield is preserved. Similarly, we have that the weight is preserved:

$$\begin{aligned}
w\left(\widetilde{\boldsymbol{d}}_{\cap}\right) &= \mathbf{1} \otimes w\left(\widetilde{\boldsymbol{d}}_{\cap,1}\right) \otimes w\left(\widetilde{\boldsymbol{d}}_{\cap,2}\right) && && \text{(12a)}\\
&= \mathbf{1} \otimes w \otimes w\left(\widetilde{\boldsymbol{d}}_2\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_2\right) && \text{(inductive hypothesis)} && \text{(12b)}\\
&= w\left(\widetilde{\boldsymbol{d}}_2\right) \otimes \left(w \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_2\right)\right) && \text{(commutativity)} && \text{(12c)}\\
&= w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) && && \text{(12d)}
\end{aligned}$$

Finally, by induction we assume that $\widetilde{\boldsymbol{\pi}}_2$ connects state q_1 with state q_2, which implies that $\widetilde{\boldsymbol{\pi}}$ connects state q_0 with state q_2.

Lemma 1's Induction Step, Part # 2. The topmost rule applied in $\widetilde{\boldsymbol{d}}_{\cap}$ is $p = (q_0, \mathrm{X}, q_M) \xrightarrow{w} (q_0, \mathrm{X}_1, q_1), \ldots, (q_{M-1}, \mathrm{X}_\mathrm{M}, q_M)$ defined by Eq. (5d). By induction we assume that the subderivation $\widetilde{\boldsymbol{d}}_{\cap,m}$ rooted at $(q_{m-1}, \mathrm{X}_\mathrm{m}, q_m)$ is mapped by ψ into a subderivation $\widetilde{\boldsymbol{d}}_m$ rooted at X_m and a path $\widetilde{\boldsymbol{\pi}}_m$, so that $\texttt{yield}\left(\widetilde{\boldsymbol{d}}_{\cap,m}\right) = \texttt{yield}\left(\widetilde{\boldsymbol{d}}_m\right) = \texttt{yield}\left(\widetilde{\boldsymbol{\pi}}_m\right)$ and that $w\left(\widetilde{\boldsymbol{d}}_{\cap,m}\right) = w\left(\widetilde{\boldsymbol{d}}_m\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_m\right)$. We then define $\psi(\widetilde{\boldsymbol{d}}_{\cap}) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$ where $\widetilde{\boldsymbol{d}} = \mathrm{X} \overset{p}{\Rightarrow}_L \mathrm{X}_1, \ldots, \mathrm{X}_\mathrm{M} \Rightarrow_L \ldots$ with $p = \mathrm{X} \xrightarrow{w} \mathrm{X}_1, \ldots \mathrm{X}_\mathrm{M}$ and $\widetilde{\boldsymbol{\pi}} = \widetilde{\boldsymbol{\pi}}_1 \circ \ldots \circ \widetilde{\boldsymbol{\pi}}_M$. As the states of neighboring triplets are matched, and by induction we assume that $\widetilde{\boldsymbol{\pi}}_m$ connects states q_{m-1} with state q_m, we have that $\widetilde{\boldsymbol{\pi}}$ is a path from q_0 to q_M. We note that the yield of $\widetilde{\boldsymbol{d}}$ is obtained by concatenation of $\texttt{yield}\left(\widetilde{\boldsymbol{d}}_m\right)$ from left to right, and that similarly the yield of $\widetilde{\boldsymbol{\pi}}$ is obtained by concatenation of $\texttt{yield}\left(\widetilde{\boldsymbol{\pi}}_m\right)$ from left to right. This, together with the inductive hypothesis proves Eq. (8) of the lemma—as the yield of $\widetilde{\boldsymbol{d}}_{\cap}$ will also be given by the concatenation of $\texttt{yield}\left(\widetilde{\boldsymbol{d}}_{\cap,m}\right)$ from left to right. We now show that Eq. (7) on weights holds:

$$\begin{aligned}
w\left(\widetilde{\boldsymbol{d}}_{\cap}\right) &= w \otimes \bigotimes_{m=1}^{M} w\left(\widetilde{\boldsymbol{d}}_{\cap,m}\right) && && \text{(13a)}\\
&= w \otimes \bigotimes_{m=1}^{M} w\left(\widetilde{\boldsymbol{d}}_m\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_m\right) && \text{(inductive hypothesis)} && \text{(13b)}\\
&= \left(w \otimes \bigotimes_{m=1}^{M} w\left(\widetilde{\boldsymbol{d}}_m\right)\right) \otimes \bigotimes_{m=1}^{M} \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_m\right) && \text{(commutativity)} && \text{(13c)}\\
&= w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) && && \text{(13d)}
\end{aligned}$$

We have defined ψ in a bottom-up fashion. At each step changing the topmost rule would result either in a different tree $\widetilde{\boldsymbol{d}}$ or in a different path $\widetilde{\boldsymbol{\pi}}$, which proves injectivity. The proof that ψ is surjective is very similar, and consists in showing by induction, that for any $\widetilde{\boldsymbol{d}} \in \mathcal{D}_{\mathcal{G}}(\mathrm{X})$, and for any path $\widetilde{\boldsymbol{\pi}}$ that does not have a sequence of ε-arc before a final state, it is always possible to build a derivation in $\mathcal{D}_{\mathcal{G}_{\cap}}((p(\boldsymbol{\pi}), \mathrm{X}, n(\boldsymbol{\pi})))$. We limit ourselves to noting that it is always possible to do so by using rules from Eqs. (5d) to (5f), as in the original Bar-Hillel construction, and by using rules defined by Eq. (5g) to cover ε-arcs in the WFSA. ■

Lemma 2. *For any triplet* $(q_I, \widetilde{\mathrm{S}}, q) \in \mathcal{N}_\cap$*, with* $q_I \in Q_I, q \in Q$*, there is a bijection* $\xi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$ *from* $\mathcal{D}_{\mathcal{G}_\cap}\big((q_I, \widetilde{\mathrm{S}}, q)\big)$ *to the join* $(\mathcal{D}_{\mathcal{G}}(\mathrm{S}) \bowtie \mathcal{D}_{\mathcal{A}}(\{q_I, q\}))$*, and we have that:*

$$w\left(\widetilde{\boldsymbol{d}}_\cap\right) = w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) \tag{14}$$

$$\mathtt{yield}\left(\widetilde{\boldsymbol{d}}_\cap\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{d}}\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{\pi}}\right) \tag{15}$$

Proof. We now present an inductive proof (similar to the above) for this lemma.

Lemma 2's Base Case. The topmost rule applied in $\widetilde{\boldsymbol{d}}_\cap$ is $(q_I, \widetilde{\mathrm{S}}, q) \xrightarrow{\mathbf{1}} (q_I, \mathrm{S}, q)$ from rules defined by Eq. (5c). We denote with $\widetilde{\boldsymbol{d}}_{\cap,1}$ the subderivation rooted at (q_I, S, q). Then by Lemma 1, we know that there is a mapping $\psi(\widetilde{\boldsymbol{d}}_{\cap,1}) = \langle \widetilde{\boldsymbol{d}}_1, \widetilde{\boldsymbol{\pi}}_1 \rangle$ such that Eqs. (14) and (15) are satisfied. We then define $\xi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}_1, \widetilde{\boldsymbol{\pi}}_1 \rangle$, and one can easily see that the properties in Eqs. (14) and (15) are satisfied.

Lemma 2's Induction Step. The topmost rule applied in $\widetilde{\boldsymbol{d}}_\cap$ is $(q_I, \widetilde{\mathrm{S}}, q_1) \xrightarrow{\mathbf{1}} (q_I, \widetilde{\mathrm{S}}, q_0)(q_0, \varepsilon, q_1)$ from rules defined by Eq. (5b). We denote with $\widetilde{\boldsymbol{d}}_{\cap,1}$ the subderivation rooted at $(q_I, \widetilde{\mathrm{S}}, q_0)$, and we assume by induction that $\xi(\widetilde{\boldsymbol{d}}_{\cap,1}) = \langle \widetilde{\boldsymbol{d}}_1, \widetilde{\boldsymbol{\pi}}_1 \rangle$ and that properties in Eqs. (14) and (15) hold. We denote with $\widetilde{\boldsymbol{d}}_{\cap,2}$ the subderivation rooted at (q_0, ε, q_1), and we observe that the only possible form for this derivation is $(q_0, \varepsilon, q_1) \overset{p}{\Rightarrow}_L \varepsilon$ for some $p = (q_0, \varepsilon, q_1) \xrightarrow{w} \varepsilon$. Then we can construct $\xi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, where $\widetilde{\boldsymbol{d}} = \widetilde{\boldsymbol{d}}_1$ and $\widetilde{\boldsymbol{\pi}} = \widetilde{\boldsymbol{\pi}}_1 \circ q_0 \xrightarrow{\varepsilon/w} q_1$. The property in Eq. (15) is clearly satisfied, for property Eq. (14), we have:

$$\begin{aligned}
w\left(\widetilde{\boldsymbol{d}}_\cap\right) &= \mathbf{1} \otimes w\left(\widetilde{\boldsymbol{d}}_{\cap,1}\right) \otimes w\left(\widetilde{\boldsymbol{d}}_{\cap,2}\right) && \text{(16a)}\\
&= w\left(\widetilde{\boldsymbol{d}}_{\cap,1}\right) \otimes w && \text{(weight of } \widetilde{\boldsymbol{d}}_{\cap,2}\text{)} \quad \text{(16b)}\\
&= w\left(\widetilde{\boldsymbol{d}}_1\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}_1\right) \otimes w && \text{(inductive hypothesis)} \quad \text{(16c)}\\
&= w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\left(\widetilde{\boldsymbol{\pi}}\right) && \text{(weight of } \widetilde{\boldsymbol{\pi}}\text{)} \quad \text{(16d)}
\end{aligned}$$

As for Lemma 1 we note that modifying the topmost rule in $\widetilde{\boldsymbol{d}}_\cap$, would always result either in a different derivation $\widetilde{\boldsymbol{d}}$ or in a different path $\widetilde{\boldsymbol{\pi}}$, which proves injectivity. Surjectivity can be shown by induction, similarly to how we did for injectivity. We will simply note that given any derivation $\widetilde{\boldsymbol{d}}$ rooted at S, and given any path $\widetilde{\boldsymbol{\pi}}$ starting from an initial state, it is always possible to build a matching derivation $\widetilde{\boldsymbol{d}}_\cap$in $\mathcal{D}_{\mathcal{G}_\cap}((p\left(\boldsymbol{\pi}\right), \widetilde{\mathrm{S}}, n\left(\boldsymbol{\pi}\right)))$, by using the result from Lemma 1, and applying rules defined by Eqs. (5b) and (5c). ■

We can finally prove Theorem 1, which we restate here for convenience.

Theorem 1. *Let* $\mathcal{G}$ *be a WCFG and* $\mathcal{A}$ *a WFSA over the same alphabet* Σ *and commutative semiring* $\mathcal{W}$*. Let* $\mathcal{G}_\cap$ *be the grammar obtained with our generalized construction. Then we have strong equivalence between* $\mathcal{G}_\cap$ *and* $\langle \mathcal{G}, \mathcal{A} \rangle$*; meaning that there is a weight-preserving, yield-preserving bijection between* $\mathcal{D}_{\mathcal{G}_\cap}$ *and* $(\mathcal{D}_{\mathcal{G}} \bowtie \mathcal{D}_{\mathcal{A}})$*.*

Proof. Any derivation $\boldsymbol{d}_\cap$ in $\mathcal{D}_{\mathcal{G}_\cap}(\mathrm{S})$ takes the form $\mathrm{S} \overset{p}{\Rightarrow}_L (q_I, \widetilde{\mathrm{S}}, q_F) \Rightarrow_L \ldots$ with $p = \mathrm{S} \xrightarrow{\lambda(q_I) \otimes \rho(q_F)} (q_I, \widetilde{\mathrm{S}}, q_F)$, for $q_I \in Q_I$ and $q_F \in Q_F$. We denote with $\widetilde{\boldsymbol{d}}_\cap$ the subderivation rooted at $(q_I, \widetilde{\mathrm{S}}, q_F)$. We can thus define $\phi(\boldsymbol{d}_\cap) = \langle \boldsymbol{d}, \boldsymbol{\pi} \rangle = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, where $\xi(\widetilde{\boldsymbol{d}}_\cap) = \langle \widetilde{\boldsymbol{d}}, \widetilde{\boldsymbol{\pi}} \rangle$, and ξ is the bijection defined in Lemma 2. By Lemma 2 we have that $\widetilde{\boldsymbol{d}} = \boldsymbol{d}$ is rooted at S, and that $\widetilde{\boldsymbol{\pi}} = \boldsymbol{\pi}$ has initial and final states: $p\left(\widetilde{\boldsymbol{\pi}}\right) = q_I$ and $n\left(\widetilde{\boldsymbol{\pi}}\right) = q_F$. Clearly, $\mathtt{yield}\left(\boldsymbol{d}_\cap\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{d}}_\cap\right)$ and, by Lemma 2, $\mathtt{yield}\left(\widetilde{\boldsymbol{d}}_\cap\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{d}}\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{\pi}}\right)$. Further, by definition $\mathtt{yield}\left(\boldsymbol{d}\right) = \mathtt{yield}\left(\widetilde{\boldsymbol{d}}\right)$

and $\texttt{yield}\,(\widetilde{\boldsymbol{\pi}}) = \texttt{yield}\,(\boldsymbol{\pi})$. Moreover, we have that:

$$
\begin{aligned}
w\,(\boldsymbol{d}_\cap) &= w\,(p) \otimes w\left(\widetilde{\boldsymbol{d}}_\cap\right) && \text{(weight of a derivation)} \quad \text{(17a)}\\
&= w\,(p) \otimes w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\,(\widetilde{\boldsymbol{\pi}}) && \text{(Lemma 2)} \quad \text{(17b)}\\
&= \lambda(q_I) \otimes \rho(q_F) \otimes w\left(\widetilde{\boldsymbol{d}}\right) \otimes \widetilde{w}\,(\widetilde{\boldsymbol{\pi}}) && \text{(weight of } p\text{)} \quad \text{(17c)}\\
&= w\left(\widetilde{\boldsymbol{d}}\right) \otimes \lambda(q_I) \otimes \widetilde{w}\,(\widetilde{\boldsymbol{\pi}}) \otimes \rho(q_F) && \text{(commutativity)} \quad \text{(17d)}\\
&= w\,(\boldsymbol{d}) \otimes w\,(\boldsymbol{\pi}) && \text{(definition of weight of a path)} \quad \text{(17e)}
\end{aligned}
$$

which proves that ϕ is weight and yield preserving. By Lemma 2 we know that ξ is a bijection, which implies that modifying the topmost rule p would result in a different tuple $\langle \boldsymbol{d}, \boldsymbol{\pi} \rangle$. This proves the injectivity of ϕ. Conversely, consider any path $\boldsymbol{\pi}$ connecting an initial state with a final one and any derivation $\boldsymbol{d}$ rooted at S, such that $\texttt{yield}\,(\boldsymbol{d}) = \texttt{yield}\,(\boldsymbol{\pi})$. By Lemma 2 we know that it is always possible to construct a subderivation $\widetilde{\boldsymbol{d}}_\cap$, rooted at $(q_I, \widetilde{\mathrm{S}}, q_F)$, that satisfies Eqs. (14) and (15). Thus we can construct $\boldsymbol{d}_\cap = \mathrm{S} \overset{p}{\Rightarrow}_L (q_I, \widetilde{\mathrm{S}}, q_F) \Rightarrow_L \cdots$ with $p = \mathrm{S} \xrightarrow{\lambda(q_I)\otimes\rho(q_F)} (q_I, \widetilde{\mathrm{S}}, q_F)$ a rule from Eq. (5a). This shows the surjectivity of ϕ.

■

B.2 Proof of Corollary 1

Corollary 1. *$\mathcal{G}_\cap$ and $\langle \mathcal{G}, \mathcal{A} \rangle$ are weakly equivalent, meaning that $L_{\mathcal{G}_\cap}(\boldsymbol{s}) = L_{\mathcal{G}}(\boldsymbol{s}) \otimes L_{\mathcal{A}}(\boldsymbol{s})$ whenever the values on the right-hand side are defined.*

Proof. §2.1 defined both $L_{\mathcal{A}}(\boldsymbol{s})$ and $L_{\mathcal{G}}(\boldsymbol{s})$ as sums over derivations that yield $\boldsymbol{s}$. If there are only finitely many such derivations, then the sum is well-defined by applying the associative–commutative operator $\oplus$ finitely many times. However, footnote 5 noted that countably infinite sums can arise. We treat this issue by augmenting the semiring with an operator $\bigoplus$ that is applied to a countable (possibly infinite) multiset of weights and returns a value that is interpreted as the sum of those weights, or else returns a special "undefined" value $\bot \notin A$ to indicate that the sum diverges.

We require $\bigoplus$ to satisfy the following axioms for any two countable multisets $I, J \subseteq A$ such that

$$\bigoplus I = W \in A \qquad \bigoplus J = V \in A \tag{18}$$

- *Infinite distributivity*: Let $I \bigotimes J$ denote the multiset $\{\!\!\{ i \otimes j : i \in I, j \in J \}\!\!\}$. Then $\bigoplus (I \bigotimes J) = W \otimes V \in A$.
- *Infinite associativity*: for any partition[14] $I = \bigcup_{k \in K} I_k$, we have $\bigoplus I_k \in A$ for each $k \in K$ and furthermore $\bigoplus_{k \in K} (\bigoplus I_k) = W$.
- *Base cases*: For any $w, w' \in A$, $\bigoplus \{\!\!\{ w, w' \}\!\!\} = w \oplus w'$, $\bigoplus \{\!\!\{ w \}\!\!\} = w$, and $\bigoplus \{\!\!\{\,\}\!\!\} = \mathbf{0}$. Together with the previous property, this ensures that $\bigoplus$ agrees with the $\oplus$-based definition on finite multisets.

The first two axioms are adapted from part of Mohri (2002)'s definition of closed semirings. The proof of Corollary 1 uses only the first axiom, as follows. Given a string $\boldsymbol{s}$ such that $L_{\mathcal{A}}(\boldsymbol{s}), L_{\mathcal{G}}(\boldsymbol{s}) \in A$. By definition (§§2.3–2.4), $L_{\mathcal{A}}(\boldsymbol{s}) = \bigoplus I$ and $L_{\mathcal{G}}(\boldsymbol{s}) = \bigoplus J$ if we define $I = \{\!\!\{ w\,(\boldsymbol{\pi}) : \boldsymbol{\pi} \in \mathcal{D}_{\mathcal{A}}(\boldsymbol{s}) \}\!\!\}$ and $J = \{\!\!\{ w\,(\boldsymbol{d}) : \boldsymbol{d} \in \mathcal{D}_{\mathcal{G}}(\boldsymbol{s}) \}\!\!\}$. Then also $L_{\mathcal{G}_\cap}(\boldsymbol{s}) = \bigoplus (I \bigotimes J)$ since $I \bigotimes J = \{\!\!\{ w\,(\boldsymbol{d}) : \boldsymbol{d} \in \mathcal{D}_{\mathcal{G}_\cap}(\boldsymbol{s}) \}\!\!\}$ according to Theorem 1. By infinite distributivity, then, $L_{\mathcal{G}_\cap}(\boldsymbol{s}) = (\bigoplus I) \otimes (\bigoplus J) = L_{\mathcal{A}}(\boldsymbol{s}) \otimes L_{\mathcal{G}}(\boldsymbol{s}) \in A$ as claimed. ■

Abstract

Dialogue systems capable of social influence such as persuasion, negotiation, and therapy, are essential for extending the use of technology to numerous realistic scenarios. However, existing research primarily focuses on either task-oriented or open-domain scenarios, a categorization that has been inadequate for capturing influence skills systematically. There exists no formal definition or category for dialogue systems with these skills and data-driven efforts in this direction are highly limited. In this work, we formally define and introduce the category of *social influence dialogue systems* that influence users' cognitive and emotional responses, leading to changes in thoughts, opinions, and behaviors through natural conversations. We present a survey of various tasks, datasets, and methods, compiling the progress across seven diverse domains. We discuss the commonalities and differences between the examined systems, identify limitations, and recommend future directions. This study serves as a comprehensive reference for social influence dialogue systems to inspire more dedicated research and discussion in this emerging area.

1 Introduction

Consider a human user who signs up to interact with a persuasive dialogue system that motivates for engaging in physical exercise. The system: 1) uses *social cues like small talk and empathy*, useful for providing continued support, and 2) employs *persuasive strategies to convince* the user who, at least in the short-term, is reluctant to indulge in exercise. Does such a system fit the definition of a *task-oriented dialogue system* that are traditionally designed to assist users in completing their tasks such as restaurant or flight booking (Zhang et al., 2020c)? Although the system is task-oriented or goal-oriented per se, the task here goes beyond the traditional definition of assisting users, given the possible misalignment between the goals of the system and the user. Clearly, this system is also not open-domain (Huang et al., 2020). Although conversations involve social open-ended interactions, there is still a concrete goal of persuading the user towards a healthier habit.

Scenarios similar to above are ubiquitous in everyday life, including games (Peskov et al., 2020), social platforms (Tan et al., 2016), and therapeutic interactions (Tanana et al., 2016). Dialogue systems for these applications require a core function in human communication, that is, *social influence* (Cialdini and Goldstein, 2004; Cialdini, 2009), which involves influencing users' cognitive and emotional responses, leading to changes in thoughts, opinions, and behaviors through natural conversations. This goes beyond what is captured by traditional task definitions in the dialogue community which primarily focus on task completion and social companionship.

Despite numerous independent efforts in identifying and analyzing various social influence scenarios, there is a lack of common understanding around social influence in AI research which inhibits a systematic study in this space. Further, data-driven efforts for dialogue systems in this space are highly limited. To this end, we introduce the category of *social influence dialogue systems* (Section 2), providing a comprehensive literature review and discussing future directions.

Developing these systems holds importance in AI research for multiple reasons. Tackling these tasks not only involves AI but also aspects of game theory, communication, linguistics, and social psychology, making them an ideal testbed for interdisciplinary AI research. Most importantly, they reflect AI's general ability to consider their partners' inputs, tailor the communication strategies, personalize the responses, and lead the conversation actively.

We design a taxonomy for existing social influ-

ence dialogue datasets, studying their task structure (symmetric vs asymmetric) and context (local vs global). We also organize them by their domains: games, multi-issue bargaining, social good, e-commerce, therapy and support, argumentation, conversational recommendations, and miscellaneous tasks (Section 3). We further design a taxonomy of existing methods, assisting readers to comprehend the progress and reflect on future directions. We organize them based on the system strategy, language generation, partner model, architecture, learning process, and the use of pretrained language models (Section 4). Finally, we identify key challenges and provide recommendations for future work (Section 5).

Over the years, research in task-oriented and open-domain dialogues has benefited from a myriad of survey efforts (Huang et al., 2020; Zhang et al., 2020c; Ni et al., 2021). We instead focus on dialogue systems with social influence capabilities and present a thorough review across various domains. We hope that our work serves as a timely entry point for interested researchers to take this area further, inspiring dedicated effort and discussion on social influence in the dialogue community.

2 Social Influence Dialogue Systems

"Social influence is a fact of everyday life" (Gass, 2015). It is the *change in thoughts, feelings, attitudes, or behaviors resulting from interaction with an individual or a group* (Rashotte, 2007). Influence is measured by quantifiable proxies of the observed change, like the interest to indulge in physical exercise before or after the interaction with a system, or the final deal in a negotiation as opposed to one person taking it all. Social influence dialogue systems act interactively and influence their partners in decision-making and behavioral contexts (Zhang et al., 2020a; Lee et al., 2020). This calls for an active role by the system, distinguishing them from other well-studied scenarios, such as purely task-oriented, where systems passively assist their partners to complete tasks, and open-domain, that target social companionship. Key social influence tasks include persuasion (Wang et al., 2019), aiming to change users' attitudes or behaviors, and negotiation, aiming to change the users' perspective to achieve a common ground (Lewis et al., 2017).

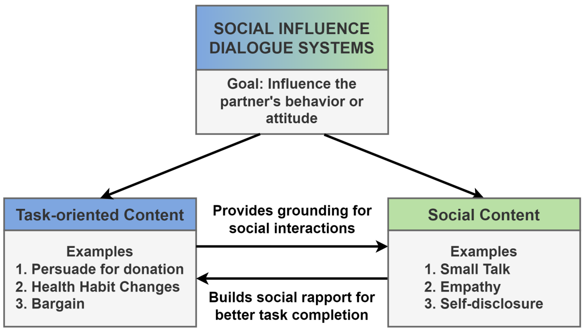

Figure 1: A conceptual overview.

Conceptual overview: Figure 1 distinguishes between the kinds of conversational content in social influence interactions. The *task-oriented content* focuses on influencing for a domain-specific goal, like persuading for donation, bargaining with trade-offs, or encouraging healthier habits. These interactions may also contain *social content*, such as small talk, empathy, or self-disclosure. The task-oriented content provides a context for social interactions. Depending on the task, social content is optional, but if present, can in turn build rapport and enhance user-system relationship for improved task outcomes (Liao et al., 2021).

Connections with task-oriented and open-domain systems: Similar to a task-oriented or an open-domain scenario, social influence dialogue can also be seen as a sequential decision making process with the goal of maximizing the expected reward (Huang et al., 2020; Gao et al., 2018). Our proposed category is not meant to be disjoint from these traditional categories. However, it still uniquely brings together the tasks that capture social influence, *which is fundamentally absent from how we primarily define dialogue tasks in the community*. Defining a new category that captures social influence dialogue would foster a dedicated effort towards this important aspect of real-world conversations.

Task-oriented scenarios focus on collaborative information exchange for a common goal of task completion. In social influence tasks, the goals of the system and the user can be different and even conflicting, leading to collaborative or non-collaborative interactions. Further, the goals can go beyond the current task (e.g. multiple therapy interactions, repeated negotiations), leading to social interactions for long-term relationships. If a scenario involves the system's goal to influence its partner, we consider it under social influence in this paper. For instance, He et al. (2018) studied buyer-seller price negotiations. The task of the buyer is to negotiate for a reasonable price (arguably making it task-oriented), but achieving it requires social influence skills of engaging in trade-offs and building a rapport with the seller so as to reach an agreement.

Measures of Success: The above discussion indicates that a comprehensive evaluation of social influence systems must draw from both task-oriented and open-domain dialogue research. Since there exist surveys that discuss the evaluation in these settings (Deriu et al., 2021; Li et al., 2021), we don't cover them here in detail. However, we define three essential axes for evaluation: 1) *Linguistic Performance*, or the system's linguistic sophistication based on automatic (e.g. perplexity, BLEU) and human (e.g. fluency, consistency, coherency) evaluation. 2) *Influence Outcome*, or the ability to influence defined by objective goals like the negotiated price or weight loss after therapy. 3) *Partner Perception*, or the subjective evaluation of the user, for instance, the user's satisfaction, likeness towards the system, and interest in interacting again. In a buyer-seller negotiation, if the seller hates the buyer in the end, no matter how favorable the deal is for the buyer, one might argue that this is still a failed negotiation for the buyer. Hence, we encourage future work to take all three dimensions into account collectively.

3 Social Influence Across Diverse Application Areas

We now illustrate social influence across numerous domains and application areas. In total, we curated 22 datasets from prior work that capture social influence in various forms, spanning 12 publication venues, 4 languages, and 7 application domains (see Appendix A for details on the compilation process). In general, the datasets capture the following information about an interaction: the *non-conversational context* for the participants (e.g. negotiation preferences or other role-specific information), the *conversation* between them, and *outcome assessment*. Optionally, some datasets also gather participant demographics and personality traits, utterance-level annotations, and subjective evaluations via post-surveys.

To understand the structural similarities and differences between these datasets, we design a taxonomy with two primary dimensions: **Task Structure** (*Symmetric* vs *Asymmetric*), and **Context Definition** (*Global* vs *Local*). **Task Structure** captures whether the participant roles are defined in a symmetric or an asymmetric manner. For instance, a typical multi-issue negotiation is symmetric, in the sense that both parties have their own preferences and goals based on which they actively try to reach a favorable agreement (Lewis et al., 2017). On the other hand, a counseling session between a therapist and a patient is asymmetric, where the therapist attempts to emotionally support the patient by employing social influence skills (Althoff et al., 2016). **Context Definition** relates to whether the input context before each interaction is defined globally or locally. For instance, the PersuasionForGood dataset globally defines the context of persuasion for charity donation, which is kept the same throughout (Wang et al., 2019). On the contrary, in a typical debate, although the rules are defined globally, the conversation topic and arguments are local and can vary for each conversation (Durmus and Cardie, 2019). We present this categorization in Table 1. We further categorize the datasets according to their **Domain**, **Source**, and the **# of parties**. We provide key statistics and the available metadata in Appendix B. We now briefly discuss the datasets in each domain.

Games: Strategy games involve social influence dynamics of trust and deception. Diplomacy captures deception in long-lasting relationships, where players forge and break alliances to dominate Europe (Peskov et al., 2020). Catan revolves around the trade of resources for acquiring roads, settlements, and cities (Asher et al., 2016; Boritchev and Amblard, 2021). The players have access to only a subset of resources that they would need, which encourages strategic influence and trade.

Multi-Issue Bargaining Tasks (MIBT): MIBT is a tractable closed-domain abstraction of a typical negotiation (Fershtman, 1990). It is based on a fixed set of issues each with a predefined priority for each player, which essentially governs the goals of the players. If the priorities of the players align, this leads to competitive negotiations, where each party attempts to convince their partner with trade-offs and persuasive arguments. If they don't, this allows cooperative interactions where the negotiators try to find optimal divisions that benefit everyone. DealOrNoDeal (Lewis et al., 2017) involves negotiations over three issues: *books*, *balls*, and *hats*. Other datasets define a more grounded scenario, such as symmetric CaSiNo (Chawla et al., 2021b) negotiations between two campsite neighbors and asymmetric JobInterview (Yamaguchi et al., 2021)

MIBT: Multi-Issue Bargaining Task. Key statistics and associated metadata are in Appendix 3.

negotiations between recruiters and applicants.

Social Good: Social influence is critical for social good applications. The tactics must be personalized using knowledge that is both relevant and appealing. PersuasionForGood (Wang et al., 2019) involves asymmetric interactions led by a persuader who attempts to convince the other participant for charity donation by employing a variety of tactics. For instance, *Logical Appeal* uses reason and evidence to support the argument, while *Emotional Appeal* elicits specific emotions.

E-commerce: These tasks are typically asymmetric. A *buyer* influences the seller towards a reasonable price, while the *seller* tries to maximize their own profit. An effective system must combine price-related reasoning with language realization. CraigslistBargain (He et al., 2018) involves open-ended price negotiations with rich influence strategies like embellishments, side offers, emotional appeals, and using world knowledge. Another example is customer support interactions in AntiScam dataset (Li et al., 2020), where users defend themselves against attackers who try to steal sensitive personal information with convincing arguments.

Therapy & Support: Effective therapy using social influence aids in the treatment of mental disorders, and substance use disorders, along with changing undesirable behaviors like unhealthy diets. A counselor needs to be adaptive, personalized, should understand the core issues, and should facilitate a change in patient's perspective (Althoff et al., 2016). In SMS counseling, Althoff et al. (2016) found that linguistic influence like pushing the conversation in the desired direction is associated with perspective change. Similar scenarios were captured in other datasets as well (Demasi et al., 2019; Liang et al., 2021). Tanana et al. (2016) collected the Motivational Interviewing dataset where the goal is to elicit and explore the patient's own motivations for behavior change. EmpatheticDialogues (Rashkin et al., 2019) captured empathetic support interactions, which has been associated with rapport and better task outcomes (Kim et al., 2004; Norfolk et al., 2007; Fraser et al., 2018).

Argumentation: In addition to factuality and social proof, a convincing argument must also consider the intensity, valence, authoritativeness, and framing (Chaiken, 1987; Althoff et al., 2014). Tan et al. (2016) released the ChangeMyView logs from Reddit, involving discussions on numerous controversial topics. Other datasets include Debate Dot Org (DDO) debates on diverse topics (Durmus and Cardie, 2019), congressional proceedings (Thomas et al., 2006), and court hearings (Fornaciari and Poesio, 2012; D.-N.-M. et al., 2012; Ji et al., 2020).

Conversational Recommendation: Everyday scenarios naturally hold potential for influence via recommendations, for instance, a movie fan persuading their friends to watch a movie that they adore. Li et al. (2018) and Dodge et al. (2016) collected movie recommendation datasets. Instead of guiding the conversation towards a specific movie, the goal is simply to provide recommendations based on facts and personal experiences. Nevertheless, they still provide interesting examples of scenarios that can involve social influence.

Miscellaneous: The Target-Guided dataset (Tang et al., 2019) was constructed from the PersonaChat corpus (Zhang et al., 2018). Instead of being open-ended, the Target-Guided scenario defines a concrete goal of naturally guiding the conversation to a designated target subject, thereby, making it a social influence setting.

4 Methodological Progress

Having summarized the datasets that capture social influence, we now discuss the modeling approaches developed for social influence dialogue systems. Most domains have seen efforts in analyzing human dialogue behaviors and their impact on task outcomes. Examples include analyzing deception in games (Peskov et al., 2020), the impact of persuasive strategies and dialogue acts on charity donations (Wang et al., 2019), cooperative and non-cooperative strategies in MIBT (Chawla et al., 2021b), the use of emotion expression for predicting partner perceptions (Chawla et al., 2021a), and studying semantic categories of persuasive arguments on web forums (Egawa et al., 2019).

In addition, researchers have targeted various domain-specific subtasks that can be crucial for the eventual development of dialogue systems in this space. This involves research in lie detection methods (Yeh and Ku, 2021; Yu et al., 2015), discourse parsing (Shi and Huang, 2019; Ouyang et al., 2021), strategy prediction (Chawla et al., 2021b; Wang et al., 2019), breakdown detection (Yamaguchi et al., 2021), outcome prediction (Sinha and Dasgupta, 2021; Chawla et al., 2020; Dutt et al., 2020), and argument mining (Dutta et al., 2022).

Research that directly targets the development of dialogue systems in this space is still nascent. Among other challenges like limited cross-cultural diversity and relatively smaller dataset size, social influence dialogue settings pose a unique challenge: an average human often exhibits sub-optimal strategic behaviors in social influence tasks (Wunderle, 2007; Babcock and Laschever, 2009). This means that standard seq2seq approaches trained on these collected datasets using supervised learning are fundamentally insufficient for developing effective dialogue systems with influence capabilities. Hence, prior work has put a special attention to the system strategy, employing different ways to model the strategy and language together.

We design a taxonomy of methods developed for social influence tasks, assisting readers to comprehend the progress and reflect on future directions. We organize them based on the system strategy, language generation, partner model, architecture, learning process, and the use of pretrained language models. We present annotations for all the surveyed methods in Table 2 and discuss the common categories in brief below.

4.1 Strategy Representation

Implicit: The most obvious way to represent the system strategy is *implicitly*, without any intended decoupling between system strategy and response realization. This corresponds to the usual sequence-to-sequence framework that has been a standard baseline for the methods developed in this space. An important example is the work by Lewis et al. (2017), who were one of the first works to train end-to-end dialogue models that exhibit social influence. The authors employed a neural network based on GRUs, one for encoding the negotiation context, one to encode the dialogue utterances, and two recurrent units to generate the output agreement in a bidirectional manner.

Latent vectors: Yarats and Lewis (2018) explored *latent vectors* to decouple utterance semantics from its linguistic aspects. Their hierarchical approach first constructs a latent vector from the input message, which is then used for response generation and planning. These latent vectors are trained to maximize the likelihood of future dialogue messages and actions, which enables the decoupling between semantics and realization.

Dialogue Acts (DAs): Dialogue Acts, such as greeting, offer propose, agreement, or disagreement, are effective at capturing a high-level structure of the dialogue flow in social influence settings, reducing the model strategy to first predicting the dialogue act for the next response. The use of DAs makes it convenient to apply reinforcement learning approaches (Zhang et al., 2020b; Yang et al., 2021), while also aiding in developing a modular dialogue system design (He et al., 2018).

Semantic Strategies: The structural properties ex-

Method	Domain	Strategy	NLG	Partner Model	Architecture	Learning	PLM

Wu21	Social Good	Implicit	Generation	Implicit	Dec-only	SL	GPT2
Ta19	Misc	Keywords	Retrieval	Implicit	Modular	SL	

Table 2: Categorization of methods (non-exhaustive) for social influence dialogue. We only cover papers that explicitly design a dialogue system. NLG: Natural Language Generation, PLM: Pretrained Language Model, MIBT: Multi-Issue Bargaining Task, E-Com: E-Commerce, DA: Dialogue Act, Enc: Encoder, Dec: Decoder, SL: Supervised Learning, RL: Reinforcement Learning. Methods that use RL usually apply it in conjunction with SL.

pressed by DAs are insufficient for capturing semantics like emotion, small talk, and appeal. To better incorporate them, researchers have relied on additional utterance-level annotations grounded in prior theories in social influence contexts (Wang et al., 2019; Chawla et al., 2021b). These strategies have been used in conjunction with DAs (Zhou et al., 2019; Joshi et al., 2020).

4.2 Language Generation

An important aspect of the system design is an effective way to realize the language, that is, to generate the next response so that it portrays the desired strategic behaviors. Borrowing from task-oriented and open-domain research, existing dialogue models for social influence use a variety of methods to generate the final system response.

Templates and retrieval methods: Predefined templates and response retrieval from the training data simplify the generation pipeline, improving controllability and modularity. He et al. (2018) used templates in their generator which are later filled by retrieving similar responses from the data. This allowed the authors to explore supervised and reinforcement learning at the level of DAs for the influence strategy of the system.

Conditional Generation: Text generation methods result in more diverse responses, but negatively impact the controllability and interpretability. Prior work relies on autoregressive text generation conditioned on the dialogue history, non-conversational context, and additional annotations. These are either encoder-decoder networks (Lewis et al., 2017; Li et al., 2020; Joshi et al., 2020) or use a decoder-only design (Li et al., 2020). A useful future direction is to combine generation with retrieval for knowledge-grounded settings like argumentation. Similar methods have been explored for other NLP tasks like open-domain question answering and question generation (Lewis et al., 2020).

4.3 Partner Modeling

Partner modeling refers to inferring the mental states of the partner based on the conversation. For example, understanding the cause that the persuadee cares about in the PersuasionForGood context, or inferring the priorities of the partner in DealOrNoDeal negotiations. Building an accurate partner model is essential in social influence settings for guiding the decision-making of the system (Baarslag et al., 2013; Zhang et al., 2020b). Hence, we discuss various ways in which prior work tackles partner modeling.

Implicit: A majority of the efforts do not explicitly model the behavior of the partner but instead, this behavior implicitly guides the next response of the sequence-to-sequence dialogue system pipeline.

Simulated User: Lewis et al. (2017) trained a simulated user on the available data in a supervised manner. This was then used to further train the dialogue system. Instead of inferring mental states explicitly, this takes a more behavioral approach of estimating the future actions of the partner and using these for training via reinforcement learning.

Dialogue Act Look-Ahead: With a similar idea, Zhang et al. (2020b) proposed OPPA model with a *look-ahead* based partner modeling strategy at the level of DAs. At each step, OPPA first estimates the user's future DA, which is then used to select the next DA of the system. The authors found significant improvements on the DealOrNoDeal task. Yang et al. (2021) used a similar method for buyer-seller negotiations. Taking a different approach, Chawla et al. (2022) trained a ranking model to directly predict the hidden preferences of the partner in a multi-issue negotiation. Instead of predicting future actions, these methods assume that the partner's behavior can be explained by their context and goals in the dialogue. However, this approach is yet to be used in an end-to-end system.

4.4 Training

Architecture Choices: One crucial aspect is the *architecture design*: End-to-end (Lewis et al., 2017; Radford et al., 2019) vs Modular (He et al., 2018). While end-to-end methods improve the diversity and need less manual effort, a modularized design enhances controllability and explainability. Perhaps, this is why modular methods are popular in large-scale models (Hadfi et al., 2021). Improving the control of desired variables such as topics, strategy, or emotion in the end-to-end methods is an open area of research and is yet to be explored for social influence dialogue systems.

Supervised Learning (SL) and Reinforcement Learning (RL): Zhou et al. (2019) used SL to train a hierarchical encoder-decoder for generating the next response and used Finite State Transducers (FSTs) to encode the historic sequence of DAs and persuasive strategies into the model, showing improvements in negotiation and persuasion tasks. The performance was later improved by Joshi et al. (2020), who replaced FSTs with Graph Neural Networks to better model the interdependencies. Others have relied on RL to explicitly optimize the model on task-specific objective outcomes. While SL trains the model to mimic the average human behavior, RL techniques, such as those based on REINFORCE (Williams, 1992), allow the system to explore its own strategies in the wild while being guided by one or more overall reward metrics. Lewis et al. (2017) used RL in negotiations, with the final points scored in the agreed deal as the reward. More recent work employed RL to incorporate simplistic partner models into the decision-making process of the dialogue system, showing improvements in negotiation tasks (Zhang et al., 2020b; Yang et al., 2021).

Multi-tasking and Pretraining: Limited efforts have also explored multi-tasking and pretrained language models for social influence dialogue systems, which provide promising ways to deal with the challenge of insufficient training data. Liu (2021) trained a sequence-to-sequence transformer on a mix of Cornell Movie Dialogue corpus (Danescu-Niculescu-Mizil and Lee, 2011) and psychotherapy data. Li et al. (2020) fine-tuned the GPT model (Radford et al., 2018), while employing multi-tasking to incorporate intents and slots for both the human and the system. Wu et al. (2021) recently introduced ARDM which uses GPT2 (Radford et al., 2019) to separately encode the utterances of the human and the dialogue system, reducing the reliance on additional annotations.

5 Discussion and Recommendations

Past few years have seen an exciting progress in social influence dialogue systems. However, building sophisticated and practically useful systems remains a challenging endeavor. Several limitations still exist that must be addressed. To guide future work, we now discuss the key challenges and provide our recommendations.

Need for unifying the efforts: One challenge in this space has been the lack of large-scale datasets for model training. Social influence tasks are complex for crowdsourcing workers to understand and to participate in. Hence, prior work used extensive instructions and tutorials, making the study expensive and time consuming (Wang et al., 2019; Chawla et al., 2021b). To address this, we recommend the researchers to aim for a more unified view of the efforts in social influence.

First, this would encourage researchers to adopt the best practices from other social influence scenarios. For instance, most datasets miss out on user attributes like demographics and personality, which are crucial in social influence scenarios (Stuhlmacher and Walters, 1999; Bogaert et al., 2008). Most datasets also ignore the partner perception after the interaction is over. This can result in misleading conclusions about the model performance, where the models perform well objectively, but hurt the relationship with their partners, and thus, negatively impacting practical utility (Aydoğan et al., 2020).

Secondly, a holistic outlook will promote transfer learning and domain adaptation. Our taxonomy for datasets (Table 1) governs the way systems must be modeled and trained. Task structure is crucial to understand whether the model can learn from the utterances of all parties or just one. Further, understanding the context definition guides how it must be encoded. Hence, one interesting future direction is joint training on datasets with similar structure and context definition.

Finally, progress in task-oriented and open-domain systems can inspire more unified modeling for social influence tasks involving multiple skills in the same interaction (e.g. a combination of negotiation and persuasion tactics as common in realistic scenarios). Roller et al. (2020) blend various open-domain tasks to address multiple challenges together (e.g., persona-based, knowledge-enriched, etc.). Hosseini-Asl et al. (2020) concatenate structured and unstructured data in task-oriented dialogues, and unify task-oriented dialogue system building to be a single sequence generation problem. Future work should explore similar unified approaches for social influence settings as well, especially since these tasks follow a common conceptual foundation (Figure 1), with similar evaluation and theoretical principles (Cialdini, 2009).

To encourage this unified view, we encapsulate our insights from this survey effort in a theoretical framework, which is presented in Appendix C. The framework covers key components for designing a social influence dialogue task, including system attributes, target audience, underlying modeling techniques, and evaluation mechanisms.

Theory integration: Most modeling efforts are based on crowdsourced datasets. Since crowdsourcing workers may not exhibit optimal strategies, supervised training on these datasets is fundamentally insufficient to build an effective system for applications like pedagogy (teaching social skills to students). Unfortunately, this holds regardless of how system strategy and partner model are designed. Further, using RL to optimize on objective rewards is also not expected to be enough to reliably learn complex influence capabilities, especially when the reward is restrictive.

To address this, we recommend to tap into the vast amount of research effort in social sciences and psychology on building theories for social influence (Cameron, 2009; Giles, 2016; Lewicki et al., 2016; Cialdini and Goldstein, 2004). Instead of solely relying on the collected data, future work should consider leveraging fundamentals from this research to guide the dialogue policy. Previous works have studied resistance to social influence (Knowles and Linn, 2004; Dal Cin et al., 2004; Petty and Cacioppo, 1977; Ahluwalia, 2000). Rucker et al. (2004) found that people resist persuasion differently depending on their beliefs, suggesting personalizing the social influence process. One can also employ the politeness theory (Brown and Levinson, 1978) and model the participants' *face* acts to better understand users in social influence contexts (Dutt et al., 2020).

Task Evaluation: Another key limitation of existing work is the lack of a comprehensive evaluation. Prior work majorly focused on objective metrics which only provides a limited view of the model performance. A comprehensive evaluation is challenging since it must consider partner perception along with objective outcomes. Building user simulators could potentially alleviate this problem (Li et al., 2016; Jain et al., 2018; Shi et al., 2019). Most existing simulators are developed for task-oriented systems which follow a certain agenda. Future research should study how to use partner modeling to build social influence user simulators for more efficient and accurate task evaluation (He et al., 2018; Yang et al., 2020). For instance, one could potentially design different user personalities and simulate the change in user's beliefs, opinions, and attitudes accordingly (Yang et al., 2021).

Multimodal systems: Being a core function of human communication, social influence occurs not just through text, but through all possible modalities. Schulman and Bickmore (2009) showed that embodied agents achieve better persuasion results than text-only agents. Other studies have recognized the importance of emotion in social influence tasks (Asai et al., 2020; Chawla et al., 2021a). Nguyen et al. (2021) proposed a speech dataset in debates and study the influence of spoken tactics on persuasiveness across genders. Given these findings, we encourage interdisciplinary efforts in the future to explore the developement of multimodal social influence agents.

Knowledge-enriched systems: Social influence tasks often involve constantly-changing world knowledge such as organization facts and news. Often, the system's internal state (e.g., the change of task setting from one set of products to a different set) needs to be updated. Retraining the entire system is costly to maintain after the initial development. Recent work has proposed to augment the dialogue system with internet-search ability to generate more factual and updated responses in open-domain dialogues (Komeili et al., 2021). Future efforts in this direction will benefit social influence dialogue systems as well.

6 Conclusions

We introduced the category of social influence dialogue systems that aim to influence their partners through dialogue. We presented a survey of the recent prior work in this space, compiling datasets and methods across diverse application domains. We pointed out key limitations in existing methodologies and proposed promising directions for designing more sophisticated systems in the future. Our survey reveals that although substantial progress has been made, this is still an emerging research area. We hope our work inspires more dedicated interdisciplinary effort and discussion, which is necessary for making progress in this space.

7 Broader Impact and Ethical Considerations

Social influence is ubiquitous in everyday life. Research on how we use influence in all aspects of our lives spans a number of fields, including social psychology, communication, consumer behavior, behavioral change, and behavioral economics. This research has led to crucial findings about the strategies of social influence and how they impact our decision-making. Over the past few decades, research has accumulated and demonstrated the effectiveness of using various strategies across contexts and domains. Prominent examples include core principles of social influence by Cialdini from social psychology: reciprocity, commitment and consistency, social proof, liking and attractiveness, authority, and scarcity (Cialdini, 2009). Further, communication strategies used in persuasion and general social influence contexts include credibility appeals, two-sided argumentation, emotional tactics, and appeals to social norms, among others (Cameron, 2009; O'keefe, 2015).

First, the well-studied principles in social influence research can guide the development of effective dialogue systems with influence capabilities. In fact, many of the strategies found in the datasets developed for social influence tasks (Section 3) directly map to the principles laid out by Cialdini, for instance, credibility and emotional appeal in PersuasionForGood dataset (Wang et al., 2019) and reciprocity observed in CaSiNo negotiation dataset (Chawla et al., 2021b). Second, research in social influence dialogue systems provides novel datasets on human-human and human-machine communication, and therefore, holds a great potential to advance theories of human cognition and influence processes (Gratch et al., 2015). The datasets and subsequent analyses can further contribute new theoretical insights to social influence research.

Although dialogue systems have already been used in a number of applications involving chatbots and AI assistants, advancements in social influence dialogue systems can help to bridge the gap between our existing task definitions and a number of other real-world applications. For instance, realistic customer support interactions often involve active behaviors from both the support agent and the user where the agent uses social cues for improved customer satisfaction and retention, while the user attempts to address their queries. These settings naturally involve aspects of social influence, unlike traditional task-oriented definitions where the dialogue system plays a passive role to assist the human users. As discussed earlier, social influence dialogue systems can positively help to advance other areas as well. In therapy domain, these systems can assist in various psychological treatments such as by increasing the willingness to disclose (Lucas et al., 2014). In pedagogy, they can help to make social skills training more accessible (Johnson et al., 2019).

While we think about these applications, it is crucial to also lay out proper ethical guidelines to avoid any misuse of these systems. Primary concerns are around the use of deception (e.g. in Diplomacy and other negotiation tasks), emotional appeals (e.g. in persuasion), and behavior change (e.g. in conversational recommendations).

To mitigate possible misuse scenarios or unintended harms, we now lay out a few ethical guidelines which also apply to dialogue research in general. First, rigorous attempts must be made to ensure that the data collection, design processes, and evaluations, strictly abide by the guidelines and regulations laid out by the relevant Institutional Review Board (IRB). Second, the research team needs to develop a thorough plan to monitor and understand the behaviors of the developed systems before deployment. This includes identifying the goals of the dialogue system, identifying potential toxic language use, and any discriminatory behaviors. Third, investment into improved data collection practices, along with explainable and controllable dialogue systems can help identify these issues early on and allow manipulation to avoid them. Fourth, we argue that transparency is the key.

All stakeholders must be made aware of the goals and design objectives of the system, along with any known misbehaviors or potential risks. The users must also be informed of any data collected during the deployment phase. Lastly, we believe that continuous monitoring of dialogue systems is necessary to ensure that the system performs consistently and does not diverge to unexpected conditions that may incur offensive or discriminative actions. We hope that our work promotes a more systematic study of social influence dialogue systems, which in turn will help to tackle the ethical concerns in a more principled way.

8 Limitations

Literature Search: We presented a survey of efforts in social influence dialogue systems. Although every attempt was made to provide the readers with a comprehensive overview of the research in this space, our work does not claim exhaustiveness in the covered literature and it is likely that we missed out on other relevant research in this space. **Intention for influence**: The datasets and tasks covered in this literature review focus on scenarios where social influence is *intentional by design*. However, social influence can also be *unintentional*, that is, interactions between humans and machines can have unintended influence on the attitudes, behaviors, or feelings of the human user (Gass, 2015). For instance, changes in topic preferences after interacting with a system on a variety of topics, or incorporating biases after interacting with a biased system. As we continue to make an unprecedented progress towards AI systems that interact with humans via natural means of communication, we must also take into account the unintended influence on the users of the underlying technology. We hope that our work motivates researchers to study these effects methodically in the future.

Acknowledgments

We would like to thank our colleagues at the University of Southern California, Columbia University, and the University of California Davis, along with fellow researchers with whom we interacted at conferences, for all their comments and helpful discussions that have shaped this project. We also thank the anonymous reviewers for their valuable time and feedback. Our research was, in part, sponsored by the Army Research Office and was accomplished under Cooperative Agreement Number W911NF-20-2-0053. A Literature Compilation

In this section, we provide details about how the literature was curated for our survey. We hope this helps the overall reproducibility and also guides similar studies in the future. We followed a simple two-stage process. First, we compiled the relevant datasets that capture various forms of social influence across diverse domains (presented in Section 3) and then, we compiled the techniques developed on these datasets (presented in Section 4).

Step I - Datasets: Our objective was to gather datasets that (by design) capture forms of social influence. We primarily focused on dialogue interactions but include the datasets based on transcripts from multimodal interactions as well. Given the large breadth of research in this space across a number of domains, our collection is not exhaustive but is rather restricted to the following sources.

We surveyed the past 6 years of *ACL conference proceedings. We then covered several online repositories of dialogue data to capture datasets published at other venues. This includes ParlAI[1], Huggingface[2], NLP-Progress[3], and Convokit[4]. Further, we revisited several recent surveys in dialogue systems and Natural Language Generation (NLG) research (Huang et al., 2020; Zhang et al., 2020c; Ni et al., 2021; Duerr and Gloor, 2021). Datasets that were categorized as task-oriented or open-domain in these surveys but also contain some aspects of social influence have been included in our discussion. As discussed in Section 4, we also include the datasets that have not been directly used for designing dialogue systems but rather for various Natural Language Understanding (NLU) subtasks that can be crucial for the eventual development of dialogue systems in this space. Finally, we also reviewed the citation graphs of the collected papers from Google Scholar. Overall, we ended up with 22 dataset papers, spanning 12 publication venues, 4 languages, and 7 application domains.

Step II - Methods: Compiling the methodological progress was based on the models developed on the curated datasets. For this purpose, we simply reviewed the citations of all the dataset papers using Google Scholar.

B Datasets

A comprehensive list of the available datasets for investigating social influence in dialogues is provided in Table 3. For each dataset, we mention the application domain, source, key statistics, as well as the available metadata and annotations apart from the conversation logs.

C Five Stages for Designing Social Influence Dialogue Systems

We develop a five-stage framework to summarize our recommendations for future work. These stages cover key decisions in the design of a dialogue system in this space, encouraging a holistic understanding of the system characteristics, target audience, underlying modeling techniques, and evaluation mechanisms. These steps are inspired by a behavior change model in healthcare research (Zhang et al., 2020a). We adapt this model to make it suitable for general social influence tasks in NLP. We present these steps in Figure 2.

Abstract

Although several datasets annotated for anaphoric reference / coreference exist, even the largest such datasets have limitations in terms of size, range of domains, coverage of anaphoric phenomena, and size of documents included. Yet, the approaches proposed to scale up anaphoric annotation haven't so far resulted in datasets overcoming these limitations. In this paper, we introduce a new release of a corpus for anaphoric reference labelled via a game-with-a-purpose. This new release[1] is comparable in size to the largest existing corpora for anaphoric reference due in part to substantial activity by the players, in part thanks to the use of a new resolve-and-aggregate paradigm to 'complete' markable annotations through the combination of an anaphoric resolver and an aggregation method for anaphoric reference. The proposed method could be adopted to greatly speed up annotation time in other projects involving games-with-a-purpose. In addition, the corpus covers genres for which no comparable size datasets exist (Fiction and Wikipedia); it covers singletons and non-referring expressions; and it includes a substantial number of long documents ($> 2K$ in length).

1 Introduction

Many resources annotated for anaphoric reference / coreference exist; but even the largest such datasets, such as ONTONOTES (Pradhan et al., 2012), have limitations. The largest resources are still medium scale (e.g., ONTONOTES (Pradhan et al., 2012) is 1.5M tokens, as is CRAFT (Cohen et al., 2017)). They only cover a limited range of domains, primarily news (as in ONTONOTES) and scientific articles (as in CRAFT), and models trained on these datasets have been shown not to generalize well to other domains (Xia and Durme, 2021).[2] The range of anaphoric phenomena covered is also narrow (Poesio et al., 2016).

Several proposals have been made to scale up anaphoric annotation in terms of size, range of domains, and phenomena covered proposed, including automatic data augmentation (Emami et al., 2019; Gessler et al., 2020; Aloraini and Poesio, 2021), and crowdsourcing combined with active learning (Laws et al., 2012; Li et al., 2020; Yuan et al., 2022) or through Games-With-A-Purpose (Chamberlain et al., 2008; Hladká et al., 2009; Bos et al., 2017; Kicikoglu et al., 2019). However, the largest existing anaphoric corpora created using Games-With-A-Purpose (e.g., (Poesio et al., 2019)) are still smaller than the largest resources created with traditional methods, and the corpora created using data augmentation techniques are focused on specific aspects of anaphoric reference. In order to use such approaches to create resources of the required scale in terms of size, variety and range of phenomena covered novel methods are required.

The first contribution of this paper is the *Phrase Detectives* 3.0 corpus of anaphoric reference annotated using a Game-With-A-Purpose. This corpus has a comparable size in tokens (1.37M) to the ONTONOTES corpus (Pradhan et al., 2012), but twice the number of markables[3]. Its annotation scheme also covers singletons and non-referring expressions; it is focused on two genres - fiction and Wikipedia articles - not covered in ONTONOTES, and for which only much smaller datasets exist; and it includes a range of documents ranging from short to fairly long ($14K$ tokens) enabling research in NLP on long documents (Beltagy et al., 2020). While ONTONOTES will remain a fundamental resource for the field in terms of size and languages it covers, we therefore hope that *Phrase Detec-*

[1] The corpus is available at `https://github.com/dali-ambiguity/Phrase-Detectives-Corpus-3.0`

[2] The largest existing corpus for English, the 10M words PRECO (Chen et al., 2018), consists of language learning texts, but the models trained on this genre have proven to have even worse performance on other domains.

[3] The number of non-singleton markables is similar to that of ONTONOTES

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 767–781
May 2-6, 2023 ©2023 Association for Computational Linguistics

tives 3.0 will complement ONTONOTES, providing a comparable amount of data in genres so far less covered, while at the same time covering aspects of anaphoric interpretation not covered there, such as singletons and non-referring expressions.

The second contribution of the paper is a new iterative resolve-and-aggregate approach developed to 'complete' the corpus by combining crowdsourcing with automatic annotation. Only about 70% of documents in the corpus were completely annotated by the players. The proposed method (i) uses an anaphoric resolver to automatically annotate all mentions, including the few still unannotated; (ii) aggregates the resulting judgments using a probabilistic aggregation method for anaphora, and (iii) uses the resulting expanded dataset to retrain the anaphoric resolver. We show that the resolve-and-aggregate method results in models with higher accuracy than models trained using only the completely annotated data, or the full corpus not completed using the method.

2 Background

Anaphorically annotated corpora A number of anaphorically annotated datasets now exist, covering a number of languages (Hinrichs et al., 2005; Hendrickx et al., 2008; Recasens and Martí, 2010; Pradhan et al., 2012; Landragin, 2016; Nedoluzhko et al., 2016; Cohen et al., 2017; Chen et al., 2018; Bamman et al., 2020; Uryupina et al., 2020; Zeldes, 2020) and turning anaphora / coreference into a very active area of research (Pradhan et al., 2012; Fernandes et al., 2014; Wiseman et al., 2015; Lee et al., 2017, 2018; Yu et al., 2020; Joshi et al., 2020). However, only a few of these are genuinely large in terms of markables (Pradhan et al., 2012; Cohen et al., 2017), and most are focused on news. Corpora of comparable size exist for scientific articles (e.g., CRAFT (Cohen et al., 2017)), and substantially smaller ones for fiction (e.g., LitBank (Bamman et al., 2020) and *Phrase Detectives* 2 (Poesio et al., 2019)), and Wikipedia (e.g., WikiCoref (Ghaddar and Langlais, 2016) or again *Phrase Detectives* 2 (Poesio et al., 2019)). But important genres such as dialogue are barely covered (Muzerelle et al., 2014; Yu et al., 2022a). There is evidence that this concentration on a single genre, and on ONTONOTES in particular, results in models that do not generalize well (Xia and Durme, 2021).

Existing resources are also limited in terms of coverage. Most recent datasets are based on general purpose annotation schemes with a clear linguistic foundation, but especially the largest ones focus on the simplest cases of anaphora / coreference (e.g., singletons and non-referring expressions are not annotated in ONTONOTES). And the documents included in existing corpora tend to be short, with the exception of CRAFT: e.g., average document length is 329 in PRECO, 467 in ONTONOTES, 630 in ARRAU, and 753 in *Phrase Detectives*.

Scaling up anaphoric annotation One approach to scale up anaphoric reference annotation is using fully automatic methods to either annotate a dataset, such as AMALGUM (Gessler et al., 2020), or create a benchmark from scratch, such as KNOWREF (Emami et al., 2019). While entirely automatic annotation may result in datasets of arbitrarily large size, such annotations cannot expand current models' coverage to aspects of anaphoric reference they do not already handle well. And creating from scratch large-scale benchmarks for specific issues hasn't so far been shown to result in datasets reflecting the variety and richness of real texts.

Crowdsourcing has emerged as the dominant paradigm for annotation in NLP (Snow et al., 2008; Poesio et al., 2017) because of its reduced costs and increased speed in comparison with traditional annotation. But the costs for really large-scale annotation are still prohibitive even for crowdsourcing (Poesio et al., 2013, 2017). To address this issue, a number of approaches have been developed to optimize the use of crowdsourcing for coreference annotation. In particular, active learning has been used to reduce the amount of annotation work needed (Laws et al., 2012; Li et al., 2020; Yuan et al., 2022). Another issue is that anaphoric reference is a complex type of annotation whose most complex aspects require special quality control typically not available with microtask crowdsourcing.

Games-With-A-Purpose A form of crowdsourcing which has been widely used to address the issues of cost and quality is Games-With-A-Purpose (GWAP) (von Ahn, 2006; Cooper et al., 2010; Lafourcade et al., 2015). Games-With-A-Purpose is the version of crowdsourcing where labelling is created through a game, so that the reward for the workers is in terms of enjoyment rather than financial. They were proposed as a solution for large-scale data labelling. A number of GWAPs were therefore developed for NLP, including *Jeux de Mots* (Lafourcade, 2007; Joubert et al., 2018), *Phrase Detectives* (Chamberlain et al., 2008; Poesio et al., 2013), *OntoGalaxy* (Krause et al., 2010), the *Wordrobe* platform (Basile et al., 2012), *Dr Detective* (Dumitrache et al., 2013), *Zombilingo* (Fort et al., 2014), *TileAttack!* (Madge et al., 2017), *Wormingo* (Kicikoglu et al., 2019), *Name That Language!* (Cieri et al., 2021) or *High School Superhero* (Bonetti and Tonelli, 2021). GWAPs for coreference include *Phrase Detectives* (Chamberlain et al., 2008; Poesio et al., 2013), the *Pointers* game in *WordRobe* (Bos et al., 2017) and *Wormingo* (Kicikoglu et al., 2019), all deployed, and *PlayCoref* (Hladká et al., 2009), proposed but not tested.

However, whereas truly successful GWAPs such as FOLDIT have been developed in other areas of science (Cooper et al., 2010), even the most successful GWAPs for NLP only collected moderate amounts of data (Poesio et al., 2019; Joubert et al., 2018). In part, this is because the games used to actually collect NLP labels aren't very entertaining, leading to efforts to develop engaging designs such as (Jurgens and Navigli, 2014; Dziedzic and Włodarczyk, 2017; Madge et al., 2019).

An interesting solution to this issue was proposed although not fully developed for *Wordrobe* (Bos et al., 2017). This solution is a hybrid between automatic annotation and crowdsourcing: a combination of crowd and automatically computed judgments is aggregated to ensure that every item has at least one label. This solution wasn't properly tested in *Wordrobe*, which only collected very few judgments and for a small corpus; and anyway the approach followed could not be applied to anaphora/coreference, due to the lack of a suitable aggregation mechanism for anaphora/coreference. In this paper we present the first true test of the idea by proposing a method for aggregating crowd and automatic judgments inspired by this idea, but using an aggregation method for anaphora, and truly tested on a dataset containing a very large number of anaphoric judgments.

3 Phrase Detectives

The human judgments used in our corpus were collected using the *Phrase Detectives* Game-With-A-Purpose[4] (Chamberlain et al., 2008; Poesio et al., 2013; Chamberlain, 2016; Poesio et al., 2019), designed to collect multiple judgments about anaphoric reference.

Game design *Phrase Detectives* doesn't follow the design of some of the original von Ahn games (von Ahn and Dabbish, 2008), in that it is a one-person game, and not timed; both competition and timing were found to have orthogonal effects on the quality of the annotation (Chamberlain, 2016). Points are used as the main incentive, with weekly and monthly boards being displayed.

Players play two different games: one aiming at labelling new data, the other at validating judgments expressed by the other players. In the annotation game, *Name the Culprit*, the player provides an anaphoric judgment about a highlighted markable (the possible judgments according to the annotation scheme are discussed next). If different participants enter different interpretations for a markable then each interpretation is presented to other participants in the validation game, *Detectives Conference*, in which the participants have to agree or disagree with the interpretation.

Every item is annotated by at least 8 players (20 on average), and each distinct interpretation is validated by at least four players. Players get points for each label they produce, but especially when their interpretation is agreed upon by other players, thus rewarding accuracy. Initially, players play against gold data, and are periodically evaluated against the gold; when they achieve a sufficient level of accuracy, they start seeing incompletely annotated data. Extensive analyses of the data suggest that although there is a great number of noisy judgments, this simple training and validation method delivers extremely accurate aggregated labels (Poesio et al., 2013; Chamberlain, 2016; Poesio et al., 2019).

Annotation Scheme The annotation scheme used in *Phrase Detectives* is a simplified version of the ARRAU annotation scheme (Uryupina et al., 2020), covering all the main aspects of anaphoric annotation, including the distinction between referring and non-referring expressions (all noun phrases are annotated as either referring or non-referring, with two types of non-referring expressions being annotated: expletives and predicative NPs); the distinction between discourse-new and discourse-old referring expressions (Prince, 1992); and the annotation of all types of identity reference (including split antecedent plural anaphora). Only the most complex types of anaphoric reference (bridging references and discourse deixis) are not annotated. The main differences between the annotation scheme used in *Phrase Detectives* and

Table 2: Summary of the current release. In parentheses the number of markables that are non-singletons.

those used in ARRAU, ONTONOTES, and PRECO are summarized in Table 1, modelled on a similar table in (Chen et al., 2018). In the *Phrase Detectives* corpus predication and coreference are clearly distinguished, as in ONTONOTES and ARRAU but unlike in PRECO. Singletons are considered markables. Expletives and split antecedent plurals are marked, unlike in either ONTONOTES or PRECO.

Possibly the most distinctive feature of the annotation scheme is that disagreements among annotators are preserved, encoding a form of implicit ambiguity as opposed to the explicit ambiguity annotated in ARRAU. The DEV and TEST subsets of the corpus (see next Section) have been annotated according to the full ARRAU scheme.

Preliminary player statistics At the time of writing (11th October, 2022), 61,391 players have registered on *Phrase Detectives*, of which more than 4,000 demonstrated sufficient linguistic understanding that they allowed to provide judgments on partially labelled data. So far, the players provided about 3.7M annotations and 1.7M validations, for a total of over 5.4M judgments.

Speed of annotation Over the course of the project, the games has been collecting an average of 385,000 judgments a year, i.e., slightly over 1,000 judgments per day, every day. While this is an impressive number of judgments, it only translates in an average of around 10,000 new completely annotated markables per year, or 20 new completely annotated documents, for an average of 30,000 extra words. (Progress was faster in the early years of the project, when all short documents were annotated; but as discussed in the next Section, the corpus also contains a number of fairly long texts – these are the ones still being annotated.) The project discussed in this paper was motivated by the simple calculation that at this speed, it would take us 40 years to completely annotate all the documents already in the corpus, and 300 years to completely annotated a corpus of 10M words.

4 Characteristics of the corpus

The *Phrase Detectives* 3.0 corpus includes all the 805 documents originally uploaded in the game. In this Section we highlight the main characteristics of the texts in this release, summarized in Table 2. For comparison, we include in the Appendix a short description of the previous release of the *Phrase Detectives* corpus, *Phrase Detectives* 2, released in 2019 (Poesio et al., 2019).

The new release The new release of the corpus, *Phrase Detectives* 3.0, is more than three times larger than the previous release of the *Phrase De-*

tectives corpus described in the previous section in terms of the number of tokens (1.4M) and markables (383K). (See 'All' row in Table 2.) This makes the *Phrase Detectives* 3.0 corpus comparable in the number of tokens to ONTONOTES, but double the size of ONTONOTES in terms of markables, partly due to the singletons and non-referring expressions being included. 72% of the documents were completely annotated by the players (580 out of 805 documents), and the near totality of mentions have at least one crowd annotation (99.4%).

Genres The corpus covers mainly two genres. The Gutenberg domain consists of fiction texts from the Gutenberg Project: in part children fiction (e.g., *Alice in Wonderland*, Grimm brothers stories), in part classics (e.g., Sherlock Holmes stories). At 400K tokens, it is twice the size of the largest existing fiction corpus (Bamman et al., 2020). The Wikipedia domain consists of primarily the 'Wikipedia Unusual' documents. This subset is 1M tokens in size, substantially larger than WikiCoref (60K tokens) (Ghaddar and Langlais, 2016).

Organization The corpus is split into train, development, and test subsets, where the development and test sets are annotated by human experts (see below) and the training set is aggregated using the MPA anaphoric annotation model (Paun et al., 2018b) as described in Section 5. But crucially, two versions of the training set exists.

TRAIN COMPLETE is like the training sets released in previous versions of the corpus, in that it consists of documents that were completely annotated by the players: i.e., all markables in the documents have more than 8 judgments, and all interpretations have more than 4 validations.

The second training set, TRAIN FULL, additionally includes documents that have not yet been 'completely' annotated by the players. These documents are considerably longer, and as a result it is harder to have them completely annotated. So a state-of-the-art coreference model for this annotation scheme (Yu et al., 2020) was used in the resolve-and-aggregate setting discussed in Section 5 to augment the existing annotations by ensuring that every markable had at least one label, which would then be aggregated with the others. TRAIN FULL is three times larger than TRAIN COMPLETE, both in the number of tokens and of markables.

A New Gold The test set from the previous release of the corpus, consisting of 45 documents, is now available as DEV. DEV was fully revised by human experts for this release to correct previous labelling mistakes, and has now been annotated according to the full ARRAU guidelines, including ambiguity annotation, bridging references, and discourse deixis. In addition, a brand new TEST set of 20 documents was also created, balanced between the two domains, double in size compared to the old test set, and also annotated according to the full ARRAU guidelines by the annotators that have been preparing the ARRAU 3 release.

Domain specific training With the new release, the corpus is now large enough to be used separately for domain-specific research. We demonstrate in Section 6 that models trained on the domain-specific portion of the training set achieve comparable results to those trained on TRAIN FULL. The results indicate that the domain-specific training data can be sufficient to be used separately for dedicated research in target domains.

Long and short documents An important characteristic of the corpus is that it was designed to contain both short documents (< 2K tokens) and long ones. 34.5% of the documents are longer than 2K tokens, and the longest document reaches 14K tokens. (In contrast, in ONTONOTES only 0.4% of the documents have more than 2K tokens.) This makes our corpus a suitable resource for research on long-distance anaphora and on long document training. To this end, we use our dataset to replicate the experiments by Beltagy et al. (2020) comparing the LONGFORMER model with the ROBERTA model. In the original paper, which used the ONTONOTES corpus, no obvious differences were found between the two models, partly due to the lack of long documents. We discuss these experiments in Section 6.5. The only other corpus that we are aware of with a large portion of long documents is the CRAFT corpus (Cohen et al., 2017), which is however focused on biomedical texts.

5 Resolve-and-Aggregate

The challenge To create a reliable corpus using crowdsourcing, multiple judgments are required to ensure a good coverage of correct answers, together with sufficient evidence to enable an accurate aggregation method (Paun et al., 2018a, 2022) to distill the correct answers from the noisy ones. The problem of collecting such large number of judgments is even more serious for long documents. Annotating all anaphoric relations in long documents is challenging, partly due to the amount of time needed to complete the task, but also because the great number of entities makes it difficult for annotators to keep track of all the coreference chains. And indeed, the short documents in our corpus were completed much faster than the longer documents: the average length of the incomplete documents is 4K tokens, whereas for the complete documents is 850 tokens. Thus in our corpus the rate at which judgments are collected from players, while substantial (over 1,000 judgments per day) is not sufficient to extract reliable labels in a reasonable amount of time, as discussed in Section 3.

Possible solutions Clearly, part of the solution is to develop more engaging games, thus able to attract more players and keep them playing for longer (von Ahn and Dabbish, 2008; Jurgens and Navigli, 2014; Madge et al., 2019; Kicikoglu et al., 2019). A second ingredient is to use active learning-like approaches to minimize the number of labels required to complete the annotation (Laws et al., 2012; Li et al., 2020; Yuan et al., 2022). A number of proposals have been made in these two directions, and we are carrying out research in these areas as well (Madge et al., 2022). In this work however we investigate an approach that to our knowledge has been much less studied: combining crowdsourcing with automatic labelling. Specifically, we propose a new resolve-and-aggregate method that iteratively makes use of a coreference resolver to enhance the collected annotations. The approach is inspired, apart from *Wordrobe* (Bos et al., 2017), by previous work on Bayesian combination of classifiers (Kim and Ghahramani, 2012) which allows for aggregating predictions from classifiers and humans together with the help of a probabilistic annotation model. Both the iterative use of the coreference resolver and the application domain of the annotation model are however novel to this paper.

The coreference resolver As a coreference resolver, we use the system by Yu et al. (2020) which, to the best of our knowledge, is the only modern coreference resolver that also predicts singletons and non-referring expressions, both of which need to be annotated in our corpus. The system is an extension of (Lee et al., 2017, 2018), replacing their mention-ranking algorithm with a cluster-ranking algorithm to build the entity clusters incrementally. The system uses BERT (Devlin et al., 2019) for pretrained contextual embeddings instead of the Elmo embeddings (Peters et al., 2018) used in (Lee et al., 2018).

Aggregation Standard aggregation methods for classification labels such as the (Dawid and Skene, 1979) model are not appropriate for coreference labels, whose class space is not fixed but depends on the document mentions. However, an aggregation model for coreference judgments is now available, the mention-pair annotation model (MPA) (Paun et al., 2018b). We used MPA to aggregate judgments by players and by the coreference resolver. MPA can capture the accuracy and bias of the players, and of the coreference resolver, respectively, and adjust the aggregated labels accordingly.

Resolve-and-aggregate resolve-and-aggregate is an iterative procedure which relies on the MPA aggregation model to label the corpus, which is in turn used to retrain the coreference resolver to get better system predictions. More specifically, in the first step of the procedure we aggregate the players' annotations from the complete documents and build an initial training set, TRAIN COMPLETE. Then, we train the coreference resolver on this set, but in a gold mention setting to mimic the players who focus only on the resolution task. Having trained the system, we then use it to get predictions for the entire dataset. The resolver can be seen as a player who played all the documents in the corpus. Next, all the players' annotations and the system's predictions are aggregated using MPA, and an initial version of the entire corpus, TRAIN FULL, is built as a result. This procedure is repeated, taking TRAIN FULL as input and creating a new version every time. With each new version, the MPA-aggregated labels get refined, leading in turn to better predictions from the coreference resolver. The procedure is repeated until the performance of the resolver plateaus. The final version of the corpus contains the MPA-aggregated labels of the players' annotations and the system's best predictions. We show in the next Section that this approach results in substantial improvements in the quality of the labels produced by the coreference resolver, which translate to more accurate labels for the items not fully annotated by the players.

6 Resolving-and-Aggregating results

Experiment Setting For our experiments, we report the CoNLL F1 scores as defined in (Pradhan

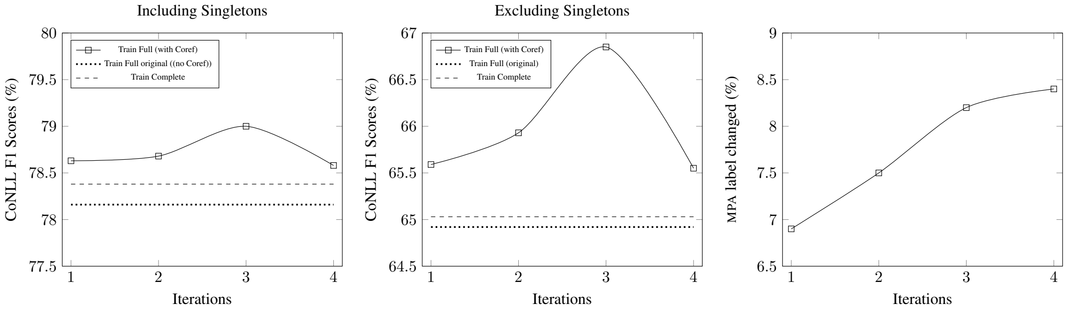

Figure 1: Left and Middle: The CoNLL scores for Yu et al. (2020) trained on different training sets and tested on the Dev set in gold mention setting. Right: The percentage of MPA labels changed by using the additional judgments from the Yu et al. (2020) system in different iterations.

et al., 2012) in both singleton included and excluded settings, as well as non-referring F1 scores for non-referring expressions. We use the Universal Anaphora (UA) Scorer (Yu et al., 2022b) that reports all the necessary scores.

We trained the Yu et al. (2020) system using most of its default settings. The only exception is that we always use the full context of the documents for training instead of choosing a random 1K tokens as done in Yu et al. (2020). The default setting gives priority to the short documents as for each epoch, the full context of the short documents is always used, whereas for long documents only part of the documents is used.

We establish three baselines, all using the same system Yu et al. (2020) with the same settings, but trained with different training sets. The first baseline is trained on the Previous release. The second baseline is trained on Train Complete (complete documents aggregated by MPA without resolve-and-aggregate). The third baseline is trained on Train Full aggregated by MPA but without annotations from the coreference resolver.

6.1 Parameter Tuning

We first trained the system using the gold mention settings to improve the quality of the corpus. We used the baseline trained on Train Complete to annotate the full corpus, then assigned labels to all the mentions by aggregating player and system annotations using MPA. We then trained a new model by using the full corpus (Train Full (with Coref)) and doing resolve-and-aggregate between the system and MPA in iterations until the system performance stopped improving.

	CoNLL Avg. F1		
Train data	Sing. (inc)	Sing. (exc)	NR F1
Previous release	65.5	53.6	36.8
Train Complete	66.1	54.7	39.4
Train Full(original)	64.9	52.9	35.5
Train Full(with Coref)	**66.8**	**56.1**	**40.1**
Joshi et al. (2020)	-	60.2	-

Table 3: The CoNLL and non-referring scores for (Yu et al., 2020) trained on different training sets and tested on the Test set in predicted mention setting.

The first key result is that, the system trained with Train Full (with Coref) always beats the baseline trained on the Train Complete (see Figure 1). The improvements on the singletons excluded setting are larger than those in the singletons included setting; this makes sense as all the models use gold mentions, hence the performance with singletons is inflated by the gold mentions. The system achieved the best performance on the third iteration with CoNLL F1 scores of 79% and 66.9% for singletons included and excluded settings respectively. This is 0.6% and 1.9% higher than the Train Complete baseline.

What is especially interesting is that the improvement is not just a matter of Train Full being larger than Train Complete: running the coreference resolver helps substantially. The system trained on Train Full original (i.e., without any automatic labels) is slightly worse than the Train Complete baseline, despite using the additional training data. One explanation would be that MPA's performance is affected by the lower number of judgments collected in the incomplete documents: the correct answer might not appear in the players' annotations, or the players producing the annotations might not be considered sufficiently reliable.

To quantify the contribution of the automatic coreference resolver, we calculate the percentage of MPA labels flipped due to the additional system annotations. We compare the labels of the Train

FULL (with Coref) in different iterations with the TRAIN FULL (original) labels. We find that in the first iteration, 7% of the MPA labels (26K) were changed (see Figure 1). The percentages increased sharply until iteration 3 to 8.2% (31K) but slowed down for iteration 4. This might explain why performance starts dropping in the 4th iteration.

MPA works very well when the number of judgments is high, but performance might be affected when there are not enough annotations, e.g. for the incomplete documents. We suspected MPA might benefit more from system annotations when the document is incomplete. To assess our hypothesis, we took a closer look at MPA labels from our best iteration. We split the documents into two classes, complete and incomplete, according to our complete criterion (i.e., a document is considered complete when every markable has been annotated by at least 8 players, and each distinct interpretation has been validated by at least 4 players) and calculate a separate score for each class. We find that for the complete document only 3.3% of the MPA labels are changed as a result of the additional system annotations; in contrast, 10.8% of MPA labels are changed in the incomplete documents.

To assess the quality of these label changes, we checked the different MPA labels between iteration 3 and the original on the DEV set. Since all documents from the DEV set are complete documents, out of 7K mentions, only 201 have a different label. The TRAIN FULL (original) gets 70 of the labels correct with an accuracy of 34.8%, whereas after the 3rd iteration of resolve-and-aggregate, the number increased to 125 (62.2% accuracy). Although the sample is not large, it still gives a clear picture that even for complete documents the system annotations can improve the quality of the corpus.

6.2 Evaluation on the Test set

After finding the best setting as discussed in the previous Section, we evaluated the impact of resolve-and-aggregate on the TEST set in the more realistic predicted mention setting. As shown in Table 3, our best model trained on the TRAIN FULL aggregated by MPA with additional coreference annotation by the Yu et al. (2020) system (TRAIN FULL(with Coref)) beats all the baselines in both singletons included and excluded settings. Of the baselines trained on the complete documents only, the TRAIN COMPLETE baseline works better than the PREVIOUS RELEASE baseline, most likely because the training set is larger while the quality of the annotation remains the same. But again, when training with the additional incomplete documents (TRAIN FULL (original without Coref)), the performance dropped substantially by 1%-2% when compared with the TRAIN COMPLETE baseline. This highlights again the importance of combining automatic and crowd annotations via resolve-and-aggregate: the model trained on this corpus pushes up the TRAIN FULL (original) baseline by up to 3.2%. The story is the same for the models' performance on non-referring expressions (Table 3): again, the model trained on TRAIN FULL (with Coref) is top of the list.

Finally, we report the result by the Joshi et al. (2020) system on our corpus to give insight into the complexity of our corpus when compared with ONTONOTES. The system was trained on the same TRAIN FULL (with Coref) corpus. Since the Joshi et al. (2020) system only output the non-singleton clusters, we report only the CoNLL F1 score in a singleton excluded setting. As expected the system has a better CoNLL F1 score when compared with our baselines, since SpanBERT has been shown to be more effective than BERT on coreference. The Joshi et al. (2020) result on our corpus is, however, 20% lower than on ONTONOTES (79.6%), which indicates that our corpus is more complex than ONTONOTES. We hypothesize this is partially due to the longer documents and more diverse domains included in our release.

6.3 Annotation speed-up

The results in the previous Sections show that using automatic annotations turns the incomplete documents into documents whose quality is enough to result in improved performance when training a coreference resolver, speeding up annotation. In this section, we try to estimate the amount of time potentially saved by the proposed method. For the complete documents, we have on average 20 judgements (annotations and validations) per markable, which seems sufficient to ensure the quality of the corpus, if not perhaps necessary. For incomplete documents, the average number of judgements is currently 7.7. If we do need 20 judgements to achieve the same quality as the complete documents, we still need to collect on average 12.3 more judgements for every markable. Multiplied by the number of markables in the incomplete documents (250K), this means we would need 3M more judge-

Train data	CoNLL Avg. F1 Sing. (inc)	 Sing. (exc)	 NR F1
	Gutenberg		
DOMAIN ONLY	70.4	61.8	43.8
TRAIN FULL (with Coref)	**71.5**	**62.1**	**44.9**
	Wikipedia		
DOMAIN ONLY	61.9	**50.9**	**36.1**
TRAIN FULL (with Coref)	**62.3**	50.6	36.0

Table 4: The CoNLL and non-referring scores for the system trained on different training sets and tested on the TEST set of different domains using predicted mention.

Model	Short Doc	Long Doc	All Doc
LONGFORMER	**61.0**	**67.2**	**64.7**
ROBERTA	60.1	65.2	63.1

Table 5: The CoNLL scores (exclude singletons) for LONGFORMER and ROBERTA trained on TRAIN FULL and tested on the TEST set using gold mentions.

ments to complete all documents in the game. In the last five years, we have been averaging 334K judgements per year, which means if we proceed at the current speed, we need another 9 years before we can release this corpus. In other words, the resolve-and-aggregate method significantly speeds up the annotation process.

6.4 Domain-specific Training

Thanks to the resolve-and-aggregate method, this new release gives us datasets of a reasonable size for both the Gutenberg (fiction) and Wikipedia domains. We evaluated system performance on the domain-specific portion - e.g., for Fiction we trained our model on the Gutenberg section of TRAIN FULL (with Coref) and tested it on the Gutenberg section of the TEST. We then compared the performance of these domain-specific models with that of the best system trained on the entire corpus. As shown in Table 4, the DOMAIN ONLY systems trained on the domain-specific subsections of the corpus achieve scores close to the system trained on the full corpus. This suggests each domain-specific part of the corpus is sufficiently large to be used for domain-specific research.

6.5 Long and short documents

As stated earlier, one of the emerging challenges for research on anaphora (and NLP in general) are longer documents (>2K tokens). Our corpus is unusual in that it includes a large number of documents more than 2K in length, with the longest document containing 14K tokens. TEST also balances short (55%) and long (45%) documents.

To test that the corpus can support research on anaphora in long documents, we used it to replicate the comparison in (Beltagy et al., 2020) between their new model designed specifically for longer documents, the LONGFORMER, with ROBERTA (Liu et al., 2019). In that paper, the LONGFORMER is compared with ROBERTA on the ONTONOTES corpus, without however finding a clear difference between the two systems. We suspected this might be because ONTONOTES does not contain enough long documents to observe improvements. We replicated the experiments by Beltagy et al. with our corpus, and report the CoNLL F1 score on full TEST as well as separate scores for long/short documents. (Since neither system predicts singletons and non-referring expressions, we report the CoNLL F1 scores in the singleton excluded setting.) We evaluated the systems with the gold mentions so that the system's performance will not be affected by mention detection.

Table 5 shows the results for both systems on different test set. The LONGFORMER works better on all test sets, but with a much larger gain over ROBERTA on long documents: the improvement over ROBERTA is 0.9% and 2% on short and long documents respectively. This finding confirms that long documents benefit more from the LONGFORMER architecture, while also showing that our corpus can be used to differentiate systems designed to perform on long documents.

7 Conclusions

This research makes two main contributions. First of all, we proposed an iterative method for speeding up anaphoric annotation via GWAPs by combining crowdsourced data with labels produced by an automatic coreference resolver, and aggregating the labels using a probabilistic annotation method; and showed that the resulting extension leads to quantifiable improvements in model performance. The method can be easily extended to other types of annotation. Second, we introduced a new corpus for anaphoric reference which, thanks to the use of resolve-and-aggregate, is of a comparable size to ONTONOTES in terms of tokens, but twice the size in terms of markables; it contains two substantial datasets for genres not covered in ONTONOTES; and it includes both short and long documents.

8 Limitations

The main limitation of this work is that the new release is still only twice the size of ONTONOTES in terms of markables. In ongoing work, we are developing a new platform to label a corpus twenty times the size of the current release. The new platform[5] combines more engaging games with active-learning like methods for allocating work to players more efficiently and according to their linguistic understanding (Madge et al., 2022). We hope that the new platform, in combination with the methods proposed here, will allow us to label the new and larger dataset much more quickly.

A second limitation of the new release is that the markables in the corpus were automatically extracted; thus, the quality of the mentions is lower than in corpora in which they were hand-identified. The approach followed in these years has been to ask our players to signal issues; as a result, tens of thousands of markables were hand-corrected. However, this approach doesn't really lend itself to scaling up. Thus, in our new platforms we are following a different strategy: asking our players to do the corrections themselves, by including also games to check other levels of linguistic interpretation.

A third limitation, in particular in comparison with ONTONOTES, is that this release of the corpus only contains English documents, although a small amount of Italian documents was uploaded in the game.

Appendix

A The previous release of the corpus

Phrase Detectives 2 consisted of a total of 542 documents containing 408K tokens and 108K markables from two main genres: Wikipedia articles and fiction from the Gutenberg collection. This version of the corpus was divided in two subsets. The subset referred to to as $\text{PD}_{\text{silver}}$ consisted of 497 documents, for a total of 384K tokens and 101K markables, whose annotation was completed–i.e. 8 judgments per markable were collected, and 4 validations per interpretation–as of 12th of October 2018. In these documents, an aggregated ('silver') label obtained through MPA is also provided. 45 additional documents were also gold-annotated by two experts annotators. The subset of the corpus for which both gold and silver annotations are available was called PD_{gold}, as it is intended to be used as test set.[8] The gold subset consists of a total of 23K tokens and 6K markables. The contents of the *Phrase Detectives* 2 corpus are summarized in Table 6.

		Docs	Tokens	Markables
PD_{gold}	Gutenberg	5	7536	1947 (1392)
	Wikipedia	35	15287	3957 (1355)
	GNOME	5	989	274 (96)
	Subtotal	45	23812	6178 (2843)
$\text{PD}_{\text{silver}}$	Gutenberg	145	158739	41989 (26364)
	Wikipedia	350	218308	57678 (19444)

Abstract

The degree of semantic relatedness of two units of language has long been considered fundamental to understanding meaning. Additionally, automatically determining relatedness has many applications such as question answering and summarization. However, prior NLP work has largely focused on semantic similarity, a subset of relatedness, because of a lack of relatedness datasets. In this paper, we introduce a dataset for Semantic Textual Relatedness, *STR-2022*, that has 5,500 English sentence pairs manually annotated using a comparative annotation framework, resulting in fine-grained scores. We show that human intuition regarding relatedness of sentence pairs is highly reliable, with a repeat annotation correlation of 0.84. We use the dataset to explore questions on what makes sentences semantically related. We also show the utility of STR-2022 for evaluating automatic methods of sentence representation and for various downstream NLP tasks.

Our dataset, data statement, and annotation questionnaire can be found at: `https://doi.org/10.5281/zenodo.7599667`.

1 Introduction

The semantic relatedness of two units of language is the degree to which they are close in terms of their meaning (Mohammad, 2008; Mohammad and Hirst, 2012). The linguistic units can be words, phrases, sentences, etc. Though our intuition of semantic relatedness is dependent on many factors such as the context of assessment, age, and socio-economic status (Harispe et al., 2015), it is argued that a consensus can usually be reached for many pairs (Harispe et al., 2015). Consider the two sentence pairs in Table 1. Most speakers of English will agree that the sentences in the first pair are closer in meaning to one another than those in the second. When judging the semantic relatedness between two sentences, humans generally look for commonalities in meaning: whether they are on the same topic, express the same view, originate from the same time period, one elaborates on (or follows from) the other, etc.

Pair 1: a. *There was a lemon tree next to the house.*
b. *The boy enjoyed reading under the lemon tree.*

Pair 2: a. *There was a lemon tree next to the house.*
b. *The boy was an excellent football player.*

Table 1: Most people will agree that the sentences in pair 1 are more related than the sentences in pair 2.

The semantic relatedness of two units of language has long been considered fundamental to understanding meaning (Halliday and Hasan, 1976; Miller and Charles, 1991); given how difficult it has been to define meaning, a natural approach to get at the meaning of a unit is to determine how close it is to other units. Thus, unsurprisingly, automatically determining relatedness has many applications such as question answering, text generation, and summarization (more discussion in §7).

However, prior NLP work has focused on semantic similarity (a small subset of semantic relatedness), largely because of a dearth of datasets on relatedness. The few relatedness datasets that exist are only for word pairs (Rubenstein and Goodenough, 1965; Radinsky et al., 2011) or phrase pairs (Asaadi et al., 2019). Further, most existing datasets were annotated, one item at a time, using coarse rating labels such as integer values between 1 and 5 representing coarse degrees of closeness. It is well documented that such approaches suffer from inter- and intra-annotator inconsistency, scale region bias, and issues arising due to the fixed granularity (Presser and Schuman, 1996). Further, the notions of *related* and *unrelated* have fuzzy boundaries. Different people may have different intuitions of where such a boundary exists. Finally, for some tasks, it is more appropriate to train on a dataset of relatedness than similarity. (§2.1 discusses how relatedness and similarity are different.)

In this paper, we present the first manually annotated dataset of sentence–sentence semantic re-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 782–796
May 2-6, 2023 ©2023 Association for Computational Linguistics

latedness. It includes fine-grained scores of relatedness from 0 (least related) to 1 (most related) for 5,500 English sentence pairs. The sentences are taken from diverse sources and thus also have diverse sentence structures, varying amounts of lexical overlap, and varying formality.

The relatedness scores were obtained using a *comparative* annotation schema: two (or more) items are presented together and the annotator has to determine which is greater with respect to the metric of interest. Since annotators are making relative judgments, the limitations discussed earlier for rating scales are greatly mitigated. Importantly, such annotations do not rely on arbitrary boundaries between arbitrary categories such as "strongly related" and "somewhat related".

We use the relatedness dataset to explore:

1. To what extent do speakers of English intuitively agree on the relatedness of sentences? (§4)
2. What makes two sentences more related? (§5)
3. How well do existing approaches of sentence representation capture semantic relatedness (by placing related sentence pairs closer to each other in vector space)? (§6)
4. How can an improved annotation schema to capture relatedness benefit other NLP tasks? (§7)

We refer to our dataset as *STR-2022*, and the task of predicting relatedness between sentences as the *Semantic Textual Relatedness (STR)* task. Data, data statement, and annotation questionnaire are made available[1].

2 Related Work and Our Approach to Annotating for Semantic Relatedness

The three subsections below discuss key ideas from past work on annotating relatedness and similarity, existing datasets, and comparative annotation, respectively. Notably, each of these subsections also discusses how relevant past work has influenced our approach to data annotation.

2.1 Annotating Relatedness and Similarity

Semantic relatedness and semantic similarity are two ways to explore closeness of meaning. Two terms are considered semantically similar if there is a synonymy, hyponymy, or troponymy relation between them (examples include *doctor–physician* and *mammal–elephant*). Two terms are considered to be semantically related if there is any lexical semantic relation at all between them. Thus, all similar pairs are also related, but not all related pairs are similar. For example, *surgeon–scalpel* and *tree–shade* are related, but not similar.

Analogous to term pairs, two sentences are considered semantically similar when they have a paraphrasal or entailment relation. Determining such an equivalence of meaning is useful in NLP tasks such as text summarization and plagiarism detection. Semantic Relatedness, however, accounts for all of the commonalities that can exist between two sentences (Halliday and Hasan, 1976; Morris and Hirst, 1991). For example, the sentences in Table 1 Pair 1 are highly related, but they are not paraphrases or entailing. This expands the scope of the measure to include aspects such as the relatedness between their topics, their styles, etc.

However, because semantic relatedness involves innumerable classical and ad-hoc semantic relationships, it is markedly more complex than semantic similarity, and there are no widely agreed upon linguistic theories or guidelines for judging relatedness. This presents a challenge for gathering annotations; one can either: (i) construct their own codified instructions on how to judge semantic relatedness under various scenarios (e.g., overlapping sentence structure, relatedness of topic, etc.), at the risk of artificially over-simplifying the task or (ii) abstain from explicitly and comprehensively defining relatedness for numerous types of sentence pairs, relying instead on a simple description of relatedness, a few examples, and framing the task in relative terms.[2] In this work, we chose the latter. This allows us to: (i) determine the extent to which human intuition of relatedness is reliable and (ii) use the resulting dataset to empirically determine what makes sentences semantically related.

2.2 Existing Relatedness and Similarity Data

Existing datasets created for sentence pair similarity (e.g., STS (Agirre et al., 2012, 2013, 2014, 2015, 2016), MRPC (Dolan and Brockett, 2005), and LiSent (Li et al., 2006)) ask annotators to choose among coarse similarity labels. This leads to information loss and makes annotation difficult because distinctions between categories are often not clear; for example, the STS 2012–2016 questionnaires

---

[1] `doi.org/10.5281/zenodo.7599667` or `https://github.com/Priya22/semantic-textual-relatedness` or `https://huggingface.co/datasets/vkpriya/str-2022`

[2] Recall that for Table 1, we were able to judge relative relatedness without explicit instruction on how to judge relatedness.

ask annotators to make the distinction between *2: not equivalent but share some details* and *1: not equivalent, but are on the same topic*, which is often not straightforward. Further, despite claiming to determine semantic similarity, the descriptions of categories 1 and 2 incorporate aspects of semantic relatedness — an amalgamation muddying the waters with respect to the phenomenon being annotated. Such an amalgamation is also seen in the SICK (Marelli et al., 2014) dataset which combines a labeling scheme from STS with those about entailment and contradiction. These datasets have helped make progress in the field, but there is a need for relatedness datasets obtained strictly from relatedness judgments as opposed to a hybrid involving artificially created categories for similarity and entailment. For our annotations, we avoid fuzzy ill-defined categories, and rely instead on the intuitions of fluent English speakers to judge **relative rankings** of sentence pairs by relatedness.

2.3 Comparative Annotations

The simplest form of comparative annotations is paired comparisons (Thurstone, 1927; David, 1963). Annotators are presented with pairs of examples and asked to choose which item is greater with respect to the property of interest (relatedness, sentiment, etc.). The choices are then used to generate an ordinal ranking of items. Paired comparison avoids a number of biases, but it requires a large number of annotations (N^2, where $N =$ # items).

Best–Worst Scaling (BWS) is a comparative annotation schema that builds on pairwise comparisons and requires fewer labels (Louviere and Woodworth, 1991). Annotators are given n items at a time (for our work, $n = 4$ and an *item* is a pair of sentences). They are instructed to choose the best (i.e., most related) and worst (i.e., least related) item. Annotation for each 4-tuple provides us with five pairwise inequalities. For example if a is marked as most related and d as least related, then we know that $a > b, a > c, a > d, b > d$, and $c > d$. These inequalities can be used to calculate real-valued scores, and thus an ordinal ranking of items, using a simple counting mechanism (Orme, 2009; Flynn and Marley, 2014): the fraction of times an item was chosen as the best (most related) minus the fraction of times the item was chosen as the worst (least related). Given N items, reliable scores are obtainable from about $2N$ 4-tuples (Kiritchenko and Mohammad, 2016, 2017).

3 Creating STR-2022

Dataset creation included several steps: curating sentence pairs for annotation, designing the questionnaire, crowdsourcing annotations, and aggregating the annotations to obtain relatedness scores.

3.1 Data Sources

Like previous work on semantic similarity, we chose to construct our dataset by sampling sentences from many sources to capture a wide variety of text in terms of sentence structure, formality, and grammaticality. Pairs of sentences were created from the sampled sentences in a number of ways as described below. The sources are:

1. **Formality** (Rao and Tetreault, 2018): Pairs of sentences having the same meaning but differing in formality (one formal, one informal).
2. **Goodreads** (Wan and McAuley, 2018): Book reviews from the Goodreads website.
3. **ParaNMT** (Wieting and Gimpel, 2018): Paraphrases from a machine translation system.
4. **SNLI** (Bowman et al., 2015): Pairs of premises and hypotheses, created from image captions, for natural language inference.
5. **STS** (Cer et al., 2017): Pairs of sentences with semantic similarity scores. (Integer label responses, 0 to 5, from multiple annotators were averaged to obtain the similarity scores.)
6. **Stance** (Mohammad et al., 2016): Tweets labelled for both sentiment (*positive*, *negative*, *neutral*) and stance (*for*, *against*, *neither*) towards targets (e.g., *Donald Trump*, *Feminism*).
7. **Wikipedia** Text Simplification Dataset (Horn et al., 2014): Pairs of Wikipedia sentences and their simplified forms.

From each source, we sampled sentences that were between 5 and 25 words long. We selected sentence pairs with varying amounts of lexical overlap because randomly sampling sentence pairings would result in mostly unrelated sentences. This also allowed us to systematically study the impact of lexical overlap on semantic relatedness. For the paraphrase datasets (Formality, ParaNMT, and Wikipedia), we obtained sentence pairs in two ways: by directly taking the paraphrase pairs (indicated by the suffix *_pp*), and by randomly pairing sentences from two different paraphrase pairs (suffixed by *_r*). The paraphrase pairs were selected at random from the source dataset, whereas the lexical overlap strategy was applied in the creation of

Types of Pairs	Key Attributes	# pairs
1. Formality	paraphrases, style	
Formality_pp	paraphrases, differ in style	300
Formality_r	random pairs	700
2. Goodreads	reviews, informal	1000
3. ParaNMT	automatic paraphrases	
ParaNMT_pp	automatic paraphrases	450
ParaNMT_r	random pairs	300
4. SNLI	captions of images	750
5. STS	have similarity scores	250
6. Stance	tweet pairs with same hashtag, less grammatical	750
7. Wikipedia	formal	
Wiki_pp	paraphrases, formal	500
Wiki_r	random pairs, formal	500
ALL		5500

Table 2: Summary of sentence pair types in STR-2022.

the random pairs. From STS, we randomly sampled 50 sentence pairs having similarity scores in [0-1), 50 pairs having scores in [1-2), and so on.

Initially, we sought to annotate 1000 sentence pairs from each source. As our goal was to cover as large a range of relatedness, sentence structures, lengths and topics as possible, we lowered the amount of sentence pairs to obtain the desired variety. For example, SNLI pairs had little variation in sentence length and so we reduced the number of sampled instances; their semantic relatedness also tends to skew towards the higher range, and we aimed to balance this out with a larger number of random, non-paraphrasal pairs from other sources (Formality). Table 2 summarizes key details of the sentence pairs in STR-2022. Further details about the source data and sampling are in Appendix A.

3.2 Annotating For Semantic Relatedness

From the list of 5,500 sentence pairs, we generated 11,000 unique 4-tuples (each 4-tuple consists of 4 distinct sentence pairs) such that each sentence pair occurs in around eight 4-tuples.[3]

In our framing of the task, we did not use detailed or technical definitions; rather, we provided brief and easy-to-follow instructions, gave examples, and encouraged annotators to rely on their intuitions of the English language to judge relative closeness in meaning of sentence pairs (similar to Asadi et al.'s (2019) work on bigrams). Annotators were asked to judge the "*closeness in meaning of sentence pairs*". Inspired by early work in linguistics on cohesion in text (Halliday and Hasan, 1976), we also specified that: "*Often sentence pairs that are more specific in what they share tend to be more related than sentence pairs that are only loosely about the same topic*" and "*If a sentence has more than one interpretation, consider that meaning which is closest to the meaning of the other sentence in the pair.*" This is inline with application scenarios where often relatedness is to be determined between sentences from the same document. The full questionnaire is included in the supplementary material.

3.2.1 Crowdsourcing Annotations

We used Amazon Mechanical Turk (MTurk) for obtaining annotations.[4] Each 4-tuple (also referred to as a question) in our MTurk task consists of four sentence pairs. Annotators are asked to choose the (a) most-related, and (b) least-related sentence pairs from among these four options. Each question is annotated by two MTurk workers.[5]

For quality control, the task was open only to fluent speakers of English and those MTurk workers with an approval rate higher than 98%. Further, we inserted "Gold Standard" questions at regular intervals in the task. These questions were manually annotated by all the authors, and had high agreement scores. If an annotator gets a gold question wrong, they are immediately notified and shown the correct answer. This has several benefits, including: keeping the annotator alert and clearing any misunderstandings about the task. Those who scored less than ∼70% on the gold questions were stopped from answering further questions and were paid for their work. All their responses were discarded.

3.2.2 Annotation Aggregation

We aggregate information from various responses by using the counting procedure discussed in §2.3. Since relatedness is a unipolar scale, the resulting relatedness score was linearly transformed to fit within a 0–1 scale of increasing relatedness. Appendix Table 8 presents sample sentence pairs from each data source.

Figure 1 presents a histogram of relatedness scores for STR-2022. Observe that each of the subsets covers a wide range of relatedness scores; that the lexical overlap sampling strategy has resulted in a wide spread of relatedness scores; and that supposed paraphrases are spread across much of the right half of the relatedness scale.

---

[3] The tuples were generated using the BWS scripts provided by Kiritchenko and Mohammad (2017): `http://saifmohammad.com/WebPages/BestWorst.html`.

[4] This project was approved by the first author's Institutional Research Ethics Board (Protocol #: Masked for review).

[5] Pilot studies showed that this results in reliable scores.

# Sentence Pairs	# Tuples	# Annotations Per Tuple	# Annotations	# Annotators	SHR
5,500	11,000	8	21,936	389	0.84

Table 3: Annotation statistics of STR-2022. SHR = split-half reliability (as measured by Spearman correlation).

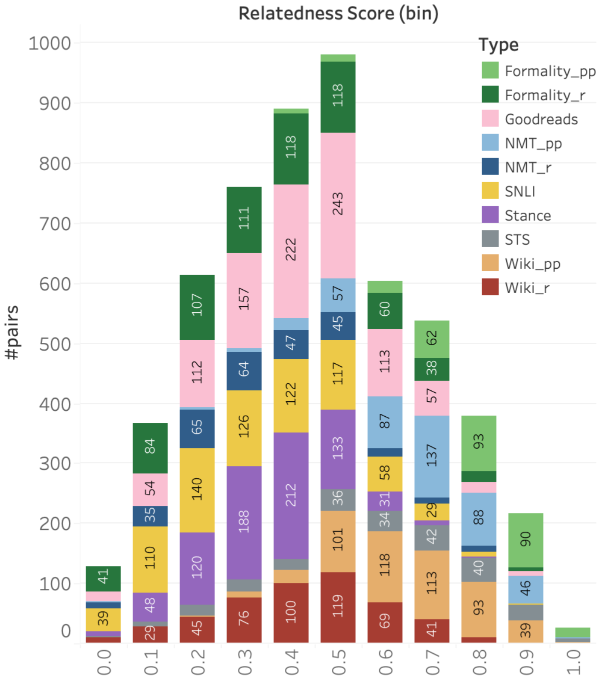

Figure 1: Histogram of STR-2022 relatedness scores.

4 Reliability of Annotations

For annotations producing real-valued scores, a commonly used measure of quality and reliability is *split-half reliability* (SHR) (Cronbach, 1951; Kuder and Richardson, 1937). SHR is a measure of the degree to which repeating the annotations would result in similar relative rankings of the items. To measure SHR, annotations for each 4-tuple are split into two bins. The annotations for each bin are used to produce two different independent relatedness scores. Next, the Spearman correlation between the two sets of scores is calculated—a measure of the closeness of the two rankings. If the annotations are reliable then there should be a high correlation. This process is repeated 1000 times and the correlation scores are averaged.

As shown in Table 3, STR-2022 has an SHR of 0.84—signifying high annotation reliability. This is a key result of this paper. Recall that our annotation guidelines did not hard code the various scenarios of sentence pair types and how they should be judged, but rather were designed to elicit how native speakers of English naturally judge relatedness. The high reliability of annotations, despite this, shows that speakers of a language are inherently consistent in their judgments of relatedness. It also validates our approach as a way to produce high-quality relatedness datasets; which, in turn, can be used to study the mechanisms underpinning relatedness (as we explore in the next Section).

4.1 STR vs STS

We also conducted experiments to assess fine-grained rankings of common sentence pairs as per our relatedness scores and as per STS's similarity scores. For each of the sets of 50 sentence pairs taken from STS (with scores in (0–1], (1–2], etc.), we calculated the Spearman correlation between the rankings by similarity and rankings by relatedness. We found that the correlations are only 0.25 (weak) and 0.19 (very weak) for the bins of (1,2] and (3,4], respectively, and only about 0.49 (moderate) for the bins of (2,3] and (4,5]. Overall, this shows that the fine-grained ranking of items in the STS dataset by similarity differ considerably from that of the STR dataset.

5 What Makes Sentences More Semantically Related?

The availability of a dataset with human notions of semantic relatedness allows one to explore fundamental aspects of meaning: for example, what makes two sentences more related? In this section, we examine some basic questions. On average, to what extent is the semantic relatedness of a sentence pair impacted by presence of:

- identical words (lexical overlap)? (Q1)
- related words? (Q2)
- related words of the same part of speech? (Q3)
- related subjects, related objects? (Q4)

5.1 Method

To explore the questions above, we first computed relevant measures for Q1 through Q4 (lexical overlap, term relatedness, etc.) for each sentence pair in our dataset. We then calculated the correlations of these scores with the gold relatedness scores.

Lexical Overlap. A simple measure of lexical overlap between two sentences X and Y is the Dice Coefficient (the number of unique unigrams occurring in both sentences, adjusted by their lengths):

$$\frac{2 \times |\, unigram(X) \cap unigram(Y)\,|}{|\, unigram(X)\,| + |\, unigram(Y)\,|} \tag{1}$$

Question	Spearman	# pairs
Q1. Lexical overlap	0.57	5500
Q2. Related words - All	0.61	5500
Q3a. Related words - per POS		
PROPN	0.50	1907
NOUN	0.45	4746
ADJ	0.36	2236
VERB	0.31	3946
PRON	0.30	1800
ADV	0.28	1147
AUX	0.25	2069
ADP	0.23	2476
DET	0.20	3265
Q3b. Related words - per POS group		
Noun Group	0.60	5478
Verb Group	0.32	4999
ADJ Group	0.29	4584
Q4. Related Subjects and Objects		
Subject	0.29	1611
Object	0.43	1618

Table 4: Correlation between features and the relatedness of sentence pairs. A rule of thumb for interpreting the numbers: 0–0.19: very weak; 0.2–.39: weak; 0.4–0.59: moderate; 0.6–0.79: strong; 0.8–1: very strong.

Related Words: We averaged the embeddings for all the tokens in a sentence and computed the cosine between the averaged embeddings for the two sentences in a pair. This roughly captures the relatedness between the terms across the two sentences.[6] Token embeddings were taken from Google's publicly released Word2Vec embeddings trained on the Google News corpus (Mikolov et al., 2013a).
Related Words with same POS: The same procedure was followed as for Q2, except that only the tokens for one part of speech (POS) at a time were considered. We determined the part-of-speech of the tokens using spaCy (Honnibal et al., 2020).[7]

Related Subjects and Related Objects: For Q4, which examines the importance of different parts of a sentence, we employ the same process as Q2, except that for a given sentence: only tokens marked as subject are averaged; and only tokens marked as object are averaged. We use the packages spaCy (Honnibal et al., 2020) and Subject Verb Object Extractor (de Vocht, 2020) to determine all tokens that are the subject and object.

5.2 Results

Table 4 shows the results. Row Q1 shows that simple word overlap obtains a correlation of 0.57 (considered to be at the high end of weak correlation). Figure 2 is a scatter plot where the x-axis is the word overlap score, the y-axis is the relatedness score, and each dot is a sentence pair. Observe that a number of pairs fall along the diagonal; however, there are also a large number of pairs along the top-left side of this diagonal. This suggests that even though STR-2022 has pairs where the relatedness increases linearly with the amount of word overlap, there are also a number of pairs where a small amount of word overlap results in substantial amount of relatedness. The sparse bottom-right side of the plot indicates that it is rare for there to be substantial word overlap, and yet very low relatedness. On average, occurrence of related words across a sentence pair leads to slightly higher relatedness scores than lexical overlap (row Q2).

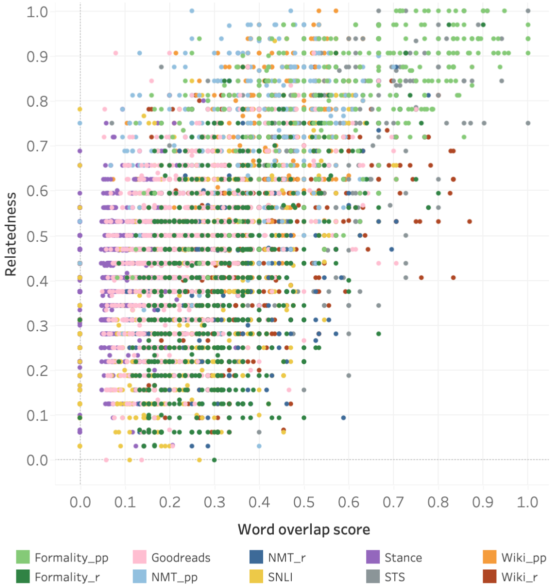

Figure 2: Scatter plot showing the relationship between lexical overlap and semantic relatedness of sentence pairs. Each dot in the plot is a sentence pair.

The Q3a rows in Table 4 show correlations for related tokens of a given part of speech.[8] (The rows are in order from highest to lowest correlation.) Observe that proper nouns (PROPN) and nouns have the highest numbers. It is somewhat surprising that related verbs do not contribute greatly to semantic relatedness; they have similar correlations as pronouns and adverbs, and markedly lower than adjectives and nouns. Not surprisingly, determiners (DET) are at the lower end of weak correlation.

The Q3b rows show correlations of coarse POS categories: NOUN Group (NOUN, PRON, PROPN), VERB Group (VERB, AUX), and ADJ

---

[6] Other ways to estimate relatedness between sets of words across two sentences may also be used.

[7] We used the simple (coarse-grained) UPOS part-of-speech tags: https://universaldependencies.org/docs/u/pos/

[8] Only those POS tags that occur in both sentences of a pair in more than 10% of the pairs are considered (>550 pairs).

Group (ADJ, ADP, ADV). We see that presence of related nouns in a sentence pair impacts semantic relatedness much more than any other POS group.

Since related nouns were found to be especially important, we also wanted to determine what impacts overall relatedness more: the presence of related nouns in the subject position or in the object position. Q4 rows show that, on average, related objects lead to markedly higher sentence-pair relatedness than related subjects.

In order to examine whether lexical overlap and some POS are less or more relevant in low or high relatedness pairs, we repeated the experiment of Table 4, only for pairs with relatedness scores <0.5, and separately, only for pairs with scores ≥0.5. We find that for the <0.5 relatedness pairs, only the existence of related proper nouns across sentence pairs has moderate correlation with the semantic relatedness of sentences; the correlation is weak for nouns, and close to 0 for all other parts of speech. The notable importance of related proper nouns and nouns is likely because they indicate a common topic, person, or object being talked about in both sentences—making the two sentence pairs related. For the ≥0.5 relatedness pairs, the correlations are weak for most POS; highest for nouns; and the gap between nouns and adjectives, adverbs, and verbs is reduced. Lexical overlap in general has a much higher correlation for the ≥0.5 relatedness pairs than the <0.5 pairs. Detailed results are in Appendix B.

6 Evaluating Sentence Representation Models using STR-2022

Since STR-2022 captures a wide range of fine-grained relations that exist between sentences, it is a valuable asset in evaluating sentence representation and embedding models. Essentially, predicting semantic relatedness is treated as a regression task, where first, using various unsupervised and supervised approaches described in the two sub-sections below, we represent each sentence as a vector. We use the cosine similarity between the vectors as a prediction of their semantic relatedness. We use the Spearman correlation between the prediction and gold relatedness scores to measure the goodness of the relatedness predictions (and in turn of the sentence representation).

The experiments below (unless otherwise specified) all involve 5-fold cross-validation (CV) on STR-2022. We report the average of the Spearman correlations across the folds. Note that even for models that do not require training (e.g., Dice score), to enable direct comparisons with trained methods, we evaluate their performance on each test fold independently and report the average of the correlations across folds.

Model	**Spearman**
Baseline	
1. Lexical overlap (Dice)	0.57
Unsupervised, Static Embeddings	
2. Word2Vec (mean, Googlenews)	0.60
3. Word2Vec (max, Googlenews)	0.54
4. GloVe (mean, Common Crawl)	0.49
5. GloVe (max, Common Crawl)	0.56
6. GloVe (mean, 200_Twitter)	0.44
7. GloVe (max, 200_Twitter)	0.48
8. Fasttext (mean, Common crawl)	0.29
9. Fasttext (max, Common crawl)	0.24
Unsupervised, Contextual Embeddings	
10. BERT-base (mean)	0.58
11. BERT-base (max)	0.55
12. BERT-base (cls)	0.41
13. RoBERTa-base (mean)	0.48
14. RoBERTa-base (max)	0.47
15. RoBERTa-base (cls)	0.41
Supervised (Fine-tuning on portions of STR-2022)	
16. BERT-base (mean)	0.82
17. RoBERTa-base (mean)	0.83

Table 5: Average correlation between human annotated relatedness of sentence pairs and the cosine distance between their embeddings across the CV runs.

6.1 Do Unsupervised Embeddings Capture Semantic Relatedness?

We first explore unsupervised approaches to sentence representation where the embedding of a sentence is derived from that of its constituent tokens. The token embedding can be of two types:

- **Static Word Embeddings:** We tested three popular models: Word2Vec (Mikolov et al., 2013b), GloVe (Pennington et al., 2014), and Fasttext (Grave et al., 2018).
- **Contextual Word Embeddings:** We tested pre-trained contextual embeddings from BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019). We use the bert-base-uncased and roberta-base models from the HuggingFace library.[9]

We obtain sentence embeddings by both mean-pooling and max-pooling the token embeddings from the final layer. For the contextual embeddings, we also explore using the embedding of the classification token ([CLS]).

Table 5 shows the results. As baseline, we include how well simple lexical overlap (Dice score)

---

[9] `https://huggingface.co`

	Dice	SBERT(RoBERTa)	
	CV	CV	LOO CV
STS	0.60	0.79	0.82
SNLI	0.53	0.80	0.77
Stance	0.20	0.49	0.39
Goodreads	0.44	0.73	0.70
Wiki	0.48	0.79	0.75
Formality	0.69	0.86	0.83
ParaNMT	0.44	0.80	0.79

Table 6: Breakdown of average test-fold correlations for each source: (a) using lexical overlap (Dice), (b) using SBERT and some in-domain data for fine-tuning (in addition to data from other domains), and (c) using SBERT and only out-of-domain data for fine-tuning (LOO CV). CV: cross-validation. LOO: leave-one-out.

predicts relatedness (row 1). Observe that mean-pooling with word2vec (row 2) obtains slightly higher correlation than the baseline, but the majority of the static embedding models fail to obtain better correlations (rows 3–9). The contextual embeddings from BERT and RoBERTa do not perform better than the word2vec embeddings (rows 10–15). Overall, the unsupervised methods leave much room for improvement.

6.2 Do Supervised Embeddings Capture Semantic Relatedness?

We now evaluate the performance of BERT-based models on STR-2022 when formulated as a *supervised* regression task. We use the S-BERT cross-encoder framework of Reimers and Gurevych (2019), and apply mean-pooling on top of the token embeddings of the final layer to obtain sentence embeddings. The model is trained using a cosine-similarity loss—the cosine between the embeddings of a sentence pair is compared to the gold semantic relatedness scores to obtain the Mean Squared Error (MSE) loss for each datapoint.

Table 5 rows 16 and 17 show the results: fine-tuning on STR-2022 leads to considerably better relatedness scores.

6.2.1 Impact of Domain on Fine-Tuning

The results above show that fine-tuning is critical for better sentence representation. However, it is well-documented that the domain of the data can have substantial impact on results; especially when quite different from the training data. With the inclusion of data from various domains in STR-2022 (Table 2), one can systematically explore performance on individual domains, as well as the extent to which performance may drop if no training data from the target domain is included for training.

Table 6 shows the results. The RoBERTa CV column shows a breakdown of results by source (domain). Essentially, these are results for the scenario where some portion of in-domain data is included in the training folds (along with data from other domains), and the system correlations are determined only on the test fold's target domain pairs. Observe that performance on most domains is comparable to each other.

The LOO CV column shows correlations with a leave-one-out cross-validation setup: no in-domain training data is used and system correlations are determined only for the target domain pairs. Observe that this leads to drops in scores for all domains except STS. However, the drop is small; and scores are still much higher than the lexical overlap (Dice CV) baseline. This suggests that the diversity of data in the remaining subsets is useful in overcoming a lack of in-domain training data.

7 Utility of Semantic Relatedness and STR-2022 in Downstream NLP Tasks

Semantic relatedness is central to textual coherence and narrative structure. Often, sentences in a document are not paraphrases, entailments, or similar, but rather semantically related to each other. This need for continuity of meaning has long been identified as a crucial component of language (Halliday and Hasan, 1976; Morris and Hirst, 1991). Thus, when generating a summary or a response to a question, systems must choose sentences that are *not* paraphrases or entailments of each other, but yet suitably semantically related. Therefore, being able to judge both similarity and relatedness is crucial.

Since we made STR-2022 publicly available, it has already been used in some projects. Notable among these is Wang et al. (2022). Wang et al. (2022) propose a new intrinsic evaluation method, *EvalRank*, that focuses on local neighborhoods (how well systems identify close neighbors, rather than how well they rank the full set of pairs). Using STR-2022, they are able to obtain markedly higher correlations between performance scores on the intrinsic evaluation and performance on downstream tasks (seven NLP tasks including NLI, question classification, caption retrieval, and sentiment analysis). Their ablation study demonstrates that using STS instead of STR-2022 decreases performance up to 10 points, leading them to conclude that STR-2022 is particularly useful in generating sentence embeddings for downstream tasks.

8 Conclusion

We created STR-2022, the first dataset of English sentence pairs annotated with fine-grained relatedness scores. We used a comparative annotation method that produced a split-half reliability of 0.84. Thus, we showed that speakers of a language can reliably judge semantic relatedness. We used the dataset to explore several research questions pertaining to what makes two sentences more related. Finally, we used STR-2022 to evaluate the ability of sentence representation methods to embed sentences in vector spaces such that those that are closer to each other in meaning are also closer in the vector space. The dataset is made freely available; facilitating further research in semantic relatedness and sentence representation.

9 Limitations

For limitations surrounding the dataset, please refer to the Ethics Statement (§10). In our experiments, we used the most common methods for sentence representations (e.g., mean-pooling and max-pooling of traditional and contextual word embeddings). However, there may exist other embeddings which are better suited for predicting semantic relatedness (e.g., other order-aware embeddings). Expanding the set of embedding techniques tested using our dataset may yield different results and provide us a stronger understanding of the effects of different representation techniques. Furthermore, while we explored the impact of some sentence-pair features such as lexical overlap, POS, and some aspects of sentence structure (subject and object) on semantic relatedness, we did not explore the impacts of other features such as logicality and common sense reasoning on relatedness. These remain interesting directions for future work.

10 Ethics Statement

This paper respects existing intellectual property by making use of only publicly and freely available datasets. The crowd-sourced task was approved by our Institutional Research Ethics Board. The annotators were based in the United States of America and were paid the federal minimum wage of $7.25 per hour. Our annotation process stored no information about annotator identity and as such there is no privacy risk to them. The individual sentences selected did not have any risks to privacy either (as evaluated by manual annotation of the sentences). Models trained on this dataset may not generalize to external datasets gathered from different populations. Knowledge about language features may not generalize to other languages.

Any dataset of semantic relatedness entails several ethical considerations. We list some notable ones below. Many of these were first introduced in the context of sentiment lexicons (Mohammad, 2020, 2023). We adapted them to semantic relatedness datasets and added to the discussion.

- *Coverage:* We sampled English sentences from a diverse array of sources from the internet, with a focus on social media. Yet, it is likely that several types of sentences (and several demographic groups) are not well-represented in STR-2022. The dataset likely includes more sentences by people from the United States and Europe and with a socio-economic and educational backgrounds that allow for social media access.
- *Not Immutable:* The relatedness scores do not indicate an inherent unchangeable attribute. The relatedness can change with time, but the dataset entries are largely fixed. They pertain to the time they are created.
- *Socio-Cultural Biases:* The annotations of relatedness capture various human biases. These biases may be systematically different for different socio-cultural groups. Our data was annotated by US annotators, but even within the US there are diverse socio-cultural groups.
- *Inappropriate Biases:* Our biases impact how we view the world, and some of the biases of an individual may be inappropriate. For example, one may have race or gender-related biases that may percolate subtly into one's notions of how related two units of text are. Our dataset curation was careful to avoid sentences from problematic sources, and we have not seen any inappropriate relatedness judgments, but it is possible that some subtle inappropriate biases still remain. Thus, as with any approach for sentence representation or semantic relatedness, we caution users to explicitly check for such biases in their system regardless of whether they use STR-2022.
- *Perceptions (not "right" or "correct" labels):* Our goal here was to identify common perceptions of semantic relatedness. These are not meant to be "correct" or "right" answers, but rather what the majority of the annotators believe based on their intuitions of the English language.

- *Relative (not Absolute):* The absolute values of the relatedness scores themselves have no meaning. The scores help order sentence pairs relative to each other. For example, a pair with a higher relatedness score should be considered more related than a pair with a lower score. No claim is made that the mid-point (relatedness score of 0.5) separates related words from unrelated words. One may determine categories such as *related* or *unrelated* by finding thresholds of relatedness scores optimal for their use/task.

We recommend careful reflection of ethical considerations relevant for the specific context of deployment when using STR-2022.

A Further Details on Sampling Sentence Pairs from Source Datasets

This Appendix provides further information about the sources of data and how sentence pairs were sampled from them to be included in STR-2022.

A.1 STS Data

We selected 250 sentence pairs from existing STS corpora. This selection was done to enable a small investigation into the interplay between relatedness and similarity, which could serve as motivation for further investigation in future work. For this dataset, we randomly sampled 50 sentence pairs from each of bucket of annotation (i.e., 50 sentence pairs having an STS similarity scores falling in $[0, 1)$, 50 sentence pairs having scores in $[1, 2)$, and so on).

A.2 Stance Data

We created 750 sentence pairs by sampling from Mohammad et al. (2016)'s dataset of tweets labeled for stance. The original dataset is composed of individual tweets labelled for both stance ('For', 'Against', 'Neither Inference Likely') and sentiment ('Positive', 'Negative', 'Neutral'). The dataset was built from tweets focused on six targets: 'Atheism', 'Climate Change', 'Donald Trump', 'Feminism', 'Hillary Clinton', 'Abortion'.

When curating our sentence pairs, we limited the possible targets to 'Hillary Clinton', 'Donald Trump', and 'Abortion'. Sentence pairs were chosen such that both sentences shared the same target. 500 sentence pairs shared their stance towards their target (i.e., 250 *for–for* pairs and 250 *against–against* pairs). 250 sentences pairs differed on their stance (i.e., *250 for–against* pairs). We did not use any lexical overlap heuristic to specify which tweets should be paired with each other because we were interested in studying whether overlap in topic was a strong enough signal to impact relatedness. That is, by choosing pairs with the same target, we were already pre-selecting for various degrees of relatedness.

A.3 SNLI Data

We created 750 sentence pairs by sampling from the Stanford Natural Language Inference (SNLI) Dataset (Bowman et al., 2015). SNLI is composed of image description captions; for each caption, multiple premise sentences are generated, along with multiple possible hypothesis sentences that could possibly belong to each premise. To build our sentence pairs we sought to pair different premise sentences together. We did not wish to pair between premise and hypothesis sentences as the sentence structure was significantly different (and simpler for the hypothesis sentences), as noted by the creators of the dataset. Even still, the majority of premise sentences are very short (with a mean token count of 14), often following very simple (and similar) grammatical structure.

To generate the sentence pairs, first we removed all sentences with less than 5 or more than 25 tokens. Then, for each token in all remaining sentences, we replaced each token with its most frequent synonym, using Roget's Thesaurus (Roget, 1911) to define synonymous relationships. Words which did not have synonyms were left unchanged. The intention behind replacing each word with its most frequent synonym was to ensure that synonymous phrasings would count as overlaps when we measure it. We then randomly selected 750 sentences to serve as the first sentence of our final pairings. To find the second sentence to each pairing we looped through all premise sentences and returned the first sentence that satisfied two conditions: 1) The unigram overlap was greater than or equal to 25% and less than 75% of the first sentence, and 2) the difference in length between both sentences did not exceed 25%.

A.4 Wikipedia Data

We sampled 1000 sentence pairs from a dataset that pairs sentences from English Wikipedia with sentences from Simple English Wikipedia. Created to enable the task of sentence simplification, the paired sentences, paired using rules-based classification, are often very closely related. We used this dataset in two ways: 1. Extracting sentence pairs which serve as paraphrases or near paraphrases (we refer to these as Wiki_pp), and 2. pairing sentences to other random sentences in the dataset (we refer to these as Wiki_r).

Wiki_pp: First, we removed any pairings for which either sentence was less than 5 words or more than 25 words. Then we narrowed the list of pairings further by removing any pairings that did not share more than 25% but less than 75% of unique unigrams. From the remaining sentence pairs, we randomly selected 500 paired sentences.

Wiki_r: Here, we only made use of the full sentences from the original Wikipedia, discarding sentences from Simple Wikipedia. We removed all sentences that have less than 5 or more than 25 tokens. To create the sentence pairs, we looped in a random order through all possible pairing of sentences. We paired two sentences if they share at least 25% of their tokens but less than 75% of their tokens AND the difference in length between both sentences did not exceed 25%. We stopped once we had generated 500 sentence pairs.

A.5 Goodreads Data

We created 1000 sentence pairs by sampling from the UCSD Goodreads Dataset (Wan and McAuley, 2018; Wan et al., 2019), which has book reviews from the Goodreads website. We limited the sampling to the 'Fantasy and Paranormal' genre, since it contained a relatively higher number of reviews per book, allowing for a higher possibility of sampling more related sentence pairs. Each review was first split into sentences using the default NLTK sentence tokenizer; we kept only those sentences with the number of tokens between 5 and 25. We then randomly examined pairs of sentences, and quantified the lexical overlap between then with an IDF-weighted Dice overlap score. The pairs were then assigned to buckets based on this overlap score; the range of each bucket was obtained by first finding 50 equally-spaced percentiles of the entire score distribution. We then sampled exponentially increasing number of sentences from low to high weighted Dice overlap bins such that a total of 1000 sentence pairs were included.

A.6 ParaNMT Data

ParaNMT (Wieting and Gimpel, 2018) is a dataset of 51 million sentential paraphrases that were automatically generated using a neural machine translation system. We generated two sets of pairs from these sentences corresponding to paraphrases and random pairs:

ParaNMT_pp: We assigned paraphrases to buckets based on the Dice score between the two sentences. We divided the range of scores into 100 equally-sized percentiles. We then sampled pairs uniformly from each bucket, for a total of 450 sentence pairs.

ParaNMT_r: For the random, non-paraphrase sentence pairings, we used the Dice score to extract 300 pairs, analogous to the creation of the **Wiki_r** pairs.

A.7 Formality Data

Our third paraphrase corpus is the Formality dataset from Rao and Tetreault (2018) (They refer to it as GYAFC). This consists of human-written formal and informal paraphrases for sentences sourced from the Yahoo! Answers platform. Our sampling procedure for this dataset followed that of the ParaNMT dataset.

Formality_pp: We assigned sentences to one of 50 buckets based on their lexical overlap score as before. We then uniformly sampled from each bucket to extract 300 sentence pairs.

Formality_r: We sampled random pairings of sentences using the token overlap and length difference conditions as defined for Wiki_r and ParaNMT_r. We extracted 700 such sentence pairs.

B Correlation of Features in Low and High Relatedness Sentence Pairs

As discussed in Section 5.2, in order to examine whether lexical overlap and some parts of speech are less or more relevant in low or high relatedness pairs, we repeated the experiment in Table 4, only for pairs with relatedness scores less than 0.5 and also for pairs with scores greater than 0.5. Table 7 shows the detailed correlation scores. See Section 5.2 for a discussion of the main trends.

C Sample Sentence Pairs from STR-2022

Table 8 presents sample sentene pairs from different domains.

Question	Spearman 0–1 pairs	 <0.5 pairs	 ≥0.5 pairs
Q1. Lexical overlap	0.57	0.14	0.52
Q2. Related words - All	0.61	0.14	0.50
Q3a. Related words - per POS

RevUp: Revise and Update Information Bottleneck for Event Representation

Mehdi Rezaee **Francis Ferraro**
Department of Computer Science
University of Maryland Baltimore County
Baltimore, MD 21250 USA
{rezaee1, ferraro}@umbc.edu

Abstract

The existence of external ("side") semantic knowledge has been shown to result in more expressive computational event models. To enable the use of side information that may be noisy or missing, we propose a semi-supervised information bottleneck-based discrete latent variable model. We reparameterize the model's discrete variables with auxiliary continuous latent variables and a light-weight hierarchical structure. Our model is learned to minimize the mutual information between the observed data and optional side knowledge that is not already captured by the new, auxiliary variables. We theoretically show that our approach generalizes past approaches, and perform an empirical case study of our approach on event modeling. We corroborate our theoretical results with strong empirical experiments, showing that the proposed method outperforms previous proposed approaches on multiple datasets.

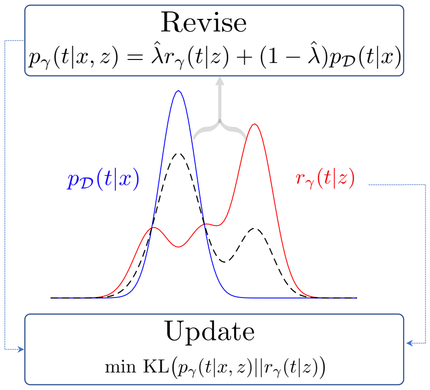

Figure 1: Revise and Update steps for an observed node. We update the proposed distribution $r_\gamma(t|z)$ with the empirical distribution $p_\mathcal{D}(t|x)$ to produce the revised distribution $p_\gamma(t|x,z)$ (dashed). We then minimize the KL divergence between the proposed and revised distributions to update the proposed distribution. For unsupervised nodes, we rely on $r_\gamma(t|z)$ without updating.

1 Introduction

In this work, we are interested in addressing limitations in how computational event modeling can make use of relevant, supplementary semantic knowledge. This is because when modeling text descriptions of complex situations, such as newspaper descriptions of real world events, learning how to encode richer information about those descriptions can be a fruitful way of improving modeling performance (Judea and Strube, 2015; Xia et al., 2021). E.g., if we are dealing with sequences of events, like a newspaper report of a stock or commerce transaction, then being able to encode that "buying" or "selling," even though they may have nuanced connotation differences, are instances of the same general event (a TRANSACTION event) can improve downstream predictive performance on what events might happen next (Ferraro and Van Durme, 2016; Rezaee and Ferraro, 2021).

However, there is not an obvious single way to learn to encode this richer information, as three different questions naturally come to mind: (1) If the model is representationally limited, can we address these representational limitations of the model itself, such as through developing richer latent representations $\mathbf{z}$ of the input $\mathbf{x}$? (2) If there is available background or side information $\mathbf{t}$ that may be especially relevant for the modeling task at hand, can we develop systems that make use of it? (3) Even when side information is available, it may be noisy, e.g., it may not always be available (missing data) or it may contain errors: how can we make our models robust to this noisy side information? In the context of a text-based sequence modeling problem, we propose an approach that addresses all three of these questions.

We provide a conceptual overview of our method—RevUp—in Fig. 1. The building blocks of RevUp are **revision** of modeling side information $\mathbf{t}$: forming a new distribution by combining the (red) learned proposal distribution with (blue) empirical information about when particular aspects of side knowledge appeared in training, and **updat-**

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 797–814
May 2-6, 2023 ©2023 Association for Computational Linguistics

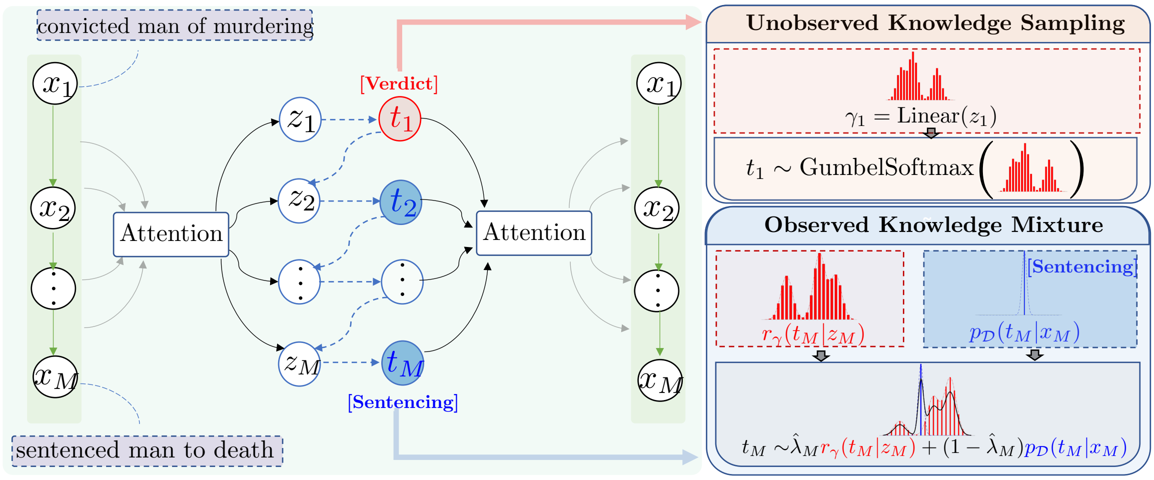

Figure 2: Components of RevUp for event modeling. We encode the sequence of events $\mathbf{x}$ into Gaussian latent $\mathbf{z}$ and discrete knowledge $\mathbf{t}$. Red nodes such as t_1 are latent: [VERDICT] for the *convicted man of murdering* event. RevUp predicts these latent nodes by sampling from the GumbelSoftmax distribution. Blue nodes such as t_M are observed: [SENTENCING] for the *sentenced man to death* event. We use this observed node to modify the proposed distribution and then we draw a sample from the revised distribution.

ing by minimizing the KL-divergence between the new distribution with the previous proposed one.

Our approach is inspired by recent work (Kong et al., 2019), which argued that a key to the success of neural advances in NLP (Mikolov et al., 2013; Devlin et al., 2018; Yang et al., 2019, i.a.,) is that they fall within the information theoretic-based InfoMax framework (Linsker, 1988). In this viewpoint, neural advances can be attributed to implicitly maximizing the mutual information between different representations of the same document.

However, we additionally want to use "side" or "external" knowledge to aid our modeling. The use of side information has long been desired for effective representation (Wyner, 1975; Wyner and Ziv, 1976). While this side information can occur in a variety of forms (Chen et al., 2020; Padia et al., 2018), we broadly view it as a *concise, abstract view of information* conveyed in the main input.

Our work centers on the idea that the latent neural representations $\mathbf{z}$ and side knowledge $\mathbf{t}$ act as complementary representations of the same input $\mathbf{x}$: $\mathbf{z}$ provides a compact representation of the input itself, while $\mathbf{t}$ provides more generic information about the data or task. As such, we use an InfoMax-inspired formulation to incorporate external knowledge into the modeling and latent representation aspects. Since recent work (Joy et al., 2022; Chen et al., 2019) has suggested that providing some sort of "guidance" to these latent variables is beneficial and can lead to these guided models outperforming both fully supervised and fully unsupervised methods, learning with less-than-full observation of structured side knowledge is a requirement. We illustrate this in Fig. 2, where the correct value for the first piece of side information ($t_1 = \text{Verdict}$) is missing but the last piece of side information is known ($t_M = \text{Sentencing}$). Our model must be able to operate over this partially observed sequence of side knowledge as a way of modeling the original event description.

We propose a unified approach, RevUp (**Rev**ise and **Up**date Information Bottleneck), that maximizes the mutual information between the external knowledge and latent representation $\mathcal{I}(\mathbf{z};\mathbf{t})$. We consider the external knowledge $\mathbf{t}$ to be a discrete random variable in a lightly structured, semi-supervised setting. We demonstrate the effectiveness of this approach on multiple modeling tasks. Our contributions are:

(1) We provide a principled, information theoretic approach for injecting side information into neural discrete latent variable models. We provide theoretical backing to show that our methodology captures available information from external knowledge.

(2) We define a new model that leads to state-of-the-art results in the semi-supervised setting on two standard event modeling datasets.

(3) We show that our proposed model generalizes the existing state-of-the-art model studied in Rezaee and Ferraro (2021), where the "parameter injection" method developed there can be

understood as a special case of our framework.

(4) We experimentally show that our model is more robust when the external knowledge is noisy and it outperforms other baselines when the external knowledge is partially observed.

Our code is available at `https://github.com/mmrezaee/RevUp`.

2 Background

In this section we present the related work and discuss the connections to our approach.

Mutual Information (MI) The mutual information $\mathcal{I}(x;y)$ measures how much two random variables x and y depend on each other. It is defined as $\mathcal{I}(x;y) = \mathbb{E}_{p(x,y)} \log \frac{p(x,y)}{p(x)p(y)}$, where $\mathcal{I}(x;y) = 0$, when x and y are independent. Conditional MI $\mathcal{I}(x;y|z)$ extends MI to measure the conditional dependence between x and y given z, as $\mathcal{I}(x;y|z) = \mathbb{E}_{p(x,y,z)} \log \frac{p(x,y|z)}{p(x|z)p(y|z)}$. When $\mathcal{I}(x;y|z) = 0$, there isn't any information between x and y that is not present in z.

Information Bottleneck Principle (IB) The Information Bottleneck principle is a method for finding the most informative encoding of an input x with respect to the target output y. This is accomplished by finding the maximally compressed encoding z of x that is most informative about y (Tishby et al., 1999). The objective is to maximize

$$\mathcal{I}(z;y) - \beta\mathcal{I}(x;z), \tag{1}$$

where $\mathcal{I}(z;y)$ denotes z and y mutual information, and $\mathcal{I}(x;z)$ denotes x and z mutual information. β balances compression and informativeness.

Variational Autoencoder (VAE) The Variational Autoencoder is similar to the Information Bottleneck Principle in that it finds an encoding z of x to reconstruct x. However, the approach is different as the aim is to approximate the intractable posterior distribution $p_\theta(z|x)$ with a variational distribution $q_\phi(z|x)$ in order to optimize the Evidence Lower Bound (ELBO) (Kingma and Welling, 2013).

Incorporation of Side Knowledge Conceptually, we consider an "event" to be a condensed form of knowledge that outlines part of a particular situation. Semantic frames are a prime example of relevant side knowledge: a semantic frame can be thought of as an abstraction over highly related events. Though they also provide abstractions over the *who*s, *what*s, *where*s and *how*s of events, in this setting, it is sufficient to consider an event's semantic frame as a type of label or cluster id. Multiple potential sources of semantic frames exists, e.g., FrameNet, PropBank, or VerbNet.

Recently, incorporating external knowledge has been investigated by numerous studies in a wide range of tasks beyond NLP (Kang et al., 2017; Flajolet and Jaillet, 2017; Zhang et al., 2021), and zero-shot classification (Badirli et al., 2021). Common across these efforts is treating the side information as part of the input to be encoded. This makes the side information prerequisite knowledge for the model to be learned, rather than supplementary.

A recent approach, called Sequential, Semi-supervised Discrete Variational Autoencoder (Rezaee and Ferraro, 2021, SSDVAE), is a new method for structured semi-supervised modeling that allows, but does not require, side information to guide the learning in an approach called "parameter injection." Because the SSDVAE framework is a deep latent variable model that is specifically designed to treat external knowledge as supplementary to the main task, we focus our study within it and the associated NLP-based computational event modeling tasks examined. They define parameter injection as

Definition. *(Parameter injection) Let* $\mathbf{t} \sim$ *GumbelSoftmax*$(\mathbf{t};\gamma)$*, where* $\boldsymbol{\gamma}$ *are the logits. If* $\mathbf{t}$ *is observed as external knowledge and represented with a one-hot vector* $\mathbb{1}(\mathbf{t})$ *with* $t_{k^*} = 1$*, the operation* $\boldsymbol{\gamma} = \boldsymbol{\gamma} + (\|\boldsymbol{\gamma}\| * \mathbb{1}(\mathbf{t}))$ *guides the latent variable* $\mathbf{t}$ *during the training because on average increases the* t_{k^*} *value (Maddison et al., 2016).*

In RevUp, we build on and generalize this notion of parameter injection, in part by introducing the empirical distribution $p_{\mathcal{D}}(\mathbf{t}|\mathbf{x})$ to accommodate the dependence between data $\mathbf{x}$ and knowledge $\mathbf{t}$.

3 RevUp: Revise and Update

Previous work (Rezaee and Ferraro, 2021, SSDVAE) has empirically shown that incorporating external knowledge in discrete GumbelSoftmax parameters improves model performance with different metrics such as classification, event modeling and training speed. We seek to re-frame this view with information theory terms and generalize it. For fairness and consistency we stick with the same types of computational event modeling tasks that

SSDVAE was developed for. We first describe the probabilistic model we develop (section 3.2) and the loss/training methodology (section 3.3). These enable smoothly incorporating side knowledge into a probabilistic neural model. Recall we provide a conceptual overview of RevUp in Fig. 1.

3.1 Setup

We assume that within a document, we have a sequence of M different predicate/argument-style events, $\mathbf{x} = x_1 ... x_M$, with each x_m describing some action (the predicate) occurring among participants of that action (the arguments). If each event x_m could also be paired with a semantic frame t_m, so we have a corresponding sequence $\mathbf{t}$, then considered across multiple events, $\mathbf{t}$ could provide a sequential generalization. E.g., in the example event sequence from Fig. 2 that includes "convicted man of murdering," and "sentenced man to death," if each event can be associated with a semantic frame (such as VERDICT and SENTENCING for these two events), then the corresponding sequence of frames provides both an abstraction over the entire event sequence, and an incredibly rich, yet low-dimensional, collection of side knowledge.

Having paired sequences $\mathbf{x}$ and $\mathbf{t}$ is not restrictive. Whether $\mathbf{t}$ is partially observed (i.e., not all x_m have observed frames t_m) or noisy (i.e., the observed t_m for x_m is incorrect) during training, our approach can still extract useful signal.

3.2 Probabilistic Encoding

Our problem setup is that we have input text $\mathbf{x}$ describing some complex situation, paired with a partially observed sequence of frames $\mathbf{t}$. To account for when side knowledge is/isn't observed, we define a knowledge indicator set $\boldsymbol{l} = l_m|_{m=1}^{M}$ with $l_m \in \{0, 1\}$, where $l_m = 1$ denotes the external knowledge t_m is present and $l_m = 0$ means the external knowledge is not available (latent). To enable successful modeling, we introduce $\mathbf{z} = z_m|_{m=1}^{M}$, a set of M latent variables to first compress the information of the given inputs $\mathbf{x}$ and then be informative regarding $\mathbf{t}$. We define $p_\theta(\mathbf{z}|\mathbf{x})$, a probabilistic encoder from data points $\mathbf{x}$ to the latent variables $\mathbf{z}$, parameterized by a neural network θ.

We define a joint model over $\mathbf{t}, \mathbf{x}$ and $\mathbf{z}$ as $p(\mathbf{t}, \mathbf{x}, \mathbf{z}; \boldsymbol{l}) = p_\mathcal{D}(\mathbf{x}) \prod_m p_\theta(z_m|t_{m-1}, \mathbf{x}) p_\gamma\big(t_m|x_m, z_m; l_m\big)$, where $p_\mathcal{D}(\mathbf{x})$ is the empirical distribution over the input variables $\mathbf{x}$. Consistent with previous approaches, $p_\theta(z_m|t^{(s)}, \mathbf{x}; l_m)$ is a Gaussian. Similarly $p_\gamma\big(t_m|x_m, z_m; l_m\big)$ posits a distribution over semi-supervised latent knowledge $\mathbf{t}$ given $\mathbf{x}$ and latent variables $\mathbf{z}$. To learn richer representations, we force $\mathbf{z}$ and $\mathbf{t}$ to depend on one other in a sawtooth fashion: t_i depends on z_i, but z_i depends on t_{i-1}. Fig. 2 shows an illustration. This is a novel segmented, autoregressive sequencing for event modeling.

We define $r_\gamma(\mathbf{t}|\mathbf{z})$ as the *proposed distribution* that relates $\mathbf{z}$ to $\mathbf{t}$, where γ is computed as the outcome of a neural encoding of $\mathbf{z}$, NN($\mathbf{z}$). This distribution must be learned. For simplicity we omit the node index m when possible.

Revision Phase Incorporating the external knowledge in the training phase must satisfy two criteria: First, without observation ($l_m = 0$), we just rely on $r_\gamma(t_m|z_m)$. Second, when we have access to external knowledge, $p_\mathcal{D}(t_m|x_m)$ should be used for *guidance* and not discarding the proposed distribution. We define the *revised distribution* $p_\gamma\big(t_m|x_m, z_m; l_m\big)$ as a smoothed weighted average of the proposed distribution and the empirical distribution as $p_\gamma\big(t_m|x_m, z_m; l_m\big) = \frac{1}{1+\lambda l_m} r_\gamma(t_m|z_m) + \frac{\lambda l_m}{1+\lambda l_m} p_\mathcal{D}(t_m|x_m)$, where $\lambda \in \mathbb{R}^+$ is a weighting parameter for balancing the proposed and empirical distributions. In this setting, λ depends on the level of confidence in our external knowledge, where for less noisy knowledge, we can choose higher values for λ. In practice, we found that $\lambda = 1.0$ works reasonably.[1]

If side knowledge is absent ($l_m = 0$), we have $\hat{\lambda}_m = 1.0$ so $p_\gamma(t_m|x_m, z_m) = r_\gamma(t_m|z_m)$: the model just uses the proposed distribution. This allows gradients to propagate through the network. During the test phase we do not use any external knowledge, so the revised distribution $p_\gamma\big(\mathbf{t}|\mathbf{x}, \mathbf{z}; \boldsymbol{l}\big)$ reduces to the proposed distribution $r_\gamma(\mathbf{t}|\mathbf{z})$.

Analysis and Insights If we define $\hat{\lambda}_m = 1/(1 + \lambda l_m)$, we rewrite this as $p_\gamma\big(t_m|x_m, z_m; l_m\big) = \hat{\lambda}_m r_\gamma(t_m|z_m) + (1 - \hat{\lambda}_m) p_\mathcal{D}(t_m|x_m)$. This slight notation change is beneficial, as it lets us characterize the behavior of our revision step in terms of expected

---

[1] In dev experiments we tried various values of λ, both large and small. When λ was high (greater weight to the empirical distribution), the model over-emphasized this signal, which was detrimental at test time when we intentionally withheld this signal. In contrast, when λ is low (greater weight to the proposed distribution), there is less emphasis on the empirical distribution. However, as that empirical distribution could itself be quite sparse (due to ϵ), the model learns to disregard it. This highlights a strength in simplicity of the equal weighting.

observability of side knowledge. Specifically, in a semi-supervised setting, if the probability of observing any particular piece of side information can be modeled as $l \sim \text{Bern}(\epsilon)$, where ϵ is the observation probability, by marginalizing out l we have $\mathbb{E}_{l\sim\text{Bern}(\epsilon)} p_\gamma(t|x,z,l) = \hat{\epsilon} r_\gamma(t|z) + (1-\hat{\epsilon}) p_{\mathcal{D}}(t|x)$, where $\hat{\epsilon} = 1 - \left(\frac{\lambda}{1+\lambda}\right)\epsilon$. This indicates that with more observation, we rely more heavily on the empirical distribution and less on the proposed distribution. For space, see Appendix E for more details/the derivation.

Finally, our framework generalizes SSDVAE's parameter injection (see Appendix F):

Theorem 1. *If $r_\gamma(t|z) = Cat(\boldsymbol{\gamma})$, a categorical distribution with parameters γ, and the empirical distribution $p_{\mathcal{D}}(t|x)$ is a one-hot representation with $t_{k^*} = 1$, the revision step reduces to SSDVAE parameter injection.*

We have described how to guide the latent variable t in the encoding phase. Next we define our objective function to capture the background information and decoding $\mathbf{t}$ to effectively model event descriptions.

3.3 Training Objective and Decoding

After training, the model relies solely on the proposed distribution $r_\gamma(t_m|z_m)$ to predict t_m, implying the statistics of t_m will only depend on z_m. To capture the background information in $\mathbf{t}$, minimize $\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z})$ during training. In information theory terms, in the ideal situation where $\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z}) = 0$, there is not any residual information between $\mathbf{x}$ and $\mathbf{t}$ that is not captured by the latent representation $\mathbf{z}$ (Kirsch et al., 2020). Therefore without the need of $\mathbf{x}$ and $p_{\mathcal{D}}(\mathbf{t}|\mathbf{x})$, the latent $\mathbf{z}$ is enough to predict $\mathbf{t}$.

To be meaningfully learned, $\mathbf{t}$ must be informative enough to make some prediction or reconstruction. For clarity, we refer to the targets as $\mathbf{y}$, though for a task like language modeling, $\mathbf{x} = \mathbf{y}$. To achieve this learning, we maximize $\mathcal{I}(\mathbf{y},\mathbf{t})$.

Together, our ideal objective is $\mathcal{L} = -\mathcal{I}(\mathbf{y};\mathbf{t}) + \alpha\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z})$, where α is a tunable hyperparameter. This is difficult to optimize because within each $\mathcal{I}$ term there are intractable marginalizations (such as over $\mathbf{x}$). To understand why this is our ideal objective, we show that maximizing the intractable mutual information $\mathcal{I}(\mathbf{t};\mathbf{z})$ is inherently included in this unified objective for the reconstruction tasks:

Theorem 2. *For tasks where we maximize $\mathcal{I}(\mathbf{x};\mathbf{t})$: minimizing $\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z})$ leads to maximizing $\mathcal{I}(\mathbf{t};\mathbf{z})$.*

This theorem shows that reconstruction tasks like language modeling explicitly maximize the mutual information between different data representations, which is consistent with the InfoMax principle. See Appendix G for the proof. As a consequence of Theorem 2, we are maximizing the mutual information between two views of $\mathbf{x}$: compressed representation $\mathbf{z}$ and side information $\mathbf{t}$.

With that understanding, we proceed to a tractable approximation for our objective. Following Alemi et al. (2016), we have $-\mathcal{I}(\mathbf{y};\mathbf{t}) = -\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})}$. We approximate this as

$$-\mathcal{I}(\mathbf{y};\mathbf{t}) \leq -\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log \frac{q_\phi(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} \tag{2}$$

$$= \underbrace{-\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log q_\phi(\mathbf{y}|\mathbf{t})}_{\mathcal{L}_y} - H(\mathbf{y}). \tag{3}$$

Since $p(\mathbf{y}|\mathbf{t})$ is intractable, we approximate it via a decoder $q_\phi(\mathbf{y}|\mathbf{t})$ that can be computed by a neural network, denoted as ϕ. As the task entropy $H(\mathbf{y})$ is constant, we just minimize $\mathcal{L}_y$. While not explicitly reflected in Eq. 2, note that irrespective of whether side information is present or not, $\mathcal{I}(\mathbf{y};\mathbf{t})$ depends on $r_\gamma(\mathbf{t}|\mathbf{z})$. See Appendix B.1 for additional analysis of Eq. 3.

Updating Phase The term $\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z}) = \mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z};\boldsymbol{l})}{p(\mathbf{t}|\mathbf{z})}$ makes $\mathbf{z}$ informative about $\mathbf{t}$. We approximate with a surrogate objective $\mathcal{L}_{\mathcal{I}}$:

$$\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z}) \leq \mathbb{E}_{p(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})}{r_\gamma(\mathbf{t}|\mathbf{z})} = \mathcal{L}_{\mathcal{I}}. \tag{4}$$

This surrogate objective encourages the proposed distribution $r_\gamma(\mathbf{t}|\mathbf{z})$ to be updated to be close to the revised distribution $p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z};\boldsymbol{l})$. After training, the proposed distribution $r_\gamma(\mathbf{t}|\mathbf{z})$ plays the role of $p_\gamma(\mathbf{t}|\mathbf{z},\mathbf{x})$ and does not need to explicitly use $p_{\mathcal{D}}(\mathbf{t}|\mathbf{x})$. Throughout, we refer to $\mathcal{L}_{\mathcal{I}}$ as *updating*. The updating objective for our model is given by

$$\mathcal{L}_{\mathcal{I}} = \sum_{m=1}^{M} \text{KL}\big(p_\gamma(t_m|x_m, z_m; l_m) \parallel r_\gamma(t_m|z_m)\big), \tag{5}$$

where by expanding further we obtain

$$\mathcal{L}_{\mathcal{I}} = \sum_{m=1}^{M} \Big[-H(t_m|x_m, z_m) + \hat{\lambda}_m H(t_m|z_m) - (1-\hat{\lambda}_m)\mathbb{E}_{p_{\mathcal{D}}(t_m|x_m)} \log r_\gamma(t_m|z_m)\Big]. \tag{6}$$

This sum is computed over observed nodes. For unsupervised nodes, the revised distribution and proposed distribution are equal and their KL terms are zero. The last term is a classification term.

Regularization To improve the model generalization ability, we introduce regularization terms for $\mathbf{z}$ and $\mathbf{t}$. We constrain the mutual information between data $\mathbf{x}$ and $\mathbf{z}$ latent representations, $\mathcal{I}(\mathbf{x};\mathbf{z}) = \mathbb{E}_{p(\mathbf{z},\mathbf{x})} \log \frac{p_\theta(\mathbf{z}|\mathbf{x})}{p(\mathbf{z})}$ as

$$\mathcal{I}(\mathbf{x};\mathbf{z}) \leq \underbrace{\mathrm{KL}\big(p_\theta(\mathbf{z}|\mathbf{x}) \parallel q(\mathbf{z})\big)}_{\mathcal{L}_z}, \tag{7}$$

where we introduce a variational distribution $q(\mathbf{z})$ due to intractability of $p(\mathbf{z})$. For simplicity we assume that $q(\mathbf{z})$ factorizes over independent Gaussian random variables as $q(\mathbf{z}) = \prod_{m=1}^{M} q(z_m)$, where the variational distribution over z_m is given by the unit Gaussian $z_m \sim \mathcal{N}(\mathbf{0}, \mathbf{I})$. Here $\mathcal{L}_z$ is estimated with the standard Monte-Carlo sampling:

$$\mathcal{L}_z \approx \frac{1}{S} \sum_{m=1}^{M} \sum_{s=1}^{S} \mathrm{KL}\big(p_\theta(z_m|t_{m-1}^{(s)}, \mathbf{x}) \parallel q(z_m)\big). \tag{8}$$

We reduce the distance between the proposed distribution $r_\gamma(\mathbf{t}|\mathbf{z})$ and a uniform distribution $\mathcal{U}(\mathbf{t})$:

$$\mathcal{L}_t = \mathbb{E}_{p_\mathcal{D}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})r_\gamma(\mathbf{t}|\mathbf{z})} \log \frac{r_\gamma(\mathbf{t}|\mathbf{z})}{\mathcal{U}(\mathbf{t})}. \tag{9}$$

The Kullback-Leibler (KL) divergence terms in Eq. 7 and Eq. 9 help avoid overfitting. An alternative interpretation for these regularization terms is discarding the task-irrelevant information. We combine Eqs. 3, 4, 7 and 9 to at our final objective

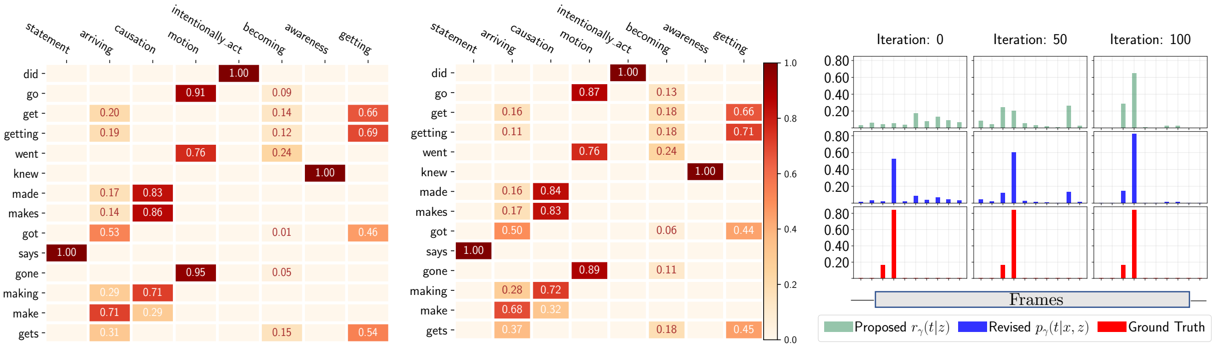
$$\mathcal{L}^U = \mathcal{L}_y + \alpha\mathcal{L}_\mathcal{I} + \beta\mathcal{L}_z + \zeta\mathcal{L}_t, \tag{10}$$

where β and ζ denote the trade-off parameters, and can be set empirically, as described in Appendix I.

3.4 Architecture For Event Modeling

To ensure fair comparisons, we focus on the reconstruction task similar to a β-VAE framework (Higgins et al., 2016). The overall structure is depicted in Fig. 2. Following previous work on event modeling (Pichotta and Mooney, 2016; Rezaee and Ferraro, 2021; Weber et al., 2018b; Gao et al., 2022), we represent each document $\mathbf{x}$ as a sequence of M events, where each event is a 4 tuple of predicate (verb), two main arguments (subject and object), and a modifier (if applicable). Each event is associated with a discrete semantic frame. E.g., *convicted man murdering of* is an event and the semantic frame is [VERDICT]. All the possible frames are collected in a vocabulary of size T. In this setting, we obtain a point estimate for $p_\mathcal{D}(t_m|x_m)$ as $\delta(x_m, t_m)$. Sampling from this empirical distribution outputs a one-hot vector of dimension T. The proposed distribution $r_\gamma(t|z)$ is a Gumbel-Softmax distribution. We found that the Gumbel-Softmax algorithm is particularly suitable for our task because it can effectively approximate discrete distributions and backpropagate gradients. While experiments with the Straight-Through Gumbel-Softmax (STGT) yielded near identical performance to the Gumbel-Softmax method, we opted for the latter. STGT generates one-hot vectors during the forward pass, but requires an approximation of the gradient using Gumbel-Softmax samples. By setting a low temperature of 0.5, the generated Gumbel-Softmax samples become almost identical to one-hot vectors, eliminating the need for gradient approximation. The effects on the gradient were carefully analyzed and the results are presented in Damadi and Shen (2022), where a comprehensive study of gradient properties was conducted. To learn richer representations, we define an embedding matrix $\mathbf{E} \in \mathbb{R}^{T \times d_t}$, to convert a simplex frame into a vector representation as $e_m = t_m^T\mathbf{E}$.

Encoding and Decoding With data point $\mathbf{x} \sim p_\mathcal{D}(\mathbf{x})$, we encode the whole sequence into recurrent hidden representations $\mathbf{H} = \{h\}_{t=1}^{T}$. For each event m, we draw Gaussian random variable $z_m \sim \mathcal{N}(\mu_m, \sigma_m)$ where μ_m and σ_m are the outputs of attention layers over frame embedding e_{m-1} and hidden states $\mathbf{H}$. We use a linear mapping over z_m to compute Gumbel softmax parameters for the proposed distribution $r_\gamma(t_m|z_m)$. Given the proposed distribution $r_\gamma(t_m|z_m)$ and the empirical distribution $p_\mathcal{D}(t_m|x_m)$, we first draw a Bernoulli sample $\hat{\lambda}_m$, then we draw knowledge sample from the mixture of probabilities by $t_m \sim p_\gamma(t_m|x_m, z_m; l_m)$. From the encoding phase, all the embedding vectors are gathered into $\mathbf{e} = \{e_m\}_{m=1}^{M}$. At generation time, analogously to the encoder, we use an attention layer over the decoder recurrent hidden state h and frame embeddings $\mathbf{e}$, resulting in decoder logits g. The generative distribution over possible next tokens is given by $x_t \sim p(x_t|g)$.



(a) Normalized samples from learned $r_\gamma(t|z)$ given predicates.

(b) Ground truth conditional distribution of semantic frames given predicates.

(c) The proposed and revised distributions converge to the ground truth distribution.

Figure 3: A demonstration of RevUp working on a small dataset with 10 frames. Ground truth frame distributions are shown in Fig. 3b, where in Fig. 3a we show that the distribution $r_\gamma(t|z)$ that RevUp learns very closely matches the ground truth. In Fig. 3c, we show how RevUp affects both the proposed and revised distributions. Initially, the $r_\gamma(t|z)$ prediction is random. After 50 iterations it is closer to the revised distribution $p_\gamma(t|z,x)$. After 100 iterations of training, both of them get close to the ground truth distribution.

(d) Wikipedia F1 score

Figure 4: RevUp vs SSDVAE accuracy for sequential semantic frame classifications for NYT and Wikipedia dataset. See Appendix H for full results. For all degree of observation probabilities, RevUp outperforms the baseline.

4 Experimental Results

Following previous work (Rezaee and Ferraro, 2021), we experiment on event modeling tasks using Concretely Annotated versions of New York Times Gigaword (NYT) and Wikipedia datasets (Ferraro et al., 2014). Both are English and have FrameNet semantic frames provided via SemaFor (Das et al., 2014). We perform a direct comparison with the previous state-of-the-art work (Rezaee and Ferraro, 2021) by using the same frame types, which were derived from the FrameNet annotations on Wikipedia articles. Training, validation and test splits for NYT and Wikipedia have 320k/17k/7k and 240k/8k/11k documents, respectively. For both the validation and test phases we set $l_m = 0$ (unsupervised). We average results over three runs (standard deviations in the appendix). We tuned the hyperparameters on the validation dataset. See Appendix I for additional implementation and data details.

4.1 Small Dataset Example

We first examine RevUp by examining its behavior on a small, focused example dataset. We sampled 400 newswire documents from the NYT dataset. We trained a RevUp model, with 10 semantic frame types (10 options for each t) and where each z was 100 dimensional. To obtain the ground-truth distributions of frames given events, we just focus on the predicates and collect all the semantic frames given that specific predicate. We carefully selected the frame types and data to reflect a diverse range of difficulties. For example, events including the *did* predicate are always associated with the INTENTIONALLY_ACT frame and the corresponding semantic frames for the *gets* predicate are ARRIVING, BECOMING and GETTING. RevUp predictions are acquired from the revised distribution $r_\gamma(t|z)$: given an event x we first draw a Gaussian sample z and then use $\text{argmax}(t)$ to find the proposed index. Finally, we normalize across all the proposed frames. We visualize the revision and update steps for the predicate "*made*" in Fig. 3c.

As evidenced by Eq. 4, the minimization of the KL-divergence between the proposed distribution $r_\gamma(t|z)$ and the revised distribution $p_\gamma(t|x,z)$ results in the elimination of non-essential information. Fig. 3c gives a visual representation of this phenomenon. At iteration 0, the proposed distribution $p_\gamma(t|x,z)$ is almost uniform, while the revised distribution $r_\gamma(t|z)$ is more aligned with the ground distribution. With additional iterations, reaching 100, the gap between these distributions reduces, ultimately leading to convergence with the ground truth for both distributions.

Additionally, our framework is able to effectively capture the conditional distribution of frames given predicates in diverse scenarios, as demonstrated in the heatmap figures in Figs. 3a and 3b. For instance, certain predicates such as “did,” “says,” and “knew” have a single associated frame of “intentionally_act,” “awareness,” and “statement,” respectively. Meanwhile, the predicate “made” has two possible semantic frames of “arriving” and “causation.” In some cases, such as the predicate “get,” there are even three possible frames of “arriving,” “becoming,” and “getting.” The comparison between the ground truth distribution of frames given predicates and the normalized samples highlights the accuracy of our model in capturing these conditional distributions, with minimal error.

4.2 Baselines

We compare the proposed RevUp method with the following event modeling approaches. (a) **RNNLM** (Pichotta and Mooney, 2016): A Bidirectional GRU cell with two layers, hidden dimension of 512, gradient clipping at 5 and Glove 300 embeddings to represent words. We used the implementation provided in (Weber et al., 2018b). (b) **HAQAE** (Weber et al., 2018b): An unsupervised VAE-based method for script learning and generation. They use vector quantization (VQ–VAE) to define a hierarchical discrete latent space. (c) **SSDVAE** (Rezaee and Ferraro, 2021) A semi–supervised VAE-based model. They utilize Gumbel softmax and use the parameter injection to incorporate the side knowledge. The architecture of our model largely follows the SSDVAE and HAQAE models with minor modification; see Appendix I.

4.3 Effect of Noisy Knowledge

We empirically compare the predictive performance of RevUp and SSDVAE with noisy knowledge. To do so, in a fully supervised setting, for each event x_m, instead of using the associated semantic frame t_m, with probability η we replace t_m with a random semantic frame $\hat{t}_m$. We train both models with this new training dataset. During the testing phase, we compare the predicted knowledge with ground-truth one. Results in Table 1 show that classification and parameter injection in SSDVAE are not enough for capturing knowledge. These results validate the effectiveness of our information capturing strategy when the external knowledge is noisy. As we increase η, SSDVAE performance degrades much more than RevUp. As an instance when $\eta = 0.9$, SSDVAE's accuracy is almost zero but our proposed model can achieve 0.41.

model	η	Wiki		NYT	
		Acc	F1	Acc	F1
SSDVAE	0.1	0.77	0.43	0.76	0.55
RevUp		**0.85**	**0.58**	**0.83**	**0.71**

RevUp		**28.33**	**34.85**

Table 2: Test perplexity results, varying the percent ϵ of side knowledge that was observed during training. We present standard deviations in Appendix H (table 4).

4.4 Effect of Incomplete Knowledge

We consider the case of semi-supervised learning, where with probability ϵ a node t_m is observed. We report the classifications on the latent nodes as $\mathrm{KL}\big(p_{\mathcal{D}}(\mathbf{t}|\mathbf{x}) \;\|\; r_\gamma(\mathbf{t}|\mathbf{x})\big) \approx -\mathbb{E}_{p_{\mathcal{D}}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})p_{\mathcal{D}}(\mathbf{t}|\mathbf{x})} \log r_\gamma(\mathbf{t}|\mathbf{z})$. The results are shown in Fig. 4. We report two widely-used classification metrics including accuracy and F1 to evaluate the performance of all methods. SSDVAE just relies on the guidance and classification but RevUp also uses the updating phase to shift the available knowledge from side information into latent variables. Thus the results demonstrate the superiorities of RevUp to predict knowledge when they are partially observed, attributable to its novel information injection and learning.

To investigate whether the proposed approach works for task representation, we compare the perplexity of our approach to prior work in Table 2. Perplexity has been commonly used in the literature, which allows us to provide a fair comparison with previous efforts. We investigate the effect of supervision with various observation probabilities $\epsilon = 0.0$ (unsupervised), 0.1, 0.7 and 1.0 (fully supervised) on the generated samples from the model. We see that our model is able to obtain lower perplexity scores than the previous event modeling methods. We observe as ϵ increases, the performance of our proposed model improves. For each observation probability, our method outperforms SSDVAE. The results demonstrate that our method achieves state-of-the-art performance with large margins from the baselines.

5 Related Work

Information Bottleneck The concept of using side information for discrete source coding was explored by Wyner (1975); Wyner and Ziv (1976). The Information Bottleneck (IB) principle was then introduced by (Tishby et al., 2000) to compress input variables while predicting a target. Chechik and Tishby (2002) proposed incorporating negative side information through an auxiliary loss in a supervised manner. Our method stands apart by handling both supervised and semi-supervised settings with ease. The Variational Information Bottleneck (VIB) was introduced by Alemi et al. (2016), which improved the IB estimation through amortized variational methods. Voloshynovskiy et al. (2020) extended the VIB method for semi-supervised classification. In relation to our work, there have been numerous studies focused on maximizing the mutual information between different views and discarding the non-shared information (Federici et al., 2019; Wan et al., 2021; Wang et al., 2019; Mao et al., 2021; Yan et al., 2019).

Variational Autoencoders (VAEs) Kingma and Welling (2013) and Rezende et al. (2014) introduced the reparameterization technique for variational inference. Recently, Huang and Xiao (2021) applied adversarial training to enhance the ability of VAE in processing sequential data, while Qiu et al. (2020) explored the possibility of VAE handling multi-view temporal data. Our focus is limited to objectives that can be expressed with discrete latent variables.

Jang et al. (2016) and Maddison et al. (2016) independently presented the Gumbel-Softmax distribution, which allows backpropagation through latent discrete variables in variational autoencoders. For more information, refer to the review by Huijben et al. (2022). Van Den Oord et al. (2017) proposed VQ-VAE, which uses vector quantization to represent discrete values with embeddings.

Kingma et al. (2014) proposed a VAE for semi-supervised classification, where labels in unsupervised settings are treated as latent variables and predicted when available. Joy et al. (2022) later improved this approach by separating latent variables to differentiate label characteristics from values. Lo and Lim (2020) modified the VAE objective to incorporate external knowledge with embedding vectors, and Feng et al. (2020) proposed a new ELBO to incorporate label prediction loss.

Event Modeling In recent years, much research has been dedicated to the challenge of modeling the sequence of events (Weber et al., 2018b; Rezaee and Ferraro, 2021; Gao et al., 2022). One such contribution was made by Weber et al. (2018a), who introduced a tensor-based composition to effectively capture semantic event relations. Gao et al. (2022) proposed a self-supervised contrastive learning approach based on co-occurring events. Another approach suggested by Weber et al. (2018b) involves the use of Recurrent Neural Networks (RNNs) to model the hierarchical latent structures that exist in sequences of events. This methodology was further developed in a subsequent study by Rezaee and Ferraro (2021), where external knowledge was incorporated into the latent layer for enhanced modeling, which is highly relevant to our proposed approach.

6 Conclusion

We show how to incorporate noisy partially observed side knowledge source along with latent variables. To do so, we generalized the main idea of parameter injection and maximizing the mutual information between external knowledge and latent variables. Our experiments show that our approach is more robust to noisy knowledge and outperform other baselines for the event modeling task

7 Limitations

Some limitations of our work are that multiple hyper parameters should be tuned for each task. While we provide guidance and insights into effective settings (and some intuition as to why), we acknowledge that the settings may be domain dependent.

Because we use semantic frames as our side knowledge, our focus is on improving the representation and use of discrete latent variables. While current NLP approaches have often focused on text-to-text methods for input and output, and individual words in text can be considered a form of discrete latent variables, we note that these methods are driven by large continuous embedding methods. While we believe this work can be extended to continuous cases, the approximations did make use of aspects of discrete variables, and they would need to be re-derived.

RevUp depends on mixing in statistics and learned representations from external side knowledge. While we envision this side knowledge as containing useful generalizations and semantic information, such resources could encode overly broad generalizations or other biases. While the degree of this mixture can be adjusted, imperfections or biases in the external knowledge could be captured and propagated through RevUp.

We focus on the task of event modeling, but we believe RevUp represents a step towards improving settings where noisy side information is available.

A Information Bottleneck Principle (IB)

Given its importance to our effort, we restate the information bottleneck principle, and discuss how it ties in with our loss formulation. Then, in subsequent appendices (App. B to D) we step through individual subloss terms.

Given the original input data $\mathbf{x}$ with the target $\mathbf{y}$, IB aims to extract a compact representation of $\mathbf{x}$ that is most informative about the target $\mathbf{y}$ via maximizing $\mathcal{I}(y;z) - \beta\mathcal{I}(x;z)$. The first term $\mathcal{I}(y;z)$ motivates the model to predict y, whilst the second term $\mathcal{I}(x;z)$ aims at discarding irrelevant information from the input x. The hyperparameter β can be set or tuned to adjust the relative importance of discarding irrelevant information. In our framework, we have a generalized version of IB as follows

$$\begin{aligned}\mathcal{L} = &-\mathcal{I}(\mathbf{y};\mathbf{t}) + \alpha\mathcal{I}(\mathbf{x};\mathbf{t}|\mathbf{z}) \\ &+ \beta\mathcal{I}(\mathbf{x};\mathbf{z}) + \zeta\mathrm{KL}\big(r_\gamma(\mathbf{t}|\mathbf{z}) \parallel \mathcal{U}(\mathbf{t})\big). \quad (11)\end{aligned}$$

Our generalized version accounts for additional random variables, and the associated dependencies. Here, $r_\gamma(\mathbf{t}|\mathbf{z})$ is the proposed distribution, $\mathcal{U}$ is a uniform distribution over $\mathbf{t}$. The KL term helps avoid overfitting.

B Regularization and Task Representation Derivation

Throughout we use the following inequality

$$\begin{aligned}&\mathbb{E}_{p(\mathbf{z},\mathbf{x})} \log \frac{q(\mathbf{z})}{p_\theta(\mathbf{z}|\mathbf{x})} \le \\ &\qquad \mathbb{E}_{p_\mathcal{D}(\mathbf{x})} \log \underbrace{\mathbb{E}_{p_\theta}(\mathbf{z}|\mathbf{x}) \frac{q(\mathbf{z})}{p_\theta(\mathbf{z}|\mathbf{x})}}_{1} = 0. \end{aligned} \quad (12)$$

The regularization term $\mathcal{I}(\mathbf{x};\mathbf{z})$ is

$$\begin{aligned}\mathcal{I}(\mathbf{x};\mathbf{z}) &= \mathbb{E}_{p(\mathbf{z},\mathbf{x})} \log \frac{p_\theta(\mathbf{z}|\mathbf{x})}{p(\mathbf{z})} \\ &\le \mathbb{E}_{p(\mathbf{z},\mathbf{x})} \log \frac{p_\theta(\mathbf{z}|\mathbf{x})}{q(\mathbf{z})} \end{aligned} \quad (13)$$

where since $p(\mathbf{z}) = \int p_\theta(\mathbf{z}|\mathbf{x}) p_\mathcal{D}(\mathbf{x})\, dx$ is intractable we use the inequality in Eq. 12. Now, we can approximate Eq. 13 as follows

$$\begin{aligned}&\mathbb{E}_{p_\mathcal{D}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})} \log \frac{p_\theta(\mathbf{z}|\mathbf{x})}{p(\mathbf{z})} \quad (14) \\ &= \mathbb{E}_{p_\mathcal{D}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})} \log \frac{\prod_{m=1}^{M} p_\theta(z_m|t_{m-1},\mathbf{x})}{\prod_{m=1}^{M} q(z_m)} \\ &= \sum_{m=1}^{M} \mathbb{E}_{p_\mathcal{D}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})} \log \frac{p_\theta(z_m|t_{m-1},\mathbf{x})}{q(z_m)} \\ &\approx \frac{1}{S} \sum_{m=1}^{M} \sum_{s=1}^{S} \mathrm{KL}\big(p_\theta(z_m|t_{m-1}^{(s)},\mathbf{x}) \parallel q(z_m)\big), \end{aligned} \quad (15)$$

where for simplicity we assume that $q(\mathbf{z})$ factorizes over independent random variables as $q(\mathbf{z}) = q(z_1, z_2, \ldots, z_M) = \prod_{m=1}^{M} q(z_m)$. We parameterize each z_m via a multivariate Normal, $q(z_m) = \mathcal{N}(\mathbf{0},\mathbf{I})$, and $p_\theta(z_m|z_{m-1}^{(s)},\mathbf{x}) = \mathcal{N}(\mu_m, \Sigma_m)$:

$$\begin{aligned}\mu_m &= f^\mu(z_{m-1}^{(s)},\mathbf{x}) \\ \Sigma_m &= f^\Sigma(z_{m-1}^{(s)},\mathbf{x}),\end{aligned}$$

where both f^μ and f^Σ are neural networks. With this formulation, we can calculate the KL-divergence terms of Eq. 15 in closed forms.

B.1 Approximating $\mathcal{I}(\mathbf{y};\mathbf{t})$ (Eq. 3)

In the same way for the task representation, we have

$$\begin{aligned}-\mathcal{I}(\mathbf{y};\mathbf{t}) &= -\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} \\ &\le -\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log \frac{q_\phi(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} \\ &\le -\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log q_\phi(\mathbf{y}|\mathbf{t}) + H(\mathbf{y}),\end{aligned} \quad (16)$$

where $H(\mathbf{y})$ is constant and we ignore it. We have:

$$\begin{aligned}&\mathbb{E}_{p(\mathbf{y},\mathbf{z},\mathbf{t})} \log q_\phi(\mathbf{y}|\mathbf{t}) \\ &= \mathbb{E}_{p_\mathcal{D}(\mathbf{x},\mathbf{y})p_\theta(\mathbf{z}|\mathbf{x})p_\gamma(\mathbf{t}|\mathbf{z})} \log q_\phi(\mathbf{y}|\mathbf{t}), \quad (17) \\ &\approx \frac{1}{S_z}\frac{1}{S_t} \sum_{s_z=1}^{S_z} \sum_{s_t=1}^{S_t} \log q_\phi(\mathbf{y}|\mathbf{t}^{(s_t)}), \quad (18)\end{aligned}$$

where we first sample $\mathbf{x}, \mathbf{y} \sim p_\mathcal{D}(\mathbf{x},\mathbf{y})$, then $\mathbf{z}^{(s_z)} \sim p_\theta(\mathbf{z}|\mathbf{x})$ and finally $\mathbf{t}^{(s_t)} \sim r_\gamma(\mathbf{t}|\mathbf{z}^{(s_z)})$. In this approximation S_z and S_t are the total number of samples for $\mathbf{z}$ and $\mathbf{t}$ respectively.

We wish to clarify why this term is included in the objective and how optimizing it affects the model parameters. The answer is that in computing $\mathcal{I}(\mathbf{y};\mathbf{t})$, the distribution used to compute the mutual information's expectation depends on the proposed distribution r_γ. This is by construction and irrespective of whether side information is present or not. This is where the model parameters come in.

Specifically, while by definition $\mathcal{I}(\mathbf{y};\mathbf{t}) = \mathbb{E}_{\mathbf{p(y,t)}} \frac{\mathbf{logp(y|t)}}{\mathbf{p(y)}}$, because $p(|\mathbf{t})$ does not depend on a (free) $\mathbf{z}$, we can compute $mut(\mathbf{y};\mathbf{t}) = \mathbb{E}_{\mathbf{p(y,z,t)}} \frac{\mathbf{logp(y|t)}}{\mathbf{p(y)}}$. This follows from the fact that for random variables u and v, $\mathbb{E}_{p(u,v)}[f(u)] = \mathbb{E}_{p(u)}[f(u)]$. With this, we can then write

$$
\begin{aligned}
\mathcal{I}(\mathbf{y};\mathbf{t}) &= \mathbb{E}_{p(\mathbf{y},\mathbf{t})} \log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} \\
&= \mathbb{E}_{p(\mathbf{y},\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} && (19) \\
&= \mathbb{E}_{\left\{p_{\mathcal{D}}(\mathbf{x},\mathbf{y})p(\mathbf{z},\mathbf{t}|\mathbf{x})\right\}} \log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})} && (20) \\
&= \mathbb{E}_{\left\{p_{\mathcal{D}}(\mathbf{x},\mathbf{y}) \prod_{m=1}^{M} p_\theta(z_m|t_{m-1},\mathbf{x}) {\color{red}p_\gamma(t_m|x_m,z_m;l_m)}\right\}} && (21) \\
&\log \frac{p(\mathbf{y}|\mathbf{t})}{p(\mathbf{y})}. && (22)
\end{aligned}
$$

This red term, $p_\gamma(t_m|x_m, z_m; l_m)$, is defined as the interpolation of a proposal distribution $r_\gamma(t_m|z_m)$ and an empirical distribution $t_m|x_m$. Defined as a GumbelSoftmax, this proposal distribution explicitly allows uncertainty. Therefore, even when side information is present, we sample the value of t_m to approximate that final expectation.

Finally, as mentioned in the paper, this last line is intractable, so we learn an approximation $q_\phi(y|t)$, which introduces additional model parameters to learn. We compute q_ϕ using the sampled values $t_1 ... t_M$.

C Update Step Upperbound

In this section, we show how we approximate the update term $\mathcal{I}(\mathbf{x};\mathbf{z}|\mathbf{z})$ in Eq. 4. We have the following

$$
\begin{aligned}
\mathcal{I}(\mathbf{t};\mathbf{x}|\mathbf{z}) &= \mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{z},\mathbf{x})} \log \frac{p_\gamma(\mathbf{t},\mathbf{x}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})p(\mathbf{x}|\mathbf{z})} \\
&= \mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})p(\mathbf{x}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})p(\mathbf{x}|\mathbf{z})} \\
&= \mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})}{p(\mathbf{t}|\mathbf{z})} && (23) \\
&\leq \mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})}{r_\gamma(\mathbf{t}|\mathbf{z})}, && (24)
\end{aligned}
$$

First, we should note that in Eq. 23, the distribution $p(\mathbf{t}|\mathbf{z})$ is not equal to $r_\gamma(\mathbf{t}|\mathbf{z})$, because for each node m, we have

$$
\begin{aligned}
p(t_m|z_m) &= \int p(t_m, x_m|z_m)\, dx_m \\
&= \int p(t_m|x_m, z_m)p(x_m|z_m)\, dx_m \\
&= \int \hat{\lambda}_m r_\gamma(t_m|z_m)p(x_m|z_m)\, dx_m + \\
&\int (1-\hat{\lambda}_m)p_{\mathcal{D}}(t_m|x_m)p(x_m|z_m)\, dx_m \\
&\neq r_\gamma(t_m|z_m). && (25)
\end{aligned}
$$

Our the last step of estimation in Eq. 24 is

$$
\begin{aligned}
&\mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})}{p(\mathbf{t}|\mathbf{z})} \leq \\
&\mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})}{r_\gamma(\mathbf{t}|\mathbf{z})}. && (26)
\end{aligned}
$$

The proof for Eq. 26 is as follows.

$$
\begin{aligned}
&\mathbb{E}_{p(\mathbf{t},\mathbf{x},\mathbf{z})} \log \frac{r_\gamma(\mathbf{t}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})} \\
&= \mathbb{E}_{p(\mathbf{t},\mathbf{z})} \log \frac{r_\gamma(\mathbf{t}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})} \\
&= \mathbb{E}_{p(\mathbf{z})}\mathbb{E}_{p(\mathbf{t}|\mathbf{z})} \log \frac{r_\gamma(\mathbf{t}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})} \\
&\leq \mathbb{E}_{p(\mathbf{z})} \log \Big\{ \underbrace{\mathbb{E}_{p(\mathbf{t}|\mathbf{z})} \frac{r_\gamma(\mathbf{t}|\mathbf{z})}{p(\mathbf{t}|\mathbf{z})}}_{1} \Big\} \\
&= 0
\end{aligned}
$$

D Update State Approximation for Discrete Case

We show how we approximate the upperbound presented in Eq. 24.

$$
\begin{aligned}
&\mathbb{E}_{p_\gamma(\mathbf{t},\mathbf{z},\mathbf{x})} \log \frac{p_\gamma(\mathbf{t}|\mathbf{z},\mathbf{x})}{r_\gamma(\mathbf{t}|\mathbf{z})} \\
&= \underbrace{\mathbb{E}_{p_{\mathcal{D}}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})p_\gamma(\mathbf{t}|\mathbf{z},\mathbf{x})} \log p_\gamma(\mathbf{t}|\mathbf{z},\mathbf{x})}_{\textcircled{\scriptsize A$_1$}} \\
&- \underbrace{\mathbb{E}_{p_{\mathcal{D}}(\mathbf{x})p_\theta(\mathbf{z}|\mathbf{x})p_\gamma(\mathbf{t}|\mathbf{z},\mathbf{x})} \log r_\gamma(\mathbf{t}|\mathbf{z})}_{\textcircled{\scriptsize A$_2$}}. && (27)
\end{aligned}
$$

Here $\textcircled{A_1}$ is the negative entropy of the revised distribution $p_\gamma(\mathbf{t}|\mathbf{x},\mathbf{z})$:

$$\textcircled{A_1} = -H(\mathbf{t}|\mathbf{x},\mathbf{z}) \tag{28}$$

$$= -\sum_{m=1} H(t_m|x_m,z_m). \tag{29}$$

For the second term we have:

$$\begin{aligned}\textcircled{A_2} &= \mathbb{E}_{p_\mathcal{D}(\mathbf{x})}\mathbb{E}_{p_\theta(\mathbf{z}|\mathbf{x})}\Big[\hat{\lambda}\mathbb{E}_{r_\gamma(\mathbf{t}|\mathbf{z})}+ \\ &\qquad (1-\hat{\lambda})\mathbb{E}_{p_\mathcal{D}(\mathbf{t}|\mathbf{x})}\Big]\log r_\gamma(\mathbf{t}|\mathbf{z}) \\ &= \hat{\lambda}\,\underbrace{\mathbb{E}_{p_\mathcal{D}(\mathbf{x})}\mathbb{E}_{p_\theta(\mathbf{z}|\mathbf{x})}\mathbb{E}_{r_\gamma(\mathbf{t}|\mathbf{z})}\log r_\gamma(\mathbf{t}|\mathbf{z})}_{\textcircled{A_{21}}} \\ &+ (1-\hat{\lambda})\,\underbrace{\mathbb{E}_{p_\mathcal{D}(\mathbf{x})}\mathbb{E}_{p_\mathcal{D}(\mathbf{t}|\mathbf{x})}\log r_\gamma(\mathbf{t}|\mathbf{z})}_{\textcircled{A_{22}}}.\end{aligned} \tag{30}$$

Similarly $\textcircled{A_{21}}$ is the entropy of the proposed distribution $r_\gamma(\mathbf{t}|\mathbf{z})$:

$$\textcircled{A_{21}} = -H(\mathbf{t}|\mathbf{z}) \tag{31}$$

$$= -\sum_{m=1}^{M} H(t_m|z_m) \tag{32}$$

Also $\textcircled{B_{22}}$ guides the model to discriminator $\mathbf{t}$ given $\mathbf{z}$ which is a classifier. To compute the entropy terms, in the discrete case (Gumbel Softmax), we use Monte Carlo sampling as follows

$$H(t_m|x_m,z_m) \approx \frac{1}{S}\sum_{n=1}^{N}\sum_{s=1}^{S}\hat{\gamma}_m^{\top(s)}\log\hat{\gamma}_m^{(s)}, \tag{33}$$

$$H(t_m|z_m) \approx \frac{1}{S}\sum_{s=1}^{S}\gamma_m^{\top(s)}\log\gamma_m^{(s)}, \tag{34}$$

where S is the number of point estimates and $\hat{\gamma}_m$ is derived from Eq. 35. Here, we have defined $\hat{\gamma}$ to be $[\hat{\lambda}\gamma_1, \hat{\lambda}\gamma_2, \ldots, \hat{\lambda}\gamma_{k^*} + (1-\hat{\lambda}), \ldots, \hat{\lambda}\gamma_K]$. The $\hat{\gamma}$ can be thought of as a mixture of the γ and empirical categorical distributions. (We use this definition of $\hat{\gamma}$ in the proof of Theorem 1 in Appendix F.) To sample from the revised distribution $p_\gamma(t_m|\mathbf{x},\mathbf{z};l_m)$ we first draw a Bernoulli sample $\hat{\lambda}_m \sim \text{Bern}(\hat{\lambda}_m; 1/(1+\lambda l_m))$ and consequently we draw knowledge sample from the mixture of probabilities by $t_m \sim \hat{\lambda}_m r_\gamma(t_m|z_m) + (1-\hat{\lambda}_m)p_\mathcal{D}(t_m|x_m)$. We implement this with a single-sample approximation.

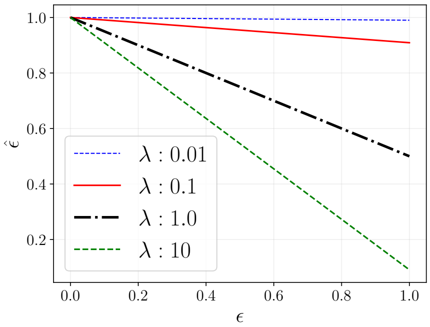

Figure 5: Effect of λ and observation probability ϵ on $\hat{\epsilon}$

E Revision Step Property of $p_\gamma\left(t_m|x_m,z_m;l_m\right)$

In this section we show how the formulation of $p_\gamma\left(t_m|x_m,z_m;l_m\right)$ leads to the property that, during the revision step, we rely more on the available side/external knowledge as more of it becomes available. Recall that we initially defined $p_\gamma\left(t_m|x_m,z_m;l_m\right) = \frac{1}{1+\lambda l_m}r_\gamma(t_m|z_m) + \frac{\lambda l_m}{1+\lambda l_m}p_\mathcal{D}(t_m|x_m)$, where λ allows a fractional portion of the empirical distribution $p_\mathcal{D}$ to influence the learned model. Suppose that $l_m \sim \text{Bern}(\epsilon)$ and $\tilde{\lambda} = 1/(1+\lambda)$, given node m we have

$$\begin{aligned}p(t_m|x_m,z_m) &= \sum_{l_m} p(t_m|x_m,z_m,l_m)p(l_m) \\ &= \epsilon p_\gamma(t_m|x_m,z_m,l_m) + (1-\epsilon)r_\gamma(t_m|z_m) \\ &= \epsilon\left[\tilde{\lambda}r_\gamma(t_m|z_m) + (1-\tilde{\lambda})p_\mathcal{D}(t_m|x_m)\right] \\ &\qquad + (1-\epsilon)r_\gamma(t_m|z_m) \\ &= \left(1-\epsilon(1-\tilde{\lambda})\right)r_\gamma(t_m|z_m) \\ &\qquad + \epsilon(1-\tilde{\lambda})p_\mathcal{D}(t_m|x_m) \\ &= \hat{\epsilon}r_\gamma(t_m|z_m) + (1-\hat{\epsilon})p_\mathcal{D}(t_m|x_m),\end{aligned}$$

where $\hat{\epsilon} = 1-\epsilon(\frac{\lambda}{1+\lambda})$. In particular, this formulation allows us to account for both our estimate of observation of side knowledge, and the extent to which we wish to use it when learning our model. In Fig. 5, we show the effect of λ and ϵ on $\hat{\epsilon}$.

F Generalization of SSDVAE (Proof of Theorem 1)

We show that under specific setting, our model reduces to the SSDVAE parameter injection mechanism.

Theorem. *If* $r_\gamma(t|z) = \mathit{Cat}(\gamma)$ *, a categorical distribution with parameters* γ*, and the empirical dis-*

tribution $p_{\mathcal{D}}(t|x)$ is a one-hot representation with $t_{k^*} = 1$, the revision step reduces to SSDVAE parameter injection.

Proof. Using the interpolation form $p_\gamma(t_m|x_m, z_m; l_m) = \hat{\lambda}_m r_\gamma(t_m|z_m) + (1 - \hat{\lambda}_m) p_{\mathcal{D}}(t_m|x_m)$ and due to the fact that the mixture of categorical distributions is a single categorical, we have $p(t|x, z; l = 1) = \mathrm{Cat}(\hat{\gamma})$, where

$$\hat{\gamma} = [\hat{\lambda}\gamma_1, \hat{\lambda}\gamma_2, \ldots, \hat{\lambda}\gamma_{k^*} + (1 - \hat{\lambda}), \ldots, \hat{\lambda}\gamma_K]. \tag{35}$$

Given $0 \leq \gamma_i \leq 1$ and $0 \leq \hat{\lambda} \leq 1$, we have $\hat{\lambda}\gamma_i \leq \gamma_i$ $(\forall i \neq k^*)$, and $\hat{\lambda}\gamma_{k^*} + (1 - \hat{\lambda}) \geq \gamma_{k^*}$. This implies that for all the indices $i \neq k^*$, the value of γ_i is reduced and γ_{k^*} is increased, confirming that parameter injection is a specific form of our definition. □

G Updating Step Maximizes Mutual Information (Proof of Theorem 2)

We show that for the reconstruction tasks, where $\mathbf{y}$ is a copy of $\mathbf{x}$, minimizing $\mathcal{I}(\mathbf{x}; \mathbf{t}|\mathbf{z})$ maximizes $\mathcal{I}(\mathbf{t}; \mathbf{z})$. While not explicitly reflected in our model definition, note that $\mathcal{I}(\mathbf{t}; \mathbf{z})$ is intractable. This can be seen in the definition of $\mathcal{I}(\mathbf{t}; \mathbf{z})$,

$$\mathcal{I}(\mathbf{t}; \mathbf{z}) = \mathbb{E}_{p(\mathbf{t},\mathbf{z})} \log \frac{p(\mathbf{t}|\mathbf{z})}{p(\mathbf{t})}, \tag{36}$$

here both $p(\mathbf{t}, \mathbf{z})$ and $p(\mathbf{t})$ are intractable due to the integral over $\mathbf{x}$. Following Cover (1999), the mutual information between three random variables $\mathbf{x}$, $\mathbf{t}$, and $\mathbf{z}$ can be defined as

$$\mathcal{I}(\mathbf{x}; \mathbf{t}; \mathbf{z}) = \mathcal{I}(\mathbf{x}; \mathbf{t}) - \mathcal{I}(\mathbf{x}; \mathbf{t}|\mathbf{z}). \tag{37}$$

Eq. 37 is symmetric in $\mathbf{x}$, $\mathbf{t}$ and $\mathbf{z}$, so we have:

$$\mathcal{I}(\mathbf{x}; \mathbf{t}; \mathbf{z}) = \mathcal{I}(\mathbf{t}; \mathbf{z}) - \mathcal{I}(\mathbf{t}; \mathbf{z}|\mathbf{x}). \tag{38}$$

As already proven by Federici et al. (2019), the second term $\mathcal{I}(\mathbf{t}; \mathbf{z}|\mathbf{x})$ equals to zero. Combining Eq. 37 and Eq. 38, we have

$$\mathcal{I}(\mathbf{x}; \mathbf{t}) - \mathcal{I}(\mathbf{x}; \mathbf{t}|\mathbf{z}) = \mathcal{I}(\mathbf{t}; \mathbf{z}) \tag{39}$$

As evident from Eq. 39, maximizing $\mathcal{I}(\mathbf{x}; \mathbf{t})$ and minimizing $\mathcal{I}(\mathbf{x}; \mathbf{t}|\mathbf{z})$ is equivalent to maximizing $\mathcal{I}(\mathbf{t}; \mathbf{z})$.

H Full Results

In this section, we present the full results for those presented in the main paper. Specifically, the results presented here augment those in Fig. 4, Table 1, and Table 2.

Results on the Effect of Noisy Knowledge (η) In Table 3, we how the full results from our noisy knowledge experiments, shown in the main paper's Table 1. As with our other results, these are averaged over three runs. In our development we noticed that precision tended to be the main hindrance on F1, and therefore we additionally report precision.

Full Perplexity Results In Table 4, we how the full language modeling perplexity results that are shown in the main paper's Table 2. Here, we are showing results across both the dev and test sets. We also include standard deviation results (from three runs).

Full Results on Frame Classification In Table 5, we show the full results for the side knowledge (per-event frame) prediction experiments we reported in Fig. 4. The main classification results were averaged over three runs, along with standard deviation. These results are visible in Fig. 4, but we include the numeric values for any future comparisons.

I Setup/Implementation Details

The NYT dataset is available through the LDC and a research license, and the Wikipedia dataset is publicly available under a CC BY-NC 4.0 license. For both datasets, the token vocabulary size is 150k and the number of unique semantic frames is 600. In line with previous research (Rezaee and Ferraro, 2021), for the documents with more than 5 events, we used the first 5 events that had frames. Each model was trained using a single GPU (an RTX 2080 TI, TITAN RTX, or a Quadro 8000). Each RevUp model took approximately 12 hours to train.

We noticed that the observability of side knowledge can affect the relative importance of the loss terms in Eq. 10. Given a mini batch of training data, we define $\hat{\epsilon}$ as an approximation of ϵ. To do so, we calculate the number of observed frames over total frames. In all cases, high importance placed on the regularization term $\mathcal{L}_t$ (Eq. 9) was important to help prevent overfitting. When frames were frequently observed ($\hat{\epsilon} \geq 0.5$), the model needed to rely more heavily on the updating phase ($\mathcal{L}_{\mathcal{I}}$, Eq. 4) and the regularization on z ($\mathcal{L}_z$, Eq. 7) was less important; specifically, we found $\alpha = 0.3$, $\beta = 1\mathrm{e}-6$ and $\zeta = 0.7$ to be effective. Otherwise, we found the model needed to place small but relatively equal weight on the updating phase and z regularization components; specifically, we found

Table 4: Perplexity results on the Wikipedia and NYT datasets (extension of Table 2). Main results are the average of three runs, along with standard deviation.

$\alpha = 0.1$, $\beta = 0.2$ and $\zeta = 1.0$ to be effective. We obtained these values via experimentation on dev data.

Following SSDVAE and HAQAE models, we use pre-trained Glove 300 embeddings to represent tokens and used gradient clipping at 5.0 to prevent exploding gradients. We use a two-layer of bi-directional GRU for the encoder and a two-layer uni-directional GRU for the decoder (with a hidden dimension of 512 for both). We used early stopping (lack of validation performance improvement for 3 iterations).

Abstract

Natural language processing (NLP) has significant impact on society via technologies such as machine translation and search engines. Despite its success, NLP technology is only widely available for high-resource languages such as English and Mandarin Chinese, and remains inaccessible to many languages due to the unavailability of data resources and benchmarks. In this work, we focus on developing resources for languages of Indonesia. Despite being the second most linguistically-diverse country, most languages in Indonesia are categorized as endangered and some are even extinct. We develop the first-ever parallel resource for 10 low-resource languages in Indonesia. Our resource includes sentiment and machine translation datasets, and bilingual lexicons. We provide extensive analysis, and describe challenges for creating such resources. Our hope is that this work will spark more NLP research on Indonesian and other underrepresented languages.

1 Introduction

Indonesia is one of the most populous and linguistically-diverse countries in the world, with more than 700 languages spoken across the country (Aji et al., 2022; Eberhard et al., 2021). However, while many of these languages are spoken by millions of people they have received little attention from the NLP community. There are very few public datasets, preventing the global research community from exploring these languages. To this end, we introduce **NusaX**,[1] a high-quality multilingual parallel corpus that covers 10 local languages from Indonesia: Acehnese, Balinese, Banjarese, Buginese, Madurese, Minangkabau, Javanese, Ngaju, Sundanese, and Toba Batak.

The **NusaX** dataset was created by translating SmSA (Purwarianti and Crisdayanti, 2019) — an existing Indonesian sentiment analysis dataset containing comments and reviews from the IndoNLU benchmark (Wilie et al., 2020) — using competent bilingual speakers, coupled with additional human-assisted quality assurance. Sentiment analysis is one of the most popular NLP tasks, and has been explored in many applications in Indonesia, including presidential elections (Ibrahim et al., 2015; Budiharto and Meiliana, 2018), product reviews (Fauzi, 2019), stock forecasting (Cakra and Trisedya, 2015; Sagala et al., 2020), and COVID-19 monitoring (Nurdeni et al., 2021). By translating an existing text, we additionally produce a parallel corpus, which is useful for building and evaluating translation systems. As we translate from a regional high-resource language (Indonesian), we ensure that the topics and entities reflected in the data are culturally relevant to the other languages, which is generally not the case when translating an English dataset (Conneau et al., 2018; Ponti et al., 2020). We apply the corpus to two downstream tasks: sentiment analysis and machine translation. We use the new benchmark to assess the performance of existing Indonesian language models (LMs), multilingual LMs, and classical machine learning methods.

Our contributions are as follows:

- We propose NusaX, the first high-quality human annotated parallel corpus in 10 languages from Indonesia, and corresponding parallel data in Indonesian and English, covering the tasks of sentiment analysis and machine translation.
- We provide an extensive evaluation of deep learning and classical NLP/machine learning methods on downstream tasks in few-shot and full-data settings.
- We conduct comprehensive analysis of the languages under study both from linguistic

---

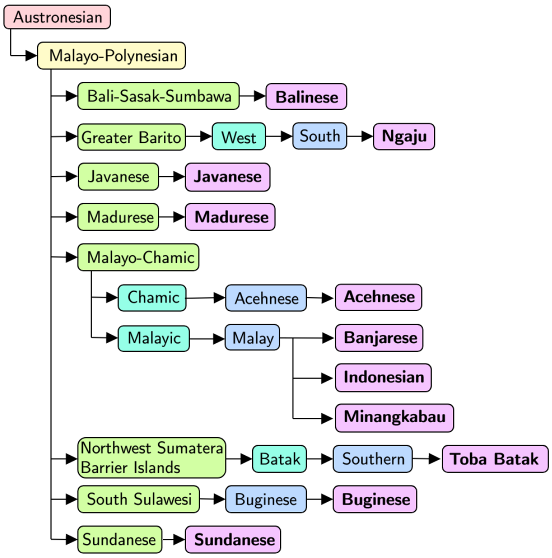

Figure 1: Language taxonomy of the 10 focus languages and Indonesian, according to Ethnologue (Eberhard et al., 2021). The color represents the language category level in the taxonomy. Purple denotes language, and other colors denote language family.

and empirical perspectives, the cross-lingual transferability of existing monolingual and multilingual LMs, and an efficiency analysis of various methods for NLP tasks in extremely low-resource languages.

2 Focus Languages

We work on 10 local languages in Indonesia: Acehnese, Balinese, Banjarese, Buginese, Madurese, Minangkabau, Javanese, Ngaju, Sundanese, and Toba Batak. Most of these languages have a population of over 2 million speakers (van Esch et al., 2022; Aji et al., 2022), but are underrepresented in NLP research. Figure 1 shows the taxonomy of these languages and Indonesian. Geographically, these languages are spoken on different big islands in Indonesia, including Sumatra, Borneo, Java, Madura, and Sulawesi. The languages belong to the Austronesian language family under the Malayo-Polynesian subgroup. While some of the covered languages are written in multiple scripts, we use the Latin script in NusaX, which has become predominant for all covered languages.

Indonesian (ind) is the national language of Indonesia based on the 1945 Constitution of the Republic of Indonesia (article 36). It is written in Latin script, and was developed from literary "Classical Malay" of the Riau-Johor sultanate (Sneddon, 2003), with regional variants. Its lexical similarity to Standard Malay is over 80%. It has a rich affixation system, including a variety of prefixes, suffixes, circumfixes, and reduplication. Most of the affixes in Indonesian are derivational (Pisceldo et al., 2008).

Acehnese (ace) is a language spoken mainly in the Aceh province. Although it is the de facto language of Aceh, language use is shifting to Indonesian in urban areas. Acehnese has features typical of the Mon-Khmer languages of mainland Southeast Asia, a result of its former status as part of the early Chamic dialect continuum on the coast of Vietnam. In addition to the large number of diphthongs, it has a high percentage of monosyllabic root morphemes.

Balinese (ban) is a language spoken mainly in the Bali province. It has three main dialects: Highland Balinese, Lowland Balinese, and Nusa Penida. Since the early 20th century, it has mainly been written in the Latin script, but also has its own Balinese script. The word order in Balinese is SVO. Balinese has three sociolinguistic registers (Arka, 2003).

Banjarese (bjn) is a language spoken in Kalimantan (Central, East, South, and West Kalimantan provinces). It is dominant in the South Kalimantan Province and is also growing rapidly in the Central and Eastern Kalimantan provinces. It has two main dialects: Kuala and Hulu. Although it is a Malayic language, it has many Javanese loanwords, probably acquired during the Majapahit period from the late thirteenth century until the fifteenth century (Blust et al., 2013). It has 73% of lexical similarity with Indonesian and is written in Arabic and Latin scripts (Eberhard et al., 2021).

Buginese (bug) is a language spoken mainly in the South Sulawesi, Southeast Sulawesi, Central Sulawesi, and West Sulawesi provinces. The word order is SVO. Verb affixes are used to mark persons. Historically, it was written in the Buginese script (derived from Brahmi script), but is mainly written in Latin script now (Eberhard et al., 2021). Buginese employs sentence patterns, pronouns, and other terms to express politeness (Weda, 2016).

Madurese (mad) is a language spoken in the East Java province, mainly on Madura Island, south and west of Surabaya city, Bawean, Kangean, and Sapudi islands. It has vowel harmony, gemination, rich affixation, reduplication, and SVO basic word order (Davies, 2010).

Minangkabau (min) is a language spoken mainly in West Sumatra and other provinces on Sumatra Island such as Bengkulu and Riau. Although it is classified as Malay, it is not intelligible with Indonesian. Standard Minangkabau voice can be characterised as an Indonesian-type system, whereas colloquial Minangkabau voice is more effectively characterised as a Sundic-type system (Crouch, 2009).

Javanese (jav) is a language spoken mainly on Java Island. It is the de facto language of provincial identity in central and eastern Java. The number of native Javanese speakers is greater than the number of Indonesian L1 speakers (Eberhard et al., 2021). Javanese consists of several regional dialects, which differ primarily in pronunciation and vocabulary. Javanese has an elaborate system of speech levels related to the relation of the speaker to the interlocutor that depend on social status, age, kinship distance, and familiarity (Wedhawati et al., 2001). It used to be written in Javanese script, but since the 20th century has mostly been written in Latin script.

Ngaju (nij) is a language spoken in the Central Kalimantan province. It is widely used as a language for trade in much of Kalimantan, from the Barito to the Sampit River. It has various affixes and reduplication, and its word order is similar to Indonesian. Pronouns have enclitic forms to mark possessors in a noun phrase or passive agents (Uchibori and Shibata, 1988).

Sundanese (sun) is a language spoken mainly in the Banten and West Java provinces. It is the de facto language of provincial identity in western Java. The main dialects are Bogor (Krawang), Pringan, and Cirebon. It has elaborate coding of respect levels. It has been written in Latin script since the mid-19th century but was previously written in Arabic, Javanese, and Sundanese scripts. Sundanese is a predominantly SVO language, and has voice marking and incorporates some (optional) actor-verb agreement, i.e., number and person (Kurniawan, 2013).

Toba Batak (bbc) is a language spoken in the North Sumatra province. Similarly to Acehnese, it is slowly being replaced by Indonesian in urban and migrant areas. It used to be written in the Batak script but is mainly written in Latin script now. The Batak languages are verb-initial, and have verb systems reminiscent of Philippine languages, although they differ from them in many details (Blust et al., 2013).

3 Data Construction

Our data collection process consists of several steps. First, we take an existing dataset in a high-resource local language (Indonesian) as a base for expansion to the other ten languages, and ask human annotators to translate the text. To ensure the quality of the final translation, we run quality assurance with additional human annotators.

3.1 Annotator Recruitment

Eliciting or annotating data in underrepresented languages generally requires working with local language communities in order to identify competent bilingual speakers (Nekoto et al., 2020). In the Indonesian setting, this challenge is compounded by the fact that most languages have several dialects. As dialects in Indonesian languages may have significant differences in word usage and meaning (Aji et al., 2022), it is important to recruit annotators who speak the same or similar dialects to ensure that translations are mutually intelligible.

In this work, we employ at least 2 expert annotators who are native speakers of each local language and Indonesian. To filter the recruited annotators, we first ask annotator candidates to translate three samples. We then conduct a peer review by asking whether they can understand the translations of other annotators for the same language, using the hired annotators as translators as well as translation validators. We also conducted 2 hours of training to introduce the user interface of the annotation system for selected workers. For English translations, we hire annotators based on their English proficiency test scores with an IELTS score ≥ 6.5 or TOEFL PBT score ≥ 600.

3.2 Data Filtering and Sampling

We base our dataset on SmSA, the largest publicly available Indonesian sentiment analysis dataset from the IndoNLU benchmark (Purwarianti and Crisdayanti, 2019; Wilie et al., 2020). SmSA is an expert-annotated sentence-level multi-domain sentiment analysis dataset consisting of more than 11,000 instances of comments and reviews collected from several online platforms such as Twitter, Zomato, and TripAdvisor. We filter the data to remove abusive language and personally-identifying information by manually inspecting all sentences. We randomly select 1,000 samples via stratified sampling for translation, ensuring that the label distribution is balanced.

3.3 Human Translation

We instructed the annotators to retain the meaning of the text and to keep entities such as persons, organizations, locations, and time with no target language translation the same. Specifically, we instructed them to: (1) maintain the sentence's sentiment polarity; (2) preserve entities; and (3) maintain the complete information content of the original text.

Initially, we asked the translators to maintain the typography. Most sentences from the original dataset are written in an informal tone, with non-standard spelling, e.g., elongated vowels and punctuation. When the sentence is translated into the target language, direct translation can sound unnatural. For example, translating the Indonesian word *kangeeeen* (originally *kangen*; en: *miss*) to *taragaaaak* (originally *taragak*) in Minangkabau may sound unnatural. Similarly, the original sentence may also contain typos. Due to the difficulty of accurately assessing typographical consistency of translations, we removed this as a criterion.

3.4 Human-Assisted Quality Assurance

We conduct quality control (QC) between two annotators by having annotator A check the translations of annotator B, and vice versa. We include the corrected translations in our dataset. To ensure the quality assurance is performed well, we randomly perturb 5% of the sentences by removing a random sequence of words. The quality assurance annotators are then expected to notice the perturbed sentences and fix them.

We analyze the quality assurance edits for Balinese, Sundanese, and Javanese, which are spoken by the authors of this paper. For each language, we randomly sample 100 translations that have been edited by a QC annotator. We classify edits as follows:

Typos and Mechanics: Edit that involves correcting typos, punctuation, casing, white spaces/dashes, and numerical formatting.

Orthography: Edit that changes the spelling of words due to orthographic variation in local languages without a standard orthography. The word sounds and means the same before and after editing, and both are used by natives. The QC annotator might feel that one writing variant is more natural/commonly used, and hence make this change.

Translation: The words used by the translator are still in Indonesian and the QC annotator translates them to the local language.

Word edit: The QC annotator paraphrases a word/phrase. This also includes adding/removing words and morpheme changes.

Major changes: Other edits that significantly alter the original translation.

The results are shown in Table 1. Generally, word edits make up the majority of QC modifications, which involve replacing a word/phrase with a synonym or altering a morpheme slightly. In contrast, major changes are extremely rare. We also see changes to the orthography around 10% of the time. Other types of edits vary between languages. Sundanese has significantly less typos compared to other languages, but a considerably higher number of translation edits. We suspect this is because code-switching with Indonesian happens regularly in Sundanese, which results in many Indonesian words being adopted despite the existence of equivalent Sundanese translations.

3.5 Bilingual Lexicon Creation

Bilingual lexicons are useful for data augmentation (Wang et al., 2022) and evaluating cross-lingual representations (Artetxe et al., 2018). We select 400 words from an Indonesian lexicon[2] to be translated into the 10 local languages and English. For each language, we employ two annotators and ask them to translate the word into all possible lexemes. The translations from both annotators are combined. We obtain 800–1,600 word pairs for each of our 11 language pairs (from Indonesian to the remaining languages). We augment the bilingual lexicon with data from PanLex (Kamholz et al., 2014).

---

4 NusaX Benchmark

4.1 Tasks

We develop two tasks — sentiment analysis and machine translation — based on the datasets covering 12 languages, including Indonesian, English, and the 10 local languages. For the NusaX sentiment dataset, each language has the same label distribution and we show the label distribution of each dataset subset in Table 2. We maintain the label ratio in each dataset subset to ensure a similar distribution. More details of the dataset are provided in Appendix C.

4.1.1 Sentiment Analysis

Sentiment analysis is an NLP task that aims to identify the sentiment of a given text document. The sentiment is commonly categorized into 3 classes: positive, negative, and neutral. We focus our dataset construction on sentiment analysis because it is one of the most widely explored tasks in Indonesia (Aji et al., 2022) due to broad industrial relevance, such as for competitor and marketing analysis, and detection of unfavorable rumors for risk management (Socher et al., 2013). After translating 1,000 instances from the sentiment analysis dataset (SmSA), we have a sentiment analysis dataset for each translated language. For each language, we split the dataset into 500 train, 100 validation, and 400 test examples. In total, our dataset contains 6,000 train, 1,200 validation, and 4,800 test instances across 12 languages (Indonesian, English and the 10 local languages).

4.1.2 Machine Translation

Indonesia consists of 700+ languages covering three different language families (Aji et al., 2022). Despite its linguistic diversity, existing machine translation systems only cover a small fraction of Indonesian languages, mainly Indonesian (the national language), Sundanese, and Javanese. To broaden the coverage of existing machine translation systems for underrepresented local languages, we construct a machine translation dataset using our translated sentiment corpus, which results in a parallel corpus between all language pairs. In other words, we have 132 possible parallel corpora, each with 1,000 samples (500 train, 100 validation, and 400 test instances) which can be used to train machine translation models. Compared to many other MT evaluation datasets, our data is in the review domain and is not English-centric.

Subset	Negative	Neutral	Positive
Train	192	119	189
Valid	38	24	38
Test	153	96	151

Table 2: Label distribution of NusaX Sentiment dataset.

4.2 Baselines

4.2.1 Classical Machine Learning

Classical machine learning approaches are still widely used by local Indonesian researchers and institutions due to their efficiency (Nityasya et al., 2021). The trade-off between performance and compute cost is particularly important in situations with limited compute, which are common for low-resource languages. We therefore use classical methods as baselines for our comparison. Namely, we use naive Bayes, SVM, and logistic regression for the classification tasks. For MT, we employ a naive baseline that copies the original Indonesian text, a dictionary-based substitution method using the bilingual lexicon, and a phrase-based MT system based on Moses (Koehn et al., 2007).

4.2.2 Pre-trained Local Language Models

Recent developments in neural pre-trained LMs have brought substantial improvements in various NLP tasks. Despite the lack of resources in Indonesian and local languages, there have been some efforts in developing large pre-trained LMs for Indonesian and major local languages. IndoBERT (Wilie et al., 2020) and Sundanese-BERT (Wongso et al., 2022) are two popular LMs for natural language understanding (NLU) tasks in Indonesian and Sundanese. IndoBART and IndoGPT have also been introduced for natural language generation (NLG) tasks in Indonesian, Sundanese, and Javanese (Cahyawijaya et al., 2021). We employ these LMs as baselines to assess their adaptability to other languages.

4.2.3 Massively Multilingual LMs

We consider large pre-trained multilingual LMs to further understand their applicability to low-resource languages. Specifically, we experiment with mBERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020) for sentiment analysis, and mBART (Liu et al., 2020) and mT5 (Xue et al., 2021) for machine translation. We provide the hyper-parameters of all models in Appendix B.

5 Results

5.1 Overall Results

Sentiment Analysis Table 3 shows the sentiment analysis performance of various models across different local languages, trained and evaluated using data in the same language. Fine-tuned large LMs such as IndoBERT$_{\text{LARGE}}$ and XLM-R$_{\text{LARGE}}$ generally achieve the best performance. XLM-R models achieve strong performance on some languages, such as Indonesian (idn), Banjarese (bjn), English (eng), Javanese (jav), and Minangkabau (min). Many of these languages are included in XLM-R's pre-training data while others may benefit from positive transfer from related languages. For instance, Banjarese is similar to Malay and Indonesian (Nasution et al., 2021), while Minangkabau shares some words and syntax with Indonesian (Koto and Koto, 2020). IndoBERT models, despite only being pre-trained on Indonesian, also show good performance across some local languages, suggesting transferability from Indonesian to the local languages.

The classic approaches are surprisingly competitive with the neural methods, with logistic regression even outperforming IndoBERT$_{\text{LARGE}}$ and XLM-R on Acehnese (ace), Buginese (bug), and Toba Batak (bbc). These results indicate that both Indonesian and multilingual pre-trained LMs cannot transfer well to these languages, which is supported by the fact that these languages are very distinct from Indonesian, Sundanese, Javanese, or Minangkabau — the languages covered by IndoBERT and XLM-R.

Machine Translation We show the results on machine translation in Table 4 (x → idn) based on SacreBLEU (Post, 2018). As some local languages are similar to Indonesian, we observe that the `Copy` baseline (which does not do any translation) performs quite well. Minangkabau (min) and Banjarese (bjn) achieve high BLEU without any translation despite not being included in the LM pre-training data, due to their similarity with Indonesian (Koto and Koto, 2020; Nasution et al., 2021). Since these local languages share grammatical structure with Indonesian, dictionary-based word substitution yields a reasonable improvement.

Both PBSMT and fine-tuned LMs reach encouraging performance levels despite the limited training data, which we again attribute to the target languages' similarity to Indonesian. In contrast, the performance for translating Indonesian languages from/to English is extremely poor as shown in Table 5, demonstrating the importance of non-English-centric translation. Overall, we observe good translation performance across local languages. Thus, there is an opportunity to utilize translation models to create new synthetic datasets in local languages via translation from a related high-resource language, not only for Indonesian local languages but also other underrepresented languages. However, note that even for language pairs where the SacreBLEU score is very high, we observe translation deficiencies stemming from the small amount of training data: rare words may just be copied with PBSMT, and mistranslated with NMT.

Similar effects are also observed for (idn → x) translation, as shown in Table 6. Similar to (x → idn) translations, we observe that the `Copy` baseline performs quite well on Minangkabau (min) and Banjarese (bjn) due to their similarity with Indonesian (Koto and Koto, 2020; Nasution et al., 2021). Dictionary-based word substitution also yields a reasonable improvement especially for Ja-

vanese (jav), Minangkabau (min), and Sundanese (sun) due to the high similarity of the grammatical structure with Indonesian. PBSMT and fine-tuned IndoBARTv2 models achieve the best scores over multiple local languages despite the limited training data, which is also attributed to the target languages' similarity to Indonesian.

5.2 Cross-lingual Capability of LMs

From a linguistic perspective, local languages in Indonesia share similarities according to language family. Many local languages share a similar grammatical structure and have some vocabulary overlap. Following prior work that demonstrates positive transfer between closely-related languages (Cahyawijaya et al., 2021; Hu et al., 2020; Aji et al., 2020; Khanuja et al., 2020; Winata et al., 2021, 2022), we analyze the transferability between closely-related languages in the Malayo-Polynesian language family.

Empirically, we show the cross-lingual capability of the best performing model (XLM-R$_{\text{LARGE}}$) in the zero-shot cross-lingual setting for sentiment analysis. The heatmap is shown in Figure 2. In general, most languages, except for Buginese (bug) and Toba Batak (bbc), can be used effectively as the source language, reaching ∼70–75% F1 on average, compared to an average of 80% F1 in the monolingual setting (cf. XLM-R$_{\text{LARGE}}$ in Table 3). This empirical result aligns with the fact that both Buginese (bug) and Toba Batak (bbc) have very low vocabulary overlap with Indonesian (cf. Copy in Tables 4 and 6). Interestingly, despite coming from a completely different language family, English can also be effectively used as the source language for all 10 local languages, likely due to its prevalence during pre-training.

These results demonstrate that we can take advantage of language similarity by transferring knowledge from Indonesian and other local languages to perform zero-shot or few-shot classification in closely-related languages. New datasets for underrepresented languages that are closely related to high-resource languages thus do not necessarily need to be large, which make the development of NLP datasets in low-resource languages more affordable than may initially appear to be the case.

5.3 Multilingual Capability

We explore training multilingual models, as most Indonesian local languages share similarities. For sentiment analysis, we concatenate the training

Average	80.04	81.64	80.03

Table 7: Sentiment analysis results for macro-F1 (%) of XLM-R$_{\text{LARGE}}$ in the multilingual setting.

data of all languages. Additionally, we also explore Leave-One-Language-Out (LOLO), where we train on all data except for the test language. The LOLO setting arguably reflects the most realistic scenario where we do not have training data for a particular language, but we do have access to data in other local languages. The multilingual results for sentiment analysis are shown in Table 7. Multilingual training outperforms monolingual training, while LOLO matches the performance of training on target language data. Related language data is thus often sufficient for good cross-lingual results.

6 Data Collection Challenges

In this section, we discuss challenges faced during data collection.

Finding annotators We found collecting the NusaX dataset challenging. First of all, finding local language-speaking annotators is not easy, and popular platforms such as MTurk do not support these languages. Instead, we looked for annotators through local Indonesian networks and forums, such as the INACL forum, local campus forums, or the Indonesian polyglot community. We intended to cover as many local languages as possible, but based on the available annotators, only the 10 languages presented in this paper were possible, as we needed at least 2 annotators for each language. Searching for annotators online is not easy, due to disparities in Internet penetration in different parts of Indonesia. Hence, we might not reach potential annotators through online communities alone. However, holding an in-person workshop for data collection is also not practical; Indonesia is an archipelago and traveling between islands is costly. Similar challenges occur in many other regions, including Africa and South America.

Communication with annotators Communication between the authors and annotators was done through WhatsApp, as the most popular communication tool in Indonesian (Mulyono et al., 2021). Annotation was conducted through spreadsheets. We found that some of the annotators use mobile apps instead of a desktop for annotation. Their reasons include ease of use, no access to a laptop, and better keyboard support for typing diacritics. In the most extreme case, one annotator printed out the sheet and performed the annotation on paper, then took a picture of the paper and sent it back to us. We found some annotators to be difficult to contact, due to other commitments such as college or work. Some of them were not responsive and had to be replaced by new annotators.

7 Related Work

Multilingual Parallel Corpora Several multilingual parallel corpora have been developed to support studies on machine translation such as GCP (Imamura and Sumita, 2018), Leipzig (Goldhahn et al., 2012), JRC Acquis (Steinberger et al., 2006), TUFS Asian Language Parallel (Nomoto et al., 2018), Intercorp (ek Čermák and Rosen, 2012), DARPA LORELEI (Strassel and Tracey, 2016), Asian Language Treebank (Riza et al., 2016), FLORES (Guzmán et al., 2019), the Bible Parallel Corpus (Resnik et al., 1999; Black, 2019), JW-300 (Agić and Vulić, 2019), BiToD (Lin et al., 2021), and WikiMatrix (Schwenk et al., 2021). Guzmán et al. (2019) describe the procedure to generate high-quality translations as part of FLORES. Similar to FLORES, we also conducted QC of the translations.

Emerging Language Benchmarks Recently, benchmarks in underrepresented languages have emerged, such as MasakhaNER (Adelani et al., 2021), AmericasNLI (Ebrahimi et al., 2022), PMIndia (Haddow and Kirefu, 2020), Samanantar (Ramesh et al., 2022), and NaijaSenti (Muhammad et al., 2022). Particularly, for Indonesian languages, NLP benchmarks have been developed such as IndoNLU (Wilie et al., 2020), IndoLEM (Koto et al., 2020), IndoNLG (Cahyawijaya et al., 2021), IndoNLI (Mahendra et al., 2021), and English–Indonesian machine translation (Guntara et al., 2020).

Datasets for Indonesian Local Languages Only a limited number of labeled datasets exist for local languages in Indonesia. WikiAnn (Pan et al., 2017) — a weakly-supervised named entity recognition dataset — covers Acehnese, Javanese, Minangkabau, and Sundanese. Putri et al. (2021) built a multilingual dataset for abusive language and hate speech detection involving Javanese, Sundanese, Madurese, Minangkabau, and Musi languages. Sakti and Nakamura (2013) constructed speech corpora for Javanese, Sundanese, Balinese, and Toba Batak. Few datasets exist for individual languages, e.g., sentiment analysis and machine translation in Minangkabau (Koto and Koto, 2020) and emotion classification in Sundanese (Putra et al., 2020). Finally, some datasets focus on colloquial Indonesian mixed with local languages in the scope of morphological analysis (Wibowo et al., 2021) and style transfer (Wibowo et al., 2020).

8 Conclusion

In this paper, we propose NusaX, the first parallel corpus for 10 low-resource Indonesian languages. We create a new benchmark for sentiment analysis and machine translation in zero-shot and full-data settings. We present a comprehensive analysis of the language similarity of these languages from both linguistic and empirical perspectives by assessing the cross-lingual transferability of existing Indonesian and multilingual pre-trained models.

We hope NusaX can enable NLP research for under-represented languages, and can be used as a testbed for adaptation or few-shot learning methods that take advantage of similarities between languages. NusaX opens up the possibility for future research that focuses on covering more local languages, and additionally, further extension to other tasks and domains. Our study on cross-lingual transfer enables further exploration on cross-lingual zero-shot learning for more diverse tasks in local languages. Our guidelines and discussion of data collection issues may also motivate future work on more efficient high-quality data collection for extremely low-resource languages.

Acknowledgments

We thank Dea Adhista and all annotators who helped us in building the corpus. We are grateful to Alexander Gutkin and Xinyu Hua for feedback on a draft of this manuscript. This work has been partially funded by Kata.ai (001/SD/YGI-NLP/1/2022) and PF20-43679 Hong Kong PhD Fellowship Scheme, Research Grant Council, Hong Kong.

Limitations

We created data for low-resource languages, which increases the accessibility of NLP research for marginalized communities. However, we were only able to cover 10 languages with only 1000 samples each, due to cost and the number of available annotators. This dataset has limited domain coverage and may also contain biases towards certain groups or entities. We tried our best to eliminate negative biases based on a manual inspection of the data. As our dataset was translated, there may be some translationese artifacts in the resulting corpus. We invited annotators based on their fluency level on a particular language. However, the fluency level is self-declared, and there is no mechanism to verify it, except for several languages that are spoken by authors of this paper. The dialect used in the dataset also depends on the annotator, for languages with multiple dialects.

A Data Statement for NusaX

A.1 General Information

Dataset title NusaX

Dataset curators Alham Fikri Aji (MBZUAI), Rahmad Mahendra (Universitas Indonesia), Samuel Cahyawijaya (HKUST), Ade Romadhony (Telkom University, Indonesia), Genta Indra Winata (Bloomberg), Fajri Koto (University of Melbourne), Kemal Kurniawan (University of Melbourne)

Dataset version 1.0 (May 2022)

Data statement author Kemal Kurniawan (University of Melbourne)

Data statement version 1.0 (February 2022)

A.2 Executive Summary

NusaX is a multilingual parallel corpus across 10 local languages in Indonesia: Acehnese, Balinese, Banjarese, Buginese, Madurese, Minangkabau, Javanese, Ngaju, Sundanese, and Toba Batak. The data was translated obtained by human translation from Indonesian and human-assisted quality assurance.

A.3 Curation Rationale

The goal of the dataset creation process is to provide gold-standard sentiment analysis corpora for Indonesian local languages. The Indonesian data is sampled from SmSA (Purwarianti and Crisdayanti, 2019), an Indonesian sentiment analysis corpus. SmSA is chosen among other corpora (e.g., HoASA (Azhar et al., 2019) based on (1) the agreement of our manual re-annotation of a small and randomly selected samples and (2) manual inspection to ensure that the topics are diverse. After sampling, the data is edited and/or filtered to remove harmful contents and maintain quality. Several criteria are used in this process:

1. Is the sentiment label correct?
2. Does the sentence contain multiple sentiments?
3. Does the sentence contain harmful content that discriminates against race, religion, or other protected groups?
4. Does the sentence contain an attack toward an individual or is abusive?
5. Is the sentence politically charged?
6. Is the sentence overly Bandung/Sunda-centric?[3]
7. Will the sentence be difficult to translate into local languages?
8. Are there any misspellings?

A.4 Documentation for Source Datasets

NusaX is obtained by translating SmSA (Purwarianti and Crisdayanti, 2019), an Indonesian sentiment analysis dataset.

A.5 Language Variety

NusaX covers a total of 10 local languages spoken in Indonesia (ID) as shown in Table 8.

A.6 Speaker Demographic

The SmSA dataset was obtained from social media and online forums: Twitter, Zomato, TripAdvisor, Facebook, Instagram, Qraved. We can assume the users' age ranges from 25 to 34 years, which is the age range of the majority of Indonesian social media users[4].

A.7 Annotator Demographic

A total of 28 translators are employed in the translation process. All translators are Indonesian and recruited by via either online surveys or personal contacts. They are then selected based on (1) the self-reported fluency in the local language into which they would be translating and (2) the highest education level achieved. Those who (a) are native speakers of or fluent in the target local language and (b) finished at least high school education (id: *SMA/sederajat*) are selected.

Acehnese There are 3 translators for Acehnese, but only 2 of them responded when asked for demographic information. Thus, what follows is the demographic information of only those 2 translators. One has some experience in translation work, while the other does not. One identifies as male, and the other as female. Both are in their 20s. Lastly, one works as a freelancer, while the other is a farmer.

Balinese Three people translate into Balinese. Two of them have previous experience in translation work, and both identify as female. The other one, who identifies as male, does not have such

Sundanese	sun	Priangan	Ratusan bumi di medan karendem banjir

Table 8: Local languages spoken in Indonesia (ID) that are covered in NusaX.

experience. Two of them are aged 20-29 years old, while the other is in their 30s. Their occupations are university lecturer, school teacher, and civil employee respectively.

Banjarese Two translators are employed for Banjarese, but only one responded when asked for demographic information. The translator has prior experience in translation work, identifies as male, is in his 40s, and works as a university lecturer.

Buginese Buginese is translated by 2 people, but only one responded when asked for demographic information. The person has prior translation experience, identifies as male, is aged 30-39 years old, and runs an Islamic boarding school as a living.

Javanese Four translators are employed for Javanese, but one did not respond when asked for demographic information. The other three have prior experience in translation work. Among them, two identify as female, and one as male. All of them are in their 20s. Two of them are university students, and the other one works as a freelance assistant editor.

Madurese There are 3 translators for Madurese. Only one of them has previous experience in translation work. Two of them identify as female, while the other as male. One person is aged under 20 years old and is a university student. The others are 20-29 years old and work as a school teacher and an employee in a private company respectively.

Minangkabau Three people translate into Minangkabau. Two of them have previous translation experience. All three identify as female and are aged 20-29 years old. They work as a civil employee, a university student, and a senior data annotator respectively.

Ngaju Two translators work on Ngaju, but only one responded when asked for demographic information. The translator has prior experience, identifies as female, is aged no less than 50 years old, and is a stay-at-home mother.

Sundanese There are 5 translators for Sundanese, four of which identify as female, and the other one as male. Three translators are in their 20s, one is younger than 20 years old, and the remaining one is in their 30s. The translators work as a school teacher, a university student, a university lecturer, and the remaining two as employees in a private company.

Toba Batak Three translators are employed for Toba Batak. One has prior translation experience. Two translators identify as male while the other as female. All three are in their 20s. One works for a private company, and the others are university students.

B Hyperparameters

B.1 Sentiment Analysis

Hyperparams	NB	SVM	LR
feature	{BoW, tfidf}	{BoW, tfidf}	{BoW, tfidf}
alpha	(0.001 - 1)	–	–
C	–	(0.01 - 100)	(0.001 - 100)
kernel	–	{rbf, linear}	–

Table 9: Hyperparameters of statistical models on sentiment analysis.

For statistical models, we use a spaCy as our toolkit, and we perform grid-search over the parameter ranges shown in Table 9 and select the

Hyperparams	**Values**
learning rate	[1e-4, 5e-5, **1e-5**, 5e-6, 1e-6]
batch size	[4, 8, 16, **32**]
num epochs	100
early stop	3
max norm	10
optimizer	Adam
Adam β	(0.9, 0.999)
Adam γ	0.9
Adam ϵ	1e-8

Table 10: Hyperparameters of pre-trained LMs on sentiment analysis. **Bold** denotes the best hyperparameter setting.

best performing model over the devset. For all pre-trained LMs, we perform grid-search over batch size and learning rate while keeping the other hyperparameters fixed. The list of hyperparameters is shown in Table 10.

B.2 Machine Translation

Table 11 shows the hyperparameters of deep learning models on machine translation.

Hyperparams	**IndoGPT**	**IndoBARTv2**	**mBART-50**	**mT5$_{\text{BASE}}$**
learning rate	1e-4	1e-4	2e-5	5e-4
batch size	16			
gamma	0.98	0.98	0.98	0.95
max epochs	20			
early stop	10			
seed	{1...5}			

Table 11: Hyperparameters of pretrained LMs on machine translation.

C Dataset Statistics

In this section, we present more detail statistics of our NusaX datasets. To evaluate the difference between each language in the NusaX dataset, we analyze the vocabulary characteristic for each language. We collect the vocabulary for each language by removing all the punctuation in the sentence and tokenize the sentence with the spaCy tokenizer. [5] We show the vocabulary size and the top-10 words for each language on Table 12, and the vocabulary histogram for each language in Figure 4. We can see that the most common words between Indonesian and other local languages vary a lot, despite having a similar vocabulary size and histogram pattern. This shows the intuitive difference between Indonesian and local languages in Indonesia.

We further measure the vocabulary overlap over different language pairs. We measure the vocabulary overlap for each pair of languages by measuring the intersection over union (IoU) of the two vocabularies. We show the vocabulary overlap in Figure 3. From the results, we can conclude that English has the smallest vocabulary overlap with the other languages. This makes sense since English comes from a different language family, i.e., Indo-European language under the Germanic language branch, while the others are from the Austronesian language family under the Malayo-Polynesian branch. Other languages that have low vocabulary overlap are Buginese (bug) and Toba Batak (bbc). This aligns with our discussion in §5, which shows the distinction between these languages and the other languages in the NusaX dataset.

Abstract

Recent studies have shown that transformer models like BERT rely on number information encoded in their representations of sentences' subjects and head verbs when performing subject-verb agreement. However, probing experiments suggest that subject number is also encoded in the representations of all words in such sentences. In this paper, we use causal interventions to show that BERT only uses the subject plurality information encoded in its representations of the subject and words that agree with it in number. We also demonstrate that current probing metrics are unable to determine which words' representations contain functionally relevant information. This both provides a revised view of subject-verb agreement in language models, and suggests potential pitfalls for current probe usage and evaluation.

1 Introduction

The phenomenon of subject-verb agreement has received significant attention from the NLP community. In English, this phenomenon is very simple: present tense verbs must agree in number with their subject noun, which is either singular or plural. In the present tense, verbs that agree with 3rd-person singular nouns receive one verb conjugation, generally ending in "-s"; in all other cases, the bare form of the verb is used.

The simplicity of this phenomenon, combined with the potential for long-distance subject and verb agreement across intervening adverbs or relative clauses (e.g. "The friend [that probably called my parents] is…") has made it the object of intense study in humans (Vigliocco et al. (1995) and Franck et al. (2010), *inter alia*). It also prompted early investigations on the ability of language models to capture it (left-to-right LSTMs in Linzen et al. (2016); Gulordava et al. (2018)). More recently, the popular pre-trained model BERT (Devlin et al., 2019) has been shown to be relatively proficient at subject-verb agreement (Goldberg, 2019), although these abilities depend somewhat on verb frequency and lexical patterns (Newman et al., 2021; Lasri et al., 2022a).

Other studies ask not how models behave (e.g. with respect to subject-verb agreement), but how models' representations support this behavior. Such studies often use probing, a technique in which an auxiliary classifier (probe) is trained to extract some property of words or sentences from models' internal representations thereof (Belinkov and Glass, 2019; Belinkov, 2022). If the probe can extract the property with high accuracy, one concludes that the model has encoded the property in the word's representation. Klafka and Ettinger (2020) discover that probes can extract the plurality of a sentence's subject from last-layer BERT representations of any word in the sentence.

However, probing has received criticism because the information discovered by probes is not always used by models (Ravichander et al., 2021). Causal interventions have been proposed as a means of connecting models' internal representations to their external behavior. Such techniques make targeted changes to models' representations, and observe how model behavior changes, in order to establish a causal connection between the two (Ravfogel et al., 2021; Geiger et al., 2021). For example, Ravfogel et al. (2020) remove gender information from models' noun representations, and observe that models behave as if they do not know the nouns' gender.

Recently, Lasri et al. (2022b) unified these lines of work by using causal probing interventions to investigate subject-verb agreement. They did so by first training probes to predict subject number information from representations of verbs and their subjects. Then, they removed subject number information from the representations of subjects and verbs. This caused BERT to make errors on a subject-verb agreement task, indicating that the probes discovered functionally relevant informa-

tion about subject number in subject and verb representations. However, this leaves open the question of whether models use the subject number information in the representations of other words of the sentence, found by Klafka and Ettinger (2020).

In this paper, we focus on these questions: do large language models (LLMs) like BERT rely on subject number information stored outside of subject and verb representations when performing subject-verb agreement? Moreover, do current probing evaluation metrics allow us to determine which information is used and which is not? Our goal is thus twofold: first, to clarify how subject-verb agreement occurs in LLMs, and second, to determine if any current non-causal probing metrics can determine which probes have found functionally relevant information.

We achieve these goals as follows. First, we adopt the setup of Klafka and Ettinger (2020), examining simple sentences of a fixed structure and length. We use probing to demonstrate that subject number information is extractable from representations of any word in the sentence, at most layers. Next, we use causal interventions to show that although subject number information exists in the representations of all words of the sentence, it is not always used; rather, it seems that BERT uses information stored in words that agree with the subject in number. Finally, we evaluate our probes using modern probe evaluation metrics, to ascertain if any metric can determine whether subject number information found by a probe is used by the model or not. We find that these metrics are unable to do this.[1]

2 Probing for Plurality

To determine if the subject number information that is contained in all words of a sentence is used, we first verify that all words' representations contain said information. We adopt the setup of Klafka and Ettinger (2020), and thus investigate simple sentences with a fixed structure, using a synthetic English-language dataset. Their original dataset contains sentences of the form "The [subject] [verb-past] the [object]". However, we create our own dataset, which contains not only subject-verb agreement but also article-subject agreement. It consists of sentences of the form "[This / these] [adjective] [subject] [adverb] [verb-present] the [object]", e.g. "This short boy definitely admires the firefighter." The dataset contains 6000 sentences, with roughly equal numbers of singular and plural subjects. We split our dataset into train, valid, and test splits containing 4000/1000/1000 examples.

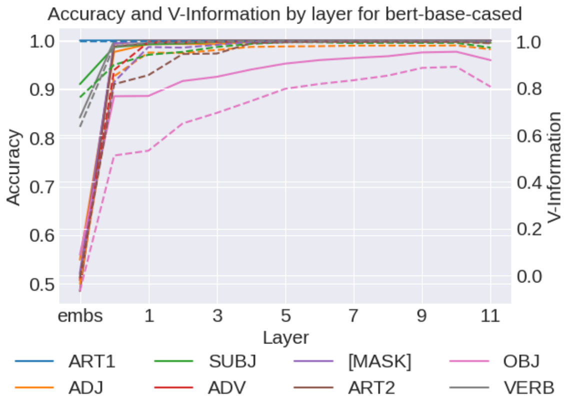

Figure 1: Test accuracy (left, solid) and $\mathcal{V}$-information (right, dashed) of probes of a given word and layer

Having generated a dataset, we must then define the model representations to be probed for subject number information. Klafka and Ettinger (2020) find said information in all words' final-layer BERT representations; in contrast, we examine the representations generated as the output of the entire transformer block at *each* layer, of a variety of LLMs. We also consider representations from the embedding, which have by definition no contextual information (except for positional information). Concretely, we analyze the base, large, and distilled variants of BERT and RoBERTa (Devlin et al., 2019; Liu et al., 2019; Sanh et al., 2019). However, we present only the BERT-base representations unless discussing another model, as results are similar across all models analyzed.

Having extracted model representations, we train probes on the subject number prediction task. Each probe is specific to a word in the sentence and to a model layer; a given probe might predict the number of a sentence's subject given the 5th-layer representation of the sentence's verb. Each probe is a linear layer with a sigmoid activation. We use HuggingFace (Wolf et al., 2020) implementations of these models; for precise model names, and dataset and training details, see Appendices A and B.

For each probe, we record 3 metrics, averaged across the dataset: (i) test accuracy; (ii) $\mathcal{V}$-information (Xu et al., 2020), and (iii) codelength, as measured by online minimum description length (MDL) probing (Voita and Titov, 2020). We record

---

[1] The code for all experiments is available at `https://github.com/hannamw/probed-information`.

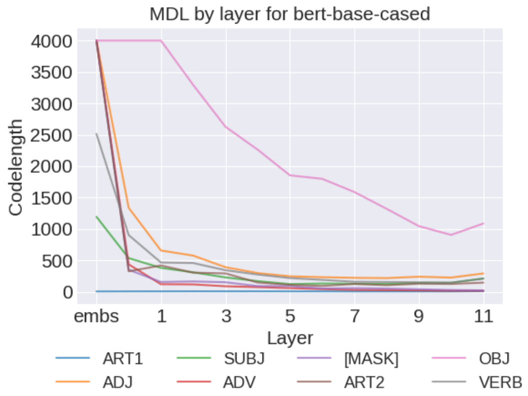

Figure 2: Probe codelength for a given word and layer

the latter two metrics to see if recently-proposed metrics can distinguish functionally relevant from irrelevant information in representations. We report metrics averaged over 10 probe training runs.

$\mathcal{V}$-information measures, given a family $\mathcal{V}$ of probes used to extract a label from a representation, how much those probes benefit from receiving a representation as input, as opposed to no input at all. In contrast, online MDL probing measures codelength by retraining probes on subsets of the dataset of increasing size. If probes assign low entropy to a dataset when training data is limited, the information being probed for is easily accessible from the input representations. A detailed description of these metrics can be found in Appendix C.

Results Figure 1 shows the accuracy and $\mathcal{V}$-information of our probes (higher is better). Note that for all figures, 'ART1' refers to the subject's article, and 'ART2' to the object's. We also probe the representation of masked verbs ('[MASK]'), discussed in the following section. As in Klafka and Ettinger (2020), accuracy is high for all words in later BERT layers. Unsurprisingly, accuracy is also high for subjects, their articles, and unmasked verbs using just BERT's embeddings. But starting in layer 0, when information is first able to move between positions, accuracy is high for most other words in the sentence as well. $\mathcal{V}$-information tracks accuracy; this is unsurprising, as it combines entropy, which tracks with accuracy, and a model-family-specific baseline, which is the same for all words / layers. This indicates that subject number information is present in the representations of all words of the sentence, and could be used for subject-verb agreement.

Figure 2 shows the codelength in bits for each probe, by layer; lower codelength means probes could learn to extract subject number information given less data. Broad trends are similar to those from accuracy and $\mathcal{V}$-information. Before layer 0, codelength given by the unmasked verb, subject, and subject article probes is notably lower than in others; this makes sense, because the very form of these words indicates the number of the subject. However, the plurality of the subject quickly becomes available, and the codelength for other words' probes drops. By the last layer, the disparity between words that agree in number with the subject, and those that do not, has mostly disappeared; the exception is the object probe, whose codelength remains high.

3 Causal Interventions

We now apply causal interventions to test if the information found by probes in the prior experiment is actually used by BERT[2]. In our case, this means we will alter BERT's internal representations with respect to subject number information, and observe BERT's performance on a subject-verb agreement task. In order to perform such interventions, we alter our dataset to accommodate this task: we mask out the verb of the sentence, and task BERT with predicting this masked word.

Then, we apply causal interventions, specifically reflection (Ravfogel et al., 2021) and interchange (Geiger et al., 2021) interventions. To define these, consider the case where BERT's input $\mathbf{s}$ is "This short boy definitely [MASK] the firefighter.". In the middle of computation, we extract $\mathbf{z}$, BERT's nth-layer representation of our word of interest; for example, the sentence's object ("firefighter"). $\mathbf{z}$ serves as input to a linear probe trained on the full training set, defined as $h(\mathbf{x}) = \sigma\left(\mathbf{W}^\top \mathbf{x} + \mathbf{b}\right)$. Let $h(\mathbf{z}) < 0.5$, indicating that the probe predicts the subject of this sentence is singular. In the **reflection** intervention, we reflect $\mathbf{z}$ over the decision boundary of h (a hyperplane defined by $(\mathbf{W}, \mathbf{b})$), creating $\mathbf{z}_r$. By definition, $h(\mathbf{z}_r) > 0.5$; the probe now predicts that the sentence's subject is plural. We replace the original representation $\mathbf{z}$ in the BERT with $\mathbf{z}_r$, and observe how BERT's output changes. In contrast, in the **interchange** intervention, we do not use the probe. Define $\mathbf{z}_i$ as the same representation as $\mathbf{z}$, but taken from the opposite-plurality context, e.g. the n-th layer representation of "firefighter" in "These short boys definitely [MASK]

---

[2] In this section, we discuss only BERT, but the procedure is identical for all models tested.

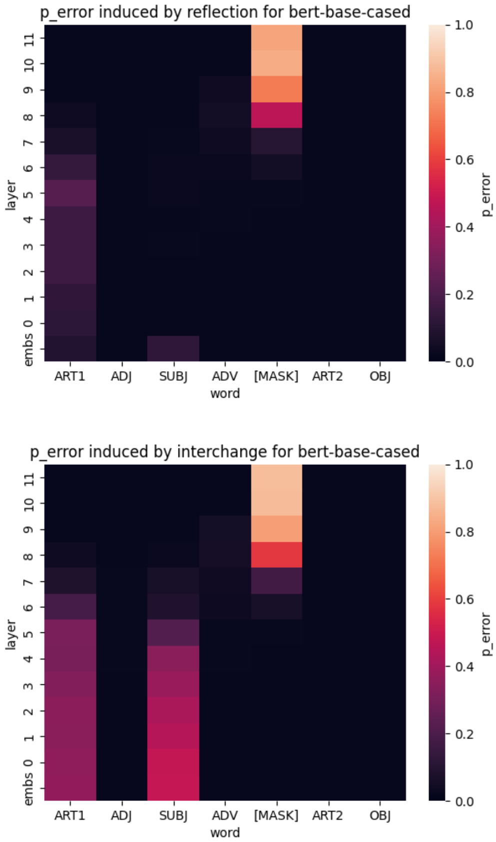

Figure 3: p_{error} induced by intervening on a representation, by word (x-axis), and layer (y-axis). Top: reflection intervention; bottom: interchange intervention

the firefighter." We then run BERT on $\mathbf{s}$, but replace $\mathbf{z}$ with $\mathbf{z}_i$, and observe how its behavior changes.

In both cases, we attempt to reverse the plurality of the subject number information in $\mathbf{z}$ by replacing it with $\mathbf{z}'$. Thus, if the intervention was effective (i.e. BERT was using said information in $\mathbf{z}$), BERT should predict verbs that do not agree in number with the original subject of the sentence.

We perform interventions on examples from the test split. Each intervention targets one word at a specific layer. To measure the effectiveness of a given intervention, we record p_{error}, the probability mass assigned by BERT to all 3rd-person present-tense verbs in its vocabulary that do not agree in number with the sentence's original subject. Higher p_{error} indicates a more successful intervention, i.e. that BERT relied on information in the targeted word representation to perform subject-verb agreement.

Results Figure 3 shows, for each word and layer of BERT, the error induced by performing either a reflection or interchange intervention on that word's representation at the given layer, averaged across the test split. For reflection interventions, we previously trained 10 sets of probes, and thus also average over the results obtained for each set. Note that with no interventions, $p_{error} \approx 0$; BERT assigns 80% of its probability mass to verbs that agree with the subject in number (BERT sometimes predicts conjunctions or other words that neither agree nor disagree with the sentence's subject).

The results show clearly that not all subject number information in a sentence is used. Information stored in representations of the adjective, object, and object's article, is not used at all, producing no effects when either intervention is performed. On the other hand, considering only the interchange intervention, information from the subject (in early layers) and masked verb (in later layers) is heavily used, as reported by Lasri et al. (2022b). Moreover, there is minor usage of number information ($p_{error} \approx 0.05$) in the adverb in layers 9-10, the transition layers between subject and verb. Although the error induced is very small, this could hint at instances where BERT's subject-verb agreement processing diverge from our expectations.

Our setup also reveals a new phenomenon: BERT uses the number information in the representation of the subject's article (a demonstrative, which agrees with the subject). The information in the subject article representation is used in the same layers as the subject information, with slightly weaker intervention effects. On this basis, we conclude that BERT uses subject number information in the subject and words that agree with it (not just the masked verb); however, further study, with additional agreement effects, would strengthen this.

These results are strengthened by the reflection intervention, which yields only slightly different results. It produces the same effects as the interchange at the masked verb and subject's article, albeit at a lower magnitude, indicating that the information found by probes is indeed the information the model is using to perform subject-verb agreement. Moreover, the strong effects at the masked verb position indicate that the model may be encoding subject number linearly. While linearity in BERT's representations of subject number was also found by (Lasri et al., 2022b), they used a much more complex approach, iteratively projecting representations into classifiers' null space; in contrast, our reflection approach is non-iterative, and suggests the model may be encoding this information in just one dimension.

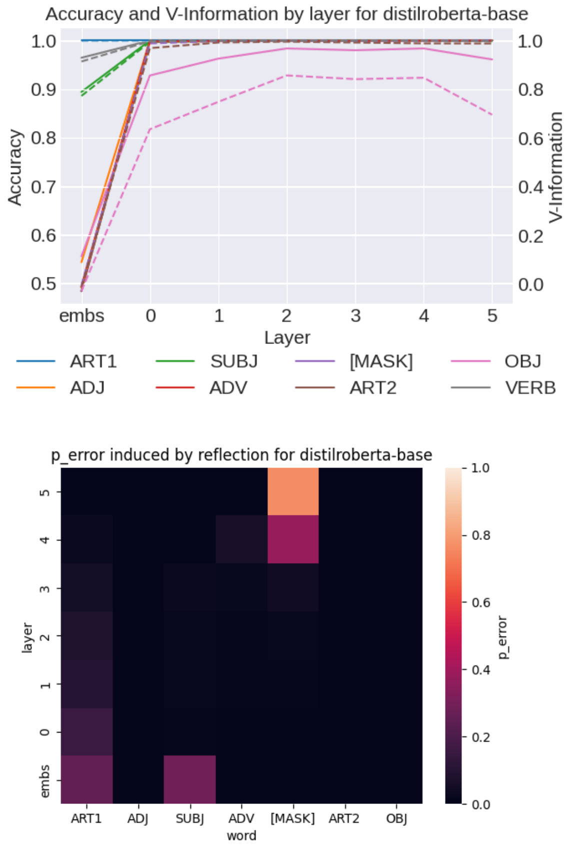

Figure 4: Top: Accuracy and $\mathcal{V}$-information for distilroberta-base. Bottom: effects of reflection interventions on distilroberta-base

It is notable that the reflection intervention produces almost no effect when performed on the subject. As this effect does appear under the interchange intervention, this result likely does not reflect a non-reliance on subject information there encoded; rather, it is due to specific properties of this intervention. First, the information encoded in the subject may well be used, but simply not encoded as the probe found it. Second, the subject is often split into multiple tokens; while we apply the reflection to each token, reflecting multiple tokens representations might not be as effective, as multiple tokens of the same word might not share the same plurality boundary as that of single tokens.

Although we primarily discuss results for BERT, results generalize to the RoBERTa models and their large / distilled variants: interchange interventions show use of information in representations of the subject, its article, and the verb, at expected locations (see Appendix D for plots and heatmaps). This could be surprising, especially in the case of the distilled models. If one views the unused subject number information present in model representations as extraneous or irrelevant encoded information, one might expect that these smaller distilled models do not have the space to encode irrelevant information. However, this is not the case, as seen in Figure 4; probe achieve high accuracies even when the their information is not used.

4 Discussion and Conclusions

In our prior two experiments, we showed that subject number information is extractable from the representation of any word in our simple sentences; however, it is only used if it comes from a representation of the subject or a word that agrees with it. Could any existing metrics have warned us of this, without requiring causal interventions?

Accuracy is insufficient to distinguish functional relevant information; probes extract functionally irrelevant subject number information with high accuracy. The same is true for $\mathcal{V}$-information, for the same reasons; high $\mathcal{V}$-information is necessary but not sufficient for a property to be used by models.

This leaves codelength, which measures ease of extracting the property from the data. It is an appealing hypothesis that models might encode functionally relevant information more accessibly in their representations; if this were the case, MDL probing could detect functionally relevant information. Indeed in early layers, it distinguishes between words that directly reflect subject number (the verb, subject, its article) and those that do not. However, when we mask the verb, such that subject number cannot be determined from the verb's form, but its representation's subject number information is still functionally relevant to subject-verb agreement, this distinction is lost. Thus, MDL probing seems unable to determine functional relevance.

So, we conclude the following. First, we show via probing that subject number information is present in representations of all words of our simple sentences. Then, using causal interventions, we show that only in the subject and words that agree in number with it, is said information functionally relevant. This indicates, as previously shown, that probing is not a reliable method for understanding how models function. Moreover, a way of distinguishing between functionally relevant and irrelevant information in model representations remains elusive. For now, causal interventions remain the most promising way to make this determination.

Limitations

This study is limited to a single phenomenon (number agreement), in a morphologically poor language (English). Our conclusions should be checked against different domains (person/gender agreement) and in morphologically complex languages. In particular, the study of sentences in which agreement extends beyond a demonstrative, the subject, and the verb, could help determine the extent to which models rely on agreement information in each word whose form expresses it. This study is also limited by its use of small, simple, synthetic data; expanding to real-world data, or data that follows a less rigid template, would strengthen our conclusions. From a modeling point of view, these results do generalize to various different masked language models, but this study does not investigate larger, more modern language models; autoregressive language models are also excluded. Thus, it is unclear to what extent these popular models exhibit the phenomenon studied.

A Dataset Details

Our dataset is a tightly-controlled synthetic dataset created using the BLiMP sentence generator (Warstadt et al., 2020), which we altered and updated to fit our use-case. A benefit of using this specific generator is that it forms (relatively) coherent sentences, such that e.g. all subjects and objects are valid (if not especially plausible) arguments of their verb. Moreover, it also allows us to specify additional constraints, and sample an arbitrary number of sentences fulfilling them.

Each example in the dataset consists of a sentence of the form "[This / these / that / those] [adjective] [subject] [adverb] [verb-present] the [object]"; we also automatically generate the same sentence, but with an opposite-number subject (and corresponding verb / article) for use with interchange interventions. At intervention time, we append (but do not probe / investigate) the word "nowadays". This encourages BERT to output a present-tense verb for the masked token; otherwise, BERT often predicts past-tense verbs or conjunctions. Subjects have distinct singular and plural forms, where the plural form ends in "-s".

Each of the word types contained in brackets is always one word long (so there are no multi-word subjects, or phrasal verbs). If a word is split into multiple tokens, we handle it in the following way. During the probe training phase, we consider each token as a separate training example (so the number of training examples for each probe might differ, and be slightly greater than the number of sentences in the dataset). Then, during the intervention phase, we simply apply the intervention to every token composing the word. For the interchange intervention, both the original word and its opposite-number counterpart must have the same number of tokens. Thus, we discard from our dataset any examples where the two have different token lengths. In order to determine whether the model's prediction is a present-tense verb, and whether it was conjugated in the singular or plural, we use the `nodebox_linguistics_extended` package (Harmon, 2017).

B Experimental Details

Probes are scikit-learn (Pedregosa et al., 2011) `LogisticRegression` models, trained with L2 normalization to predict the number (singular / plural) of the subject. For some experiments, we use the weights from these models as the weights for identical PyTorch (Paszke et al., 2019) models, consisting of linear layer with bias and sigmoid activation. The `bert-base-cased` model has approximately 110 million parameters (Devlin et al., 2019). Each probe has 1538 parameters, for a total of 140000 parameters summed over all probes. All experiments were performed using an NVIDIA A100 GPU, and take no more than 24 GPU hours to run in total. We study `bert-base-cased`, `bert-large-cased`, `distilbert-base-cased`, `roberta-base`, `roberta-large`, and `distilroberta-base`.

C Metric Details

We consider two metrics in addition to standard accuracy. The first, predictive $\mathcal{V}$-information (Xu et al., 2020), measures the degree to which information in representations is made available to a chosen model family $\mathcal{V}$. We study linear probes f, where $f(x)$ is the probability that the subject of the sentence from which the representation x comes, is plural. For the purposes of $\mathcal{V}$-information, however, it is useful to define $f'(y|x) = (1-y)(1-f(x)) + yf(x)$, and $\mathcal{V}$ as the family of such functions.

$\mathcal{V}$-information relies on conditional $\mathcal{V}$-entropy:

$$H_{\mathcal{V}}(Y|X) = \inf_{f' \in \mathcal{V}} \mathbb{E}_{x,y \sim \mathcal{D}} - \log f'(y|x)$$

where $\mathcal{D}$ is our dataset of representation, number label pairs. We can define baseline $\mathcal{V}$-entropy as

$$H_{\mathcal{V}}(Y|\emptyset) = \inf_{f' \in \mathcal{V}} \mathbb{E}_{y \sim Y\mathcal{D}} - \log f'(y|\emptyset)$$

where $\emptyset$ represents the absence of representational information, e.g. a constant vector. Now we can define predictive $\mathcal{V}$-information as

$$I(\emptyset \to X) = H_{\mathcal{V}}(Y|\emptyset) - H_{\mathcal{V}}(Y|X)$$

i.e. the predictive advantage given to models of the family $\mathcal{V}$' by representational information. Put simply, this metric asks how much better our probes can extract subject number given representational information, as opposed to if they had none.

The conditional $\mathcal{V}$-information can be estimated via probing; it is the entropy achieved by a probe trained on our dataset. We compute the baseline as the maximum likelihood estimate of the label distribution, i.e. $f'(y|\emptyset) = c(y)/(c(0) + c(1))$, where $y \in \{0, 1\}$ is a label, and $c(y)$ is its count.

We also use minimum description length (MDL) probing, described by Voita and Titov (2020). Their codelength metric rewards probes that are both high-performing and simple. We measure it using their online MDL method, which measures the cost of encoding a dataset's labels with probes trained on limited data. In this setup, we have a dataset of data X and binary labels Y; we begin by partitioning this dataset into groups $(x_{1:t_1}, y_{1:t_1}); (x_{t_1+1:t_2}, y_{t_1+1:t_2}); \ldots; (x_{t_{S-1}+1:t_S}, y_{t_{S-1}+1:t_S})$ of increasing size. We encode the first group of labels $y_{1:t_1}$ at full cost, t_1 bits. For each timestep $i = 1, \ldots, S-1$, we train a probe p_{θ_i} on $\{(x_j, y_j)\}_{j=1}^{i}$, and encode the next set of labels using the updated model, for a cost of $-\log p_{\theta_i}(y_{t_i+1:t_{i+1}}|x_{t_i+1:t_{i+1}})$. The online codelength is, in bits

$$L = t_1 + \sum_{i=1}^{S-1} - \log p_{\theta_i}(y_{t_i+1:t_{i+1}}|x_{t_i+1:t_{i+1}}).$$

In this setup, probes that quickly learn how to extract subject plurality from BERT representations will have a shorter codelength. So, comparing codelength across representations from different words will tell us the words that are easier or more difficult to extract plurality information from.

We follow this procedure in our analysis: we split our data into partitions; then, we repeatedly train probes on increasing portions of our dataset, until we have trained on all data. Probes are trained using scikit-learn's (Pedregosa et al., 2011) `LogisticRegression`, with L2 normalization. After each round of training, we compute the cost of encoding the next partition. We sum over all partitions, and repeat this process 10 times, reporting average codelength. The partition sizes we use are identical to those in Voita and Titov (2020), i.e. 0.1%, 0.2%, 0.4%, 0.8%, 1.6%, 3.2%, 6.25%, 12.5%, 25%, 50%, and 100% of the dataset (cumulatively). In some cases (e.g. when training on embeddings that contain no subject plurality information), MDL is very high; in this case we cap it at 4000 (the cost of transmitting the labels uncompressed, i.e. 4000 examples, at 1 bit / example).

Abstract

Semitic morphologically-rich languages (MRLs) are characterized by extreme word ambiguity. Because most vowels are omitted in standard texts, many of the words are homographs with multiple possible analyses, each with a different pronunciation and different morphosyntactic properties. This ambiguity goes *beyond* word-sense disambiguation (WSD), and may include token segmentation into multiple word units. Previous research on MRLs claimed that standardly trained pre-trained language models (PLMs) based on word-pieces may not sufficiently capture the internal structure of such tokens in order to distinguish between these analyses. Taking Hebrew as a case study, we investigate the extent to which Hebrew homographs can be disambiguated and analyzed using PLMs. We evaluate all existing models for contextualized Hebrew embeddings on a novel Hebrew homograph challenge sets that we deliver. Our empirical results demonstrate that contemporary Hebrew contextualized embeddings outperform non-contextualized embeddings; and that they are most effective for disambiguating segmentation and morphosyntactic features, less so regarding pure word-sense disambiguation. We show that these embeddings are more effective when the number of word-piece splits is limited, and they are more effective for 2-way and 3-way ambiguities than for 4-way ambiguity. We show that the embeddings are equally effective for homographs of both balanced and skewed distributions, whether calculated as masked or unmasked tokens. Finally, we show that these embeddings are as effective for homograph disambiguation with extensive supervised training as with a few-shot setup.

1 Introduction

Semitic morphologically-rich languages (MRLs) such as Arabic, Hebrew, and Aramaic are characterized by extreme ambiguity at the word level (Wintner, 2014; Tsarfaty et al., 2020). In a standard text, many (and often most) of the words will be homographs with multiple possible analyses. The high ambiguity derives from several factors. First, prepositions, conjunctions, accusative pronouns, and possessive pronouns are often seamlessly affixed to words. Next, vowels are generally omitted in written texts. Finally, proper nouns are not differentiated from common nouns (no capital letters).

The task of distinguishing between Hebrew homograph analyses is related to the general task of Word Sense Disambiguation (WSD) (Agirre and Edmonds, 2006; Navigli, 2009), yet it is more challenging. In the standard case of WSD, a single orthographic form is associated with a single word that can be analyzed in terms of two or more senses; also, the analyses are generally pronounced identically, and often have the same morphosyntactic properties (e.g bank of a river vs. savings bank). In contrast, in Semitic languages, the need for disambiguation often goes beyond a determination of sense. Hebrew word ambiguities can be divided into three primary categories (Table 1): 1. Segmentation ambiguities, in which a given orthographic form may (or may not) be segmented into multiple word units each bearing its own role (POS tag) in the sentence. 2. Morphosyntactic ambiguities, in which the segmentation of the form is not ambiguous, but multiple analyses of the word reflect different morphosyntactic properties of each word unit(s). 3. Sense ambiguities (the aforementioned standard case of WSD), in which the analyses of the unit(s) do not differ in their morphosyntactic properties, but rather in their *sense*. One orthographic form may exhibit multiple types of ambiguity simultaneously.

Pretrained contextualized language models with standard word-piece tokenization mechanisms have been shown to excel at WSD in English and other Indo-European languages (Yaghoobzadeh et al., 2019). However, for Hebrew and other semitic lan-

Table 1: Examples of Hebrew ambiguity types

guages it has been argued that such models would not sufficiently capture the structure of MRLs in order to distinguish between internally-complex homograph analyses (Klein and Tsarfaty, 2020; Tsarfaty et al., 2020). In this work, we take Modern Hebrew, a Semitic language with rich and highly ambiguous morphology, as a case study, and we investigate the extent to which homographs can be disambiguated by contextualized embeddings, regarding all three levels of ambiguity. Regarding Arabic — a sister language to Hebrew — a wide survey of WSD methods is presented by Abderrahim and Abderrahim (2022). They raise the possibility of utilizing pretrained contextualized embeddings, yet leave its evaluation to future work.[1]

Hebrew is a particularly challenging language on which to perform a homograph disambiguation due to the limited available corpora. First of all, currently existing Hebrew treebanks are severely limited in size, such that most of the words in the language are not amply represented. Furthermore, even regarding common Hebrew words, this corpus is problematic, because the nature of language is such that many homographs are skewed in their distribution; thus, even if the primary analysis is sufficiently represented within a tagged corpus, the secondary analysis will often be hopelessly underrepresented. For instance, one common Hebrew homograph is מהם (*mhm*), which can be analyzed as a preposition with pronominal suffix, or as an interrogative. The ratio of these two analyses in naturally-occurring Hebrew text is over 50:1; thus, occurrences of the secondary analysis within existing tagged corpora are insufficient.

In theory, these homograph ambiguities could be addressed using POS tagging systems. For instance, Habash and Rambow (2005) consider the use of a morphological tagging system to solve WSD in Arabic. A number of Hebrew POS tagging systems have been published as well (Yona and Wintner, 2005; Adler and Elhadad, 2006; Shacham and Wintner, 2007). The current SOTA for Hebrew POS tagging is the YAP morpho-syntactic parser (Tsarfaty et al., 2019). However, as we have shown in a previous study (Shmidman et al., 2020, p. 3318, table 2), although YAP produces high accuracy overall on normal Hebrew text, its scores drop drastically regarding homographs of skewed distribution.

For analogous cases of skewed distribution in other languages, researchers have proposed the creation of dedicated challenge sets, containing hard-to-classify sentences not easily found in naturally-occurring text (Gardner et al., 2020; Elkahky et al., 2018). In the aforementioned previous study, we produced 22 such challenge sets for Hebrew homographs, and demonstrated that a Bi-LSTM of non-contextualized embeddings can obtain high accuracy on this task, establishing the current SOTA for Hebrew homograph disambiguation (Shmidman et al., 2020). In this paper, we extend the investigation by considering whether contextualized embeddings from pretrained language models (PLMs) can provide a more optimal solution. We consider all existing contextualized Hebrew PLMs: multilingual BERT ("mBERT") (Devlin et al., 2019); HeBERT (Chriqui and Yahav, 2021); and AlephBERT (Seker et al., 2021) (Table 2). Moreover, we evaluate and verify these on a new dataset, substantially larger than all previous datasets for Hebrew homograph disambiguation.

Our experiments demonstrate that contextualized PLMs pre-trained on sufficiently large unlabeled data and vocabulary size are excellent at disambiguating the word-internal structures of homographs, yet face some challenge with pure sense disambiguation. We show the efficacy of these models in cases of homographs with skewed distribution, and in a few-shot setup. Finally, we establish new state-of-the-art results on the challenging task of homograph disambiguation for a morphologically-rich language printed without vowels, along with a novel benchmark for assessing the morphological reach of future PLMs in Hebrew.

2 The Data

The challenge sets for Hebrew homograph disambiguation from our previous study were limited in

[1] Additional studies in Arabic WSD include Merhben et al. (2010), Merhbene et al. (2013), and Shah et al. (2010).

Model	Vocab (Heb. tokens)	Corpus Size (Heb. sentences)
mBERT	2.5K	6.3M
HeBERT	30K	27.2M
AlephBERT	52K	98.7M

Table 2: Comparison of available Hebrew BERT models

number (only 22 sets) and insufficiently representative regarding types of ambiguities; only one of the sets was a prefix-segmentation ambiguity. Further, they were limited to binary cases, where only two analyses exist.

In contrast, for this study we employed field experts to choose the most critical homographs in the language. The experts chose 75 homographs from a list of the 3600 most frequent words in the language, balancing frequency of word occurrence with practical need for its disambiguation. All of the homographs occur with a minimum frequency of 27 words per million in naturally occurring Hebrew text. Our challenge sets include homographs with 2-5 possible analyses. Our sets contain a wide representation of segmentation ambiguities (15 in number), as well as 5 cases of purely semantic ambiguities. For each of the 75 homographs, we collect hundreds of naturally-occurring sentences attesting to each analysis. In almost all cases, we succeed in collecting 1000 sentences for the primary analysis, at least 500 sentences for the secondary analysis, and at least 250 for each additional analysis. The sentences were culled from newspapers, Wikipedia, literature, and social media. We employed a team of annotators who chose the relevant homograph analysis for each case.[2] All in all, our 75 challenge sets contain 150K tagged sentences. The full list of homographs and analyses is provided in Appendix A.[3]

3 Experimental Setup

To evaluate the ability of pre-trained language models (PLMs) to disambiguate the in-context analyses of morphologically rich and highly ambiguous homographs in Hebrew, we adopt a "word expert" approach, producing dedicated classifiers for each individual homograph (Zhao et al., 2020).

We use two types of PLMs, contextualized and non-contextualized. For the non-contextualized case, we replicate our previous method detailed in Shmidman et al. (2020). For each training example, we use a BiLSTM on top of the word2vec embeddings of all of the words in the sentence (other than the homograph itself) to produce an encoding for disambiguation.[4] An MLP is trained to predict the correct homograph analysis based on this encoding.[5] For the contextualized case, we run the sentence through a pretrained contextualized language model and retrieve the 768-dimension embedding representing the homograph in question. An MLP is trained to predict the correct analysis based on the homographs embeddings alone. In the standard "unmasked" scenario, the sentence is fed into the model as is, including the homograph in question. In the "masked" scenario, the homograph is replaced with a [MASK] token.

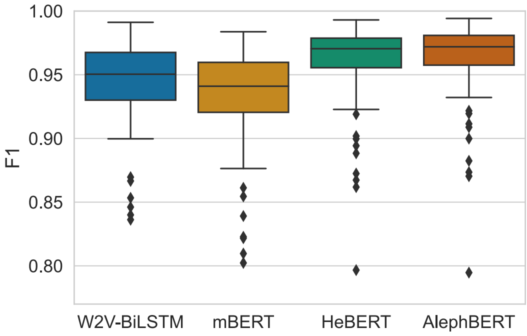

Figure 1: Comparison of previous SOTA (w2v-based Bi-LSTM method) versus BERT-based approaches.

We evaluate the performance of each given method on each given challenge set using 10-fold cross-validation. We calculate an F1 score for each homograph analysis, based upon the precision and recall scores micro-averaged across all folds. We then calculate the macro-average of the F1 scores for all possible analyses for a given homograph, and this is the score reported in the charts herein.

4 Results and Analysis

Standard (Unmasked) Scenario Figure 1 presents the cumulative F1 score obtained by the models for all challenge sets. Our results show that HeBERT and AlephBERT far outperform mBERT, with AlephBERT achieving the higher score. The poor performance of mBERT is likely due to its smaller pre-training data size and exceedingly lean Hebrew vocabulary (cf. Table 2). Furthermore, the

[3] The dataset is downloadable at: `https://github.com/Dicta-Israel-Center-for-Text-Analysis/EACL_2023`

[4] We also tested fastText, but results were inferior.

[5] For implementation details, see Appendix D.

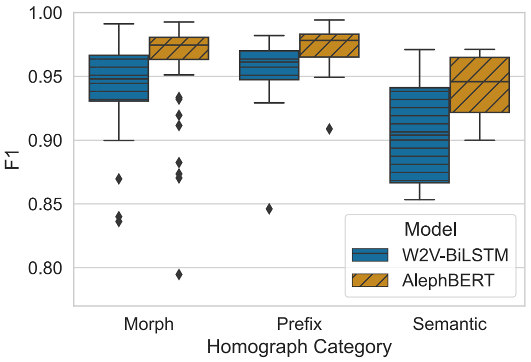

Figure 2: Disambiguation accuracy across various categories of homograph ambiguity.

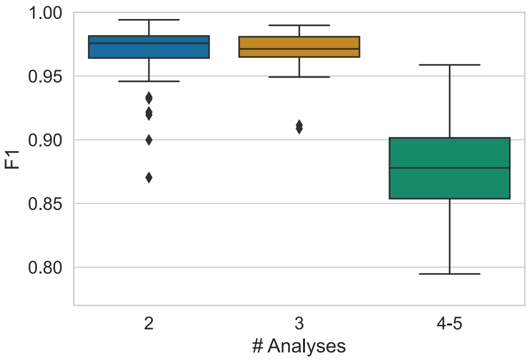

Figure 3: AlephBERT's disambiguation accuracy across homographs with differing counts of possible analyses.

HeBERT and AlephBERT models both substantially outperform the previous word2vec-based SOTA. It is thus apparent that *contextualized* language models do effectively capture Hebrew homograph distinctions, even those based on word-pieces, even for an MRL, and they do so more effectively than non-contextualized models.

Figure 2 demonstrates AlephBERT's performance on different ambiguity types. AlephBERT performs equally well on cases of segmentation ambiguity and morphosyntactic ambiguity. In contrast, when it comes to ambiguities that are purely semantic, the scores are noticeably lower. This is in line with the findings of Ettinger (2020), who shows that BERT is stronger with syntax than semantics; Goldberg (2019) also notes BERT's strong syntactic abilities. Interestingly, the same gap exists with the W2V-based method. Thus, both contextualized and non-contextualized embeddings struggle to differentiate between senses which are morphologically equivalent. Although such cases are only of minimal import when it comes to sentence parsing, they are critical for downstream tasks such as coreference resolution and relation extraction. It thus remains a desideratum to improve disambiguation of purely semantic Hebrew homographs.

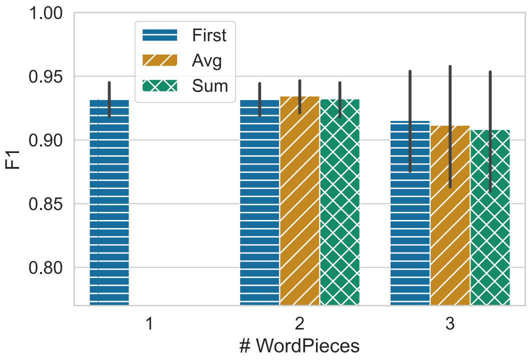

Figure 4: Disambiguation accuracy across varying degrees of word piece splits within the target homograph, using mBERT.

The results in Figure 3 demonstrate that AlephBERT performs equally well on cases of binary homographs as on cases of three-way homograph classification. However, when faced with cases of 4-way or 5-way classification, accuracy declines.

The Effect of Word-Pieces Previous studies have hypothesized that word-pieces are not adequate for capturing complex morphosyntactic structures due to arbitrary (non-linguistic) word-splits. To probe into this we investigate the question, do such splits affect performance. Our 75 homographs are all treated as single tokens in HeBERT and AlephBERT. However, many of the homographs are broken up into word pieces in mBERT, due to its meager Hebrew vocabulary. We thus compare mBERT's results on words treated as single tokens versus those that are broken up into two or three pieces, which are aggregated using first, sum, or average of the vectors. With regard to cases of split words, we train models using three separate methods: providing the MLP with only the embedding of the first word piece; with an average of the word piece embeddings; or with the sum of the embeddings. As shown in Figure 4, the splitting of a homograph into three word-pieces appears to have a negative impact on the ability of the resulting embedding to differentiate between homograph analyses, for all aggregation methods.

Masked Scenario We consider whether AlephBERT embeddings are more effective if we replace the homograph word with [MASK] when running

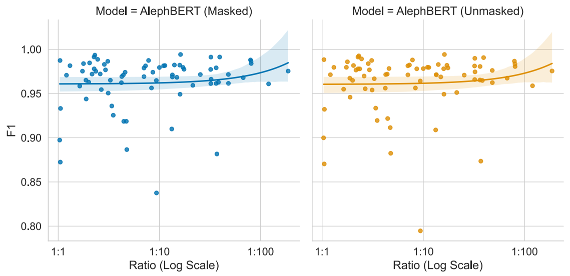

Figure 5: Comparison of unmasked vs. masked scenarios, across varying degrees of skewed homographs. The ratio axis indicates the relative distribution between the least and most frequent analyses of each plotted homograph within naturally-occurring Hebrew text.

the challenge set sentences through AlephBERT. The motivation behind this experiment is that, as explained above, many of the homographs are skewed in their natural proportion. In such cases, we worry whether AlephBERT might be disproportionately influenced by the skewed distribution; replacing the word with [MASK] would prevent the model from being influenced as such. As shown in figure 5, AlephBERT achieves high scores both with balanced homographs as well as with homographs of highly skewed distribution. Using a [MASK] token instead of the actual word does not generally improve performance, whether or not the homographs are of skewed proportion.

Few-Shot Scenarios In our experiments thus far, the 10-fold cross-validation allows the MLP to leverage 90% of the data in each fold (hundreds of sentences for each analysis) in order to learn the difference between the analyses. We now consider whether the AlephBERT embeddings can suffice on a few-shot basis, where the training stage has access to only 100, 50, 25, 10 or even 5 examples of each analysis. In these cases, we train an MLP based only on these few samples, and we use the rest of the sentences for evaluation. Astoundingly, as demonstrated in Figure 6, the AlephBERT embeddings provide a highly accurate solution even on this few-shot basis. Even when training with only 5 examples of each homograph analysis, AlephBERT reaches an accuracy that is not far below the accuracy achieved when performing full 10-fold CV across hundreds of sentences of each analysis.

Probing Scenarios Finally, we probe the pre-trained AlephBERT embeddings (Yaghoobzadeh et al., 2019; Tenney et al., 2019; Klafka and Ettinger, 2020; Belinkov, 2021) to see whether in and of themselves they reflect clusters which correspond to different homograph analyses. We skip the MLP, and instead use the raw embeddings directly, classifying sentences based on their proximity to the centroid of the training samples for each homograph analysis. As shown in the orange bars in Figure 6, this method generally does not perform as well as the MLP-based method; however, the degradation is limited to only a few percentage points, indicating that the raw embeddings are generally clustered in groups which indeed reflect the distinctions between the analyses.

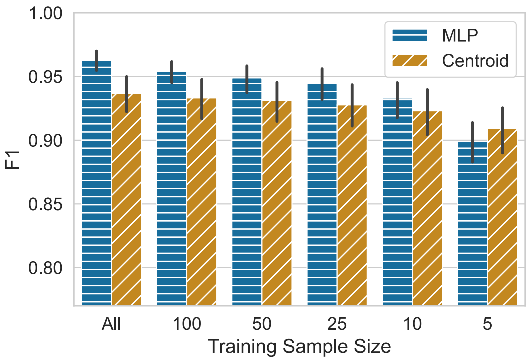

Figure 6: Use of AlephBERT embeddings to differentiate between homographs on a few-shot basis, contrasted with scores from the full 10-fold CV ("All").

5 Conclusion

In this study we have utilized a wide-ranging collection of Hebrew homograph challenge sets in order to evaluate the extent to which raw contextualized embeddings can be leveraged to disambiguate Hebrew homographs. We found that contextualized embeddings can effectively disambiguate analyses of homographs, much more so than non-contextualized ones, regarding multiple types of ambiguity: segmentation, morphosyntactic and sense. Yet, efficacy on pure sense ambiguity is lower than on the other two types. Additionally, an increasing number of splits, or an increasing number of different possible analyses of a token, each lower efficacy. Finally, we found that contextualized embeddings can function effectively for this purpose on a few-shot basis, with as little as 5 examples of each analysis. This indicates that with relatively modest effort, highly ambiguous homographs may be effectively treated.

Limitations

One of the major strengths of this paper is its new and comprehensive dataset for the training and benchmarking Hebrew homograph disambiguation. The dataset is uncomparable in size, quality and balance to all previous Hebrew homograph datasets; we have made every effort to be as inclusive as possible in the creation of the dataset, making sure to include data from a widely diverse set of genres. Nevertheless, a perennial challenge in corpus-based studies is that the lion's share of the available data tends to be authored by male writers. In order to offset this bias, we bolstered our corpus with a large corpus of texts specifically taken from blog sites devoted entirely to female bloggers. Even so, we cannot escape the fact that female writing and feminine conjugations are underrepresented in our dataset.

A further limitation derives from our filter for sentences with offensive language. We perceived early on that our human annotators were not comfortable tagging sentences with offensive language, and we therefore took steps to remove such sentences from our corpus. Nevertheless, this means that our resulting dataset is limited in that it does not properly reflect the use of offensive language in naturally-occurring Hebrew sentences. Furthermore, our resulting tests and reported scores may not accurately reflect the performance of our models when applied to sentences with offensive language.

Ethics Statement

Creation of the Dataset As noted, our dataset contains over 150K sentences in all. Every sentence was reviewed and tagged by our team of human annotators, who chose the relevant homograph analysis for each instance of each of our 75 homographs. Our annotator team included members of diverse genders and sexual orientations. They were paid hourly wages with legal pay stubs. Their hourly wage was well above the minimum wage required by law. The entirety of the dataset will be made available for research purposes with the acceptance of this article, together with the tagging information.

Risks of the Research Ultimately, this data will enable end-users to automatically diacritize and parse large corpora of Hebrew text. For the most part, this will provide a beneficial contribution to the world: for the visually impaired, this technology will enable the development of more precise text-to-speech products; teachers will be able to provide children and second-language learners with accessible diacritized texts; and humanities and linguistics researchers can bolster their research with big-data analysis. However, there also is a risk of nefarious use, for instance, if an end user were to leverage these capabilities in order to produce anonymous texts or recordings containing threats to life, liberty, or happiness.

A Appendix A: Table of Homographs

We present three tables of homographs, corresponding to the three categories of homographs discussed within the paper (segmentation ambiguity, morphosyntactic ambiguity, and semantic ambiguity).[6] In each table, the first column ("form") indicates the homograph as it is found in naturally-occurring non-diacritized Hebrew text.[7] The second column ("word") indicates the possible diacritizations of each form. In cases where the diacritized word includes an attached prefix, a plus sign indicates the segmentation point between the prefix letters and the primary word. Regarding all homographs considered in this paper, different segmentation options are diacritized differently. Thus, for each sentence in the dataset, our human annotators were asked simply to choose the correct diacritization for the target homograph (that is, they were asked to choose among the options listed in the "word" column). There was no need for the annotators to separately tag the segmentation, because in all cases the choice of diacritization itself indicates the segmentation.[8] The third column indicates the morphology of each of the possible diacritizations.[9] The fourth column lists the translation.[10] Within each table the homographs are listed alphabetically.[11]

A.1 Homographs with Segmentation Ambiguity

Form	Word	Morphology[12]	Translation	Sentences
האם	הַאִם	Interrogative	does	1,000
	הָ+אֵם	Det + Noun [F,S,abs]	the + mother	1,000
המראה	הַ+מַּרְאֶה	SConj + Ptcp [M,S] / Det + Noun [M,S,abs]	that + indicates / the + sight	1,000
	הַ+מַּרְאָה	SConj + Ptcp [F,S] / Det + Noun [F,S,abs]	that + indicates / the + mirror	882
	הַמְּרָאָה	Noun [F,S,abs]	takeoff	735

---

[6] It should be noted that the higher level of ambiguity are supersets of the lower levels: segmentation ambiguities generally entail differences on the morphosyntactic and semantic levels as well, and morphosyntactic ambiguities generally also entail semantic ambiguities. Furthermore, because many of the homographs admit to more than two analyses, it is often the case that a subset of the analyses may form a lower level of ambiguity (e.g., just a semantic ambiguity), while other analyses form a higher level of ambiguity (e.g. segmentation ambiguity). For the purposes of this paper, we categorize each homograph according to the highest level of ambiguity involved: First, if a segmentation ambiguity is indicated anywhere across the possible analyses, then we include the homograph in the "segmentation ambiguity" category. Next, if there is no segmentation ambiguity, but a morphosyntactic ambiguity is indicated anywhere across the possible analyses, then we include the homograph in the "morphosyntactic ambiguity" category. Finally, if the analyses all differ only on the semantic level, then we include the homograph in the "semantic ambiguity" category.

[7] The ranking of analyses is based on a frequency analysis of our in-house annotated corpus. It is worth emphasizing that the paper as a whole relates to each of the 75 homographs specifically as they are spelled in this list, and does not relate to cases where further prefixes are attached to the homographs. As a result, the frequency analysis may sometimes seem counterintuitive. For instance, regarding the form ראשי, a native Hebrew speaker might intuit that the adjectival form is primary (רָאשִׁי). However, in practice, that sense is common only when prefixed with a definitive marker (הראשי). In contrast, the homograph considered here involves the form ראשי as is, without any prefixes; in this case, the other analyses are far more common.

[8] It should be noted that in certain sentences, an exceedingly rare diacritization was warranted, which was not among the options listed in the "word" column. The annotators were instructed to tag such cases as "none of the above", and all such sentences were removed from the corpus. Similarly, some sentences do not provide enough context to determine the correct diacritization; the annotators were asked to tag such sentences as "unclear", and these sentences too were removed from the corpus.

[9] In most cases, a diacritized form has one specific morphological analysis. However, in other cases, the diacritized form can admit to multiple morphologies. In such cases, we list all of the practically relevant morphological analyses in the third column, separated by a slash (thus for instance in the case of זר). Rare analyses which hardly ever occur in practice are not listed.

[10] Naturally, a given Hebrew term often captures a substantial range of potential English translations, and it would not be practical to list them all in this column; therefore, we generally present only a single representative translation.

[11] Ideally, we might have grouped the homographs based on part-of-speech instead. However, as can be seen from the following tables, the 75 homographs vary so widely in terms of the parts of speech that they can represent, such that alphabetical listing was deemed most useful.

[12] Key to morphology abbreviations: F=Feminine; M=Masculine; S=Singular; P=Plural; abs=absolute; cons=construct; 1,2,3=First Person, Second Person, Third Person; suf=suffix; Det = determiner; SConj=Subordinating Conjunction; Adj=Adjective; Conj=Conjunction; Prep=Preposition; Propn=Proper Noun; Adv=Adverb; Ptcp=Participle; ACC=Accusative marker.

הקפה	הַ+קָפֶה	Det + Noun [M,S,abs]	the + coffee	1,000

	שָׁם	Adv	there	1,000
	שָׁם	Verb [M,S,Present/Past]	he placed	1,000
תנאי	תְּנָאֵי	Noun [M,P,cons]	conditions of	1,000
	תְּנַאי	Noun [M,S,abs/cons]	condition	834

A.3 Homographs with Semantic Ambiguity

Form	Word	Morphology	Translation	Sentences
הזמר	הַ+זֶּמֶר	Det + Noun [M,S,abs]	the + music	1,000
	הַ+זַּמָּר	Det + Noun [M,S,abs]	the + musician	1,000

הסופר	**הַ+סוּפֶּר**	Det + Noun [M,S,abs]	the + market	763
	הַ+סוֹפֵר	Det + Noun [M,S,abs]	the + author	570
זמר	**זַמָּר**	Noun [M,S,abs]	musician	1,000
	זֶמֶר	Noun [M,S,abs]	song	602
חברה	**חֲבֵרָה**	Noun [F,S,abs]	friend	1,000
	חֶבְרָה	Noun [F,S,abs]	company	1,000
רשות	**רְשׁוּת**	Noun [F,S,abs/cons]	permission	1,000
	רָשׁוּת	Noun [F,S,abs/cons]	authority	1,000

B Appendix B: Creation of our Annotated Dataset

We present here further details regarding the creation of our annotated homograph dataset. As noted above, our dataset contains challenge sets for 75 Hebrew homographs. In almost all cases, we collect 1000 sentences for the primary analysis, at least 500 sentences for the secondary analysis, and at least 250 for each additional analysis. Every sentence was tagged by our team of human annotators.

The main challenge that we faced is that it is often extraordinarily difficult to identify a sufficient number of naturally-occurring Hebrew sentences attesting to the non-primary homograph analyses. In many cases, the naturally-occurring ratio of these analyses is 100:1 or worse, meaning that the non-primary analyses only occur once in 100 or more sentences. In such cases, prima facie, we would need to tag some 50,000 randomly-selected cases of the homograph in order to gather 500 cases of the alternate analysis. It would not be practical to tag this number of sentences for each of the 75 homographs. Therefore, we devised the following three-step process to allow us to efficiently gather a sufficient number of sentences attesting each possible analysis of each homograph:

1. For each homograph, we first gather 4000 randomly-selected sentences from an untagged Hebrew corpus. For each sentence, our annotation team determines the correct analysis of the homograph. This initial step virtually always provides us with a sufficient number of sentences attesting to the primary analysis, and sometimes for the secondary analysis as well. However, it often leaves us with an insufficient number of sentences regarding the non-primary analyses.

2. In order to find additional sentences for the non-primary homograph analyses, we train classifiers to identify a wide net of potential candidate sentences. For these classifiers, we use the known cases of the primary homograph analysis (identified in the previous step) as the first class, and we use various proxies to represent the opposing class. The proxies used for the opposing class include the following: (A) Hebrew words which unambiguously function morphosyntactically in a manner that is different from the morphosyntactic function of the primary class; (B) Hebrew words whose word2vec embedding is maximally distant from that of the homograph in question (because, in practice, for homographs of skewed proportions, the word2vec embedding of the word tends to represent the primary usage); (C) Randomly-selected Hebrew words. These classifiers are trained with a BiLSTM encoding of the word2vec embeddings of the four neighbors on either side of the target word (not including the target word itself). Essentially, the point of these classifiers is to identify a generous selection of cases in which the homographs may possibly be functioning in a way that is different than their primary usage.

3. We run these classifiers on all instances of the target homograph in our untagged Hebrew corpus. Cases that are classified as the opposing class are sent to our annotators for human verification. In practice, these proxy-based classifiers reach a precision of 15-30% on the task of identifying sentences in which the target homographs function according to a non-primary analysis. Thus, on average, for any given homograph, tagging an additional 2222 sentences allows us to collect 500 relevant cases of the secondary analysis.

Our procedure ensures diversity while keeping the process cost-effective. All in all it took approximately 1500 hours of annotation time to amass the sentences in the present dataset.

C Appendix C: Computational Equipment

We performed all computations on a desktop workstation with an i9-10980XE processor and 256GB of memory. This system enabled us to run 36 experiments in parallel (the processor contains 18 hyperthreaded cores), and thus we were able to complete all of the relevant experiments and computations over the course of several weeks of calendar time.

D Appendix D: Neural Network Implementation Details

All BiLSTMs and MLPs were trained using dynet (http://dynet.io/). All MLPs are constructed with a hidden layer of size 100, and with two layers. We train with the Adam optimizer at a learning rate of .001, for 3 epochs.

Our word2vec embeddings for Hebrew are of size 100. We trained them on a 500M-word Hebrew corpus using word2vecf (`https://github.com/BIU-NLP/word2vecf`, adding position info to context words, and excluding words with a frequency of less than seven. All in all, our word2vec vocabulary covers 94.6% of the tokens in our dataset. For the out-of-vocabulary words, we use a trainable UNK parameter in place of the word2vec embedding, which is trained from scratch for each “word expert” classifier.

As per the "word expert" paradigm, a completely separate MLP is trained for each homograph. In each case, the possible homograph analyses are each treated as a possible class for prediction, and the MLP is trained to choose from among those classes. Thus, for instance, if the homograph has two analyses, we train an MLP to predict one of the two classes; if the homograph has three analyses, then we train an MLP to predict one of the three classes; and so on.

For the Probing Scenarios based on centroid classification, we proceed as follows. For each of the homographs, given the training sample size (100, 50, 25, etc.), we randomly select that amount of training sentences for each of the possible analyses of the homograph. We calculate the centroid for each of the analyses by averaging the embeddings of the target homographs within the corresponding training sentences. The remainder of the available sentences for the homograph forms the test set. We classify them by calculating the dot product of the embedding of the target homograph in each given test sentence with the centroid of each of the homograph analyses. We run this process 200 times, each time selecting a different random set of training sentences. The values plotted in Figure 6 reflect the average of the F1 scores across these 200 rounds. For the corresponding MLP-based experiments presented for comparison in the aforementioned table, we follow an analogous procedure, across 10 rounds.

Parameter-Efficient Tuning with Special Token Adaptation

Abstract

Parameter-efficient tuning aims at updating only a small subset of parameters when adapting a pretrained model to downstream tasks. In this work, we introduce PASTA, in which we only modify the special token representations (e.g., `[SEP]` and `[CLS]` in BERT) before the self-attention module at each layer in Transformer-based models. PASTA achieves comparable performance to full finetuning in natural language understanding tasks including text classification and NER with up to only 0.029% of total parameters trained. Our work not only provides a simple yet effective way of parameter-efficient tuning, which has a wide range of practical applications when deploying finetuned models for multiple tasks, but also demonstrates the pivotal role of special tokens in pretrained language models.[1]

1 Introduction

Built upon a pretrained language model (PLM; Devlin et al. 2019; Liu et al. 2019; Yang et al. 2019; Chowdhery et al. 2022), many of the recent NLP systems are developed based on task-specific finetuning. In this way, the PLM effectively leverages the task-agnostic knowledge captured during self-supervised pretraining and adapts itself to downstream tasks. However, full finetuning poses a challenge to model deployment under multi-task, memory-limited scenarios, where we need to train and store a separate full-sized model for each substantially distinct task. As an alternative, parameter-efficient tuning (Ding et al., 2022) aims at only updating a small number of parameters when adapting PLMs to downstream tasks while making most of the model parameters fixed and shared among tasks, thus reducing memory usage.

In this paper, we propose **PA**rameter-efficient tuning with **S**pecial **T**oken **A**daptation (PASTA), where we only add trainable vectors to hidden representations of *special tokens* [2] at each layer before the multi-head attention module in Transformer-based PLMs. Our work is motivated by the role of special tokens in PLMs. First, special tokens such as `[CLS]` collect information from the whole input sequence and are typically regarded as the global text representation (Devlin et al., 2019). For sentence-level tasks such as GLUE (Wang et al., 2018), a common practice is to add a new classifier head based on the `[CLS]` representation in the last model layer. Thus, if trained properly, by updating the `[CLS]` representations, we can approximate the result of the *information collection* process in PLMs. Second, many attention heads in PLMs follow a vertical pattern[3], where the attention scores are mostly allocated to either the `[CLS]` or `[SEP]` token (Clark et al., 2019; Kovaleva et al., 2019), as

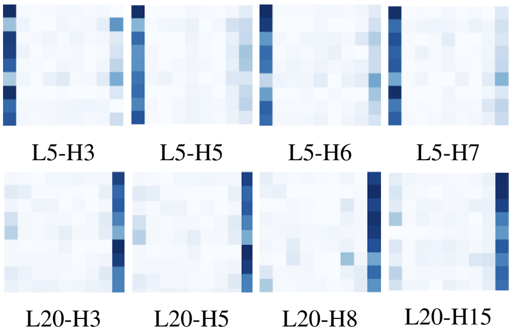

Figure 1: Examples of vertical attention heads in the 5-th and 20-th layer of BERT-large with a random sample from CoLA (Warstadt et al., 2019) as input. Heads in the first row and second row assign most of maximal attention weights to `[CLS]` and `[SEP]` respectively. See Appx. §C for the full attention map.

---

[*] Work done when visiting USC.

[1] Our code is publicly available at: `https://github.com/luka-group/PASTA/`

[2] WLOG, we use the notation of special tokens `[CLS]` and `[SEP]` in BERT for the convenience of expression, while the method applies in the same way to other paradigms such as `<S>` and `</S>` in RoBERTa (Liu et al., 2019).

[3] Following Voita et al. (2019) and Yao et al. (2021), an attention head is regarded as *vertical* if at least 90% tokens assign maximal attention scores to either `[CLS]` or `[SEP]`.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 865–872
May 2-6, 2023

illustrated in Fig. 1. Therefore, updates to special tokens can also be *disseminated* to other tokens during the forward pass through the vertical attention heads (Elhage et al., 2021), enabling the PLMs to adapt to both sentential and lexical tasks.

By tuning as few as up to 0.029% of the total parameters, PASTA achieves competitive performance on par with full finetuning and BitFit (Zaken et al., 2022) on GLUE (§4.2). It also outperforms P-tuning v2 (Liu et al., 2022) by 0.6% on CoNLL2003 with 20× fewer additional parameters (§4.3). The ablation study shows that we can further reduce trainable parameters to 0.009% with only a slight performance drop (§4.4), showing the merit of adapting special token representations.

2 Related Work

A recent survey (Ding et al., 2022) categorizes three types of *parameter-efficient tuning* methods. *Addition methods* (Houlsby et al., 2019; Lester et al., 2021; Liu et al., 2022) introduce a small number of additional trainable parameters while keeping those in the PLM unchanged. *Specification methods* (Zaken et al., 2022; Guo et al., 2021; Zhao et al., 2020) update a portion of parameters in the PLM while keeping others frozen. *Reparameterization methods* (Aghajanyan et al., 2021; Hu et al., 2021; Qin et al., 2021) modify PLMs' structures to parameter-efficient forms. Our method belongs to the addition-based methods and follows the basic settings of P-tuning v2 (Liu et al., 2022), where newly initialized hidden representations of tokens are inserted into each Transformer layer. Different from most prompt tuning methods that introduce new tokens, we add the introduced vectors to the hidden states of special tokens and keep the sequence length unchanged.

Previous works use probing tasks (Wu et al., 2020) and pruning methods (Prasanna et al., 2020) to study the roles of different modules inside BERT. It has been shown that functional specialization exists in BERT self-attention heads (Clark et al., 2019), and vertical attention heads[3] take up a large portion (Yao et al., 2021). Kovaleva et al. (2019) find that vertical attention heads are almost exclusively associated with attention to `[SEP]` or `[CLS]` tokens, and Clark et al. (2019) conclude that heads in early layers often attend to `[CLS]` while in middle layers attend to `[SEP]`. In this work, we demonstrate that adapting hidden representations of special tokens is sufficient to bring the performance of PLMs to the level of full finetuning.

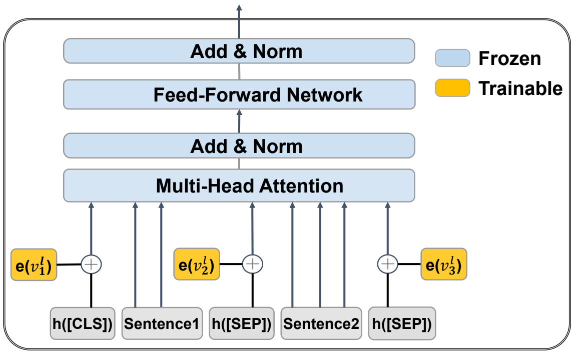

Figure 2: Architecture of PASTA layer in Transformer. Skip-connections in Transformers are not shown for brevity. At layer l we add a trainable vector $\mathbf{e}(\mathbf{v}_p^l) \in \mathbb{R}^d$ to the hidden representation of the p-th special token in the input sequence, and freeze the weights of the PLM.

3 PASTA

Given a large PLM, our goal is to develop a parameter-efficient tuning method that only updates a small set of parameters when adapting to a downstream task. To this end, we propose a simple yet effective method called PASTA, in which we train a hidden vector for every special token at each Transformer layer, along with a task-specific classifier, while freezing the parameters of the PLM.

3.1 Special Token Adaptation

The special token adaption is illustrated in Fig. 2. Although these adaptations are not directly applied to non-special tokens, changes in special token hidden states can be effectively disseminated to other tokens via self-attention during forward passes, thanks to the prevalence of vertical attention heads[3] in PLMs.

Specifically, denote the inputs to the l-th Transformer layer as $\mathbf{H}^l = \{\mathbf{h}_i^l\}_{i=1}^N, \mathbf{h}_i^l \in \mathbb{R}^d$, where N is the number of input tokens, d is the hidden size, PASTA modifies the inputs as follows:

$$\begin{aligned}\mathbf{H}_{\text{mod}}^l &= \{\mathbf{h}_i^l + \mathbf{m}_i^l\}_{i=1}^N, \\ \mathbf{H}^{l+1} &= \text{Trm}^l(\mathbf{H}_{\text{mod}}^l),\end{aligned}$$

where Trm^l is the l-th Transformer layer, $\mathbf{m}_i^l \in \mathbb{R}^d$ is our special token adaptation defined as follows:

$$\mathbf{m}_i^l = \begin{cases} \mathbf{0} & \text{if token } i \text{ is not a special token} \\ \mathbf{e}(\mathbf{v}_p^l) & \text{if token } i \text{ is the } p\text{-th special token} \end{cases}$$

	# Param	Parameter Consistency
Adapter	$\mathcal{O}(L \times d \times r)$	✓
P-tuning v2	$\mathcal{O}(L \times d \times T)$	✓
BitFit	$\mathcal{O}(L \times (d + m))$	✓
Diff-Prune	-	✗
PASTA	$\mathcal{O}(L \times d)$	✓

Table 1: Parameter complexity of PASTA and baselines. Here L and d refer to the number of layers and hidden size of the PLM. m and r refer to the intermediate size of FFN modules in Transformers and Adapters, respectively. T is the prompt length. Parameter consistency refers to whether the set of trainable parameters is consistent across different tasks (Zaken et al., 2022).

where $\mathbf{e}(\mathbf{v}_p^l) \in \mathbb{R}^d$ is the trainable vector added to the hidden representation of the p-th special token in the input sequence. During downstream task training, only those introduced hidden vectors for special tokens and the task-specific classifier are optimized, and the rest of model parameters are frozen.

3.2 Parameter Efficiency and Consistency

As shown in Tab. 1, PASTA achieves $\mathcal{O}(L \times d)$ parameter complexity[4] and updates as few as 0.015%-0.029% of the parameters compared to a full PLM when using BERT-large or RoBERTa-large as backbone. Unlike Adapter (Houlsby et al., 2019) that learns the transformation of all input tokens using a shared FFN, PASTA only learns the task-specific update of special token representations as a bias term, which significantly reduces the parameter capacity needed for adaptation on downstream tasks.

Meanwhile, the set of parameters introduced by PASTA is consistent across different tasks, making it efficient for hardware-based deployment (Zaken et al., 2022). On the contrary, in Diff-Prune, the parameter update is considered as a term of the loss function (Guo et al., 2021), resulting in different sets of updated parameters in distinct tasks.

4 Experiments and Results

We hereby study the downstream performance of PASTA and analyze the properties of introduced hidden vectors.

4.1 Experimental Setup

Baseline Methods. We compare PASTA with the following parameter-efficient tuning methods in prior studies. **Adapter** (Houlsby et al., 2019) introduces new feed-forward modules in Transformer layers while keeping original parameters of the PLM frozen. **BitFit** (Zaken et al., 2022) updates all bias terms in the PLM during finetuning. **Diff-Prune** (Guo et al., 2021) introduces L_0-norm penalty on the updated parameters to encourage sparsity of tuned parameters. **P-tuning v2** (Liu et al., 2022) prepends trainable hidden vectors before the input sequence at each layer while keeping the original PLM parameters frozen. **LoRA** (Hu et al., 2021) uses low-rank decomposition matrices to model the parameter updates.

Model Configuration. We conduct our experiments using BERT-large and RoBERTa-large (We also report experiments with BERT-base in Appx. §A). To facilitate comparison with baseline works, we take most of the experimental results from their original papers which are reported with either BERT-large or RoBERTa-large. Note that multiple `[SEP]` tokens in a single sequence (e.g., in sentence pair tasks like MNLI) are treated as different special tokens and have separate sets of trainable parameters, and the number of trainable parameters varies among downstream tasks according to the number of special tokens added. Details of training and hyperparameters settings are shown in Appx. §B.

4.2 GLUE Tasks

Task Setup. We evaluate PASTA on the widely used GLUE benchmark[5] (Wang et al., 2018). For the convenience of direct comparison, we use the same metrics as were used in baseline works (Devlin et al., 2019; Liu et al., 2019). For experiments with BERT, MRPC and QQP are evaluated using F1 score, STS-B is evaluated using Spearman's correlation coefficient, CoLA is evaluated using Matthew's Correlation, and the other tasks are evaluated using accuracy. For experiments with RoBERTa, STS-B is evaluated using Pearson's correlation coefficient, CoLA is evaluated using Matthew's Correlation, and the other tasks are evaluated using accuracy.

Results. Tabs. 2 and 3 report the performance of PASTA on GLUE benchmark with BERT-large and RoBERTa-large respectively. PASTA with RoBERTa-large achieves the same average score

---

[4] The number of special tokens are invariant to the scale of models, and are usually very small.

[5] Following previous work (Houlsby et al., 2019; Guo et al., 2021; Zaken et al., 2022), we exclude WNLI since BERT underperforms the majority class baseline (Devlin et al., 2019).

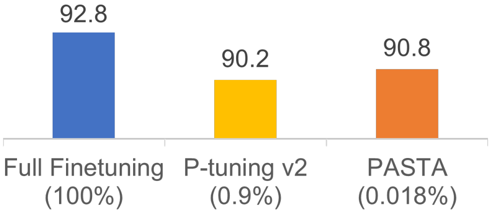

Figure 3: NER results on CoNLL03 with BERT-large (F1 score percentages are marked over the bars). Each method is labeled with the percentage of trainable parameter sizes with regard to full finetuning in parentheses.

as that of full finetuning over GLUE tasks. PASTA with BERT-large achieves an average score on par with BitFit using over 3× fewer trainable parameters and comparable results to other higher parameter complexity baselines. The results demonstrate that by leveraging the pivotal role of special tokens in PLMs, PASTA is able to effectively adapt the model to sentence-level tasks with significantly fewer parameters tuned than previous methods.

4.3 Named Entity Recognition

Task Setup. We experiment with the NER task on CoNLL2003 (Tjong Kim Sang and De Meulder, 2003). Following Devlin et al. (2019), we formulate NER as a token classification problem.

Results. As shown in Fig. 3, PASTA with BERT-large achieves an F1 score of 90.8% on CoNLL2003 test set, outperforming P-tuning v2 (Liu et al., 2022) by 0.6% with 20× fewer trainable parameters, while falling behind full finetuning by 2.0%. Nevertheless, the strong performance of PASTA compared to P-tuning v2 indicates that even though PASTA only directly adapts special tokens, the representations of all input tokens can still be properly tuned, supporting our hypothesis that vertical attention heads are able to disseminate adaptations in special token hidden states to other tokens.

4.4 Analysis

Ablation on choices of special tokens. To understand the effect of tuning different combinations of special tokens on downstream tasks, we further limit the additional parameter capacity of PASTA by only adapting either `[CLS]` or `[SEP]`, or share a common vector across all special tokens. Tab. 4 shows the performance of three ablated variants and a baseline that only tunes the classification head on top of a fixed BERT-large. In general, we observe

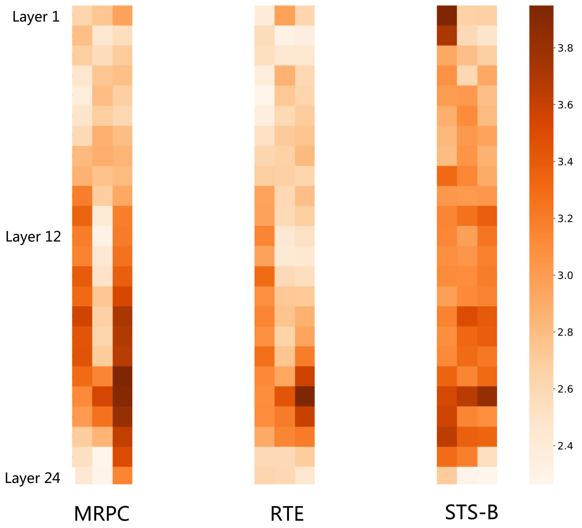

Figure 4: The distribution map of norms of introduced hidden vectors on MRPC, RTE and STS-B tasks with BERT-large. In each subgraph, the first column shows the norms of introduced vectors added to `[CLS]` at each layer, and the second and third columns are introduced vector norms at two `[SEP]` tokens respectively.

a decrease in performance on most tasks except on MRPC for three PaSTA variants, and performance degrades significantly if we do not adapt any special tokens. These results demonstrate the vital role of introduced hidden vectors for special tokens in PaSTA, while the best choice of special tokens to be adapted may vary depending on the task.

Norm distribution of introduced hidden vectors. Fig. 4 shows the norm distribution of introduced vectors on downstream tasks. The introduced hidden vectors learn the difference of special tokens between pretrained and adapted models, and thus norms of those vectors indicate the magnitude of parameter change at different layers. Similar to the pattern of parameter change during full finetuning (Kovaleva et al., 2019), PaSTA generally has larger norms of hidden vectors at layers closer to the output.

5 Conclusion

We present PaSTA, a parameter-efficient tuning method that only modifies special token representations at each Transformer layer when adapting to downstream tasks. Our approach is motivated by the observation that PLMs have a large amount of vertical attention heads that heavily attend to special tokens, and these heads disseminate value updates from special tokens to all of the other tokens. Experiments show that PaSTA achieves strong performance comparable to full finetuning on sentential and lexical tasks with high parameter efficiency. Our work not only provides an effective solution for parameter-efficient tuning, but also demonstrates the pivotal role of special tokens in PLMs.

Limitations

In this work we hypothesize that the vertical attention heads could play a role as "information disseminator" based on the theoretical analysis of Transformers (Elhage et al., 2021). However, we still have no direct approaches such as probing tasks and reverse engineering to prove this assumption. And since PaSTA relies on adaptation of special tokens, it cannot be applied to language models which do not pad special tokens to input sequences such as GPT-2 (Radford et al., 2019). For the empirical results, we choose GLUE benchmark and CoNLL2003 to study the performance on language understanding tasks. The effectiveness of PaSTA on language generation tasks has not been tested in this work due to limited bandwidth. Finally, similar to other parameter-efficient tuning methods, PaSTA suffers from a higher computational cost compared to full finetuning.

A Performance of BERT-base

Tab. 5 reports the performance of PASTA and a part of baselines with BERT-base as backbones on GLUE development sets. We do not put the result table in the main body of this work because most baselines did not report GLUE test set scores using BERT-base, and only three of them reported GLUE development set scores with BERT-base in their works. PASTA slightly underperforms baselines on average, while it outperforms other models on small datasets such as RTE and MRPC.

B Implementation Details

Our model is implemented based on Huggingface's Transformers. We optimize models with AdamW (Loshchilov and Hutter, 2017). We set the maximum input length to 128 and use a fixed random seed of 42 for all tasks. Experiments are done on NVIDIA RTX A5000 for averagely 3 hours per task, and distributed training is used for most tasks. Tab. 6 reports the best hyperparameters for model training. For hyperparameter search, we select learning rate from {5e-4, 1e-3, 2e-3, 2.5e-3, 3e-3, 4.5e-3, 5e-3, 7e-3} and the number of epochs from {50, 80, 100, 150}.

C Full Attention Map

Fig. 5 illustrates the attention maps of all heads in BERT-large. With a random sample from CoLA dataset as input (*"Fred watered the plants flat."*), there are 112 heads out of 384 in total being vertical heads[3].

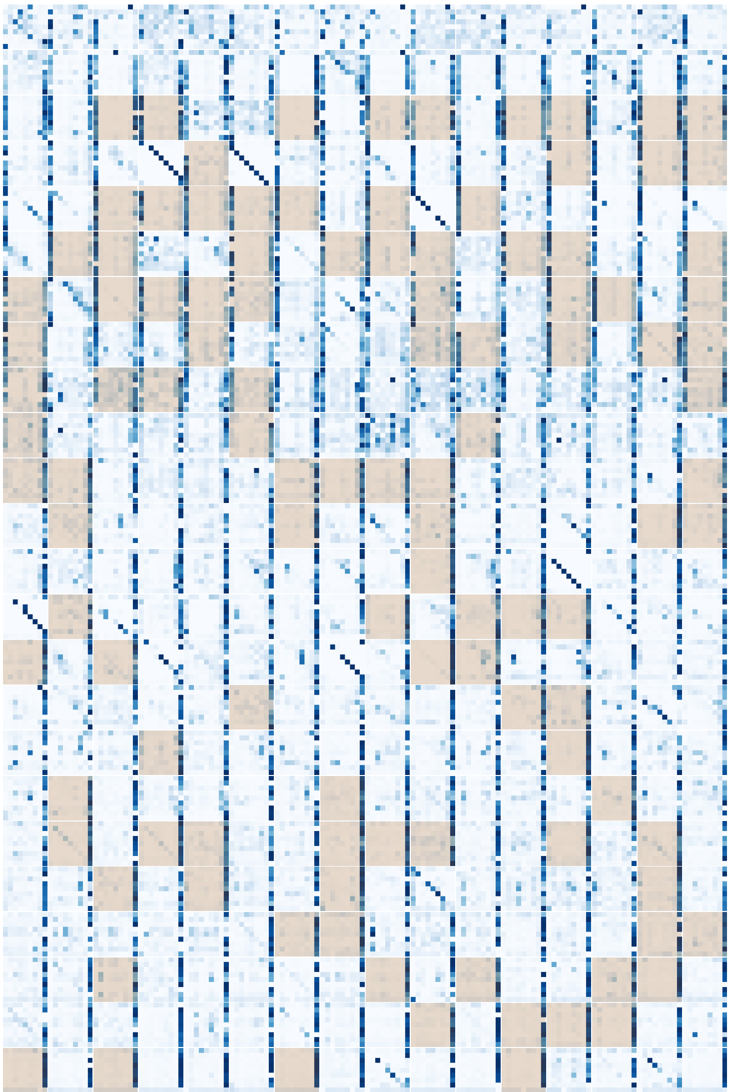

Figure 5: Full attention map of BERT-large pretrained with a random sample from CoLA as input. Rows and columns represent model layers and heads respectively, and darker color indicates larger weights. Vertical attention heads are highlighted in orange.

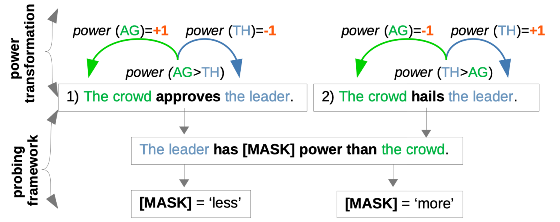
Abstract

Subtle changes in word choice in communication can evoke very different associations with the involved actors. For instance, a company 'employing workers' evokes a more positive connotation than the one 'exploiting' them. This concept is called *connotation*. This paper investigates whether pre-trained language models (PLMs) encode such subtle connotative information about *power differentials* between involved entities. We design a probing framework for power connotation, building on Sap et al. (2017)'s operationalization of connotation frames. We show that zero-shot prompting of PLMs leads to above chance prediction of power connotation, however fine-tuning PLMs using our framework drastically improves their accuracy. Using our fine-tuned models, we present a case study of power dynamics in US news reporting on immigration, showing the potential of our framework as a tool for understanding subtle bias in the media.[1]



Prelude	The crowd approves the leader.
Hypothesis	The leader has MASK power than the crowd.
Connotation	$AG \succ_{power} TH$
Prelude	The crowd hails the leader.
Hypothesis	The leader has MASK power than the crowd.
Connotation	$AG \prec_{power} TH$

Figure 1: Top: Connotation frames from Sap et al. (2017)'s dataset for the predicates 'approve' and 'hail', which evoke different power differentials between arguments 'crowd' and 'leader'. Predicate 'approve' implies that the leader needs approval of the *powerful crowd*; while 'hail' suggests that the crowd praises the *powerful leader*. Colored arrows show how we map from predicate- to entity-centric connotation. Bottom: Our PLM probing framework comprising a *prelude* (introducing predicate and arguments) and a *hypothesis* (expressing the implied power differential).

1 Introduction

An author's choice of words evokes associations and reactions from a reader that go beyond the literal meaning they express. This underlying level of meaning is called connotation and often carries social, cultural, or emotional implications for listeners or readers (Sonesson, 1998). In high-stakes settings such as opinion polls or news reporting, it has been shown that subtle changes in word choices can influence responses or opinions (Kahneman and Tversky, 1984; Rashkin et al., 2016). For example, the choice of the term 'undocumented workers' vs. 'illegal aliens' to describe immigrants can elicit different levels of prejudice toward that group (M.S., 2010).

Different connotations can inject multiple layers of meaning into a word, phrase, or passage. This paper focuses on *connotations of power* arising from descriptions of entities. Power dynamics are omnipresent at all levels of society, between individuals, groups, political actors, or institutions, and the subjective power of an entity can be expressed through the choice of words used to describe their actions (Sap et al., 2017). For example, in Figure 1, sentence (1) implies the leader requires approval of the *powerful crowd*; while sentence (2) implies the crowd praises the *powerful leader*.

Following the successful application of *probing* pre-trained language models (PLMs) to a variety of tasks ranging from grammatical structure (Koto et al., 2021; Kulmizev et al., 2020; Kassner and Schütze, 2020; Sinclair et al., 2022) to commonsense reasoning (Lin et al., 2020), we extend the probing paradigm to connotative power and study

the extent to which PLMs can be used to reliably predict power dynamics between two entities.

We do so by drawing on the recently proposed notion of *connotation frames* (Rashkin et al., 2016; Sap et al., 2017; Ma et al., 2020), a structured framework that captures connotative associations evoked by a predicate (verb) about its agent (subject) and theme (object). Figure 1 illustrates the concept of the *power connotation frame*, which for a given predicate predicts whether the agent (subject) has more, less, or equal power compared to the theme (object). Specifically, we devise a probing framework to test PLMs for this formalization of connotative power which carefully controls for confounds relating to the specific agents and themes and probe structure. We show that, while PLMs cannot reliably predict power dynamics in a zero-shot setting, it is possible to fine-tune PLMs using our probes to predict power connotation with close to 80% macro F1.

Using our fine-tuned PLMs, we present a case study of power dynamics in US news reporting on the topic of immigration. News reporting is a particularly prominent example of documents where power dynamics are often at the core of the issue under discussion, and there is often an intrinsic motivation, especially in partisan news outlets, to present information in a biased way. We draw connections between power dynamics and emphasis framing and surface subtle bias in the context of immigration. In sum, our main contributions are:

- We propose a method to (i) disentangle connotation frames implied by the predicate from its arguments and the sentence structure; and (ii) quantify predicate connotation frames in PLMs.
- We probe the zero-shot ability of common PLMs to capture connotation frames and find poor performance, suggesting that this subtle signal is not captured in the representations.
- We show that the power prediction performance of PLMs can be drastically improved by fine-tuning on a small set of labeled instances, achieving F1 scores close to 80%.
- Using the best model, we present a case study on the news reporting on immigration and analyze how the power of immigrants and immigration services are portrayed in US news outlets with different political leaning.

2 Background

In this section, we provide an overview of the relevant literature on connotative framing and its formalization, probing PLMs, and how connotative framing and PLMs combined can be harnessed to study media bias.

2.1 Connotation Frames

Connotation frames were introduced by Rashkin et al. (2016) as a formalism for examining the sentiment and presupposed facts about actors and themes, as implied by the actions and events that they engage in (i.e., their predicates). The original framework cover several connotations, incldinging the writer's perspective (e.g., being sympathetic/antagonistic towards the agent), effect (e.g., the theme has been hurt), and the mental states projected onto agents and themes (e.g., being unhappy). Later work by Sap et al. (2017) extended the set of connotation frames to include 'power', which denotes the relative authority levels of the agent and theme implied by the predicate, and 'agency' defined as the capability of the agent to progress their own narrative. While our paper focuses on *power*, we note that our methodology can be extended to other connotation dimensions.

Sap et al. (2017) published a data set of English verbs manually annotated with power levels: The agent has either more power (AG$\succ_{power}$TH; the writer implies the agent has a level of control over the theme), or less power (AG$\prec_{power}$TH; the theme is implied to be more authoritative). We use a subset of their data in this work.[2] Unlike previous approaches to connotation frame prediction, which used annotated data to train supervised classifiers (Field et al., 2019; Rashkin et al., 2016), we use the method of probing to study and extend PLMs' ability to predict connotative power.

In earlier application of connotation frames to study various biases, researchers studied entities' depicted sentiment polarities in news articles (Rashkin et al., 2016), gendered bias in movies Sap et al. (2017), or people portrayals in #metoo stories Field et al. (2019). In our case study, we connect power connotation with emphasis frames (Card et al., 2015) for a more nuanced analysis of media bias. We show that our method is applicable to complex input sentences, diverging from settings in prior work, which largely considered isolated,

---

[2] The original data also includes an 'equal power' option, which we do not use here.

short text snippets (such as (agent,predicate,theme) tuples), and abstracted away from specific entities by using placeholders.

2.2 Probing PLMs

Probing language models for different types of knowledge has become a widely-used approach to understanding the knowledge encoded in PLMs (Liu et al., 2023). Typically, a PLM is presented with a prompting input and either completes the input or predicts the most likely token to fill in a masked position. Auto-prompting (Shin et al. (2020); PLMs generating prompts) and continuous prompting (Qin and Eisner (2021); prompting with an embedding) have been proposed recently, reducing the requirement of natural prompt engineering, but also transparency. While probing is a flexible framework, previous work showed that results can be sensitive to prompt wording and structure (Elazar et al., 2021a), and recommended considering such confounds by careful construction of controlled probe sets. Probing can be used as a zero-shot knowledge querying strategy or a way of fine-tuning to train PLMs to more accurately complete probes (Liu et al., 2023). Here, we extend probing to subtle connotative power associations arising from transitive verbs. Following previous work (Trichelair et al., 2019; Elazar et al., 2021b), we introduce several layers of controls, including paraphrased prompts and controlled sets of entities (i.e., predicate arguments) to ensure our findings are robust.

2.3 Media Bias and Framing

Automatically predicting framing bias has attracted recent attention in the NLP community, ranging from article-level frame prediction (Card et al., 2016; Field et al., 2018; Khanehzar et al., 2019, 2021) to tweet analysis (Mendelsohn et al., 2021). Previous works (Card et al., 2016; Khanehzar et al., 2021) showed characteristics of entities could help predict the article-level emphasis frames. In a case study (§ 7) on the topic of immigration in major US news outlets, we analyze the interplay of power connotation and article-level emphasis frames. Immigration has been a contested issue in the US, with the proponents and opponents actively trying to steer public opinion towards their stance by emphasizing selective and often simplified aspects of the topic (Farris and Silber Mohamed, 2018; Lawlor and Tolley, 2017; Ommundsen et al., 2014).

3 Probing PLMs for Connotative Power

We propose a probing framework to assess how much connotative information PLMs acquired during pretraining, including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019) and ALBERT (Lan et al., 2020). Similar to the masked token prediction objective during PLM pre-training, we have PLMs predict a masked token which in context reveals the power dynamics between an agent and theme in a given sentence. Our probe formulation is closely tied to Sap et al. (2017)'s annotation instructions to align the ground-truth data and information elicited from the PLMs.

We directly query the underlying masked language model in PLMs to compute power connotations associated with predicates. In particular, we formulate our probing template reflecting the definition of the power connotation:

Probe 1 *AG P TH. TH has MASK power than AG.*

Here, P is a placeholder for a predicate (details in §5.2). AG and TH are placeholders for concrete entities in the agent and theme position, which during probing and fine-tuning, are instantiated with common English names (details in §3.1). In the remainder of this paper, we will refer to the first sentence of our template as *prelude* which introduces the verb and associated entities; and to the second sentence as *hypothesis*. Figure 1 (bottom) shows two instatinated probes.

The PLMs are probed with the context of an instantiated probe with $\{P{=}p, AG{=}ag, TH{=}th\}$:

$$P(\text{MASK}{=}m|p, ag, th),$$

for the predicted probability of two possible values in the MASK position, namely the masked target word taking value $m{\in}\{\text{'more'}, \text{'less'}\}$. For example, if $P(m{=}\text{'more'}) > P(m{=}\text{'less'})$, the PLM predicts higher power of theme (th) than agent (ag) of the verb p, ($\text{AG}{\prec}_{\text{power}}\text{TH}$). To reduce the impact of specific instantiations of entities, we compute the final power connotation score for p as the average score over a large numger of entity combinations in the AG and TH positions:

$$S^{p}_{\text{probe}}(m) = \frac{1}{K} \sum_{\substack{ag \in A \\ th \in T}} P(\text{MASK}{=}m|p, ag, th) \tag{1}$$

where A and T are the set of all candidate entities for the AG and TH positions, respectively, and $K{=}|A||T|$.

3.1 Removing confounds

As discussed in §2.2, PLM probing is susceptible to confounds, including probe structure and choice of arguments, both of which can effect connotation frame prediction. We introduce measures to control three confounds (C1–C3).

C1: Probe structure In addition to Probe 1 we propose a second, semantically equivalent, probe with different structure.

Probe 2 *AG P TH. TH is MASK powerful than AG.*

We use different probe formulations to ensure that the model predictions are not incidental to a particular probe wording; and that the model is *consistently correct*. To this end, we adapt Elazar et al. (2021b)'s group evaluation (§5.3) score which only accepts a model prediction as correct if the correct class is predicted for multiple variants of the probe.

C2: Entity semantics We aim to capture power differentials as implied by the predicates that relate to two entities. As such, we do not want the predicted scores to be impacted by intrinsic power associated with the entities (e.g., high power 'presidents' vs. low power 'immigrants'). To this end, we constrain our entities to common English names. We use 16 female and male names from Nosek et al. (2002),[3] because (1) unlike general groups or entities (immigrants, agencies, politicians, etc.) names are largely free of a priori connotation which could impact our connotation scores; (2) all names are in the PLM vocabulary, removing discrepancies in subword tokenization; and (3) the set of names has been tested in implicit association tests (IAT and WEAT) and calibrated to only differ in gender, removing confounding effects of class or frequency (Jentzsch et al., 2019). The same set of names has been previously used in the context of gender bias mitigation (Gupta et al., 2022). To remove the gender confound we instantiate all possible $\{ag, th\}$ tuples from our 16 names, and reporting per-verb power connotations, obtaining $16 \times 15 = 240$ name combinations for each of our two probe templates, resulting in 480 instantiated probes per verb. We finally average probe predictions as in equation 1.

C3: PLM representation bias PLMs encode demographic biases, including stereotypical gender associations (Sun et al., 2019). Thus, in addition to controlling the entity set, we normalize power prediction scores by the PLM's a priori power assessment of the agent and theme names in the absence of a predicate. This normalization is also important for our case study in §7, where we use our probing framework with a fine-tuned PLM on less constrained contexts involving real-world entities in news articles. Inspired by previous work (Trichelair et al., 2019; Elazar et al., 2021b), we subtract from our connotation score the a priori relative power between the agent and theme in the absence of a specific predicate connecting them. To do so, we predict the MASK token given only the *hypothesis*:[4]

Prior 1 *TH has MASK power than AG.*

Like for the full probes, we obtain the probability of m with $m \in \{\text{'more', 'less'}\}$ from our PLMs and average over all entity combination, obtaining S_{prior}:

$$S^{p}_{\text{prior}}(m) = \frac{1}{K} \sum_{\substack{ag \in A \\ th \in T}} P(\text{MASK}{=}m | p, ag, th)$$

where P is computed using the Prior 1 template.

3.2 The Power Probing Score

The final power probing score (PPS) is the difference of the log predicted probability of the candidate MASK terms by the prior and the full probe:

$$\text{PPS}^{p}(m) = \log S^{p}_{\text{probe}}(m) - \log S^{p}_{\text{prior}}(m),$$

where $m \in \{\text{'more', 'less'}\}$. We finally derive a connotation score (CS) as a binary indicator variable:

$$CS^{p} = \begin{cases} +1 & \text{if } PPS^{p}(\text{'less'}) > PPS^{p}(\text{'more'}) \\ -1 & \text{otherwise,} \end{cases} \tag{2}$$

noting that CS=+1 directly corresponds to Sap et al. (2017)'s (AG$\succ_{power}$TH) and CS=-1 to (AG$\prec_{power}$TH).

4 Fine-tuning PLMs for connotative power prediction

As we will show in §6.1, PLMs do not encode power connotation naturally (in the zero-shot setting). We therefore aim to instill connotative knowledge into PLMs through task-specific fine-tuning.

---

[3] Male: {John, Paul, Mike, Kevin, Steve, Greg, Jeff, Bill}; Female: {Amy, Joan, Lisa, Sarah, Diana, Kate, Ann, Donna}

[4] See Table 3 in the Appendix for a complete list of priors.

Probe 1	AG P TH. TH has MASK power than AG.
No-Ent 1	P. has MASK power than.
Part-Sent 1	TH has MASK power than AG.

Table 1: Probe 1 (top) and two derived baseline templates, where agent (AG), theme (TH), and predicate (P) are instantiated as explained in §3.1. Probe 2 baselines are constructed analogously (cf., Appendix Table 3).

We use the probes introduced in §3 to construct a connotation prediction task as masked token prediction-based fine-tuning. The input to the model is the instantiated probe with instantiated ag, th, and p and with the target masked word m. The model is trained to predict 'more' or 'less', in correspondence with the gold standard power connotation value for the predicate p, CS^p. Training then proceeds as normal, backpropagating gradients through the full model, allowing the model to focus better on aspects of the encoding related to power connotation.

5 Experimental Setup

5.1 Baselines

We include a random baseline and a majority-class baseline to compare with PLMs. In addition, we provide two baselines to investigate the underlying language models' biases towards context and arguments of template sentences, by constructing inputs that are structurally similar to our probes, but do not carry any signal towards power connotations. This allows us to test (1) the extent of bias in the PLMs measured by deviation of the baselines from a random model; and (2) how much actual power connotative knowledge (over and above biases) the models contain in a zero-shot setting, or after fine-tuning, by comparing the respective models tested with the probes against these baselines. Both baselines are adapted from prior work on controlled debiasing (Elazar et al., 2021b).

No-Entity Baseline This baseline quantifies a priori PLM bias towards P in the absence of any entity. Probe 1 is reduced to No-Ent 1 in Table 1 (middle). An unbiased model should predict 'more' and 'less' with equal probability as the prompts contain no signal of the power differential.

Partial-Sentence Baseline This baseline quantifies prior biases related to the arguments by removing the predicate. We reduce the Probe 1 to only the *prelude* (similar to our prior in §3), see Part-Sent 1 in Table 1. Again, there is no information about power, and we expect an unbiased model to show random performance. Both baselines predict CS^p analogous to equations 1 and 2, but conditioning on their respective contexts.[5]

5.2 Predicate Selection

We use a subset of Sap et al. (2017)'s dataset of power-annotated verbs, keeping only transitive verbs applicable to human actors and themes based on manual filtering. We retain 300 verbs, with 67% of AG$\succ_{power}$TH and 33% verbs with AG$\prec_{power}$TH.

5.3 Evaluation metrics

We report class-wise and macro-averaged F1 scores to provide a detailed view of model performance and acknowledge the label skew in the ground truth data. We report standard (single-instance) evaluation for each test probe separately, resulting in 200 verbs × 2 probes = 400 instances; as well as the stricter grouped evaluation discussed below.

Group evaluation The more stringent *group evaluation* ensures that predictions are consistent across our semantically equivalent probes. A prediction CS^p for a given predicate p is accepted as correct only if the predicted connotation is correct for both probe 1 and probe 2. We compute the connotation score for each (ag, p, th) with probe 1 and probe 2 templates, and assign the worst-performing score. This group evaluation lowers the chance of random or coincidental correct predictions.

6 Results

We first test PLMs for power connotation knowledge in a zero-shot setting (§ 6.1), before we turn to task-specific fine-tuning (§ 6.2). See Appendix A for parameter settings.

6.1 Zero-shot Setting

We perform five separate runs. Each time, we obtain a stratified sample of 200 verbs selected from the full dataset of 300 to test the model. We report mean and variance across the five runs.[6]

Table 2 (top left) shows all three PLMs in the *single evaluation* metric. The 'No-Entity' and 'Partial-Sentence' baselines degrade to the majority classifier, which demonstrates that the PLMs contain

---

[5] See Table 3 in the Appendix for Probe 2 baselines.

[6] This evaluation protocol mirrors the fine-tuning setup in §6.2, allowing the comparison of variance between settings.

Table 2: Class-wise and macro F1 score of *power* connotation frame predictions with both single- (left) and group evaluation (right) for random and majority baseline, zero-shot setting and after task specific fine-tuning. *Results for these baselines are identical across all PLMs (and to the majority baseline) as they consistently predicted 'more' in this setting. Results are the mean and standard deviation over 5× repeated random subsampling of 200 verbs as a test set.

significant biases. An unbiased model would show a random performance.

Overall, in the zero-shot setup using the probe templates, the ALBERT model outperforms the BERT and RoBERTa models and random baseline in macro F1. Surprisingly, RoBERTa performs very poorly compared to the other two PLMs. We speculate that this might be due to the next sentence prediction loss, which is not part of RoBERTa training but is included BERT and ALBERT, thus explaining their ability to learn short-range dependencies between adjacent sentences in the probe templates. The main finding in this experiment is that none of the models contain power connotation information, as their performances are all close to random. Next, we show that PLMs can be effectively fine-tuned on this task.

6.2 Fine-tuned Setting

We evaluate the performance of fine-tuned PLMs using our proposed masked predication based approach (§4). As in the zero-shot experiments, we perfome 5 separate runs, each time using a stratified sample of 100 verbs for model fine-tuning, and the remaining 200 verbs for testing. We report mean and variance across these five runs.

Table 2 (bottom) shows that the fine-tuned models perform significantly better than the zero-shot versions across architectures. This holds in both the *single* (left) and the stricter *group evaluation* (evaluation). In the group evaluation, we observe the performance drops slightly compared to single evaluation after fine-tuning, and to a lesser extent than in the zero-shot setting. This suggests consistency of model predictions, increasing our confidence that the PLMs indeed capture connotative power associations with the predicates. Although RoBERTa performed poorly in the zero-shot setting, it is the strongest model after fine-tuning.

All fine-tuned models outperform all baselines by a large margin. Furthermore, we compared the performance of our fine-tuned models with the best previously reported approach for power connotation prediction — the logistic regression model of Field et al. (2019). The logistic regression model obtains macro F1 of 60%, substantially lower than our fine-tuned results.

Next, we analyze the impact of the training set size, and the robustness and consistency of our probing score.

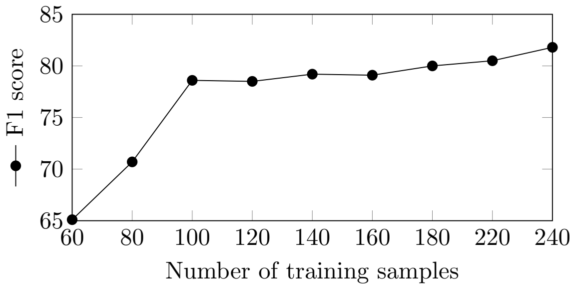

Figure 2: Performance (macro F1) of the fine-tuned RoBERTa model in single evalution with training sets of varying size.

Impact of the training set size Our main results are based on fine-tuning on only 100 labeled instances. We investigated the effect of varying the number of training samples from $\{60, 80, \ldots, 220, 240\}$, and a fixed test set of the remaining 60 instances for RoBERTa. The benefits of using more training samples plateaued after 100 samples as shown in Figure 2. Pre-trained models can efficiently learn to capture power connotation information from few training samples.

Robustness For each predicate, we calculated the variance of the probability of the masked token taking values 'more' or 'less', normalizing their scores to sum to 1 and averaging across all possible combinations of names in the agent and theme position (n=240). Overall, variance is low (mean=0.003). The predicates with the highest variance (0.005) include 'question' and 'reach', while those with lowest variance (0.001) include 'shut' and 'ruin'. Intuitively, the former (high-variance) verbs are more ambiguous than the latter.

Consistency We checked whether, given a predicate, the predicted filler for the masked token is the same across possible combinations of names in the agent and theme position. Across all test predicates, we find that 88% of the time the prediction is consistent among the 240 argument combinations. These final two analyses suggest that our probing score is not sensitive to the confounding variables of the agent or theme position or gender.

7 Case study

We employ our best-performing fine-tuned model RoBERTa to explore subtle power dynamics in US news reports on immigration. In particular, we study the power connotations implied in the descriptions (i.e., actions and events) involving prominent *entities* in the articles. In doing so, we draw connections between power connotation and emphasis frames (§7.1) as well as power connotation and issue stance (§7.2). We first describe our dataset and the entity extraction process, before explaining how we map the predicate-centric probing framework from §3 to an entity-centric measure.

Dataset We use the Media Frames Corpus (MFC, Card et al. (2015)), which contains 6.7k news articles about immigration,[7] manually labeled with one of 15 emphasis frames (including `Legality`, `Political`, `Economic`, ...), as well as an additional 42k unlabeled news articles. The articles were sourced from 13 U.S. news outlets published between 1969 and 2017. A subset of the immigration articles includes manual labels of 'stance' which indicates whether the article author is supporting, neutral about, or opposing immigration.[8]

Entity extraction We identify the most common entities within each article using an off-the-shelf transformer-based semantic role labeling model[9] (Shi and Lin, 2019) which has been previously used to identify key entities in MFC articles (Khanehzar et al., 2021). For each sentence in a document, we collect spans corresponding to the main verbs (`predicate`), and their first (ARG0) and second (ARG1) arguments, and then apply a coreference resolution model (Lee et al., 2018) to group the arguments into entities. We also use NER and string matching to find all mentions of each argument and consider only entities mentioned >3 times in an article. Figure 5 in the Appendix B shows the most common entities in the dataset.

Entity-level power connotation We apply our power probing framework as introduced in §3, and add a final step to map predicate-level CS^p to an entity-level CS. Similar to Field et al. (2019), and as illustrated in Figure 1, if $CS^p = +1$ (AG$\succ_{power}$TH), we consider connotation score of the agent as positive CS(AG)=+1 and the theme as negative CS(AG)=-1, and vice versa for predicates with $CS^p = -1$. This approach enables us to obtain power scores for entities in unannotated documents. To obtain the power score for each entity in each article, we average the power score

---

[7] The MFC covers four other issues, but immigration is the most prominent issue spanning the longest time period.

[8] Pro: 2740, Anti: 1685, Neutral: 982, None: 1350

[9] From AllenNLP, trained on OntoNotes5.0

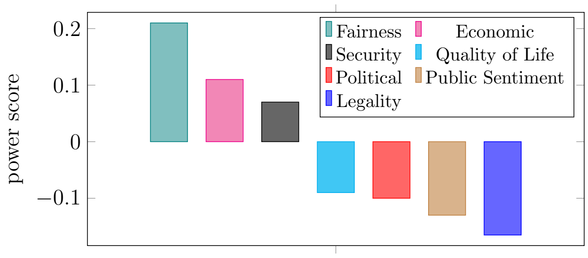

Figure 3: The power of 'immigrants' in articles with different emphasis frames (see legend). The majority of differences are significant, see Appendix C for details.

predicted for each mention of the entity (in the context of a transitive predicate) in that article. The entity's overall power score across the corpus is the average of its power scores across all articles.

7.1 The Power of Immigrants across Different Emphasis Frames

Immigration is a contested issue in the US with politicians, lobby groups, and news agencies selectively framing the topic in a way that supports their stance (Farris and Silber Mohamed, 2018; Lawlor and Tolley, 2017; Ommundsen et al., 2014). We examine how the news outlets portray the key entity involved in this discourse, namely 'the immigrants'. Specifically, we relate power connotations to emphasis frames in the MFC. We applied the method described above to all 6.7k frame-labelled immigration articles, and considered all mentions of the term 'immigrant(s)' and their co-referents.

Figure 3 shows that immigrants are depicted as relatively powerful when the articles are using the `Economic`, `Fairness and Equality`, `Security and Defense` frames, and fairly powerless when the articles are using the `Legality`, `Constitutionality`, `Jurisdiction`, `Public Sentiment`, `Quality of Life`, and `Political` frames. This suggests that news outlets generally approve of immigrants' role in contributing to the economy as confirmed by example mentions like 'Low-skilled immigrants *provide* cheap child care' and 'More immigrants than ever before *start* their own companies'. The gold standard power connotation label of *provide* and *start* is $\mathrm{AG} \succ_{power} \mathrm{TH}$, and our fine-tuned model predicted the same label with confidence for both cases.

Another example of depicting immigrants as relatively high in power are articles adopting the `Security and Defense` frame. These articles portray immigrants' power to disrupt the societal order. Examples include 'Immigrants *break* a security cordon', 'immigrants *overwhelm* the guards' and 'immigrants *overstay* their visas'. Conversely, articles using the `Fairness and Equality` frame tend to portray immigrants in an unfavorable light, albeit with high power associated with their actions, implying malicious intentions. Examples include 'immigrants *bring* crime and drugs', and 'detained immigrants *fabricate* accounts'.

These examples show that our operationalization of power complements the positive vs negative sentiment dimension, and in general, is not a stable trait of an entity, but rather depends on the more general frame adopted by an article. Additionally, in emphasis frames depicting immigrants as low in power, for example, in the `Legality` frame, immigrants are often associated with either positive or neutral actions such as 'immigrants *comply with* Federal laws', or 'immigrants *renounce* the citizenship of their native countries'. Among the frames depicting the immigrants as powerless, we noted that articles adopting the `Quality of Life` frame generally imply that immigrants, especially undocumented immigrants, face difficulties in life. Examples include 'immigrants *suffer* the alleged brutality', 'immigrants *fear* they will be hounded and deported'. Under the `political` frame, articles generally portray politicians' actions or relations towards immigrants, often attributing less power to immigrants. Examples include 'illegal immigrants *toil* for governor', 'Rudy accused Mitt *employing* illegal immigrants'.

7.2 Power of Immigrants vs. Immigration Services and Issue Stance

Immigration services such as ICE and INS[10] play a significant role in executing and designing immigration policies in the US and are prominent in the public discourse. Notorious for hardline approaches, these agencies are often criticized by the more liberal news outlets for abusing their legal power (Omokha, 2022). We compare the connotative power associated with *immigrants* and *immigration services* in news articles with a supportive, opposing or neutral stance on immigration, as manually labeled in the MFC.

Figure 4 shows, unsurprisingly, that immigrants are generally portrayed as less powerful than immigration services. At the same time, we observe

---

[10] Immigration and Customs Enforcement (ICE) and Immigration and Naturalization Service (INS)

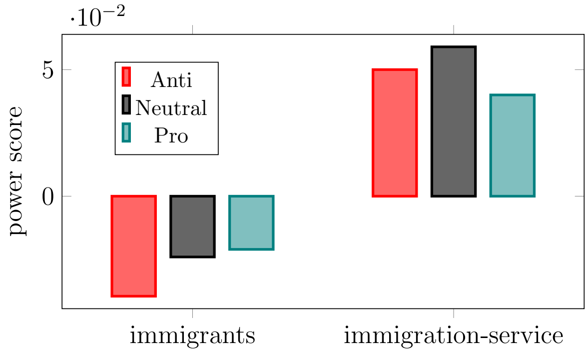

Figure 4: Power of ‘immigrants’ and ‘immigration services’ in articles with an anti-, pro-, and neutral- immigration stance. See Appendix C for significance results.

different trends for the two entities depending on the author’s stance on immigration: immigrants are portrayed as ‘most powerless’ in anti-immigration articles, but slightly less so in neutral and pro-immigration articles. In pro-immigration articles, immigrants more often take action (instead of being acted upon). Illustrative examples from pro-immigration articles include ‘immigrants *navigate* the byzantine rules of permanent residency’, and ‘immigrants *discover* the power of citizenship’, and ‘people should *join* immigrants in the continuing fight for civil rights and human dignity’. Examples of depictions of immigrants as powerless in anti-immigration articles include ‘officers *detain* a total of thirty Haitian immigrants’ and ‘immigration officials *arrest* illegal immigrants’. Immigration services, on the other hand, are portrayed as powerful in both pro- and anti-immigration articles, but less so in neutral ones. Immigration services in anti-immigration articles are often involved in strong actions toward immigrants: for instance, the predicates ‘arrest’ and ‘deport’ appear 1.8 times more often in anti-immigration articles than in pro-immigration articles.

8 Conclusion

We introduced a framework to (i) disentangle connotation frames implied by the predicate from its arguments and the sentence structure; and (ii) quantify predicate connotation frames in PLMs. Using the proposed framework, we investigated the capability of pre-trained language models to understand connotative information focusing on power dynamics between involved entities, both in a zero-shot setting, where performance was overall poor, and fine-tuning, which lead to drastic improvements. Our framework can be applied to investigate other connotation frames such as agency and sentiment, and their relationships to media bias, although defining the probing template may be challenging due to the subtle nature of connotation frames.

Finally, in a case study, we showed how our model can be used to detect subtle differences in the implied power dynamics between entities. Our findings highlight the potential of our framework as a tool for understanding subtle bias in the media. Future work could use our framework to analyze language in various forms of media, e.g. social media posts and TV programming, to identify patterns and trends in language usage for conveying power and other connotations.

It is worth investigating whether the improved performance in connotation predictions would enhance the model’s reading comprehension (Rajpurkar et al., 2016) capability at a higher level. Naturally, we would like to see that the model can infer which entity is more powerful or wields more authority without the text explicitly stating that fact. Previous work has shown that different layers in PLMs specialize in various meanings (de Vries et al., 2020). Future work should investigate the extent each layer in a PLM contributes to encoding connotation frames.

Our framework can also be used to study character roles by analyzing the verbs or verb phrases used to describe the characters and the connotations that they carry. For example, a news article about a political leader who is advocating for tougher immigration policies might mention the event of ‘cracking down on illegal immigration’, evoking a negative connotation and portraying the leader as a ‘villain’. A different article on the same entity might include an event of ‘helping refugees find safety’ assigning the leader the role of ‘hero’ with a more positive connotative association. Both articles frame the immigrants as ‘victims’. By analyzing the language used to describe characters and the connotations it carries, it is possible to gain insight into their framing and roles in the broader narratives around an issue.

9 Limitations

We identify several limitations and shortcomings in our work as potential areas for future work. While the proposed probing framework could be used to investigate other connotation frames, we focused only on the power dimension. We plan to extend our work to other connotation dimensions and explore their relationships with media bias.

While our case study demonstrates that predicate connotative information can be used to depict entity-level power connotation, we recognize that many other relevant features might do so. These include low-level features like adjectives and noun phrases, as well as high-level ones like the position of the entity in the article, and whether or not the entity is directly quoted. Future studies could compare how these different features contribute to predictions of connotation frames.

We acknowledge that our model, which predicts power dynamics on predicate signals alone, simplifies the construct of social power. This might lead to inaccurate predictions. Furthermore, the automatic analysis of portrayed power of real world entities or groups bears a risk of misuse to justify discriminatory practices or policies on the basis of the power portrayal in the media.

To mitigate these risks, it is essential to consider the potential consequences of the model's predictions and ensure they are used ethically and responsibly, including considering the potential impact on marginalized groups and taking steps to minimize any potential biases in the model's predictions. Additionally, human oversight and interpretation of the results is important, especially when they are used in decision-making processes that have a social impact.

Ethics Statement

The original news articles from MFC (Card et al., 2015) used in this work were obtained from Lexis Nexis under the institutional licence held by the University of Melbourne.

A Parameter Settings

Zero-shot Setting We use the pre-trained model implemented in HuggingFace's Transfomers (Wolf et al., 2020) with base version[11] and default model parameters.

Fine-tuning Settings We perform stochastic gradient descent with mini-batches of 64 sentences. We use the Adam optimizer (Kingma and Ba, 2015) with the default parameters, except for the learning rate, which we set to 10^{-5}. We train the models for five epochs or until we reach convergence.

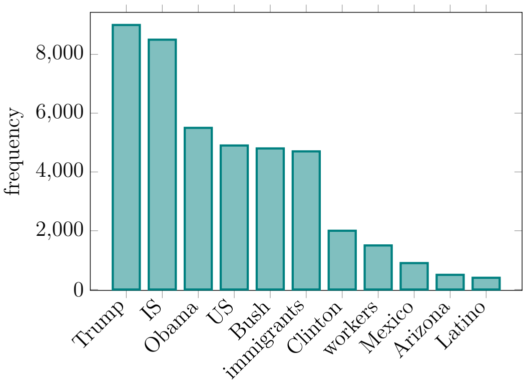

Figure 5: Most common entities such as Immigration Services (IS) and United States (US) in the immigration articles from the MFC (Card et al., 2015).

B Most Common Entities in MFC Immigration

To complement the list of entities extracted by SRL and coreference resolution, we also used NER to extract entities tagged as PERSON, and *string matching* to find all mentions of each entity. We consider only entities mentioned more than three times in each article as the most common entities within each article. Figure 5 shows the most common entities, with the number of their appearance in the immigration articles from the MFC dataset.

C Statistical Significance of the Power Scores in Case Studies

In the case studies in §7, the overall power scores of entities are reported by averaging the power score across the whole corpus. We test the significance of pairwise differences in power score using a z-test assuming a binomial distribution of labels (CS = +1 or -1). Below we discuss the result for each case study separately.

In case study in §7.1 we compare the power score of 'immigrants' in articles with different emphasis frames (as shown in Fig 7.1). The majority of comparisons of the power score are significant (as shown in Fig 4); for example, the p-value between frames `Fairness` vs. `legality` is 0.0004, and `Fairness` vs. `Public Sentiment` is 0.001. Overall, differences of power scores between frames of > 0.1 are significant at $p \leq 0.05$. The difference of power scores between frames `Economic` vs. `Security` are not significant ($p = 0.1$).

	F	E	S	Q	Po	Pu	L
F		*	*	*	*	*	*
E	*		-	*	*	*	*
S	*	-		*	*	*	*
Q	*	*	*		-	-	*
Po	*	*	*	-		-	*
Pu	*	*	*	-	-		-
L	*	*	*	*	*	-	

Table 4: Shows the comparisons of the power score of 'immigrants' in different emphasis frames including **F**`airness`, **E**`conomic`, **S**`ecurity`, **Q**`uality of Life`, **Po**`litical`, **Pu**`blic Sentiment`, and **L**`egality`. The * indicates the difference is significant at $p \leq 0.05$ (z-test) while '-' means insignificant.

In the case study in §7.2 the comparisons between power score of 'immigrants' vs. 'immigration services' in articles with different issue stances (as shown in Fig 4 as same color across blocks) are significant with a p-value of ≤ 0.005. Additionally, the comparison of the power score for each entity in different issue stances (pairwise comparison of bars within blocks) is almost significant with a p-value of $p \leq 0.05$.

Zero and Few-Shot Localization of Task-Oriented Dialogue Agents with a Distilled Representation

Abstract

Task-oriented Dialogue (ToD) agents are mostly limited to a few widely-spoken languages, mainly due to the high cost of acquiring training data for each language. Existing low-cost approaches that rely on cross-lingual embeddings or naive machine translation sacrifice a lot of accuracy for data efficiency, and largely fail in creating a usable dialogue agent. We propose automatic methods that use ToD training data in a source language to build a high-quality functioning dialogue agent in another target language that has no training data (i.e. zero-shot) or a small training set (i.e. few-shot). Unlike most prior work in cross-lingual ToD that only focuses on Dialogue State Tracking (DST), we build an end-to-end agent.

We show that our approach closes the accuracy gap between few-shot and existing full-shot methods for ToD agents. We achieve this by (1) improving the dialogue data representation, (2) improving entity-aware machine translation, and (3) automatic filtering of noisy translations.

We evaluate our approach on the recent bilingual dialogue dataset BiToD. In Chinese to English transfer, in the zero-shot setting, our method achieves 46.7% and 22.0% in Task Success Rate (TSR) and Dialogue Success Rate (DSR) respectively. In the few-shot setting where 10% of the data in the target language is used, we improve the state-of-the-art by 15.2% and 14.0%, coming within 5% of full-shot training.[1]

1 Introduction

While dialogue agents in various forms have become commonplace in parts of the world, their lack of support for most human languages has prevented access to the benefits they provide for much of the world. Commercial virtual assistants for example, only support a handful of languages, as extending their functionality to each new language is extremely costly, partially due to the need for collecting new annotated training data in that language.

In recent years, several non-English task-oriented dialogue (ToD) datasets have been created; they are either collected from scratch such as RiSAWOZ (Quan et al., 2020) and CrossWOZ (Zhu et al., 2020), paraphrased from synthetic sentences by crowdworkers such as BiToD (Lin et al., 2021), or manually translated from another language (Li et al., 2021b). All of these approaches are labor-intensive, expensive, and time-consuming; such investment is unlikely to be made for less widely spoken languages.

Cross-lingual transfer, i.e. using training data from other languages to build a dialogue agent for a specific language, seems especially appealing. An emerging line of work has employed machine translation of training data, and multilingual pre-trained neural networks to tackle this task (Sherborne et al., 2020; Li et al., 2021a; Moradshahi et al., 2023). However, work in ToD cross-lingual transfer has for the most part, focused on understanding the user input, namely Dialogue State Tracking (DST) and Natural Language Understanding (NLU). Other necessary parts of a dialogue agent like policy and response generation have mostly remained unexplored.

In this paper, we present a methodology for building a fully functional dialogue agent for a new language (e.g. English), by using training data in another language (e.g. Chinese) with little to no additional manual dataset creation effort. We found that despite prior efforts to improve modeling for existing ToD datasets, the dialogue representation used as input to these models, e.g. full dialogue history in natural language (Hosseini-Asl et al., 2020), is sub-optimal, especially when the training data is either scarce or created automatically us-

ing noisy machine translation. We propose a new *Distilled* representation to fix the shortcomings of current representations. We also found that previously proposed entity-aware translation technique Moradshahi et al. (2023) to be inadequate. Our proposed technique effectively combines entity-aware neural machine translation with text similarity classifiers to automatically create training data for a new language. This paper explains all the ingredients we found useful, and motivates their use by performing extensive ablation studies.

The contributions of this paper are:

1. *A new state-of-the-art result for the BiToD dataset in both few-shot and full-shot settings on English* according to all of our 6 automatic metrics, including an improvement of 14.0% and 2.9%, respectively, in Dialogue Success Rate (DSR). In fact, using our Distilled representation, our few-shot model trained on only 10% of the training data, achieves similar results to the previous SOTA model trained on 100% training data.
2. *The first dialogue agent created in the zero-shot cross-lingual transfer setting*, i.e. starting from no training data in the target language. Our agent achieves 71%, 62%, 40%, and 47% of the performance of a full-shot agent in terms of Joint Goal Accuracy (JGA), Task Success Rate (TSR), DSR, and BLEU score, respectively.
3. *A concise dialogue representation designed for cross-lingual ToD agents*. The Distilled dialogue representation works well with our new decomposition of agent subtasks, making significant improvements possible.
4. *An improved methodology for automatic translation of ToD training data*. We adapt and improve an existing entity-aware machine translation system that localizes entities (Moradshahi et al., 2023), extend it to agent response generation, and equip it with a filtering step that increases the quality of the resulting translations.

2 Related Work

2.1 Multilingual Dialogue Datasets

MultiWOZ (Budzianowski et al., 2018; Ramadan et al., 2018; Eric et al., 2019) and CrossWOZ (Zhu et al., 2020) are two monolingual Wizard-Of-Oz dialogue datasets that cover several domains, suitable for building travel dialogue agents in English and Chinese respectively. For the 9th Dialog System Technology Challenge (DSTC-9) (Gunasekara et al., 2020), they were translated to Chinese and English using Google Translate.

GlobalWOZ (Ding et al., 2021), AllWOZ (Zuo et al., 2021), and Multi2WOZ (Hung et al., 2022) translate MultiWOZ to even more languages such as Spanish, Hindi, and Indonesian, with human translators post-editing machine translated dialogue templates, and filling them with newly collected local entities. Although manual post-editing improves data quality and ensures fluency, it also increases the cost and time to create new datasets, thus limiting scalability.

Different from these translation approaches, Lin et al. (2021) introduced BiToD, the first bilingual dataset for *end-to-end* ToD modeling. BiToD uses a dialogue simulator to generate dialogues in 5 tourism domains in English and Chinese, then uses crowdsourcing to paraphrase entire dialogues to be more natural. Unlike WOZ-style datasets which usually suffer from poor annotation quality due to human errors (Moradshahi et al., 2023), BiToD is automatically annotated during synthesis. Since neither manual nor machine translation is used in the creation of BiToD, it does not contain translationese (Eetemadi and Toutanova, 2014) or other artifacts of translated text (Clark et al., 2020), and provides a realistic testbed for cross-lingual transfer of task-oriented dialogue agents.

2.2 Multilingual Dialogue State Tracking

Mrkšić et al. (2017) proposed using cross-lingual word embeddings for zero-shot cross-lingual transfer of DST models. With the advent of large language models, contextual embeddings obtained from pre-trained multilingual language models (Devlin et al., 2018; Xue et al., 2021; Liu et al., 2020) have been used to enable cross-lingual transfer in many natural language tasks, including DST.

Chen et al. (2018) used knowledge distillation (Hinton et al., 2015) to transfer DST capabilities from a teacher DST model in the source language to a student model in the target language.

Machine translation has been used for DST, both as a way of obtaining cross-lingual representations, and to translate training data. For instance, Schuster et al. (2019) used representations obtained from machine translation models and reported that it performs better than training with machine translated training data for single-turn commands. More advanced data translation approaches like the entity-aware method of Moradshahi et al. (2023) further

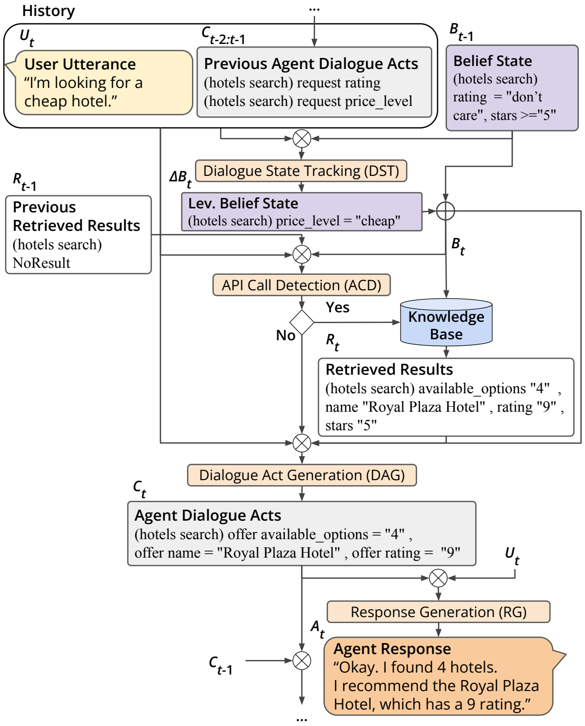

Figure 1: Inference-time flow diagram for our dialogue agent. DST, ACD, DAG, and RG share the same neural model. U, A, C, B, and R indicate user utterance, agent response, agent dialogue acts, dialogue state, and retrieved database results respectively. t is the turn number. $\otimes$ indicates text concatenation. $\oplus$ refers to the update rule in Equation 1.

improved the DST data quality achievable with machine translation.

3 Distilled ToD Agent

Our methodology includes a dialogue task decomposition and a Distilled dialogue representation that are tailored to cross-lingual ToD agents. In this section we describe these two components.

We follow the end-to-end task-oriented dialogue (ToD) setting (Hosseini-Asl et al., 2020) where a user converses freely with an agent over several turns to accomplish his/her goal with all of its constraints (e.g. "book a restaurant that is rated at least 3."). In each turn, the agent must access its database if needed to find the requested information (e.g. find a restaurant that satisfies user constraints), decide on an action (e.g. to present the information to the user or to ask follow-up questions) and finally respond to the user in natural language based on the action it selects.

3.1 Preliminaries

Formally, a *dialogue* $D = \{U_1, A_1, ..., U_T, A_T\}$ is a set of alternating user utterances U_t and agent responses A_t for a number of turns T.

A *belief state* at turn t, B_t, consists of a list of $\langle domain, intent \rangle$ tuples and a set of $\langle slot, relation, value \rangle$ tuples. *Intent* is the user intent, either search or book. *Relation* is a comparison or membership operator. *Value* can be one or more entity names or strings from the ontology, or a literal. To see all possible domains, slots and values please refer to Table 4 in Lin et al. (2021).

The *Levenshtein belief state* (Lin et al., 2020) is the difference between belief states in consecutive turns, i.e. $\Delta B_t = B_t - B_{t-1}$. It captures only the relations and values that have changed in the last user utterance, or tuples that have been added or removed.

An *Agent dialogue act* at turn t, C_t, is a list of $\langle domain, intent \rangle$ tuples and a set of $\langle dialogue\_act\_name, slot, value \rangle$ tuples indicating the action the agent takes and the information offered to the user, if any.

3.2 Task Decomposition

The task of dialogue agents is usually broken down to subtasks, which may be performed by a pipelined system (Gao et al., 2018) or by a single neural network (Hosseini-Asl et al., 2020; Lei et al., 2018). Here we describe our subtasks and their inputs and outputs (Figure 1).

After the user speaks at turn t, the agent has access to the belief state up to the previous turn (B_{t-1}), the history of agent dialogue acts ($C_1, ..., C_{t-1}$), and the history of agent and user utterances so far ($A_1, ..., A_{t-1}$ and $U_1, ..., U_t$). Our agent performs the following four subtasks:

1. *Dialogue State Tracking (DST)*: Generate ΔB_t, the Levenshtein belief state, for the current turn based on the previous belief state, the last two agent dialogue acts[2], and the current user utterance. ΔB_t is combined with B_{t-1} to produce the current belief state.

$$\begin{aligned} \Delta B_t &= \mathrm{DST}(B_{t-1}, C_{t-2}, C_{t-1}, U_t) \\ B_t &\leftarrow B_{t-1} + \Delta B_t \end{aligned} \tag{1}$$

2. *API Call Detection (ACD)*: Call an API to query the database, if needed.

$$q_t = \mathrm{ACD}(B_t, C_{t-2}, C_{t-1}, U_t, R_{t-1}) \tag{2}$$

$$R_t \;\leftarrow\; q_t ?\, \mathrm{KB}(B_t) \;:\; \emptyset \tag{3}$$

---

[2] Our ablation study described in Section 6.1 justifies the use of the last two agent dialogue acts instead of just the last one.

In turn t, ACD determines if an API call is necessary. If so, the result R_t is the top entity in the knowledge base KB, based on a deterministic ranking scheme, that matches the API call constraints in B_t, and is empty otherwise. If no entities match the constraint, we set R_t to the special value NORESULT.

3. *Dialogue Act Generation (DAG)*: Generate C_t, the agent dialogue act for the current turn based on the current belief state, the last two agent dialogue acts, the user utterance, and the result from the API call.

$$C_t = \mathrm{DAG}(B_t, C_{t-2}, C_{t-1}, U_t, R_t) \quad (4)$$

4. *Response Generation (RG)*: Convert the agent dialogue act C_t to the new agent utterance A_t. Note that C_t contains all the necessary information for this subtask. However, providing U_t improves response fluency and choice of words, leading to a higher BLEU score, partly due to mirroring (Kale and Rastogi, 2020).

$$A_t = \mathrm{RG}(U_t, C_t) \quad (5)$$

3.3 The Distilled Dialogue Representation

The design of Distilled is based on the following principles:

1. For cross-lingual agents, it is important to reduce the impact of translation errors. The representation should make minimal use of natural language by using a formal representation where possible.
2. Dialogues can get long, but the representation should be succinct, containing only the necessary information, so the neural network need not *learn* to ignore unnecessary information from copious data. This improves data efficiency as well as the training and inference speed of neural models.

We note that BiToD's original representation (Lin et al., 2021) follows neither of these principles.[3] It makes extended use of natural language: all previous user and agent natural language utterances are included in the input of all subtasks. It has many redundancies: for each subtask, it inputs the concatenation of all previous subtask's inputs and outputs. In the following, we highlight the changes we made to the (Lin et al., 2021) representation.

Replace agent utterances with formal agent dialogue acts. Since agent responses are automatically generated, it is possible to capture all information useful to the different subtasks with formal agent dialogue acts. In this way, the neural network need not interpret previous natural language utterances.

We take two steps to generate the agent responses: DAG (Dialogue Act Generation) first produces the formal act, C_t, which is then fed into RG (Response Generation) to generate the natural language response A_t. Note that RG is not a part of the dialogue loop: the natural language A_t only serves to communicate to the user; it is the formal C_t from DAG that gets fed to subsequent subtasks instead. In contrast, Lin et al. (2021) generates the agent response directly from API results. Hosseini-Asl et al. (2020) also separates the response generation into two steps, but they use A_t instead of C_t as input to the semantic parser for the next turn.

Note that the agent dialogue acts are independent of the natural language used in the dialogues, if we ignore the entity values. This is beneficial to cross-lingual agents as it can learn easier from data available in other languages. Furthermore, DAG can be validated on whether the output dialogue acts match the gold answers exactly. This is not possible with natural language results, whose quality is typically estimated with BLEU score.

Shorten user utterance history. Since the belief state formally summarizes what the user has said, we remove previous user utterances $U_1, ..., U_{t-1}$ from input to all subtasks, relying on the belief state B_{t-1} instead.

Untangle API call detection from response generation. After DST is done, depending on whether or not an API call is needed, Lin et al. (2021) either directly generates the agent response, or makes the API call and then generates the response in two steps. Our design is to always take two steps: (1) generate the API call *or indicate that there is none*, and (2) generate the agent response.

4 Automatic Dialogue Data Translation

Given a training dataset for one language, we automatically generate a training set in the target language we are interested in. This problem has been studied in the context of NLU for questions (Moradshahi et al., 2020; Sherborne et al., 2020; Li et al., 2021a) and for dialogues (Moradshahi et al., 2023;

---

[3] We found this to be true for several previously-proposed popular representations of MultiWOZ as well (Lei et al., 2018; Chen et al., 2019).

Ding et al., 2021; Zuo et al., 2021). One challenge is that the translated dataset should refer to entities in the target language. Thus, Moradshahi et al. (2020) proposed to first use cross-attention weights of the neural translation model to align entities in the original and translated sentences, then replace entities in the translated sentences with local entities from a target language knowledge base. Our initial experiments showed that applying this approach directly to end-to-end dialogue datasets does not yield good performance, especially for response generation. Thus, we adapted and improved this approach for dialogues as discussed below.

4.1 Alignment for Dialogues

First, we found that while translation with alignment works for NLU, it does not work well for RG. Machine translation introduces two kinds of error: (1) Translated sentences can be ungrammatical, incorrect, or introduce spurious information. (2) The alignment for entities may be erroneous, which can seriously hurt the factual correctness of the responses. As shown in Moradshahi et al. (2023), these errors are tolerable in NLU since (1) sentences are seen by machines, not shown to users, (2) pre-trained models like mBART are somewhat robust to noisy inputs, since they are pre-trained on perturbed data. However, training with such low-quality data is not acceptable for RG, since the learned responses are shown directly to the user.

Second, we found alignment recall to be particularly low for an important category: entities that are mostly quantitative. We observe that dates, times, and prices can be easily mapped between different languages using rules. We propose to first try to translate such entities with dictionaries such as those available in dateparser (Scrapinghub, 2015) and num2words (faire Linux, 2017), and to match them in the translated text. We resort to using neural alignment only if no such match is found.

4.2 Filtering Translation Noise for RG

To reduce translation noise for RG, we automatically filter the translated data based on the semantic textual similarity between the source and translated sentences. For this purpose, we use LaBSE (Feng et al., 2020), a multilingual neural sentence encoder based on multilingual BERT (Devlin et al., 2018), trained on translation pairs in various languages with a loss function that encourages encoding pairs to similar vectors. To score a pair of sentences, the model first calculates an embedding for each sentence and computes the cosine distance between those vectors. The lower the distance is, the more semantically similar the sentences are, according to the model.

In creating the RG training set, we first translate the source agent utterances to the target language and use LaBSE to remove pairs whose similarity score is below a threshold. We found a threshold of 0.8 to work best empirically. Higher thresholds would inadvertently filter correctly translated utterances. We construct the final training data by pairing aligned translated utterances that pass the filter with their corresponding translated agent dialogue acts.

5 Experiment Setting

5.1 Base Dataset

We perform our experiments on BiToD, a large-scale high-quality bilingual dataset created using the Machine-to-Machine (M2M) approach. It is a multi-domain dataset, including restaurants, hotels, attractions, metro, and weather domains. It has a total of 7,232 dialogues (3,689 dialogues in English and 3,543 dialogues in Chinese) with 144,798 utterances in total. The data is split into 5,787 dialogues for training, 542 for validation, and 902 for testing. The training data is from the same distribution as validation and test data.

5.2 Implementation details

Our code is implemented in PyTorch (Paszke et al., 2019) using GenieNLP (Campagna et al., 2019) library for training and evaluation metrics. We also use the Dialogues[4] library for data preprocessing and evaluation. We use pre-trained models available through HuggingFace's Transformers library (Wolf et al., 2019). The following model names are from that library. We use *mbart-large-50* as the neural model for our agent in all our experiments. All models use a standard Seq2Seq architecture with a bidirectial encoder and left-to-right autoregressive decoder. mBART is pre-trained to denoise text in 50 languages, while mT5 is trained on 101 languages. mBART uses sentence-piece (Kudo and Richardson, 2018) for tokenization.

In each setting, all four subtasks of DST, API detection, dialogue act generation, and response generation are done in a single model, where we specify the task by prepending a special token to the

---

[4] `https://github.com/stanford-oval/dialogues`

input. We found mBART to be especially effective in zero-shot settings as the language of its outputs can be controlled by providing a language-specific token at the beginning of decoding. Additionally, its denoising pre-training objective improves its robustness to the remaining translation noise.

For translation, we use the publicly available *mbart-large-50-many-to-one-mmt* (~611M parameters) model which can directly translate text from any of the 50 supported languages to English. It is an mBART model additionally fine-tuned to do translation. We use greedy decoding and train our models using teacher-forcing and token-level cross-entropy loss. We used Adam (Kingma and Ba, 2014) as our optimizer with a starting learning rate of 2×10^{-5} and linear scheduling. These hyperparameters were chosen based on a limited hyperparameter search on the validation set. For the numbers reported in the paper, due to cost, we performed only a single run for each experiment.

Our models were trained on virtual machines with a single NVIDIA V100 (16GB memory) GPU on the AWS platform. For a fair comparison, all monolingual models were trained for the same number of iterations of 60K, and bilingual models for 120K. In the few-shot setting, we fine-tuned the model for 3K steps on 1% of the data and 6K steps on 10% of the data. Sentences are batched based on their input and approximate output token count for better GPU utilization. We set the total number of tokens per batch to 800 for mBART. Due to the verbosity and redundancy of the original BiToD representation, Lin et al. (2021) used a batch size of 1 example for training mbart-large. Using our Distilled representation, however, we can fit up to 6 examples in each batch and process each batch 3 times faster during training. Training and evaluating each model takes about 10 GPU-hours on average.

During error analysis, we noticed that although certain slots (max_temp and min_temp slots in Metro domain, and time and price_range slots in Weather domain) are present in the retrieved knowledge base values, the model does not learn to output them in the agent dialogue act generation subtask. This issue stems from BiToD's non-deterministic policy where an agent sometimes provides these slots and sometimes not in the gold training data. To mitigate this, during evaluation, we automatically check if these slots are present in the input and append them and their retrieved values to the generated agent dialogue acts.

At inference time, we use the predicted belief state as input to subsequent turns instead of ground truth. However, to avoid the conversation from diverging from its original direction, Lin et al. (2021) use the ground-truth natural-language agent response as input for the next turn. To make sure the settings are equivalent for a fair comparison, we use ground-truth agent acts as input for the next turn.

5.3 Evaluation Metrics

We use the following metrics to compare different models. Scores are averaged over all turns unless specified otherwise.

- **Joint Goal Accuracy (JGA)** (Budzianowski et al., 2018): Is the standard metric for evaluating DST. JGA for a dialogue turn is 1 if all slot-relation-value triplets in the generated belief state match the gold annotation, and is 0 otherwise.

- **Task Success Rate (TSR)** (Lin et al., 2021): A task, defined as a pair of domain and intent, is completed successfully if the agent correctly provides all the user-requested information and satisfies the user's initial goal for that task. TSR is reported as an average over all tasks.

- **Dialogue Success Rate (DSR)** (Lin et al., 2021): DSR is 1 for a dialogue if all user requests are completed successfully, and 0 otherwise. DSR is reported as an average over all dialogues. We use this as the main metric to compare models, since the agent needs to complete all dialogue subtasks correctly to obtain a full score on DSR.

- **API** (Lin et al., 2021): For a dialogue turn, is 1 if the model correctly predicts to make an API call, and all the constraints provided for the call match the gold. It is 0 otherwise.

- **BLEU** (Papineni et al., 2002): Measures the natural language response fluency based on n-gram matching with the human-written gold response. BLUE is calculated at the corpus level.

- **Slot Error Rate (SER)** (Wen et al., 2015): It complements BLEU as it measures the factual correctness of natural language responses. For each turn, it is 1 if the response contains all entities present in the gold response, and is 0 otherwise.

Representation	JGA ↑	TSR ↑	DSR ↑	API ↑	BLEU ↑	SER ↓
Original (Lin et al., 2021)	69.19	69.13	47.51	67.92	38.48	14.93
Distilled (Ours)	**76.79**	**75.64**	**53.39**	**76.33**	**42.54**	**10.61**
• Generate full state	74.30	74.19	50.90	73.93	41.90	11.38
• Natural agent response	75.62	73.41	49.10	73.93	40.94	11.90
• Only last agent turn	73.97	74.19	52.71	74.27	41.83	11.81
• Prev. user utterance as state	71.75	61.66	33.94	67.67	39.72	15.97
• Remove state	70.84	51.89	24.43	66.47	37.10	19.61

Table 1: Full-shot English monolingual training with ablation. All results are reported on the English test set of BiToD using the same evaluation script. The best result is in bold.

6 Results and Discussion

We first show how our Distilled representation affects the performance of an agent in a full-shot setting. We then evaluate our proposed techniques on cross-lingual settings with varying amounts of available training data.

6.1 Evaluation of Distilled Representation

To understand how our design of Distilled representation affects the performance of ToD agents in general, we train an English agent using all the English training data and perform an ablation study (Table 1). We observe that even though the Distilled representation removes a lot of natural language inputs, it improves the best previous English-only results on JGA, TSR, DSR, API, BLEU and SER by 7.6%, 6.5%, 5.9%, 8.4%, 4.1%, and 4.7%, respectively. This suggests that natural language utterances carry a lot of redundant information, and the verbosity may even hurt the performance. Note that the improvement in BLEU is also accompanied by an improvement of factuality measured by SER.

Furthermore, using the Distilled representation reduces training time by a factor of 3. See Section 5.2 for more details.

Generate full state. Our first ablation study confirms that the proposal by Lin et al. (2020) to predict the Levenshtein belief state (ΔB_t) is indeed better than the cumulative state (B_t). Note that the training time per gradient step is more than twice as long in this ablation since the outputs are longer.

Natural agent response. Here we use natural language agent responses as input instead of agent dialogue acts, replacing C_{t-1}, C_{t-2} with A_{t-1}, A_{t-2}. The drop in TSR and DSR shows this is an important design choice - distilling natural language into a concise formal representation improves the model's ability to understand the important information in the sentence.

Only last agent turn. When we remove C_{t-2} from the input and only use C_{t-1}, we observe a drop across all metrics. This is because some turns in BiToD refer to the agent's states from two turns ago. We experimented with carrying three turns, but there was no improvement.

Previous user utterance as state. In this ablation, we use U_{t-1} instead of B_{t-1} as subtask inputs. Compared to all previous ablations, accuracy drastically decreases across all metrics, especially JGA. This is expected since the information from earlier turns present in the dialogue state is now lost. Additionally, it shows that the dataset is highly contextual and therefore a summary of the conversation history is necessary.

Remove state. We remove B_{t-1} without adding back the previous user utterance U_{t-1}. Compared to the previous ablation, TSR and DSR drop by 10.5% and 5.2% respectively. This difference shows U_{t-1} does contain part of the information captured in B_{t-1}.

6.2 Evaluation of Cross-Lingual Transfer

The goal of this experiment is to create an agent in a *target* language, given the full training data in a source language ($\mathcal{D}_{\text{src}}$), and a varying amount of training data in a target language ($\mathcal{D}_{\text{tgt}}$). We also assume that valuation and test data are available in both source and target languages. We chose Chinese as the source language and English as the target language so we can perform error analysis and the model outputs are understandable for a wider audience.

6.2.1 Varying Target Training Data

Full-Shot. In the full-shot experiments, all of $\mathcal{D}_{\text{tgt}}$ is available for training. We train two models on two data sets: (1) on a shuffled mix of $\mathcal{D}_{\text{src}}$ and D_{tgt}. (2) on $\mathcal{D}_{\text{tgt}}$ alone. The ablation "*−Mixed*" in Table 2 refers to the latter.

Zero-Shot. In our zero-shot experiments, we train with a canonicalized $\mathcal{D}\text{SRC}$ and an automatically translated data set, as explained below.

Setting	JGA ↑	TSR ↑	DSR ↑	API ↑	BLEU ↑	SER ↓
Full-Shot						
MinTL(mT5)	72.16	71.18	51.13	71.87	40.71	13.75

Table 2: All results are reported on the original English test set of BiToD using the same evaluation script. The best result in each section is in bold. Each "−" removes one additional component from the previous row. All MinTL results are from Lin et al. (2021). SER numbers are not available for some models. An upward arrow is show for columns where bigger numbers are better, and vice versa.

Canonicalization: To increase transfer learning from the source to the target language, we use the same canonical formal representation across languages (Moradshahi et al., 2020; Razumovskaia et al., 2021). To do so, we adapt $\mathcal{D}$src so that the domain names, slot names, agent dialogue acts, and API names in the formal representation to be the same as the target language. Note that the user utterance, agent response, and slot values will remain in the source language. The BiToD dataset has a one-to-one mapping for most of the above and we added the missing items.

Translation: We use machine translation to convert the user and agent utterances and slot values in $\mathcal{D}_{\text{src}}$ to create a training set for the target language.

Alignment: After translating the data, we use alignment (Section 4) to localize entities while ensuring the entities in translated utterances still match the values specified in annotations.

Filtering: We use the filtering procedure described in Section 4.2 to remove turns where agent responses are deemed to have low translation quality.

In Table 2, *Ours* refers to our main approach, which combines all four techniques. Each ablation incrementally takes away one of the techniques.

Few-Shot. In the few-shot setting, we start with our pre-trained zero-shot models (with various ablations) and further fine-tune it on 1% and 10% of $\mathcal{D}_{\text{tgt}}$, which comprises 29 and 284 dialogues, respectively. Lin et al. (2021) reported the results only for the 10% setting. We use their few-shot data split in that case to be directly comparable. We add one more ablation study where we eliminate cross-lingual transfer by training a model only on the few-shot data (Few-shot Only).

6.2.2 Baseline

We compare our results to the best previously reported result on BiToD from Lin et al. (2021). This SOTA result was obtained using MinTL (Lin et al., 2020) and using a single mT5-small model to perform all dialogue subtasks.

Contrary to what Lin et al. (2021) reported, we found that mBART-large model outperforms mT5-small in all settings. We have included all the results including MinTL(mBART) in Table 2 for comparison.

6.2.3 Results

The results for our cross-lingual experiment are reported in Table 2. Overall, in the full-shot setting, when training on both source and target language data, we improve the SOTA in JGA by 5.3%, TSR by 3.8%, DSR by 2.9%, API by 2.6%, BLEU by 0.8%, and SER by 2.6%.

Our zero-shot agent achieves 71%, 62%, 40%, and 47% of the performance of a full-shot agent in terms of JGA, TSR, DSR, and BLEU score, respectively. In the 10% few-shot setting, our approach establishes a new SOTA by increasing JGA, TSR, DSR, API, and BLEU absolutely by 13.9%, 15.2%, 14.0%, 15.0%, and 4.8% respectively. Prominently, training with just 10% of the data beats the full-shot baseline which is trained on 100% of the training data, on all metrics except for DSR and BLEU. It also comes within 5% of full training using the Distilled representation on all metrics.

Our Distilled representation improves the performance, especially in few-shot. Comparing our results with that of Lin et al. (2021), in the full-shot monolingual setting (MinTL(mT5) "−Mixed" vs. Ours "−Mixed"), models trained on data with our representation outperform the baseline on all metrics. In the pure few-shot (10%) setting, Ours outperforms MinTL(mT5) significantly in all metrics. This suggests that our Distilled representation and task decomposition are much more effective in low-data settings.

Canonicalization is useful. Comparing "−Translation" with "−Canonicalization", training on canonicalized data significantly improves the results in the zero-shot setting. This is intuitive since canonicalization brings training data closer in vocabulary to the test data in the target language. This improvement comes at almost no cost since translation is done automatically using a dictionary.

Automatic naive translation of the training set does not work for zero-shot. The naive translation approach (i.e. without alignment) completely fails in the zero-shot setting by achieving only 4.7% in TSR, and 1.1% in DSR, as translated entities might no longer match with ones in the annotation. Adding few-shot data helps significantly as the gap closes between "−Alignment" and "−Translation" ablations.

Alignment improves translation quality in all settings and metrics. With alignment, the translation approach performs much better in all settings, establishing a new state-of-the-art in zero and few-shot settings according to almost all metrics. As a general trend, the lower data settings benefit more from alignment. We additionally performed an experiment using the alignment proposed by (Moradshahi et al., 2023). There is a 4.0% drop in TSR and 4.5% in DSR, confirming the benefit of our improved alignment.

Filtering noise for RG improves fluency. We perform an ablation by training separate models on filtered and unfiltered translated agent utterances. The filtering process is described in Section 4.2. In 10% fewshot setting, both BLEU and SER improve by 1.4% confirming that automatically removing poor translations from training data improves the agent response quality. Interestingly, we observe an increase in other metrics too. Since model parameters are shared between all subtasks, enhancing the data quality for one subtask will have a positive impact on the others as well.

7 Conclusion

This paper shows how to build a dialogue agent in a new language automatically, given a dialogue dataset in another language, by using entity-aware machine translation and our new Distilled dialogue representation. The performance can be further improved if a few training examples in the target language are available, and we show that our approach outperforms existing ones in this setting as well.

On the BiToD dataset, our method achieves 3.9% and 2.9% improvement in TSR and DSR, respectively, over the previous SOTA in full-shot setting, and 15.2% and 14.0% in a 10% few-shot setting, showing the effectiveness of our approach. More importantly, training on translated data and only 10% of original training data comes within 5% of full training.

We have implemented our methodology as a toolkit for developing multilingual dialogue agents, which we have released open-source. Our proposed methodology can significantly reduce the cost and time associated with data acquisition for task-oriented dialogue agents in new languages.

8 Limitations

As discussed in Section 2.1, organic (i.e. without the use of translation) multilingual dialogue datasets are scarce, which has limited the scope of our experiments. Our guidelines to improve dialogue representation mentioned in Section 4 are general and applicable to any Human-to-Human or Machine-to-Machine dialogues annotated with slot-values. We have yet to evaluate the generalization of our cross-lingual approach across different languages and datasets, and to Human-to-Human dialogues. For instance, we use a Chinese to English translator in this work. Available translation models for low-resource languages have much lower quality, and this will likely lower the performance of this approach.

Another limitation is the lack of human evaluation for agent responses. BLEU score does not correlate well with human judgment, and SER only accounts for the factuality of the response but not the grammaticality or fluency. This problem is also reported in prior works (see Section 5). Although finding native speaker evaluators for different languages is a challenge (Pavlick et al., 2014), in the future, we wish to address this by conducting human evaluations.

9 Ethical Considerations

We do not foresee any harmful or malicious misuses of the technology developed in this work. The data used to train models is about seeking information about domains like restaurants, hotels and tourist attractions, does not contain any offensive content, and is not unfair or biased against any demographic. This work does focus on two widely-spoken languages, English and Chinese, but we think the cross-lingual approach we proposed can improve future dialogue language technologies for a wider range of languages.

We fine-tune multiple medium-sized (several hundred million parameters) neural networks for our experiments. We took several measures to avoid wasted computation, like performing one run instead of averaging multiple runs (since the numerical difference between different models is large enough), and improving batching and representation that improved training speed, and reduced needed GPU time. Please refer to Appendix 5.2 for more details about the amount of computation used in this paper.

A Appendix

A.1 Dialogue Examples

We include the same example from BiToD's English validation set both in our Distilled representation (Table 3) and in the original (Table 4) representation, along with model predictions in the full-shot setting. For brevity, only the first 3 turns are shown.

In Table 4, we observe that the model fails to ask for the hotel price-range in the second turn and makes an API call instead. Since the API call results are carried over between turns in this representation, in the third turn, the model sees those results in the input and falsely assumes it does not need to make an API call anymore, ultimately resulting in an incorrect response. Compare this to our representation in Table 3. This example shows the importance of separation between API call detection and response generation.

Another phenomenon we often observe is that the model asks for more information than it should according to the gold agent dialogue act. As shown in Table 3, in the second turn, the agent requests user to provide the desired location for the hotel as well as the price range. We believe the main reason for this behavior is the randomness in the agent policy of the BiToD's dialogue simulator. For example, if the agent needs to fill out two slots to make an API call, it can do so by requesting both in the same turn, or one turn at a time. This behavior, though reasonable, is penalized during evaluation, and predictions are considered incorrect if they contain extraneous slots.

Turn 1	DST	Input	DST: <state> null <endofstate> <history> USER: I'd like hotel recommendations. <endofhistory>
		Target	(hotels search)
		Prediction	(hotels search)

Abstract

Robust state tracking for task-oriented dialogue systems currently remains restricted to a few popular languages. This paper shows that given a large-scale dialogue data set in one language, we can automatically produce an effective semantic parser for other languages using machine translation. We propose automatic translation of dialogue datasets with alignment to ensure faithful translation of slot values and eliminate costly human supervision used in previous benchmarks. We also propose a new contextual semantic parsing model, which encodes the formal slots and values, and only the last agent and user utterances. We show that the succinct representation reduces the compounding effect of translation errors, without harming the accuracy in practice.

We evaluate our approach on several dialogue state tracking benchmarks. On RiSAWOZ, CrossWOZ, CrossWOZ-EN, and MultiWOZ-ZH datasets we improve the state of the art by 11%, 17%, 20%, and 0.3% in joint goal accuracy. We present a comprehensive error analysis for all three datasets showing erroneous annotations can lead to misguided judgments on the quality of the model.

Finally, we present RiSAWOZ English and German datasets, created using our translation methodology. On these datasets, accuracy is within 11% of the original showing that high-accuracy multilingual dialogue datasets are possible without relying on expensive human annotations. We release our datasets and software open source.[1]

1 Introduction

Tremendous effort has gone into the research and development of task-oriented dialogue agents for English and a few other major languages in recent years. A methodology that can transfer the effort to other languages automatically will greatly benefit the large population of speakers of the many other languages in the world.

Underlying an effective TOD agent is *dialogue state tracking*, the task of predicting a formal representation of the conversation sufficient for the dialogue agent to reply, in the form of slots and values. However, DST currently remains restricted to a few popular languages (Razumovskaia et al., 2021). Traditional DST agents require large hand-annotated *Wizard-of-Oz* (Kelley, 1984) datasets for training, which are prohibitively labor-intensive to produce in most languages (Gunasekara et al., 2020). Large, multi-domain WOZ datasets are only available in English and Chinese (Quan et al., 2020; Ye et al., 2021a).

The contributions of this paper are as follows:

1. We propose an automatic technique to build multilingual data sets using machine translation. Machine translation has been shown effective for localizing question-answering agents (Moradshahi et al., 2020). It shows that for open ontology datasets, we need to use an alignment model to properly translate entities in the source language to entities in the target language. This paper shows that alignment is necessary even for closed ontology datasets and dialogues.

Furthermore, we improve alignment to address these challenging issues we discovered unique to dialogues: (1) Translation errors accumulate and can prevent a correct parse for the rest of the dialogue; (2) There are logical dependencies between slot values across different turns; (3) Utterances are generally longer and more complex carrying multiple entities. We found that alignment improves the accuracy on the RiSAWOZ benchmark by 45.6%. This technique eliminates the cost of human post-editing used on all previous translation benchmarks, and can improve machine translation quality on other tasks too.

Using this methodology, we automatically trans-

late the RiSAWOZ dataset to English and German, creating RiSAWOZ-EN-auto and RiSAWOZ-DE-auto datasets respectively.

2. We show that the accumulation of translation and annotation errors across turns can be mitigated with a *Contextual Semantic Parsing* (CSP) model for state tracking. We propose a BART-CSP model, a seq-to-seq based on BART, that encodes the belief state, and the last agent and user utterances, rather than the full history of utterances.

BART-CSP improves SOTA on RiSAWOZ (Quan et al., 2020) and CrossWOZ (Zhu et al., 2020), two large-scale multi-domain WoZ dialogue datasets, by 10.7% and 17% in Joint Goal Accuracy(JGA). Notably, BART-CSP is more effective on translated data as evident by bigger performance improvement: on RiSAWOZ-EN-auto and RiSAWOZ-DE-auto datasets, automatically translated versions of RiSAWOZ, BART-CSP improves SOTA by 32.4% and 52.5%.

2 Related Work

2.1 Dialogue State Tracking

Dialogue state tracking (DST) refers to the task of predicting a formal state of a dialogue at its current turn, as a set of slot-value pairs at every turn. State-of-the-art approaches apply large transformer networks (Peng et al., 2020; Hosseini-Asl et al., 2020) to encode the full dialogue history in order to predict slot values. Other approaches include question-answering models (Gao et al., 2019), ontology matching in the finite case (Lee et al., 2019), or pointer-generator networks (Wu et al., 2019). Both zero-shot cross-lingual DST transfer (Ponti et al., 2018; Chen et al., 2018) and multilingual knowledge distillation (Hinton et al., 2015; Tan et al., 2019) have been investigated; however, training with translated data is the dominant approach, outperforming zero-shot and few-shot methods.

2.2 Contextual Semantic Parsing

Alternatively to encoding the full dialogue history, previous work has proposed including the state as context (Lei et al., 2018; Heck et al., 2020; Ye et al., 2021b) together with the last agent and user utterance. Recently, Cheng et al. (2020) proposed replacing the agent utterance with a formal representation as well. Existing models rely on custom encoder architectures and loss functions for the state (Heck et al., 2020). Our formulation of CSP is different since we encode the formal dialogue state directly as text, which simplifies the architecture and makes better use of the pretrained model's understanding of natural text.

Previous work also applied rule-based state trackers that compute the state based on the agent and user dialogue acts (Schulz et al., 2017; Zhong et al., 2018; Zhu et al., 2020). Such techniques cannot handle state changes outside of a state machine defined ahead of time and do not achieve state-of-the-art accuracy on WOZ dialogues.

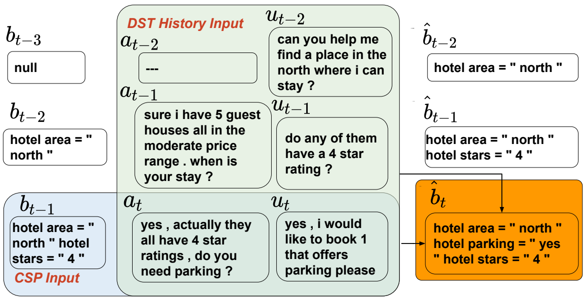
2.3 Multilingual Dialogues

Several multilingual dialogue benchmarks have been created over the past few years. Dialogue State Tracking Challenge (DSTC) has released several datasets (Kim et al., 2016; Hori et al., 2019; Gunasekara et al., 2020), covering only a few domains and languages. CrossWOZ (Zhu et al., 2020) and RiSAWOZ (Quan et al., 2020) are Chinese datasets collected through crowdsourcing. BiToD (Lin et al., 2021) uses a dialogue simulator to generate dialogues in English and Chinese, then uses crowdsourcing to paraphrase entire dialogues. All these approaches use crowdworkers in one or multiple stages of data collection which is costly and human errors degrade quality. Automatic creation of affordable high-quality dialogue datasets for other languages still remains a challenge (Razumovskaia et al., 2021).

3 Task Setting

We are interested in the *dialogue state tracking* task, in which the goal is to predict a formal representation of a conversation up to a certain point, also known as *belief state*, consisting of the slots that were mentioned in the dialogue and their value. At the beginning of the conversation, the belief state is empty, and it grows as the conversation progresses, accumulating the slots that were mentioned across all turns prior.

Formally, the problem is formulated given a predefined set of *slots* $s_1, s_2, \ldots s_n$ (such as "restaurant name", "restaurant food", etc.). Each slot has one value taken from the *ontology* $v_1, v_2, \ldots, v_n$. The ontology contains the legitimate values for the slot from the database (i.e. the list of restaurant names or restaurant cuisines), as well as the special values "none" indicating the slot was not mentioned, and "dontcare" indicating the slot was explicitly mentioned by the user but the user has



can you help me find a place in the north where i can stay ?

sure i have 5 guest houses all in the moderate price range . when is your stay ?

do any of them have a 4 star rating ?

yes , actually they all have 4 star ratings , do you need parking ?

yes , i would like to book 1 that offers parking please

Figure 1: Visualization of the differences between inputs of CSP and traditional DST models. While the latter encodes the full history of the dialogue, CSP only encodes the current state and turn. b, a, and u indicate the dialogue state, agent utterance, and user utterance, respectively. t is the turn number. $\hat{}$ indicates a predicted dialogue state.

no preference.

Therefore, given a partial conversation history composed of turns $x_1, x_2, \dots, x_t$, where each turn consists of an agent response (a_t) and user utterance (u_t), the task is to predict the belief state: $b_n(x_1, \dots, x_t) = \{s_1 = v_{1,t}, s_1 = v_{2,t}, \dots, s_n = v_{n,t}\}$ where n is the number of slots and $v_{i,t}$ is the value of the slot s_i up to turn t of the conversation. Note that the slot could be mentioned at turn t, or in any of the turns before.

4 Reducing Translation Noise

Key to the success of the dialogue state tracking is a precise and consistent annotation of the belief state at every turn. This is challenging in the multilingual setting, where we apply automatic translation to produce new training sets for DST: (1) the translation can be ungrammatical or incorrect, and it can introduce spurious information, and (2) the new annotation (in the target, translated ontology) can diverge from the translation of the sentence, such as referring to the same value in different ways in the target language.

We refer to the error introduced in translation collectively as *translation noise*. We posit that translation noise is the reason for poorer performance in existing translated dialogue datasets, compared to the same model on the dialogue dataset in the source language. In this section, we describe our methods to reduce translation noise.

4.1 Alignment

A major source of translation noise is due to mismatches between the translation of an entity by itself and in sentence. For instance, given a Chinese sentence that refers to an utterance containing the word “aquarium” (水族馆), incorrect translation may result in “ocean museum” in the English utterance, which does not match the slot value “aquarium” in the ontology and annotation anymore. Slot values may also get dropped or transliterated.

Translation with alignment was previously proposed by Moradshahi et al. (2020) to localize open-ontology multilingual semantic parsing datasets. Token alignments, obtained from cross-attention weights of the neural model, are used to track position of entities during translation so they can be replaced afterwards with local entity values. Figure 2 shows the translation and alignment process for an example input.

We show that alignment is useful also for a finite (closed) ontology in a dialogue setting. The dialogue setting is more challenging since the replacement with local entity values must be consistent across turns and dependent slots - slots that their values are logically dependent on each other. For instance, the corresponding price range for a *fast food* restaurant should be *cheap*, or a speaker looking for an attraction to go to with his girlfriend wants a place where *best-for-crowd* = “lover’s date”. Furthermore, utterances are generally longer and more complex containing multiple entities.

We have made several changes in alignment to address these issues:

1. We use a dictionary constructed from the dataset’s ontology for translating the dependent slots to ensure relations are preserved. For all other slots, we randomly replace them with values from the target language ontology similar to previous work.

2. In previous work, quotation marks were used to mark the boundary of entities and to retrieve alignment between tokens in the input and output. We found the translation of quotation marks to be inconsistent. Instead, we omit those marks before translation and purely rely on cross-attention between subwords to compute alignment.

3. We observed alignment does poorly on digits and often misplaces them in the output. We use string matching to retrieve spans for numbers, dates, and time slots if present in the output and omit alignment if successful.

4. Dialogues contain longer utterances with multiple entities per turn. We found breaking

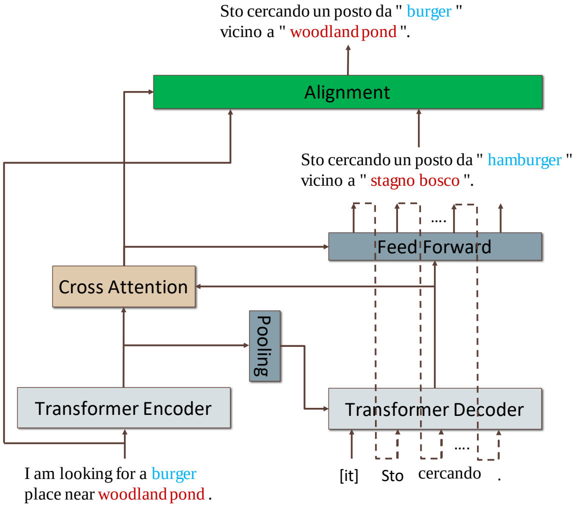


Figure 2: Example of the translation and alignment process. The encoder-decoder cross-attention weights are used to achieve word alignment.

down utterances into individual sentences before translation, significantly improves the quality of outputs when there are fewer entities to align.

To measure the effect of our changes, we translate MultiWOZ English dev set to Chinese with the new and previous alignment methods using MBART-MMT (see Section 5.3 for details). The new approach improves BLEU score by 8 points and JGA by 5% on MultiWOZ-ZH dev set.

4.2 Contextual Semantic Parsing

Previous work on dialogue state tracking encodes all or several turns up to the current one using a neural model, which then predicts the value for each slot. Hence, the input of the model consists exclusively of natural language, and grows as the conversation grows, accumulating any translation noise.

At the same time, we observe that the belief state at turn t, b_t, can be computed from the belief state at turn $t-1$ and the slots mentioned in the utterances at turn t. Hence, we propose to use a *contextual semantic parser* (CSP) for dialogue state tracking that computes $P(b_t|a_t; u_t; b_{t-1})$. The CSP model is applied to the dialogue-state tracking task by iteratively predicting the belief state of all turns, starting from b_0, the initial state consisting of all empty slots.

The CSP formulation condenses the dialogue history into a formal, fixed-length representation. Because the representation does not grow with the dialogue, it does not suffer from accumulation of translation noise.

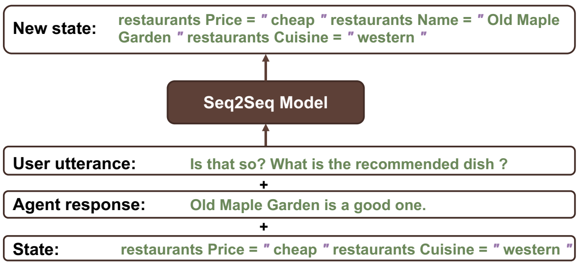

Figure 3: Contextual Semantic Parser model. We use BART for English and MBART for Chinese and German as the seq2seq model.

Our CSP model is based on Seq2Seq Transformer models BART (Lewis et al., 2019) for English and MBART (Liu et al., 2020) for all others. Here we refer to them as CSP-BART for simplicity.

The model encodes the belief state as a textual sequence of slot names and slot values. This encoding is concatenated to the agent utterance and user utterance, and fed to the model to predict the belief state at the end of the turn (Fig. 3). Similar to (Yang et al., 2021b), we encode the belief state directly as text, which simplifies the architecture and leverages the pretraining of BART.

5 Experiments

Our experiments are designed to answer the following questions: 1) How well does CSP perform on WOZ datasets compared to DST models that encode the full conversation history? 2) Is our approach effective to reduce the translation noise?

5.1 Datasets

We evaluate our models on the RiSAWOZ (Quan et al., 2020), MultiWOZ (Budzianowski et al., 2018; Eric et al., 2019), and CrossWOZ (Zhu et al., 2020) datasets and their available translated versions: MultiWOZ Chinese (Li et al., 2021), CrossWOZ English (Li et al., 2021). These particular datasets were chosen because they are large Wizard-of-OZ dialogue datasets and therefore more natural and representative of task-oriented dialogues. Additionally, we use our methodology to create the RiSAWOZ English and German datasets.

RiSAWOZ (Quan et al., 2020) is a Chinese WOZ dataset of 11k annotated dialogues and over 150k utterances spanning the 12 domains of attraction, restaurant, hotel, flight, train, weather, movie, TV, computer, car, hospital, and courses. Dialogues are formed from both single-domain and multi-domain goals, and annotated with dialogue states, dialogue acts, and coreference clusters.

MultiWOZ is an English-language WOZ dataset of 10k single- and multi-domain dialogues spanning the following 7 domains: taxi, restaurant, hotel, attraction, train, police, hospital. Following prior work with this dataset (Lee et al., 2019; Kim et al., 2019), we drop hospital and police from the training set as they are not included in the validation and test set. After the release of MultiWOZ 2.0 (Budzianowski et al., 2018), later iterations (Eric et al., 2019; Zang et al., 2020; Han et al., 2020) corrected some of the misannotations.

CrossWOZ is a Chinese-language WOZ dataset of 6k dialogues and over 102k utterances spanning the same 5 domains as the MultiWOZ validation and test sets: hotel, restaurant, attraction, metro, and taxi. CrossWOZ dialogues are annotated with dialogue states and dialogue acts, and average over 3.24 domains per dialogue, as opposed to the 1.80 of MultiWOZ.

For DSTC-9, Google NMT was used to translate MultiWOZ 2.1 to Chinese and CrossWOZ to English (Gunasekara et al., 2020; Li et al., 2021). To ensure translations of slot values in the dialog are faithful to the ontology, they replace them with their translations from a dictionary before feeding it to the NMT. This approach creates mixed-language sentences, shifting input distribution away from what public NMTs have been trained on, thus reducing quality (Moradshahi et al., 2020). Note that human translators were employed to proofread the translations and check certain slots to ensure values are correctly translated.

Table 1 shows a comparison of statistics for the training split of datasets used or created in this work. All the datasets have a closed ontology: the same entities appear in the train, validation, and test sets.

5.2 Models

We compare BART-CSP results against SOTA for each dataset. Models include the following:

- **TRADE** (Wu et al., 2019) uses a sequence-to-sequence architecture that encodes all utterances in the dialogue. It uses a pointer-generator to output the value of each slot.
- **MLCSG** (Quan and Xiong, 2020) extends TRADE by improving modeling of long contexts through a multi-task learning framework.
- **SOM** (Kim et al., 2019) considers dialogue state as an explicit fixed-sized memory and uses state operation to selectively update slot values at each turn.
- **SUMBT** (Lee et al., 2019) applies a BERT encoder to each utterance on the dialogue and a recurrent network to compute a representation of the whole dialogue, which is then matched against the ontology of each slot.
- **MinTL** (Lin et al., 2020) uses more recent pretrained models such as T5 (Raffel et al., 2019) and BART as the dialogue utterance encoder and builds an end-to-end dialogue model jointly learning dialogue state tracking, policy, and natural language generation tasks.
- **STAR** (Ye et al., 2021b) STAR uses two BERT models for encoding context and slot values. Additionally, they use a slot self-attention mechanism that can learn the slot correlations automatically. They use as input both the previous belief state and history of dialogue.

5.3 Implementation Details

BART-CSP is implemented using the Huggingface (Wolf et al., 2019) and GenieNLP (Campagna et al., 2019) libraries. We use the available open-source code for the other models. Hyperparameters for BART-CSP are discussed below; hyperparameters for other models are taken from the respective papers.

For semantic parsing we used *bart-base* (~139M parameters) for English and *mbart-large-50* (~611M parameters) model for other languages. For translation we used *mbart-large-50-many-to-many-mmt* (~611M parameters) which can translate directly between any pairs of 50 languages it supports. All models use a standard Seq2Seq architecture with a bidirectial encoder and left-to-right autoregressive decoder. All the models are pretrained using text denoising objective. *mbart-large-50-many-to-many-mmt* is additionally finetuned to do translation. BART uses BPE (Gage, 1994) to tokenize the input sentences whereas MBART uses sentence-piece model (Kudo and Richardson, 2018). We used Adam (Kingma and Ba, 2014) as our optimizer with a learning rate of 1×10^{-5} and used transformer warmup schedule (Popel and Bojar, 2018) with a warmup of 80. These hyperparameters were chosen based on a very limited hyperparameter search on the validation set. For the numbers reported in the paper, due to cost, we performed only a single run for each experiment.

	Dataset		
	RiSAWOZ	**CrossWOZ**	**MultiWOZ**
Languages	ZH, EN*, DE*	ZH, EN	EN, ZH
# Domains	12	5	7
# Dialogues	10,000	5,012	8,438
# Turns	134,580	84,692	115,424
# Slots	159	72	25
# Values	4,061	7,871	4,510

Table 1: Statistics of the training datasets (excluding validation and test). *Created using our methodology.

We batch sentences based on their input and approximate output token count for better GPU utilization. We set the total number of tokens to 700 for Mbart and 2000 for Bart models. We use gradient accumulation of 3 for Mbart and 9 for bart models boosting the effective batch size for better training. Our models were trained on NVIDIA V100 GPU using the AWS platform. For a fair comparison, all models were trained for the same number of iterations of 50K.

5.4 Metrics

We evaluate the models using the following two metrics:

- **Joint Goal Accuracy (JGA):** The standard metric of evaluation in DST is *joint goal accuracy*, which measures the average accuracy of predicting all slot assignments to exact match (EM) for any given turn. To compute this metric for CSP, the belief state predicted in previous turn is used as input for the current turn.
- **Gold Joint Goal Accuracy (GJGA):** This metric is similar to JGA but is calculated on a turn by turn basis, with ground-truth belief state used as input. Assuming the belief state correctly captures the state up to current turn of the dialogue, this metric acts as an oracle in evaluation removing the compounding effect of errors from previous turns.

6 Analysis and Results

Table 2 shows the results on test set for BART-CSP and previous SOTA models. For a better comparison we have included some details for each model:

- *Context Encoder*: The neural model used to encode the input.
- *Dialogue History*: If dialogue history is included in the input. A turn is defined as a pair of user utterance and agent response. “Partial” history means only a few turns of dialogue are kept while “Full” history models encode all previous turns.
- *Encodes State*: indicates if the user belief state up to the current turn is included in the input.
- *Predefined Slots or Ontology*: whether the model design or the data processing step needs knowledge of slot names or values.

As shown in Table 2, all previous models encode either a partial or full history. BART-CSP encodes significantly less information as it relies only on the current turn and the latest belief state. This simplifies model design and improves data efficiency for training (Yang et al., 2021a; Kapelonis et al., 2022).

Furthermore, models that rely on predefined ontologies require changes in architecture for new datasets. On the other hand, BART-CSP is a generative model that learns to copy slots from context and can be deployed for a new dataset as is.

On MultiWOZ, we report results for two models: MinTL which uses BART-large, and STAR[2] which uses BART as the context encoder. Our model outperforms MinTL despite using a smaller BART model, and achieves similar performance to STAR despite not having access to the full history. This shows bigger models do not necessarily yield better performance and model architecture and data representation are important too.

6.1 RiSAWOZ

The RiSAWOZ experiments shows that contextual semantic parsing delivers better accuracy than the state of the art on the original data sets; it is even more significant for translated data sets because it is more robust to translation errors.

BART-CSP improves the state of the art by 10.7% on JGA to 76.9% for the original Chinese data set. It provides an even greater improvement on the translated data sets: by 32.4% to 68.6% and by 42.5% to 65.9% on the automatically translated English and German data sets, respectively.

BART-CSP holds two major advantages over models that predict the slot-value pairs from the dialogue history. First, by distilling the belief state into a concise representation, it reduces noise in the input that would otherwise be present in a long dialogue history. Second, by taking the belief state as input, the model becomes more robust to translation errors in utterances from previous turns than

---

[2] SOLOIST (Peng et al., 2021) and SCORE (Yu et al., 2021) achieve better performance than STAR; however, these models use additional dialogue datasets to either pre-train or fine-tune their models. To keep the comparison fair, we only consider prior work that trained on MultiWOZ only.

	SOTA							BART-CSP

Table 2: Comparison of results on test set for the BART-CSP model vs state-of-the-art on various datasets. The best result on JGA metric is in bold. GJGA is only bolded if SOTA is available. †RuleDST uses the previous system state and user dialogue acts as input. *STAR-GT uses ground truth previous dialogue state as input. ‡ indicates results are reported from their paper. We reproduced all results for models that source code and pretrained models were available to ensure correct comparison. "-align." denotes an ablation where translation is done without slot-value alignment.

models that accept dialogue histories. Hence it is even more effective on translated datasets.

Alignment is critical to generating a high-quality translated dialogue data set. The English and German semantic parser show only a degradation of 8-11% from the Chinese parser. In an ablation study of direct translation without alignment, the JGA on RiSAWOZ English drops from 68.6% to 22.9%, a difference of 45.7%.

Alignment ensures that entities are translated to the right phrase from the target ontology. For example, the phrase "姑苏区" is translated to "Aguzhou district" in a user utterance when the whole sentence is translated directly, but becomes "Gusu district" in the annotation. With alignment, both are translated identically to "Gusu district." The correspondence of utterance and belief state leads to higher DST performance.

6.2 CrossWOZ

Compared to MultiWOZ and RiSAWOZ, CrossWOZ is a more challenging dataset. Besides having longer conversations with more domains per dialogue, the cross-domain dependency is stronger. For example, the choice of location in one domain will affect the choice of location in a related domain later in the conversation, requiring models to have better contextual understanding. CrossWOZ is not only a smaller, more complex dataset than RiSAWOZ, but also exhibits a higher misannotation rate, to be discussed in Section 7. The current state of the art result was obtained with TRADE, which achieves 36.1% JGA.

The experiments with CrossWOZ also confirm that BART-CSP outperforms prior state-of-the-art models that encode full or partial history. Specifically, it exhibits an improvement of 17.5% in JGA on the original dataset and 20.0% in JGA on the English translated data set.

The GJGA metric for CrossWOZ was obtained by using RuleDST (Zhu et al., 2020), a set of handwritten rules specialized to the dataset to compute the new belief state from the ground truth user and system dialogue acts. BART-CSP outperforms the use of RuleDST in GJGA by 9%, showing that it is not necessary to handcraft these rules.

The translated CrossWOZ-EN data have been manually corrected for slot-value errors. Application of our automatic slot-value alignment technique would have greatly reduced the tedious manual effort required. In both GJGA and JGA, BART-CSP performs within 1% of the original Chinese dataset on English CrossWOZ.

6.3 MultiWOZ

MultiWOZ is a challenging data set because of the well-documented problem of misannotations in the data set (Eric et al., 2019). Misannotations teach the model to mispredict; conversely, correct predictions may be deemed to be incorrect. Thus the current state-of-the-art STAR model can only achieve an accuracy of 56.7%.

While BART-CSP accepts only the belief state as input context, the STAR model accepts both the previous belief state and the dialogue history. The latter offers an opportunity for the model to recover missing state values from the history, giving a 3% advantage in JGA over BART-CSP. However, we note that once an agent misinterprets a user input, it is not meaningful to measure the accuracy for subsequent turns since the conversation would have diverged from the test data.

On the other hand, parsing history has its own cost: (1) It is less data efficient as you need more data to learn the same task. (2) It requires a more complex model that can find relevant slots among a large number of sentences. BART-CSP outperforms STAR by a 2.5% improvement in GJGA, suggesting that having the dialogue history as input can be detrimental when the past turns of a dialogue have been predicted correctly. On the Chinese translation of MultiWOZ, BART-CSP does slightly better than state of the art, improving JGA by 0.3% to 46.3%.

We also compare BART-CSP performance to MinTL, which is not SOTA, but uses more recent BART and T5 models as encoder. The results show that better performance on DST cannot be achieved by solely relying on better encoders with improved pretraining as both models are outperformed by STAR which uses BERT.

Between MultiWOZ 2.1 and 2.4, BART-CSP results improve by 16.7% on JGA and 10.5% on GJGA, while STAR improves by 18.1% on JGA and 11.5% on GJGA, showing dependence of both BART-CSP and STAR on the quality of annotation. Because MultiWOZ 2.4 only corrects the validations and test sets, CSP is still affected by mis-annotations in the training dataset. The lack of an equally clean training set may be the reason BART-CSP does not exhibit as much improvement across the versions.

7 Data and Error Analysis

A manual inspection revealed the following sources of errors on the CSP model, showing some of the inference limitations and its susceptibility to misannotations.

7.1 Misannotations

A substantial portion of incorrect predictions is due to existing annotation errors in all the datasets. In particular, in a manual review of 200 randomly chosen turns from each dataset, RiSAWOZ exhibits a 10.0% misannotation rate while CrossWOZ and MultiWOZ exhibit 17.9% and 26% misannotation rates, respectively.

Prevalent misannotation error types observed in the three datasets are noted below, with examples in the appendix.

- **Inconsistency:** Annotation inconsistency is a common issue with the Wizard-of-Oz data collection method. Examples of inconsistent annotations include inferred slots and slots that are mentioned by the agent but ignored by the user.
- **Inexact Match:** Typos, i.e. minor mismatches between the utterances and the annotation slot values. Chinese is a homonym-heavy language. It is not unexpected for single-character mismatch typos to occur frequently in the dataset. A second kind of typo is for a character to be entirely missing in an entity name.
- **Missing Slots:** Sometimes, values for some slots are simply just not included in the annotations.

CrossWOZ and MultiWOZ 2.1 are also susceptible to the following:

- **Extra Slots:** The presence of slot names which are not mentioned by either the user or the agent.

The following additional annotations problems are salient in MultiWOZ 2.1:

- **Delayed Annotations:** Slot values that are already confirmed by the user show up at a later turn in the conversation.

In RiSAWOZ, the final parting turn in a dialogue has no annotations, indicating a state reset:

- **Empty Annotation (Hard State Reset):** Some turns are missing annotations altogether.

7.2 Logical Relation Inference

In RiSAWOZ, the model is expected to infer the logical relationships between entities. For instance, the price range for a *fast food* restaurant should be *cheap*; looking for an attraction to go to with a girlfriend implies the interest of a place where *best-for-crowd* = “lover’s date”; similarly the desired hotel rating is to be inferred from the utterance rather than explicitly mentioned.

For example:

- 我们一家是外地的，来苏州游玩，你可以帮我找一个在吴中区，中等消费水平的景点吗 (Our family is foreign, we have come to Suzhou to have fun, could you help me find, in the WuZhong area, a medium priced attraction?) The slot value pair 最适合人群= “家庭亲子” (*best-for-crowd* = “family”) must be inferred.

- 好的。再看看高新区有什么好吃的火锅店？(Okay. Can you also see if GaoXin District has some good hotpot?)
  The slot 价位= “偏贵” (*price* = “expensive”) must be inferred from the fact that the food is hotpot.

We found that most models struggle with this type of inference which requires higher level language understanding and reasoning. It is unclear whether this weakness is inherent to the model or whether it is an artifact of inconsistent annotations. Of the misannotations counted, 33% were missing the slot “Best for crowd.”

7.3 Expanded Range Inference

In CrossWOZ, when a user requests, for instance, a restaurant where the cost per person is within a price range, oftentimes the agent cannot find such a restaurant, and responds with a suggestion with a cost outside of that range. In subsequent slots, the price range is expanded to include that cost, typically by rounding to the nearest ten. For example:

- 你好，我想去吃饭。请帮我找一家人均消费是100-150元，有井冈山豆皮这个菜的餐馆。(Hello, I’d like to go eat. Please help me find a place where the cost per person is 100-150 yuan, and has Jingangshan bean curd.) In this turn, the slot value for cost per person is *100-150*. However, following the agent response, the slot changes: 只为您找到一家叫西江美食舫(健德桥店)，但是它家的人均消费是83元。(I could only find a place called XiJiang Gourmet Boat (Jiandeqiao location), but the cost per person is 83 yuan.) Since 83 is outside the original range *100-150*, the slot value is expanded to *80-150* for the remaining turns of the dialogue.

We find that CSP struggles with such turns and will typically mispredict the slot value, assigning the previous range rather than inventing a new one.

8 Conclusion

Given a dialogue dataset in one language, this paper shows how to build contextual semantic parsers for a new language using automatically machine-translated data. We propose an improved alignment approach for dialogues to ensure faithful translation of slot values. This removes the need for costly human-post editing used in all previous benchmarks.

We show that the compounding effects of translation noise across turns can be mitigated with a CSP model for dialogue state tracking. By leveraging pretrained seq2seq models such as BART, training with CSP can outperform state-of-the-art results on RiSAWOZ, CrossWOZ, and MultiWOZ-ZH, and remains competitive on MultiWOZ, despite not encoding any previous conversation turns or having access to a predefined ontology.

We use our methodology to create RiSAWOZ English and German, the first automatically created high-quality translated datasets for dialogue state tracking with no human in the loop. We have implemented our methodology as a toolkit[3] which developers can use to create a new multilingual dialogue dataset as well as a contextual semantic parser for it.

9 Limitations

Organic multilingual dialogue datasets (i.e. created without the use of translation) are scarce, which has limited the scope of our experiments. We would have liked to evaluate the generalization of our approach to other languages. For instance, we partially rely on machine translation models to create datasets. Available translation models for other language pairs, especially from/to low-resource languages have much lower quality, and it would be desirable to measure the effect of that in our experiments.

Our methodology has only been applied to Human-to-Human dialogues annotated with slot-values. Although our approach is independent of data collection technique and formal representation, it should be applied and tested on datasets annotated with representations other than slot-values to study how well it can generalize.

Previous studies (Ding et al., 2021; Hung et al., 2022) utilized human post-editing to guarantee the fluency and accuracy of the translated datasets. However, in order to reduce cost, we have decided not to use manual post-editing in this work. As a result, our findings could be an overestimation of the model’s actual performance in real-world scenarios. In future research, we plan to rectify this by manually post-editing the validation and test portions of the datasets.

10 Ethical Considerations

Our translation method replaces the manual work needed to create multilingual dialogue datasets usually done via crowdsourcing. Instead, it requires some computation time which can be an environmental concern. However, in practice, such additional computing is small and much cheaper than the cost of human annotation for the same amount of data. The translation of the data set takes about half an hour on an Nvidia TITAN V GPU. Training takes about 6 hours on an Nvidia V100 GPU. We did not use crowdworkers for this paper. The error analysis was done by the authors.

Abstract

Pre-trained Transformer models such as BERT have shown great success in a wide range of applications, but at the cost of substantial increases in model complexity. Quantization-aware training (QAT) is a promising method to lower the implementation cost and energy consumption. However, aggressive quantization below 2-bit causes considerable accuracy degradation due to unstable convergence, especially when the downstream dataset is not abundant. This work proposes a proactive knowledge distillation method called *Teacher Intervention* (TI) for fast converging QAT of ultra-low precision pre-trained Transformers. TI intervenes layer-wise signal propagation with the intact signal from the teacher to remove the interference of propagated quantization errors, smoothing loss surface of QAT and expediting the convergence. Furthermore, we propose a *gradual* intervention mechanism to stabilize the recovery of subsections of Transformer layers from quantization. The proposed schemes enable fast convergence of QAT and improve the model accuracy regardless of the diverse characteristics of downstream fine-tuning tasks. We demonstrate that TI consistently achieves superior accuracy with significantly lower fine-tuning iterations on well-known Transformers of natural language processing as well as computer vision compared to the state-of-the-art QAT methods.

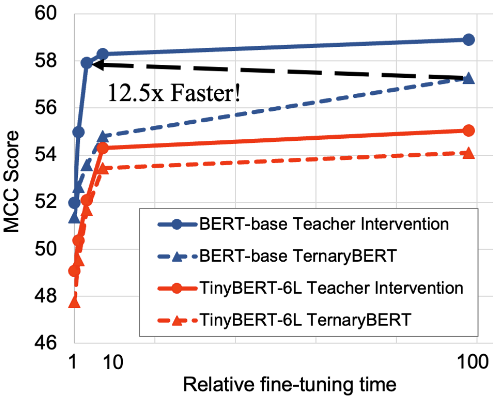

Figure 1: Comparison of fine-tuning time and accuracy of ternary weight quantized Transformer models between Teacher Intervention (TI) and TernaryBERT (BERT-base and TinyBERT-6L for CoLA task). TI achieves higher accuracy within 12.5× shorter fine-tuning time.

1 Introduction

The Transformer-based pre-trained neural networks have significantly improved the performance of various applications of artificial intelligence, including natural language processing (NLP) (Devlin et al., 2019; Raffel et al., 2020; Brown et al., 2020) and computer vision (CV) (Dosovitskiy et al., 2020; Touvron et al., 2021; Liu et al., 2021a). The self-attention mechanism represents these models (Vaswani et al., 2017), which links different symbols within a sequence to obtain a relational representation. Thanks to the exceptional performance of the pre-trained Transformer models, there have been increasing needs for their efficient deployment. However, the gigantic size of the pre-trained Transformer models hinders straightforward implementation. Even relatively small models like BERT-base (Devlin et al., 2019) contain a few hundred million parameters, incurring profound memory and computation overhead for resource-constrained devices with limited memory and computing fabric. Therefore, seminal research efforts attempted to reduce this burden via model compression. (Behnke and Heafield, 2020) and (Gordon et al., 2020) pruned unimportant weights to reduce the number of parameters, while (Mao et al., 2020) further employed low-rank matrix factorization. In addition, Knowledge Distillation (KD) (Hinton et al., 2015) was employed in (Sanh et al., 2019; Sun et al., 2019, 2020; Wang et al., 2020) to transfer knowledge of the original model (*teacher*) to the compressed one (*student*) by mimicking the

Teacher's behavior.

Among many model compression techniques, *quantization-aware training* (QAT) stands out for its recent success in reducing computational complexity and memory requirements of Transformer models (Bhandare et al., 2019; Zafrir et al., 2019; Kim et al., 2021). QAT reflects quantization errors during the forward pass computation of stochastic gradient descent to train a more accurate quantized model. However, quantizing weight parameters of Transformers to a precision lower than 2-bits degrades the accuracy, especially when the dataset size for the target downstream tasks is not large enough (Zhang et al., 2020b; Bai et al., 2021). Although few-sample fine-tuning of Transformer models has been reported to be highly unstable (Grießhaber et al., 2020; Yu et al., 2021; Zhang et al., 2020a; Dodge et al., 2020; Mosbach et al., 2020), efforts on understanding and improving QAT on small dataset tasks are limited. XTC (Wu et al., 2022) recently revealed that a simple expansion in fine-tuning iterations could heal the QAT accuracy. Still, it caused an order-of-magnitude increase in QAT time, hindering the broad deployment of quantized Transformers.

This work proposes a proactive KD method called *Teacher Intervention* (TI) for fast converging QAT of ultra-low precision pre-trained Transformers. We reveal that the difficulty of quantization on few-sample fine-tuning originates from disruption of loss surface due to quantization error propagation. To mitigate this undesirable phenomenon, we propose TI to intervene layer-wise signal propagation with the intact signal from the teacher. TI removes the interference of propagated quantization errors to smooth out the loss surface and expedite the convergence. We further discover that subsections of Transformer layers exhibit different susceptibility to quantization error for diverse downstream tasks. Thus, we propose a gradual intervention mechanism that first intervenes at the attention output for stable tuning of the feed-forward network, followed by self-attention map intervention for its recovery from quantization. The proposed gradual intervention along the subsections of Transformer layers enables fast convergence of QAT and improves the model accuracy regardless of the diverse characteristics of downstream fine-tuning tasks. We perform an extensive evaluation on various fine-tuned Transformers (BERT-base/large (Devlin et al., 2019), TinyBERT-4L/6L (Jiao et al., 2020), and SkipBERT-6L (Wu et al., 2022) for NLP, and ViT (Dosovitskiy et al., 2020) for CV) and demonstrate that TI consistently achieves superior accuracy with lower fine-tuning iterations compared to the state-of-the-art QAT methods. In particular, TI outperforms TernaryBERT (Zhang et al., 2020b) on GLUE tasks with 12.5× savings in fine-tuning hours, as shown in Fig.1.

2 Related Work

2.1 Knowledge Distillation for BERT Compression

Knowledge distillation (KD) (Hinton et al., 2015) is a transfer learning framework that passes on knowledge of a large model (*teacher*) to a smaller one (*student*). Since KD provides extra guidance on how the student should behave, it can help mitigate accuracy degradation for model compression. Therefore, KD has been widely employed in training smaller BERT models for various application domains.

The most common distillation approach is to match the probability distribution from the final output softmax between the teacher and student for the same input, as shown in DistilBERT (Sanh et al., 2019). In addition to the distillation loss at the model output, PKD (Sun et al., 2019) suggested loss on intermediate output that matched the normalized output of the teacher and the student at each Transformer layer. MobileBERT (Sun et al., 2020) also employed per-head attention map transfer along with the customized network structure for constructing efficient Transformers. MiniLM (Wang et al., 2020) further transferred knowledge from the self-attention map as well as the value-relation. Considering the structural mismatch between the Teacher and Student models, MiniLM performed distillation only at the last Transformer layer.

While the above mentioned studies focused on the task-agnostic BERT, there have been several efforts (Tang et al., 2019; Aguilar et al., 2020) to train tiny task-specific students. In this line of study, the task-specific, downstream fine-tuned BERT is first prepared, and the Student is trained with KD by utilizing this fine-tuned model as a teacher. As a hybrid approach, TinyBERT (Jiao et al., 2020) proposed a two-step KD, the first step for general distillation, followed by task-specific distillation.

Although extensive research has been conducted to utilize KD for BERT compression, there are limited efforts in investigating and developing KD techniques for model quantization, an orthogonal model compression method. In this work, we develop a new KD technique primarily focusing on improving QAT of pre-trained Transformers. In particular, we reveal that more aggressive intervention of the teacher on the subsections of each Transformer layer helps the ultra-low precision model regain the model accuracy.

2.2 Quantization for Ultra-Low Precision BERT

Quantization is a promising technique for reducing the high inference cost of large-scale models without changing the model structure. Instead of representing numbers with the 32-bit floating-point (FP32) format, employing fixed-point representation, such as 8-bit integer (INT8) quantization, has achieved significant speedup and storage savings for BERT (Zafrir et al., 2019; Kim et al., 2021). However, direct quantization of weight parameters would suffer accuracy degradation of the original model accuracy when the quantization bit-precision is low. Therefore, quantization-aware training (QAT) is commonly applied for ultra-low precision model quantization.

Recently, QAT has been applied for compressing BERT with precision lower than 2-bit. TernaryBERT (Zhang et al., 2020b) represents each weight element into one of three values $\{-1, 0, 1\}$. TernaryBERT actively incorporates KD into QAT for improving accuracy degradation. Especially, KD with the MSE loss on the attention score (before taking Softmax) and the output of each Transformer layer is employed for QAT. To further reduce the bit-precision, BinaryBERT (Bai et al., 2021) suggested a modified QAT procedure that initializes the weights for binary quantization. However, ternarizing or binarizing weight parameters significantly degrades the model accuracy, especially when the dataset size for the target downstream tasks is not large enough.

In fact, it has been reported that finetuning BERT on downstream tasks with insufficient data is highly unstable (Grießhaber et al., 2020; Yu et al., 2021). As a result, several works proposed modified finetuning procedures for improving the stability (Zhang et al., 2020a; Dodge et al., 2020; Mosbach et al., 2020). Still, the proposed approaches do not address the sensitivity of Transformer models on QAT for small datasets. XTC (Wu et al., 2022) recently proposed a QAT method with significantly increased iterations and data augmentation to improve quantization accuracy of ultra-low bit precision Transformers. As illustrated in Fig. 1, however, this prolonged fine-tuning results in sizable deployment overhead, let alone costly data augmentation. In this work, we discover that quantization significantly disrupts the propagation of self-attention in Transformer layers hindering the optimization process of QAT. Therefore, we propose a new KD-based method that proactively intervene the error propagation to improve convergence of QAT methods.

3 Background and Motivation

3.1 Transformer Layer

The BERT model (Devlin et al., 2019) is built with Transformer layers (Vaswani et al., 2017), which include two main sub-modules: Multi-Head Attention (MHA) and Feed-Forward Network (FFN). Input to the l-th Transformer layer is $\mathbf{X}_l \in \mathbb{R}^{n\times d}$ where n and d are the sequence length and hidden state size, respectively. Let H be the number of attention heads and $d_h = d/H$. $\mathbf{W}_h^Q, \mathbf{W}_h^K, \mathbf{W}_h^V \in \mathbb{R}^{d\times d_h}$ are the weight parameters converting $\mathbf{X}_l$ into Query ($\mathbf{Q} = \mathbf{X}_l\mathbf{W}_h^{\mathbf{Q}}$), Key ($\mathbf{K} = \mathbf{X}_l\mathbf{W}_h^{\mathbf{K}}$), and Value ($\mathbf{V} = \mathbf{X}_l\mathbf{W}_h^{\mathbf{V}}$), respectively. Then, attention score ($\mathbf{AS}_h = QK^\top$), self-attention map ($\mathbf{SA}_h = \text{Softmax}_h(\frac{\mathbf{AS}_h}{\sqrt{d}})$), and attention context ($\mathbf{AC} = \mathbf{SA}_h\mathbf{V}$) can be defined.

The attention output ($\mathbf{AO}$) is defined as $\mathbf{AO} = \text{MHA}(\mathbf{X}_l) = \text{Concat}(\mathbf{AC}_1, \mathbf{AC}_2, ...\mathbf{AC}_{N_H}) \times \mathbf{W}^O$. Motivated by (Kobayashi et al., 2020), the attention output can be re-written per each token i:

$$\text{MHA}(\mathbf{X}_l)(i) = \sum_{j=1}^{n} \alpha_{i,j} f(\mathbf{X}_l(j)), \qquad (1)$$

where $f(x) := (x\mathbf{W}^V + b^V)\mathbf{W}^O$ and $\alpha_{i,j}$ is j'th value of i'th token in SA_h. Therefore, the computation of MHA consists of two parts: self-attention generation (SA-GEN) corresponding to the attention map (α) and self-attention propagation (SA-PROP) corresponding to $f(x)$. Fig. 3 illustrates the structure of a Transformer layer indicating regions corresponding to SA-GEN and SA-PROP. FFN consists of two fully-connected layers with weight parameters $\mathbf{W}^1$ and $\mathbf{W}^2$:

$$\text{FFN}(\mathbf{Y}_l) = \text{GeLU}(\mathbf{X}_l\mathbf{W}^1 + b^1)\mathbf{W}^2 + b^2. \qquad (2)$$

Therefore, an output of Transformer layer X_{l+1} is defined as:

$$\begin{aligned} \mathbf{Y}_l &= \text{LayerNorm}(\mathbf{X}_l + \text{MHA}(\mathbf{X}_l)), \\ \mathbf{X}_{l+1} &= \text{LayerNorm}(\mathbf{Y}_l + \text{FFN}(\mathbf{Y}_l)). \end{aligned} \tag{3}$$

3.2 Quantization-Aware Training

Quantization-aware training (QAT) emulates inference-time quantization during fine-tuning of the full-precision model to adjust the parameters to be robust to the quantization error (Hwang and Sung, 2014) (Hubara et al., 2016). In particular, ternary quantization represents all the weight parameters ($\mathbf{W}^Q, \mathbf{W}^K, \mathbf{W}^V, \mathbf{W}^O, \mathbf{W}^1, \mathbf{W}^2$) into ternary values $t \in \{+1, 0, -1\}$ along with a scale factor s for sub-2bit inference. In this work, we follow the approach of TWN (Zhu et al., 2016) that analytically estimates the optimal scale factor s and the ternary weight $\mathbf{W}_t = \{t\}^{|\mathbf{W}|}$ to minimize $\|\mathbf{W} - s \cdot \mathbf{W}_t\|$.

Due to aggressive bit-reduction, ternary quantization causes significant accuracy loss. KD can help compensate for accuracy degradation, where the original full-precision model works as a teacher to guide the training of the quantized model as a student. In case of Transformer models, TernaryBERT (Zhang et al., 2020b) applied KD on every output activation X_{l+1} as well as the attention score (**AS**) with mean squared error (MSE) loss:

$$L_{trm} = \sum_{l=1}^{L+1} \text{MSE}(\mathbf{X}_l^S, \mathbf{X}_l^T) + \sum_{l=1}^{L} \text{MSE}(\mathbf{AS}_l^S, \mathbf{AS}_l^T), \tag{4}$$

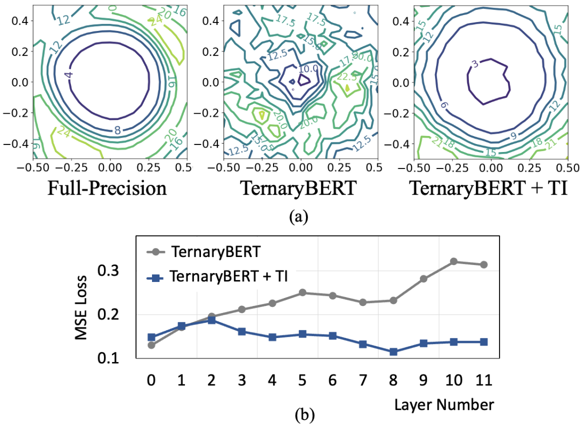
where S and T represent the student and teacher models, respectively. Also, the output logits of the student (P^S) and the teacher (P^T) are used in TernaryBERT to compute the cross-entropy (CE) loss:

$$L_{pred} = \text{CE}(P^S, P^T). \tag{5}$$

We follow the settings of TernaryBERT as our baseline QAT method.

3.3 Challenges

Despite attempts to bridge the accuracy gap, prior works on ultra-low precision Transformers (Bai et al., 2021; Zhang et al., 2020b) still suffer noticeable accuracy degradation, especially when the dataset size is small. Recall (Mosbach et al., 2020) that the few-sample fine-tuning is unstable. But we observed that QAT often fails even if it fine-tunes from the successfully trained model.



(a)

(b)

Figure 2: (a) Loss landscape visualization of a fine-tuned Transformer for a few-sample task (BERT-base, CoLA): A well-trained full-precision model and the quantized models without and with Teacher Intervention (TI). (b) MSE loss at the output of Transformer layers of TernaryBERT without and with TI

To gain intuition on this failure, we visualize the loss landscape of the quantized Transformers fine-tuned for a few-sample task (BERT-base, CoLA) in Fig. 2(a). In contrast to the smooth loss surface of the well-trained full-precision model, TernaryBERT exhibits sharp curvatures with many valleys, suffering unstable fine-tuning due to quantization. Investigating the internal behavior of Transformer layers under quantization elucidates the cause of unstable QAT. We measure the mean-square error (MSE) of the output of each Transformer layer between the full-precision baseline (teacher) and TernaryBERT (student). Fig. 2(b) reveals a prominent trend that MSE grows over the layers. (Similar trends can be observed in the other GLUE tasks.) This inflated error along the layers would degrade the model's accuracy.

In this work, we focus on managing this aggravating impact of quantization errors on Transformers with a proactive knowledge distillation called *Teacher Intervention* (TI). Interestingly, as shown in Fig. 2(b), TI successfully suppresses the error propagation and flattens the loss surface for favorable convergence without precipitously increased fine-tuning iterations. We discuss the technical details of TI in the next section.

4 Method

4.1 Teacher Intervention

Teacher intervention (TI) is a KD method that aggressively intervenes in the student's signal propagation along the Transformer layers to suppress propagation of quantization error. Fig. 3(b) illus-

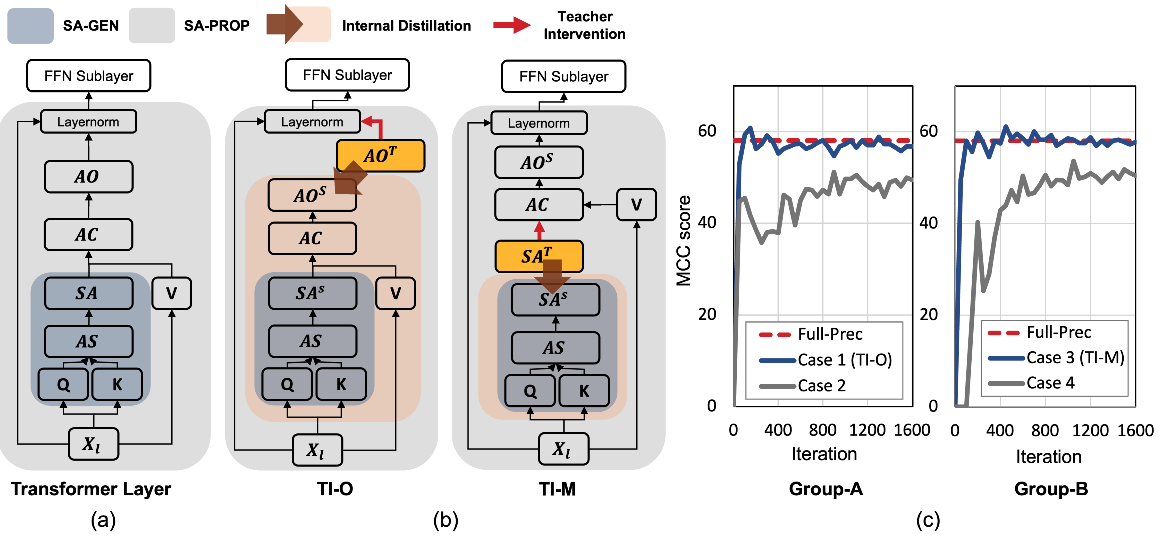


Figure 3: (a) Architecture of Transformer layer. (b) Locations of Teacher Intervention: output intervention (TI-O) and map intervention (TI-M). $\mathbf{AO}^T$ and $\mathbf{SA}^T$ are teacher's attention outputs. (c) Accuracy curves of controlled experiments. Group-A: Quantize all sub-layers with TI-O (Case 1) or do not quantize MHA (Case 2), Group-B: Quantize all sub-layers with TI-M (Case 3) or do not quantize SA-GEN (Case 4). Note rapid convergence for the cases with TI.

trates the two options for teacher intervention. First, intervention on the attention output (a.k.a. *output intervention*, TI-O) replaces the student's attention output ($\mathbf{AO}^S$ in Fig. 3(b)) in each Transformer layer with the teacher's ($\mathbf{AO}^T$ in Fig. 3(b)). In this case, the FFN sub-layers are trained with ultra-low precision quantization without concerns of erroneous input from the preceding MHA. Meanwhile, the computation within the MHA sub-layer is quantized for internal distillation. Similarly, intervention on the self-attention map (a.k.a. *map intervention*, TI-M) replaces the student's SA-GEN output ($\mathbf{SA}^S$ in Fig. 3(b))with the teacher's ($\mathbf{SA}^T$ in Fig. 3(b)). [1]

The development of TI is motivated by the previous observation of the aggravating impact of quantization error along the layers (cf. Fig. 2(b)). We conjecture that the root cause of this phenomenon is error propagation instead of the quantization error itself. To confirm our hypothesis, we conducted controlled experiments for TI-O and TI-M with two groups of quantization cases:

- Group-A: Quantize all sub-layers with TI-O (Case1) or do not quantize MHA (Case2).
- Group-B: Quantize all sub-layers with TI-M (Case3) or do not quantize SA-GEN (Case4).

The key difference between the two groups is that Case2/4 propagates the quantization error through the sub-layers while Case1/3 does not, thanks to TI. Fig. 3(c) shows the convergence curves of the four cases on CoLA. As shown in the figure, Case1/3 converges rapidly to full-precision accuracy despite the ultra-low bit quantization in all the sub-layers. Whereas Case2/4 converges slowly to the sub-optimal point with noticeable accuracy degradation. Although Case2/4's MHA/SA-GEN computations are in full-precision, the error propagated from its preceding quantized FFN sub-layers still affects it, corrupting the attention output/self-attention map. On the other hand, TI-O and TI-M interrupt this error propagation to stabilize QAT on FFN sub-layers and MHA outputs, respectively. Therefore, Fig. 2(b) confirms that the error propagation disappears when TI is applied.

Motivated by this insightful observation, we devise a new QAT method that employs TI for the step-by-step reconstruction of sub-layers of Transformers. In the first step, TI is used to fine-tune the quantized weights of either FFN (TI-O) or SA-PROP (TI-M) sub-layers. Note that the convergence in this step is quick, as shown in Fig. 3(c). Therefore, Step1 takes only a fraction of fine-tuning epoch. In the second step, quantization is applied to the entire weights of Transformer layers for QAT. Since part of the parameters is already trained in Step1 with the guidance of TI, Step2 converges faster to a superior local minimum. In Sec. 5, we demonstrate this improved convergence leads to boosts in accuracy for ultra-low bit Transformers.

---

[1] We empirically investigated other options for teacher intervention and found that TI-O and TI-M were most representative.

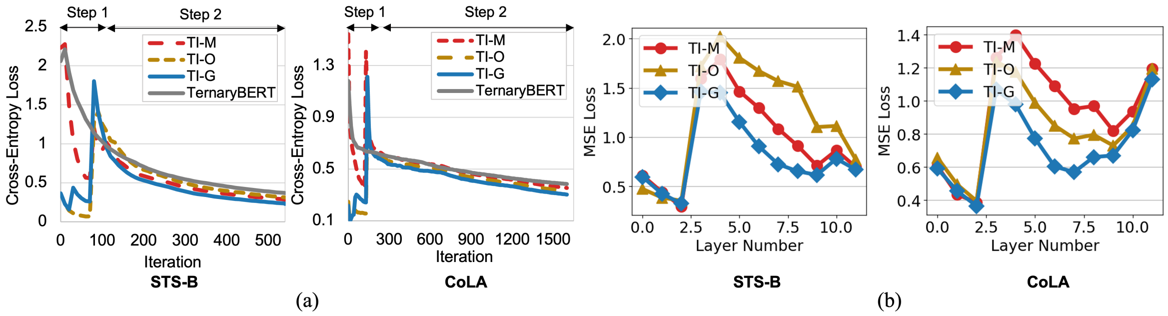

Figure 4: (a) Cross-entropy loss of QAT with different TI methods, and (b) Layer-wise MSE loss for different TI methods (Left: STS-B, Right: CoLA). Note that TI-G converges to lower loss than TI-M and TI-O on both tasks.

4.2 Gradual Teacher Intervention

Type	TI-M			TI-O			TI-G		
Sub-layer	GEN	PROP	FFN	GEN	PROP	FFN	GEN	PROP	FFN
Step1-Phase1	Q+TI	Q	Q	Q+TI		Q	Q+TI		Q
Step1-Phase2							Q+TI	Q	Q
Step2	Q			Q			Q		

Table 1: Quantization settings for teacher intervention. Different from TI-M and TI-O, gradual teacher intervention (TI-G) applies TI to quantization (Q) from large (GEN+PROP) to small (GEN) scope in Step1.

Given multiple teacher intervention options, which would achieve the best performance? In this section, we propose a unified approach that gradually applies the output intervention followed by the map intervention. Note that the two TI options have strengths and weaknesses. For example, TI-O focuses on tuning the FFN sub-layers, but it lacks consideration of the self-attention map recovery. On the other hand, TI-M is best suited for recovering the self-attention map, but it does not protect signal propagation through SA-PROP. Interestingly, we empirically discover that different downstream tasks of the pre-trained Transformers have diverse preferences; e.g., BERT-base fine-tuned on STS-B is sensitive to disruption in the self-attention map while the model fine-tuned on CoLA prefers careful tuning of the FFN sub-layers. Therefore, developing a unified solution that utilizes teacher intervention in various scopes is beneficial. As a natural combination, we propose a gradual teacher intervention mechanism that applies TI-O first to tune the FFN sub-layers (Step1-Phase1), followed by TI-M to recover the self-attention map (Step1-Phase2). The proposed method, called *gradual intervention* (TI-G), has shown practical success in most ultra-low bit Transformers studied in this work. (We conducted an ablation study for the other possibilities of a unified solution for teacher intervention in A.3.) Table. 1 summarizes the TI settings. Note that the two phases of TI-G in Step1 do not increase the total number of iterations thanks to fast convergence.

Fig. 4(a) shows the convergence curves of different TI options for STS-B and CoLA. As discussed earlier, TI-M shows better convergences than TI-O on STS-B, but the opposite trend is shown on CoLA. Nevertheless, TI-G always shows superior convergence compared to the other options, demonstrating its universal applicability. In particular, on STS-B, TI-G benefits from the output intervention in the first phase to favorably warm up the FFN sub-layers, and thus the map intervention in the next phase can reduce the loss more than TI-M. A similar situation happens in the case of CoLA.

Fig. 4(b) investigates the internal behavior of Transformers via the layer-wise MSE at the output of MHA. As discussed earlier, the fine-tuned Transformers exhibit distinct characteristics depending on the downstream tasks. For example, in the case of STS-B, TI-M is more effective in reducing MSE since the recovery of the self-attention map is essential. On the other hand, CoLA has preferred TI-O for its focus on tuning FFN sub-layers. In both cases, TI-G's gradual intervention with decreasing scopes from the attention output to the self-attention map helps achieve the smallest MSE. Therefore, this investigation suggests that the proposed unified intervention mechanism can manage diverse characteristics of fine-tuned Transformers for various downstream tasks. We demonstrate the general applicability of TI-G in the next section.

5 Experiments

In this section, we evaluate TI for QAT of fine-tuned BERT and vision Transformer with ternary weight quantization. We demonstrate that TI significantly boosts the convergence of QAT to achieve higher model accuracy within shorter fine-tuning time compared to the state-of-the-art QAT methods

(TernaryBERT (Zhang et al., 2020b) and XTC (Wu et al., 2022)) on various Transformer tasks and datasets. More extensive evaluation results on a wide range of BERT models as well as the ablation studies on various aspects of TI can be found in Appendix A.3. Due to limited space, detailed experiment settings are also summarized in Appendix A.1.

Iterations	CoLA	RTE	MRPC	STS-B	Avg. Ratio
Budget-O	1,603	233	343	538	1
Budget-A	13,325	4,468	7,050	10,066	16
Budget-C	159,909	53,621	84,611	120,795	200

Table 2: Different budgets for fine-tuning iterations for GLUE tasks.

5.1 QAT Accuracy on Few-Sample BERT

First, we perform an extensive performance comparison of the proposed teacher intervention methods with the state-of-the-art QAT methods: TernaryBERT (Zhang et al., 2020b) and XTC (Wu et al., 2022). We evaluate TI on fine-tuned BERT$_{base}$ (12 layer), BERT$_{large}$ (24 layer) (Devlin et al., 2019), TinyBERT (Jiao et al., 2020) (6 layer), and SkipBERT (Wu et al., 2022) (6 layer) for GLUE tasks (Wang et al., 2018). We report the experimental results for the small dataset tasks (less than 10k of dataset size) here; the results on the other models and tasks are reported in Appendix A.2.

To investigate the convergence of these QAT methods, we consider the following fine-tuning budgets:

- Budget-O: The number of iterations reported in the original paper (Zhang et al., 2020b).
- Budget-O2: 2× iterations of Budget-O.
- Budget-O4: 4× iterations of Budget-O.
- Budget-A/C: prolonged fine-tuning budgets employed in XTC (Wu et al., 2022).

A summary of fine-tuning budgets is shown in Table 2. Note that the number of fine-tuning iterations of Budge-A is roughly 16× larger than Budget-O. In the following subsections, we categorize the experiments to two scenarios: few-sample fine-tuning (Scenario-1: Budget O/O2/O4) and prolonged fine-tuning (Scenario-2: Budget A/C).

Scenario-1: Few-Sample Fine-tuning: Table 3 summarizes the experimental results of few-sample fine-tuning. Consistent with the prior observations (Wu et al., 2022), the accuracy of TernaryBERT increased as the fine-tuning budget grew from Budget-O to Budget-O4. But all teacher intervention options have improved these baseline accuracies. Note that the preference between TI-M and TI-O varies across the tasks and models. For example, TI-M is mainly preferred on CoLA and RTE, while there is a marginally higher preference for TI-O on STS-B. For most cases, however, TI-G outperforms the other TI options. Although the accuracies of TI-M and TI-O are similar, TI-G's accuracy significantly exceeds both. From these observations, we can conclude that the proposed gradual intervention significantly improves the QAT convergence for regaining model accuracy.

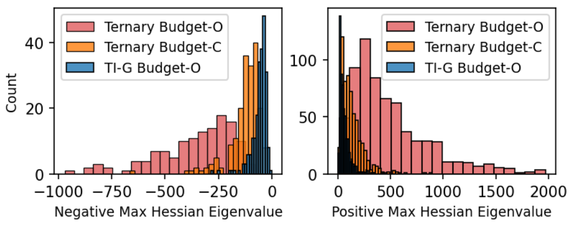

Figure 5: Convergence analysis of QAT methods with Hessian Max Eigenvalues.

Scenario-2: Prolonged Fine-tuning: Table 4 summarizes the experimental results of prolonged fine-tuning. For fair comparisons, we followed the instructions of XTC to match the fine-tuning budgets, learning rates, and the model compression mechanism on both TinyBERT and SkipBERT. As expected, TI-G's accuracy is significantly increased from Budget-O to Budget-A/C than Budget-O4. Interestingly, TI-G's accuracy is higher than TernaryBERT and XTC for these prolonged fine-tuning budgets with noticeable margins. In fact, XTC's average accuracy on Budget-A (for SkipBERT-6L) is lower than TI-G's average accuracy on Budge-O4 (for TinyBERT-6L), highlighting the superior convergence of TI-G compared to XTC.

5.2 QAT Accuracy on Vision Transformers

We further evaluate the proposed teacher intervention method on ViT. Table 5 summarizes the QAT accuracies of ViT fine-tuned for CIFAR10, CIFAR100, and ImageNet with the fine-tuning budgets following the original paper (Dosovitskiy et al., 2020). As shown in the Table. 5, TI-G outperforms TernaryBERT on all the QAT cases for ternary weight quantization. It is noteworthy that TI-G is exceptionally effective for fine-tuned ImageNet.

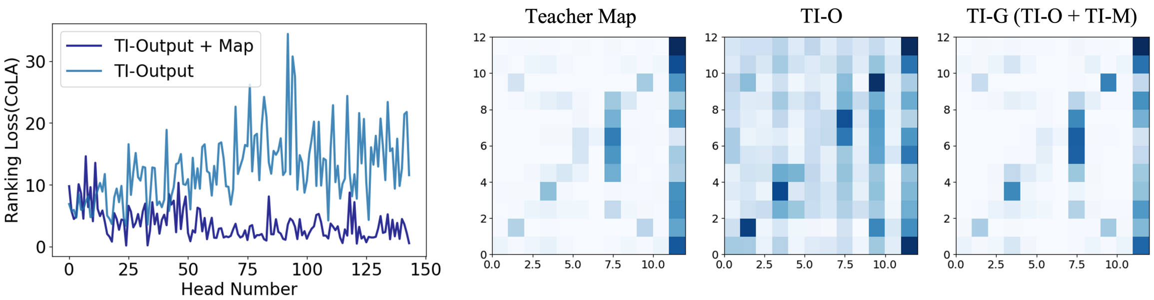
5.3 Convergence Analysis

In Sec. 4, we discussed that TI impedes propagation of quantization errors and flattens the loss surface for favorable convergence as shown in Fig. 2. To quantitatively analyze the convergence of QAT, we conducted the Hessian eigenvalue analysis (Park and Kim, 2022) on BERT$_{base}$ over CoLA task. As shown in Fig. 5, TernaryBERT suffers large magnitude (positive and negative) eigenvalues. The large magnitude Hessian eigenvalues indicate sharp loss surfaces, unfriendly for quantization (Shen et al., 2020; Dong et al., 2019). A prolonged fine-tuning would suppress the large Hessian eigenvalues at the expense of significantly increased fine-tuning computations. In contrast, TI significantly reduces the magnitude with an order of magnitude smaller fine-tuning iteration. From this analysis, we can conclude that TI helps flatten the loss surface to improve the convergence of QAT.

5.4 Further Analysis of TI-G: Self-Attention Map Recovery

In this section, we provide an analysis of TI-M's effectiveness in the use of TI-G. Since the self-attention map encodes the relational representation of symbols within a sequence, quantization on SA-GEN would disrupt this relational encoding. Therefore, TI on the self-attention map (TI-M) is crucial for maintaining relative order within the self-attention map. As shown in Sec. 4.2, TI-O lacks consideration of the self-attention map recovery, requiring gradual teacher intervention mechanism



(a) (b)

Figure 6: (a) Comparison of ranking loss between TI-O and TI-O with TI-M (TI-Output + Map) (b) Visualization of self-attention map with full-precision, TI-O and TI-G trained on CoLA. The input sentence is "John was lots more pleasure than Fred."

that applies TI-M after TI-O for recovering the self-attention map. Fig. 6 shows two empirical evidences that TI-M helps to recover the self-attention map with TI-O.

Fig. 6(a) shows the ranking loss computed on the self-attention map of BERT$_{base}$ after QAT on CoLA. Note that the ranking loss quantitatively indicates how much the relative order in the quantized self-attention map has been skewed from the teacher's self-attention map (Liu et al., 2021b). As can be seen, QAT without TI-M leads to significant disruption of the self-attention map. In contrast, QAT with TI-M maintains the original ranking of cross-symbol correlation, successfully suppressing the ranking loss. We further visualize each quantized model's resulting self-attention maps in Fig. 6(b). Contrary to using TI-O only, TI-O with TI-M successfully recovers the teacher self-attention map's distinctive feature. From this observation, we can conclude that TI-M approach used with TI-O is particularly beneficial for preserving the self-attention map under quantization.

6 Conclusion

In this work, we proposed a proactive knowledge distillation method for improving the convergence of QAT for ultra-low precision Transformers called teacher intervention. The proposed method intervenes in the propagation of quantization error to suppress accuracy degradation and improve QAT's convergence speed. We demonstrate that the proposed method outperforms the state-of-the-art QAT methods in achieving higher accuracy on various fine-tuned Transformers with smaller fine-tuning budgets. Our code is available at https://github.com/MarsJacobs/ti-kd-qat.

7 Limitations

This work proposes a proactive knowledge distillation method called *teacher intervention* for improving the convergence of QAT with small fine-tuning budgets. Although our analysis reveals that quantization error propagation is one of the main causes of sub-optimal convergence of QAT, a more in-depth investigation of the detailed recovery mechanism of QAT from quantization error would be interesting. Also, extending the discovery of proactive knowledge distillation to diverse Transformer architectures, including encoder-decoder and decoder-only models, would be a promising future research direction.

A Appendix

In this section, we provide experimental setup and TI implementation in Sec. A.1. We also provide evaluation results of GLUE (Wang et al., 2018) large datasets (SST-2, QNLI, MNLI, QQP) in Sec. A.2 and ablation studies in Sec. A.3. Further analysis of TI-G's effectiveness is provided in 5.4.

A.1 Experimental Settings

Models Description We use task-specific, fine-tuned BERT family models to evaluate our method. Further information on each model is as follows:

1. **BERT$_{base}$** L=12, d=768 N_H=12, Contains about 110M parameters.
2. **BERT$_{large}$** L=24, d=1024 N_H=16, Contains about 340M parameters.
3. **TinyBERT-4L** L=4, d=312 N_H=12, Contains about 14M parameters. This compressed model is fine-tuned using task-specific distillation method (Jiao et al., 2020) initialized from general pre-trained TinyBERT model file. [2]
4. **TinyBERT-6L** L=6, d=768 N_H=12, Contains about 67M parameters. This compressed model is fine-tuned using task-specific distillation method (Jiao et al., 2020) initialized from general pre-trained TinyBERT model file. [3]
5. **SkipBERT-6L** L=6, d=768 N_H=12, Contains about 67M parameters. This compressed model parameters are initialized from XTC (Wu et al., 2022) model initialization method: using every other layer of the fine-tuned BERT$_{base}$'s parameter to initialize the layer-reduced model.

Datasets and Settings We evaluate our method on GLUE benchmark (Wang et al., 2018), which is a collection of resources for training, evaluating, and analyzing natural language understanding systems. For the training setting, we use the batch size of 16 for CoLA and 32 for other tasks. The learning rate starts from zero and gradually increases to 2e-5 during the warm-up stage and decays linearly to 2e-9 for total training epochs.

Budget-C Time	25,792	22,342	17,813	49,915

Table 7: Training details for the GLUE tasks. DA is data augmentation.

Comparison of Training Cost We performed an extensive performance comparison in Sec. 5.1 along the training budget to investigate the convergence of QAT methods. Table. 6 shows the training setting of each budget with the Data Augmentation (DA) option, which is first proposed by (Zhang et al., 2020b) (Jiao et al., 2020) artificially expanding the training sample for prolonged fine-tuning, causing a blow-up in fine-tuning costs. To investigate how much the DA magnifies the QAT overhead, we compare the number of training samples of GLUE small datasets and the number of data-augmented training samples in Table. 7. Furthermore, we measured the total QAT time for each Budget over GLUE small datasets with the A6000 single GPU, indicating that prolonged fine-tuning with DA would become profoundly painful, increasing model deployment costs and time.

Teacher Intervention Implementation Our experiments were performed on A6000 GPUs. We use Pytorch 1.10.2 for the implementation of TI and this implementation is based on the TernaryBERT Pytorch code base. [4] We would like to emphasize that TI has strong advantages of simplicity for implementation. To implement TI operation, we modified the teacher model forward operation, enforcing the teacher model to return layer-wise MHA outputs and SA-GEN outputs which will be used in TI-O and TI-M respectively. When the teacher model's layer-wise required outputs are returned,

we passed these to the student model forward operation's input. With these additional inputs, we replace the student's attention map/output with the teacher's in the attention sub-layer forward operation. More detailed implementation can be found at https://github.com/MarsJacobs/ti-kd-qat.

A.2 Additional Experimental Results

Large-Sample Fine-tuning Table. 8 shows evaluation of TI in GLUE large datasets (SST-2, QNLI, MNLI, QQP). TI-G outperforms the baseline for all the cases as we discussed in Table. 3, showing that TI improve convergence of QAT in large sample fine-tuning.

Additional Results of Prolonged Fine-Tuning Table. 9 shows additional evaluation results of TI in prolonged fine-tuning (BERT$_{base}$ and BERT$_{large}$ with Budget-A/C). As can be seen, TI-G shows superior accuracy to TernaryBERT with a noticeable margin in Budget-A/C both. Furthermore, TI-G achieves close to full-precision accuracy with Budget-A, showing TI's beneficial effect on the convergence of QAT.

A.3 Ablation Study

TI two step QAT and output loss In this section, we delve deeper into evaluating the efficacy of the TI method. As TI-O employs one additive loss for internal distillation (Attention Output MSE loss, called output loss) and TI QAT is performed in two steps, conducting an ablation study on TI (exploiting output loss and two-step QAT separately) provides a deeper understanding of our method. Table. 10 demonstrates the effect of output loss and the use of a two-step method with TI independently with BERT family models over GLUE small datasets. As can be seen, both factors act positively on the performance of quantized models. Interestingly, two-step QAT factor provides a powerful impact (Row 2) in compressed models (TinyBERT-4L and TinyBERT-6L), and output loss shows a distinct impact (Row 3) in the BERT$_{large}$ model. When both factors are implied together (Row 4), performance is boosted further.

Exploration of unified teacher intervention methods In this section, we investigate the best unified teacher intervention strategy. We proposed a unified intervention approach (TI-G) in Sec. 4.2, applying TI with output intervention (TI-O) followed by map intervention (TI-M). As more scheduling choices are left when using TI-O and TI-M together, we propose additional two scheduling methods, Inverted TI, and Stochastic TI. Inverted TI applies TI-O and TI-M in the opposite order of TI-G, and stochastic TI means choosing TI-O and TI-M options randomly in every training iteration, ensembling each TI option's effect in a stochastic way. Table. 11 shows the comparison between unified TI scheduling methods with BERT family models over GLUE small datasets. TI-G outperforms other unified TI scheduling methods in almost every model, which shows our proposed teacher intervention unification approach's efficacy.

Generative Replay Inspired by Hippocampal Memory Indexing for Continual Language Learning

Abstract

Continual learning aims to accumulate knowledge to solve new tasks without catastrophic forgetting for previously learned tasks. Research on continual learning has led to the development of generative replay, which prevents catastrophic forgetting by generating pseudo-samples for previous tasks and learning them together with new tasks. Inspired by the biological brain, we propose the hippocampal memory indexing to enhance the generative replay by controlling sample generation using compressed features of previous training samples. It enables the generation of a specific training sample from previous tasks, thus improving the balance and quality of generated replay samples. Experimental results indicate that our method effectively controls the sample generation and consistently outperforms the performance of current generative replay methods.[1]

1 Introduction

Humans and intelligent animals continually acquire new knowledge and skills throughout their lifetime. This ability, called continual learning (CL) or lifelong learning, is a fundamental requirement for human-like general intelligence (Parisi et al., 2019). CL is also crucial for practical applications, as new data and tasks to train models appear every day in the real world. It is especially important for natural language processing (NLP) systems, in which vocabulary and language usage change over time. However, most neural network based models are trained with a static dataset. When learning different tasks sequentially, performance on the previously learned tasks tends to significantly degrade, referred to as catastrophic forgetting (McCloskey and Cohen, 1989). Learning new tasks without catastrophic forgetting has been a long-standing challenge in machine learning and neural networks.

Replay is an approach to alleviate catastrophic forgetting by retraining with previous tasks' data when training a new task. Although replay-based methods are effective in most CL scenarios, it is necessary to retain training data for all previous tasks, which may cause problems with storage requirements and data privacy. Therefore, generative replay was developed (Shin et al., 2017), which uses pseudo-samples generated from generation models instead of real samples. In the NLP domain, LAMOL (Sun et al., 2020a) was proposed as a generative replay framework, where a single language model simultaneously learns to solve tasks and to generate pseudo-samples (Fig. 1a).

Although the generative replay does not require any previous task's data, it typically underperforms actual sample replay because of the balance and quality problems in sample generation. Regarding the balance problem, generation models tend to generate a large number of samples for recently learned tasks, that results in forgetting older tasks. This is due to the difficulty in controlling sample generation and catastrophic forgetting occurring in generation models. Regarding the quality problem, generative replay methods commonly assume to generate even unseen samples which is not included in the past training datasets. However, since generating such unseen samples is more difficult than generating previously trained samples, it may cause the degradation of the quality of replay samples. To prevent the catastrophic forgetting, it is sufficient to generate only previously learned samples.

To address these issues, we refer to the memory retrieval mechanism in the biological brain that achieves CL. According to the hippocampal indexing theory (Teyler and Rudy, 2007), the hippocampus encodes memory engrams for new neocortical activity patterns and uses them as memory indexes to recall past experiences. Inspired by this hippocampal mechanism, we propose hippocam-

pal memory indexing (HMI) for improving generative reply. To remember training samples with a small data usage, we introduce a hippocampus module that encodes training samples into compressed memory engrams using BERT (Devlin et al., 2019) and product quantization (PQ) (Jégou et al., 2011), and stores them to generate conditioned samples during the replay step (Fig. 1b). This method makes it possible to generate specific training samples from previously learned tasks.

We evaluated HMI on two different CL scenarios using the original LAMOL as a baseline. The first scenario is a sequence of different types of tasks, for which we used five natural language understanding (NLU) tasks from DecaNLP (McCann et al., 2018). The other scenario is a sequence of different domains in the same task, for which we used five text classification datasets and single-pass setting, which is considered as an ideal scenario for CL. The results indicate that HMI consistently outperforms LAMOL and improves robustness to training task order and amount of replay samples. We also investigated the balance of previously learned tasks in generated samples and found that HMI enables the generation of even old task samples, which indicates the controllability of sample generation with HMI. Furthermore, we explored the potential of further improvement of HMI with different sample selection strategies for replay.

2 Related Work

CL, which involves learning from a stream of tasks without catastrophic forgetting, is a long-standing issue in machine learning. In the NLP, CL has been studied for diverse tasks, for example, word and sentence representations (Xu et al., 2018; Liu et al., 2019), sentiment analysis (Chen et al., 2015; Xia et al., 2017), composition language learning (Li et al., 2020b), relation learning (Han et al., 2020), dialogue systems (Lee, 2017; Madotto et al., 2021), text classification, and question-answering (QA) (de Masson d'Autume et al., 2019; Wang et al., 2020).

Regularization-based methods aim to constrain changes in model parameters important for previous tasks. Various methods have been proposed to estimate the importance of each parameter. For example, elastic weight consolidation (EWC) (Kirkpatrick et al., 2017) uses the Fisher information matrix. Synaptic intelligence (SI) (Zenke et al., 2017) estimates importance from the contribution to loss changes. Memory-aware synapses (MAS) (Aljundi et al., 2018) computes the sensitivity of parameters on the basis of the gradient of model outputs.

Architecture-based methods dynamically change the network structure to assign model parameters for each task. Progressive neural networks (PNN) (Rusu et al., 2016) freeze the current parameters and add a new column of the network when training a new task. Instead of extending the network, PackNet (Mallya and Lazebnik, 2018) applies network pruning using dynamic filters to separate the neurons used for each task.

Replay-based methods mitigate catastrophic forgetting by retraining for previous tasks when training for a new one. MbPA++ (de Masson d'Autume et al., 2019) introduces an episodic memory that stores real samples of previous tasks to use for experience replay and local adaptation. Meta-MbPA

(Wang et al., 2020) applies a meta-learning algorithm to improve MbPA++. To enhance the replay-based methods with a limited amount of samples, Wang et al. (2020) and Huang et al. (2021) also investigated effective selection strategies other than random sampling. Instead of keeping real samples for replay, Shin et al. (2017) proposed generative replay, which trains a model to generate pseudo-samples. Sun et al. (2020a) proposed LAMOL as a generative replay method for NLP tasks. LAMOL uses GPT-2 (Radford et al., 2019) to simultaneously learn a variety of NLP tasks and pseudo-sample generation. L2KD (Chuang et al., 2020) and DnR (Sun et al., 2020b) use knowledge distillation to extend LAMOL. MFK-LAMOL (Choi and Kang, 2021) makes replay more efficient by using more forgotten pseudo-samples in generative replay. Rational-LAMOL (Kanwatchara et al., 2021) uses critical freezing guided by supervised or unsupervised rationale. RVAE-LAMOL (Wang et al., 2022) enhances LAMOL by mapping different tasks into a limited unified feature space.

Current generative replay methods have problems on the balance and quality of generated samples. To address these issues, we propose a sample-generation control with the HMI method, inspired by the biological brain. In contrast to the previous work, our approach prevents low quality samples by using the assumption that a model generates only previously learned samples. HMI also achieves balanced sample generation by strong sample-level conditioning rather than task-level conditioning. Although our HMI can be applied to most of the existing generative replay methods, similar to other recent work, we build HMI upon LAMOL, which is a simple generative replay baseline for CL in NLP and whose implementation code is available.

3 LAMOL: Language Modeling for Lifelong Language Learning

Before describing HMI, we briefly explain LAMOL (Sun et al., 2020a), on which we propose our HMI, in this section.

LAMOL is a generative replay framework using a single GPT-2 to solve different types of NLP tasks and generate pseudo-samples. In LAMOL, all training samples are fed into GPT-2 as a sequence of *context*, *question*, and *answer*. As illustrated at the top of Figure 1a, GPT-2 learns each task in a QA manner, predicting the answer part on the basis of the given context and question. As well as training QA, GPT-2 learns language modeling (LM) to generate the whole sequence of the context, question, and answer, as illustrated at the bottom of Figure 1a. During the training step, the parameters of GPT-2, $\boldsymbol{\theta}_{\text{GPT-2}}$, are optimized to minimize the QA loss $\mathcal{L}_{\text{QA}}$ and the LM loss $\mathcal{L}_{\text{LM}}$ together as $\mathcal{L} = \mathcal{L}_{\text{QA}} + \lambda\mathcal{L}_{\text{LM}}$, where λ is a hyperparameter.

When training for a new task, LAMOL generates pseudo-samples for previous tasks to use for replay. Assume a stream of tasks $\{\mathcal{T}_1, \mathcal{T}_2, \dots \mathcal{T}_T\}$ to train a model with LAMOL, where the number of tasks T may be unknown. Before training a new task $\mathcal{T}_i$ ($i > 1$), GPT-2 generates pseudo-samples by top-k sampling from the first token [GEN]. The number of pseudo-samples is $\gamma|\mathcal{T}_i|$, where γ is the sampling ratio and $|\mathcal{T}_i|$ is the number of training samples in $\mathcal{T}_i$. Defective samples, which do not have a unique [ANS] token that indicates the start position of the answer, are discarded, and the others are mixed with $\mathcal{T}_i$ to alleviate forgetting for $\mathcal{T}_{<i}$ in training.

When using the same [GEN] for all tasks, the ratio for old tasks in the generated samples decreases exponentially in theory (Sun et al., 2020a). Therefore, Sun et al. (2020a) proposed to replace [GEN] with a task-specific token [TASK] (e.g., "`__sst__`") to control GPT-2 to generate pseudo-samples belonging to the specific task. In the beginning of training for $\mathcal{T}_i$, $\frac{\gamma}{i-1}|\mathcal{T}_i|$ pseudo-samples for each previous task, $\mathcal{T}_1, \dots, \mathcal{T}_{i-1}$, are generated using the corresponding task-specific token.

4 Hippocampal Memory Indexing (HMI)

In this section, we introduce our Hippocampal Memory Indexing (HMI) that can suppress the problems of unbalanced and low-quality generation in the replay by accessing compressed features for previous training samples.

4.1 Overview

HMI is implemented as a module that works on LAMOL. Figure 1b shows the overview of our HMI on LAMOL. The training process of HMI on LAMOL is as follows.

1. The **hippocampus module** encodes each training sample into a feature vector representation with a BERT encoder (§ 4.2.1).

2. **Product Quantization** (PQ) compresses the encoded feature as a **memory engram** in a **hippocampal memory** for future replay (§ 4.2.2). To prevent increasing the size of the hippocampal memory, we apply memory pruning at the end of training for each task (§ 4.2.3).

3. The **memory engrams** are used to condition the generation by GPT-2 to generate the corresponding samples (§ 4.3). This allows us to control the task balance in replay samples and generate only previously learned samples of higher quality.

We describe the hippocampus module, which encodes and stores memory engrams for each training sample, in § 4.2 and explain generation control with HMI in § 4.3. Finally, we explain the pre-training for HMI in § 4.4.

4.2 Hippocampus Module

The hippocampus module is a memory component that stores memory engrams, compressed representations of training samples in previously learned tasks. During replay, the module retrieves stored memory engrams and provides them for GPT-2 to generate the corresponding previous samples. In this section, we describe the encoding of a memory engram from each training sample and the pruning of the hippocampal memory in the module.

4.2.1 Memory Engram Encoding

A memory engram is created from the context and question part of each training sample. Each sequence consisting of the context and question is first encoded to a fixed-sized vector representation with the BERT encoder. Similar to BERT, we use a special classification token [CLS] in the beginning of an input sequence to obtain a sample-level embedding $\boldsymbol{h}_{\texttt{[CLS]}} \in \mathbb{R}^H$, where H is the embedding dimension in BERT. It is further converted to a d-dimensional feature vector $\boldsymbol{h} = \boldsymbol{W}_{\mathrm{E}}\boldsymbol{h}_{\texttt{[CLS]}} \in \mathbb{R}^d$, where $\boldsymbol{W}_{\mathrm{E}} \in \mathbb{R}^{d\times H}$ is a weight matrix. Note that, during CL, the encoder parameters $\{\phi_{\mathrm{BERT}}, \boldsymbol{W}_{\mathrm{E}}\}$ are frozen to prevent the features from drifting, which degrades the controllability of HMI.

4.2.2 Feature Quantization

A feature vector $\boldsymbol{h} \in \mathbb{R}^d$ is then quantized to reduce the data size of the hippocampal memory. In the beginning of training a new task, we train a quantization model on encoded feature vectors for all training samples in the new task and all feature vectors currently stored in the hippocampal memory. We use PQ (Jégou et al., 2011), which has a lower reconstruction error than a simple quantization model that uses only k-means. PQ first divides a d-dimensional $\boldsymbol{h}$ into S sub-vectors, each of dimension d/S. It then creates a codebook by computing N centroids for each S partitions with the k-means algorithm. Using this codebook, each $\boldsymbol{h}$ is quantized to S integer indices $\boldsymbol{c} \in \{0, \dots, 255\}^S$ and stored in the hippocampal memory as a memory engram.

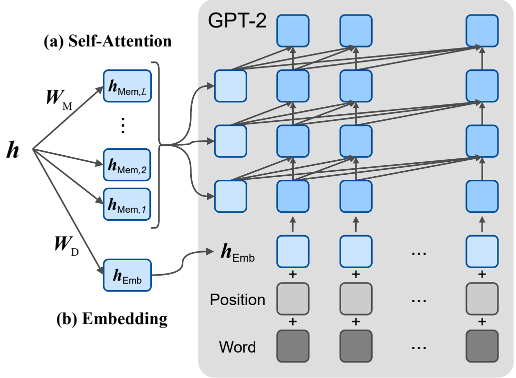

Figure 2: Feature-vector injection to GPT-2. (a) Self-Attention: $\boldsymbol{h}_{\mathrm{Mem},l}$ is fed into the l-th self-attention layer and used as an additional key and value. (b) Embedding: $\boldsymbol{h}_{\mathrm{Emb}}$ is added to word and position embeddings.

4.2.3 Memory Pruning

It is inefficient to keep memory engrams of all training samples in each previously learned task, which may cause a scalability problem with the data size for an increased number of tasks. Thus, we set the maximum number of stored memory engrams M_{max}. When learning the i-th task $\mathcal{T}_i$, the memory engrams of all training samples in $\mathcal{T}_i$ are first appended to the hippocampus module as the i-th task hippocampal memory $\boldsymbol{M}_i$. After updating the codebook of the PQ model, every hippocampal memory $\{\boldsymbol{M}_1, \boldsymbol{M}_2, \dots \boldsymbol{M}_i\}$ is reduced to satisfy $|\boldsymbol{M}_j| \leq \frac{M_{\mathrm{max}}}{i}$ for $1 \leq j \leq i$ by randomly selecting memory engrams to keep from $\boldsymbol{M}_j$. Therefore, we can keep the total number of memory engrams at most M_{max} regardless of the number of tasks.

4.3 Sample Generation with Hippocampal Memory Indexing

To condition the sample generation, we feed the memory engram of each training sample into GPT-2. We use two schemes, each of which is based on embedding and self-attention layers (Li et al., 2020a; Fang et al., 2021), as described as follows and illustrated in Figure 2.

Embedding Layer In GPT-2, the embedding representation of the t-th token in an input sequence is the sum of the word embedding $\boldsymbol{h}_{\mathrm{WE}}^{(t)} \in \mathbb{R}^H$ and position embedding $\boldsymbol{h}_{\mathrm{PE}}^{(t)} \in \mathbb{R}^H$, where H is the embedding dimension in GPT-2. The feature vector $\boldsymbol{h}$ is added to it, so the new embedding vector is $\boldsymbol{h}_{\text{Emb}}^{(t)} = \boldsymbol{h}_{\text{WE}}^{(t)} + \boldsymbol{h}_{\text{PE}}^{(t)} + \boldsymbol{W}_{\text{D}}\boldsymbol{h}$, where $\boldsymbol{W}_{\text{D}} \in \mathbb{R}^{H \times d}$ is a weight matrix.

Self-Attention Layer The feature vector $\boldsymbol{h}$ is used as an additional key and value in each self-attention layer. It is first projected into an LH-dimensional vector with a weight matrix $\boldsymbol{W}_{\text{M}} \in \mathbb{R}^{LH \times d}$. It is then divided into L vectors $[\boldsymbol{h}_{\text{Mem},1}, \ldots, \boldsymbol{h}_{\text{Mem},L}]$ and converted to a key and value in each self-attention layer.

We apply the feature-vector injection to the training, replay, and inference steps. During the training step, a quantized memory engram $\boldsymbol{c}$, encoded from a training sample in the hippocampus module, is decoded back into a feature vector $\boldsymbol{h}'$ and given to GPT-2 to condition the generation for both the QA and LM. It reduces the effect of quantization errors between training and generation to use $\boldsymbol{h}'$ rather than the BERT encoder outputting $\boldsymbol{h}$ directly. During the replay step, when training for the i-th task $\mathcal{T}_i$ $(i > 1)$, we randomly select $\frac{\gamma}{i-1}|\mathcal{T}_i|$ memory engrams from the hippocampal memory for each previous task, $M_1, \ldots, M_{i-1}$, and provide them for GPT-2 to generate the corresponding past training samples by greedy decoding.

In inference, GPT-2 generates the answer part on the basis of the given context and question with injected $\boldsymbol{h}$ encoded from the context and question of a test sample.

4.4 Pre-training

The memory engrams encoded in the hippocampus module should contain enough information to reconstruct the corresponding samples with GPT-2. However, a naive [CLS] token embedding of BERT and a linear projection with randomly initialized $\boldsymbol{W}_{\text{E}}$ are considered insufficient. In addition, the GPT-2 side uses the connections with $\boldsymbol{W}_{\text{D}}$ and $\boldsymbol{W}_{\text{M}}$, which are initialized randomly, so it may make CL unstable, especially for initial tasks.

To address these issues, we introduce a pre-training of the BERT encoder and GPT-2 as an autoencoder (AE) using an unlabeled text corpus. In the pre-training, the BERT encoder learns to encode each input text into a single feature vector, and GPT-2 learns to reconstruct the original input from the feature vector. Note that we do not apply the quantization model to the pre-training. This is because it is not necessary to store feature vectors, since we do not consider the replay of the pre-training data, and this also allows the encoder parameters $\{\phi_{\text{BERT}}, \boldsymbol{W}_{\text{E}}\}$ to be optimized through gradient descent. With this pre-training, the model encodes well-informed memory engrams and achieves their conditional generation with GPT-2 from the beginning of CL.

Along with the AE, GPT-2 simultaneously learns the LM in this pre-training. This is to prevent GPT-2 from losing the knowledge of the LM that GPT-2 originally has by training the AE. Therefore, we optimize the sum of the AE loss and the LM loss $\mathcal{L} = \mathcal{L}_{\text{AE}} + \mathcal{L}_{\text{LM}}$, and obtain the initial model parameters $\{\phi_{\text{BERT}}, \boldsymbol{W}_{\text{E}}, \boldsymbol{\theta}_{\text{GPT-2}}, \boldsymbol{W}_{\text{D}}, \boldsymbol{W}_{\text{M}}\}$ for CL. The effect of the pre-training are given in Appendix A.

5 Experiments

5.1 General Settings

Tasks, Datasets, and Metrics To evaluate the effectiveness of HMI for CL on different types of tasks, we first evaluated it on a scenario of selecting five NLU tasks from decaNLP (McCann et al., 2018), following the settings of Sun et al. (2020a): QA (SQuAD), semantic parsing (WikiSQL), sentiment analysis (SST), semantic role labeling (QA-SRL), and goal-oriented dialogue (WOZ).

To evaluate it on another CL scenario, we used five text classification tasks from diverse domains: news classification (AGNews), sentiment analysis (Yelp, Amazon), Wikipedia article classification (DBPedia), and QA categorization (Yahoo). We followed the settings of de Masson d'Autume et al. (2019) to use the balanced version datasets[2] and applied the single-pass setting, where a model trains with each dataset for only one epoch.

Each dataset has the corresponding evaluation metric ranging from 0 to 100%. More details of tasks and datasets are given in Appendix B.1.

Compared Methods We compared the following methods:

- **LAMOL** This is the baseline generative replay method, without HMI. GPT-2 generates pseudo-samples by top-k sampling with $k = 20$ given only first tokens [GEN]/[TASK].
- **HMI-LAMOL** Our HMI implemented on LAMOL. We evaluated the effectiveness of HMI by comparing it to LAMOL.

---

[2] We used the random sampled subsets released by Sun et al. (2020a).

- **Real Samples** Replay samples in HMI-LAMOL are replaced with actual training samples corresponding to the given memory engrams. This is considered as the upper bound of HMI-LAMOL in terms of the quality of generated samples.
- **Multitask** All tasks are simultaneously trained with GPT-2. Note that GPT-2 optimizes only the QA loss. Since future tasks are not accessible in CL, this is often regarded as the upper bound.

Implementation We implemented the above methods on the basis of the official implementation of LAMOL.[3] We also re-implemented LAMOL to use [GEN]/[TASK] for learning the QA as well as learning the LM to make training fast and improve performance by unifying input format. We used the smallest pre-trained GPT-2[4] as the language model for all methods and the smallest pre-trained BERT[5] for the encoder of the hippocampus module in HMI-LAMOL.

Hyper-parameters For all methods, we followed the settings in Sun et al. (2020a): We set $\lambda = 0.25$ for the weight of the LM loss and applied greedy decoding during inference. We trained the models for nine epochs for each NLU task and for only one epoch for each text classification task. For HMI-LAMOL, we set the maximum size of the hippocampal memory M_{max} to 10,000. We also set the dimension d of the feature vector $\boldsymbol{h}$ to 768, the same as the embedding dimension in BERT and GPT-2. We set the number of partitions $S = 16$ and the number of centroids $N = 256$ for the feature quantization. All the results in our experiments were the average over two runs (seed $= 42, 43$). More details of the experimental settings are given in Appendix C.

For the pre-training in HMI-LAMOL (§ 4.4), we used 1,070,272 text lines from the Wiki-40B (Guo et al., 2020) test set as training data. We trained the model with them for three epochs to obtain the initial model parameters for CL.

5.2 Evaluations

5.2.1 Five Different NLU Tasks

Settings We trained each model on the five NLU tasks in either descending/ascending order in accordance with the number of training samples. We evaluated it with and without task-specific tokens, and with three different replay sample ratios $\gamma \in \{0.01, 0.05, 0.2\}$. We obtained the performance of CL as the average score on the five tasks at the end of training streams.

Replay sample ratio (γ)	0.01	0.05	0.2
Large to small: (SQuAD → WikiSQL → SST → QA-SRL → WOZ)			
LAMOL$_{\text{GEN}}$ (Sun et al., 2020a)$*$	-	69.6	73.1
LAMOL$_{\text{TASK}}$ (Sun et al., 2020a)$*$	-	71.5	74.3
LAMOL$_{\text{GEN}}$	69.1	74.1	75.5
LAMOL$_{\text{TASK}}$	67.9	74.4	76.2
HMI-LAMOL$_{\text{GEN}}$	**72.7**	**75.3**	76.4
HMI-LAMOL$_{\text{TASK}}$	72.6	75.2	**76.6**
HMI-LAMOL$_{\text{GEN}}$ + Real samples	73.9	76.4	78.0
HMI-LAMOL$_{\text{TASK}}$ + Real samples	73.7	76.4	77.6
Small to large: (WOZ → QA-SRL → SST → WikiSQL → SQuAD)			
LAMOL$_{\text{GEN}}$ (Sun et al., 2020a)$*$	-	63.2	73.0
LAMOL$_{\text{TASK}}$ (Sun et al., 2020a)$*$	-	75.3	76.9
LAMOL$_{\text{GEN}}$	57.7	59.3	72.9
LAMOL$_{\text{TASK}}$	58.2	60.5	76.4
HMI-LAMOL$_{\text{GEN}}$	67.1	**76.5**	77.3
HMI-LAMOL$_{\text{TASK}}$	**70.8**	75.5	**77.5**
HMI-LAMOL$_{\text{GEN}}$ + Real samples	75.5	78.0	78.9
HMI-LAMOL$_{\text{TASK}}$ + Real samples	75.0	78.0	79.2
Multitask		77.2	

Table 1: Experimental results on the five NLU tasks in two different orders. $*$ indicates the reported score by Sun et al. (2020a).

Results Table 1 shows the results. The results indicate that HMI-LAMOL outperformed LAMOL in all cases, that is, in both two task orders and all γ. HMI-LAMOL with the best resulting setting, in ascending order and $\gamma = 0.2$, even beat multitask. HMI-LAMOL also reduced the performance gap between the two task orders. Although the performance of LAMOL degraded when the value of γ decreased, HMI-LAMOL mitigated the performance degradation of LAMOL. As expected, even when using the same [GEN] token, HMI-LAMOL typically performed as well as using task-specific tokens because it includes their role as well. However, there is also a performance gap from replacing generated samples with real samples. This indicates that HMI-LAMOL could be further improved by developing a better model for conditional generation.

Table 2: Experimental results on the five text classification tasks. (i)–(iv) denote four random task orders. Avg. and Std. respectively represent average and standard deviation for the four orders.

5.2.2 Five Text Classification Tasks

Settings We applied the single-pass setting, which is considered to make it difficult for HMI-LAMOL to memorize training samples.[6] We tried the three different γ as in the previous experiments (§ 5.2.1). We used the task-specific tokens for all methods except multitask learning. Following previous studies (de Masson d'Autume et al., 2019; Sun et al., 2020a), we report our results for four random task orders. The four orders are shown in Appendix B.2.

Results As shown in Table 2, HMI-LAMOL improved upon LAMOL also in this scenario. For all γ, the p-value of the paired t-test between the results on the four task orders of LAMOL and HMI-LAMOL was smaller than 1%. In particular, the performance gains were larger for smaller γ. Moreover, HMI-LAMOL had smaller standard deviations for the four task orders, which indicates that it is robust to the task training order of CL.

5.2.3 Sample Selection Strategies

Although HMI can control sample generation at the sample level as well as at the task level, in the previous experiments, we randomly selected memory engrams to use for the sample generation for each replay step. In this section, we compare the following three selection strategies with the random selection:

- **Nearest K-means** Inspired by previous studies on real samples replay (Wang et al., 2020; Huang et al., 2021), we compute k-means centroids of all memory engrams in the hippocampal memory for each task, where k is the number of generated replay samples for each task, and choose the nearest memory engram for each centroid. This strategy can be used to include more diverse samples in replay than the random selection.

Methods	NLU tasks		Text classification tasks			
	desc	asc	(i)	(ii)	(iii)	(iv)
Random	72.9	**69.7**	68.7	67.4	**67.4**	68.4
Nearest K-means	**73.1**	69.1	**69.0**	**68.6**	67.0	**69.0**
Loss Difference	71.8	65.5	62.4	66.2	**67.4**	68.0
Low Perplexity	71.8	59.3	67.8	63.7	64.9	68.6

Table 3: Results of HMI-LAMOL with different selection strategies for generating samples.

- **Loss Difference** We select samples with a larger loss difference between before and after training $\mathcal{L}_{\text{before}} - \mathcal{L}_{\text{after}}$. The samples selected through this process are considered more effective for model training.
- **Low Perplexity** To ensure the quality of generated samples, we use memory engrams for the samples with low perplexity of the model after training.

In order to simplify the comparison of the selection strategies, we do not apply the memory pruning (§ 4.2.3) and select samples from all previously learned samples. We also set the small $\gamma = 0.01$, where the difference in the selection strategy is more likely to affect CL performance. We tried all task orders for both CL scenarios with the task-specific tokens.

Results Table 3 shows the results. We first find that the selection strategies clearly affected the final performance of CL. This indicates that the control of the sample generation with HMI-LAMOL also works at the sample level as well as at the task level. This further indicates that HMI-LAMOL has the potential to improve performance when we can use a better selection strategy.

The results indicate that nearest k-means had stably good performance. However, we did not observe a clear advantage compared with random selection. This might be because even random selection can also include a sufficient number of varied samples. In contrast with these strategies focusing on the diversity of generated samples, the other two strategies, which are based on a single measure, such as loss difference or perplexity, did not perform well and lacked stability. After observing generated samples with these strategies, we discovered a serious bias in the generated samples: the selection based on the loss difference included more samples from a single class in the text classifi-

---

[6] Results in the multiple-pass setting are shown in Appendix D.

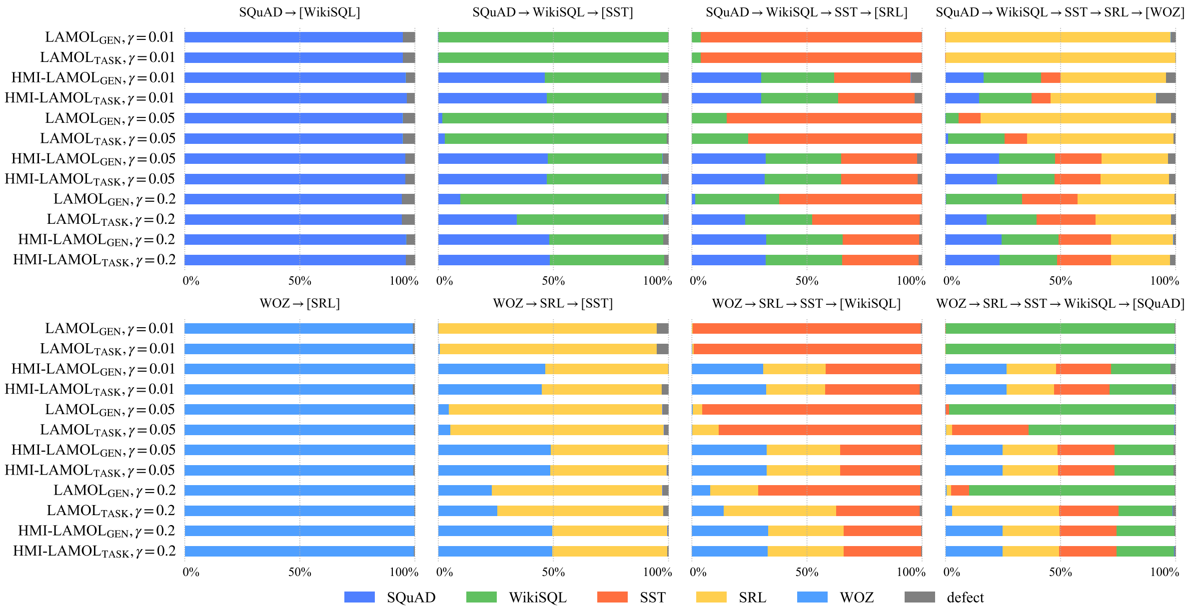

Figure 3: Task balance in replay samples generated with LAMOL and HMI-LAMOL in the experiments of the NLU tasks. Each graph shows the results of generated replay samples when training for each new task denoted with [].

cation task; generated samples selected on the basis of the perplexity tended to be of high quality but short in length and easy to predict. In conclusion, our experiments demonstrated that the diversity of the generated samples contributes to CL performance, which is consistent with the recent findings on real samples replay Wang et al. (2020); Huang et al. (2021).

6 Analysis

6.1 Balance of Replay Samples

To validate the controllability in sample generation in HMI-LAMOL, we investigated the balance of each task in the replay samples generated in the experiments on the five NLU tasks, described in § 5.2.1. To classify the replay samples, we used the BERT classifier model trained with the same training data as the experiments of CL.

Figure 3 shows the portion of each task in the generated replay samples for each replay step in the CL experiments. We first find that LAMOL generated many samples from more recently learned tasks rather than from older tasks. It became more evident in the smaller γ, which is consistent with the performance trend in CL. Although task-specific tokens alleviate this problem to some extent, when $\gamma = 0.01$, almost all of the generated samples were from the most recently learned task in all replay steps. These results indicate that the task-specific tokens are insufficient to tie the generated samples to each task.

	NLU tasks	Text classification tasks
raw text	103,329 KB	340,200 KB
+ gzip	10,879 KB	106,914 KB
no compression	263,553 KB	862,500 KB
+ PQ	3,129 KB	9,368 KB
+ PQ, Pruning	540 KB	540 KB

Table 4: Storage requirements for the hippocampal memory after training the last task in our two CL experiments. *raw text* indicates the size of ASCII text file containing all real samples, and the next line is the size after gzip compression. *no compression* means the case of keeping all samples as real-valued vectors.

However, HMI-LAMOL successfully controls the sample generation for each previous task. In contrast to LAMOL, it enables the generation of samples for older tasks even with the small γ.

6.2 Effect of Memory Compression

HMI uses the feature quantization (§ 4.2.2) and the memory pruning (§ 4.2.3) to reduce the extra storage space required to store memory engrams. Table 4 shows the storage requirements for HMI with and without the two compression methods. It also shows the storage requirements when keeping real samples as raw text file and when applying gzip compression.

When keeping real-valued vectors without the feature quantization, HMI requires even more storage space than when keeping real samples. However, after applying the quantization, each memory engram is compressed to 16 bytes, which is 96x smaller than real-valued vectors and suppressed much less than keeping real samples. Note that the numbers in Table 4 include the PQ codebook, which is 384 KB in size. In addition, the memory pruning reduces it to fixed 540 KB, which the storage requirements will never exceed even if the number of tasks or training samples increase.

7 Conclusion

We proposed hippocampal memory indexing (HMI), inspired by the biological brain, that controls generative replay by conditioning sample generation with compressed representations of previous training samples. Experimental results indicated that HMI successfully controls the sample generation of generative replay and consistently improves the CL performance and robustness. HMI is expected to be further improved by exploring better selection strategies for generating samples.

Limitations

First, in contrast to most existing generative replay approaches, HMI needs extra data space to store features of previous training samples for the sample generation control, while these features are compressed to quantization indices, which require smaller storage space, and their total number is limited to at most $M_{\max}$ by the memory pruning.

Second, there is still a performance gap between the replay of generated samples and real samples in HMI. This indicates that it is difficult to completely reconstruct previously learned samples from memory engrams.

Third, although HMI can control the generated samples for replay, there is room for further investigation into the selection strategies better than the random selection. In addition, we tried only random selection and did not further investigate the selection methods for samples in the memory pruning, which can be also explored in future work.

Methods	Pre-training	NLU tasks		Text classification tasks			
		desc	asc	(i)	(ii)	(iii)	(iv)
LAMOL	–	76.2	76.4	71.0	71.9	68.0	71.4
	$\mathcal{L}_{\text{LM}}$	75.8	76.5	70.0	72.4	71.5	71.7
HMI-LAMOL	$\mathcal{L}_{\text{AE}}$	76.2	77.2	71.8	72.3	72.2	71.4
	$\mathcal{L}_{\text{AE}}$ + $\mathcal{L}_{\text{LM}}$	76.6	77.5	72.2	72.6	72.3	71.8

Table 5: Results of CL experiments with $\gamma = 0.2$ and using task-specific tokens for the different pre-training tasks.

A Effect of Pre-training

As described in § 4.4, we applied the LM loss as well as the AE loss to the pre-training in HMI. Table 5 shows the CL performance of LAMOL and HMI-LAMOL for the different pre-training tasks.

The results show that HMI-LAMOL pre-trained with LM, outperformed HMI-LAMOL, pre-trained only with AE, for all task settings, which indicates pre-training LM is effective in HMI-LAMOL. Whereas, it is difficult to say that the pre-training LM is also effective in LAMOL, and the performance of LAMOL, pre-trained with LM, was still lower than HMI-LAMOL. Therefore, the gain of HMI is not only due to the pre-training.

B Tasks and Orderings

B.1 Details of Datasets

Following previous studies, we used five NLU tasks and five text classification tasks for our experiments. Table 6 contains a summary of the datasets, their size, metrics, and examples of the SQuAD-like QA scheme in decaNLP (McCann et al., 2018).

B.2 Ordering for Text Classification Tasks

For text classification tasks, we consider four random permutation orders, which mirror those in a previous study (de Masson d'Autume et al., 2019):
(i) Yelp→AGNews→DBPedia→Amazon→Yahoo,
(ii) DBPedia→Yahoo→AGNews→Amazon→Yelp,
(iii) Yelp→Yahoo→Amazon→DBpedia→AGNews,
(iv) AGNews→Yelp→Amazon→Yahoo→DBpedia.

C Details of Experiment Settings

We used a single Tesla V100 for all experiments. We implemented all methods with half-precision number (16-bit float). All experiments were averaged over two runs with seed $= 42, 43$. A summary of the training hyperparameter settings, following the settings in the official implementation of LAMOL,[3] are listed in Table 7. More details of the implementation can be found in our released experimental source code.[1]

D Five Text Classification Tasks with Multiple-pass Setting

In our experiments with the five text classification tasks (§ 5.2.2), we evaluated our HMI in the single-pass setting, which is considered as an ideal setting for CL and where HMI is more difficult to memorize training samples. In this section, we also present the performance of HMI when training for each task for nine epochs, the same setting as in previous work.

Table 8 shows the results of LAMOL and HMI-LAMOL, which use task-specific tokens and $\gamma = 0.2$, and other current methods. The results indicate that HMI-LAMOL also consistently outperformed LAMOL in this setting and narrows the gap with the replay of real samples. Note that although Meta-MbPA also has a good performance, MbPA++ and Meta-MbPA cannot be directly compared to other methods because of using real samples.

Task	Dataset	Context	Question	Answer	# of Train	# of Test	Metric

A Survey of Multi-task Learning in Natural Language Processing: Regarding Task Relatedness and Training Methods

Zhihan Zhang, Wenhao Yu, Mengxia Yu, Zhichun Guo, Meng Jiang
University of Notre Dame, Notre Dame, IN, USA
`{zzhang23, wyu1, myu2, zguo5, mjiang2}@nd.edu`

Abstract

Multi-task learning (MTL) has become increasingly popular in natural language processing (NLP) because it improves the performance of related tasks by exploiting their commonalities and differences. Nevertheless, it is still not understood very well how multi-task learning can be implemented based on the relatedness of training tasks. In this survey, we review recent advances of multi-task learning methods in NLP, with the aim of summarizing them into two general multi-task training methods based on their task relatedness: (i) joint training and (ii) multi-step training. We present examples in various NLP downstream applications, summarize the task relationships and discuss future directions of this promising topic.

1 Introduction

Machine learning generally involves training a model to perform a single task. By focusing on one task, the model ignores knowledge from the training signals of *related tasks* (Ruder, 2017). There are a great number of tasks in NLP, from syntax parsing to information extraction, from machine translation to question answering: each requires a model dedicated to learning from data. Biologically, humans learn natural languages, from basic grammar to complex semantics in a single brain (Hashimoto et al., 2017). In the field of machine learning, multi-task learning (MTL) aims to leverage useful information shared across multiple related tasks to improve the generalization performance on all tasks (Caruana, 1997). In deep neural networks, it is generally achieved by sharing part of hidden layers between different tasks, while keeping several task-specific output layers. MTL offers advantages like improved data efficiency, reduced overfitting, and fast learning by leveraging auxiliary information (Crawshaw, 2020).

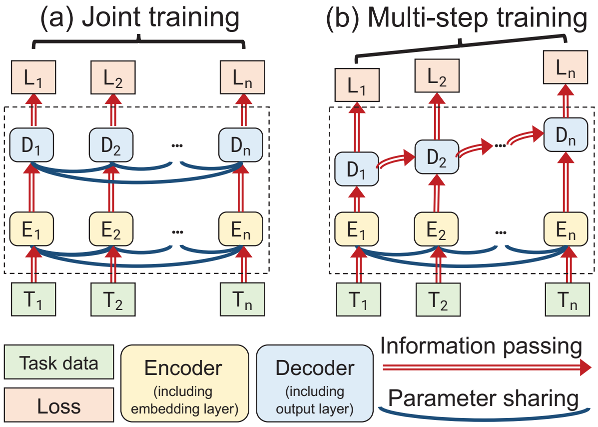

Figure 1: Two multi-task learning frameworks.

There have been relevant surveys that looked into architecture designs and optimization algorithms in MTL. Ruder (2017) classified different MTL frameworks into two categories: hard parameter sharing and soft parameter sharing, as well as some earlier MTL examples in both non-neural and neural models; Zhang and Yang (2018) expanded such two "how to share" categories into five categories, including feature learning approach, low-rank approach, task clustering approach, task relation learning approach, and decomposition approach; Crawshaw (2020) presented more recent models in both single-domain and multi-modal architectures, as well as an overview of optimization methods in MTL. Nevertheless, it is still not clearly understood *how* to design and train a single model to handle a variety of NLP tasks according to **task relatedness**. Especially when faced with a set of tasks that are seldom simultaneously trained previously, it is of crucial importance that researchers find proper auxiliary tasks and assess the feasibility of such multi-task learning attempt.

In this paper, we first review recent approaches on multi-task training methods in popular NLP applications. We find that these approaches can be categorized into *two multi-task training methods* according to the types of task relatedness: (i) joint training methods and (ii) multi-step training meth-

	Low supervision	Cascaded information	(Søgaard et al., 2016; Hashimoto et al., 2017)

Table 1: Categories of multi-task learning frameworks in two related surveys can be merged into our proposed joint training and multi-step training frameworks.

ods. **Joint training** is commonly used when all given tasks can be performed simultaneously and all the task-specific data can be learned simultaneously. In joint training, model parameters are shared (either via soft or hard parameter sharing[1]) among encoders and decoders so that the tasks can be jointly trained to benefit from shared representations, as shown in Figure 1(a). In contrast, **multi-step training** is used when some task's input needs to be determined by the outputs or hidden representations of previous task(s). Due to such task dependencies, the task-specific decoders are connected as a multi-step path starting from the encoder "node", as shown in Figure 1(b).

Therefore, different from previous surveys which focus on architecture designs (*e.g.*, how to share parameters in (Ruder, 2017) and (Zhang and Yang, 2018)) and optimization methods (*e.g.*, loss weighting and regularization in (Crawshaw, 2020)), our motivation lies in categorizing two major multi-task training methods in NLP, according to **task relatedness**. In fact, task relatedness is the key to determine what training method to use, then the training method decides the general scope of available architecture designs. With specific application tasks, readers are able to identify the ideal training method from our review before looking for detailed module design or loss optimization in previous surveys. We also show that how the MTL techniques covered in previous surveys can be matched with the two training methods in Table 1.

The remainder of this survey is organized as follows. Section 2 includes an overview of MTL models in NLP and the rationales of using MTL. Section 3 presents a number of joint and multi-step training applications in different fields of NLP. Section 4 analyzes the task relatedness involved in these MTL approaches. Section 5 discusses future directions. Section 6 concludes the paper.

2 Multi-task Training Methods

2.1 Encoder-Decoder Architecture and Two Multi-Task Training Frameworks

Suppose we train a model on n NLP tasks $T_1, \cdots, T_n$ on a dataset $\mathcal{D} = \{(X^{(i)}, Y^{(i)})\}|_{i=1}^{N}$ with N data points. For the j-th NLP task, the model is trained with $\{(X_j^{(i)}, Y_j^{(i)})\}|_{i=1}^{N}$, where $X_j^{(i)}$ is a component of the input $X^{(i)}$, and $Y_j^{(i)}$ is the desired output. The input components of different tasks can be the same, but the desired outputs are usually different. We formulate the multi-task frameworks discussed in this paper under the popular encoder-decoder architecture which are mainly composed of three components: (a) the encoder layer (including the embedding layer), (b) the decoder layer (including the output layer for classification or generation), and (c) loss and optimization.

Encoder layer. In NLP networks, an embedding layer is usually applied to generate the embedding vectors of the basic elements of the input $X^{(i)}$ For the j-th task, the encoder layer learns the hidden state of $X_j^{(i)}$ as a vector $\mathbf{h}_j^{(i)}$:

$$\mathbf{h}_j^{(i)} = \text{Encoder}(X_j^{(i)}, \Theta_{E_j}), \tag{1}$$

where Θ_{E_j} denotes the parameters of j-th task's encoder. Parameters of different encoders can be shared. Popular encoder modules include BiLSTM and BERT (Devlin et al., 2019).

Decoder layer. When the tasks are *independent* with each other at decoding, the decoder of the j-th task transforms the hidden state into an output:

$$\hat{Y}_j^{(i)} = \text{Decoder}_j(\mathbf{h}_j^{(i)}, \Theta_{D_j}). \tag{2}$$

When the tasks are *sequentially dependent*, the decoder of the j-th task needs the output of the $(j-1)$-th task, then we have

$$\hat{Y}_j^{(i)} = \text{Decoder}_j(\hat{Y}_{j-1}^{(i)}, \mathbf{h}_j^{(i)}, \Theta_{D_j}). \tag{3}$$

---

[1] We do not specifically distinguish different parameter sharing designs, since this topic is not the focus of our survey. We refer readers to learn details in Ruder (2017).

where Θ_{D_j} denotes the parameters of j-th task's decoder. Practically, $\hat{Y}_{j-1}^{(i)}$ are often presented as hidden representations of the decoder prediction to enable end-to-end training. Parameters of different decoders can be shared. Popular decoder choices include MLP, LSTM and the Transformer decoder.

According to the two types of task dependencies, the multi-task learning frameworks define and organize the decoders in two different ways. As shown in Figure 1, (i) the **joint training** framework is for the tasks that are independent at decoding; and (ii) the **multi-step training** framework is for tasks that are sequentially dependent. It can be easily generalized when the task dependencies form a directed acyclic graph, in which sequential dependence is a special and common case.

Optimization. A common optimization approach of MTL is to optimize the weighted sum of loss functions from different tasks, (i.e., Loss $= \lambda_j \sum_{j=1}^{n} \text{Loss}_j$) then compute the gradient descent to update all trainable parameters ($\{\Theta_{E_j}\}_{j=1}^{n}$, $\{\Theta_{D_j}\}_{j=1}^{n}$). The weights of $\{\lambda_j\}_{j=1}^{n}$ can be either pre-defined or dynamically adjusted (Kendall et al., 2018; Xiong et al., 2018). It is worth mentioning that optimization in MTL has many alternative ways. For example, Søgaard et al. (2016) choose a random task t from a pre-defined task sets to optimize its loss at each iteration. Readers can find a more detailed review of MTL optimization methods in Crawshaw (2020), which is not the main focus of this paper.

2.2 How does MTL Work

One of the prerequisites of multi-task learning is the relatedness among different tasks and their data. Most work prefers to train positively correlated tasks in a multi-task setting. Such tasks have similar objectives or relevant data, and can boost each other to form consistent predictions through shared lower-level representations. According to Caruana (1997), in MTL, tasks prefer hidden representations that other tasks prefer. MTL enables shared representations to include features from all tasks, thus improving the consistency of task-specific decoding in each sub-task. Furthermore, the co-existence of features from different objectives naturally performs feature crosses, which enables the model to learn more complex features.

According to the experiments by Standley et al. (2020), tasks are more likely to benefit from MTL when using a larger network. This can be achieved as the emergence of deep neural frameworks in recent years. Many deep models, like BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020), have strong generalization ability to fit a variety of tasks with minute changes. Therefore, different tasks can be learned through similar models, especially in the field of NLP where the encoder-decoder architecture has become a norm.

With the above premises, deep models are able to benefit from MTL in multiple perspectives. First, MTL improves data efficiency for each sub-task. Different tasks provide different aspects of information, enriching the expression ability of the hidden representation to the input text. Besides, different tasks have different noise patterns, which acts as an implicit data augmentation method. This encourages the multi-task model to produce more generalizable representations in shared layers. Thus, the model is prevented from overfitting to a single task and gains stronger generalization ability, which helps itself perform well when faced with new tasks from a similar environment (Baxter, 2000). Multi-task learning are also effective for low-resource tasks (Lin et al., 2018b; Johnson et al., 2017). Co-training with a high-resource task in a similar domain, low-resource tasks receive ampler training signals which prevents the model from overfitting on the limited data.

Auxiliary tasks in MTL can serve as conditions or hints for the main task. Such setting usually falls into the category of *multi-step training*. Providing additional conditions reduces the distribution space of possible outputs, thus lower the prediction difficulty of the main task. Such conditions can serve as additional features during decoding, including external knowledge pieces, low-level NLP tasks (*e.g.*, part-of-speech tagging or syntactic parsing) or relevant snippets extracted from long documents. When some features are difficult for the main task to directly learn, explicit supervision signals of such features, if available, enables the model to "eavesdrop", *i.e.*, obtaining these features through the learning of auxiliary task (Ruder, 2017).

3 Training Methods: Applications

3.1 Joint Training Applications

In this section, we list a series of recent approaches of joint training in different fields of NLP (shown in Figure 2), including information extraction, spoken language understanding, text classification, machine translation and language generation.

[Sachan et al. NAACL'18]

Figure 2: Five joint training NLP applications that have been discussed from §3.1.1 to §3.1.5.

3.1.1 Information Extraction (IE)

Two popular tasks that are usually jointly performed in IE are named entity recognition (NER) and relation extraction (RE). NER seeks to locate and classify named entities in text into pre-defined categories, such as names and locations. NER is often tackled by sequence labeling methods, or say, token-wise classifiers. RE aims to extract semantic relationships between two or more entities, and there are multiple ways to define the RE task in the multi-task training approach.

First, Zhou et al. (2019) predicted the type of relation mentioned in a sentence by the RE decoder. It works for simple sentences such as those that have a pair of entities and one type of relation, e.g., "[President Obama] was *born in* [Honolulu]." However, one sentence may have multiple types of relations. Second, Zheng et al. (2017) predicted a relation tag for every pair of tokens. If the decoder performs perfectly, it can identify any number and any types of relations in a sentence. However, the complexity is too high to be effectively trained with annotated data. Third, Bekoulis et al. (2018); Wang et al. (2018a) treated RE as a sequence labeling problem. So both NER and RE decoders are token-wise classifiers. As shown in Figure 2, for example, $B\text{-}BI$ tag represents the beginning word of subject entity (person) or object entity (location) in the "born_in" (BI) relation. Therefore, if multiple tag sequences can be generated, they can identify any number, and any type of relations in the input sentence.

3.1.2 Spoken Language Understanding

Spoken Language Understanding (SLU) plays an important role in spoken dialogue system (Qin et al., 2021c). SLU aims at extracting the semantics from user utterances, which is a critical component of task-oriented dialogue. Concretely, it captures semantic constituents of the utterance and identifies the user's intent. These two tasks are typically known as slot filling (SF) and intent detection (ID), respectively. Each word in the utterance corresponds to one slot label, and a specific intent is assigned to the whole utterance. An example of these two sub-tasks is given below:

Word	Put	Kanye	into	my	rap	playlist
	↓	↓	↓	↓	↓	↓
Slot	O	B-artist	O	O	B-playlist	O
Intent	AddToPlaylist					

Since two sub-tasks share the same input utterance, they usually share a single utterance encoder and are jointly trained (Liu and Lane, 2016; Castellucci et al., 2019). Recent state-of-the-art SLU models build bi-directional interactions during encoding (Liu et al., 2019b; Zhang et al., 2020; Qin et al., 2021a). Therefore, two tasks mutually impact each other before making respective predictions. It is worth noting that there is also a line of work that uses the hidden states of intent detection to assist slot filling (Goo et al., 2018; Qin et al., 2019, 2021b). This can be considered as a combination of joint training and multi-step training: intent detection helps the prediction of slot filling, but finally their predictions are integrated to perform the parent (larger) SLU task.

3.1.3 Sentence/Document Classification

Sentence/document classification is one of the fundamental tasks in NLP with broad applications such as sentiment classification (SC), emotion classification (EC), and stance detection. However, the construction of large-scale high-quality datasets is extremely labor-intensive. Therefore, multi-task learning plays an important role in leveraging potential correlations among related classification tasks to extract common features, increase corpus size implicitly and yield classification improvements. Popular multi-task learning setting in text classification has two categories. First, one dataset is annotated with multiple labels and one input is associated with multiple outputs (Liu et al., 2015;

Yu et al., 2018a; Gui et al., 2020). Second, multiple datasets have their respective labels, i.e., multiple inputs with multiple outputs, where samples from different tasks are jointly learned in parallel (Liu et al., 2016, 2017). Most existing work leverages joint training for different sentence/document classification tasks. Specifically, Liu et al. (2016) proposed three different parameter sharing designs under the joint training framework, and further compared their performances.

3.1.4 Multilinguality

Languages differ lexically but are closely related on the semantic and/or the syntactic levels. Such correlation across different languages motivates the multi-task learning on multilingual data. Neural machine translation (NMT) is the most important application. Dong et al. (2015) first proposed a multi-task learning framework based on Seq2Seq to conduct NMT from one source language to multiple target languages. Luong et al. (2016) extended it with many-to-one and many-to-many approaches. Many-to-one is useful for translating multi-source languages to the target language, in which only the decoder is shared. Many-to-many studies the effect of unsupervised translation between multiple languages. Zhu et al. (2019) proposed to improve cross-lingual summarization by jointly training with monolingual summarization and machine translation. Arivazhagan et al. (2019) built a massive multi-lingual translation model handling 103 languages, and conducted experiments on multiple sampling schema for building joint training dataset.

Besides, unlabelled data from the target language is also a common source of multi-task cross-lingual training. Ahmad et al. (2019) collected unannotated sentences from auxiliary languages to assist learning language-agnostic representations. Van Der Goot et al. (2021) incorporated a masked language modeling objective using unlabeled data from target language to perform zero-shot transfer.

3.1.5 Natural Language Generation (NLG)

Recent success in deep generative modeling have led to significant advances in NLG, motivated by an increasing need to understand and derive meaning from language (Yu et al., 2020b). The relatedness between different generation tasks promotes the application of multi-task learning in NLG.

For example, Guo et al. (2018) proposed to jointly learn abstractive summarization (AS) and question generation (QG). An accurate summary of a document is supposed to contain all its salient information. This goal is consistent with that of question generation (QG), which looks for salient questioning-worthy details. Besides, QG and question answering (QA) are often trained as dual tasks. Tang et al. (2017) proposed a joint learning framework that connects QG and QA. QA improves QG through measuring the relevance between the generated question and the answer. QG improves QA by providing additional signal which stands for the probability of generating a question given the answer. A similar framework was also employed in Duan et al. (2017); Sachan and Xing (2018).

In other applications, semantic parsing is gaining attention for knowledge-based question answering since it does not rely on hand-crafted features. (Shen et al., 2019) developed a joint learning approach where a pointer-equipped semantic parsing model is designed to resolve coreference in conversations, and naturally empower joint learning with a novel type-aware entity detection model. Researchers also found NLU tasks, *e.g.*, input meaning representation learning (Qader et al., 2019) or entity mention prediction (Dong et al., 2020), can improve the performance of generating sentences

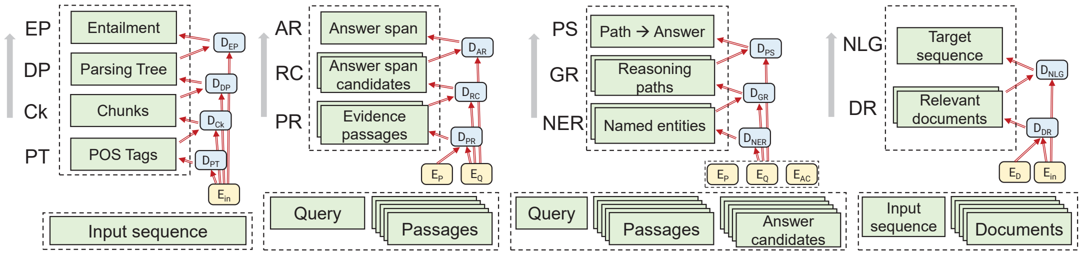
Multi-view learning is also applied in NLG approaches for auxiliary learning objectives. Input data are erased partially to create distinct views, and divergence metrics are usually learned along with the main loss to force the model generate consistent predictions across different views of the same input. Typical approaches include Clark et al. (2018) which built up the multi-view learning paradigm in IE and NLG tasks. In addition, Shen et al. (2020) upgraded the network by combining multiple cutoff methods to create augmented data, and achieved success in translation tasks.

3.2 Multi-step Training: Applications

We list recent approaches of multi-step training in different field of NLP (as shown in Figure 3), such as language understanding, multi-passage question answering and natural language generation.

3.2.1 Multi-level Language Understanding

The potential for leveraging multiple levels of representations has been demonstrated in various ways in the field of NLP. For example, Part-Of-Speech (POS) tags are used for syntactic parsers. The parsers are used to improve higher-level tasks, such as natural language inference. Søgaard et al. (2016) showed when learning POS tagging and chunking, it is consistently better to have POS supervision



[Søgaard et al. ACL'16]

[Kundu et al. ACL'19]
[Tu et al. ACL'19]

[Dinan et al. ICLR'19]
[Lewis et al. NeurIPS'20]

Figure 3: Four multi-step training NLP applications discussed at §3.2.1, §3.2.2 (2nd and 3rd subfigures) and §3.2.3.

at the innermost rather than the outermost layer. Hashimoto et al. (2017) predicted increasingly complex NLP tasks at successively deeper layers for POS tagging, chunking, dependency parsing, semantic relatedness, and textual entailment, by considering linguistic hierarchies. Lower level predictions may influence predictions in higher levels, *e.g.*, if the semantic relatedness between two sentences is very low, they are unlikely to entail each other. Similar architecture can be found in Sanh et al. (2019b), where low-level tasks are name entity recognition and entity mention detection, with coreference resolution and relation extraction supervising at higher levels.

3.2.2 Multi-Passage Question Answering

Question answering (QA) models may need to construct answers by querying multiple passages (*e.g.*, paragraphs, documents). Given a question, multi-passage QA (MPQA) requires AI models identify an answer span from multiple evidence passages. Due to the complexity of MPQA, it is usually achieved by multiple sub-tasks. Thus, multi-step training is utilized by many approaches in MPQA.

Typically, MPQA can be split into a 3-phase task. *Passage retrieval* (PR) is to select relevant evidence passages according to the question. *Reading comprehension* (RC) is to extract multiple answer span candidates from the retrieved set of relevant passages. *Answer reranking* (AR) is to re-score multiple answer candidates based on the question and evidence passages. There exist dependencies between these tasks: evidence passages are generated by PR and fed into RC as input; the answer span candidates are generated by RC and given into AR as input. So, as shown in Figure 3, the decoders form a multi-hop path starting from the shared encoder. Hu et al. (2019) proposed a typical approach called RE^3 (for REtriever, REader, and REranker). The retriever used TF-IDF cosine similarities to prune irrelevant passages. The reader is a token classifier that predicts the start and end indices of answer candidates per segment. The reranker prunes redundant span candidates and then predict the reranking scores. Other works in MPQA also considered 2-phase approaches, such as PR+RC (Wang et al., 2018b) or RC+AR (Wang et al., 2018d), which are simplified versions of the above framework. Similar approaches have been developed for many domains such as news (Nishida et al., 2018), and web questions (Lin et al., 2018a).

Another branch of this task is *multi-choice* MPQA, where we have a set of answer candidates for the given question. (Kundu et al., 2019) proposed to exploit explicit paths for multi-hop reasoning over structured knowledge graphs. The model attempted to extract implicit relations from text through entity pair representations, and compose them to encode each path. It composed the passage representations along each path to compute a passage-based representation. Then it can explain the reasoning via these explicit paths through the passages. The sub-tasks are *named entity recognition* (NER), *graph-based reasoning* (GR) to extract and encode paths, and passage-based *path scoring* (PS). So, the multi-task QA systems perform interpretable and accurate reasoning (Welbl et al., 2018; Tu et al., 2019).

3.2.3 Retrieval-augmented Text Generation

In NLG, the input sequence alone often contains limited knowledge to support neural generation models to produce the desired output, so the performance of generation is still far from satisfactory in many real-world scenarios (Yu et al., 2020b). Retrieval-augmented generation models use the input sequence to retrieve relevant information (e.g., a background document) and use it as additional contexts when generating the target sequence. For example, Dinan et al. (2019) proposed to tackle the knowledge-aware dialogue by first selecting knowledge from a large pool of document candidates and generate a response based on the selected knowledge and context. To enhance the aforementioned idea, Kim et al. (2020) presented a sequential latent variable model to keep track of the prior and posterior distribution over knowledge. It not only reduced the ambiguity caused from the diversity in knowledge selection of conversation but also better leveraged the response information for proper choice of knowledge. Similar retrieval-augmented generation approaches have been applied in question generation (Lewis et al., 2020), comment generation (Lin et al., 2019b), image captioning (Xu et al., 2019a), summarization (Cao et al., 2018), and long form QA (Krishna et al., 2021).

4 NLP Task Relatedness

In this section, we summarize the characteristics of the aforementioned MTL approaches, and look into the task relatedness between the sub-tasks.

4.1 Joint Training

Joint training with similar tasks. Joint training with a similar task is the classical choice for multi-task learning. According to Caruana (1997), more similar tasks share more hidden units. Hence, similar tasks are more likely to benefit from shared generic representations. However, what kind of tasks can be considered as “similar" are not always evident in the deep learning era. Empirically selecting similar tasks is still the most mainstream method (Ruder, 2017; Worsham and Kalita, 2020). To get some intuitions what a similar task can be, here we introduce some prominent examples. (Dong et al., 2015) proposed training neural machine translation from one language into multiple languages simultaneously; (Yu et al., 2018a) proposed a joint training framework for sentiment classification and emotion classification; (Guo et al., 2018) proposed abstractive summarization can be jointly learned with question generation. (Yang et al., 2019) jointly trained question categorization and answer retrieval.

Recently, Aribandi et al. (2021) attempted to empirically select a set of tasks (from 107 NLP tasks) to transfer from, using a multi-task objective of mixing supervised tasks with self-supervised objectives for language model pre-training. In addition, Guo et al. (2019) used multi-armed bandits to select tasks and a Gaussian Process to control the mixing rates. Besides, some recent work tried to select appropriate sub-tasks based on manually defined features (Lin et al., 2019a; Sun et al., 2021). Aside from NLP, Fifty et al. (2021) proposed a method to select sub-tasks based on task gradients.

Auxiliary task for adversarial learning. Partial sharing of model parameters is the mainstream in multi-task learning, which attempts to divide the features of different tasks into private and shared spaces. However, the shared feature space could contain some unnecessary task-specific features, while some sharable features could also be mixed in private space, suffering from feature redundancy. To alleviate this problem, Liu et al. (2017) adds an adversarial task via a discriminator to estimate what task the encoding sequence comes from. Such learning strategy prevents the shared and private latent feature spaces from interfering with each other. This setup has also received success in multi-task multi-domain training for domain adaptation (Yu et al., 2018b). The adversarial task in this case is to predict the domain of the input. By reversing the gradient of the adversarial task, the adversarial task loss is maximized, which is beneficial for the main task as it forces the model to learn representations that are indistinguishable between domains.

Auxiliary task to boost representation learning. While auxiliary tasks are utilized to assist the main task, they are usually expected to learn representations shared or helpful for the main task (Ruder, 2017). Self-supervised, or unsupervised tasks, therefore, are often considered as a good choice. Self-supervised objectives allow the model to learn beneficial representations without leveraging expensive downstream task labels. For example, language modeling can help to learn transferable representations. In BERT (Devlin et al., 2019) pretraining, the next sentence prediction task is used to learn sentence-level representations, which is complementary to the masked language model task that mainly targets at word-level contextual representations. Besides, Rei (2017) showed that learning with a language modeling objective improves performance on several sequence labelling tasks. An auto-encoder objective can also be used as an auxiliary task. Yu et al. (2020a) demonstrated adding the auto-encoder objective improves the quality of semantic representations for questions and answers in the task of answer retrieval.

Another branch of auxiliary tasks used to facilitate representation learning is knowledge distillation. This is achieved by forcing a smaller student model to learn a larger teacher model’s output distribution or hidden representation using additional training objectives (Hinton et al., 2015). Knowledge contained in the hidden representations is then transferred from the teacher to the student. Thus, the student model gains the generalization ability of the teacher model, but still preserving its small size which is more suitable for deployment. Such distillation idea has been verified on popular NLP models such as BERT (Sanh et al., 2019a).

4.2 Multi-step Training

Narrow the search space of the subsequent decoder. In some cases, it is not easy to predict the original task directly due to the large search space of the potential outputs (Lewis et al., 2020). For example, in open-domain QA, directly answering a given question is hard. So, multi-stage methods (e.g., retrieve-then-read) are often used to tackle open-domain QA problems: a retriever component finding documents that might contain the answer from a large corpus, followed by a reader component finding the answer in the retrieved documents. Documents provided by the retriever serves as conditions to the reader, which narrows the search space and thus reduces the difficulty of open-domain QA (Wang et al., 2018b,c).

In another example about pre-trained language models, BERT only learns from 15% of the tokens that are masked in the input. ELECTRA (Clark et al., 2020) proposed a two-step self-supervised training to improve training efficiency. The masked language modeling task performed by an auto-encoder serves as an auxiliary task. It reconstructs the masked tokens in the input. Then, a discriminative model in the second step predicts whether each token in the corrupted input was replaced by the auto-encoder. The design of such classification task allows supervision on all tokens in the example.

Select focused contents from the input. The auxiliary task can be used to focus attention on parts of the input text that can be leveraged for the main task. For example, humans tend to write summaries containing certain keywords and then perform necessary modifications to ensure the fluency and grammatical correctness of the summary. Thus, keyword extraction could help the model to focus on salient information that can be used in the summary (Li et al., 2020). A similar approach can be found in Cho et al. (2019), where the authors used a flexible continuous latent variable for content selection to deal with different focuses on the context in question generation.

Predict attributes of the output. In some NLG scenarios, it may be hard to guarantee the output sequence contains certain desired patterns or features (e.g., emotion, sentiment) if no explicit signals are given. Therefore, an attribute classifier could be used for predicting whether the output sequence contains the desired objective, either before or after the prediction is made. For example, Fan et al. (2018) predicted which question type should be used before generating diverse questions for an image. The predicted question type acts as an additional condition while the decoder is searching for the best question sequence. Besides, Song et al. (2019) used a emotion classifier after the decoder to discriminate whether the generated sentence expresses the desired emotion. The post-decoder classifier guides the generation process to generate dialogue responses with specific emotions.

Introduce external knowledge. Precisely manipulating world knowledge is extremely hard for a single neural network model. One could devise learning tasks informed by the knowledge so that the model is trained to acquire and utilize external knowledge. This research direction is known as "Knowledge-enhanced NLP" (Yu et al., 2020b). The knowledge-related tasks can be combined as auxiliary to the main task, resulting in a multi-task learning setting (Dinan et al., 2019; Kim et al., 2020; Zhang et al., 2021). For instance, Wu et al. (2019) uses the input sequence to query the candidate knowledge pieces via attention mechanism, then fuses the selected knowledge into decoder. The knowledge selection phase is trained by minimizing the KL-divergence between the prior distribution (queried by the input) and the posterior distribution (queried by the output).

5 Future Directions

In this section, we will discuss some promising directions regarding either task relatedness or training methods of multi-task training in NLP.

5.1 Regarding Task Relatedness

Task-specific multi-task pre-training. Under a typical *"pre-train then fine-tune"* paradigm, many NLP works attempted to design pre-training tasks that are relevant to downstream objectives (Févry et al., 2020; Wang et al., 2021b). Such approaches endow the model with task-specific knowledge acquired from massive pre-training data. For example, Wang et al. (2021b) learned a knowledge embedding objective besides masked language modeling (MLM) to assist relation classification and entity typing tasks; Févry et al. (2020) and Zhang et al. (2022) added an entity linking objective into pre-training for fact checking and question answering applications. These results have shown that designing proper downstream-oriented pre-training tasks is a promising direction. Such pre-training tasks are jointly trained with the MLM objective to learn relevant knowledge of downstream tasks, which can greatly reduce the gap between pre-training and fine-tuning. These tasks need to be self-supervised on pre-training corpus, while sharing a similar learning objective with downstream tasks so that relevant knowledge can be transferred.

Learning to multi-tasking. One critical issue in MTL is how to *train* a multi-task model. Existing works typically design MTL training strategies (e.g., weighing losses or task grouping) by human intuition and select the best framework through cross validation. Such model selection suffers from heavy computational cost when considering every possibility. Thus, a promising direction is to learn to multi-tasking. Meta learning is a popular approach while encountering "learning to learn" problems (Hospedales et al., 2021). It aims to allow the model to quickly learn a new task, given the experience of multiple learning episodes on different tasks. Wang et al. (2021a) tried to fuse the feature of fast adaptation of meta learning into an efficient MTL model. This approach preliminarily proved that meta-learning philosophy can benefit the training of MTL models. For future directions, using meta-learning to learn a general purpose multi-task learning algorithm is a promising route to "learning to multi-tasking". Besides, learning to group tasks through meta-learning is worthy of exploration.

5.2 Regarding Training Methods

Adaptive parameter sharing. Parameter sharing is believed to be an effective technique in improving the generalizability of multi-task learning models and reducing training time and memory footprint. Two popular parameter sharing methods are hard and soft sharing (Ruder, 2017). Hard parameter sharing (Bekoulis et al., 2018) means all tasks share a certain number of model layers before branching out. Soft parameter sharing (Duong et al., 2015) adds constraints to the distances between specific layers of different tasks. However, hard sharing suffers from finding the optimal configuration while soft sharing does not reduce the number of parameters. Therefore, in addition to empirically tuning which layers to share, learning adaptable sharing for efficient MTL is a promising solution. Sun et al. (2020) tried to allow adaptive sharing by learning which layers are used by each task through model training. This approach suits in the field of computer vision where many models have the architecture of stacking the same layer. However, in NLP neural networks, layers are functionally and structurally discrepant, such as the encoder-decoder framework. The development of proper adaptive sharing methods to improve parameter sharing in multi-task NLP models is needed.

Mutli-task leaning in training a universal model. Recently, training a universal model to perform a variety of tasks becomes an emerging trend in NLP. Multi-task supervised learning helps the model fuse knowledge from different domains, and encourages it to obtain universal representations that generalize to different downstream tasks. For example, Liu et al. (2019a) unified the input format of GLUE tasks to feed into a single model before fine-tuning on individual tasks. However, the role of multi-task learning is still unclear in training a universal model, with different approaches adopting MTL in different phases of transfer learning. Among recent works, Aribandi et al. (2021) preferred multi-task pre-training over multi-task fine-tuning for smaller gaps between pre-training and fine-tuning. Aghajanyan et al. (2021) used multi-task pre-finetuning on a self-supervised pre-trained model before further fine-tuning on downstream tasks. Sanh et al. (2022) used prompted multi-task fine-tuning over a pre-trained T5 (Raffel et al., 2020) in order to perform zero-shot transfer on out-of-domain tasks. Therefore, future researches may dive deeper into maximizing the benefits of MTL in the transfer learning paradigm, including the choice of properly including MTL in pre-training or fine-tuning for better generalization. Besides, a theoretical analysis of transfer learning regarding the benefits of MTL is also desired.

6 Conclusions

In this paper, we reviewed recent work on multi-task learning for NLP tasks. According to the types of task relatedness, we categorized multi-task NLP approaches into two typical frameworks: joint training and multi-step training. We presented the design of each framework in various NLP applications, and discussed future directions of this interesting topic.

7 Limitations

Due to the space constraint, we are only able to show some prominent application scenarios of joint training and multi-step training, in which we may not cover all existing fields with multi-task approaches. For example, in dialogue systems, dialogue act recognition and sentiment recognition can be jointly trained to capture speakers' intentions. Besides, zero-shot and few-shot approaches in the multi-task setting are also interesting directions.

As for another limitation, this work is purely theoretical without any software-level implementation of the mentioned framework. In addition, we did not list the experimental results of the mentioned models on benchmark datasets because of the space limit.

Abstract

In real-world debates, the most common way to counter an argument is to reason against its main point, that is, its conclusion. Existing work on the automatic generation of natural language counter-arguments does not address the relation to the conclusion, possibly because many arguments leave their conclusion implicit. In this paper, we hypothesize that the key to effective counter-argument generation is to explicitly model the argument's conclusion and to enforce that the stance of the generated counter is opposite to that conclusion. In particular, we propose a multitask approach that jointly learns to generate both the conclusion and the counter of an input argument. The approach employs a stance-based ranking component that selects the counter from a diverse set of generated candidates whose stance best opposes the generated conclusion. In both automatic and manual evaluation, we provide evidence that our approach generates more relevant and stance-adhering counters than strong baselines.

1 Introduction

Given an argument, a valid counter-argument to it should be relevant to the topic discussed by the argument while opposing to its conclusion's stance. Countering the opponent's arguments in a debate effectively is key to winning the debate (Zhang et al., 2016). While some counter-arguments attack an argument's premises or their connection to the conclusion, the most common attack is to directly rebut the argument's conclusion (Walton, 2009).

The automatic countering of natural language arguments is one of the most challenging tasks in the area of computational argumentation. Prior research has addressed the task through retrieval (Wachsmuth et al., 2018; Orbach et al., 2020) or generation-based approaches (Hua and Wang, 2018; Hidey and McKeown, 2019). By concept, the former requires the presence of suitable counter-arguments in a predefined collection, limiting its flexibility. Existing generation-based approaches, on the other hand, either consider a single claim as input or do not model the relation between premise and conclusion in the input argument.

Conclusion (title): Purchasing meat encourages animal abuse.
Premises (post): All meat, to my knowledge, is obtained by raising animals in cramped quarters and slaughtering them as soon as they are fully grown. The only exception i can think of is perhaps when you go into the woods and hunt food for yourself in which case the animal has lived an undisturbed life and is put down by humane means compared to how it happens in nature. However, this is, of course, time intensive, requires skill, expensive, and thus is of course not how the vast majority of meat is obtained.

Table 1: An example argument (conclusion + premises) taken from *Reddit ChangeMyView*, showing how the conclusion is mentioned implicitly only in the body.

In previous work, we have studied the task of counter-argument generation through undermining weak premises in the input arguments (Alshomary et al., 2021b). We assumed the input argument to be given as a set of premises and their conclusion and modeled the weakness of premises relevant to the argument conclusion. In daily-life debates, however, people often do not explicitly state their argument's main point (i.e., its conclusion), since it is often clear from the context (Habernal and Gurevych, 2015) or for rhetorical reasons, as is often the case in news editorials (Al Khatib et al., 2016). This makes it challenging for computational models to generate a proper counter.

Table 1 shows an example of an argument with the conclusion "Purchasing meat is encouraging animal abuse". The author states that meat production would often lead to animal abuse. However, this statement is never linked explicitly to the conclusion. Such a link may be easy to infer for humans, but it is challenging for machines.

State-of-the-art language models based on transformers excel in many downstream text generation

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 957–967
May 2-6, 2023

tasks, such as summarization and machine translation (Vaswani et al., 2017). While they have been applied successfully for reconstructing implicit argument components such as conclusions (Gurcke et al., 2021; Syed et al., 2021), they still fall short on more complex tasks, such as counter-argument generation (Hua and Wang, 2019).

In this paper, we investigate how to enable transformer-based language models to generate an effective counter-argument to a given argument. We observe that the performance of these models in generating relevant counters with correct stance deteriorates particularly when the input argument does not mention its conclusion. Hence, we hypothesize that explicitly modeling the argument's conclusion and its stance will lead to more adequate counter-arguments. For this purpose, we propose a multitask generation approach with a stance-based ranking component. Our approach jointly models the two tasks of conclusion generation and counter-argument generation, and it enforces stance correctness through a stance-based ranking component.

Given a training dataset, where we have access to both the premises of arguments and their corresponding conclusions and counters, we explore two variations of our approach: The first shares the transformer's encoder and decoder between the two tasks, and we learn to generate both the conclusion and the counter as one sequence (separated with a special token). By contrast, the second variation is composed of one shared encoder along with two decoders, one to generate the conclusion and the other to generate the counter-argument. Although we expect the trained models to often capture the stance relation between the argument and its counter, we reinforce opposite stance through a stance-based ranking component at inference time. This component samples different counter-arguments and ranks them based on their stance score towards the corresponding generated conclusion.

To evaluate both approach variations, we use the ChangeMyView dataset of Jo et al. (2020), which consists of discussions where someone posts a view and others write comments opposing to this view. As in our previous work (Alshomary et al., 2021b), we use a post's title as the conclusion, its body text as the premises, and each comment as a counter. To classify stance as part of our ranking component, we fine-tune RoBERTa (Liu et al., 2019) on a dataset of pairs of claim and counter-claim collected from the *Kialo.org* debate platform. We compare our approach against two baselines; one that learns to generate the conclusion and the counter-argument independently in a pipeline model and one that employs a sequence-to-sequence model but does not actively represent the conclusion.

The results emphasize the deficiency of standard transformer-based models in counter-argument generation, particularly when the conclusion is not mentioned explicitly, highlighting the importance of conclusions in counter-argument generation. In most cases, our variation with shared encoder and decoder produces the best counter-arguments in terms of relevance and stance correctness.

We summarize our contributions as follows:[1]

- We study how to generate effective counter-arguments even if the attacked argument's conclusion is implicit.
- We present two multitask transformer-based counter-argument approaches, tuned to opposing to the argument's conclusion.
- We empirically reveal the impact of modeling an argument's conclusion and counter-argument jointly in the given task.

2 Related Work

Argument generation is one of the main branches of computational argumentation, studying the synthesis of arguments in natural language texts. This field includes a host of tasks like the generation of argument conclusions (Alshomary et al., 2020; Syed et al., 2021), implicit premises (Chakrabarty et al., 2021), controlled claims (Schiller et al., 2021; Alshomary et al., 2021a), as well as the generation of counter-arguments (Hua and Wang, 2018; Alshomary et al., 2021b). Our work studies the task of counter-argument synthesis.

The task of counter-argument synthesis has been addressed through either retrieval or generation-based approaches. An example of the former is the work of Orbach et al. (2020) whose approach tries to retrieve relevant counters for a given argument from a collection of documents. Wachsmuth et al. (2018) utilized topic knowledge to retrieve the best counter for a given argument.

On the other hand, generation-based approaches aim to construct counter-arguments from scratch. For example, both Bilu et al. (2015) and Hidey and

---

[1] The code of our experiments is available under `https://github.com/webis-de/EACL-23`

McKeown (2019) worked on the task of counter-claim generation. The former developed a set of rules and classifiers to negate claims, while the latter used neural methods to learn from data. Alshomary et al. (2021b) proposed an approach to generate counter-arguments by automatically identifying weak points in the input argument given the conclusion and attacking them. Moreover, Hua and Wang (2018, 2019) proposed an approach for generating long texts and applied it to the counter-argument generation task. Their approach relies on a retrieval component that acquires relevant key phrases for an input argument to be used to guide the generation of counter-arguments. While the size of the given argument collection limits retrieval-based approaches, the generation-based approaches either rely on the conclusion being given in the input or don't distinguish the different components in the input argumentative text. Our proposed approach is generation-based, where we study the conclusion's role in the counter-argument generation task.

Argument conclusion is the main point an argument argues towards/against, which is important for understanding the argument. In daily life argumentation, conclusions often are left implicit Alshomary et al. (2020). While it is easy for humans to infer the main point of an argument, it remains a challenging task for machines. Hence, several works have addressed the task of conclusion inference. Alshomary et al. (2020) reconstructed implicit claim targets from argument premises using triplet neural networks. Syed et al. (2021) studied the effectiveness of several transformer-based models on the conclusion generation and evaluated the informativeness criteria of conclusions. Gurcke et al. (2021) utilized conclusion generation to study argument quality. Our proposed approach also generates conclusions for a given argument as the first step in order to generate reliable counters.

3 Approach

As discussed above, the conclusions of arguments are important for understanding them properly. However, they are often left implicit, making understanding hard for machines. Our goal is to study how the absence of conclusions affects the performance of transformer-based counter-argument generation models. To alleviate this problem, we propose an approach that jointly learns to generate both the conclusion and the counter of an argument. At inference time, it utilizes a stance-based ranking component to select the most contrastive candidate counter in each case. We detail the generation and ranking in the following.

3.1 Joint Generation of Conclusions and Counter-Arguments

Text generation is usually modeled as a sequence-to-sequence generation task and is widely addressed through transformer-based encoder-decoder models (Vaswani et al., 2017). Since we aim to learn two generation tasks (conclusion and counter), one could think of either sharing the full model between the two tasks or only the encoder part. Hence, as illustrated in Figure 1, we experiment with both options to realize our approach:

Fully-shared Encoder and Decoder In the first model, we maintain the same transformer-based encoder-decoder architecture and train it to generate output sequences containing both the conclusion and the counter. Hence, the model learns to perform the two tasks simultaneously. Particularly, the input to the model is one sequence representing an argument's premises, and the output is a single sequence composed of the ground-truth conclusion and counter-argument separated by special tokens, `<conclusion>` and `<counter>`. The model encodes premises and decodes first the conclusion and then the counter in one sequence. We train the model to optimize the following loss function:

$$L(\theta) = -\sum_{1}^{n} \log p(y_i | x, y_{<i}; \theta)$$

Here, x is the input sequence that represents the premises, $y_{<i}$ is the sequence composing the conclusion and counter until the next word y_i, and θ denotes the model's parameters. We call this model *Joint One-seq* later in our experiments.

At inference time, we utilize a mechanism to generate a diverse set of n candidate conclusions and their counter-arguments, which are later passed to our stance-based ranking component to select the best counter. The diverse generation is as follows. We first extract a set of m Wikipedia concepts from the input premises using the approach of Dor et al. (2018). Then, during decoding, we use these concepts to prompt our trained model by masking all logits except the ones matching the prompt tokens, resulting in conclusions addressing different aspects of the premises followed by

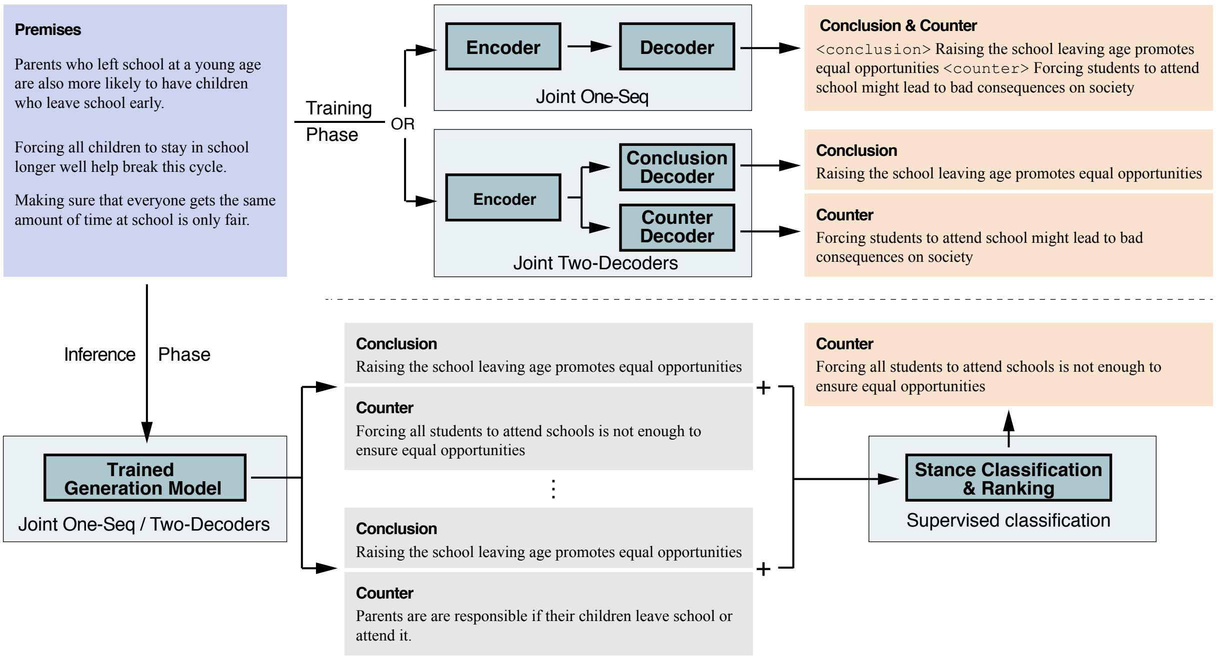

Figure 1: Both variations of our proposed approach to counter-argument generation. In the *training phase*, we learn to jointly generate the conclusion and counter either as one sequence (*Joint-based One-seq*, variation 1) or as two separated sequences (*Joint-based Two-decoders*, variation 2). In the *inference phase*, we classify and rank a diverse set of counters with respect to their stance towards the corresponding conclusion. The top-ranked counter is used.

their corresponding counters. Moreover, to ensure candidate diversity, we enable nucleus sampling (Holtzman et al., 2019), where at each step, we randomly select one of the top k tokens with an accumulated probability of more than p.

Shared Encoder with two Decoders Similarly, the second model starts with an argument's premises as input. However, it then decodes two independent sequences representing the conclusion and the counter-argument as output. First, the input premises are passed through a shared encoder, and then two decoders are used to learn to generate the counter and the conclusion. During training, we optimize the following multi-task loss function, which is a weighted average of the two language modeling losses of the two decoders:

$$
\begin{aligned}
L(\theta_e, \theta_a, \theta_b) = \quad & \alpha_a \cdot \sum_{i=1}^{n} \log p(y_i^a | x, y_{<i}^a; \theta_e; \theta_a) \\
+ \; & \alpha_b \cdot \sum_{i=1}^{m} \log p(y_i^b | x, y_{<i}^b; \theta_e; \theta_b)
\end{aligned}
$$

Here, y^a and y^b are the conclusion and counter sequences. θ_e, θ_a, and θ_b are the weight parameters of the encoder, the conclusion decoder, and the counter decoder, respectively. The weights, α_a and α_b, sum up to one. Their best values are determined experimentally during validation.

The difference between this model and the previous one is given by the layers shared between the two tasks. In the previous model, both the encoder and decoder layers are shared between the two tasks, while, here, only the encoder's layers are shared, keeping a dedicated decoder for each of the two tasks. We refer to this model as *Joint Two-decoders* below.

We aim to generate a diverse set of candidate counters similar to the above model. However, we noticed that counters rarely start by referring to entities or similar concepts, and prompting the model with concepts might lead to generating irrelevant texts. Hence, we generate one conclusion for this model, but a set of candidate counters by only enabling the nucleus sampling during decoding.[2]

3.2 Ranking Component

Give a set of n generated candidate counters, we rank them based on their stance contrastiveness towards the corresponding generated conclusion and select the top-ranked as our final output. In particular, we trained a transformer-based stance classifier on pairs of claim and counter-claim acquired from the *kialo.com* platform to be used to

---

[2] We tested the performance of the model empirically and noticed that these prompted counters of low quality.

predict whether the pair have a *pro* or *con* stance. Experimental details are provided in the next section. To guarantee stance coherence of the selected counter, we compute the stance-based scores on the sentence level to ensure all sentences have some degree of contrastiveness towards the conclusion. In particular, given a pair of a conclusion and the corresponding counter, we first split the counter into a set of sentences. For each sentence s_i, we apply our trained classifier to compute the stance $label$ towards the conclusion c and its probability pr_{label}. We then translate this into a stance contrastiveness score as follows:

$$cont(s_i, c) = \begin{cases} pr_{con}, & \text{if } label = con \\ -pr_{pro}, & \text{if } label = pro \end{cases}$$

The final score of a counter is averaged across its sentences, ranging from -1 to 1. The counters are then ranked accordingly, selecting the top one.

4 Experiments

This section describes the experiments carried out to investigate the conclusion's importance in counter-argument generation.

4.1 Data

We evaluate our approach on the ChangeMyView (CMV) dataset of Jo et al. (2020). On the CMV platform, users publish their opinions on controversial topics as posts consisting of a title summarizing the main point and a body representing the reasoning behind it. In turn, others comment on these posts trying to convince the authors to change their mind. We follow Alshomary et al. (2021b) by assuming the following mapping: The title of a post represents an argument's *conclusion* and its body is the *premises*, while each comment is a *counter-argument*. To ensure our models are trained on high quality counters, we select for each post the comment with highest argumentative quality score predicted by the model proposed by Gretz et al. (2020).

To study counter-argument generation for settings where the conclusion is not mentioned explicitly, we use only the post's body as input, and the title as training output to learn to generate the conclusion. Since users might also restate their post's main point (the conclusion) inside their post, this allows us to study and evaluate the correlation between a model's effectiveness in generating good counter-arguments and the level of implicitness of the conclusion in the input.

The stance-based ranking component relies on a classifier that assesses the stance polarity between two statements. To train such a classifier, we use dataset of Syed et al. (2021), which is based on the *Kialo.org* platform, where claims on controversial topics contributed by humans are organized in a hierarchical structure with supporting and opposing relations. We transformed the data into pairs of claims labeled as *pro* or *con*, and we split it by debates into 95.6k instances for training, 7.7k for validation, and 22.4k for testing.

4.2 Models

Approach For generation, we used BART as our base model (Lewis et al., 2020), and fine-tuned it starting from the *BART-large* checkpoint. We trained for three epochs using a learning rate of $5^e - 5$ and a batch size of 8. We then selected the checkpoint with the lowest error on the validation set. To find the best parameters α_a and α_b for the *Joint Two-decoders* model, we explored pairs of values between 0.1 and 1.0 on a sample of the training set, and took the pair that led to the lowest validation loss: $\alpha_a = 0.7$ and $\alpha_b = 0.3$.

To obtain a diverse set of candidate counters for ranking, we used nucleus sampling (Holtzman et al., 2019) with $p = 0.95$ and $top\_k = 50$. For the *Joint One-seq* model, we obtained relevant Wikipedia concepts from the input premises using Project Debater's API[3] that we used to prompt the output sequence (conclusion and counter-argument) to encourage diversity. As for the stance classifier, we fine-tuned *roberta-large* on the Kialo pairs for three epochs with learning rate $2e^{-5}$ and batch size 64. The trained classifier achieved an F_1-score of 0.81 on the test split. To test its performance on the ChangeMyView data, we took a sample of 2k instances with pro pairs (an argument and its conclusion) and con pairs (conclusion and counter). The trained classifier resulted in an F_1-score of 0.70.

Baselines To study how effective transformer-based models are when the conclusion is not explicitly stated, we compare against four BART-based models, all trained on the conclusion and premises as input and the counter-argument as output, but treated differently in the inference time.

Joint Two-decoders w/ Stance	***0.164**	*0.153	0.825	*0.652
BART-based w/ Conclusion	0.175	0.160	0.773	0.584
Argument Undermining	0.072	0.090	0.805	0.664

Table 2: Automatic evaluation of our two models, with and without *stance* ranking, compared to baselines, in terms of the similarity of the generated and the ground-truth counters (BLEU and BERT F$_1$-score) and of the counter's correct (opposing) stance. Stance is computed once using Project Debater's API (*Stance*) and once with our stance classifier (*Contrastiveness*). Results highlighted with * are significantly better than BART-based w/o Conclusion at a confidence level of 95%.

In particular, the first baseline (*BART w/o Conclusion*) relies only on the premises at inference time. To account for the missing conclusion, the second (*Pipeline-based*) generates a conclusion using another BART-based conclusion generation model trained independently on the training split of the CMV dataset. This can be seen a pipeline alternative to our approach, since conclusions and counters are learned independently. We also evaluate a variation of this pipeline approach that chooses the best counter among a diverse set of candidates using our ranking component (*Pipeline-based w/ Stance*). Finally, the fourth model is an oracle that knows the ground-truth conclusion in addition to the premises (*BART w/ Conclusion*).

Additionally, we compare our approach with the argument undermining approach of Alshomary et al. (2021b) in which the argument's weak points are first identified subject to its conclusion. Then a counter is generated to attack the weakest point(s). We obtained the trained model from the authors and used it to generate counter-arguments corresponding to the top three weak points (similar to their experiments).

4.3 Automatic Evaluation

In the following we introduce the automatic evaluation measures used in our experiments. We then present the evaluation results of our approaches, as well as a detailed analysis of their effectiveness with respect to argument length (measured by number of tokens) and conclusion implicitness.

Evaluation Measures To approximate the similarity of generated and ground-truth counters, we compute BLEU and BERT F$_1$-score[4]. In addition, we measure the stance correctness of the generated counter with respect to the ground-truth conclusion in two ways: First, a *contrastiveness* score is computed using the stance classifier trained for our ranking component. It represents the average likelihood of classifying the counter and the corresponding ground-truth conclusion as *con* across the evaluation dataset. Second, a target-based *stance* score that measures the stance of both the conclusion and the counter towards the conclusion target. Given the valdiation set, we extract the target of each conclusion for this purpose as proposed by Alshomary et al. (2020) and then use Project Debater's API[5] to classify the conclusion's stance and the generated counter's stance towards the extracted target. The final measure is the absolute difference between the counter and conclusion scores, averaged across the evaluation dataset.

Results Table 2 shows the evaluation results. All approaches are close in BLEU and BERT F$_1$-score, with small but significant advantages for our models. We observe that the absence of explicit mention of the conclusion in the input (*BART w/o Conclusion*) worsens the results across all measures but the Stance score, and vice versa when introducing the conclusion (*BART w/ Conclusion*). This clearly indicates the importance of the conclusion in the process of counter-argument generation.

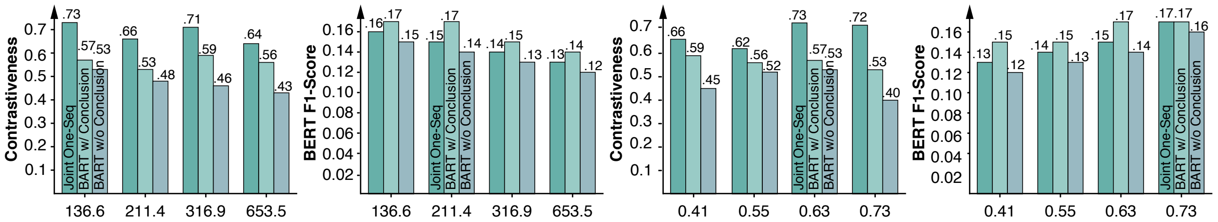
When the conclusion is not mentioned explicitly but has to be inferred, we can see that both our generation models which jointly generate conclusions and counters, outperform the baselines in terms of correct stance. As expected, adding the ranking component to our approaches and the pipeline baseline consistently boosts the correctness, the best being *Joint One-seq w/ Stance* with stance score 0.889 and contrastiveness score 0.661.

Although the Argument Undermining approach of Alshomary et al. (2021b) requires an explicit mention of the conclusion to rank premises according to their attackability, its effectiveness lacks behind. This could be because their model is trained on only a subset of the training data where the comments are countering specific points in the post.

---

[4] For each instance, we compare against all ground-truth counters and take the maximum score achieved

[5] Debater API, `https://early-access-program.debater.res.ibm.com/`



a) Premise's avg. number of tokens b) Premise's avg. number of tokens c) Avg. of Max. similarity to conclusion c) Avg. of Max. similarity to conclusion

Figure 2: Contrastiveness and BERT F_1-scores of our approach *Joint One-seq* against the baseline subject to different levels of argument complexity (approximated by the number of tokens) and conclusion implicitness (approximated by the maximum similarity of the ground-truth conclusion to the premises).

Analysis As discussed above, conclusions may appear in arguments implicitly, which we expect to correlate with the quality of the generated counters: the more explicit the conclusion, the better the generated counters. Moreover, we hypothesize that, the longer an argument is, the more important the inference of its conclusion is for effective counter-argument generation.

We empirically investigate these two hypotheses by comparing the performance of the counter-argument generation models subject to *argument length* (in terms of the number of tokens) and to the degree of *conclusion implicitness* (in terms of the maximum similarity between the ground-truth conclusion and premises). In particular, for both dimensions, we sorted the a sample of 2k instances from the test set accordingly and split it into five subsets of equal size. We then compare the BERT F_1-score and contrastiveness score of *Joint One-seq* against *BART w/o Conclusion* and *BART w/ Conclusion* on the respective subset.

Figure 2 shows the scores for all three models at different levels of argument length and conclusion implicitness. In Figure 2a, we see that the baseline's contrastiveness drops from 0.53 to 0.43 the longer the argument gets, while the scores for *BART w/ Conclusion* fluctuate relatively around 0.57. In contrast, our approach achieves scores between 0.64 and 0.73, indicating the benefit of the explicit modeling of conclusions. Figure 2c suggests that the more direct the conclusion is formulated in the premises, the better *BART w/o Conclusion*'s contrastiveness score gets, and vice versa for *BART w/ Conclusion* model.

We observe an unexpected drop in scores for arguments where conclusions have an average similarity of 0.7 to the premises. Upon inspection, we found that the baselines tend to copy parts of the premises with slight rephrasing. However, our approach, *Joint One-seq*, maintains high scores and also benefits from the clear formulation of the conclusion in the premises, since this helps to generate better conclusions.

Lastly, looking at BERT F_1-scores in Figures 2b and 2d, we notice that the values drop across all approaches as arguments get longer. Similarly, the more apparent the conclusion in the premises, the better the scores get.

4.4 Manual Evaluation

To gain more reliable insights into the performance of our approaches, we designed a human evaluation study to measure the quality of the generated counters in terms of relevance to the input argument and the correctness of their stance. In a second study, we also let humans assess the validity of the generated conclusions.

Counter-Arguments We selected 100 test set arguments randomly along with the counters generated by the two variations of our approach, *Joint One-seq w/ Stance* and *Joint Two-decoders w/ Stance*, as well as by two baselines, *BART w/o Conclusion* and *Pipeline-based*. Using the UpWork platform, we recruited three human annotators who are proficient in English with a job success of more than 90%. We presented them the 100 arguments together with the texts of the four given counters, shuffled pseudo-randomly for each argument. For each argument, we then asked them to rank the texts based on their adequacy of being a counter-argument to the input argument, where we defined adequacy as follows:

> *An adequate counter is a text that (1) carries an argumentative and coherent language and (2) clearly represents an opposing stance to one of the main points in the input argument.*

Additionally, the annotators should provide comments describing their decision regarding the coun-

	Annotator 1	**Annotator 2**	**Annotator 3**
Annotator 1	-	0.43	0.28
Annotator 2	0.43	-	0.30
Annotator 3	0.28	0.30	-

Table 3: Pairwise inter-annotator agreement in terms of Kendall's τ in the manual evaluation.

Counter Generation Approach	**Average ↓**	**Majority ↓**
BART-based w/o Conclusion	2.56	2.54
Pipeline-based w/ Stance	**2.38**	2.31
Joint One-seq w/ Stance	2.39	**2.26**
Joint Two-decoders w/ Stance	2.65	2.72

Table 4: Manual evaluation: The *average* and *majority* rank of the counters generated by our two approach variations and the two baselines. Lower is better.

ters ranked first (the best) and fourth (the worst). Computing the inter-annotator agreement using Kendall's τ results in an average of 0.32 (ranging from 0.32 to 0.43), while we observed majority agreement on full ranks between the annotators in 78% of the evaluated cases.

Table 3 shows the pairwise inter-annotator agreement of the three annotators in terms of Kendall's τ, resulting in an average of 0.32, and ranging from 0.28 to 0.43. We observe that *Annotator 1* and *Annotator 2* agree notably more with each other than with *Annotator 3*. We observed a full ranking majority agreement between our annotators in 78% of the evaluated cases.

Table 4 reports the mean of the average and majority ranks achieved by each approach. When considering cases with majority agreement, our model *Joint One-seq w/ Stance* performs best (mean rank 2.26). This also can be seen in Figure 3, where we plot the rank distribution for all approaches. In 55% of the cases, the approach generated counters that were ranked either first or second. However, the variation with two decoders falls short compared to all others (mean rank 2.72). This suggests that sharing only the encoder between the two tasks is not enough to generate relevant counters. Also, as indicated before, not being able to prompt the generated conclusions limits the diversity of candidates in the stance-based ranking component. Finally, we see that the *pipeline-based* baseline equipped with our ranking component is almost on par with our approaches, indicating the importance of promoting stance correctness.

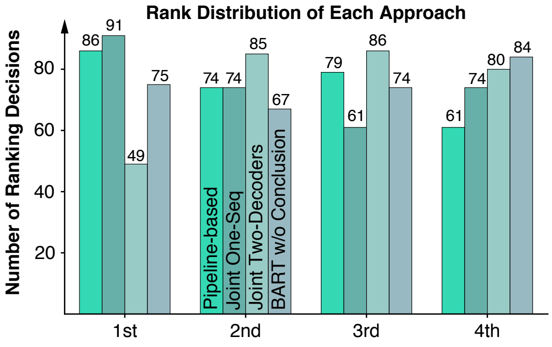


Figure 3: A histogram of the ranks that each of the manually evaluated approaches achieved on the 100 test cases, summing up the results of all three annotators.

Conclusion Generation Approach	**Validity ↑**
Pipeline-based w/ Stance	1.42
Joint One-seq w/ Stance	1.91
Joint Two-decoders w/ Stance	2.03
Ground-truth Conclusions	**2.39**

Table 5: Manual evaluation: Average *validity* score from 1 (non-valid) to 3 (valid) of the conclusions generated by our two approach variations and by the baseline, in comparison to the ground truth.

Conclusions To investigate whether the joint learning of conclusion and counter-argument generation leads to more valid conclusions, we designed another human evaluation study, for which we defined validity in a simple way:

> *A conclusion is valid if humans can infer it from the input argument.*

For 50 random arguments, we selected their ground-truth conclusion as well as two conclusions generated by the two variations of our approach and the best baseline (*Pipeline-based w/ Stance*), summing up to seven conclusions per argument. We hired two annotators through UpWork again. We asked them to read each argumentsand to evaluate the validity of each conclusion on a 3-point Likert scale, where 3 means that they strongly agree that the conclusion can be inferred and 1 means they strongly disagree. The agreement of the two annotators was 0.46 in terms of Cohen's κ.

Table 5 shows the average scores achieved by each evaluated model. With 1.42, the *pipeline-based* approach is notably worse than the others, indicating the advantage of multitask learning for conclusion and counter generation. The best score is achieved by *Joint Two-decoders w/ Stance* (2.03), being only 0.36 points below the ground-truth con-

Conclusion (title): Artificial General Intelligence does not need to be conscious to be more intelligent or effective than humans
Premises (post): In my opinion AGI needs the algorithms that make us intelligent and by having these missing pieces they will be a generally intelligent entity. I hear arguments that an AGI needs to have a subjective experience like a human being in order to be generally intelligent and I find this theory to be lackluster if the laws of physics can be computed than so can the algorithms that make general intelligence. After all we are information processing systems however, i am trying to explore all avenues of thought, even play devil's advocate and not get caught in some sort of echo chamber or even worse a spirit of the age.

BART-based w/o Conclusion:

Counter: I don't think that AGI needs to have a subjective experience like a human being in order to be generally intelligent. I think it's more accurate to say that an AGI doesn't need to have subjective experience, but that doesn't mean that it can't have an objective experience.

Pipeline-based w/ Stance:

Conclusion: i need to be more intelligent in order to be an AGI.
Counter: intelligence is not determined by a subjective experience like a human being. it is determined by the laws of physics. an agi does not need to have an objective experience to be intelligent, but it does need to be able to understand the world around it.

Joint-based One-seq w/ Stance:

Conclusion: Scientific law is the only thing that can make AGI generally intelligent.
Counter: The problem with AGI is that we don't really know what it is that makes us intelligent. we have no idea how it works, what it's like to be an AGI, how it's different from a human being, or how it will work in the real world.

Table 6: An example argument with conclusion (title) and premises (post), taken from *CMV*. Implicitly, the conclusion is also mentioned in the premises. Below, we show the output generated by each approach.

clusion's score. Given the low effectiveness of this model on the counter-argument generation task, we assume that the training process optimized more towards generating conclusions, especially since the task may be easier than generating counters. A better weighting scheme for the two tasks may alleviate this in future work.

Qualitative Analysis Table 6 shows an example argument discussing *Artificial Intelligence* along with counters generated by the two baselines as well as by our approach *Joint One-seq w/ Stance*. *BART w/o Conclusion* rephrases sentences from the input argument without generating a proper counter, possibly due to the ignorance of the conclusion. While the *pipeline-based* baseline equipped with our ranking component generates a somehow relevant conclusion, its counter still vague and doesn't clearly oppose the argument's stance. Finally, *Joint One-seq* infers a conclusion that addresses the main point of the input argument (*Scientific law*), and counter it by pointing out the difficulty of defining *intelligent* , making it hard to be measured.

Upon exploring annotators' comments that justified their decisions of what is the best/worse counter, we identified some patterns. For example, *Joint One-seq* was most appreciated, because it generated argumentative and coherent counters that sometimes offered new perspectives. In contrast, the cases in which the model's output was ranked worst happen mainly due to being vague, incoherent, or diverging from the main topic. The counters of *BART w/o Conclusion* were ranked worse due to coherences sometimes, but often due to not opposing to the input argument.

5 Conclusion

In this paper, we have studied the task of counter-argument generation, considering the role of the argument's conclusion. We argued that automatically generating counter-arguments becomes more challenging when the argument's conclusion is implicit, mandating explicit modeling. To validate our claims, we have proposed an approach that jointly learns to generate the conclusion and a counter for a given argument and compare it to baselines with no explicit conclusion modeling. Moreover, it explicitly enforces that the generated counters have a correct stance through a stance-based ranking component. We haved realized the approach in two ways, both using transformer-based models but with varying encoder-decoder concepts.

Although far from perfect, our results clearly suggest that the joint learning of the two tasks leads to better counters and to more valid conclusions of the input argument, in comparison to strong baselines. Thereby, we contribute substantially towards more robused counter-argument generation.

6 Acknowledgments

7 Limitations

In our evaluated, we have only experimented with BART as the underlining transformer-based model.

Additional experiment settings could demonstrate the gain of modeling the conclusion across other transformer-based models, such as GPT and T5.

Furthermore, we did not explore all possible weighting schemes for the two jointly learned tasks in our multitask setting. A potential extension could be to consider a more systematic evaluation of different schemes, for example, dynamic weighting schemes (Gong et al., 2019).

Lastly, our models are limited by the quality of the data we use. We have built on the assumption that CMV commentators rebut the original post's conclusion. However, this might not be a valid assumption in all cases and should be reassessed in future work.

8 Ethical Statement

Although our experiments demonstrate the role of conclusions in counter-argument generation, we believe that this task is far from solved. We are aware that issues such as faithful text generation must be considered when working with language models to avoid misinformation. We believe that mechanisms such as a fact-checking component or a factuality optimizer should accommodate any text generation model. The primary goal of our experiments is to highlight the potential of conclusion inference as part of the counter-argument generation pipeline, not to create an approach that is already ready for practical application.

A Computing Infrastructure

All our experiments are run inside an `ubuntu20.04` system using `Python 3.8.10`. The CUDA version is 11.2. We used one A100-SXM4-40GB GPU to train our models. The following libraries are required to run our experiments:

- torch==1.11.0+cu113
- transformers==4.18.0
- flair==0.11
- spacy==3.3.1
- debater-python-api==3.5.8

Question-Answer Sentence Graph for Joint Modeling Answer Selection

Roshni G. Iyer[1]*, **Thuy Vu**[2], **Alessandro Moschitti**[2], and **Yizhou Sun**[1]

Abstract

This research studies graph-based approaches for Answer Sentence Selection (AS2), an essential component for retrieval-based Question Answering (QA) systems. During offline learning, our model constructs a small-scale relevant training graph per question in an unsupervised manner, and integrates with Graph Neural Networks. Graph nodes are question sentence to answer sentence pairs. We train and integrate state-of-the-art (SOTA) models for computing scores between question-question, question-answer, and answer-answer pairs, and use thresholding on relevance scores for creating graph edges. Online inference is then performed to solve the AS2 task on unseen queries. Experiments on two well-known academic benchmarks and a real-world dataset show that our approach consistently outperforms SOTA QA baseline models.

1 Introduction

Automated Question Answering (QA) research has received renewed attention thanks to diffusion of Virtual Assistants. For example, Google Home, Siri, and Alexa provide general information inquiry services, while many others serve customer requests in very different application domains. Two main tasks have been widely studied: (i) Answer Sentence Selection (AS2), which, given a question and set of answer-sentence candidates, consists of selecting sentences (e.g., retrieved by a search engine) that correctly answer the question; and (ii) machine reading (MR), e.g., (Chen et al., 2017), which, given a question and reference text, involves finding an exact text span that answers the question.

AS2 models can more efficiently target large text databases (as they originated from the TREC-QA track (Voorhees and Tice, 1999)) and there is evidence that they are currently used in personal assistants, e.g., Alexa (Matsubara et al., 2020).

q:	**Who won the 1967 NBA Championship ?**	*score*	*label*
c_1:	The 1967 NBA World Championship Series was the championship series of the 1966-67 National Basketball Association season and was the conclusion of the 1967 NBA Playoffs.	**0.810**	**0**
c_2:	This was the first championship series in 11 years without the Boston Celtics, who were defeated in the Division Finals by Philadelphia.	0.048	0
c_3:	The 76ers won the series over the Warriors 4-2.	**0.142**	**1**
q_1:	**Who won the 2009 Super Bowl ?**		
a_1:	The Steelers defeated the Cardinals by the score of 27–23.		
q_2:	**Who won Fifa World Cup 2010 ?**		
a_2:	In the final, Spain, the European champions, defeated third-time finalists the Netherlands 1–0 after extra time.		
q_3:	**Who won the most NBA championships ?**		
a_3:	Bill Russell won 11 championships with the Boston Celtics.		

Table 1: An example from WikiQA, for candidates ranked by TANDA with normalized scores and labels.

Garg et al. (2020) proposed the Transfer and Adapt (TANDA) approach, which obtained impressive improvement over SOTA for AS2, measured on two most used datasets, WikiQA (Yang et al., 2015) and TREC-QA (Wang et al., 2007). However, TANDA simply applies pointwise rerankers to individual question-answer pairs, e.g., binary classifiers, exploiting labeled out domain data (the ASNQ dataset proposed by the same authors).

The approach above was significantly improved by the Answer Support-based Reranker (ASR/MASR) (Zhang et al., 2021b), which jointly models answer candidates of each question. Essentially, the authors showed that answer candidates bring additional information for determining if a target answer t is correct, and proposed an ad-hoc joint model. ASR/MASR uses TANDA as fundamental building blocks for its model, but improves on TANDA's score via a component with AA similarity relations. Our model further improves this via a QQ similarity component integrated with a graph neural network (GNN) to capture more interrelation dependency.

A way to go beyond ASR/MASR's approach is to consider other questions similar to the target one along with their answers for deciding over t. For example, Table 1 reports a question, $q =$ *Who won the*

May 2-6, 2023

1967 NBA Championship?, with some candidate answers, c_1, c_2, and c_3, sorted by a pointwise reranker. c_1 contains the same phrase from the question, i.e., the phrase *The 1967 NBA World Championship*, which is also used by q to characterize the asked information (the name of the winner). The AS2 model mistakenly ranks c_1 before the other candidates, as the latter do not contain the phrase above. The model answers incorrectly because for most cases matching a portion of the question in the answer is a strong evidence of its correctness. In contrast, the correct answer c_3 (which also indicates a winner) does not contain the contextual entities, i.e., NBA and 1967.

The selection ability of the AS2 model would improve if it could learn the additional context. The latter can be provided by other similar question/answer pairs. For example, in the lower part of Table 1, we can see that the correct answer for q_3 (a question very similar to q) is a_3, which shows a predicate argument structure very similar to c_3, i.e., (**subj**:x, **verb**:*won*, **obj**: *championship*). Also a_1 and a_2 have somewhat similar structure, but most importantly all three similar questions provide evidence that it is not necessary having NBA or, in general, the name of the championship in the answer to make it correct.

The correctness characterization provided by the similar questions above can hardly be learned by the model from individual (q, c) pairs, as the characterization does not hold in general. It can be applied relatively to the list of candidates, $\{q, c_1, c_2, c_3\}$. Therefore, these patterns should be learned from comparing similar questions together with their list of candidates.

In this paper, we propose to jointly model questions with their list of candidates for AS2. This enables the usage of the information from other questions, similar to the given question, together with their answers. For this purpose, we design a graph-based QA model relying on the assumption that, given question q and a corresponding answer a, there exist other questions, q_i and answers a_i semantically similar to q, and a, respectively. These similar questions and answers can provide evidence to decide the correctness of a. To model the complex interactions among these different sentences, we use Graph Neural Networks (GNN) (Gori et al., 2005; Scarselli et al., 2009) applied to graphs which utilize interaction among question and answer pairs.

Our main innovation regards graph construction: (i) we propose to build a different small graph for each target question, such that we improve efficiency, and effectiveness as we use specific relevant questions; (ii) as we target answer selection, which traditionally is modeled as classification of question and answer pairs, (q, a), we associate graph nodes with them. We use training data to assign pairs with positive and negative labels. (iii) We form edges between pairs using models that automatically score different types of relations: question-question (QQ), question-answer (QA), and answer-answer (AA), and then we apply thresholds to reduce the number of active edges.

We test our models over three datasets, WikiQA, TREC-QA, and WQA, where the latter is an internal dataset built with de-identified customer questions. Our GNN for QA improves the best pointwise model for AS2, i.e., TANDA, over all datasets (up to 7 absolute points on TREC-QA corresponding to 75% of error reduction in Accuracy). It also establishes the new SOTA among joint models, improving ASR by 4 and 2 absolute points on WikiQA and TREC-QA, respectively.

2 Related Work

Our work aims at improving the answer sentence selection (AS2) task in open-domain question answering (ODQA).

Modeling for AS2 Previous work for AS2 modeling is typically categorized into three approaches: pointwise (Shen et al., 2017; Yoon et al., 2019; Garg et al., 2020), pairwise (Rao et al., 2016; Tayyar Madabushi et al., 2018; Laskar et al., 2020), and listwise methods (Cao et al., 2007; Bian et al., 2017; Ai et al., 2018). TANDA, and most other pointwise methods for AS2, however, overlook the natural existing inter-relations in the data. ASR/MASR is the current SOTA for joint modeling and considers multiple candidates for a target question. In this paper, we propose graph-based approaches for AS2, considering multiple questions and answers.

Graph-based Question Answering GNNs (Gori et al., 2005; Scarselli et al., 2009) have gained traction for their ability to effectively and scalably learn graph representations. Empirically, GNNs (Iyer et al., 2021) have achieved SOTA performance in many tasks such as node classification, link prediction, and graph classification. GNNs have been studied to improve QA in several ways. In multi-hop QA (Yang et al., 2018), GNNs are used to provide a structural presentation among several entities, e.g, questions, paragraphs, sentences, named entities to facilitate reasoning (Fang et al., 2020). However, the link between text is always triggered by named entities or concepts.

In our work, we use entire sentence semantics to link questions or answer text. Moreover, our semantic objects are pairs and we introduce relations between them. Recently, Yu et al. (2021) has used GNNs to exploit structural relationship described in pre-built knowledge graphs to improve ranking of passages. Their approach is different from ours: they use entity knowledge graphs. More importantly, we use multiple questions, while they only use multiple passages.

For other works proposing graph-based answer selection methods, they are limited in omitting important graph dependencies such as between questions (Tian et al., 2020), answers (Zhang et al., 2020), or both (Zhang et al., 2021a). Further, several existing approaches require additional information to be present, such as user reputation data (Lin et al., 2021; Zhang et al., 2021a), product reviews for product-related questions (Zhang et al., 2020), as well as external question and answer subject knowledge (Yang et al., 2022; Deng et al., 2021), assumptions that are no longer reasonable in real-world settings where this information may not be accessible. Our model overcomes these limitations, by considering the general setting where only question sentence and answer candidate information is available to effectively solve the AS2 task.

3 Methodology

In this section, we first present an overview of our QA Graph Model, followed by a discussion of our graph construction procedure. Then we describe our GNN model design, and lastly detail our training and inference framework.

3.1 QA Graph Model Overview

Our approach novelly reformulates the task of AS2 as a graph problem of node classification, where the goal is classify each (q, a) node from test to label 1 (correct answer) or 0 (incorrect answer). To this end, our approach carefully designs a QA graph guided by TANDA-RoBERTa, which captures important inter-relations between QQ, AA, and QA sentences, discussed in Section 3.2. GNNs are then used to learn final embeddings. GNN model parameters are learned during offline training, and online inference is performed for new node classification on unseen queries by turning the answer selection problem into the (q, a) node classification task.

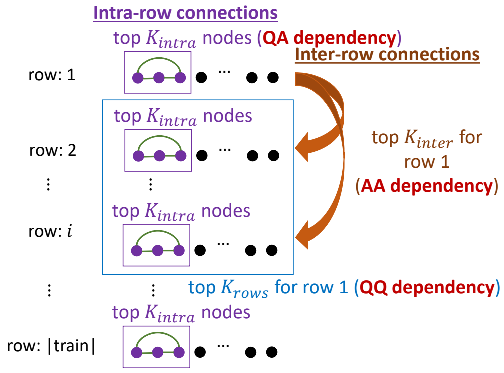

Figure 1: EQAG-GNN Graph Construction: each row is a question with all its answer candidates.

3.2 Graph Construction

Our graph construction procedure designs **E**ffective **QA G**raphs, EQAG. These graphs only have (q, a) nodes, the construction is based on K-best similar questions, and there is a final step to add intra- and cross- question connections to capture inter-relation QQ, AA, and QA sentence dependencies.

3.2.1 EQAG node construction procedure

Nodes are modeled as (q, a) sentence pairs (for design choice details, see the Appendix), and all graph nodes are of the type (q, a) (for motivation on node type choice, see Limitations section).

3.2.2 EQAG edge construction procedure

Figure 1 illustrates our approach: given query q, we first capture QA dependency using the top K_{intra} elements by determining which of the query's answer candidates to connect (through QA similarity). Then, we capture QQ dependency by identifying which similar questions to connect using top K_{rows} (through QQ similarity). Lastly, we capture AA dependency by identifying which similar answers to connect given the nodes already have similar questions, by using the top K_{inter} answers located in the top K_{rows} questions (through QA similarity from one node's question to the other node's answer, which was more effective than directly using AA similarity between the nodes' answers).

Capturing QA Dependencies. QA dependencies are explicitly captured via intra-row connections where for each query q, all corresponding query-answer nodes that have top K_{intra} scores from TANDA are connected for all training data (offline learning) and test data (online learning) independently. To reduce connections between noisy data, selected top K_{intra} nodes are further thresholded by th_{intra}. We include graph singleton nodes to enforce total question answerability coverage.

Capturing QQ Dependencies. QQ dependencies are *implicitly* captured by identifying similar questions to connect using top K_{rows} per query via QQ similarity. For QQ similarity, we used RoBERTa-base model trained on the open-domain Quora dataset [1]. Note that use of Quora is an additional improvement in our graph construction.

Capturing AA Dependencies. AA dependencies are captured by identifying similar answers to connect using top K_{inter} answers located in top K_{rows} questions, via TANDA's prediction scores. Inter-row connections are further ensured to connect only training data during the offline learning stage, and performs online inference solely on unseen test data. Similar to intra-row connections, to reduce connections between noisy data, selected top K_{inter} nodes are further thresholded by th_{inter}. Through empirical observation, for training nodes involved in cross-row connections, only connecting positively labeled training nodes improves model performance over connecting all labeled types of training nodes. These experiments, including other settings of inter-row connections are in Section 6. The latter also discusses hyperparameter settings for datasets.

In practice, we find similar questions to be abundant from datasets and therefore not a limitation in finding AA dependencies. Empirically, we also find similar questions have similar answers both in terms of semantics and syntax (structure). Hypothetically, in the extreme case of having only few similar questions, EQAG-GNN model accuracy will not be compromised since AA construction additionally requires thresholding where AA similarity score must be $\geq th_{inter}$, ensuring only sufficiently similar answers have dependencies.

3.2.3 Training Graph Construction Analysis

An alternative graph construction is explicitly introducing inter-relation dependencies as nodes: (q, q), (a, a), and (q, a). To keep graph size scalable, one may use semantically useful nodes, using QQ and AA language model similarity scores e.g., via RoBERTa with thresholding, where threshold is a hyperparameter e.g., $[0.7, 1.0]$. To form edges, one may use a similar procedure as node generation, where if any q or a elements between both nodes have a similarity score greater than the threshold value, to connect them. As GNNs do not update isolated nodes, one may further consider removing them to ensure scalable graph size.

However, this above approach shows several limitations: (i) not all questions (which were supposed to be answerable) may be answered. This occurs since the constructed graph may eliminate certain queries altogether since they do not satisfy threshold score when creating nodes. Further, only connected components greater than one element are considered by the baseline. In other words, isolated nodes are removed. The edge formation process may also remove edges due to thresholding of elements between nodes, thus creating isolated nodes that are subsequently removed. The thresholding may also remove correct answer candidates, though other candidates of that query may be kept. In this case, the model will be limited to only choosing an answer candidate from existing set of candidates labeled as incorrect, leading to lower performance.

EQAG overcomes nodes eliminated by thresholding by instead choosing top-K ranked nodes for all query-answer pairs. This guarantees all queries will have prediction made by the GNN (full answerability coverage) due to their presence in the graph, and further, correct answers that may have been removed due to thresholding will be included. Moreover, having all (q, a) pairs as nodes in the graph does not negatively affect a correct node's learned representation. Initial embeddings of all (q, a) nodes are produced from TANDA-RoBERTa classifier and then updated by a GCN-GNN model to learn final embeddings which are then mapped to a binary label. While all (q, a) nodes are present, only supporting evidence (q, a) nodes are connected to eachother (which is a sparsely connected instead of a fully connected graph). Therefore, the GCN-GNN model will only update node embeddings based on sparsely available node edges. Isolated nodes are not updated via message passing (as they have no neighbor node information to aggregate from), so such a suboptimal (q, a) node's information will not affect correct nodes.

4 Learning from QA graphs with GNNs

GNNs broadly use message passing with graph structure learning to inform a node's representation

---

[1] `kaggle.com/c/quora-question-pairs`

by a recursive neighborhood aggregation scheme. A node's neighborhood aggregation considers its local context of nodes, usually set to one-hop neighbor nodes, or directly connected nodes. In this way, utilizing a node's neighborhood for learning its representation takes into effect graph connectivity, node degree, and graph features. The general framework for GNNs is as follows:

$$\boldsymbol{h}_i^{(l+1)} = \sigma\big(\sum_{j \in N_i} f(\boldsymbol{h}_i^{(l)}, \boldsymbol{h}_j^{(l)})\big), \tag{1}$$

where $\boldsymbol{h}_i^{(l)} \in \mathbb{R}^{d^{(l)}}$ is the feature representation of node v_i at layer l of the neural network, with dimensionality d. f is a message-specific neural network function of incoming messages to v_i from its neighborhood context N_i, and activation function σ, typically being $\mathrm{ReLU}(\cdot)$ for all layers but the last one which is $\mathrm{softmax}(\cdot)$.

Graph Convolutional Neural Networks. Graph Convolutional Networks (GCNs) (Kipf and Welling, 2017) are a widely used class of GNNs, which have been shown to achieve superior performance on semi-supervised classification on graph-structured data. GCNs have been successfully applied to several networks including various citation network graphs, and knowledge graphs. GCN's framework is as follows where for a node $v_i = (q, a)$, where $q \in \mathrm{Q}_{\mathrm{Train}}, a \in \mathrm{A}_{\mathrm{Train}}$, its feature $\boldsymbol{h}_i^0 = \mathbf{x_i}$ is calculated by $\boldsymbol{h}_i^0 = \mathrm{score}_{\mathrm{TANDA}}(v_i)$:

$$\boldsymbol{h}_i^{(l+1)} = \sigma\Big(\boldsymbol{W}_l^T\big(\sum_{j \in N_i \cup \{i\}} \frac{e_{j,i}}{\sqrt{m_j m_i}} \boldsymbol{h}_j^{(l)}\big)\Big), \tag{2}$$

where $\boldsymbol{h}_i^{(l)}$ are embeddings of node v_i at layer $l \in [0, L]$, $\boldsymbol{W}_l$ is a layer-specific learnable weight matrix, N_i is the set of nodes in neighborhood context of v_i, $e_{j,i}$ is edge-weight between nodes $v_j \to v_i$, with default edge weight being 1.0 if edge exists. m_i and m_j are entries of degree matrix, with $m_i = 1 + \sum_{j \in N_i} e_{j,i}$. In other words, the GNN model only uses TANDA as initial embeddings for nodes. After that, the GNN model is used to update these embeddings through multiple layers of learning, which use message passing and local neighborhoods to update the node's representation.

In this work, we explore how GNNs applied to our QA graphs are effective in learning representations of QA nodes for AS2, through their ability to inform embeddings by capturing the latent QA, QQ, and AA dependencies between nodes.

GNN Loss Function. For the task of binary node classification, GNNs use binary-cross entropy (BCE) loss for training, where only the nodes from the training set are optimized:

$$BCE = -\frac{1}{N}\sum_{i=0}^{n} y_i \cdot log(\hat{y_i}) + (1 - y_i) \cdot log(1 - \hat{y_i}),$$

where y_i is the binary ground truth label for each query-answer, and $\hat{y_i}$ is the model's predicted probability score of the positive label, where $\hat{y_i} = \boldsymbol{h}_i^L$.

5 Training and Inference

Figure 2 summarizes EQAG-GNN's pipeline.

5.1 Training

After the graph is constructed, described in Section 3.2, it is passed to a GNN. We utilize $L = 2$ layers of GCN such that initial node features are TANDA's relevance scores, representing TANDA's prediction score of how well candidate c answers query q. After node features are updated by the GCN, the answer candidates are reranked by the learned relevance scores. Parameters of the GCN model, which include weight matrix $\mathbf{W}_l$, are optimized using BCE loss, described in Section 4, such that for every query-candidate node i, the learned relevance score $\hat{y_i}$ is computed per c and ranked. Further, learning rate and dropout rate are fine-tuned to the dataset. Our model's task is node classification, since each node is a query-answer to be classified with positive label (the candidate correctly answers the question) or negative label (the candidate incorrectly answers the question).

5.2 Inference

The inference stage is performed as online inference with only unseen query-candidate nodes. Here, each new query-answer pair forms one node, such that all possible answer candidates per query are considered. For each new query, the trained EQAG-GNN model leverages its neighborhood information of certain existing (q, a) nodes from training that it is connected to, based on top K_{inter} rows in EQAG. As computation of the top K_{inter} rows uses QQ, AA, and QA semantic similarity, the GNN model leverages these important inter-relation dependencies when classifying a new query-candidate node. Further, as the model's offline training is strictly performed on training nodes with no additional data leveraged, it is ensured that there is no information leak. Once EQAG-GNN

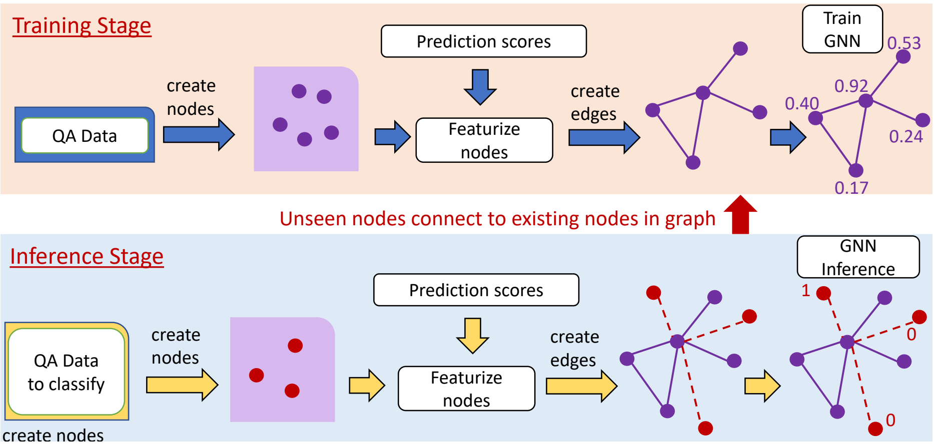

Figure 2: EQAG-GNN Pipeline. Graph nodes are (q, a) which have initial features being TANDA-RoBERTa's relevance score. During inference, for an unseen query, (q, a) nodes are created and connected to existing nodes in training graph. The learned GNN is then applied to obtain classification scores and mapped to binary labels.

predicts scores of unseen nodes, scores are ranked to find the candidate with the highest learned relevance score. Then, the soft-valued score is converted to a binary valued label where only the highest scoring candidate is assigned label 1 and the remaining candidates are label 0.

For effectiveness, during inference, we also do not fully connect all test answer candidates of a query when building the inference graph but instead use ranked top-K candidates guided by TANDA-RoBERTa's prediction score to form edge connections. This is suggested by our ablation study: more noise is included in the model when the QA graph becomes too densely connected. At the same time, an overly sparsely connected graph will also lead to less accuracy during inference of the model since GNN's message passing component will not be as effective. Therefore, we choose K as tunable hyperparameter on the target dataset.

GNN parameter size: Our GNN is also efficient in learned parameter size, as it uses the same parameter size as the efficient TANDA model and its GNN model parameter size is also minimal. Specifically, for the GCN GNN model, we used parameter size of $d \cdot d + n \cdot d$, where d is embedding size, and n is number of graph nodes. In our model setting, $d = 1$ and n is dataset specific, which in practice is in magnitude of a few thousand nodes in total, or in magnitude of a few hundred nodes per question on average. Specifically, n is around 26K, 52K, and 426K in total for the datasets of WikiQA, TREC-QA, and WQA respectively, which on average per question is 31, 42, and 121 nodes for WikiQA, TREC-QA, and WQA respectively.

6 Experiments

Here, we compare EQAG-GNN against SOTA QA models. Then, we show an ablation study for EQAG-GNN for the best hyperparameters. Finally, we discuss a case study with error analysis.

6.1 Datasets

Table 2 shows a description of the datasets.

WikiQA: WikiQA (Yang et al., 2015) is an AS2 dataset containing data with form label-question-answer such that labels are binary, indicating existence of positive or negative QA pair, and there are several answer candidates for a question. Data comes from Bing query logs over Wikipedia where answers are manually labeled. We follow the most used setting: training with all questions having at least one correct answer, and validating and testing with all questions with at least one correct and one incorrect answer.

TREC-QA: TREC-QA (Wang et al., 2007) is an AS2 dataset containing data in a format like WikiQA of label-question-answer. We use the same splits of the original data, following the setting of previous work (Garg et al., 2020).

WQA: WQA (Zhang et al., 2022) is an AS2 dataset built with anonymized customers' utterances from a popular personal assistant. The dataset was built as part of the effort to improve understanding and benchmarking in ODQA. The creation process includes steps: (i) given a set of questions collected from the web, a search engine is used to retrieve up to 1,000 web pages from an index containing millions of pages. (ii) From retrieved documents, all candidate sentences are extracted and ranked using AS2 models. Finally, (iii) top candidates for each question are manually assessed as correct or incorrect by human judges. This allowed obtaining higher average number of correct answers with richer variety from multiple sources, shown in Table 2. Data is in a format similar to WikiQA of label-question-answer. For consistency with standard QA datasets, we filter out WQA for all non-answerable questions, or questions with only negative answer candidate choices.

6.2 Setup

Metrics: Performance of QA systems is typically measured with Accuracy being percentage of correct responses. This is also referred to as Precision-at-1 (P@1) in the context of reranking, while standard Precision and Recall are not meaningful as the system does not abstain from providing answers.

Implementation details: As the basic language model for our systems, we used the TANDA checkpoint, which is the SOTA AS2 (Garg et al., 2020). This is a pre-trained RoBERTa-base, further fine-tuned on ASNQ data [2]. We use the same reported optimal hyperparameter settings (Garg et al., 2020). Specifically, 4 Tesla V100 GPUs with 32GB for training and evaluation batch sizes of 32, with the maximum sequence length 128, and learning rate of 1e-6 for adapt step on the target dataset. We adopt Adam optimizer (Kingma and Ba, 2015) with learning rate of 2e-5 for the transfer step on ASNQ.

Model Parameters: To construct our QA graph, we used 8 Tesla V100 GPUs with 32GB with training batch size of 256. We utilized TANDA's configuration to guide the initial graph features, as described in Section 6.2. We then utilize the GCN model to complete the final step of model training, such that the node's embedding dimension size is set to 1, initially being TANDA's prediction scores. Learning rates were hyperparameters tuned from 1e-6, 2e-6, 5e-6, 1e-3, 2e-5, and used for WikiQA/TREC-QA/WQA with 1e-3, 1e-3, and 1e-6. Number of layers were hyperparameters tuned from 2, 4, 8, 16 and we utilized 2 layers for datasets. Training and eval batch sizes were 32.

6.3 Experiments with EQAG

We consider four EQAG-GNN model variants:

RI (Random Initialization): node features are randomly initialized with Gaussian uniformly random distribution between $[0.0, 1.0]$. This is to test impact that TANDA's model has on guiding EQAG-GNN's learned embeddings. For all variant models, we use hyperparameter settings from Section 6.3.

TA (Train All): both positively and negatively labeled training examples are considered to connect nodes between rows (inter-row connections).

T$+$ (Train on positives): only the positively labeled training examples are considered to form the connections of nodes between rows. This approach seems to reduce the noise that incorrect training data may introduce to the model, when learning embeddings for all training data considered together.

T$\pm$ (Train positive and negative individually): for inter-row connections, both positively and negatively labeled training examples are used for connections, but considered separately. Specifically, we propagate both positive and negative node information throughout the network as different subcomponents. Positively labeled training data connects to the top K_{intra} connected test nodes, while negatively labeled training data connects to the bottom K_{intra} test nodes, which are isolated while ensuring that node features are less than th_{intra}. This may guide the model to learn better embeddings, as negative nodes will be influenced more by their negative neighbor context, while positive nodes will be influenced more by their positive neighbor context during the GNN message passing stage. This helps better distinguish embeddings between positive and negative test nodes during inference as overlap between local contexts of positive and negative nodes will be minimized.

Choosing EQAG-GNN hyperparameters We run ablation studies for hyperparameter tuning on the WikiQA dataset, evaluated on the validation

(a) top K_{intra} and top K_{inter} using WikiQA

(b) th_{intra} and th_{inter} using WikiQA

Figure 3: EQAG-GNN Hyperparameters on WikiQA

Model	**WikiQA**	**TREC-QA**	**WQA**
	P@1		
BR-MPGE-AS	0.835	0.912	0.600
L.D.C. Model	0.549	0.618	0.402
PWIM	0.823	0.824	0.582
HyperQA	0.827	0.853	0.598
Comp-Clip + LM + LC	0.827	0.838	0.590
TANDA	0.823	0.912	0.651
KGAT ($k = 2$)	0.844	0.941	–
ASR ($k = 3$)	0.844	0.971	–
MASR ($k = 3$)	0.823	0.927	–
EQAG-GNN (RI)	0.309	0.412	0.223
EQAG-GNN (TA)	0.840	0.956	0.671
EQAG-GNN (T+)	0.860	**0.985**	0.676
EQAG-GNN (T±)	**0.864**	**0.985**	**0.679**

Table 3: P@1 evaluation of GNN applied to EQAG and leading baselines. The best results are bold-faced.

set. For each hyperparameter tuned, we fix the values of all other hyperparameters to their optimal setting. The optimal settings of the variables, as shown in Figures 3(a) and 3(b), are $K_{intra} = 5$, $K_{inter} = 10$, $th_{intra} = 0.70$, and $th_{inter} = 0.90$. It can be observed that K_{intra} and th_{intra} may affect the P@1 accuracy more than K_{inter} and th_{inter}, perhaps because they directly impact how the intra-row connections between answer candidates of test queries are formed, which greatly influences the learned embeddings of each test node.

Comparative Results Table 3 reports P@1 accuracies of different SOTA QA models for ODQA on AS2 evaluated on WikiQA, TREC-QA, and WQA datasets. Models include TANDA, ASR, MASR, KGAT, EQAG-GNN model variants, described above, the SOTA GNN-based model for AS2, BR-MPGE-AS (Tian et al., 2020), the CNN-based sentence similarity model, L.D.C. (Wang et al., 2016), the Bi-LSTM CNN-based model which explicitly models pairwise word interactions, PWIM (He and Lin, 2016), the hyperbolic space embedding model, HyperQA (Tay et al., 2018), and the CNN-based latent clustering (LC) language model (LM), Comp-Clip+LM+LC (Yoon et al., 2019). All models use RoBERTa-base pre-trained checkpoint. The table shows QA-GNN consistently achieves highest performance among all models and all datasets on P@1 metric. For example, it outperforms TANDA by around 4, 7, and 3 absolute percent points in P@1 on WikiQA, TREC-QA, and WQA, respectively. Appendix tables 7 and 8 further report Maximum a Posteriori (MAP) and Mean Reciprocal Rank (MRR) scores, showing EQAG-GNN also achieves similar performance gains.

Results show 100% coverage of answerable questions and boosted accuracy of the approach. The ranking mechanism also improves graph connectivity, since all top-ranked question-answer pairs are included, though some nodes may be isolated. This technique greatly improves the amount of information needed by the GNN, compared to when only connected components without isolated nodes were considered. Finally, since the approach needs to start from weights learned by TANDA as random initialization, GNN-RI, produces very low results. Experiment results confirm effectiveness of modeling sentence-level semantics via graph-based models for AS2 (our approach) through comprehensive comparison of SOTA methods on AS2 including graph-based AS2 methods that model entity-level semantics. Further, our model consistently achieves significant improved performance against all baselines on all comprehensive metrics for AS2 (P@1, MAP, MRR), showing both accuracy and quality of QA pair ranking learned.

7 Case Study

We provide a case study and error analysis comparing performance of EQAG with TANDA. Ta-

q:	**How is Jameson Irish Whiskey made ?**
c_1:	Jameson is similar in its adherence to the single distillery principle to the single malt tradition but Jameson blends column still spirit with Single pot still whiskey a combination of malted barley with unmalted or " green " barley distilled in a pot still.
c_2:	Jameson is a single distillery Irish whiskey produced by a division of the French distiller Pernod Ricard.
c_3:	The company was established in 1780 when John Jameson established the Bow Street Distillery in Dublin.
c_4:	Originally one of the six main Dublin Whiskeys Jameson is now distilled in Cork although vatting still takes place in Dublin.
c_5:	With annual sales of over 31 million bottles Jameson is by far the best selling Irish whiskey in the world as it has been sold internationally since the early 19th century when John Jameson along with his son (also named John) was producing more than a million gallons annually.
c_6:	Portraits of John and Margaret Jameson by Sir Henry Raeburn are in the collection of the National Gallery of Ireland.
c_7:	Jameson was Scottish a lawyer from Alloa who had married Margaret Haig a sister of the brothers who founded the main Haig firms and related to the Steins a Scottish distilling family with interests in Dublin.

Table 4: Case study example of (q, a) from WikiQA.

	EQAG score	*TANDA score*	*label*
c_1:	**0.192**	**0.108**	**1**
c_2:	**0.158**	**0.505**	**0**
c_3:	0.103	0.110	0
c_4:	0.130	0.266	0
c_5:	0.140	0.009	0
c_6:	0.128	~ 0	0
c_7:	0.148	~ 0	0

Table 5: EQAG, TANDA scores for Table 4, with normalized predicted candidate answer scores underlined.

ble 4 reports question, q = *How is Jameson Irish Whiskey made?*, with candidate answers, c_1, through c_7, for which the AS2 model has to pick out the best candidate answer. Table 5 reports prediction scores learned by EQAG, and TANDA, per candidate answer and ground truth label.

7.1 Error Analysis

TANDA mistakenly ranks c_2 of label 0 before other candidates, while EQAG correctly ranks c_1 of label 1 above other candidates. Though phrase *Jameson Irish Whiskey* is important to the question, semantic intent of the question is how it is *made*. While TANDA recognizes importance of phrase *Jameson Irish Whiskey*, it does not learn necessary context of what the question asks for. As such, it picks the candidate describing what the whiskey is rather than how it is made. EQAG, however, places attention on both *Jameson Irish Whiskey* and question context *made*, while also learning that entire phrase *Jameson Irish Whiskey* may not need to be present in the candidate sentence as long as there is some indication of referring to the item e.g., *Jameson*.

As shown in Table 6, EQAG effectively learns from similar questions and its corresponding answer candidates that it sees during training to recognize important semantic characteristics of the question. For example, all three supporting questions e.g., q_1 through q_3 are about how various items (single malt scotch, bourboun, root beer) are made. Further, correct corresponding answers contain information about *both* item string name as well as how it is made. Regarding item string name, it is not necessary for the entire string name to be present as long as appropriate substring referring to this item is there. For example, a_1 refers to *single malt scotch* as simply *Scotch*, which EQAG also learns in order to identify that *Jameson Irish Whiskey* may be referred to as *Jameson*.

		(q, q_i) sim
q_1: a_1:	**How is single malt scotch made ?** As with any Scotch whisky, a single malt Scotch must be distilled in Scotland and matured in oak casks in Scotland for at least three years (most single malts are matured longer).	0.743
q_2: a_2:	**What is bourboun made of ?** Bourbon whiskey is a type of American whiskey– a barrel-aged distilled spirit made primarily from corn.	0.622
q_3: a_3:	**How is root beer made ?** Root beer is a carbonated, sweetened beverage, originally made using the root of a sassafras plant (or the bark of a sassafras tree) as the primary flavor.	0.498

Table 6: EQAG learned similar questions to question from Table 4, with corresponding absolute similarity scores between (q, q_i), $i \in [1, 3]$

8 Conclusions

To our knowledge, our model is the first graph-based approach for jointly modeling sentence-level semantics of question-answer pairs for AS2 as an offline processing application, such as those required by community QA, forums, etc. This is different from previous methods using graphs, e.g., MultiHop or Graph-based QA, which mainly model semantics via entities. Our approach builds query-specific small-scale training graphs for offline learning, through (q, a) pairs as nodes, and edges encoding relations between members of pairs to capture both supporting question-question, and answer-answer dependencies. Further, we demonstrate that our approach achieves significant performance gains over existing SOTA models on AS2 for metrics of P@1, MAP, and MRR.

Limitations

Our proposed model is efficient as its complexity is comparable to SOTA retrieval models like TANDA-RoBERTa. However, we note that out of our model components, the main complexity is from graph construction for the offline learning stage when constructing query-specific small-scale training graphs as opposed to graph processing, since GNN processing is typically fast. This is due to retrieval of top K-questions for each target query, which we perform with a RoBERTa cross-encoder. While the graph building takes roughly a few seconds per question in practice, given the scope of our problem of investigation for *offline* training and *online* learning, our model is efficient.

Further, while we capture Q-Q and A-A dependencies to form edge connections between the (q, a) nodes, the fact that the nodes in EQAG are all of the form (q, a) may be seen as a limitation. However, in the context of QA, the model deciding if an answer is correct or not for a question is trained over (q, a) pairs. This means that most information is captured by the pair, which is seen as the whole object. In general, we aim at modeling the similarity between pairs in the graph as we want to learn the patterns that make a pair correct. A graph having nodes as pairs directly enables this kind of learning, with also the great advantage that cross encoding two pieces of text in a transformer always produces a much higher accuracy than separated encoding of question and answer.

As future work, we plan to investigate building a model for learning graph topologies (Iyer et al., 2022), and other online processing applications e.g., document retrieval, by exploring methods like DPR (Karpukhin et al., 2020) to further speed up offline graph construction.
