A Example Annotations

We report in Table 5 some example tweets with different degrees of annotators' agreement and the corresponding category & subtype. In particular, A^{++} corresponds to total agreement (5/5 crowdsourced annotations with the same label); A^{+} - mild agreement (4 vs 1 labels); A^{0} - disagreement (3 vs 2 labels).

Agreement	Offensiveness	Example	Category	Subtype
A^{++}	N^{++}	Google bans ads on coronavirus conspiracy theory content -url	-	-
A^{+}	N^{+}	@user Freaking love it	Missing Info	No Context
A^{0}	N^{0}	@user How many more George Floyd will die under white domination! Sad!	Ambiguity	Rethorical question
A^{0}	O^{0}	He is another nut case.	Subjectivity	Personal bias
A^{+}	O^{+}	@user You're a bumbling fool #elections2020	Subjectivity	Personal bias
A^{++}	O^{++}	f %* king insanity	-	-

Table 5: Examples of tweets with different degrees of crowd-workers' agreement. N=Not offensive, O=Offensive. $++/+/0$ correspond to high, medium and low agreement respectively. The last two columns include disagreement category and subtype.

B Annotation Guidelines

In order to annotate a text by assigning a category and a subtype of disagreement from the proposed taxonomy, annotators should perform the following steps:

1. Check the text for sources of disagreement: detect the main one and assign it to a category among *Sloppy annotation*, *Ambiguity*, *Missing Information* and *Subjectivity*;
2. Choose a fine-grained class to specify the main source of disagreement
3. Check for a secondary source of disagreement (if any): assign the text to another category (it could be the same as the previous one, with a different subtype)
4. Choose a secondary subtype to specify the secondary source of disagreement

We also report questions to guide the assignment of labels to text instances.

- **Sloppy Annotation** (Label = Sloppy_Annotation)
  - **Noise**: is the text clearly not offensive but marked as such (or vice versa)? (Label = Noise)
- **Ambiguity**: are there multiple interpretations to the text but is it not clear which is the correct one? (Label = Ambiguity)
  - **Analogy**: does the text include a figure of speech that comprehends mechanisms of comparison (included: simile and metaphor) or is the user referring to someone with a periphrasis (e.g., "orange monkey", "bunker boy" for Donald Trump)? (Label = Analogy)
  - **False assertion**: does the user express the opposite of what they think or something wrong with respect to a context? (Label = False_Assertion)
  - **Rhetorical question**: does the text include a question asked in order to make a point rather than to elicit an answer? (Label = Rhetorical_Question)
  - **Sarcasm**: is the text employed to communicate the opposite of its surface meaning in a humorous way or to mock someone/something? (Label = Sarcasm)
  - **Word Play**: does the text include any acronyms, alliterations or puns? (Label = Word_Play)
  - **Reported Speech**: does the text report something someone else stated? For example a newspaper headline? (Label = Reported_Speech)
- **Missing Information**: is the disagreement caused by difficulty of interpretation? (Label = Missing_Info)
  - **Ungrammatical**: does the text include typos or non standard expressions nullifying its comprehension? Do not consider "your/you're", "its/it's" since they are very frequent and do not affect text comprehension (Label = Ungrammatical)
  - **No context**: does the text contain (Label = No_context):
    - ∗ Reference to other users?
    - ∗ Links?
    - ∗ Anaphoric or deictic pronouns without an explicit referent?
    - ∗ Demonstrative pronouns?
  - **Not complete**: some parts are missing: is the text not complete? (Label

= Not_Complete)

- **Subjectivity**: does the text contain information that makes annotators' opinions interfere in their judgment? (Label = Subjectivity)
  - **Personal Bias**: does the text contain specific words that can be interpreted in a subjective way by the annotator (for example: "racist", "fascist", "clown", "pathetic", "liar", "pig") or refer to specific, critical opinions (no vax, wearing or not wearing masks)? (Label = Personal_Bias)
  - **Swearing**: does the text include swearing words (for example: "prick", "turd", "crap", "bullshit", "moron", "dumb")? Does it include ableist insults such as "retarded", "psycho" and expressions containing "shit" (for example: "cut the shit", "don't know shit"). Do not consider WTF, SMFH and similar acronyms containing "fuck". (Label = Swearing)
  - **Threatening**: does the text contain linguistic violence (for example: "shut up", "get out", "you are going to prison")? (Label = Threatening)

Analyzing Challenges in Neural Machine Translation for Software Localization

Abstract

Advancements in Neural Machine Translation (NMT) greatly benefit the software localization industry by decreasing the post-editing time of human annotators. Although the volume of the software being localized is growing significantly, techniques for improving NMT for user interface (UI) texts are lacking. These UI texts have different properties than other collections of texts, presenting unique challenges for NMT. For example, they are often very short, causing them to be ambiguous and needing additional context (button, title text, a table item, etc.) for disambiguation. However, no such UI data sets are readily available with contextual information for NMT models to exploit. This work aims to provide a first step in improving UI translations and highlight its challenges. To achieve this, we provide a novel multilingual UI corpus collection ($\sim 1.3M$ for English $\leftrightarrow$ German) with a targeted test set and analyze the limitations of state-of-the-art methods on this challenging task. Specifically, we present a targeted test set for disambiguation from English to German to evaluate reliably and emphasize UI translation challenges. Furthermore, we evaluate several state-of-the-art NMT techniques from domain adaptation and document-level NMT on this challenging task. All the scripts to replicate the experiments and data sets are available here.[1,2]

1 Introduction

There is a rapid increase in access to technology for people from around the globe. For software to be used by everybody, it is essential to provide User Interface (UI) texts in their native languages for monolingual speakers. However, many applications are created in English and later localized to various languages. To decrease the translation time, localization companies take the help of machine translation (MT). Human annotators use the MT system for generating initial translations and post-edit the system's output to increase efficiency in computer-assisted translation tools (Flournoy and Duran, 2009; Skadiņš et al., 2014). When producing high-quality translations, costs can be saved by decreasing the annotator's time on editing and making the localization process cheaper. Thus, enabling more companies to localize in several languages at low cost.

Neural Machine Translation (NMT) (Sutskever et al., 2014; Bahdanau et al., 2015; Vaswani et al., 2017) is the current state-of-the-art (SOTA) approach for generating the initial "draft" for the translations. Although conventional NMT models are sufficient in many cases, they use only the source sentence alone to predict the target translation (*Locality Assumption*) (Maruf et al., 2021). However, this is problematic when translating several types of concise UI texts that need more information.

It has been a decade since Muntés Mulero et al. (2012) have shown the need for integrating additional context into MT models for software localization and have pointed out several issues. For example, consider translating the English source word "Login" into German. Here, the translation depends on where the text is. If it is on a button, the correct translation is the verb form "Anmelden". In the case of a title text (FAQ, Documentation, etc.), the translation might rather be the noun form "Anmeldung". Depending on the application, the translation can also be simply "Login" even on a button.

Another common phenomenon to deal with when translating these short UI texts is semantic ambiguity. For example, if we want to translate the word "Home", we need to know the context where the sentence is present. Although the translation is often the German word "Haus", it is not correct in the context of Linux applications. In this case, we would need to translate "Home" as "Benutzerverzeichnis" ($HOME directory). Apart from the issues

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2442–2454
May 2-6, 2023

mentioned above, gender (the gender of the item in a table depends on the gender of the table title text), and consistency in terminology and style (e.g formal v/s informal) are problematic when translating UI. However, sentence-level NMT models lack the contextual information to generate suitable target translations.

Several approaches were proposed to integrate contextual information into NMT models. Domain adaptation and Multi-Domain models using tags are common techniques in NMT to inform the models about the type of content it is translating (Kobus et al., 2017; Chu et al., 2017; Pham et al., 2020; Xu et al., 2020). Knowing the domain/topic of the text enables NMT to select and generate appropriate translations in a particular setting. Another recent and growing field that tries to make models context-aware is document-level NMT (Doc-NMT) (Tiedemann and Scherrer, 2017; Voita et al., 2018; Maruf et al., 2019, 2021; Bao et al., 2021; Sun et al., 2022). The surrounding source and/or target sentences usually can provide significant cues and hints for the NMT model to understand the domain and the context in which the source sentence is occurring. These approaches are promising and could benefit localizing UI segments, but the lack of sufficient annotated UI data with contextual information is the main hindrance to applying them.

Although localization files of software like GNOME, UBUNTU, and KDE are present in the OPUS corpus (Tiedemann, 2012), they do not provide the document structure or any other metadata. Also, the segments in the corpora do not come from a vast amount of domains. Neither large amounts of UI data are publicly available nor a targeted test set to measure the model's ability to use context for UI translations. These constraints limit the potential to improve NMT for software localization and are necessary as a first step.

This work addresses the limitations mentioned above by creating a corpus for UI data with document-level information extracted from multiple domains, a targeted test suite, and baselines using current SOTA methods. Our main contributions in this paper are the following

- We present a task of translating UI texts and show their unique properties requiring additional context. Furthermore, we provide a novel multilingual UI corpus covering multiple domains with contextual information to enable NMT for this task. (Section 2)
- To identify the limitations in current NMT systems, we propose a targeted evaluation framework with test sets replicating realistic conditions and solving disambiguation. (Section 3)
- We analyze domain adaptation and Doc-NMT techniques on our collected corpora and evaluation sets to highlight challenges in the proposed task. (Section 4)

2 Addressing Data Scarcity for UI

For improving NMT for UI segments, the first challenge to address is the lack of parallel data with contextual information. To achieve this, we present a novel UI corpus that we assemble from software localization files of publicly available repositories.

First, we briefly explain the structure and contents of the localization files which we search and collect to create our data set. Then, we highlight what types of contextual information are available in these files that are useful for NMT. Finally, we describe how we scraped large amounts of these PO files for multiple languages.

2.1 Portable Object for Localization

Portable Object (PO) files[3] are one of the standard file formats used in the localization industry. These are plain text-based files and do not need specialized tools for reading. Although this is not the only format used for localization, it is widely used in the GNU gettext[4] tool for free software's.

Figure 1 shows an example of a PO file along with a screenshot. A PO file consists of several entries, each containing a unique source and target pair. Each typical entry consists of the following items:

- **msgid:** The source string that needs to be translated and is usually in English for software applications (Game, View, Control, etc.).
- **msgstr:** The translation of the text present inside double quotes in the **msgid** entry (Spiel, Ansicht, Steuerung, etc.).

---

[3] For detailed information on PO files, please refer to this blog post. `http://pology.nedohodnik.net/doc/user/en_US/ch-poformat.html`

msgstr "S_teuerung"

#: src/window.c:1815
msgid "_Help"
msgstr "_Hilfe"

#: src/window.c:1820
msgid "Start a new game"
msgstr "Eine neue Spielpartie beginnen"
```

Figure 1: Screenshot from Klondike[5](Solitaire) game in GNOME with UI texts (LEFT). The German translations of the texts in the menu bar (RED ARROW) with their corresponding translations in the PO file (RIGHT)

- **Source Reference[6]:** Comment above each entry indicating where the texts are extracted from including the file name and line number (*#: src/window.c:1811*). Translators can look up the source code for more context. Note that this can be more than one file and can include multiple references.

2.2 Contextual Information in PO

PO files contain more information than the source and target sentence pairs. However, it is not straightforward how and what information to include in the NMT models. Moreover, it is unlike the contextual information in the traditional sense to address phenomena like co-reference resolution or gender (Stojanovski and Fraser, 2019; Wong et al., 2020; Lopes et al., 2020). Below, we describe three sources of information that are relevant and useful for UI translation:

Domain: All segments in a PO file belong to one application or software. Hence, we can loosely classify these segments belonging to finer-grained domains containing specific properties. Furthermore, new UI texts added to the software should maintain consistency according to terms and phrasing with previous translations. Therefore, knowing that the sentence is from a particular PO file can help NMT choose a similar translation style.

Neighbours: The order of the entries in the PO file maintains some relation to what users see when using the software. Although there is no semantic relation between the entries in the document, surrounding segments can provide information about the current entry. For example, consider a scenario where we must translate the word "Home" into German. If we know that the surrounding two sentences are "Change Directory" and "Print Working Directory," we can infer that it is in the context of a Linux application. Hence, we can translate it as "Benutzerverzeichnis" by inferring information from other entries/neighbors.

Source Reference: Specific to PO files, source reference can provide high-quality information. Almost all entries have a reference to the source code from which it was extracted. Human translators often look at the source code in case of ambiguity. NMT models can also exploit such information while predicting. For translating "Login" to German, we need to decide on choosing the noun (title text) or verb form (button). If all the texts having the same source reference were translated as the verb form, it is more likely that the current word is also a verb form. Therefore, source references can also be beneficial to integrate into NMT models.

Developers can also add context to each entry in the form of comments or by adding a **msgcxt** in the entry. We illustrate such occurrences with the toy

---

[6] **Source Reference** is the file path in the source code for a source-target sentence pair. We follow the convention and clarify that it is unrelated to the source or reference texts.

example from the blog post[3]:

```
#. TRANSLATORS: First letter in 'Scope'
#: tools/observinglist.cpp:700
msgid "S"
msgstr ""

#: tools/observinglist.cpp:700
msgctxt "First letter in 'Scope'"
msgid "S"
msgstr ""
```

Note that there is no standard or consistent process on how developers provide context to the translators. For example, it can be the case that a comment for an entry also applies to the subsequent entries. However, it is trivial for humans to determine which entries are related to the comment. Also, some entries do not have any comments or *msgcxt*. Furthermore, this information is in natural language needing complex models to use this information. Therefore, it is not straightforward to leverage the comments/*msgcxt* as a context in an NMT model, and we do not include this information while conducting our baselines in Section 4.

One possible workaround is to use the actual source code using the source reference entry to provide more information. Extracting contextual information from code can save developers time annotating and enable the NMT model to translate a wide range of applications.

Another category of contextual metadata that could be beneficial for translating UIs with NMT models is the element type of the text (button, title, table item, etc.,). However, this is rarely present in open-source data, and developers do not explicitly mention such information in PO files usually. Moreover, there is also no consistency in this case to specify such information.

2.3 Multilingual UI Corpus

Although we have shown that PO files are useful, there is no large corpus containing these files. Having UI texts from a limited amount of applications does not cover different domain-specific choices or styles. Collecting UI data from as many different domains as possible is crucial. Therefore, we create the UI corpus by searching for PO files in public GitHub repositories.

By convention, developers name the PO file with the language code and *.po* extension. For example, the name of PO files in German is **de.po | De.po | DE.po | dE.po**. Therefore, we search and download files ending with such names depending on the language in publicly available repositories. We use Sourcegraph to query the repositories and download PO files for multiple languages. Afterward, we parse the PO files using the polib library and extract translation pairs with the contextual information described in Section 2.2. Table 1 shows the number of source-target pairs we extracted for different languages.

Language	Repositories	Total Sentence Pairs
German	22248	1.33M
Japanese	13196	0.89M
Spanish	20996	1.38M
Hindi	3095	128K

Table 1: Total number of repositories and parallel sentence pairs extracted between English ↔ German, Japanese, Spanish or Hindi. Note that PO files for many more languages are often present and can be scraped. We provide links along with commit hashes (to replicate our data set) to download the corpus from public Github repositories.

Although we extract bilingual translation data, it is possible to create a multi-way UI data set using repositories containing PO files for multiple languages. Therefore, such data can also be fruitful in improving Multilingual NMT for non-English translation directions (Aharoni et al., 2019; Liu et al., 2020).

3 Realistic & Targeted Evaluation

The previous section described how we collected the data and its characteristics. The next step is to design a realistic evaluation framework to showcase challenges in UI translation and estimate the NMT model's quality reliably.

In this section, first, we propose two test sets considering different use cases while evaluating. Then, to highlight one fundamental phenomenon when dealing with UI strings, we create a challenge set for disambiguation based on heuristics and human annotation. We explain how we curated the different test sets below.

3.1 Intra & Cross-application Test Sets

Splitting the data appropriately into train/dev/test sets is vital in evaluating NMT models. Furthermore, the splits should also capture realistic conditions. Therefore, we propose the following scenarios:

Intra-application: The software gets updated regularly. With the updates, we need to translate newly added and modified strings. However, we have access to human-annotated translations for the strings in the previous version providing accurate information about the domain. Therefore, we consider a case where the test set is from applications that the model has seen during training. From the training data, we randomly select samples and discard them from our training set.

Cross-application: Localization companies also need to translate new applications for which there is no gold human-annotated data. To imitate these scenarios, we keep out a few applications entirely for evaluation. Instead of randomly selecting for evaluation, we choose 10 applications containing between 100 and 300 translation pairs. We set these bounds to maximizing the number of domains covered during testing.

Both test sets also provide insights into how much contextual information is consistent across applications. For example, suppose the context-aware NMT system performs better than sentence-level NMT on the Intra and not the Cross-application test set. In that case, we can conclude that such information does not generalize for new applications. However, it can be used only to improve translations for applications already present in the training data.

3.2 Targeted Disambiguation Test Set

The test sets described above assess the model's ability in different scenarios. However, it does not explicitly measure the model's ability to capture context. The need for targeted test sets (Bawden et al., 2018; Voita et al., 2018; Stojanovski et al., 2020) to use context was shown in Doc-NMT. Several complicated architectures were proposed for integrating context using limited amounts of document-level annotated data and showed improvements on standard test sets. However, proper regularization parameters on the sentence-level model led to the same performance improvements (Li et al., 2020; Sun et al., 2022). Hence, it is necessary to evaluate context-aware NMT models on targeted test sets to not draw false conclusions.

In the case of UI texts, a prevalent phenomenon where context is needed is disambiguation. Long sentences often contain enough context for the models to generate the translation correctly. However, a large number of short sentences are present in UI data (refer to Appendix A.3). Therefore, we create a targeted disambiguation test set when translating English to German as a benchmark to evaluate context-aware NMT models.

We use heuristics to extract and filter source sentences with multiple target translations. Then, we manually evaluate these instances and filter those where the context is insufficient, or it is unnecessary as the translations are paraphrases. We explain the process in the following.

3.2.1 Automatic Filtering

After lower-casing the data, we extract source sentences with multiple target translations and ended up with numerous pairs ($\sim 50k$) consisting of many paraphrases. Therefore, to only extract disambiguation pairs, we perform the following steps:

1. We only keep word-word translations. This step was necessary to filter out paraphrases using a database later.
2. Translations from the same PO files are more likely to be paraphrased as they belong to the same domain. Hence, we only keep where target translation occurs across different files.
3. The source-target pairs that occur only once were filtered out as they might be noise from incorrect translations.
4. We discard pairs consisting of characters such as "#,,_,!" (IP-address v/s IPaddress) by checking for punctuation symbols.
5. We match with the German paraphrase database[7] (Ganitkevitch et al., 2013; Ganitkevitch and Callison-Burch, 2014) to eliminate target translations that are synonyms. We only keep target words that occur in the database but are not considered paraphrases. We do not set a threshold score and consider all the entries in the database to have high precision.

After several steps of filtering, we end up with 293 segment of pairs. Upon manual inspection, we find it impossible to disambiguate several instances, even when we look at the PO files for

---

[7] Note that using the multilingual paraphrase database (Ganitkevitch and Callison-Burch, 2014), it is possible to extend this approach into several languages

Table 2: Examples from the targeted disambiguation test set. We only show 2 surrounding entries in the table but the human annotators were shown 5 to provide more information. The actual translation is highlighted in **bold**.

context. In some cases, it is not clear if the translation of the text is a noun or verb, even by looking at the whole file. Although it is possible that looking at the source code may prove beneficial, we ignore these pairs. Moreover, words like "Settings" and "Preferences" are not paraphrased according to the database but are usually synonymous in the UI context. To eliminate such occurrences, we perform a final step of manual filtering and clean the data using native speakers.

3.2.2 Manual Annotation

We split the test set into three parts. Then, we send each part to two annotators for the final filtering. We gave the annotators the surrounding 5 translation pairs (context) and the source word. Given this information, they were given multiple target translations as options, and we asked them to select the appropriate target given the source and context. Furthermore, we allow them to choose multiple options if they believe that more than one translation is appropriate. Moreover, we also provide a "None of the above" option for every question if they think the context is insufficient or the translations are incorrect. Finally, we selected the ones where both annotators chose the same target word as translation. After annotation, we had 95 entries in the final disambiguation test set. We present a few examples from the test set in Table 2.

Note that many pairs were discarded due to insufficient context but it might be possible to disambiguate with screenshots of application showing the specific UI element. However, we do not have text-image aligned data but it shows the potential advantage of Multi-Modal NMT (Elliott et al., 2017). An overview of the sizes of the data splits for our English ↔ German experiments can be found in Appendix Table 7.

4 Baselines

To evaluate the current NMT approaches with contextual information on UI translations, we provide baselines (English → German) using the current SOTA techniques. We build context-aware NMT models on our UI corpus and measure their ability to use context and highlight their shortcomings.

First, we describe how we integrate multiple types of contextual information in NMT. Then, we present the results and analyze the performance of the models on the multiple test sets.

4.1 Context-aware NMT models

As shown in Section 2.2, we have access to different sources of contextual information. The next step is to integrate them into the NMT model. We perform experiments by including them in the following ways:

Domain: We want to exploit the fact that we have already seen a particular PO file. Therefore, we take the help of tags to indicate this information similar to Kobus et al. (2017). We assign a unique domain tag to each repository and prepend it to each source sentence in a file. During training, we initialize each tag with a random embedding. While testing, the model can know the origin of the file by looking at the domain tag to translate appropriately. If it is from an unseen repository, we assign a random embedding

Example: *<KLONDIKE> _Game* ||| *_Spiel*

Neighbours: In this scenario, we consider the whole PO file as a document. Knowing the surrounding entries in the document can provide cues about the current segment. Therefore, we exploit them by following approaches in Doc-NMT (Tiedemann and Scherrer, 2017). We concatenate the source with the surrounding (left and right if possible) two segments in the file. Note that we only add the source context and not the target side.

Example: *_View _Control <TAG> _Game* ||| *_Spiel*

Source Reference: Specific to PO files, file paths of the string in the source code can capture standard naming conventions across different applications. Like the neighbor's approach above, we concatenate the path with the source sentence. However, we remove the punctuation to maximize the overlap across paths having similar naming structures.

Example: *src window c <TAG> _Game* ||| *_Spiel*

4.2 Experimental Setup

Note that we initially pre-train the models on WMT 14 English-German data (Luong et al., 2015) and then fine-tune on our corpus. We perform this two-step training following the success in transfer learning (Zoph et al., 2016; Kocmi and Bojar, 2018) and improve the translation capabilities. The pre-processing and training parameters for both stages is described in Section A.1.

4.3 Results

We present results on the different evaluation scenarios described in Section 3. First, to understand the performance of context-aware models in realistic scenarios, we report the results on *Intra* and *Cross* test sets in Table 3. Then, we evaluate the models on the targeted disambiguation test set to highlight the need for context in this challenging task and present scores in Table 4. Instead of BLUE (Papineni et al., 2002) or CharacTER (Wang et al., 2016), we report the accuracy for this test set as both source and target are word-translations. The scores for $De \rightarrow En$ demonstrate the ability to map different German words to the same English word. However, it is not completely accurate as the English translations that the model generates can be paraphrased.

Do context-aware NMT models perform better where training data is from known applications? All the context-aware models in Table 4 obtain higher score than the sentence-level model on the *Intra-application* test set. The only exception being the *Neighbour* approach in English → German on BLEU (49.21 ± 0.26) but par with the standard NMT baseline (49.03 ± 0.76).

We hypothesize that the model knows how to use the context when translating segments from the *Intra-applicaton* test set. For example, consider the *Source Reference* approach and the file in Figure 1. By knowing that the text "*Control*" present in "*src/window.c*" was translated as a noun ("*Steuerung*") and not a verb ("*Steuern*"), the model knows how to translate ambiguous texts in that file. Such phenomena are also possible when using the other context-aware NMT approaches. Therefore, we need to integrate contextual information when translating new segments from seen applications.

Does the contextual information generalize to entirely new software? Contrary to the gains observed above, all the context-aware models do not obtain significant improvements on the *Cross* test set. Although there is a slight improvement in a few conditions, it is around 0.5 in BLEU and 0.4% in CharacTER. Moreover, in the case of *Domain Tag* approach, all the texts are assigned a new random domain tag that was not seen during training. Hence, it performs significantly worse than the other methods.

The results show that the contextual information does not generalize well to entirely new applications. Therefore,

we need better context-aware NMT approaches than the baselines we proposed, which capture context more abstractly and benefits software localization in realistic conditions.

How well do the context-aware NMT models perform on the challenging targeted disambiguation test set? While the sentence-level NMT model obtains an accuracy of 20.0% on the targeted test set, the *Domain Tag* approach reaches 41.0%. Furthermore, it performs the best out of all other approaches, with the next best model reaching only 29.4%.

However, it can be the case that most segments in the disambiguation test belong to applications present in the training data. Hence, allowing the *Domain Tag* approach to perform better. Nevertheless, if the example is from a cross-application, this approach can perform worse due to the random initialization of the tag. Moreover, the other approaches are better than the sentence-level model by only a maximum of 10%. The proposed baseline methods are insufficient in this challenging test set and call for better context-aware NMT models.

Are the context-aware NMT models ignoring the context? We also need to investigate the influence of context, if at all, on the model's translations. If the system uses the context, providing false/incorrect context to the model should hurt the performance. Otherwise, we can conclude that the current NMT model ignores the contextual in-

Context Type	*Evaluation Setup*							
	BLEU (↑)				*CharacTER* (↓ %)			
	Cross		Intra		Cross		Intra	
	En → De	De → En	En → De	De → En	En → De	De → En	En → De	De → En
No context	47.15 ± 0.12	57.14 ± 0.44	49.03 ± 0.76	56.05 ± 0.29	37.04 ± 0.08	29.51 ± 0.02	34.75 ± 0.33	29.18 ± 0.32

Neighbour (2)	46.93 ± 0.06	57.30 ± 0.27	49.21 ± 0.26	**56.92 ± 0.38**	36.94 ± 0.12	**29.13 ± 0.16**	**34.04 ± 0.21**	**28.22 ± 0.11**
Source Reference	**47.79 ± 0.09**	57.82 ± 0.33	**51.09 ± 0.33**	**58.53 ± 0.35**	**36.67 ± 0.14**	**29.12 ± 0.04**	**32.38 ± 0.41**	**27.00 ± 0.20**

Table 3: Baseline experiments using different sources of contextual information described in Section 2.2 and evaluated on both Intra and Cross application scenarios. We perform each experiment 3 times to account for randomness and report using both BLEU (↑) and CharacTER % (↓) metrics. We highlight the score in **bold** if the gains are statistically significant compared to the baseline model (*No context*)

	Accuracy (%)	
Context Type	En → De	De → En
None	21.05 ± 0.85	43.85 ± 0.49
Domain Tag	**41.03 ± 0.85**	**56.46 ± 2.14**
Neighbour (2)	26.26 ± 1.5	45.93 ± 1.79
Source Reference	30.8 ± 0.98	52.23 ± 1.79

Table 4: Accuracy of context-aware NMT models on targeted disambiguation test set ($En \leftrightarrow De$). The scores from $De \leftrightarrow En$ denote the accuracy in predicting the same English word given different German words. We run the experiment 3 times and report the confidence intervals.

formation as shown in previous works (Sun et al., 2022).

For this purpose, we conduct an experiment using the "*Neighbors*" approach and provide incorrect context by randomly sampling consecutive segments from different PO files. We report the results in Table 5. Although it is not better than a simple NMT system trained without context, there is always a drop in performance when using incorrect context. Thus, the model uses the context for generating translations but with degradation in general translation quality.

To show the role of context, we provide an example in our test sets in Table 6. The word "*driver*" in this case can be translated to German as either "*Fahrer*" (vehicle driver) or "*Treiber*" (software driver), depending on the domain. In both cases, the model correctly predicts the translation using the context. However, the scores do not show overall improvement, indicating that the context might add additional noise, causing a drop in general translation quality.

5 Related Work

Domain-Adaption in NMT: NMT models for software localization have to deal with texts coming from vast amount of domains. Hence, Domain-Adaptation techniques (Saunders, 2022) are highly relevant in this challenging task. Many works use different domain-tagging schemes to indicate the type of data where the segment's labels are either known or unknown (Kobus et al., 2017; Poncelas et al., 2018; Mino et al., 2020; Wang et al., 2021). Another line of approach is to modify the network to indicate and generate domain-specific translations (Zeng et al., 2018; Pham et al., 2021; Lin et al., 2021). Building on this, few works also propose to add and adapt using domain-specific parameters (Bapna and Firat, 2019; Abdul-Rauf et al., 2020).

Document-level NMT: Exploiting the context from the surrounding texts is necessary for both software localization and Doc-NMT. The initial straightforward approaches for Doc-NMT explored concatenating the source/target with surrounding sentences (Tiedemann and Scherrer, 2017; Agrawal et al., 2018; Ma et al., 2020). These methods do not change the NMT architecture or training methods but can be applied by simply altering the data or the embedding. In contrast, several works investigated creating a different representation for the context sentences using additional encoders (Jean et al., 2017; Zhang et al., 2018; Voita et al., 2018; Werlen et al., 2018; Wang et al., 2019a). Few recent works also propose either modifying the architecture of augmenting data to show the benefit of Document-Document translation (Bao et al., 2021; Sun et al., 2022). For targeted evaluation, Gonzales et al. (2017) also manually constructs a word-sense disambiguation test in English ↔ German. However, our test set is mostly automatic and calls for

Evaluation Setup	True Context		False Context		No Context	
	En → De	De → En	En → De	De → En	En → De	De → En
Intra	49.21 ± 0.26	56.92 ± 0.38	47.95 ± 0.28	55.0 ± 0.35	49.03 ± 0.76	56.05 ± 0.29
Cross	46.93 ± 0.06	57.30 ± 0.27	46.38 ± 0.22	55.94 ± 0.08	47.15 ± 0.12	57.14 ± 0.44

Table 5: BLEU scores for the "*Neighbor (2)*" model evaluated using True and False context during inference. For "*No Context*", we report the scores of the baseline model trained simply on the parallel data without any additional information. We report the confidence interval by running the experiment 3 times.

Source	Current Driver
Reference	Aktueller Fahrer
Source + True Context	Create a new vehicle status <tag> Date when the vehicle has been immatriculated <tag> Current Driver
Neighbour (2) Hypothesis	Aktueller Fahrer
Source + False Context	% s updates a cartridge <tag> Unknown file <tag> Current Driver
Neighbour (2) Hypothesis	Aktueller Treiber

Table 6: Example from our test set where the Neighbour approach (Table 3) uses the context and generates the proper translation. *Source + True context* is the concatenation of the true neighbors in the same PO file with the source sentence whereas *Source + False Context* appends a random context from another PO file.

solving the disambiguation by focusing on neighboring entries and not the sentence itself.

NMT for UI: One of the major limitations for building NMT for UI is the lack of data. The OPUS corpus (Tiedemann, 2012) makes such data available but with no contextual information. The closest to our work is Wang et al. (2019b), building NMT for mobile applications. However, the data is neither public nor addresses the several contextual issues occurring in software localization.

6 Conclusion

We presented a multilingual UI corpus with additional meta-information for researchers in the community to exploit and build context-aware NMT models for software localization. We also have proposed two evaluation setups to replicate conditions occurring in localization companies and show the difficulty in tackling new applications. Furthermore, we experiment using domain adaptation and Doc-NMT techniques to provide baselines and present the benefit of using different types of context in intra-applications while showing its ineffectiveness in cross-application scenarios. Moreover, we suggest an automatic procedure to create a targeted disambiguation test set where context is necessary to generate the correct target word translation. Finally, we show that the baseline systems fail in such challenging settings and call for sophisticated context-aware NMT models to improve the process of software localization.

7 Limitations

While we have presented UI data with contextual information, it does not contain any meta-data (button, table title, etc.,) of the textual elements. Having access to such resources can prove highly beneficial and are lacking in our presented data set. Furthermore, we do not provide any visual context to develop Multi-Modal NMT systems that implicitly contain the meta-data. However, we consider them as potential directions and include them in our future work. Finally, we do not analyze or experiment on non-European languages that might contain specific and unique properties which need to be addressed during localization. Another important limitation is the quality of the translations. We don't know whether they have been produced by professional translators or by multilingual speakers creating inaccurate translations. Although we filter the fuzzy (e.g MT outputs) translations, it can be that not all of them are marked completely. Therefore, qualitative analysis of the data is further necessary.

Acknowledgement We thank Christian Lieske and Jens Scharnbacher for providing insights into the localization process. We also thank Fabian Retkowski, Christian Huber, and Leonard Bärmann for annotating and making it possible to create the disambiguation test set.

A Appendix

A.1 Pre-processing and Training Parameters

For pre-processing, we first tokenize the data with the Moses Tokenizer (Koehn et al., 2007). Then, we learn a joint sub-word vocabulary from $30k$ merge operations using BPE (Sennrich et al., 2016) and apply on the data.

For experiments in Table 4, we first pre-train the model using WMT14 English-German data (Luong et al., 2015). We use the standard Transformer model (Vaswani et al., 2017) with 6 encoder and decoder layers. We use 4 attention heads for every layer an embedding dimension of 512. We use 0.1 for label-smoothing 0.2 for dropout. We set max-tokens to 3000 and a learning rate of 0.0001. For the experiments, we use the Fairseq toolkit (Ott et al., 2019) and set all other parameters to default. While fine-tuning, we reload the model and continue using the same optimization and regularization parameters.

A.2 Data Split Overview

Data Split	*Number of Sentence Pairs*
Train	1.26M
Intra	2.6K (2.6K)
Cross	2.6K (2.4K)
Disambiguation	95

Table 7: Overview of UI data split for English $\leftrightarrow$ German. () indicates the number of validation sentences for the Intra and Cross application test sets.

A.3 Characteristricts of UI segments

	Average Sentence Length English	Average Sentence Length German	Vocabulary Size English	Vocabulary Size German
UI	36	43	167375	321602
News Domain	142	157	626914	1444840

Table 8: Comparing UI (Git scraped) v/s WMT 14 English-German Data. It can be seen the UI sentences are much shorter than the data available in the general domain. Also in both data types, we see that the German sentences consist of more unique words due its complex morphology

Bootstrapping Multilingual Semantic Parsers using Large Language Models

Abstract

Despite cross-lingual generalization demonstrated by pre-trained multilingual models, the translate-train paradigm of transferring English datasets across multiple languages remains to be a key mechanism for training task-specific multilingual models. However, for many low-resource languages, the availability of a reliable translation service entails significant amounts of costly human-annotated translation pairs. Further, translation services may continue to be brittle due to domain mismatch between task-specific input text and general-purpose text used for training translation models. For multilingual semantic parsing, we demonstrate the effectiveness and flexibility offered by large language models (LLMs) for translating English datasets into several languages via few-shot prompting. Through extensive comparisons on two public datasets, MTOP and MASSIVE, spanning 50 languages and several domains, we show that our method of translating data using LLMs outperforms a strong translate-train baseline on 41 out of 50 languages. We study the key design choices that enable more effective multilingual data translation via prompted LLMs.

1 Introduction

Enabling language technologies across several languages is an important goal for serving a diverse range of users in an inclusive manner. Recent advances in large-scale self-supervised multilingual language models hold immense promise in bridging the quality gap that currently exists between English and many other low resource languages (Conneau et al., 2020; Brown et al., 2020; Xue et al., 2021). Even though multilingual models exhibit cross-lingual generalization, getting meaningful performance across several languages still requires significant amounts of task-specific labeled data.

We consider the problem of automatically synthesizing semantic parsing datasets across several languages. Semantic parsing (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Berant et al., 2013) is the task of mapping natural language text into an executable *logical-form*. For example, given a user instruction (x) : "`Wake me up by 5 am`", mapping it to the logical-form (y): `[IN:CREATE_ALARM [SL:DATE_TIME 5 am ]]`. Manual annotation of queries with their logical forms requires human expertise which makes data collection across multiple languages challenging.

A common approach to automatic multilingual dataset creation is translating existing English datasets into target languages. Prior methods utilize an off-the-shelf machine translation model for translating the English utterance into the target language $x_{\text{eng}} \rightarrow x_{\text{tgt}}$, followed by projecting language specific components in the English logical-form y_{eng} to obtain the logical-form y_{tgt} in the target language (Moradshahi et al., 2020, 2021; Xia and Monti, 2021; Nicosia et al., 2021; Gritta et al., 2022; Wang et al., 2022). The projection step is often learned independent of the translation service, resulting in poor generalization across languages.

In this work we aim to utilize the few-shot generalization abilities exhibited by large language models (LLMs) (Brown et al., 2020; Chowdhery et al., 2022; Scao et al., 2022) for bootstrapping semantic parsing datasets across fifty languages. We propose a recipe of using LLMs to translate an English semantic parsing dataset containing `(utterance, logical-form)` pairs: $\mathcal{D}_{\text{eng}} = \{(x^i_{\text{eng}}, y^i_{\text{eng}})\}$ into a corresponding dataset in a target language: $\mathcal{D}_{\text{tgt}} = \{(x^i_{\text{tgt}}, y^i_{\text{tgt}})\}$. The generated dataset $\mathcal{D}_{\text{tgt}}$ is then used to train a semantic parser in the target language. Our method uses a small amount of manually translated semantic parsing examples to *teach* the LLM how to translate English examples in the target language via in-context learning (Min et al., 2022).

Figure 1 describes our data-translation pipeline which we refer to as LLM-T (§ 3). In contrast

```
Seed Examples in English

x: Wake me up in two hours
y: [IN:CREATE_ALARM [SL:DATE_TIME two hours]]

x: Set an alarm to ring in 20 minutes
y: [IN:CREATE_ALARM [SL:DATE_TIME 20 minutes]]

x: Clear all alarms
y: [IN:DELETE_ALARM [SL:AMOUNT all]]
```

```
Translated Seed Examples in Target Language

x: मुझे दो घंटे में जगाएं
y: [IN:CREATE_ALARM [SL:DATE_TIME दो घंटे ]]

x: 20 मिनट में बजने वाला अलार्म लगाओ
y: [IN:CREATE_ALARM [SL:PERIOD 20 मिनट में ]]

x: सभी अलार्म को क्लीर करो
y: [IN:DELETE_ALARM [SL:AMOUNT सभी ]]
```

Figure 1: **Proposed semantic parsing data translation pipeline using LLMs** (§ 3): With the help of human translators, we first collect translations of a small seed set of English examples in the Target Language (e.g. Hindi; § 3.1). Given a new English example, a small subset from this initial seed set of examples with their respective translations is chosen to prompt the LLM (§ 3.2). The prompted LLM translates the given English example in the Target Language. We repeat this process for each example in the English training data to generate a training dataset in the Target Language. To ensure high-quality of the resulting dataset, we generate diverse translations via top-p (nucleus) sampling (§ 3.3) and apply consistency filtering (§ 3.4).

to prior translation based methods that involved a two-staged process requiring different modules, our method uses the LLM to *jointly translate* an English $(x_{\text{eng}}, y_{\text{eng}})$ pair directly into the target language $(x_{\text{tgt}}, y_{\text{tgt}})$. We identify two important choices that make the LLM translated data more effective for training a downstream parser: **(i) Sampling diverse translations** (§ 3.3): Decoding translations using top-p (Fan et al., 2018) and top-k (Holtzman et al., 2019) sampling leads to improved downstream performance compared to using greedy decoding. Sampling multiple diverse translations per example further improves the downstream performance; **(ii) Filtering inconsistent examples** (§ 3.4): Decoding via sampling can result in noisy joint translations of the (utterance, logical-form) pairs. To filter out the inconsistent pairs, we propose a slot-value match based filtering technique that improves the training data quality.

We perform experiments on two multilingual semantic parsing datasets: MTOP (Li et al., 2021) and MASSIVE (FitzGerald et al., 2022). On *4 out of 5* languages in MTOP and *41 out of 50* languages in MASSIVE, our method LLM-T outperforms TAF (Nicosia et al., 2021), a strong baseline that utilizes a supervised translation service (§ 5.1). Further, we see that LLM-T achieves 93% of the performance obtained by "fully-supervised" models that use 30× more manually translated examples (§ 5.2). We justify the importance of generating multiple translations using sampling, filtering out inconsistent examples, and using larger-sized LLMs in improving translated data quality (§ 5.3). Finally, we perform an error analysis of our parser and show the key sources of disagreements between the model predictions and the ground truth (§ 5.4).

2 Background

In this section, we provide an overview of semantic parsing and prior translation-based methods for creating multilingual semantic parsing datasets.

2.1 Semantic Parsing

Semantic parsing is the task of mapping text queries to their meaning representations or *logical forms* (Zelle and Mooney, 1996; Zettlemoyer and Collins, 2005; Berant et al., 2013). We focus on task-oriented semantic parsing (Gupta et al., 2018) where the user utterance needs to be parsed into a high-level intent specifying the overall goal, and fine-grained slots containing details about the utterance. The intents and slots come from a task-specific vocabulary. For example, given an utterance x: "`How is the rainfall today?`", the parser should generate the logical-form
y: `[IN:GET_WEATHER [SL:ATTRIBUTE rainfall] [SL:DATE today ] ]`

Here, `IN:GET_WEATHER` is the high-level intent, `SL:ATTRIBUTE` and `SL:DATE` are the slots that specify details about the intent. We refer to the logical-

form with its slot values removed as its "signature". For example, the signature of y is
`[IN:GET_WEATHER [SL:ATTRIBUTE][SL:DATE]]`

2.2 Translating Semantic Parsing Datasets

Given an English semantic parsing dataset containing (utterance, logical-form) pairs $\mathcal{D}_{\text{eng}} = \{(x^i_{\text{eng}}, y^i_{\text{eng}})\}$, many methods aim to translate $\mathcal{D}_{\text{eng}}$ to a dataset $\mathcal{D}_{\text{tgt}} = \{(x^i_{\text{tgt}}, y^i_{\text{tgt}})\}$ in the target language (tgt). Here x^i_{tgt} is the translation of x^i_{eng}, and y^i_{tgt} is the logical form grounded in the translated utterance x^i_{tgt}. Target logical form y^i_{tgt} has the same signature as y^i_{eng} and only differs in terms of the translated slot values. Most translation based approaches (Moradshahi et al., 2020, 2021; Xia and Monti, 2021; Nicosia et al., 2021) translate an English example $(x^i_{\text{eng}}, y^i_{\text{eng}})$ to the corresponding target language example $(x^i_{\text{tgt}}, y^i_{\text{tgt}})$ via a two step process: (i) **Translate**: Use a supervised translation service to convert the English utterance x^i_{eng} into the target language utterance x^i_{tgt}; and (ii) **Project**: Replace the English slot values in y^i_{eng} with spans copied from the translated utterance x^i_{tgt} via a learned alignment model. The translated examples are then used to train a downstream multilingual semantic parser. For example, Nicosia et al. (2021) implement the project step by training a filler module on English data to fill slot-values in a logical-form signature by copying spans from the utterance. During inference, the trained filler module is then used in a zero-shot manner to fill logical-form signatures with spans copied from the translated utterances.

3 Our Method: Prompting LLMs for Dataset Translation

Our goal is to learn a multilingual semantic parser capable of parsing user queries in many languages. Towards this goal, we propose a method for generating multilingual training datasets via few-shot prompting of an LLM to translate existing English datasets into several languages.

In contrast to prior approaches, we jointly perform example translation by prompting an LLM with a few exemplars of translating English $(x_{\text{eng}}, y_{\text{eng}})$ pairs to target language $(x_{\text{tgt}}, y_{\text{tgt}})$ pairs. Figure 1 describes our data-translation method which we refer to as LLM-T. With the help of human translators we first collect a small seed set of exemplar translations used for prompting the LLM (§ 3.1). Given an input English example, we dynamically construct the LLM prompt by identifying a relevant subset of seed exemplars (§ 3.2). The LLM translates the English example into the target language by in-context learning from the exemplars provided in the prompt. Instead of decoding the most likely translation, we generate multiple diverse translations (§ 3.3) using top-p (nucleus) sampling (Holtzman et al., 2019). While sampling improves the text diversity, it can lead to more noisy generations. We filter out the noisy generations using a simple string-match based technique before training a parser on the translated data (§ 3.4).

3.1 Selecting Seed Exemplars for Translation

Given an English semantic parsing dataset $\mathcal{D}_{\text{eng}} = \{(x^i_{\text{eng}}, y^i_{\text{eng}})\}$, we first want to identify a small seed set $\mathcal{S}_{\text{eng}} \subset \mathcal{D}_{\text{eng}}$ that will be translated into the target language ($\mathcal{S}_{\text{tgt}}$) with the help of human translators. The examples in $\mathcal{S}_{\text{eng}}$ and their corresponding translations in $\mathcal{S}_{\text{tgt}}$ will be used for prompting the LLM. Therefore, the choice of the seed examples in $\mathcal{S}_{\text{eng}}$ that are manually translated into $\mathcal{S}_{\text{tgt}}$ becomes important—we would like that the multiple domains (e.g. `Alarms, Music, News, Weather, etc.`) and the intents and slot types in each domain are covered. This ensures that for a given English example to be translated, we will be able to prompt the LLM in a manner such that at least one of the few-shot exemplars will share the intent and slots with the test English example. In practice, we select seed examples in a manner to cover all the intents and slots in a domain at least once. If the selected examples are less than 20 for a domain, we select the remaining examples randomly.

3.2 Constructing the Prompt using Translation Pairs in the Seed Sets

LLM inference is constrained by the maximum number of tokens in the input. Hence, we can only fit a limited number of examples to construct the LLM prompt. The choice of prompt examples and their ordering is known to significantly impact the quality of the generations (Kumar and Talukdar, 2021; Rubin et al., 2021; Lu et al., 2022). To improve the likelihood of correctly translating an English example $(x_{\text{eng}}, y_{\text{eng}})$, we retrieve seed examples $\{(x^s_{\text{eng}}, y^s_{\text{eng}}, x^s_{\text{tgt}}, y^s_{\text{tgt}})\}$ that share the same domain with y_{eng}. To bias the LLM further, we order the more relevant prompt examples closer to the input English example. Here, relevance between two examples is considered higher if they share the same intent. The remaining examples are

LLM INPUT:

Translate examples from English to Hindi

x^{1}_{eng} : Wake me up in two hours
y^{1}_{eng} : [IN:CREATE_ALARM [SL:DATE_TIME two hours]]
x^{1}_{tgt} : मुझे दो घंटे में जगाएं
y^{1}_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME दो घंटे]]

x^{2}_{eng} : Please set an alarm for 2 pm
y^{2}_{eng} : [IN:CREATE_ALARM [SL:DATE_TIME 2 pm]]
x^{2}_{tgt} : कृपया दोपहर दो बजे का अलार्म लगाएं
y^{2}_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME दो बजे]]

x_{eng} : Set the alarm for the flight next week
y_{eng} : [IN:CREATE_ALARM [SL:DATE_TIME next week]]

LLM OUTPUT:

x_{tgt} : फ्लाइट के लिए अगले सप्ताह अलार्म सेट करें
y_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME अगले सप्ताह]]

Figure 2: **Constructing the LLM Prompt** (§ 3.2): The input to the LLM contains a brief task description in the beginning followed by a series of English examples $(x^s_{\text{eng}}, y^s_{\text{eng}})$ and their translations in the target language $(x^s_{\text{tgt}}, y^s_{\text{tgt}})$ chosen from the seed sets $\mathcal{S}_{\text{eng}}$ and $\mathcal{S}_{\text{tgt}}$ respectively. Following the prompt examples, we append the new English example $(x_{\text{eng}}, y_{\text{eng}})$ to the input prompt which is fed to LLM. In the output, the LLM generates the translation for the new English example $(x_{\text{tgt}}, y_{\text{tgt}})$.

arbitrarily arranged to appear earlier in the prompt. Figure 2 shows an example translation—the *LLM input* contains two exemplars and then the English example that needs to be translated. The *LLM output* shows the translated output from the LLM.

3.3 Decoding Diverse Outputs from LLM

The text decoded from language models using the standard greedy decoding or beam search is often repetitive (Vijayakumar et al., 2016; Shao et al., 2017). To mimic how users express the same intentions in diverse ways, we experiment with the top-k and top-p sampling techniques (Fan et al., 2018; Holtzman et al., 2019) to decode multiple diverse translations per example. We expect sampling multiple translations to yield a better quality training dataset which in turn should result in better downstream semantic parsing performance compared to training on greedily decoded examples.

3.4 Data Filtering using Slot-Consistency

While the sampling techniques produce more diverse text, the sampled translations can be relatively noisy if they have lower likelihoods as per the model (Zhang et al., 2021). Thus, the translated pairs $(x_{\text{tgt}}, y_{\text{tgt}})$ in the LLM output can be inconsistent w.r.t. each other. For example, consider the LLM translated pair $(x^3_{\text{tgt}}, y^3_{\text{tgt}})$ shown in Figure 3. Here, y^3_{tgt} contains a slot value (in red) that does not appear in the corresponding utterance x^3_{tgt} making the pair $(x^3_{\text{tgt}}, y^3_{\text{tgt}})$ inconsistent. As per the task definition, for a given example (x, y), the slot-values in the logical form y should come from the spans of the utterance x. Thus, we filter out the translated examples $(x_{\text{tgt}}, y_{\text{tgt}})$ like these where the slot-values in y_{tgt} do not appear *exactly* as an exact sub-span in x_{tgt}. Figure 3 shows examples of slot-consistent and slot-inconsistent generations by an LLM through top-k sampling.

x_{eng} : Set the alarm for the flight next week
y_{eng} : [IN:CREATE_ALARM [SL:DATE_TIME next week]]

x^{1}_{tgt} : फ्लाइट के लिए अगले सप्ताह अलार्म सेट करें
y^{1}_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME अगले सप्ताह]]

x^{2}_{tgt} : अगले हफ्ते के लिए उड़ान के अलार्म को सेट करो
y^{2}_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME अगले हफ्ते के लिए]]

x^{3}_{tgt} : फ़्लाइट के लिए अलार्म सेट करें
y^{3}_{tgt} : [IN:CREATE_ALARM [SL:DATE_TIME अगले सप्ताह]]

x^{4}_{tgt} : अगली हफ्ते के उड़ान के लिए अलार्म सेट करें
y^{4}_{rgt} : [IN:CREATE_ALARM [SL:DATE_TIME अगले हफ्ते]]

Figure 3: **Slot Consistency Based Filtering** (§ 3.4): We present the input English example $(x_{\text{eng}}, y_{\text{eng}})$ and its four translated samples $\{(x^i_{\text{tgt}}, y^i_{\text{tgt}})\}$) the target language. The first two samples are *slot-consistent* as the slot-values (in green) in the logical forms appear exactly in the text utterances, while the last two samples are *slot-inconsistent* as the slot-values (in red) do not appear as an exact sub-string of the text utterance.

4 Experimental Set-up

We describe our experimental setup in this section.

Datasets We experiment on two public datasets — MTOP (Li et al., 2021) and MASSIVE (FitzGerald et al., 2022). MTOP contains examples from six languages: English, French, German, Hindi, Spanish, and Thai, spanning 11 domains covering 117 intents and 78 slot types. On average, MTOP contains 12.3K examples in the train split, 1.5K in the dev split, and 2.7K in the test split per language. MASSIVE contains examples from 51 typologically diverse languages including English spanning 18 domains covering 60 intents and 50 slot types. For each language, MASSIVE contains roughly 11.5K examples in the train split, 2K examples in the dev split and 3K examples in the test split.

Evaluation Metric Prior work (Li et al., 2021; Nicosia et al., 2021) uses Exact Match (EM) accuracy as a primary metric which compares predicted and gold logical-forms strings. However, the exact string-match penalizes correct predictions where the order of slots within an intent is different. For example, consider the following logical-forms:

LF-1: `[IN:GET_WEATHER [SL:ATTRIBUTE rainfall] [SL:DATE today ] ]`

LF-2: `[IN:GET_WEATHER [SL:DATE today][SL:ATTRIBUTE rainfall ] ]`

LF-1 and LF-2 are equivalent but the difference in the ordering of slots results in a negative match. Thus, we correct the EM metric by making the match function agnostic to the ordering of slots within an intent in the logical-form. We compare different models as per this corrected EM metric.

Semantic Parsing Model We use a pre-trained mT5-Large checkpoint (1.2B parameters) to initialize the downstream semantic parsing models that map utterances in the input to logical-forms in the output. We finetune the mT5 model on the original English dataset mixed with the translated datasets in target languages. We train using the Adafactor optimizer (Shazeer and Stern, 2018) with a fixed learning rate of $1e{-}3$ and a batch size of 256, for 30K steps using the T5X library (Roberts et al., 2022) on 64 TPU-v3 chips. Examples from each language are sampled uniformly for batch creation. For model selection, we choose the best performing checkpoint as per the dev splits and report our results on the test splits.

LLM-T (Our Method) We experiment with 8B, 62B, and 540B sized variants of PaLM (Chowdhery et al., 2022) as our LLM, and primarily utilize LLM-540B for translating English examples in different languages. For the seed set $\mathcal{S}_{\text{tgt}}$ used for prompting the LLM, we borrow roughly 250 examples covering 11 domains from MTOP's train set and 350 examples covering 18 domains from MASSIVE's train set (§ 3.1). During decoding, we sample 8 translations per example using top-p sampling (§ 3.3), with $p = 0.95$ and temperature scaling $T = 0.7$, followed by filtering out slot-inconsistent examples (§ 3.4). We present an analysis of our design choices in § 5.3.

Baselines (i) **Zero-Shot**: Train the model only on the English data and evaluate on other languages in a zero-shot manner. (ii) **Few-Shot**: In addition to the English training data, use the seed set of examples $\mathcal{S}_{\text{tgt}}$ for each language during training. For MTOP, $|\mathcal{S}_{\text{tgt}}| \approx 250$ and for MASSIVE, $|\mathcal{S}_{\text{tgt}}| \approx 350$. (iii) **TAF**: We implement the method from Nicosia et al. (2021) that uses an off-the-shelf translation service (§ 2.2) to construct $\mathcal{D}_{\text{tgt}}$ in all the target languages. We borrow $\mathcal{D}_{\text{tgt}}$ from Nicosia et al. (2021) for MTOP and from Nicosia and Piccinno (2022) for MASSIVE.

5 Results and Analysis

We first present downstream performance of semantic parsing models trained on data generated by our method (§ 5.1) and compare with zero-shot setting, few-shot setting, and the TAF method (Nicosia et al., 2021). We then compare our method against the "full-shot" skyline where we utilize the original training datasets that were manually translated with the help of human annotators in the target languages (§ 5.2). We then present an analysis of different design choices that result in effective data translation using LLM-T (§ 5.3). Finally, we present an error analysis to show the key sources of disagreements between the parser predictions and the ground truth (§ 5.4). All the experiments use our corrected EM metric (§ 4; Evaluation Metric).

5.1 Evaluation on MTOP and MASSIVE

In Table 1, we compare performance of different methods for the 5 non-English languages in the MTOP dataset. The Zero-Shot baseline trains an mT5 model only on the English part of the train-split. The Few-Shot baseline additionally includes the human translated seed sets $\mathcal{S}_{\text{tgt}}$ for each language. Both TAF and LLM-T train on the original English train set mixed with their respective translated datasets in each language. As all the baselines utilize the original English train set, we see comparable performance on English (around 85.0 EM). We observe LLM-T outperforms TAF in 4 out of 5 languages by 3.6 EM. Since LLM-T uses $\mathcal{S}_{\text{tgt}}$ for prompting, we also mix $\mathcal{S}_{\text{tgt}}$ with TAF data and still observe that LLM-T improves over TAF+Few-Shot by 2.9 EM. On relatively low-resource languages, Hindi (`hi`) and Thai (`th`), LLM-T leads to much larger improvements over TAF.

Figure 4 shows the performance difference between our LLM-T method and TAF for the MASSIVE dataset (FitzGerald et al., 2022). On 41 out of 50 languages, we find LLM-T to be better than TAF. For nine languages LLM-T outperforms TAF by more than 5.0 EM—Simple Man-

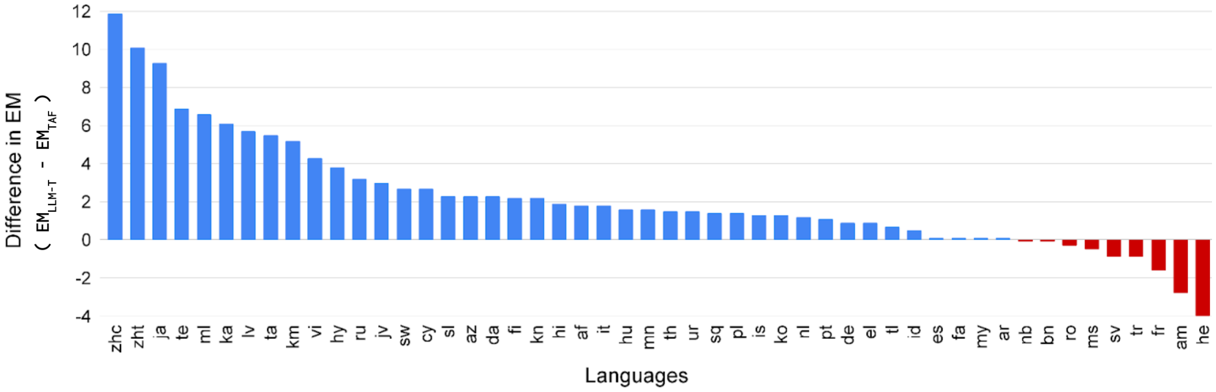

Figure 4: **EM accuracy difference between LLM-T and TAF across the 50 languages in MASSIVE dataset** (§ 5.1). LLM-T outperforms TAF on 41 out of 50 languages, with gains of more than 5 EM for nine of these languages. Only for Hebrew (he), LLM-T performs worse than TAF by more than 3 EM.

Method	**de**	**es**	**fr**	**hi**	**th**	**Avg**
Zero-Shot	54.4	57.8	62.8	42.3	42.1	51.9
Few-Shot	62.8	69.5	65.9	55.3	53.9	61.5
TAF	75.0	74.9	78.0	63.0	60.8	70.3
TAF + Few-Shot	**75.1**	74.5	78.5	63.9	62.9	71.0
LLM-T (ours)	74.0	**75.4**	**79.6**	**72.3**	**68.0**	**73.9**

Table 1: **EM accuracy comparison on MTOP** (§ 5.1): Data generated using LLM-T yields better performance on 4 out of 5 languages in MTOP. We observe large improvements for low-resource languages hi and th.

Dataset	**Few-Shot**	**TAF**	**LLM-T**	**Gold**
MTOP	61.5	70.3	73.9	**79.5**
MASSIVE	55.9	61.0	63.2	**67.7**

Table 2: **Comparison with Gold skyline** (§ 5.2): While training on the human translated datasets (Gold) yields the best performance, LLM-T results in a smaller performance gap compared to TAF. All numbers are averaged over the 5 non-English languages in MTOP.

darin (`zhc`, +11.9), Traditional Mandarin (`zht`, +10.1), Japanese (`ja`, +9.3), Telugu (`te`, +6.9), Malayalam (`ml`, +6.6), Kannada (`ka`, +6.1), Latvian (`lv`, +5.7), Tamil (`ta`, +5.5), and Khmer (`km`, +5.2). Only for Hebrew (`he`, −4.0), LLM-T is worse by more than 3.0 EM. Averaged across all languages, LLM-T outperforms TAF by 2.2 EM. In Appendix A.1, we provide detailed baseline comparisons for all the 50 languages.

5.2 Comparison with gold translations

An ideal translate-train method should be competitive w.r.t. training on fully human translated datasets. Table 2 provides a comparison between training on TAF, LLM-T, and the datasets fully translated with the help of human annotators in the target languages (Gold). Between TAF and Gold, we observe a significant gap of 9.2 EM in MTOP and 6.7 EM in MASSIVE. Our method LLM-T, reduces this gap by 3.6 EM in MTOP and 2.2 EM in MASSIVE. Overall, LLM-T achieves roughly 93% of the performance obtained by the Gold skyline that use more than 30× human translated examples. Appendix A.1, provides per-language comparisons with the Gold skyline for both the datasets.

Decoding Strategy	**de**	**es**	**fr**	**hi**	**th**	**Avg**
Greedy	71.1	71.7	72.6	68.1	66.0	69.9

Table 5: **Impact of LLM size**: EM performance of semantic parsers trained on translated datasets improve with increasing the size of LLMs used for translation.

5.3 Analysis of Design Choices

We now present an analysis of the design choices that enabled more effective data translation via LLM-T. All the experiments in this section are carried out on the MTOP dataset.

Role of decoding strategy and filtering In Table 3, we present the EM accuracy of parsers trained on datasets translated using various combinations of decoding (§ 3.3) and filtering (§ 3.4) methods. For generating the translated outputs we experiment with greedy decoding, top-k (Fan et al., 2018) and top-p (Holtzman et al., 2019) sampling. Like prior translate-train methods, we begin with only one translation per example and observe sampling to be comparable with greedy decoding in downstream EM accuracy. In contrast, decoding two translations per example via sampling boosts the EM accuracy across all the languages. However, further increasing the translated samples to 4 and 8 results in only marginal performance differences. Manual inspection of the translated data revealed inconsistent utterance and logical-form pairs which motivated our design of slot-consistency based filtering (§ 3.4). Training the parser on filtered data provides further gains over training on unfiltered data. In Appendix A.2, we also present the results for top-k sampling. Overall, utilizing upto 8 top-p translated samples per English example followed by slot-consistency filtering provides the best performance averaged over all the languages.

Impact of Prompt Length We expect prompts containing more exemplars to yield higher quality translated examples owing to more information for in-context learning. In Table 4, we compare EM performance when using maximum prompt-lengths of 768, 1024, and 1792 tokens. Training on datasets translated using prompt-length of 1792 tokens provides the best downstream EM performance across all the languages. However, longer prompts lead to considerably longer inference times. Hence, we conduct our main experiments with prompt the length of 1024 tokens.

Role of LLM size In Table 5, we compare parser performance when trained on data generated by LLMs of different sizes. Training on larger LLM generated data leads to better performance—LLM-T-540B yields the best performance on all the languages, followed by LLM-T-62B which outperforms LLM-T-8B on all the languages.

5.4 Error Analysis

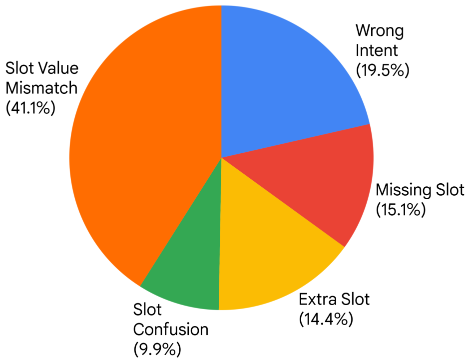

Figure 5: **Distribution of error categories**: estimated across all five languages on MTOP's dev set.

We analyze the examples where the predictions from our semantic parser do not match with the ground truth. In Table 6, we categorize all the erroneous examples into five broad categories (with English examples): (i) Slot Value Mismatch (ii) Wrong Intent (iii) Missing Slot (iv) Extra Slot and (v) Slot Confusion. Figure 5 presents the distribution of the error categories aggregated across all the languages on the MTOP dev-split. The "Slot Value Mismatch" is the most frequent error category (41.1%)—here the predicted parse structure is correct but the slot-values do not match perfectly with the gold parse. After manually inspecting 300 such errors we found that in roughly 50% of the cases the predicted and gold slot-values often have minor mismatches which may not be recognized as error by another human annotator and should not lead to incorrect output upon logical form execu-

Slot Value Mismatch (41.1%)	Utterance: Set an alarm for 5 pm tomorrow Prediction: [IN:CREATE_ALARM [SL:DATE_TIME for 5 pm] [SL:DATE_TIME tomorrow] Target: [IN:CREATE_ALARM [SL:DATE_TIME 5 pm] [SL:DATE_TIME tomorrow]
Wrong Intent (19.5%)	Utterance: What can I do today Prediction:[IN:QUESTION_NEWS [SL:DATE_TIME today]] Target: [IN:GET_EVENT [SL:DATE_TIME today]]
Missing Slot (15.1%)	Utterance: Play Justin Timberlake 's newest single Prediction:[IN:PLAY_MUSIC [SL:MUSIC_TYPE single]] Target: [IN:PLAY_MUSIC [SL:MUSIC_ARTIST_NAME Justin Timberlake] [SL:MUSIC_TYPE single]]
Extra Slot (14.4%)	Utterance: play music on the speaker Prediction: [IN:PLAY_MUSIC [SL:MUSIC_TYPE music] [SL:MUSIC_TYPE speaker]] Target: [IN:PLAY_MUSIC [SL:MUSIC_TYPE music]]
Slot Confusion (9.9%)	Utterance: audio call wedding planner please Prediction:[IN:CREATE_CALL [SL:CONTACT wedding planner]] Target: [IN:CREATE_CALL [SL:GROUP wedding planner]]

Table 6: **Examples of Error Categories** (§ 5.4) The errors in the predicted parse can be broadly classified into five categories: (i) Slot Value Mismatch: Predicted parse has the correct signature but the slot-values are incorrect, (ii) Wrong Intent: High-level intent of the predicted parse is incorrect, (iii) Missing Slot: One or more slots in the gold parse do not appear in the output, (iv) Extra Slot: Output contains extra slot(s) compared to the gold, (v) Slot Confusion: Prediced parse contains the correct correct intent and number of slots but the wrong slot-types.

tion. For example, in the first row of Table 6, the predicted value for the `DATE_TIME` slot is `'for 5 pm'`, while the target value is just `'5 pm'`.

6 Related Work

Multilingual Semantic Parsing Multilingual semantic parsers are typically initialized with a foundation model (Bommasani et al., 2021) pre-trained on vast amounts of multilingual data (Conneau et al., 2020; Xue et al., 2021; Li et al., 2021; FitzGerald et al., 2022) followed by supervised training on synthetic or real multilingual datasets. A standard approach for constructing multilingual datasets is to translate and localize English datasets with the help of multilingual speakers or machine translation. For example, MTOP (Li et al., 2021), MASSIVE (FitzGerald et al., 2022), and MultiAtis++ (Xu et al., 2020) were constructed by translating TOP (Gupta et al., 2018), SLURP (Roberts et al., 2022), and ATIS (Price, 1990) respectively through human translators.

Machine Translation based methods Machine translation based approaches continue to be important for multilingual task-specific models (Hartrumpf et al., 2008; Liang et al., 2020; Hu et al., 2020; Fang et al., 2021; Ladhak et al., 2020) including semantic parsing. Machine translation can either be used during the inference time to translate a user query into English for feeding it to an English-only model. This approach is referred to as *translate-test* (Artetxe et al., 2020; Uhrig et al., 2021). A more common way of using machine translation is in the form of data augmentation, referred as *translate-train* where English text in training data is translated into several languages (Sherborne et al., 2020; Moradshahi et al., 2020, 2021; Xia and Monti, 2021; Nicosia et al., 2021; Gritta et al., 2022; Wang et al., 2022). In practice, *translate-train* methods tend to outperform *translate-test* methods while also reducing the latency associated with translating text during the inference time (Yang et al., 2022).

LLMs and Few-Shot learning Transformer (Vaswani et al., 2017) based generative LLMs (Radford et al., 2019; Brown et al., 2020; Thoppilan et al., 2022; Soltan et al., 2022; Smith et al., 2022; Zhang et al., 2022; Chowdhery et al., 2022) trained on massive amounts of web-scale text corpora using next token prediction objective exhibit strong few-shot generalization abilities. When prompted with a task description and a handful of task-specific examples, LLMs can often match the performance of finetuned models via in-context learning (Xie et al., 2021; Min et al., 2022; Wei et al., 2022; Zhou et al., 2022). We utilize LLMs for translating English datasets in several languages using few-shot prompting.

7 Conclusion

We present a method of utilizing large language models (LLMs) for bootstrapping multilingual semantic parsers across several languages. In comparison to using off-the-shelf translation services that rely on significant amounts of human supervision, we demonstrate that prompting self-supervised LLMs can be a more effective and scalable alternative for dataset translation. We find that generating multiple diverse translations using sampling techniques followed by consistency-based filtering make the translated datasets more effective for training multilingual semantic parsers. On 41 out of 50 typologically diverse languages within two large datasets spanning several domains, our method outperforms a strong translate-train method that utilizes a supervised translation service.

8 Limitations

While translating English queries in different languages is a useful form of data augmentation, we think that further performance improvements can be obtained by careful localization of entities in the text queries. This will result in examples where the training dataset contains entities that are often talked about in the target language and might lead to less train-test domain shift. LLMs contain language specific priors which can be harnessed to perform such localization of the translated queries thus enabling more realistic data augmentations. In this work we presented a simple string-match based filtering technique to remove noisy translations. Data filtering can be further improved with the help of learned models. We observed that larger LLMs are important to generate more effective translated data. However running these experiments is constrained by the availability of large amounts of compute resources. We hope future work will address these limitations of our approach.

9 Ethical Considerations

We utilize large language models to translate datasets initially available in English into several languages. The real-world deployment of models trained on LLM-translated data should undergo a careful review of any harmful biases. However, the LLM-translated data and the logical-forms generated by a semantic parser are not user-facing, thus a smaller risk of any direct harms. The intended users of any semantic parsing model must be made aware that the answers returned by the model could be incorrect, more so for user-queries in low-resource languages. We do not immediately foresee any serious negative implications of the specific contributions that we make in this work.

10 Acknowledgment

We thank Rahul Goel, Slav Petrov, and Kartikeya Badola for discussions and their feedback on an earlier draft of this paper. We thank Massimo Nicosia for sharing the TAF translated datasets and helpful discussions during this project.

Abstract

Event scenarios are often complex and involve multiple event sequences connected through different entity participants. Exploring such complex scenarios requires an ability to branch through different sequences, something that is difficult to achieve with standard event language modeling. To address this, we propose a question-guided generation framework that models events in complex scenarios as answers to questions about participants. At any step in the generation process, the framework uses the previously generated events as context, but generates the next event as an answer to one of three questions: *what else a participant did, what else happened to a participant, or what else happened*. The participants and the questions themselves can be sampled or be provided as input from a user, allowing for controllable exploration. Our empirical evaluation shows that this question-guided generation provides better coverage of participants, diverse events within a domain, comparable perplexities for modeling event sequences, and more effective control for interactive schema generation[1].

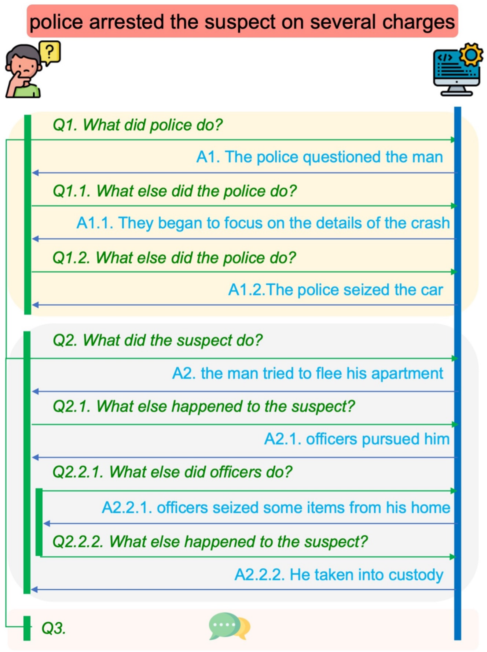

Figure 1: Question-guided event sequence generation. The user can interact with the system by asking questions regarding the entities and the system will generate corresponding events. Different questions can lead to different paths as shown with different colored boxes.

1 Introduction

Event scripts (Schank and Abelson, 1977), also known as event schemas, describe a sequence of events in a particular context. Representing and modeling such schemas is central to applications in AI such as question answering, discourse understanding, and information extraction (Balasubramanian et al., 2013). Early work used hand-crafted event schemas as a starting point (Schank and Abelson, 1977; Mooney and DeJong, 1985), but modern techniques attempt to extract these at a large scale from unlabeled data (Chambers and Jurafsky, 2008; Chambers, 2013; Pichotta and Mooney, 2016; Weber et al., 2018b).

Event language models can also be used to approximate schematic knowledge via event sequences. They can be trained to generate a sequence of events with their participating roles describing a real-life scenario. However, these scenarios can often be complex and don't always fit as simple sequences (Weber et al., 2018b). For example, suppose we have the following event: `police arrested suspect on several charges`, with **`police`**, **`suspect`** and **`charges`** as entities. The scenario can be described in multiple ways depending on which entities we want to focus on and what roles they play in the subsequent events. We may be interested in knowing what the **`police`** did, what the **`suspect`** did or what happened to the **`charges`**, each of which can be explored as its own sequence,

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2468–2483
May 2-6, 2023

yielding many interconnected sequences of events in the scenario. An event language model, however, will simply generate events conditioned on the previous events in the discourse, with no direct mechanism to guide generation towards areas of interest within the scenario. As a result, with standard decoding strategies we often end up with a sequence of events that might be relevant to the scenario, but not necessarily cover the broad set of diverse paths in the scenario; we would only know the fate of certain entities if the system samples events that included them. This lack of control will make it difficult to use the system, as one must keep sampling events until it just happens to produce events with roles one is interested in.

We propose a simple modification in which event language models are trained to also condition on the entities and the roles they play in a scenario through a set of simple questions, as illustrated in Figure 1. Given the same example event and its entities, one can then explore the scenario through various paths by asking the system to generate the events with their desired entities and roles. Such a question-guided model can be used in interactive settings to model and construct diverse paths that cover various aspects of complex scenarios.

A key challenge, however, is in creating the necessary training data at scale. We show that we can repurpose standard event sequences to create training data for question-guided models: we take a partial sequence of events as context and derive a role-based question involving an entity for which a future event in the sequence can be an answer. This allows for creating large scale training instances that are (Context, Question, Answer) triples, which then allows us to train models that can better respond to user control in the form of questions.

Our analysis shows that question-guided event language models can generate sequences with more diversity and comparable quality as an event language model. Our human evaluation of the model in an interactive setting, shows that the controllability of the question-guided model allows for generation of sequences that lead to better quality, broader-coverage schemas with fewer interactions. This interactive evaluation is a step toward constructing schematic/common-sense knowledge for analyzing events, an application in the intelligence analysis community.

In summary, this paper makes the following contributions; (i) It argues the need for control in event language models to explore complex scenarios; (ii) It provides a simple yet effective way for training event language models that can be guided to explore different aspects of complex scenarios; (iii) It provides empirical evidence showing improved control and utility via automatic and manual evaluations.

2 Related Work

Event Schema Induction Event scripts (or schemas) originally proposed by (Schank and Abelson, 1977), consist of a set of events and actors (also known as slots) playing different roles. The event schemas are capable of analyzing complex situations by encoding information from prototypical events and their participants.

Early works on scripts considered them as structured representations of events and their participants with the causal relationships between them (Schank and Abelson, 1977; Mooney and DeJong, 1985). However, the manual construction of scripts is too time-consuming and does not scale, so the scripts could only focus on specific domains of interest and have not been used more broadly.

Event schemas can also be induced automatically from text using statistical techniques in an unsupervised fashion (Chambers and Jurafsky, 2008, 2009; Balasubramanian et al., 2013). These models are easily interpretable but fail to capture long-distance complex relationships between events. Event language modeling is a type of schema induction via language modeling techniques (Rezaee et al., 2021). Given a sequence of events, the event language model predicts the probability of the next event (Manshadi et al., 2008). Framing schema learning as a language modeling problem with various ways to represent events, including word sequences annotated with predicate-argument structure (Pichotta and Mooney, 2016), OpenIE tuples (Rudinger et al., 2015; Weber et al., 2018a,b) or compositional embeddings (Modi, 2016), is another direction towards realizing large-scale schema libraries.

Graph schema induction methods (Li et al., 2020, 2021) model different relations between entities and their arguments to capture the multi-dimensionality of scenarios. Reasoning about complex relations between events requires going beyond the single dimension of event cooccurrence and capturing different types of semantic relations between events such as causal, counterfactual, etc. (Han et al., 2021). Our approach uses the standard language models and provides them with the guidance to also produce different aspects of a scenario via simple control codes.

Controlled text generation Language models have shown promising results in text generation, however, it is not easy to have control over different aspects of generation (Keskar et al., 2019), an issue that has been studied in previous works (Dathathri et al., 2019; He et al., 2020; Lu et al., 2021; Mireshghallah et al., 2022). The key components of these methods differ in the types of controls provided and how they are provided and their applications. CTRL (Keskar et al., 2019) trains a very large language model by conditioning on texts with appended control codes that are used to guide the generation towards specific styles, contents, and task-specific behaviors. CTRLSum (He et al., 2020) uses the entity/length controls which are in forms of keywords that are automatically extracted from the text and trains a summarization system which is capable of generating summaries in an interactive manner. These approaches, however, require finetuning. Dathathri et al. (2019) and Mireshghallah et al. (2022) propose variants of controllable generation with no need to finetune or retrain the whole system.

Learning latent representations or codes from the input towards diverse generation is another direction that has been explored for machine translation (Shu et al., 2019), dialogue generation (Huang et al., 2018) and causal relations generation (Weir et al., 2020). Controllable generation to generate diverse events has been previously studied in Kwon et al. (2021), where the system uses automatically generated control codes to generate diverse preconditions of events.

In this work, we use controllable generation to model complex event scenarios. We introduce simple role-based questions about participants (agentive or non-agentive) as an effective means for control. Asking questions to get specific information about events is the focus of many existing approaches. While there has also been a body of work on semantic role labeling using QA pairs (Roit et al., 2020; Klein et al., 2020; Michael and Zettlemoyer, 2021; Pyatkin et al., 2021), the main distinction here lies in the fact that these approaches use QA pairs to identify the semantic roles, whereas our approach makes use of role-based questions to generate the next event with a specific entity playing a specific role. We show how to train for these control codes using automatically derived training sequences and demonstrate its utility for describing complex scenarios in an interactive setting.

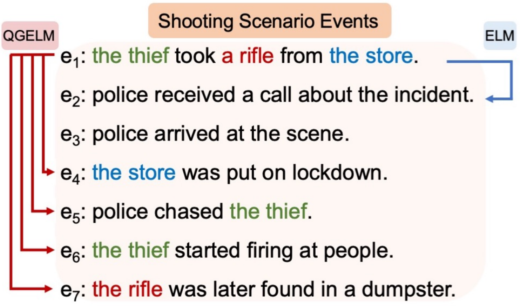

Figure 2: The shooting scenario events extracted from a news article. Typical LMs only see e_2 as the immediate next event, whereas for the question-guided LMs, any of the e_4, e_5, e_6 and e_7 involving *the store*, *the thief*, or *the rifle* can be considered a next event.

3 Question-guided Event Language Modeling

Event language models aim at predicting the probability of an event given a set of events via a conditional probability distribution. Formally, these models try to find an event $\hat{e}$ by maximizing the probability of a function parameterized by a model over a given context including a set of events:

$$\hat{\mathrm{e}} = \mathrm{argmax}_{\mathrm{e} \in \mathrm{E}} \mathrm{P}_\theta(\mathrm{e} \mid \mathrm{context})$$

where E is the set of all events. A model trained with this objective learns to generate the most probable event based on a set of cooccurring events from discourse. Suppose that shooting scenario events are extracted as shown in Figure 2. Given the first event in the sequence, a typical language model is trained to generate the next event, e_2, which does not include any entities from the prior context. What if we are interested in looking for events regarding the initial participants (*the thief*, *a rifle*, or *the store*) in this example? Given the same context, we can have multiple next events depending on the participant and the role they can have (agent or theme). If we are interested in knowing what *the thief* did, e_6 should be the next event, what happened to *the thief* is described in e_5. We can have some information about *the store* with e_4 as the next event and finally, the fate of *the rifle* is described in e_7. Controlling the model to generate the outputs based on the participants involved cannot be easily achieved with unguided (text ordered) event language models. However, we will show

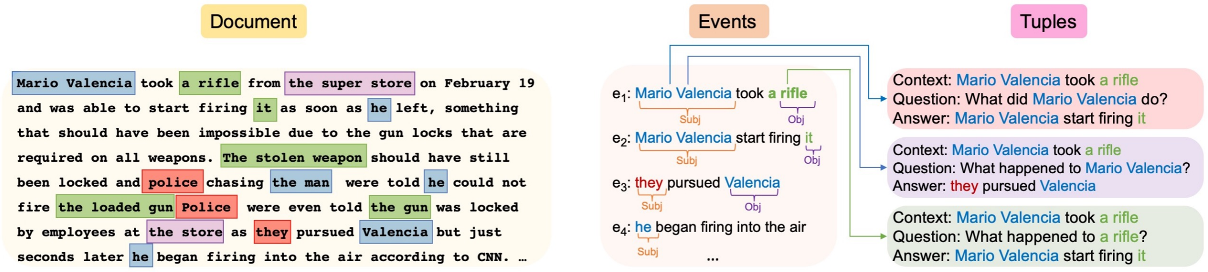

Figure 3: Data processing to create instances for a question-guided event language model. Given a document, we extract all the coreferring clusters (color-coded in the document). Next, we extract OpenIE tuples as events representations. By identifying the roles of noun phrases in the events as well as knowing which cluster they belong to, we create questions for each one of them and similarly find the events that can serve as the answers to those questions. The context can be of any length whereas the answer event is of length 1.

how the language models can be guided such that given the same context, they can directly generate events for its participants.

3.1 Problem Definition

We propose a new framing in which an event language model can be guided to generate events by not only conditioning on the events but also on specific entity-based questions of interest.

These entity-aware event language models also look to find $\hat{e}$, but by maximizing the probability of a function parameterized by a model over a given context *and* a question regarding an entity:

$$\hat{\mathrm{e}} = \mathrm{argmax}_{\mathrm{e} \in \mathrm{E}} \mathrm{P}_{\theta}(\mathrm{e} \mid \mathrm{context}, \mathrm{question})$$

The objective now conditions on a question as well, and the goal is to use the question to train a system to generate the most probable event for a specific entity (or a noun phrase referring to that entity) in a specific role (agent or theme). As shown in Figure 1, questions can either ask about what an entity did as an agent of an action (*what did X do?*) or what happened to an entity as a theme of an action (*what happened to X?*). By conditioning on the question as well, the system will learn to generate an event with the entity in question as well as the role specified by that question.

3.2 Question-guided Training

Event language models are typically trained using event sequences extracted from documents. Our goal, however, is to train event language models to generate events as *answers* to *questions* about entities from a given *context*. To this end, we convert event sequences in text to *(Context, Question, Answer)* tuples (CQA instances) that can be used as training data for question-guided generation.

Consider a sequence $e_1, e_2, ...e_n$ of OpenIE event tuples extracted from a document D. We create *(Context, Question, Answer)* tuples for each event e_t in the sequence as outlined in Algorithm 1 in Appendix A.1 and Figure 3. The key idea behind this process is as follows: Suppose we observe an entity in an event e_i. If this entity also appears in a subsequent event e_k, then we can see this new event as an answer to a role-based question about the entity (what did the entity do or what happened to the entity), given what we know about all the events that have been observed thus far in the sequence as context. For example, as shown in Figure 3, the entity `Mario Valencia` appears in two events e_1 and e_2. Given the context e_1, we can create the question *What did Mario Valencia do?* for which the answer is e_2 i.e., *Mario Valencia started firing it*. Formally, for each entity (any noun phrase) np that appears as an argument in the event e_i, we do the following. If np appears in an agentive role in some subsequent event e_k ($k > i$), then we associate the question *What else did* np *do?* with the context and use event e_k as the answer to the question. If np appears in a non-agentive role, we associate *What else happened to* np*?* as the question and e_k as the answer. In either case, for the next step the context is extended to include e_k and the process is repeated for all arguments in e_k. To handle events e_k that introduce new entities as arguments, we use *What else happened?* as the question.

We use automatically identified coreference clusters to locate event mentions involving a specific entity. We use simple dependency-based heuristics to determine the role of an entity in an event. Given the noun phrases of an event, we use a dependency parser to identify their roles. An entity is deemed to appear in an agentive role if it appears as a sub-

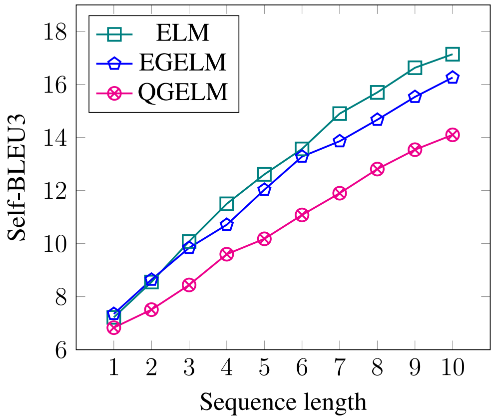

Figure 4: Diversity of generated sequences of events with varying lengths. Lower Self-BLEU scores are better as they represent more diverse sequences. QGELM is the most diverse across all sequence lengths.

		beam	sampling	
Criteria	**System**	**Fail %** ▼	**Fail %** ▼	**Avg # samples**

Table 1: Controllability Assessment: Fail % denotes the number of instances where the model fails to generate the specified entity. For sampling, we also show the average number of samples needed before an event with the specified entity is generated. ND denotes NeuroLogic decoding (Lu et al., 2021), a beam-search based controllable method with no sampling strategy.

ject and in a non-agentive role if it appears as an object. We only use these two broad categories (subject and object) to identify events as responses to specific questions. This process will automatically filter out the nonsensical questions as for such questions, no event can be found within the given sequence of events.

Note this training data has two properties that are different from standard auto-regressive training over event sequences. First, for the same conditioning context of event tuples, the model learns to generate multiple subsequent events depending on the question being asked, thus ensuring better control and diversity. Second, the model also learns to generate events that are not always adjacent to the end of the current sequence, which can be seen as a form of data augmentation shown to be effective (Koupaee et al., 2021).

4 Experimental Setup

4.1 Models

All models used in our experiments are trained using event sequences, which are OpenIE (Mausam et al., 2012) tuples extracted from articles in their discourse order.

ELM Our baseline is an **E**vent **L**anguage **M**odel trained such that given a context (a set of events), it will generate the next event. The baseline model follows the existing mechanisms used in recent prior ELM work (Manshadi et al., 2008; Rudinger et al., 2015; Pichotta and Mooney, 2016; Weber et al., 2018a,b). We train a T5 base model to learn $P(e_n \mid \text{context})$ where context $= e_1, ..., e_{n-1}$.

EGELM The **E**ntity-**G**uided **E**vent **L**anguage **M**odel generates the next event conditioned both on the context and one of its entities by learning the following probability distribution:

$$\mathrm{P}(\mathrm{e_n} \mid \mathrm{context}, \mathrm{entity})$$

In this setting, the system learns to maximize the probability of the next event with respect to a specific entity from the context but without considering the specific role in which the entity appears in the generated event. The training instances in this case are (Context, Entity, Answer) tuples that are obtained by replacing the question with the entity mention present in the question in the training instances described in Section 3.2.

QGELM The **Q**uestion-**G**uided **E**vent **L**anguage **M**odel generates the next event conditioned both on the context and a question regarding one of the entities in the context and a ***role*** the entity plays in the event. Here, the system learns the following probability distribution:

$$\mathrm{P}(\mathrm{e_n} \mid \mathrm{context}, \mathrm{question})$$

The main difference with the entity-only system is the different roles an entity can have through the question's surface form.

4.2 Data Statistics

We train all the models on the 2007 portion of the Annotated NYT corpus (Sandhaus, 2008). This subset contains a total of around 38k articles spanning over a 6 month period. Following the steps

System	Perplexity ▼	NC Accuracy▲
ELM	24.64	46.2%
EGELM	22.45	48.6%
EGELM (margin)	25.06	46.8%
QGELM	**22.11**	**49.3%**
QGELM (margin)	26.63	46.0%

Table 2: Perplexity and the narrative cloze accuracy. Lower perplexity and higher accuracy is desirable.

Metric	ELM	QGELM	change
# accepted events▲	6.2	8.8	42% ↑
# rejected steps▼	5.2	3.2	38% ↓
% rejected steps▼	41.0	26.6	35% ↓
# resamples▼	4.9	3.2	35% ↓
total steps▲	11.3	12.0	6% ↑
tree depth▲	5.8	8.8	52% ↑

Table 3: Quantitative analysis of schema generation using the ELM and QGELM models. With QGELM, users accepted more of its suggested events, rejected fewer steps, used fewer resamples for a given context, and produced longer event sequences. The higher the average the better a system is for metrics with ▲ whereas lower values are desired for metrics with ▼.

described earlier on these number of articles, we end up having over 700k instances (consisting of (context:$e_1, e_2, ..., e_{t-1}$, question:q, answer:e_t) tuples) used to train the guided systems. For more details on the data statistics and experimental settings, please refer to the Appendix A.1.1 and A.2. The code will be released upon acceptance.

5 Evaluation

We assess the utility of the question-guided event language modeling in terms of four aspects: (i) Diversity: are they able to generate diverse sets of events that relate to a scenario? (ii) Control: do they generate events involving the specific entities in desired roles? (iii) Sequence modeling ability: how well can it predict observed events?, (iv) Interactive Utility: do users generate better sequences when using the model to collect events that fit a scenario?

5.1 QGELM Improves Diversity

We want event language models to generate diverse sequences covering different aspects of a scenario. To assess diversity in generation, we first sample multiple sequences from the models. Given a context (starting with a context of length 1), we incrementally generate events by sampling one event at a time until we generate a sequence of a predefined length. We repeat this process to generate multiple sequences. We then measure the diversity of these sequences using Self-BLEU (Zhu et al., 2018), which is the average of the BLEU scores (Papineni et al., 2002) when using one of the generated sequence as the output and the rest as references.

First, we collected test instances that had a context length of one, which amounted to 938 instances. The models were used to generate five sequences of lengths one through ten (i.e., five sequences of length one, five of length two and so on). For EGELM and QGELM we randomly choose an entity/question to generate the next event. For each model, we then compute the Self-BLEU score of its five sequences of a specific length. Figure 4 shows the average Self-BLEU over the test instances when generating sequences of different lengths. Lower Self-BLEU scores represent more diverse sequences. Self-BLEU of question-guided outputs are lower compared to that of the other two models showing improved diversity. With longer sequences Self-BLEU increases for all models as there is more potential for overlap. However, the question-guided model retains higher levels of diversity compared to the rest. Standard event language modeling tends to cover the same types of events across different samples and to some extent conditioning on entities helps improve this to a small degree. Conditioning on the questions, however, yields significant gains in diversity showing promise for improved coverage of scenarios.

5.2 QGELM Controls for Entity Roles

To quantify controllability, we introduce a metric that measures how many times a system is capable of generating an event in which a specified entity of interest is present. We generate a fixed number of outputs from each model under two decoding strategies: sampling and beam decoding. We report the percentage of times the specified entity or a coreferent mention[2] of it fails to appear in the outputs. In addition to ELM, we also use NeuroLogic decoding (ND) (Lu et al., 2021), a state-of-the-art controllable generation system as a baseline.

The top block of Table 1 (Any presence) compares the models on the number of times they failed to generate an event with the specified entity within a beam of size 40 or within 40 sampling attempts

---

[2] A mention is considered coreferent to the input noun phrase if the mention and original noun phrase appear in the same coreference cluster extracted from the sampled sequence of events which includes the original context event.

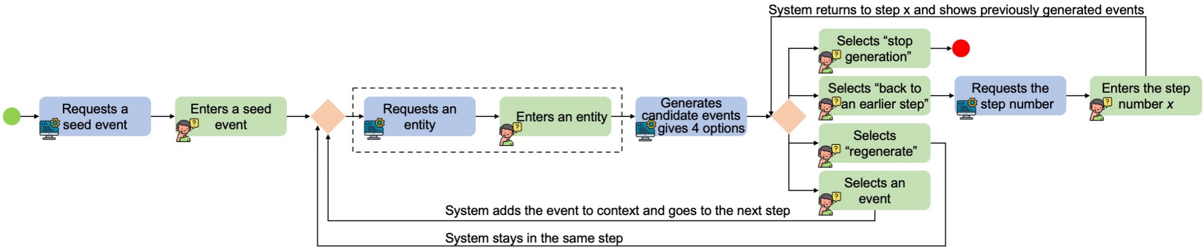

Figure 5: The overview of the interactive schema generation tool. The dashed box is only used for QGELM. The interaction starts by system asking for a seed event and the user entering an event. For QGELM, the user is asked for an entity of interest. This part is shown with a dashed box (this part is not needed for ELM). The system then samples 4 events (If QGELM, it automatically creates questions for the given entity and generates two responses per question.) These 4 events will be presented to the user where they can select an option out of 4 choices. 1. Select one of the given events. 2. Ask the system to generate a new set of events. 3. Return to an earlier step to explore a different path by entering the step number and 4. Stop the generation for the given seed.

(%Fail), and the average number of events that had to be sampled to see the entity or its coreferent mention in the output when sampling (Avg #samples). With beam decoding, ELM performs the worst since it has no control over the generation. NeuroLogic decoding does a better job at searching for events that meet the entity constraints in the model's beam. EGELM which is trained to generate events with the given entity does better even with standard beam decoding. QGELM fares even better outperforming all methods by a significant margin. With sampling, ELM works better but still fails to produce events with the input entity in more than a quarter of the cases. Both entity and question guided models respond to the input control, almost always yielding events with the input entity and much earlier in the ranked list.

The bottom block of Table 1 (Role specific presence) compares the models when we are looking for events where the input entity is expected to appear in a specific role. We use the same dependency-based heuristics we described in Section 3.2 for determining the role of an entity in a given event. With beam decoding, NeuroLogic decoding (ND) is worse than QGELM with a larger margin since it can only be constrained to generate the entity but not in ***specific*** position and role. The larger gap here shows the superiority of our question control codes to not only generate an entity but also to generate it in a specific role. ELM fares even worse, with more failures and requiring even more samples to generate the entity in the specified role. Also, as expected, EGELM has a larger gap compared to QGELM which is trained to account for the roles in which the entities appear.

Note that the coreference resolution system and the dependency parser are not perfect and therefore our heuristics for deciding both when a entity is mentioned in an event and when it appears in a specific role can be faulty. A manual inspection of the outputs for 50 entities across all systems showed that the heuristic is more than 75% accurate and the mistakes are uniform across the models.

5.3 QGELM is a good event LM

How does question-guided training affect the raw ability to generate "standard" event sequences? Predicting observed events in a discourse can be seen as a downstream evaluation. To assess this, we compare the perplexities as well as the narrative cloze task accuracy of the models using the event sequences we observe in the test set. The results are presented in Table 2. One way to turn the question guided-model into a standard event language model is to marginalize its probabilities for outputs over all possible questions we can ask at every step (marked as margin in the table): $P(e_n \mid C) = \sum_{q \in Q} P(q \mid C) P(e_n \mid q, C)$, where we assume a uniform prior distribution $P(q \mid C)$ over questions that can be asked. Similarly, for the entity guided model we can marginalize over the set of noun phrases in the most recent event in the context (this setting is similar to how we created the training instances). While this allows for fair comparison as a standard event language model, this is likely a lower bound for the model's ability for its intended use as a controllable model.

We compute the average per token perplexities for the instances of the test set (including (C,Q,A) tuples) which are shown in Table 2. Although the marginalized performance is lower because the model is forced to generate the event given sub-

	Crimes	Outbreak	Disaster	Kidnapping	Cyberattck	IED	Shooting	Conflict	Overall
ELM	10.71	16.39	23.81	8.00	11.11	13.89	21.05	**30.56**	16.24
QGELM	**28.57**	**27.87**	**33.33**	**14.00**	**16.67**	**16.67**	**23.68**	25.00	**23.22**

Table 4: Percentage of the overlap between system-generated events and manually curated schemas. Overall, the QGELM system generates more diverse set of events, therefore having a higher recall (higher percentage of overlap) compared to the ELM (for all domains except one). More details can be found in Appendix A.3.4

Domain	ELM	QGELM
mass shooting	police evacuated the surrounding buildings after the shooting. the area resuscitated as soon as officials arrived. the area in search of survivors. a police helicopter carrying three officers fired at the shooting center. the police still searching for victims. the police found the bodies of four people. the bodies of two of them found in a second car.	police evacuated the surrounding buildings after the shooting. he identified as a man. a detective questioned the suspect. the police identified the gunman. the officers heard noise from the building. they spoke with him. he moved in an apartment that was recently renovated. they worked on the scene to identify the gunman. the officers involved in an investigation. he notified about the shooting. the police found no weapon in the apartment. officers searched two buildings in the immediate area near the building. the shooting began on saturday. police officers questioned him about the shooting. The officer called victims at 6:45. the officer questioned again in the area. the shooter shot two times. the shooting began with three or four shots of the gunman. he started firing slowly his gun
kidnapping	the kidnapper ambushed the target. the kidnappers shot in the arm. they shot the men. he still not identified by the authorities. the other men also gunshot wounds. the attack left six people in critical condition and his condition.	the kidnapper ambushed the target. the kidnapping triggered by an act of rebellion. he left the scene. the target captured by a surprise attack. the kidnapping of the target essentially a symbolic step in the long struggle. mr. seymour to talk about the kidnapping. the police found a handgun. the hideout an informal area of community groups in rural part of town

Table 5: Generated examples through human interaction. A mass shooting scenario in the first example, can include high level schemas such as planning, occurrence, immediate response, investigation, etc. The QGELM covered more aspects compared to the ELM. As for the QGELM, the entities can easily be tracked based on the questions asked, and therefore there are fewer ambiguous red entities (not clear what/who they are referring to.) compared to ELM in the second example. More examples can be found in Appendix A.3.6.

optimal conditions, we see that with appropriate guidance (the question from the dataset itself), the perplexity of the true event is lower. Moreover, QGELM achieves the lowest perplexity in these settings, indicating that its control is most fine-grained and allows users the highest degree of control. We also computed the accuracy of the cloze task in which each system has to correctly predict the gold output from a fixed set of events. Following Weber et al. (2018b), for each article from the test set, we randomly select an instance (context, question, answer) and then for each instance we create 5 confounding events as answers by randomly selecting instances from other documents. The task would be then picking the correct option from the given six choices (gold+confoundings). The results show that the accuracy trends align with the perplexity trends indicating that QGELM is comparable as a event language model to the baselines we build on.

5.4 Interactive Schema Generation

Event language models can be used to generate event sequences that approximate a schematic description of how events typically happen in certain scenarios (i.e. event schemas) (Weber et al., 2018a,b; Pichotta and Mooney, 2016).

Task setup We evaluate the utility of our new question-driven models when used in an interactive system, where a user collects a set of output events from the model that they think best describes a scenario. The overview of the system is depicted in Figure 5. We manually selected 35 seeds from 8 common domains and asked 7 users (graduate students from NLP and non-NLP labs) to spend 4 minutes interacting with each system. They were asked to generate sequences of events for given seeds using ELM and QGELM systems in a randomized order. For each scenario, the user is given a seed event and is tasked with collecting a set of events that *best describe the scenario*. At each step the user is presented with a set of generated events from the model and the user selects one of the events to add it to their collected set. The added events optionally become part of the conditioning context for more events. The user has the option to either regenerate events for the same context or go back and choose a subset of context from which to generate events. For the guided model, the events are generated by conditioning on questions. Since this is a timed practice, instead of asking the users to type in a full question, we only ask them to provide the system with an entity of interest. The system then automatically forms two questions (agentive, non-agentive) with the entity and outputs a mix of the events generated with all the questions. Additional details of this study including the settings, motivations for the timed version as well as instructions for the users are listed in Appendix A.3.

At each step the user selects the best event that meets the following criteria: (i) *Sensibleness*: whether the generated event is grammatically correct, sensible and easy to understand. (ii) *Uniqueness*: events do not duplicate each other and describe different subevents. (iii) *Relatedness*: events are related to the domain. (iv) *Typicality*: the events are quite common for things in this domain and not too niche. For each event, the users make a binary judgment on whether each criteria is satisfied. If any of the criteria is not satisfied then the event is not selected. If no event meets all these criteria then the user either regenerates from the same context or moves to an earlier context. Each user interaction with the system results in a sequence of events in the form of a tree, as users might have explored different paths by selecting different events at each step. Table 5 shows example outputs.

Analysis Table 3 shows that with the QGELM based interactive system, users accept more of the system suggested events, which means that more events meet the criteria we set for good events. They ask for fewer resampling steps, require fewer returns to earlier steps and thus having fewer reject steps or wasted steps in their interaction. They also produce longer descriptions of the scenarios with higher tree-depth i.e. the length of the longest sequence they generated within a domain.

We further analyze the output generated using the interactive system to assess their utility in creating complex schematic knowledge. The seeds we use come from 8 different domains relevant to the intelligence analysis community. For each domain we have access to manually curated schemas created by ten language experts in collaboration with the intelligence analysis experts over multiple days. An example of such schema is presented in Table 9 in Appendix A.3.5. We used these schemas as references and compared the percentage of overlap between system generated events selected by the users (within the four minute interaction) and the events in the reference schemas. The results in Table 4 show that both automatic systems can generate events that are expected to describe certain scenarios, however, the events generated by QGELM tend to have higher recall compared to the ELM (in 7 out of 8 domains).

6 Conclusion

Controlling event language models to generate events with respect to the participants is not trivial. We propose a simple yet effective question-guided approach that learns to generate events by not only conditioning on the events but also on specific entity-based questions of interest. Our empirical analysis shows that this approach can be used to generate more diverse sequences with better coverage and controllability allowing for better modeling of complex scenarios.

7 Limitations

One of the limitations of our proposed approach is the coverage of the entity roles. We have used two broad categories of roles, mainly agentive (subject) and non-agentive (object) roles, however, there can be more fine-grained semantic roles for the participating entities in the events such as agent, patient, theme, manner, etc. Considering this taxonomy of semantic roles can lead to finer-grained questions which might lead to even richer descriptions of the scenarios. Also, the human evaluation setting is limited since it is timed and users can not explore the models to their fullest extent. However, our analysis of the systems, when not timed, shows even a higher margin in terms of performance with the QGELM model.

8 Ethics Statement

The models presented in the paper make use of the existing pretrained systems that train on large collections of data and are known to inherit biases that are existent in the training data. The event language models we train are also susceptible to these biases, which can result in generation of event sequences with these biases.

A Appendix

A.1 Data Processing Details

QGELM uses the data in the form of (Context, Question, Answer) tuples. The details of the data processing is outlined in Algorithm 1.

Algorithm 1 Data Processing

```
Input: $D$, Document, Output: $T$, List of (Context, Question, Answer) tuples
extract OpenIE event tuples $E$ from $D$
find co-referring clusters $Clusters$ from $D$
for $e_i$ in $E$:
    find all nps $N_{e_i}$
    for each $np$ in $N_{e_i}$:
        generate $Q_{np}$
        for each $q_j$ in $Q_{np}$ for $np$ with role $r_j$
            find an event $e_k$ $(k > i)$ with $np$ with role $r_j$
            add $(e_1..e_i, q_j, e_k)$ to $T$
```

We use AllenNLP (Gardner et al., 2018) for coreference resolution to find the clusters in a document and the spaCy (Honnibal et al., 2020) dependency parser to identify all the noun phrases and their roles within an event.

A.1.1 Data Statistics

We initially extract Open IE event tuples from $37,924$ articles from the 2007 portion of the NYT Annotated Corpus using Ollie (Schmitz et al., 2012). All the extracted events from a single document are concatenated to form a single event sequence for that document. Therefore, we end up having $37,924$ event sequences with average length of 27 events.

Then, we run the data processing algorithm on the extracted sequences to generate (Context, Question, Answer) tuples. Table 6 shows the data statistics of the dataset.

split	Total	Q1	Q2	Q3
All data	762,004	466,757	188,300	106,947
Train	752,004	460,573	185,582	105,579
Dev	5,000	3,091	1,212	697
Test	5,000	3,093	1,236	671
Common Test	18953	11,712	4,412	2,829

Table 6: Data Statistics of the (Context, Question, Answer) tuples for different types of questions. Q1 refers to *what else happened?*, Q2 is *what else did np do?* and Q3 is *what else happened to np?*

A.2 Experimental Settings

A.2.1 Input/Output format

For the ELM, the input will be the context and the output will be the next event. For EGELM and QGELM, the input will be the concatenation of the context and the entity/question, separated by [SEP] token. Since the input can be more than 512 tokens (in case of long contexts), we need to truncate the input. Truncating the input from its end (for EGELM and QGELM) will result in input sequences without entity/question. To avoid this, we instead truncate from the beginning of the input sequence by removing the earlier events in the context. We remove events and not tokens from the context until its length is within the model input size. The length of the output is also fixed at 50 tokens.

A.2.2 Systems Details

Our systems finetune a pre-trained T5-base model and tokenizer with the implementation from Huggingface library (Wolf et al., 2020). Adam optimizer (Kingma and Ba, 2014) is used with an initial learning rate of $6.25e-5$.

We use a batch size of 4. Each training epoch takes almost 24 hours to run. We use the dev set for early stopping. All the systems will converge after 3 epochs.

A.3 Evaluation

A.3.1 Interactive Evaluation Setup

The details of the settings of the interactive evaluation are presented in Table 7.

A.3.2 Interactive Evaluation Design Choices

Some design choices for this evaluation are constrained by practicalities that would ensure a fair comparison. We initially had used an untimed version where users could interact with the system indefinitely. However, we found that users spent different amounts of time working, making it near impossible to do fair comparisons across systems. Further, users found it difficult to retain focus over longer periods of time.

As for using an entity of interest instead of typing questions, typing questions at every stage induces a burden on the user and introduces variance because of typing speeds. But note that even though they only select an entity, the roles are used as part of the questions we generate for the entity. Half of the generated answers are with the entity in the subject role and the other half are in the object role. Users can pick whatever role they want to explore.

Parameters	**Values**
number of seed events	35
number of users	7
number of seeds per worker	5
allotted minutes	4
number of generated events per step	4
number of domains	8
domains: disease outbreak, cyberattack, ied, international conflict, kidnapping, disaster, mass shooting, financial crimes	

Table 7: The parameters of the human generation task.

Domain	**# seeds**	**# gold events**
Crimes	4	28
Outbreak	6	61
Disaster	5	42
Kidnapping	4	50
Cyberattck	3	54
IED	3	36
Shooting	5	38
Conflict	5	36

Table 8: The statistics of the human evaluation in terms of number of seeds and the number of gold sequence events.

A.3.3 Instructions for Users

Below, you can find the guidelines that were provided to the users prior to starting the task.

User Manual This study is aimed at evaluating the capabilities of the event language models in generating a sequence of events with their participating arguments that can be used to describe a scenario. For each scenario, a seed event will be given. Using the seed event, you can start generating the sequence incrementally by selecting the best event at each step based on the following set of criteria:

At each step select an event that is: grammatical/understandable non-redundant or unique: events do not duplicate each other and describe different subevents on-topic: events are related to the domain and not unrelated typical: the events are quite common for things in this domain and not too niche (for example, earthquake could cause a nuclear reactor to meltdown but it's not common)

You will use two different systems to do this task. For one system you only need to select the events at each step while for the other, at each step you initially type an entity of interest and then pick the best event. This task will be timed, and you keep interacting with the system for 4 minutes, exploring different paths and entities. Once the time is over, the generation stops automatically.

User Interface: Once you run the commands, the system will load the pretrained models which will take a few seconds and then it will ask you to enter the seed event (The seeds will be given to you). Then you need to follow the prompts at each step for the allotted time. At each step there will be 4 actions you can take: Choose a preferred event generated at that step. You will be shown a set of events from which you can pick the best one according to the above criteria. Regenerate events for the last step. If you feel none of the generated events satisfy the criteria, you can choose this option so that the system will generate a different set of events for this step. Please use this option if NONE of the generated events satisfy the criteria. Choose an earlier step to return to. If you get stuck in one path and cannot generate events, you can choose to go back to an earlier step and continue the generation from a different path. Once you choose to return, the current set of events will be saved. Stop generation for the given seed event. If you think the system has generated enough events to describe the scenario or if it is no longer generating good events, then you can decide to stop the generation even if the allotted time is not yet over.

Notes regarding the entities: If you are asked for an entity, you can have the following things in mind: You are given an initial set of entities that are relevant to the given scenario. You can pick entities from this set, think of other entities that might be relevant, pick entities from already generated events or just select 'none' if you cannot think of an entity. You do not need to use all the given entities and you can choose the same entity if you think that is a main entity in the scenario or if you are interested in knowing more about that entity. You can generate a sequence which is centered around one specific entity. For instance, you can have an event sequence like this for the earthquake scenario where 'earthquake' is an argument in all the generated events: earthquake struck city, earthquake magnitude measured on scale, earthquake killed people, earthquake injured people, earthquake damaged buildings, earthquake disrupted services,...

A.3.4 System-generated events VS Manually-curated schemas

We tried to show the plausibility of the system-generated events by comparing the system outputs with schemas that are curated by a group of experts for different domains. We initially used a number of seed events from these domains and provided the users with these seeds to interact with the system. Then for all seeds from a single domain, we grouped all the generated events and measured the amount of overlap with human-written schemas. The statistics of this experiment is presented in Table 8. An event is considered to have an overlap with an event from the gold set if it either shares the exact predicate or a predicate with similar meaning. To do this, we provided a user with the list of system-generated events (not knowing which system this is coming from) and asked them to find the mappings between the gold set and the generated set. We then counted the number of events that are considered as overlapping with the gold events.

A.3.5 Manually curated schemas

Real-life scenarios can be described with a sequence of events and their relations. Manually curated schemas represent the events that can unfold a scenario in a hierarchical structure. The events in this structure can be either primitive or non-primitive, depending on whether they can be further expanded into additional events. We use the term “schema” to refer to the non-primitive events. Table 9 shows an example of such schemas for the disaster domain. As can be seen, the events are represented in multiple levels. For the sake of the evaluation conducted in this work (to make the comparison of the system-generated sequences with curated schemas more compatible), we consider the flattened representations of the schemas which consists of concatenating all the primitive events into a single sequence of events.

We also did the comparison on predicate level. The reason is that the system-generated events are instantiated events with specific arguments as the models are trained on news articles whereas the curated schemas are generalized forms of events.

A.3.6 System generated event sequences

Table 10 shows examples of generated event sequences through users interaction with the interactive tool described in section 5.4.

Schema name	Level	Events
natural disaster progression	0	detection and tracking* preparations* damages* immediate responses* rescue organization* rescue* rescue outcome* economic assistance* rebuild damaged property*
detection and tracking	1	scientists detect warning signs scientists track progress scientists assess threat scientists warn public media broadcasts information

Abstract

Argument mining seeks to extract arguments and their structure from unstructured texts. Identifying relations (such as attack, support, and neutral) between argumentative units is a challenging task because two units may be related to each other via implicit inferences. These inferences often rely on external commonsense knowledge to discover how one argumentative unit relates to another. State-of-the-art methods, however, rely on predefined knowledge graphs, and thus might not cover target pairs of argumentative units well. We introduce a new generative approach to finding inference chains that connect these pairs by making use of the Commonsense Transformer (COMET). We evaluate our approach on three datasets for both the two-label (attack/support) and three-label (attack/support/neutral) tasks. Our approach significantly outperforms the state-of-the-art, by 2-5% in F1 score, on two out of the three datasets with minor improvements on the remaining one.

1 Introduction

In argumentation, such as in a debate, it is important to understand the key arguments put forward and how the arguments relate to each other based on a specific context. Ideally, we would like to empower systems to extract arguments and the relations between arguments automatically. Such systems could be used to aggregate opinions (Cocarascu et al., 2019), participate in debates (Slonim et al., 2021), or they could assist humans in making informed decisions by considering different points of view.

Toulmin (1958) defines an argument as a claim backed by one or more grounds (or premises) based on a warrant (i.e., the inference link between the grounds and the claim). For example, consider the following two sentences: *Drunk driving hurts innocent people. Therefore, drunk driving is wrong.* Based on Toulmin's model, we have the claim *drunk driving is wrong*, supported on the grounds that *drunk driving hurts innocent people*. In what follows, we will call the claim and grounds *argumentative units* (AUs). To justify the claim, the author relies on the reader's ability to uncover the implicit warrant that *hurting innocent people is wrong* which connects the grounds to the claim. While Toulmin's warrants model only arguments in which the units are connected by support relations, we extend the definition to also allow for attacks and neutral relations. We do this to enable us to apply the notion of warrants to the relational argument mining task, as proposed by Carstens and Toni (2015), to better identify attack/support/neutral relations between pairs of AUs.

Finding the correct warrant is a challenging task that requires deep reasoning, which pre-trained language models struggle with (Helwe et al., 2021). However, by iteratively generating knowledge, we can chain together inferences to get a series of causes and effects that connect two AUs together similar to chain-of-thought reasoning (Wei et al., 2022). We propose the use of the Commonsense Transformer (COMET) (Hwang et al., 2021) which is equipped with social commonsense to generate warrants as a series of inferences. The knowledge contained in COMET is qualitatively different from other knowledge sources in that it contains normative commonsense. This depends upon the culture and beliefs of various groups compared with static commonsense knowledge graphs (KGs), such as ConceptNet (Speer et al., 2017), which focus on globally accepted knowledge. For this reason, we suggest that COMET is better able to identify the reasoning behind human arguments and that a generative approach based on COMET is better suited to finding warrants compared to a static knowledge graph as proposed by Paul et al. (2020).

Section 4 introduces our approach to test this hypothesis, where we articulate an algorithm,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2484–2495
May 2-6, 2023

ArgCon (Section 4.2), to generate warrants between a pair of argumentative units and use these warrants as additional input to the classifier of argument relations to evaluate whether this improves the model's ability to distinguish between attack, support or neutral relations. We then compare the use of three external knowledge sources: ConceptNet$^+$ the commonsense knowledge extracted by Paul et al., the knowledge generated by ArgCon, to obtain novel commonsense inferences (Section 4.2), and ArgCon + Link which enriches the generated knowledge with additional relations via a link prediction model (Section 4.3).

In Section 5, we compare our work to (Paul et al., 2020), which is the only other work we are aware of to address the task of relational argument mining by uncovering commonsense relations. We show that our method for generating warrants with COMET outperforms their method with a 1-2% increase in F1 scores on two datasets. We further evaluate our model on a three-class dataset, which includes an additional neutral relation, and witness a 5% improvement of the F1 score over a RoBERTa baseline. Hence, we set a new benchmark for the three-class task in relational argument mining. We share our findings in Section 6 and conclude with our future directions in Section 7.

2 Background

In this paper, we investigate the effectiveness of COMET (Bosselut et al., 2019) for generating implicit warrants that link arguments together. COMET is a generative model which has been fine-tuned on a human-authored commonsense knowledge graph ATOMIC (Sap et al., 2019). By training on ATOMIC, COMET extends the knowledge captured by the knowledge graph to new domains and is able to synthesize new commonsense knowledge based on knowledge captured during pre-training. The model is able to generate knowledge along multiple relations- a few examples are shown in Table 1. COMET takes as input a sentence and a relation along which to generate inferences. For example, given an input *PersonX's house was foreclosed* and relation *CausedBy*, COMET would generate *PersonX failed to pay their mortgage*.

Some successful applications of COMET include the generation of potential outcomes of events for abductive reasoning (Bhagavatula et al., 2020), question answering (Branco et al., 2021) and text generation (Guan et al., 2020). Closely related to our work, Chakrabarty et al. (2021) shows that COMET can be used to generate logically sound premises for incomplete arguments. While previous works have considered using COMET for single-hop inference, we found that for our task of relational argument mining, often multiple inference steps are needed to get from the first argumentative unit to the second; we address this challenge in Section 4.2.

3 Related Work

Various approaches have been proposed to infer argumentative structure from unstructured text. These include Long-Short Term Memory (LSTM) models (Cocarascu and Toni, 2017; Paul et al., 2020), pre-trained transformers (Ruiz-Dolz et al., 2021) and logic programming (Jo et al., 2021). Pre-trained transformers, in particular, have been shown to perform exceptionally well on this task with no additional feature engineering (Ruiz-Dolz et al., 2021; Fromm et al., 2019); this suggests that the introduction of external knowledge encoded within the transformers due to pre-training on large corpora is necessary to make significant progress on this task. Of these works, only Fromm et al. (2019) makes use of external knowledge to identify the stance of arguments towards a given topic. This differs from our task in that we wish to identify the relationship between pairs of AUs and so have the added challenge of finding paths that link the AUs together.

Commonsense knowledge has proven repeatedly to aid in tasks such as natural language inference (Wang et al., 2019) and question answering (Lv et al., 2020). The majority of these works focus mainly on deriving knowledge from ConceptNet (Speer et al., 2017); however, a key limitation of knowledge graphs (Pan et al., 2016) is their inherent incompleteness.

Recent trends in argument mining have shown a move towards incorporating external knowledge for various argument-mining tasks. Two works explore the use of automatically constructed knowledge graphs extracted from Wikidata and Google search, which, however, fail to achieve better results than BERT with no additional knowledge (Fromm et al., 2019; Li et al., 2021). On the other hand, a work using LSTM-based models for knowledge-enhanced argument mining with ConceptNet$^+$, shows that the introduction of knowledge indeed improves performance upon their baselines (Paul et al., 2020).

One of the key limitations of existing works is their use of static knowledge graphs which are unable to handle arbitrary pairs of AUs due to their limited coverage. To address this issue, we use COMET to generate conmmonsense inferences on-the-fly to connect AUs and therefore generalize to new domains.

4 Our Approach

In this section, we describe the design of our model as well as our procedures for obtaining knowledge on the fly with COMET and enriching the knowledge with additional links.

4.1 KE-RoBERTa

Given a pair of Argumentative Units, AUs, we aim to predict the relation between these AUs by the use of external knowledge relevant to this pair. Ruiz-Dolz et al. (2021) show that RoBERTa is a strong baseline for the classification of argument relations when compared to other transformer-based architectures. Hence, we introduce KE-RoBERTa, which is a knowledge-enhanced RoBERTa-based model as depicted in Figure 1.

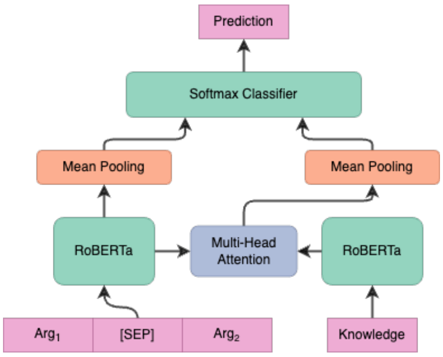

Figure 1: KE-RoBERTa, our proposed Siamese model for Commonsense Knowledge injection with Arg_1 and Arg_2 being the input AUs

In order to inject knowledge into RoBERTa, we use a Siamese model to separately encode the two AUs as well as the commonsense knowledge much like the S-BERT model (Reimers and Gurevych, 2019); in other words, the parameters of the two RoBERTa blocks are shared. The model then combines the two representations by concatenating them together. We also introduce a multi-head attention mechanism (Vaswani et al., 2017) to attend to relevant information and block out noise. We use mean pooling to combine individual token representations before concatenating the result. This allows us to use a fix-sized feed-forward network to compute predictions from the combined AU and knowledge representations.

The notion of knowledge is loosely defined in the literature but can be viewed as a set of beliefs about the world that approximate truth. In our case this knowledge is represented as the set of all knowledge graph paths that could connect two AUs. While there are many ways to represent knowledge graph paths, in this work, we convert each knowledge graph relation into its natural language equivalent and concatenate the nodes and relations together to form a sentence in natural language. For each pair of AUs we then concatenate all possible paths together in order to input the knowledge into a transformer. The source of knowledge graph paths we refer to in the following sections as ConceptNet⁺ combines knowledge from ConceptNet, and WordNet, with additional links predicted by neural networks; ConceptNet⁺ is proposed by Paul et al. and the extracted knowledge was provided to us by the authors. Since the authors did not experiment on the three class task we did not have ConceptNet⁺ relations for M-Arg.

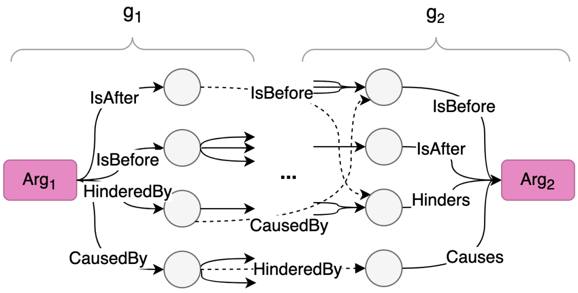

Figure 2: Knowledge graph generation by ArgCon with link inference enabled. The figure shows how two graphs, g_1 and g_2, are generated from each AU, Arg_1 & Arg_2, and then merged. Dashed lines show additional relations found by Link.

4.2 ArgCon: A new way to generate knowledge with COMET

All previous works using COMET seek to generate a possible outcome, a_2, from a known event, a_1, and a relation. For this task, we seek to invert this and find a path to connect a_1 and a_2. What makes this more challenging is that AUs are often connected by multi-hop inferences and so multiple intermediary outcomes o_i may be needed to connect a_1 and a_2. The types of inference we wish to generate can be represented as:

$$a_1 \xrightarrow{r_1} o_1 \xrightarrow{r_2} o_2 \cdots o_{n-1} \xrightarrow{r_n} a_2$$

where r_i is a relation connecting events/outcomes, and neither the o_i nor r_i are known in advance. To do this, we propose a new technique using an improved version of COMET, trained on ATOMIC$^{20}_{20}$, a larger and more extensive version of the original ATOMIC knowledge graph (Hwang et al., 2021), to generate deep commonsense inference chains that connect two AUs together.

Relation	Inverse
Causes	*CausedBy*
HinderedBy	*Hinders*
isAfter	*isBefore*
isBefore	*isAfter*

Table 1: ATOMIC$^{20}_{20}$ relations (R) used to generate knowledge from COMET with corresponding inversions

ATOMIC$^{20}_{20}$ consists of several classes of relations, including 'causes for a person to perform an action', 'effects of an action on others', and 'event-centred'. In this paper, we focus on 'event-centred' relations to generate knowledge from, which is a subset of the relations contained in ATOMIC$^{20}_{20}$. In Table 1, we show the four relations selected. In Section 5, we will report our results on three existing datasets that include AUs focusing on event-centred knowledge.

Algorithm 1 provides pseudocode for our knowledge generation method *Argument Connector* (ArgCon). Our algorithm takes three inputs, a pair of AUs, (a_1 and a_2) as well as a boolean flag ($wlink$) to indicate whether additional link prediction should be performed as described in Section 4.3. The algorithm then returns the paths that connect a_1 to a_2.

Starting from the pair of AUs, we first initialise two single-node graphs, g_1 and g_2, from a_1 and a_2 (lines 1-2). For each of these graphs, we take the set of their nodes N, and for each node n and each relation r we generate new nodes n' using COMET (lines 8-13). We then update N to contain the set of nodes at the current depth i (line 14) and repeat this process d times until each graph has a tree with a maximum depth of d (line 4). Note that graphs g_1 and g_2 now contain only paths from a_1 and a_2, meaning that a_2 cannot be reached from any other node. In order to get paths from a_1 to a_2, we need to flip the relations in g_2 replace them with their corresponding inverse, as shown in Table 1, and then merge the two graphs wherever they share a common node (line 15). We now have a single merged graph g_m containing a_1 and a_2. If $wlink$ is set to `true`, the Link model will be used to infer additional relations that connect g_1 to g_2 (line 16-18) which are then appended to g_m. The algorithm returns all paths that connect a_1 and a_2 (line 19).

Algorithm 1: ArgCon$(a_1, a_2, wlink)$

```
Data: $R$, the set of relations to consider
Data: $d$, the depth of a tree
Data: COMET, commonsense transformer
Data: Link, our Link model
1  $g_1 \leftarrow$ makeGraph$(a_1)$
2  $g_2 \leftarrow$ makeGraph$(a_2)$
3  forall $g \in \{g_1, g_2\}$ do
4      for $i = 0$ to $d$ do
5          if $i = 0$ then
6              $N \leftarrow g.nodes()$
7          $N' \leftarrow []$
8          forall $n \in N$ do
9              forall $r \in R$ do
10                 $n' \leftarrow$ genNode$(n, r,$ COMET$)$
11                 if $n' \neq NULL$ and $n' \neq n$ then
12                     $g \leftarrow g.addtriple(n, r, n')$
13                     $N' \leftarrow N'.append(n)$
14         $N \leftarrow N'$
15 $g_m \leftarrow$ mergeGraphs$(g_1,$ flip$(g_2))$
16 if $wlink$ then
17     $new\_edges \rightarrow$ Link$(g_1, g_2)$
18     $g_m.append(new\_edges)$
19 return computePaths$(a_1, a_2, g_m)$
```

4.3 Link Prediction Between Nodes

It may not be always possible to find a path between the AUs by using only the merging operation described above. We introduce an additional inference step to identify the relationships between the nodes of the two knowledge graphs.

To achieve this, e trained a link prediction model (Link) to identify the most likely relations that exist between two nodes, which are provided as inputs. Link is a BERT model fine-tuned on the ATOMIC$^{20}_{20}$ training set to predict the relation between two nodes of the knowledge graph. In order to identify unrelated node pairs, we sample 4000 pairs that are not connected in ATOMIC$^{20}_{20}$ and assign them a 'None' label. Table 2 shows the training and validation performance of Link when trained to predict the relations in Table 1 and the 'None' relation.

	Accuracy	Precision	Recall	F1
val	0.91	0.89	0.88	0.88
test	0.90	0.85	0.85	0.85

Table 2: Validation and testing performance of LINK model for COMET link prediction after 5 epochs.

Given a pair of graphs and their corresponding node sets, N_1, N_2, generated by COMET, we use LINK to predict the most likely relationships between the two graphs. Explicitly, we pass all node pairs $(a, b) \in N_1 \times N_2$ to LINK and add the predicted relation to g_{merged} (line 15 in Algorithm 1, $wlink$ is set to 1 to enable further inference) before computing paths. Figure 2 depicts our method when link inference is enabled.

5 Evaluation

In this section, we describe the datasets we have chosen, our choices of parameters for knowledge extraction, our training setup, and the results of our experiments on three datasets.

5.1 Datasets and Knowledge

We consider three datasets for our experiments: the Student Essay corpus (Opitz and Frank, 2019), Debatepedia (Paul et al., 2020), and the M-Arg Presidential Debate corpus (Mestre et al., 2021). We may refer to the datasets as Essay, Debate, and M-Arg for brevity.

The first two datasets were annotated with two labels (attack/support). Student Essay is a collection of argumentative essays written in English by second-language speakers, while Debatepedia contains arguments selected from a wiki of controversial topics and pro/con arguments[1] where controversial topics are discussed by multiple authors. These are the datasets used by Paul et al. (2020) which we use for comparison and we have taken the same dataset splits as used in their experiments. M-Arg consists of transcripts from five presidential debates in 2020; sentence pairs in this dataset were annotated with three labels (attack/support/neutral). Table 3 shows how the data has been split.

		A	S	N
Debate	train	3250	3236	-
	val	1088	1075	-
	test	1035	1127	-
Essay	train	273	2797	-
	val	130	1012	-
	test	91	1009	-
M-Arg	train	94	302	2887
	val	11	40	359
	test	15	42	342

Table 3: Distribution of labels (**A**ttack/**S**upport/**N**eutral) across datasets. While Debatepedia is balanced, the other two datasets show drastic imbalances making the task of detecting minority classes more challenging.

5.2 Experimental Setup

As a baseline, we trained a RoBERTa model[2], with no additional knowledge. We trained our models to minimize the cross-entropy loss on the labeled data with a batch size of 10 and a learning rate of $1e^{-5}$. The models were trained using the same hyperparameters for 10 epochs, and the model with the highest F1 validation score was selected for testing. Our code and the data can be found on GitLab[3].

We used ARGCON with a maximum depth limit of $d = 3$ to generate a list of paths from Arg_1 to Arg_2. Each path is given as lists of nodes and relations, which, by using a simple set of rules, we convert into natural language and concatenate the result. This is common practice when using COMET and the reader can refer to the code-base for more details on how this was done.

5.3 ARGCON vs ARGCON+LINK

We first investigate the proportion of AU pairs for which ARGCON and ARGCON+LINK could generate knowledge for (Table 4). We observe that nearly half of the pairs are not covered by ARGCON while ARGCON+LINK gives an improvement of 30% on Debatepedia and Student Essay and 40% on M-Arg.

5.4 Relational Argument Mining Results

Table 5 shows the results from the classification experiments; the first two rows, (Paul et al., 2020) and RoBERTa, are existing approaches. We also apply RoBERTa to the ConceptNet+ extracted by Paul et al. to compare the performance against our COMET-based knowledge extraction methods. The results show that the common-

		ARGCON	ARGCON+LINK
Debate	train	0.56	0.85
	val	0.53	0.83
	test	0.54	0.83
Essay	train	0.42	0.71
	val	0.37	0.68
	test	0.42	0.70
M-Arg	train	0.20	0.69
	val	0.23	0.74
	test	0.22	0.72

Table 4: Coverage of ARGCON vs. ARGCON+LINK.

sense enhanced KE-RoBERTa models improve upon RoBERTa in almost all cases. In addition, ARGCON and ARGCON+LINK give the best results on the Debate and Essay datasets respectively. For significance testing we used the Almost Stochastic Order test (Dror et al., 2019; Del Barrio et al., 2018) implemented in Python using the `deep-significance` library (Ulmer et al., 2022). We compared all models against the baseline based on the sample predictions on a single trial, with a confidence level of $\alpha = 0.05$ (before adjusting for all pair-wise comparisons using the Bonferroni correction). We consider the results significant when $\epsilon_{\text{min}} < \tau$ with $\tau = 0.3$.

We conducted further experiments on the M-Arg dataset to evaluate our knowledge extraction method on a three-label (attack, support, and neutral) task. The results in Table 6 confirm that our methods do indeed perform better than RoBERTa with no external knowledge.

6 Analysis and Discussion

In order to interpret the results better, we analyze the inference chains generated by ARGCON, and we also investigate the performance of the models across different topics. In Table 7, we provide some examples from the data to discuss our findings. For clarity, we have kept the table concise and omitted information not relevant to the points being made.

6.1 Performance Across Different Topics

The performance of the model varies across different topics. Figure 3 depicts the macro F1 scores of the KE-RoBERTa model for each topic in the M-Arg dataset. We observe significant improvements across some of the topics such as ‘Taxes’, ‘Racism’, ‘Families’ and ‘Climate Change’. COMET has been exposed to these topics in the training set and so is better able to provide relevant knowledge.

One topic in which RoBERTa outperforms both knowledge-enhanced models is ‘Why They Should Be Elected’. Our analysis of the class level precision (Appendix A) indicates that the drop in precision in Table 6 is actually due to this missidentification of support relations when we add external knowledge, we discuss this in Subsection 6.4.

6.2 Noisy Connections

The injected knowledge could be detrimental in some cases. The COMET generated knowledge can introduce noise by generating irrelevant relationships between two arguments. Consider Ex1 in Table 7, where ARGCON makes an incorrect prediction while the RoBERTa model correctly predicts a support relation. Here, the generic word ‘good’ is used to link Arg_1 and Arg_2. While useful, the analysis shows that the attetion mechanism in KE-RoBERTa does not solve the issue.

ARGCON *can sometimes infer relations when there are in fact none present.* The existence of a commonsense inference path between the arguments causes the model to favor the support relation over the neutral one. In Ex3 of Table 7, the first argument attacks the speaker’s opponent while the second deflects the argument by addressing something unrelated. However, COMET connects the first sentence to the second on the basis that ‘the country is in decline’ supports ‘being weaker’.

6.3 ARGCON vs. ConceptNet$^+$

The nature of the injected knowledge can change the outcome. Ex4 in Table 7 shows a comparison of knowledge extracted with ARGCON+LINK and ConceptNet$^+$. In the example the model provided with input from ARGCON+LINK predicts the correct relation while ConceptNet$^+$ fails. By examining the knowledge we observe that ARGCON+LINK is able to deduce that the first argument hinders the ability of parents to teach their children and therefore prevents students from learning skills. This allows the model to make the correct prediction. However, ConceptNet$^+$ can only deduce that a parent has a child that can learn.

As seen in this example, ConceptNet$^+$ provides some information about causality (learning causes intelligence) but this information is limited and often too simplistic to provide meaningful information for understanding the underpinning arguments.

		Student Essay			Debatepedia		
Model	**KG**	**P**	**R**	**F1**	**P**	**R**	**F1**
(Paul et al., 2020)	ConceptNet$^+$	0.56	0.63	0.60	0.64	0.64	0.64
RoBERTa	-	0.64	0.68	0.66	0.75	0.75	0.75
KE-RoBERTa	ConceptNet$^+$	0.66	0.70	0.68	0.74	0.74	0.74
	ArgCon	0.66	0.69	0.67	**0.76**	**0.76**	**0.76**
	ArgCon+Link	**0.70**	**0.71**	**0.70***	0.75	0.75	0.75

Table 5: Macro-averaged F1, precision, recall scores of our experiments on the test sets for the 2-class task. Asterisk indiciates significant stochastic dominance over the baseline.

		M-Arg		
Model	**KG**	**P**	**R**	**F1**
RoBERTa	-	**0.57**	0.41	0.44
KE-RoBERTa	ArgCon	0.48	0.51	0.48*
	ArgCon+Link	0.54	**0.48**	**0.49***

Table 6: Macro-averaged F1, precision, recall scores of our experiments on the test sets for the 3-class task. Asterisk indicates significant stochastic dominance over the baseline.

On the other hand, COMET is well equipped to handle more complex causal relations due to the nature of the data it was trained on. This supports our claim that the nature of COMET is better suited to providing useful commonsense for argument mining tasks compared to ConceptNet$^+$.

6.4 Uncovering Hidden Biases in Arguments

In argument understanding, the ability to capture and make some of the implicit biases explicit can be helpful. Ex2 in Table 7 shows an argument made by the speaker to attack [PERSON X]'s candidacy. The argument made relies on the implicit reasoning that [PERSON X] did not fight [COUNTRY Y] because he is a communist. While there are many controversial assumptions being made when generating this knowledge, the COMET knowledge reflects the beliefs underlying the argument pair.

One of the key differences between fact-based and commonsense knowledge graphs is that the latter are more likely to capture cultural and normative biases. This is amplified by the fact that COMET is built on a pre-trained BART model, which captures biases present in the training corpus.

7 Conclusion

In this paper, we introduced a new method, ArgCon, to investigate the role of the commonsense knowledge encoded in COMET for the task of relational argument mining. In particular, ArgCon can reveal implicit commonsense reasoning chains (i.e., warrants) and these chains provide useful information for classifying argument relations such as attack, support, and neutral. Our experiments on three different datasets show that the chains generated by this method outperform existing approaches. Our analysis shows that the performance of our models varies given the topic under discussion and in some cases ArgCon creates noisy connections as a result of injected knowledge. We also observe that our model performs well in its ability to handle complex causal relationships and reason about social norms and biases.

In this work, we only consider pairs of AUs without taking into account any additional context. However, incorporating the text surrounding the pair of arguments is often necessary to be able to determine their relationship. In future work, we would like to incorporate such contextual information into our approach and explore the impact this has on the final performance. Another direction that we want to explore is considering other relations of COMET knowledge such as *intents*, *needs*, and *wants* to investigate whether this kind of social commonsense improves classification accuracy. Another avenue of investigation we would like to pursue is the role that external knowledge plays in increasing explainability and improving the diagnosis of end-to-end model predictions. Beyond argument mining, we believe that ArgCon is useful for other inference tasks such as recognizing textual entailment and question answering, we hope to experiment with other datasets to test this.

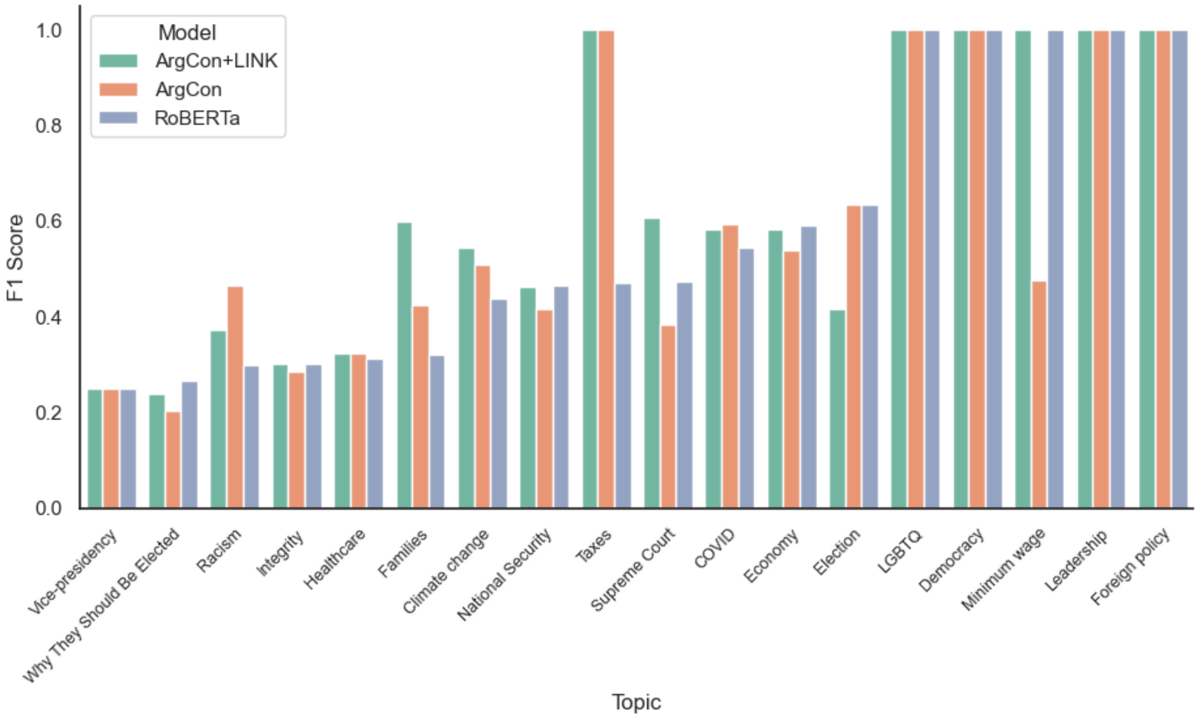

Figure 3: Comparison of F1 scores of our models on various topics in the test set of the M-Arg dataset.

Ex1	**Arg$_1$**	Congress will not ultimately cut Medicare to pay for reform.
	Arg$_2$	The 2010 US health care reform legislation is a good idea.
	ArgCon+Link	[Arg$_1$], isAfter, PersonY is not a member of the government, isAfter, PersonY is a lawyer, Causes, good, CausedBy, [Arg$_2$]
	Label: Support	**RoBERTa Prediction**: Support, **ArgCon+Link Prediction**: Attack
Ex2	**Arg$_1$**	[PERSON X] never fought it.
	Arg$_2$	[PERSON X] has been a cheerleader for communist [COUNTRY Y] over the last several decades.
	ArgCon	[Arg$_2$], HinderedBy, [PERSON X] is a good person., HinderedBy, [PERSON X] is a communist., Hinders, [Arg$_2$]
	Label: Support	**ArgCon Prediction**: Support
Ex3	**Arg$_1$**	Under this president, we become weaker, sicker, poor, more divided and more violent.
	Arg$_2$	With regard to being weaker, the fact is that I've gone head to head with [PERSON X] and made it clear to him we're not going to take any of his stuff.
	ArgCon	[Arg$_2$], HinderedBy, under this president, the country is in decline, HinderedBy, with regard to being weaker, Hinders, [Arg$_2$]
	Label: Neutral	**ArgCon Prediction**: Support
Ex4	**Arg$_1$**	Parents are usually too busy with their daily jobs to teach their children the life skills
	Arg$_2$	Students can learn practical skills after school hours from their parents
	ArgCon+Link	[Arg$_2$], Causes, parents are lazy, HinderedBy, parents are teaching their children, CausedBy, [Arg$_2$]
	ConceptNet$^+$	parent Antonym child used for learning, learning Causes intelligence related to mind HasA parent, parent Antonym child CapableOf learn
	Label: Attack	**ArgCon+Link Prediction**: Attack, **ConceptNet$^+$ Prediction**: Support

Table 7: Examples of knowledge and model predictions from the data: Ex1 is taken from the Debate dataset, Ex2 and Ex3 are taken from M-Arg, and Ex4 is taken from Student Essay. One interesting finding is that due to inductive biases in ArgCon *HinderedBy* and *Hinders* do not always reflect negative relations between nodes. The tags [PERSON X] and [COUNTRY Y] have been used to remove mentions of named individuals and countries in this table to avoid causing political offense.

Acknowledgements

The work was supported by the Edinburgh-Huawei Joint Lab and Huawei's grant CIENG4721/LSC. We would like to thank Paul et al. for providing their datasets and code-base allowing us to compare our work and improve upon their results.

Limitations

One limitation comes from our reliance on manually-constructed knowledge graphs. Given that different cultures and communities have varying notions of what is and is not commonsense, what is left out between arguments will also depend on the culture. For example, a knowledge graph constructed by English speakers in the UK, may not be able to provide useful knowledge about arguments about politics in the US due to differences in cultural values.

Similarly, our approach does not apply to low-resource languages that do not have sufficiently large commonsense knowledge graphs to train a transformer model such as COMET. Machine Translation of existing knowledge graphs may also prove insufficient due to cultural differences.

Ethics Statement

The datasets we use in this paper are publicly available. These datasets are anonymized and do not include sensitive information. A source of ethical concern is our reliance on generative models to provide warrants for arguments. These models, being trained on large web-based corpora may potentially generate problematic or biased outputs.

A Class level performance of our model

Table 8 shows the breakdown of our models' performance across the different classes. To begin with, the performance on Debatepedia is mixed, with a slight improvement in the F1 score of the support class due to ARGCON. However, there is no clear winner as all models perform similarly to the baseline. This suggests the need for further investigation to identify the cause of the performance bottleneck which is not mirrored by the other 2 datasets.

In the Student Essay, we observe that knowledge indeed helps to identify the minority attack class, both in terms of precision and recall with ARGCON+LINK providing the greatest contribution to the precision of the attack class and a slight improvement in the recall of support. This gives strong evidence to support our hypothesis that the knowledge provided by our methods is effective for distinguishing between relation types.

We see a similar phenomenon emerge in the M-Arg dataset, where there is a consistent improvement in the identification of the smallest attack class, as we go from no knowledge to ARGCON to ARGCON+LINK. We also notice a significant, 33% increase in the recall of supporting AU pairs. However, as we introduce knowledge to our model, we see that the recall of neutral pairs decreases alongside the precision of support. This is what was observed in Subsection 6.4 due to the appearance of supporting inference chains when we generate knowledge with ARGCON.

To summarise, the improvement of our model on the Student Essay and M-Arg dataset provides evidence to support continued investigation and improvement of commonsense-aided relational argument mining with COMET. In particular, we see that external commonsense knowledge significantly improves the identification of minority classes in imbalanced datasets which are particularly common to the domain of argumentation.

Abstract

Current studies of bias in NLP rely mainly on identifying (unwanted or negative) bias towards a specific demographic group. While this has led to progress recognizing and mitigating negative bias, and having a clear notion of the targeted group is necessary, it is not always practical. In this work we extrapolate to a broader notion of bias, rooted in social science and psychology literature. We move towards predicting interpersonal group relationship (IGR) — modeling the *relationship between the speaker and the target* in an utterance—using fine-grained interpersonal emotions as an anchor. We build and release a dataset of English tweets by US Congress members annotated for interpersonal emotion – the first of its kind, and 'found supervision' for IGR labels; our analyses show that subtle emotional signals are indicative of different biases. While humans can perform better than chance at identifying IGR given an utterance, we show that neural models perform much better; furthermore, a shared encoding between IGR and interpersonal perceived emotion enabled performance gains in both tasks.

1 Introduction

Currently, most work studying bias in NLP situates bias as negative or pejorative language use towards an individual or group based on traits like race, gender, etc (Kaneko and Bollegala, 2019; Sheng et al., 2019; Sap et al., 2020; Webson et al., 2020; Pryzant et al., 2020; Sheng et al., 2020). While these approaches greatly advance our understanding of bias in language and its impact and mitigation in NLP, focusing on specific demographic dimensions or an individual's intent is limiting and not always practical. Research in psychology and social science suggests a different perspective. Bias can be seen as a relationship between people and groups, situated in context (Van Dijk, 2009); as such, bias refers to differences in behavior (in this case language use) as a result of differences in the relationship between speaker and target. The language we produce is biased in one way or another, whether we intend to or not, and whether that bias is positive, negative, or not clearly associated with any valuation (Beaver and Stanley, 2018).

In psychological work on Linguistic Intergroup Bias (Maass, 1999), bias originates from the relationship between the speaker and target of an utterance, i.e. their **interpersonal dynamics**, and manifests later in subtle ways. Consider the utterances (tweets) in (1), drawn from our collected data in which the identity of the speaker and target are masked:

(1) a. **In-group**: We stand w @Doe, who has seen a lot worse than cheap insults from an insecure bully. #MLKDAY weekend.
   b. **Out-group**: Parents and families live in constant fear for their children with food allergies. A worthy bipartisan cause - thank you @Doe for your leadership on this issue.

Both express support and admiration towards the target referent *Doe* – however, the second example uses words indicative that the speaker and target do not share a relevant social identity (in this case, their political party), expressed by words like *bipartisan*. The intensity of admiration expressed is also greater in (1-a) than (1-b). Thus, these two seemingly similar statements differ along interpersonal dimensions that are instructive as to how the bias of the speaker seeps into the utterance.

We now introduce two new tasks that directly model language use in terms of two interpersonal dimensions: (i) **interpersonal group relationship (IGR) prediction**, where we seek to understand how people talk about others who they consider to be in their same social group (in-group), versus those they consider outside their social group (out-group), and (ii) *perceived* **interpersonal emotion**

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2496–2506
May 2-6, 2023 ©2023 Association for Computational Linguistics

detection, where we situate these differences in terms of the emotion expressed in text *towards or in connection with* a target individual described in the utterance. Note that *interpersonal* emotion is different from a more standard, utterance level emotion detection task, as illustrated in row 2 of Table 1 which has seemingly opposing emotions.

We present a first-of-its-kind, *annotated* dataset for fine-grained interpersonal emotion detection, consisting of 3,033 tweets from members of the US Congress; all of these tweets mention another Congress member, hence providing us with 'found supervision' for IGR prediction (whether the speaker and the target belong to the same political party). Our analyses show that while positive interpersonal emotions appear in both in- and out-group situations, negative emotions like anger and disgust are overwhelmingly present in the latter. Meanwhile, human judgments for in vs. out-group membership on this dataset are overly reliant on the polarity of emotion; specifically, human judges are much *less* likely to attribute positive emotions towards out-group targets.

Baseline performances for perceived interpersonal emotion detection shows that this is a challenging task, as is consistent with existing work in emotion detection in general (Demszky et al., 2020). In particular, emotions in this dataset are often expressed with considerable subtlety, likely a characteristic of official political speech. To investigate whether IGR and emotions are intertwined and useful towards each other, we further developed a multi-task model for the prediction of both. We found compelling evidence that multi-tasking IGR and interpersonal emotion improves performance on both tasks with over 10% improvement in detection of disgust in out-group contexts, and 3% improvement in IGR prediction.

To summarize the contributions of this paper, we tackle *generalized intergroup bias*, a notion of bias rooted in social psychology that applies to all the various differences in the ways that people talk about others in their in-group or out-group. Standard bias tasks in NLP, and the broader goal of debiasing models could thus be set in a more general context. We present the first dataset to study both interpersonal group membership and emotion, which allows us to analyze both human and model behavior in terms of how the two interact with each other. We release our code and data online at `github.com/venkatasg/interpersonal-bias`.

2 Interpersonal Contexts & Emotions

Our aim is to build a generalized, data-driven approach towards studying bias situated in **interpersonal utterances**, which we define as any utterance where there is a target individual being talked about or referred to. Our goal is to model two novel tasks described below; examples are shown in Table 1.

Interpersonal Group relationship IGR is defined by the relationship between the speaker and target of an utterance. People belong to multiple social groups as part of their identity, however usually only some identities are salient in an utterance in context. We define *in-group* utterances as ones where the speaker and target are in the same social group, and *out-group* utterances as one where they are in different social groups. Given an utterance u written by an individual s with target t, the IGR prediction task classifies whether s and t belong to the same social group within the context of u.

Interpersonal Emotion We define *perceived* interpersonal emotion as the emotion expressed by a speaker s *towards, or in connection with* the target t of the utterance u, as perceived by a reader. We use the Plutchik wheel of emotions, which is widely adopted in the community, as the basis of our emotion taxionomy (Plutchik, 2001); we use the 8 fundamental emotions (*admiration, anger, disgust, fear, interest, joy, sadness, surprise*) instead of the full 24 emotions in the wheel due to data sparsity. Interpersonal emotions may be different, or a subset of, emotion for the whole of an utterance, as illustrated in rows 2, 3 and 4 of Table 1. Given an utterance u written by an individual s with target t, the interpersonal emotion detection task identifies the perceived emotion of s towards the target t.

3 Data Collection

In our area of focus, we require natural language data which satisfies the following criteria: *(1)* Each utterance must have at least one target about whom the utterance mainly concerns. *(2)* The relationship between the speaker and the target must be inferred based on metadata or other information. Specifically, we are interested in aspects of their social identity that they share or differ on.

The dataset we collect comes from tweets by members of US Congress where other members are mentioned in the same tweet. We use this as

Tweet	Interpersonal Emotion	In/Out group?
As @Doe says, the times have found each and every one of us to Defend our Democracy For The People. Worth reading every line.	Admiration	In-group
Freedom has no greater nor tougher champion than @Doe. My prayers are with him and his family.	Admiration & Sadness	In-group
You don't get to decide what's "fine," @Doe. The constitution does. #DefendOurDemocracy #WednesdayThoughts	Anger & Disgust	Out-group
Thank you again Senator @Doe for leading the SRF WIN Act[...] I'm proud to be a co-sponsor	Admiration & Joy	Out-group

Table 1: Example utterances from our dataset with in/out group and interpersonal emotion labels

a convenient testbed: each member's group affiliation (i.e., their party identity) is public, thus we can easily know whether the speaker is tweeting to a target in their own party or not.[1] In other words, this dataset gives us "found supervision" for our first task of IGR prediction. For our second task, we annotate a subset of these tweets for perceived interpersonal emotion; this is, to our knowledge, the first dataset dedicated to interpersonal emotion.

3.1 Data Sources and Preprocessing

Social media text like tweets offer a fertile ground for our study. A focus on tweets with *mentions* in them satisfies our first criterion – people generally use mentions to say something about or towards another individual on twitter. Tweets by members of US Congress are a matter of public record, and we can infer the social relationship (in terms of party affiliation) between speaker and target using publicly available information. We prioritize working with a dataset of tweets by members of US Congress (downloaded using the Twitter API) between 2010 and 2021, spanning two presidencies, during which both parties held power in Congress. We filter these tweets to exclude retweets, and include those tweets that mention *at most* one other member of Congress whose party affiliation is known. We believe these 2 assumptions are sufficient to arrive at a dataset of tweets where the speaker is talking towards/about *one* target. Thus, we restrict ourselves to two social groups in this sphere — Democrat and Republican parties in the US. We sample an equal number of in-group and out-group tweets from a large sample consisting of all tweets by members of Congress. Apart from years 2010–2012 and 2021 which contained fewer tweets due to sparsity issues, we sampled at least 300 tweets each year.

3.2 Interpersonal Emotion Annotation

While we can infer whether a tweet is in-group or out-group based on the identity of speaker and target whose political affiliations are known, we still require annotated data on perceived interpersonal emotions. Interpersonal emotions vary in subtle ways from sentiment or overall sentiment of utterances: an utterance can have negative sentiment overall, but still convey positive emotions towards the target of the sentence (expressing admiration at someone's death for instance). For this reason, we devise an annotation schema for annotating *the emotion expressed by speaker s towards target t.*

Instructions Annotators are presented with a tweet, with the identity of the speaker unknown and that of the target masked with a placeholder name **@Doe** to minimize potential biases of the annotators' prior knowledge of party affiliation intruding into the annotation:

(2) If **@Doe** can get her hair done in person, Congress can vote in person...

Annotators are instructed to read the tweet and select only the most notable emotion(s) they think are expressed by the tweet author *in connection with* **@Doe**. To aid annotators, we provide examples of the 8 Plutchik emotions (*joy, admiration, fear, suprise, sadness, digust, anger and interest*) expressed as interpersonal emotions in tweets. Annotators are also shown a schematic of the Plutchik wheel of emotions, which acquaints them with how the emotions are related to one another in our framework. Annotators are allowed to select more than one emotion to account for emotion co-occurrence. We also explicitly tell annotators that more than one of the emotions can be present in the tweets, to encourage them to select all interpersonal emotions expressed. They are also allowed to not choose any emotion.

---

[1] For simplicity, we do not consider other factors such as the home state of a congress member.

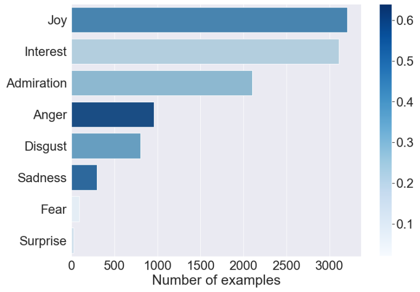

Figure 1: Emotions ordered by the number of examples where at least one rater uses a particular label. The color indicates the average interrater correlation.

Annotation To obtain reliable annotations, we prequalify annotators using a qualifying task. Annotators were recruited on Mechanical Turk using a qualifying task where they were asked to annotate 6 tweets using the schema shown above. We restricted the qualification task to annotators living in the USA who had attempted at least 500 HITS and had a HIT approval rate $\geq 98\%$. After manual inspection, 6 annotators were qualified for bulk annotation. Each tweet was annotated by three different annotators. To ensure annotators were paid a fair wage of at least 10$ an hour, we paid annotators $0.50 per HIT. Each HIT involved annotating 3 tweets, which we estimate to take on average 3 minutes to complete. In total, 3,033 tweets between 2010 and 2021 were annotated with perceived interpersonal emotion.

Agreement To measure agreement between annotators on the Plutchik-8 emotion wheel, we use the Plutchik Emotion Agreement (PEA) score from Desai et al. (2020). The PEA score addresses the issue of penalizing all disagreements equally, by penalizing dissimilar emotion annotations higher than more similar ones (according to the Plutchik wheel). Our PEA score is 0.73. The original PEA formulation used the best(max) pair of emotion annotations between two workers. Taking the *worst* combination of emotions between two workers (averaged over all tweets and workers), the PEA (min) score is 0.60. Overall, we find moderate to high agreement on fine-grained interpersonal emotions. In Figure 1 we also present interrater correlation, a metric used in Demszky et al. (2020); we see that distributions are similar.

Emotion	**Train**	**Dev**	**Test**
Admiration	467	64	58
Anger	225	40	46
Disgust	206	32	43
Fear	1	0	0
Interest	701	83	84
Joy	801	107	106
Sadness	72	11	11
Surprise	1	0	0
No Emotion	519	56	63

Table 2: Distribution of emotions in train-dev-test split

Emotion	**All**	**In-Group**	**Out-Group**
Admiration	15.5	22.2	9.1
Anger	8.2	1.0	15.1
Disgust	7.4	0.3	14.2
Interest	22.9	27.2	18.6
Joy	26.7	32.2	21.4
Sadness	2.5	2.6	2.4
No Emotion	16.8	14.5	19.1

Table 3: Proportion of emotions in different interpersonal contexts

Aggregation We consider a tweet to have a certain emotion label if at least 2 out of 3 annotators agree that the particular emotion was present in the tweet. A total of 638 tweets have no interpersonal emotion associated with them. We employ a 80-10-10 train-dev-test split on our data.

The number of annotated examples (tweets) per emotion is shown in Table 2. We omit *fear* and *surprise* from future tables due to the absence of annotated examples.

4 Preliminary Analysis

How are emotions distributed? When observing the distribution of aggregated emotion labels themselves, a clear pattern emerges as seen in Table 3. Negative emotions such as anger and disgust are almost always expressed in out-group settings, while positive emotions are present in both in-group and out-group settings. A similar distribution of emotions was observed for Democrats and Republicans — members of both parties reserved their public anger and disgust for members of the other party. This reflects an innate bias in terms of the distribution of interpersonal emotions per situation, and warrants future work to explore negative interpersonal emotions in an in-group setting.

Figure 2 shows the co-occurrence of interpersonal emotions in our dataset. We can see that emotions that are farther apart and more dissimilar, such as admiration and disgust, joy and sadness, co-occur infrequently. Emotions that are closer such as anger and disgust, admiration and joy, co-occur much more often. The only outlier is the higher than normal co-occurrence of admiration with sadness — after a closer examination, this can

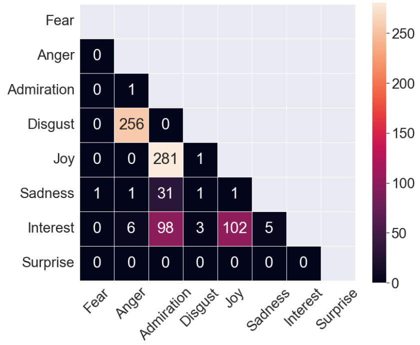

Figure 2: Co-occurence of emotions in our dataset.

be attributed to tweets expressing admiration and sadness at the passing, or end of the career, of a fellow congressperson.

Who were the targets of negative emotions? On further analysis, it appears that most of the out-group disgust and anger is directed at 3 handles – @speakerryan, @speakerpelosi, and @speakerboehner who were all Speakers of the House of Representatives over most of the time period of our dataset. 63.7% of disgust and 64.3% of anger is directed towards these three twitter handles. 11.9% of all tweets in our dataset are directed at these handles, indicating the preponderance of negative interpersonal emotion directed at the Speaker of the house. However, we note that negative emotions like anger and disgust were still expressed towards 51 and 45 different individuals in our dataset, respectively.

Can humans predict in/out-group? While our data naturally comes with "gold" IGR labels, what is unexplored is whether the distinction between in-group and out-group speech is prominent and noticeable by humans. Additionally, it is also unclear if humans might have their own expectation of how in/out-group speech should be characterized.

Concretely, we investigate if human annotators were capable of accurately performing the IGR prediction task when the speaker and target are masked. Two authors of this paper, one a social science graduate student, and the other a computational linguistics graduate student, annotated 50 random tweets from our validation data which they had not been exposed to earlier for in/out group labels. Their Fleiss κ agreement score was 0.64, indicating moderate agreement.

To check how accurate their judgements were, we calculate for each annotator their F1 score against our "gold" in/out group labels. Their F1 scores on these 50 tweets were 0.67 and 0.63, which as we will discuss in Section 6, only match simple baselines of supervised systems. Annotators comments indicate that they overly relied on the sentiment of tweets to make the classification — positive sentiment means in-group and negative sentiment means out-group. While negative emotions are over-represented in out-group situations as Table 3 shows, our dataset contains a substantial presence of out-group tweets with positive interpersonal emotions as well. Annotators also noticed some lexical cues like 'bipartisan' that are indicative of out-group tweets.

Do pre-trained representations capture interpersonal emotions? Pre-trained language models have been found to learn sentence representations that cluster by domain without supervision (Aharoni and Goldberg, 2020). We wished to investigate if any of our annotated properties cluster inherently in reduced representations of the tweets in our data. To obtain unsupervised representations, we use BERTweet (Nguyen et al., 2020), a language model pre-trained on 850M English tweets. We take the 768 dimensional embeddings from the final layer of the <s> token in BERTweet, and dimensionally reduce them to 2 dimensions using UMAP (Sainburg et al., 2021). Figure 3 shows the distribution of tweets, color coded for interpersonal emotions. While there is a lot of overlap between representations when stratified by emotion, we can see that some emotions that are intuitively opposite, like admiration & disgust, joy & sadness are moderately separable. This indicates that interpersonal emotions do define some topic or domain level properties of a tweet.

5 Experiments

We detail our experiments for the two novel tasks discussed in Section 2: predicting the IGR (in-group or out-group) given a tweet, and predicting the interpersonal emotion given a tweet. We present baselines for the two tasks separately, and also present a multi-task model to gauge the extent to which knowledge of IGR may help in predicting interpersonal emotion, and vice versa.

5.1 Interpersonal Group Relationship

Sentiment-Rule Our first baseline is a rule-based one leveraging coarse sentiment: if a tweet's sentiment is predicted to be negative, classify it as out-group; if positive, classify it as in-group; and if

Figure 3: Distribution of interpersonal emotions in unsupervised representations of tweets in our dataset. Orange indicates the emotion was present for that tweet. Each point represents one tweet from our dataset.

neutral, classify it as either in-group or out-group randomly. We use a RoBERTa-Base model finetuned for sentiment on tweets (Barbieri et al., 2020) to extract the sentiment of each tweet in our dataset.

NB-SVM As a second baseline, we build an SVM model that uses Naive-Bayes log-counts ratios of unigrams and bigrams (Wang and Manning, 2012).

BERTweet We use BERTweet (Nguyen et al., 2020), a language model pre-trained on 850M English tweets as our dataset consists purely of English language tweets. A classification head is placed on top of the language model. We also experiment with a version where the language model parameters are frozen, and only the classification head parameters are finetuned (BERTweet-ft).

The input to all models is only the tweet with no other context, and the target masked with a placeholder `@USER`.

5.2 Interpersonal Emotion

EmoLex As a baseline model for interpersonal emotion identification, we rely on EmoLex (Mohammad and Turney, 2013). EmoLex consists of 14,182 crowdsourced words associated with the 8 basic Plutchik emotions. Critically, these words appear in emotional contexts, but are not necessarily emotion words themselves. EmoLex counts occurrences of words from its lexicon in an utterance, and assigns a normalized score for each emotion based on occurrence frequency. We consider an emotion to be on, if it's normalized score is $\geq$ 0.001. While EmoLex has issues with regards to its context insensitivity and the social biases built into its lexicon (Zad et al., 2021), we include it as a baseline to understand to what extent interpersonal emotions can be deduced using a lexicon.

BERTweet We use the same BERTweet model as earlier. We add a dense output layer on top of the pretrained model for the purposes of finetuning, with a sigmoid cross entropy loss function to support multi-label classification. The loss is weighted for each of the 8 emotion labels with the ratio of positive and negative examples to increase precision. If none of the 8 emotion labels are flipped on, we consider that to be the 'No Emotion' label, i.e. there is no interpersonal emotion between speaker and target in the tweet. We experiment with a version of the model where the language model parameters are frozen and only the labelling head parameters are finetuned (BERTweet-ft).

5.3 Multi-Task Model

In § 4, we observed that the emotions anger and disgust are overwhelmingly present in out-group situations. Thus, we hypothesize that IGR information would be useful towards interpersonal emotion identification, and vice versa. To test this hypothesis we train a multi-task model. The model is trained to predict *both* the IGR label and emotion using shared parameter finetuning.

We use the same BERTweet model as earlier. We add two dense output layers on top of the pretrained model, one for classifying IGR and another for labelling interpersonal emotion. Both heads share the same parameters below. These are trained with same loss as earlier individual models. The model alternates between finetuning for group relationship and emotion over every training item.

5.4 Implementation

We use `bertweet-base` pretrained embeddings from Huggingface's models hub (Wolf et al., 2020). All models are finetuned for a maximum of 20 epochs with early stopping. Early-stopping patience for models trained on each task separately is 3. The patience for the multi-task model is set at 5 as the multi-tasking setup led to slower convergence. The learning rate for the classification heads was set at 5e-3 while the learning rate for the internal language model parameters was set at 2e-5. Dropout probabilities in classification heads

Model	F1	Model	F1
Majority class	51.1	BERTweet	74.1 (3.3)
Sentiment-Rule	56.3	BERTweet-ft	66.5 (1.6)
NB-SVM	62.5	Multitask	77.3 (0.8)
Human	66.7		

Table 4: Results on test set, with SD in parentheses, for interpersonal group relationship prediction task.

In-group	Out-group
thanks, love, count me birthday, my colleague	thanks, bipartisan, restore kind, resignation

Table 5: Top unigram and bigram features from NB-SVM model for each class.

	Emo Lex	BERTweet	BERTweet -ft	Multi-task
Admir.	37.5	70.3 (3.7)	40.7 (1.1)	68.9 (1.6)
Anger	26.6	71.3 (11.2)	23.0 (3.4)	69.3 (3.3)
Disgust	25.5	47.1 (21.6)	13.0 (4.1)	74.5 (7.1)
Interest	0	53.1 (3.3)	5.8 (2.4)	51.5 (8.5)
Joy	48.4	85.9 (1.9)	71.3 (1.4)	83.6 (1.3)
Sadness	4.3	11.1 (9.6)	0	33.6 (18.5)
No Emotion	22.2	49.1 (1.2)	43.4 (3.8)	71.6(1.2)

Table 6: F1 scores on test set, with SD in parentheses, for interpersonal emotion labelling task.

Emotion	BERTweet	MultiTask
Admiration	77.9 (2.6)	72.8 (3.9)
Anger	71.7 (9.9)	69.4 (3.4)
Disgust	48.2 (22.4)	75.9 (6.5)*

Table 7: F1 scores on test set, SD in parentheses on out-group tweets. * indicates statistical significance ($p<0.05$)

was set at 0.1. The best performing model before early stopping on validation data was chosen in all cases. We report F1 scores averaged over 3 random restarts for all models, with the standard deviation in parentheses next to the mean.

6 Results and Analysis

Interpersonal Group relationship In modeling IGR, we find that `Sentiment-Rule` performs not much better than chance (Table 4). This underscores one strength of our data, which contains a sizable number of out-group tweets with positive interpersonal emotion attached to them. The `NB-SVM` model based on unigrams and bigrams performs slightly better, and picks up on some obvious out-group lexical cues like the lemma 'bipartisan', as shown in Table 5. The `BERTweet` model performs substantially better, performing over 10 points better than humans. The model, with only the classification head finetuned, leaving the language model parameters intact(`BERTweet-ft`) performs about 10 points above chance — indicating that there may be features advantageous towards this task in the vanilla LM itself.

Interpersonal Emotion We find that the `EmoLex` baseline, which relies purely on lexical cues, performs dismally on our data, with poor performance in both in-group and out-group settings(Table 6). This is a strong indication that emotions are expressed more implicitly in this dataset. The `BERTweet` model performs substantially better, indicating that interpersonal emotions, even if implicit, can be learned.

Multitask Model As Table 4 shows, Multitasking the two tasks leads to a noticeable improvement in F1 for IGR prediction, with the differences being statistically significant using a bootstrap test ($p<0.05$; Berg-Kirkpatrick et al., 2012); the multi-task model is also more stable with much lower variance across runs. These results suggest that interpersonal emotion is useful towards IGR prediction.

Table 6 shows that the performance of the multitask model on predicting interpersonal emotions is significantly better that the BERTweet model ($p<0.05$) on emotions like *disgust*, which suggests that IGR is useful towards the task of emotion identification. Furthermore, multitasking boosted performance at predicting the *no emotion* label by 20%. Table 7 compares the multitask model's performance against the BERTweet model in *out-group* settings (where most of the gains were found) for 3 emotions — illustrating the boost in performance afforded by joint modeling of IGR and emotion for *digust*. The 3 emotions listed also showed significant differences in their distribution in in-group and out-group settings.

Humans vs. Models Comparatively, we find that model performance exceeds human performance on the task of in-group versus out-group prediction, albeit not on the same dataset. The model's main driver of performance is its high accuracy on positive intergroup emotion out-group tweets, such as those expressing admiration or joy. Human annotators consistently fall back on the heuristic that sentences with positive affect probably imply that the speaker is talking about someone in their in-group. But it is not the case in the political domain, where overtures to bipartisanship serve as useful signals. For instance, both (3-a) and (3-b) express admiration towards the target Doe, where the first is in-group while the second is out-group. The call to civility is the only subtle linguistic cue that this tweet may constitute out-group speech.

(3) a. Admire @OfficialCBC Chairman @Doe's moral voice on issues of racism and restorative justice. He is a real leader for our nation and Congress.
b. A decade has passed, but our friendship is the same. Proud to work with @Doe to #ReviveCivility. #tbt Read more about our efforts here:

Future work needs to look into what information the embeddings are using to make their classification decision.

Model Errors While the multitasking setup improves model performance on the task of predicting IGR, and outperforms human labelers in our small pilot, it still gets some easy examples wrong, such as labelling (4) as in-group even though it expresses some disgust at the target. The model also falls into the same trap as human labelers — for instance assuming that a tweet expressing admiration must be in-group (5).

(4) Trump selected @USER for HHS Secretary. Price has undeniable history of cutting access to healthcare to millions, especially women.

(5) Inspiring speech from @USER - we have a duty to represent our country with respect & dignity. #NationalDayofCivility.

To ensure that model performance on IGR prediction is not limited by the size of our training data, we experimented with training `BERTweet` models on larger datasets. Since we have 'found supervision' for IGR labels, we only need to increase training data size by sampling more tweets from relevant accounts using the same procedure detailed in § 3.1. We found that F1 score does not increase with more training data.

Future work needs to look into linguistically motivated ways to improve model performance on the IGR task. Since we have observed that the multi-task setup improves model performance, perhaps other multi-task setups, such as modeling the overall affect towards the target expressed by the speaker might help in modeling IGR better.

7 Related Work

Emotion and Stance Detection A wealth of work has looked at corpora and models for the detection of perceived emotion in social media text (Mohammad, 2012; Wang et al., 2012; Mohammad and Kiritchenko, 2015; Abdul-Mageed and Ungar, 2017; Desai et al., 2020; Demszky et al., 2020). However existing work doesn't distinguish between emotion of a sentence as a whole, versus interpersonal emotion towards a target. The task closest to our study of interpersonal emotions is stance detection: whether the author has a favourable, neutral, or negative position towards a proposition or target. Mohammad et al. (2016) looked at stance in five target domains are given: abortion, atheism, climate change, feminism and Hillary Clinton. While stance detection focuses on a collection of utterances with the same topic, our interest is in modeling interpersonal emotion towards a target individual which is more fine-grained and can vary in each utterance.

Intergroup bias in Psychology The Linguistic Intergroup Bias (LIB) theory (Maass et al., 1989; Maass, 1999) states that there is a systematic asymmetry in language production qualities of a speaker as a function of the social category to which the referent of an utterance belongs. Through psycholinguistic experiments, LIB seeks to explain why stereotypes are transmitted and persist in daily life: in an interpersonal situation, socially desirable in-group behaviors and undesirable out-group behaviors are encoded at a higher level of **abstraction**, whereas socially undesirable in-group behaviors and desirable in-group behaviors are encoded at a lower level of abstraction. Work in psychology and psycholinguistics reproduced LIB in various domains such as political news reporting (Anolli et al., 2006) and crime reporting (Gorham, 2006); as well as work exploring how LIB can be used as an indicator for a speaker's prejudicial attitudes (Hippel et al., 1997), or as a predictor for racism (Schnake and Ruscher, 1998).

Contemporaneous studies on LIB, however, are hand-coded and have so far tended to focus on narrow concepts such as abstractness of the verb and coarse notions of sentiment. Nonetheless, the LIB hypothesis connects the two dimensions of interpersonal dynamics studied here with a third dimension directly related to semantic properties of the utterance.

8 Conclusion

Taking a cue from studies of bias in social science and psychology, we situate bias in language use through the lens of interpersonal relationships between the speaker and target of an utterance, and the speaker's interpersonal emotional state with respect to the target. Over a corpus of tweets by members of US Congress, we introduce two novel tasks – interpersonal group relationship prediction (IGR) and interpersonal emotion labelling, to better understand variation in language as a function of social relationship between speaker and target in interpersonal utterances. We find certain interpersonal emotions like anger and disgust are overrepresented in out-group situations, with the majority of the negative emotions directed at leaders of the two political parties. Through modeling studies, we find that transformer based models perform better than humans at predicting IGR given an utterance, raising the question as to what latent features of language the model uses to make this decision. Finally, we also find that joint modelling of the two dimensions is beneficial to prediction of certain interpersonal emotions in out-group situations. Future work needs to look into what information is useful for predicting IGR and emotions – with the Linguistic Intergroup Bias literature offering a clue as to which higher level semantic features vary systematically.

Ethics Statement

For our corpus of tweets on which we performed annotations, we downloaded the tweets using the official Twitter API. In accordance with the Twitter Terms of Service, we release tweet IDs and usernames, but not the tweet text itself. Our dataset was built through crowdsourced annotations on Amazon Mechanical Turk. To ensure annotators were paid a fair wage of at least $10 an hour, we paid annotators $0.50 per HIT. Each HIT involved annotating 3 tweets, which we estimate to take on average 3 minutes to complete.

Limitations

Our results show the importance of having reliable and accurate emotion prediction models, which is an open problem in psychology and computer science. Future work might look into identifying different fine-grained emotional constructs and study their correlations with the underlying linguistic biases. Future work may also look into the generalizability of the results presented here in other domains of language use.

While we present the utterances as constituting natural speech by one speaker (the congressperson who sent the tweet), it is likely most congresspeople employ social media teams that help in crafting the language of some of their tweets. However, we believe for the sake of interpersonal group membership, the relationship between the speakers and their targets would not be affected.

Finally, while we show that transformer based models perform better at IGR prediction than humans, we note that the human performance was on a small subset of test data. While it is possible that these models discovered latent features that could explain their better performance, the model could also be using spurious features idiosyncratic to our dataset, rather than true differences in in-group versus out-group speech.

Semantic Parsing for Conversational Question Answering over Knowledge Graphs

Laura Perez-Beltrachini[1], **Parag Jain**[1], **Emilio Monti**[2], **Mirella Lapata**[1]

Abstract

In this paper, we are interested in developing semantic parsers which understand natural language questions embedded in a *conversation* with a user and *ground* them to formal queries over definitions in a general purpose knowledge graph (KG) with very large vocabularies (covering thousands of concept names and relations, and millions of entities). To this end, we develop a dataset where user questions are annotated with SPARQL parses and system answers correspond to execution results thereof. We present two different semantic parsing approaches and highlight the challenges of the task: dealing with large vocabularies, modelling conversation context, predicting queries with multiple entities, and generalising to new questions at test time. We hope our dataset will serve as useful testbed for the development of conversational semantic parsers.[1]

1 Introduction

Conversational information seeking is the process of acquiring information through conversations (Zamani et al., 2022). Recent years have seen an increasing number of applications aiming to build conversational interfaces based on information retrieval (Radlinski and Craswell, 2017) and user recommendation (Jannach et al., 2021). The popularity of intelligent voice assistants such as Amazon's Alexa or Apple's Siri has further stimulated research on question answering over general purpose knowledge graphs (e.g., Wikidata). Key to question answering in this context is the ability to ground natural language onto concepts, entities, and relations in order to produce an *executable* query (e.g., SPARQL) which will retrieve an answer or *denotation* from the knowledge graph (KG).

This grounding process, known as *semantic parsing* has been studied in the context of one or few domain-specific databases (Yu et al., 2019a; Jain and Lapata, 2021; Suhr et al., 2018) or without taking the conversational nature of the task into account (Reddy et al., 2014; Yih et al., 2016; Dubey et al., 2019; Gu et al., 2021). However, due to the complexities of the semantic parsing task, there are no large scale datasets consisting of information seeking conversations with executable queries against a KG. Conversational semantic parsing over KGs requires handling very large vocabularies covering thousands of concept names and relations, and millions of entities rather than specialized terms consisting of hundreds of tables and column names. Moreover, information seeking conversations are by nature incremental involving interrelated rather than isolated questions.

In this work, we create 𝕊ℙ𝕀ℂ𝔼, a **S**emantic **P**ars**I**ng dataset for **C**onversational qu**E**stion answering over Wikidata. 𝕊ℙ𝕀ℂ𝔼 consists of user-assistant interactions where natural language questions are paired with SPARQL parses and answers provided by the system correspond to SPARQL execution results. We derive this dataset from CSQA (Saha et al., 2018), an existing benchmark originally proposed for retrieval-based conversational question answering (Lan et al., 2021). Although CSQA does not have executable queries, it contains a large number of natural language questions and their corresponding answers, highlighting a range of conversational phenomena such as coreference, ellipsis, and topic change as well as different types of questions exemplifying varying intents.

Table 1 shows a conversation from 𝕊ℙ𝕀ℂ𝔼 illustrating how questions (utterances on the left) are annotated with SPARQL queries (SP on the right blue box). To create a large-scale dataset (197k conversations), we develop SPARQL templates for different question intents; entity, relation, and class symbols are initially under-specified and subsequently filled automatically to generate full SPARQL queries. CSQA questions have been previously associated with logical forms generated with

custom-made grammars (Guo et al., 2018; Kacupaj et al., 2021; Marion et al., 2021). As a result, semantic parsers based on them operate with different sets of grammar rules and are not strictly comparable, since the grammars may have different coverage and semantics (e.g., terminal symbols may encapsulate different degrees of execution complexity). In SPICE, questions are represented with SPARQL, a standard query language for retrieving and manipulating RDF data.[2] This allows us to compare parsers developed on the dataset on an equal footing and facilitates further extensions (e.g., new question intents), without the need to redefine the grammar and its execution engine. In an attempt to build semantic parsers which generalise to new user questions, we further create different data splits where new intents appear only at test time (Finegan-Dollak et al., 2018).

For our semantic parsing task, we establish two strong baseline models which tackle the large vocabulary problem and the prediction of logical forms in different ways. The first approach (Gu et al., 2021) uses *dynamic vocabularies* derived from KG subgraphs for each question and a simple sequence-to-sequence architecture to predict *complete* SPARQL queries. The other approach (Kacupaj et al., 2021) predicts SPARQL *query templates* and then fills in entity, relation, and type slots by means of an entity and ontology classifier. Our experiments reveal several shortcomings in both approaches, such as not being able to encode large sets of KG elements and generate the same entity several times. Both approaches struggle with ellipsis, they cannot resolve coreference when the referent appears in the conversation context beyond the previous turn, have reduced performance on questions with multiple entities, and struggle with unseen question intents. We discuss these challenges and outline research directions for conversational semantic parsing.

2 The SPICE Dataset

The CSQA dataset (Saha et al., 2018) aims to facilitate the development of QA systems that handle complex and inter-related questions over a knowledge graph. In contrast to simple factual questions that can be answered with a single KG triple (i.e., {subject, relation, object}), complex questions require manipulating sets of triples and reasoning over these. In Table 1, a question like *How many sports teams participated in that tournament?* requires numerical reasoning and answering the question in turn $\mathcal{T}_2$ relies on correctly interpreting $\mathcal{T}_1$.

Questions and answers in this dataset were elicited from human experts playing user and system roles as well as from crowd-workers. In a second stage, templates derived from the human-authored QA pairs were used to automatically augment the dataset. Human experts also suggested complex reasoning questions and derived templates thereof. Conversations were built as sequences of

Table 2: $\mathbb{SPICE}$ statistics (top); general question types (middle); linguistic phenomena (bottom).

QA pairs exploring paths in the KG. By construction, the QA pairs in a conversation are connected through one or several entities in the KG. Questions fall into two coarse categories, *simple* and *reasoning*-based, and the way QA pairs are organised in a sequence introduces various *conversational phenomena* which we summarize below.

Simple Questions are factoid questions, seeking information related to an entity (e.g., *Which tournament did Detroit Tigers participate in?* in Table 1) or set of entities (e.g., *What are the countries of those sports teams?*).

Reasoning Questions are complex questions which require the application of numerical and logical operators over sets of entities. For instance, to answer the question *How many sports teams participated in that tournament?* requires finding the set of sports teams that participated in a given tournament (e.g., *1909 World Series*) and taking its count. Questions in this category also involve General Entities (GE) such as *tournament*, in addition to Named Entities (NE), and multiple entities (both NE and GE) in a single question (e.g., *Which tournaments have less number of participating sports teams than 1909 World Series?*). Some question types also combine multiple reasoning operators.

Conversations contain sequences of mixed-initiative interactions where the system requests clarification on ambiguous questions. Conversations also include discourse phenomena such as coreference (e.g., *Which sports team was the champion of that tournament?* in Table 1) and ellipsis (e.g., *And what about 1910 World Series?* as a follow up question to *How many sports teams participated in that tournament?*).

There are 10 question types and 47 question subtypes. In Table 2, we only list question types but provide all subtypes in Table 9 in Appendix A.

2.1 Question Semantics Described by Actions

Saha et al. (2018) envisaged CSQA as a benchmark for retrieval-based conversational question answering (Bordes et al., 2015; Dong et al., 2015; Jain, 2016; Lan et al., 2021). These methods embed natural language questions and KG triples into high dimensional spaces and rely on neural reasoning modules to match questions to candidate answers. Hence, questions do not have associated logical forms, only gold answers are available.

Our success in creating semantic parse annotations is partly due to the fact that CSQA provides useful KG information. Each interaction (i.e., user and system turn) comes with annotations about KG entities, types, and relation symbols as well as some information about the triple patterns involved in the question (illustrated in Table 1 with ENT, REL, TYP, and TRIPLE fields). It also provides information pertaining to question types and subtypes (see INTENT in Table 1).

Taking advantage of these annotations, follow-on work (Guo et al., 2018) defined a semantic parsing task over CSQA, modeling the meaning of questions as a sequence of actions. The set of actions encompasses find (or find_rev when the entity is in object position) to retrieve sets of entities in a subject (object) position, as well as actions operating on sets of entities (e.g., filter_type). For instance, the question in turn $\mathcal{T}_1$ in Table 1 would be parsed to [filter_type, find_rev, Q650855, P1923, Q500834], meaning "find the set of entities that are in relationship *participating team* with *Detroit Tigers* and then filter those that are of type *tournament*". A breadth-first search algorithm generates action-grammar annotations for each question and a sequence of grammar-actions is considered correct if upon execution it returns the gold answer. Subsequent work (Shen et al., 2019; Kacupaj et al., 2021; Marion et al., 2021) expanded this action-grammar greatly improving its coverage (i.e., the number of successfully annotated questions).

2.2 From Actions to SPARQL Queries

In this work, we take a step further and map CSQA natural language questions into vanilla SPARQL queries. We first analysed how intent is expressed

	ATIS	SParC	CoSQL	SPICE

Logical form	SQL	SQL	SQL	SPARQL
Database type	Rel	Rel	Rel	KG

Table 3: Conversational semantic parsing datasets (Rel: relational database; KG: knowledge graph).

in question types and subtypes and then manually defined SPARQL templates for each question subtype. A SPARQL template is a query with unspecified triple patterns in the WHERE clause. For instance, the template for the question in turn $\mathcal{T}_1$ is {SELECT ?x WHERE **triple**(?x, ENTITY, RELATION). ?x wdt:P31 TYPE.}. We finally modified the tool provided in Kacupaj et al. (2021) to automatically instantiate the SPARQL templates, providing annotations for the entire dataset (e.g., by filling missing slots and determining subject/object positions for **triple**($\cdot$) elements as SELECT ?x WHERE {?x wdt:P1923 wd:Q650855. ?x wdt:P31 wd:Q500834.}).

We imported the Wikidata snapshot provided by Saha et al. (2018) into a KG in a SPARQL server (see Appendix B for more details) and assessed the correctness of SPARQL queries by executing them and comparing results to gold answers. For some questions the annotation procedure did not produce a SPARQL parse that recovered the gold answer. In these rare cases, we redefined the answer if it did not affect the conversation flow or truncated the conversation up to that point.

Table 2 shows various statistics for SPICE while Table 3 compares it to related conversational datasets such as ATIS (Suhr et al., 2018), SParC (Yu et al., 2019b), and CoSQL (Yu et al., 2019a). As can be seen, SPICE contains a sizeable number of training instances, its conversations are longer, and the semantic parsing task is real-scale.

3 The Semantic Parsing Task

We consider the semantic parsing task over a sequence of dialogue turns $d = (d_1, d_2, \cdots, d_{|d|})$, where turn d_t corresponds to a user-system interaction with user question x_t and system answer a_t. Each turn has a conversation context c_t made of interactions d_i such that $i < t$. Given interaction d_t with context c_t and user question $x_t = (x_{t1}, x_{t2}, \cdots, x_{t|x_t|})$, our goal is to predict a SPARQL query $y_t = (y_{t1}, y_{t2}, \cdots, y_{t|y_t|})$ that represents the intent of x_t and, upon execution over knowledge-graph $\mathcal{K}$, yields denotation a_t. y_t is a sequence over a target vocabulary $\mathcal{V} = \mathcal{V}_f \cup \mathcal{V}_\mathcal{K}$ where $\mathcal{V}_f$ is fixed and contains SPARQL keywords (e.g., SELECT) and special tokens (e.g., beginning of sequence token, BOS), and $\mathcal{V}_\mathcal{K}$ contains all knowledge-graph symbols (e.g., entity IDs such as Q76 for *Barack Obama*).

We propose two approaches for this semantic parsing task which establish strong baseline performance and highlight various challenges. These differ in the way they handle large KG vocabularies and how they generate logical forms. Figure 1 provides a sketch of the two models discussed below.

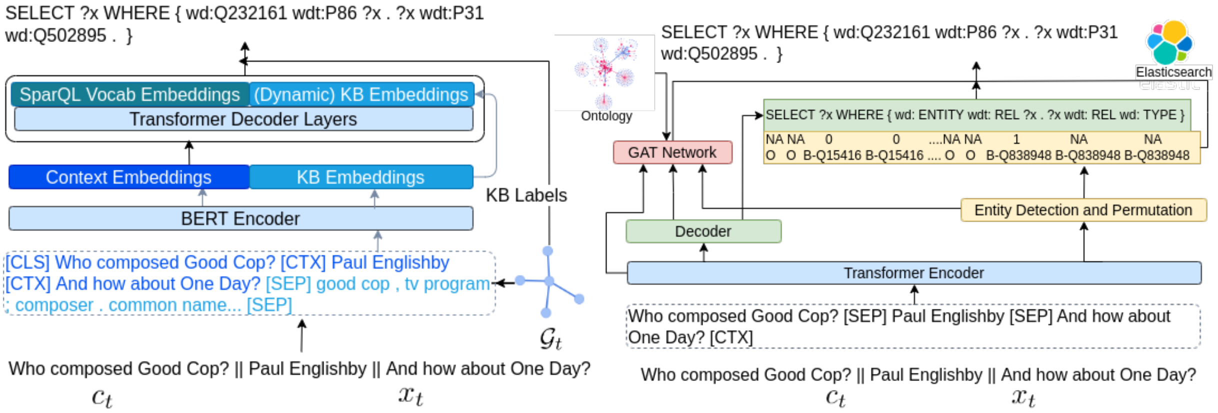
3.1 Parsing with a Single Decoder and Knowledge Subgraphs

Our first model is parameterised by an encoder-decoder Transformer neural network (Vaswani et al., 2017), and an adaptation of the semantic parsing architecture proposed in Gu et al. (2021).

Dynamic Vocabulary Since the KG vocabulary $\mathcal{V}_\mathcal{K}$ can be extremely large, we parse question x_t with a smaller vocabulary $\mathcal{V}_t \subseteq \mathcal{V}_\mathcal{K}$ which only contains KG symbols related to x_t. Following previous work (Gu et al., 2021; Marion et al., 2021), we assume the symbols related to x_t are those appearing in subgraph $\mathcal{G}_t$ of knowledge-graph $\mathcal{K}$, $\mathcal{G}_t \subseteq \mathcal{K}$. Given question x_t and its context c_t, we identify KG entities $\mathcal{E}_t = \{e_{t1}, e_{t2}, \cdots, e_{t|\mathcal{E}_t|}\}$ which correspond to mentions in x_t and c_t. We then obtain $\mathcal{G}_t$ by taking the one-hop neighbourhood for each entity $e_{ti} \in \mathcal{E}_t$. In other words, we include all KG triples (s, r, o) where the entity appears in subject ($s = e_{ti}$) or object position ($o = e_{ti}$). When e_{ti} is a subject, we include triple (e_{ti}, r, τ_o) where τ_o is the type of entity o; analogously, when e_{ti} appears in an object position, we add (τ_s, r, e_{ti}). For entities e_{ti} we include their types $\tau_{e_{ti}}$. When e_{ti} is a general entity (e.g., a type such as *tournament*) we add relations from $\mathcal{K}$ that have instances of type e_{ti} as their subject (object). The final vocabulary $\mathcal{V}_t$ contains all entities in $\mathcal{E}_t$, all relations r and types (τ_o, τ_s, and $\tau_{e_{ti}}$) found in the set of triples in $\mathcal{G}_t$.

Note that context c_t is defined as a window over the conversation so far. Following previous work (Marion et al., 2021; Kacupaj et al., 2021), we set the conversation context to the previous user-system interaction $c_t = \{d_{t-1}\}$.

Encoder-Decoder Model Our encoder is a BERT (Devlin et al., 2019) model fine-tuned on



(a) Encoder-decoder model with dynamic vocabularies.

(b) Semantic parser based on Lasagne multi-task model.

Figure 1: Two modeling approaches to conversational semantic parsing.

our semantic parsing task. The decoder is a randomly initialised Transformer network (Vaswani et al., 2017). To account for the difference in initialisation between the encoder and decoder networks, we follow the training scheme proposed in Liu and Lapata (2019). We provide details in Appendix C.

The input to our semantic parser is a tuple $(x_t, c_t, \mathcal{G}_t)$ consisting of natural language question x_t, its context c_t, and subgraph $\mathcal{G}_t$ which we adapt to BERT's input format as follows (Gu et al., 2021). We concatenate the sequence of natural language questions and answers appearing in c_t and x_t, using the special token [CTX] as a delimiter and prepend the [CLS] token in the beginning of the sequence. Special token [SEP] denotes the end of sequence followed by the linearised KG subgraph $\mathcal{G}_t$. The linearisation procedure goes over entities in $\mathcal{G}_t$, enumerating their types and relations. Importantly, we denote entities by their label rather than their KG identifiers. The order of entities in $\mathcal{G}_t$ is random. Figure 1(a) shows an example of the input to our BERT-based encoder.

More formally, the encoder takes token sequences $x'_t = \text{[CLS]}x'_{t_{\text{text}}}\text{[SEP]}x'_{t_{\text{graph}}}\text{[SEP]}$ as input where $x'_{t_{\text{text}}}$ is the natural language subsequence and $x'_{t_{\text{graph}}} = (g^t_1, \cdots, g^t_{|\mathcal{G}_t|})$ is the sequence of knowledge-graph symbols from the linearised graph $\mathcal{G}_t$. Note that these knowledge-graph symbols constitute the target dynamic vocabulary $\mathcal{V}_t$ and $|\mathcal{G}_t|$ represents the number of KG symbols which is equal to the size of the target vocabulary $|\mathcal{V}_t|$. The encoder maps input sequences x'_t into sequences of continuous representations $\mathbf{z_t} = (\mathbf{z}_{t1}, \ldots, \mathbf{z}_{t|x_t|})$, and the decoder then generates the target SPARQL parse $y_t = (y_{t1}, \ldots, y_{t|y_t|})$ token-by-token autoregressively, hence modelling the conditional probability: $p(y_{t1}, \ldots, y_{t|y_t|}|x'_t)$.

The linearised graph $\mathcal{G}_t$ can exceed BERT's maximum number of input positions (which is 512). To avoid throwing away useful information, we adopt a solution similar to Gu et al. (2021). For question x_t with $\mathcal{G}_t$ containing k entities, we create k input sequences $x_t'^1, \cdots, x_t'^k$. These k sequences share the natural language subsequence but have different KG symbol subsequences. Given an input sequence $x_t'^1, \cdots, x_t'^k$, we obtain contextualised representations as $\mathbf{z}_t^1, \cdots, \mathbf{z}_t^k = \text{BERT}(x_t'^1, \cdots, x_t'^k)$.

The model further splits the sequence of continuous representations $\mathbf{z}_t^j$ into textual representations $\mathbf{z}^j_{t_{\text{text}}}$ and knowledge-graph symbols $\mathbf{z}^j_{t_{\text{graph}}}$ both of which are contextualised. We then average representations $\mathbf{z}_{t_{\text{text}}} = \text{AVG}(\mathbf{z}^j_{t_{\text{text}}})$ and feed them as input to the decoder (see Figure1(a)). From representations $\mathbf{z}^j_{t_{\text{graph}}}$, we derive the embeddings for the elements in the target dynamic vocabulary $\mathcal{V}_t$. Recall that the decoder parses input questions x_t using target vocabulary $\mathcal{V} = \mathcal{V}_f \cup \mathcal{V}_t$ which consists of a set of fixed ($\mathcal{V}_f$) and dynamic ($\mathcal{V}_t$) target tokens. The decoder then predicts the probability of each SPARQL token y_{ti} as $p(y_{t_i}|y_{t_{<i}}, x_t'^1, \cdots, x_t'^k) = \text{softmax}(\mathbf{W}_o \mathbf{h}_i^L)$ where $\mathbf{h}_i^L$ is the decoder top layer hidden representation at time step i. $\mathbf{W}_o \in \mathbb{R}^{|\mathcal{V}_f \cup \mathcal{V}_t|}$ is the output embedding matrix with $\mathbf{W}_o = [\mathbf{W}_f; \mathbf{W}_t]$, where $[;]$ denotes matrix concatenation, $\mathbf{W}_f$ is the embedding matrix for the fixed target vocabulary, and $\mathbf{W}_t$ is derived from the encoder representations $\mathbf{z}^j_{t_{\text{graph}}}$.

3.2 Parsing with Multiple Decoders and an Ontology Classifier

Our second model is an adaptation of the Lasagne architecture proposed in Kacupaj et al. (2021).

Lasagne generates logical forms following a multi-stage approach where a backbone sketch is first predicted and then fleshed out. Their sketch is a sequence of actions from a custom grammar which we modify to be a sketch of SPARQL queries.

SPARQL Template Prediction Lasagne employs an encoder-decoder model based on Transformers (Vaswani et al., 2017) to convert a user question x_t in a conversation into a logical form template. The input to the encoder is the conversation context $c_t = \{d_{t-1}\}$ and user question x_t. Utterances are separated via [SEP] tokens, while the special context token [CTX] denotes the end of sequence (see Figure 1b). The input sequence is encoded via multi-head attention (Vaswani et al., 2017) to output contextualized representations which are then fed to the decoder to predict a sequence of actions (without grounding to KG elements) token-by-token. Instead, our decoder predicts SPARQL queries with place-holders for KG symbols. For instance, for the WHERE clause of turn $\mathcal{T}_1$ in Table 1, it predicts {ENTITY RELATION ?x. ?x wdt:P31 TYPE.} instead of {wd:Q5582479 wdt:P161 ?x. ?x wdt:P31 wd:Q502895.})

Entity Recognition and Linking An entity recognition module detects entities in the input and links them to the KG (Shen et al., 2019; Kacupaj et al., 2021). Initially, entity spans are identified using an LSTM which performs BIO sequence labelling.[3] Entity spans are subsequently linked to KG entities via an inverted index (created using Elasticsearch[4]) which maps entity labels to entity IDs. Once identified, the entities are further filtered and reordered so that they match their order of appearance in the SPARQL (see Figure 1(b)).

Predicting Types and Relations Finally, an ontology graph with types and relations appearing in $\mathbb{SPICE}$'s KG is constructed.[5] The graph is encoded with a Graph Attention Network (GAT; Velickovic et al. 2018) and the prediction of type and relation fillers for the SPARQL template is modeled as a classification task over graph nodes, given the conversational context and the decoder hidden state.

Learning All modules outlined above are trained in a multi-task manner, optimizing the weighted average of the following individual losses $L = \lambda_1 L^{\mathrm{F}} + \lambda_2 L^{\mathrm{G}} + \lambda_3 L^{\mathrm{R}} + \lambda_4 L^{\mathrm{O}}$ where L^{F} is the loss of the SPARQL template decoder, L^{G} is the type and relation prediction loss using the GAT network, L^{R} is the entity recognition loss, and L^{O} the entity reordering loss (and weights $\lambda_{1:4}$ are learned during training). We refer the interested reader to Kacupaj et al. (2021) for mode details.

4 Results

We examine how the two models just described fare on different question types and subtypes. We report results on $\mathbb{SPICE}$ i.i.d train/valid/test splits (containing 152,391/16,813/27,797 conversations, respectively) but also create new splits that assess out-of-distribution generalisation. In all cases, following previous work (Saha et al., 2018; Kacupaj et al., 2021), we use execution-based automatic metrics. Micro *F1-score* evaluates question parses that return a set of entities, while *Accuracy* is used for question parses that evaluate to True/False or return a numerical value. In addition, we report *Exact Match* (EM) against the gold SPARQL parse.

4.1 Performance per Question Type

Table 4 shows our results on the $\mathbb{SPICE}$ i.i.d test split. BertSP variants differ in how they obtain the set of KG entities $\mathcal{E}_t$ (cf. Section 3.1) to build the dynamic vocabulary. BertSP$_{\mathrm{G}}$ has access to oracle entities, types, and coreference annotations which allows us to disassociate the complexity of the SPARQL generation task from the problem of grounding and disambiguating entities to KG symbols. Variants BertSP$_{\mathrm{S}}$ and BertSP$_{\mathrm{A}}$ do not have access to oracle annotations. BertSP$_{\mathrm{S}}$ grounds mentions to KG entities with a simple algorithm based on string matching (Marion et al., 2021); while BertSP$_{\mathrm{A}}$ relies on AllenNLP's Named Entity Recognizer (NER) and the Elasticsearch inverted index for Named Entity Linking (NEL). Both have to identify coreferring entities using the conversation context c_t. Both BertSP$_{\mathrm{S}}$ and BertSP$_{\mathrm{A}}$ use string matching for type linking (i.e., grounding general entities to KG types).

Note that it is not straightforward to perform oracle analysis for LasagneSP without compromising the model structure which predicts entities, their types, and relations in multiple stages.

Exact Match Performance We observe that execution based metrics (F1-score and Accuracy) are generally higher than EM. This is because in some

---

[3] BIO labels for training are obtained by preforming string matching between entity annotations and user utterances.

Overall	81.50	85.74	81.18	**70.96**	59.00	48.60	79.50	66.32

Table 4: Accuracy (AC), and exact match (EM) on SPICE i.i.d test split. BertSP$_\text{G}$ has access to oracle entities, types, and coreference annotations. Best EM predictions are shown in bold.

cases the SPARQL parse may be incorrect and still yield some results. For instance, a parse requiring the UNION of two graph patterns may yield a partially correct answer by only including one graph pattern; similarly, a parse can evaluate to False and agree with the gold answer just because it included a wrong relation symbol.

The Importance of Entity Grounding Not surprisingly, the model with access to oracle information (variant BertSP$_\text{G}$) obtains the best performance. Results improve not only for questions with entities referring to previous context but also indirectly for other types of questions. Since entities are correctly grounded in previous conversation turns c_t, the model operates with more accurate graphs $\mathcal{G}_t$ and richer dynamic vocabularies $\mathcal{V}_t$.

Both BertSP$_\text{S}$ and BertSP$_\text{A}$ perform coreference resolution using limited conversation context and thus performance decreases. These models also have to ground named (*Detroit Tigers*) and general (*tournament*) entity mentions to KG symbols. BertSP$_\text{S}$ which relies on string matching performs overall better than BertSP$_\text{A}$ which struggles with compound named entities such as *President of the Czech Republic*) and disambiguation during NEL (e.g., *Saint Barbara* the painting versus the Saint).

Model Comparison BertSP$_\text{S}$ and LasagneSP are similar in the way they handle NER/NEL with a task-specific approach, but differ in their conceptualization of the semantic parsing task (encoder-decoder vs. multi-tasking). LasagneSP outperforms BertSP$_\text{S}$ in Comparative, Quantitative, and Comparative-Count questions. These encompass many question subtypes with general entities which are very common in both training and testing. LasagneSP has access to *all* types and relations encoded with the graph network. In contrast, BertSP$_\text{S}$ relies on types which in the first place need to be present in the entity neighbourhood subgraph and then be preserved after truncating the input to fit the model's maximum sequence length. An advantage of BertSP$_\text{S}$ over LasagneSP, is that it allows for easier adaptation to new types and relations by relying on dynamic vocabularies, while LasagneSP would need to be retrained to accommodate them.

In Simple questions, where each question involves fewer but more diverse types, BertSP$_\text{S}$ predicts more accurate types (thanks to the input text and KG symbol contextualisation) and thus performs better. LasagneSP does poorly on Verification, Logical, and Quantitative-Count (which includes logical operators). This can be explained by a modelling limitation, i.e., it is not able to point to the same input entity more than once.

Errors in Predicted SPARQLs Manual inspection of SPARQL predictions revealed several common system errors including: prediction of erroneous entities and relations, failure to enumerate all required entities (for questions with multiple entities), and mistakes in argument order (i.e., entities and variables are correct but placed in incorrect subject/object positions). To a lesser extent, we also observed SPARQL queries with incorrect intent predictions and ill-formed syntax.

Phenomena	BertSP$_G$	BertSP$_S$	BertSP$_A$	LasagneSP
Coref$_{=-1}$	81.40	70.65	49.39	43.65
Coref$_{<-1}$	67.82	0	0	0
Ellipsis	75.93	54.33	26.39	46.54
Entities	83.37	65.40	41.64	66.52

Unseen Combinations (Train/valid/test)	BertSP$_S$ EM	LasagneSP EM
COUNTLOGIC	0.94	0
UNIONMULTI	19.74	16.89
VERIFY3	0	0

Table 6: Exact match (EM) for BertSP$_S$ and LasagneSP on 𝕊ℙ𝕀ℂ𝔼 non-i.i.d splits.

4.2 Linguistic Analysis

Table 5 shows model performance across-different question subtypes aggregated for specific phenomena. These include Coreference, Ellipsis, and Multiple Entities (Entities). We distinguish between cases where coreference can be resolved in the previous turn (Coref$_{=-1}$) and further back in the conversation history (Coref$_{<-1}$). In addition, some question subtypes contain plural mentions, i.e., they are linked to multiple entities which the semantic parser must enumerate in order to build the correct parse. Ellipsis can be often resolved within the previous interaction (Coref$_{=-1}$), but not within the wider discourse context. Questions with multiple entities bring further disambiguation challenges. In Appendix A, we provide the list of question subtypes for each phenomenon in Table 5.

As can be seen, the oracle BertSP$_G$ model which has access to gold annotations is superior to variants which rely on automatic entity and type linking. BertSP$_S$ is better than LasagneSP at handling coreference within immediate context (i.e., $c_t = \{d_{t-1}\}$). Due to the fact that LasagneSP predicts entity positions in SPARQL, it is particularly bad at resolving mentions to multiple entities in the previous context or even multiple mentions of the same entity in the output parse (as is the case with Verification questions). Perhaps unsurprisingly, neither BertSP$_S$ nor LasagneSP can resolve mentions to non-immediately preceding utterances. BertSP$_S$ performs better than LasagneSP in questions with ellipsis; we conjecture that the input context and contextualisation of KG symbols help in grounding elided relation mentions. Ellipsis and multiple entities improve by a large margin with access to gold annotations (see BertSP$_G$ in Table 5).

4.3 Generalisation

We further evaluate the models' ability to generalise by creating "query-based" splits (Finegan-Dollak et al., 2018), i.e., splits with query patterns seen only at test time. Our splits include: (a) question subtypes that involve a count operation over a union operator (COUNTLOGIC; individual operators are seen at training time but not the combination thereof); this split has 153,562/14,262/29,177 instances for training/validation/testing; (b) question subtypes that involve a union operator over two graph patterns with different relations (UNIONMULTI; the union of two graph patterns with the *same* relation is seen during training); this split contains 157,331/14,426/25,244 instances; and (c) verification questions with three entities involving 154,027/13,869/29,105 instances (VERIFY3; questions with 2 entities only are seen during training).

As shown in Table 6, both BertSP$_S$ and LasagneSP perform poorly across different splits. While in some cases the models grasp the overall SPARQL structure for unseen questions (e.g., *Which watercourses are located in the neighbourhood of Bremen or are the tributaries of Ob? in* UNIONMULTI), they ignore specific query details and simply default to familiar patterns seen in the training (e.g., *Which people are the creators of The Theory of Everything or Ten Minutes to Live?*). In the UNIONMULTI split, the models produce an appropriate SPARQL template but systematically copy the *same* relation in *both* graph patterns. BertSP$_S$ performs slightly better than LasagneSP; we hypothesize that contextualised KG embeddings occasionally help the model select different relations. We observe a similar trend for COUNTLOGIC and VERIFY3. Appendix D shows examples of unseen questions, their SPARQLs, and common errors.

5 Related Work

Much previous work on semantic parsing focuses on mapping stand-alone utterances to logical forms. Relatively few datasets have been constructed for *conversational* semantic-parsing (Suhr et al., 2018; Dahl et al., 1994; Yu et al., 2019b,a) partly due to the difficulty of eliciting annotations in an interactive context. As a result, existing benchmarks are either single-domain or small-scale (see the comparison in Table 3). For instance, although ATIS (Suhr et al., 2018) exemplifies several challenging long-range discourse phenomena (Jain and Lapata, 2021), it is restricted to a single domain with a simple database schema. SParC (Yu et al., 2019b) and CoSQL (Yu et al., 2019a) present cross-domain challenges in mapping natural language queries onto SQL, but the conversation length is fairly short and the databases relatively small-scale.

Large KGs, like Wikidata (Vrandečić, 2012), are becoming an increasing valuable source of information. Various question-answering datasets have been recently released (Dubey et al. 2019; Talmor and Berant 2018; Christmann et al. 2019, 2022, *inter alia*), which are either not conversational or contain sequences of dialogue turns but the questions are not annotated with executable queries like SPARQL. The CSQA dataset introduced in Saha et al. (2018) is conversational and covers a wide range of linguistic phenomena (e.g., ellipsis, coreference) but frames the QA task as an information retrieval problem. Follow-on work (Marion et al., 2021; Kacupaj et al., 2021; Shen et al., 2019) has used hand-crafted grammars to automatically obtain semantic annotations which are are not executable with a real KG engine (e.g., Blazegraph), and cumbersome to extend to new question intents.

6 Conclusion

In this work we introduce SPICE, a conversational semantic parsing dataset over knowledge graphs. Our dataset contains SPARQL annotations which are executable on a real KG engine and requires handling complex questions, type, relation, and entity linking on a large scale. Moreover, it showcases multiple linguistic phenomena such as coreference and ellipsis. We establish two strong baselines for the semantic parsing task and present detailed analysis stratifying performance by question type and linguistic phenomena. We also study generalisation to unseen intents and create multiple dataset splits with different query patterns. To move forward conversational semantic parsing over large scale KGs would need to improve entity linking, modelling of conversation context, and generalisation capabilities. We hope our dataset will serve as a useful testbed for the development of conversational semantic parsers.

8 Limitations

Both models discussed in this work make simplifying assumptions. BertSP variants need to truncate the linearised graphs for computational cost reasons. LasagneSP works with a smaller graph ontology which can easily fit in memory. However, this restricts the model to predicting seen types or relations which is unrealistic. A real-world semantic parser should ideally have access to the full Wikidata. Our results show that both models do not generalise to unseen question intents, which is a known limitation of current neural sequence-to-sequence architectures (Furrer et al., 2020; Finegan-Dollak et al., 2018; Keysers et al., 2020; Kim and Linzen, 2020; Li et al., 2021). Finally, our results also suggest that there is scope for improvement in handling previous context (including questions and answers).

A The SPICE Dataset: Question Types and Subtypes

Table 9 provides the list of question types and subtypes in SPICE. For each question subtype we provide an example user question. For cases involving ellipsis and coreference, we include the conversation context (in grey colour).

Table 7 provides the list of question subtypes grouped grouped according to linguistic phenomena. Coreference ($_{=-1}$ and $_{<-1}$), Ellipsis, and Multiple Entities.

Coreference
More/Less | Mult. entity type (Coreference) # More/-Less | Single entity type (Coreference) # Single Entity (Coreference) # 2 entities, one direct and one indirect, object is indirect # 2 entities, one direct and one indirect, subject is indirect # 3 entities, 2 direct, 2(direct) are query entities, subject is corefered # one entity, multiple entities (as object) corefered # Count | Logical operators (Coreference) # Count | Single entity type (Coreference) # Count over More/Less | Mult. entity type (Coreference) # Count over More/Less | Single entity type (Coreference)
Ellipsis
Difference | Single Relation (Ellipsis) # Intersection | Single Relation (Ellipsis) # Union | Single Relation (Ellipsis) # More/Less | Mult. entity type (Ellipsis) # More/Less | Single entity type (Ellipsis) # object parent is changed, subject and predicate remain same # Incomplete count-based ques # Count over More/Less | Mult. entity type (Ellipsis) # Count over More/Less | Single entity type (Ellipsis)
Multiple Entities
Difference | Multiple Relation # Intersection | Multiple Relation # Union | Multiple Relation # Atleast/ Atmost/ Approx. the same/Equal | Mult. entity type # Min/Max | Mult. entity type # More/Less | Mult. entity type # More/Less | Mult. entity type (Ellipsis) # More/Less | Mult. entity type (Coreference) # Mult. Entity (Simple Question Direct and Coreference) # one entity, multiple entities (as object) coreferred # Count over Atleast/ Atmost/ Approx. the same / Equal | Mult. entity type # Count | Mult. entity type # Count over More/Less | Mult. entity type # Count over More/Less | Mult. entity type (Ellipsis) # Count over More/Less | Mult. entity type (Coreference)

Table 7: Question subtypes grouped according to linguistic phenomena.

Table 8 provides the list of unseen question subtypes for each of the non-i.i.d splits.

CountLogic
Count | Logical operators # Count | Logical operators (Coreference)
UnionMulti
Union | Multiple Relation
Verify3
3 entities, 2 direct, 2(direct) are query entities, subject is indirect # 3 entities, all direct, 2 are query entities

Table 8: Unseen question subtypes in SPICE non-i.i.d splits.

B Creating a Knowledge Graph from the CSQA Data

Deploying a full copy of Wikidata locally as a standalone service requires huge resources in addition to cluster dependent tweaking to obtain fast query processing and high-performance.[6] To enable easier deployment and fast access for research purposes we created a smaller graph from the CSQA data files. We mapped the contents of these files[7] onto triples which we subsequently converted to `ttl` format[8] with full URI to allow loading them to the KG query engine. We also filled missing information where possible, for example, missing relations such as "instance of" was filled with relation P31 and added data type information when this was omitted from the original files.

We used Blazegraph[9] to deploy the local server, which uses only CPU-based resources and has access to 150G of RAM. Further details along with the script to host the server will be released upon acceptance.

C BertSP Model Configuration

Our model is implemented using pytorch (Paszke et al., 2019). For all experiments, we used the ADAM optimizer (Kingma and Ba, 2015) with 20,000 BERT warmup steps and 10,000 steps for decoder warm up. We use separate optimizers for the BERT encoder and decoder. BERT was fine-tuned during training with the initial learning rate set to 0.00002. A learning rate of 0.001 was set for the rest of model parameters. Our model was trained for 100,000 steps; we used 4 GPUs with 12GB of memory. We performed model selection on the validation set. We report results with the best performing model which had 6 decoder layers.

D Examples on Generalisation Splits

Table 10 shows examples from the generalisation splits: similar question subtypes see during train-

ing, unseen question subtype, and error on prediction. The most common error across different splits is that models use similar SPARQLs seen during training but fail to adapt them to the details (entities, types, relations, argument positions) in the unseen question subtype. Other errors encompass using the incorrect SPARQL query (incorrect question intent) and incorrect entities and types.

Table 9: Full list of question subtypes (intents) in SPICE. For each subt-type we show an example question, whenever the question subtype involves a conversational phenomenon (coreference or ellipsis); previous conversation interactions necessary for the interpretation of the question are shown in grey.

Question Subtype	Example User Question
Clarification	
Simple Question | Single Entity (Coreference)	U: *Which political territory is that sporting event located in?* S: *Did you mean Speed skating at the 2010 Winter Olympics – Men's 500 metres?* U: *Yes*
Logical Reasoning (All)	
Difference | Multiple Relation	U: *Which people were awarded with Order of Merit for Arts and Science and are not working as singer?*
Difference | Single Relation	U: *Which international organizations had Poland but not Bulgaria as their member?*
Difference | Single Relation (Ellipsis)	U: *Which city was Pierre Laffont born in?* S: *Marseille* U: *Which administrative territories are the sister cities of that city?* S: *Shanghai, Odessa, Naples* U: *But not Bologna*
Intersection | Multiple Relation	U: *Which human settlements are situated close to Trave and have an adjacent border with Herzogtum Lauenburg?*
Intersection | Single Relation	U: *Which works of art were filmed at Edinburgh and Berlin?*
Intersection | Single Relation (Ellipsis)	U: *Which language does José María Lassalle speak in?* S: *Spanish* U: *And also Sergio Gil*
Union | Multiple Relation	U: *Which watercourses are located in the neighbourhood of Bremen or are the tributaries of Ob?*
Union | Single Relation	U: *Which people are the creators of The Theory of Everything or Ten Minutes to Live?*
Union | Single Relation (Ellipsis)	U: *What is the profession of Mai Yamada?* S: *announcer* U: *Or Kazimierz Rogoyski?*
Quantitative Reasoning (All)	
Min/Max | Single entity type	U: *Which musical instruments are played by min number of people?*
Min/Max | Mult. entity type	U: *Which organizations are the main building contractors of max number of architectural structures and buildings?*
Atleast/ Atmost/ Approx. the same/Equal | Single entity type	U: *Which musical instruments are played by exactly 5 people?*
Atleast/ Atmost/ Approx. the same/Equal | Mult. entity type	U: *Which events are demonstrated in atleast 3 prints and genres of sculpture?*
Comparative Reasoning (All)	
More/Less | Mult. entity type	U: *Which landforms are known for containing lesser number of chemical compounds or minerals naturally than Stetind pegmatite?*
More/Less | Mult. entity type (Ellipsis)	U: *Which landforms are known for containing lesser number of chemical compounds or minerals naturally than Stetind pegmatite?* S: *Euboea, Izalco, Mount Nyiragongo* U: *And also tell me about Tuften quarry?*
More/Less | Mult. entity type (Coreference)	U: *Which administrative territory is that person a civilian of?* S: *Spain* U: *Which administrative territories are the countries of origin of lesser number of television programs or works of art than that administrative territory?*
More/Less | Single entity type	U: *Which television programs have been dubbed by more number of people than Puss in Boots: The Three Diablos?*
More/Less | Single entity type (Ellipsis)	U: *Which television programs have been dubbed by more number of people than Puss in Boots: The Three Diablos?* S: *House, K-On!, K-On!!* U: *And also tell me about Chip 'n Dale Rescue Rangers?*
More/Less | Single entity type (Coreference)	U: *Which languages are max number of literary works composed in?* S: *English* U: *Which languages are the mother tongues of less number of people than that language?*
Simple Question (Direct)	
Simple Question	U: *Which type of sport did Amel Tuka participate in?*
Single Entity	U: *What is the capital of Sweden?*
Mult. Entity	U: *Who were the writers of On being and essence, De vegetabilis et plantis libri septem and Historia de regibus Gothorum, Vandalorum et Suevorum?*
Simple Question (Ellipsis)	
only subject is changed, parent and relation remains same	U: *Which organizations are the sponsors of Janice Anderson?* S: *Montrail, Patagonia, Inc.* U: *And also tell me about Manikala Rai?*
object parent is changed, subject and relation remain same	U: *Which watercourses are situated nearby Munich?* S: *Eisbach, Würm, Isar* U: *And which river?*
Simple Question (Coreference)

Abstract

Large pre-trained models have proved to be remarkable zero- and (prompt-based) few-shot learners in unimodal vision and language tasks. We propose MAPL, a simple and parameter-efficient method that reuses frozen pre-trained unimodal models and leverages their strong generalization capabilities in multimodal vision-language (VL) settings. MAPL learns a lightweight mapping between the representation spaces of unimodal models using aligned image-text data, and can generalize to unseen VL tasks from just a few in-context examples. The small number of trainable parameters makes MAPL effective at low-data and in-domain learning. Moreover, MAPL's modularity enables easy extension to other pre-trained models. Extensive experiments on several visual question answering and image captioning benchmarks show that MAPL achieves superior or competitive performance compared to similar methods while training orders of magnitude fewer parameters. MAPL can be trained in just a few hours using modest computational resources and public datasets. We release our code and pre-trained model weights at `https://github.com/oscmansan/mapl`.

1 Introduction

Over the past few years, natural language processing and computer vision have witnessed impressive progress in learning models capable of transferring to unseen tasks or benchmarks (Brown et al., 2020; Zhang et al., 2022; Radford et al., 2021; Jia et al., 2021). Recently referred to as foundation models (Bommasani et al., 2021), these can be adapted to a wide range of *unimodal* vision and language tasks without any additional training.

In this work, we study reusing such powerful *unimodal* foundation models for *multimodal* vision-language (VL) downstream tasks. In particular, we propose to connect a vision encoder, such as CLIP (Radford et al., 2021), to an autoregressive language model (LM), such as GPT (Radford et al., 2018, 2019; Brown et al., 2020), with minimal additional training on multimodal data. Our goal is to obtain a single VL model that can leverage the in-context learning abilities (Brown et al., 2020) of the pre-trained LM to generalize to unseen VL tasks from just a few examples.

One challenge in connecting vision encoders with LMs is aligning the visual and textual representation spaces. Recent works have approached this by adapting the LM to visual representations, either by fine-tuning the entire LM (Dai et al., 2022) or training adapter layers (Eichenberg et al., 2021; Alayrac et al., 2022). These systems are computationally expensive to train as they have a large number of learnable parameters (hundreds of millions to a few billions) and use large-scale multimodal training data. On the other hand, Frozen (Tsimpoukelli et al., 2021) keeps the LM frozen, thus learning $\sim$10× less parameters than the above methods. However, it requires training a visual encoder from scratch, which is also computationally expensive.

Differently, we aim to reuse large pre-trained unimodal models while keeping them completely frozen and free of adapter layers. We present **MAPL** (**M**ultimodal **A**daptation of **P**re-trained vision and **L**anguage models), a simple and parameter-efficient VL model capable of tackling unseen VL tasks. MAPL learns a lightweight mapping between the representation spaces of pre-trained unimodal models. MAPL has orders of magnitude fewer parameters than previous methods (including Frozen) and can be trained in just a few hours. Moreover, MAPL's modularity makes it general-purpose and easily extensible to newer and/or better pre-trained models. We evaluate MAPL on various image captioning and visual question answering (VQA) benchmarks and compare with Frozen (Tsimpoukelli et al., 2021) in a controlled setup. MAPL significantly outperforms

---

[*] denotes equal contribution.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2523–2548
May 2-6, 2023

Frozen and achieves competitive performance compared to other methods (Eichenberg et al., 2021; Dai et al., 2022) trained on comparably sized data.

We further investigate the parameter efficiency of MAPL by training on only 1% of multimodal data (thousands of examples); we call this setting *low-data* learning. We also study *in-domain* learning: training on image-text pairs from the same domain as the downstream task domains. We train MAPL directly on 100% and 1% of in-domain data for each downstream task, without first pre-training on large-scale domain-agnostic data. Thus, we train specialized versions of MAPL for each downstream domain. Such low-data and in-domain learning are particularly useful when it is difficult to pre-train on large-scale domain-agnostic data. We found MAPL to be more effective than Frozen trained under the same settings.

To summarize, our contributions are: 1) we introduce MAPL, a parameter-efficient method capable of tackling unseen VL tasks, which can be trained using only modest computational resources and public datasets; 2) we conduct extensive experiments spanning various image captioning and VQA benchmarks, demonstrating MAPL achieves superior or competitive performance compared to similar methods while training orders of magnitude fewer parameters; and 3) we further investigate the parameter-efficiency of MAPL in two settings: low-data and in-domain. Our experiments show that MAPL is more effective than the considered methods in both settings.

2 Related Work

Fine-tuning based VL methods. A popular family of VL methods are based on the pre-training + fine-tuning paradigm. These methods are either encoder-only (Lu et al., 2019; Tan and Bansal, 2019; Chen et al., 2019; Li et al., 2020; Zhang et al., 2021) or encoder-decoder methods (Cho et al., 2021; Wang et al., 2021; Jin et al., 2022; Li et al., 2021) and use transformer-based architectures. These transformers are first pre-trained on domain-agnostic image-text pairs (e.g., Conceptual Captions (Sharma et al., 2018)) using self-supervised objectives, and then fine-tuned for each downstream task (e.g., VQA, image captioning). More recent models that are designed specifically for the task of image captioning use large pre-trained LMs (e.g., GPT-2 (Radford et al., 2019)) and fine-tune these models with image-caption pairs (Chen et al., 2021; Mokady et al., 2021; Luo et al., 2022). While all these approaches yield state-of-the-art performance for the tasks they are fine-tuned on, the learned model weights are highly specialized for a single task and cannot transfer to new tasks with zero or few examples. Differently, MAPL reuses the same set of weights for all downstream tasks without any additional training.

Few-shot learning based VL methods. Most similar to MAPL are methods that tackle unseen VL tasks in a zero/few-shot manner, by leveraging the in-context learning abilities of large pre-trained LMs (e.g., GPT-3 (Brown et al., 2020). These methods connect a vision encoder with a pre-trained LM to tackle VL tasks. Some methods (Dai et al., 2022; Hao et al., 2022) achieve this connection by fine-tuning the entire LM on image-text data, while others only train adapter layers inserted into the LM (Eichenberg et al., 2021). The vision encoder is pre-trained and kept frozen in both cases. Concurrent work Flamingo (Alayrac et al., 2022) pushes this idea even further by scaling up the amount of training data and the LM size. While inserting adapter layers requires training fewer parameters compared to fine-tuning the entire LM, the number of trainable parameters is still >100M; in contrast, MAPL only has 3.4M trainable parameters. Additionally, inserting adapter layers is not straightforward since it requires modifying the computational graph of the LM; MAPL only adds an external mapping network, which is easier to incorporate on top of pre-trained models. On the other hand, Frozen (Tsimpoukelli et al., 2021) keeps the pre-trained LM frozen and instead trains a vision encoder from scratch. This approach does not scale well with larger vision encoders (Sec. 4.5). MAPL keeps both the vision encoder and the LM frozen (thus further reducing the number of trainable parameters) and only learns a lightweight mapping network to connect both frozen models. Similar to MAPL, concurrent work LiMBeR (Merullo et al., 2022) also proposes to connect a frozen vision encoder with a frozen LM but using a linear mapping, which is not as parameter- and compute-efficient as MAPL (Sec. 4.5).

Mapping networks. MAPL trains a mapping network to align the visual and textual representations of the visual encoder and the LM, respectively. The architecture of our mapping network has some similarities with that in ClipCap (Mokady et al., 2021) and the Perceiver Resampler in Flamingo (Alayrac

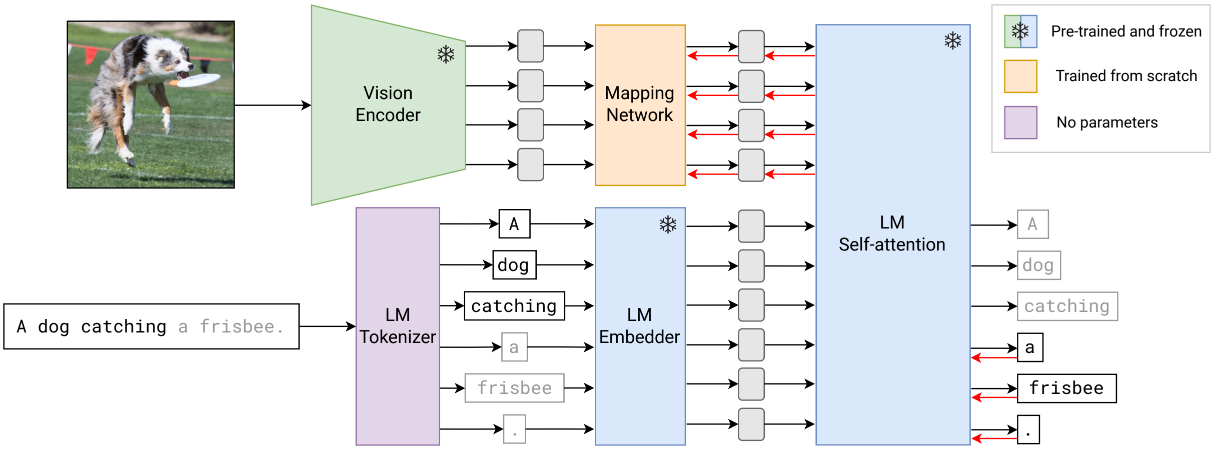

Figure 1: MAPL leverages a pre-trained vision encoder and a pre-trained LM, and learns a small *mapping network* to convert visual features into token embeddings. During training, only the mapping network is updated, keeping the vision encoder and the LM frozen (red arrows indicate gradient flow). At inference time, the system can take as input an arbitrary sequence of interleaved images and text, and generates free-form text as output.

et al., 2022). They all share a core transformer stack and a fixed number of learned constant embeddings. However, MAPL's mapping network is specifically designed to be parameter-efficient while maintaining expressivity (Sec. 3.1), containing only 3.4M parameters – orders of magnitude fewer than ClipCap's (43M) and Flamingo's (194M).

3 Method

MAPL is a vision-language (VL) multimodal model capable of generating text from a combination of visual and textual inputs. Our model builds on top of pre-trained vision-only and language-only models and leverages their strong generalization capabilities (e.g., zero-shot transfer, in-context learning) to tackle unseen VL tasks. MAPL is agnostic to the choice of these pre-trained unimodal models as long as they show such capabilities (Sec. 4.5). Concretely, MAPL maps the image representations from a vision encoder's output embedding space to a LM's token embedding space, so that the LM can be conditioned both on visual and textual information. To this end, we train a *mapping network* with an image captioning objective (Sec. 3.1, 3.2), while keeping the weights of the vision encoder and the LM frozen. Once the mapping network is trained, MAPL can be prompted with a few examples of unseen VL tasks and predict the response via text generation (Sec. 3.3). The overall model architecture is depicted in Figure 1.

3.1 Architecture

Pre-trained vision encoder. The vision encoder extracts a compact representation from an image. We use a CLIP (Radford et al., 2021) pre-trained vision encoder, which is trained on web-scale data and has shown strong zero-shot transfer capabilities to unseen image domains. In particular, we use CLIP's ViT-L/14 backbone (Dosovitskiy et al., 2020) since we empirically found it yields the best downstream VL performance among all variants. We use the flattened grid of spatial features (16×16) before the final projection layer and the representation corresponding to the `[class]` token, resulting in a sequence of $L_i = 257$ vectors of dimensionality $D_i = 1024$ each. This sequence of vectors is then fed to the mapping network.

Pre-trained autoregressive language model. Given an input text, the language model (LM) predicts its most likely completion by generating free-form text. For our LM, we use a pre-trained GPT-J model (Wang and Komatsuzaki, 2021) [1], a publicly-released 6B-parameter autoregressive LM trained on the Pile dataset (Gao et al., 2020). We chose this LM due to its strong in-context learning abilities, similar to that of GPT-3 (Brown et al., 2020) (which is not publicly available). The LM takes as input a text string, which is first divided into a sequence of discrete tokens by the LM's tokenizer. Each token is then individually transformed into a continuous embedding (of size $D_o = 4096$) by the LM's embedder. The sequence of token embeddings is fed to the self-attention layers in the LM's transformer block (using causal attention), which outputs a sequence of categorical distributions over the token vocabulary. Finally, a decoding mechanism generates free-form text from these distributions (greedy

---

[1] We also experiment with an OPT model, see Sec. 4.5.

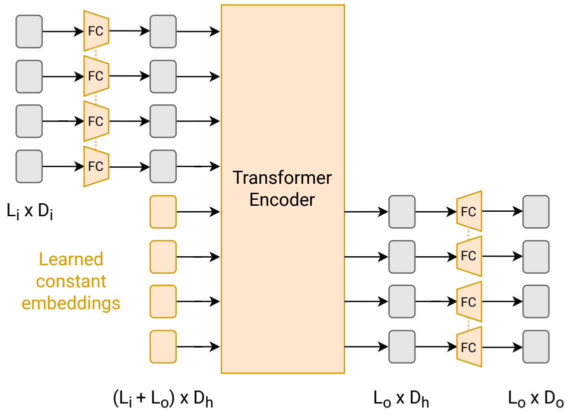

Figure 2: The mapping network takes a flattened grid of L_i visual features of dimension D_i each from the vision encoder and transforms it into a sequence of token embeddings of length L_o and dimension D_o, where D_o is the token embedding dimension of the LM. Note that the parameters are shared across fully-connected (FC) layers, on both sides of the encoder transformer.

decoding in our case).

Mapping network. The mapping network transforms a sequence of visual features from the vision encoder to a sequence of continuous embeddings which can be consumed by the LM's transformer. We design our mapping network considering the trade-off between expressivity (to learn a good mapping) and parameter count. Our architecture is based on a transformer encoder with 4 layers and 8 heads each. This transformer could directly take a sequence of projected visual features (from D_i to D_o) and output a sequence of embeddings of size D_o. However, in order to keep a low parameter count, we decouple the transformer hidden size D_h from the visual feature size D_i and the LM embedding size D_o by introducing a dimensionality bottleneck (Figure 2). In particular, each visual feature is first linearly projected from $D_i = 1024$ to $D_h = 256$ using a set of fully-connected (FC) layers. This sequence of projected features is then fed to the transformer, and the output representations are linearly projected from D_h to $D_o = 4096$ using another set of FC layers. To further reduce the parameter count of our mapping network, we share parameters across all FC layers in each set.

Yet another idea we use in our mapping network is to decouple the output sequence length of the transformer (L_o) from the input sequence length (L_i). We do this to obtain a much smaller $L_o = 32$ compared to $L_i = 257$, in order to reduce the computational complexity in the subsequent LM's self-attention layers, which in turn speeds up training and inference time. To achieve this decoupling, inspired by DETR (Carion et al., 2020), we concatenate a small and fixed number (L_o) of learned constant embeddings with the input sequence of the transformer and only use the output representations corresponding to these constant embeddings (Figure 2). Note that these output representations are conditioned on the input visual features via cross-attention in the transformer. The resulting mapping network architecture is shown in Figure 2. In total, our mapping network contains only 3.4M parameters. Since this is the only trainable component of our model, MAPL has orders of magnitude fewer total trainable parameters than existing methods such as Frozen (40.3M) or Flamingo (10.2B).

3.2 Training

Following previous works (Tsimpoukelli et al., 2021; Eichenberg et al., 2021), we train our model using a standard language modeling objective on image captions with teacher forcing (Lamb et al., 2016), i.e., we minimize the negative log-likelihood of the reference captions under the LM conditioned on the corresponding images. We only train the mapping network (from scratch) while keeping the vision encoder and the LM entirely frozen. This preserves the pre-trained models' capabilities while making the system modular and parameter-efficient. Even though the LM's weights are kept frozen, gradients are still back-propagated through its self-attention layers to train the mapping network.

3.3 Zero- and Few-shot Evaluation

Once the mapping network is trained, MAPL can tackle unseen VL tasks by prompting the LM with a combination of visual and textual inputs. We study zero-shot transfer to unseen image captioning benchmarks and few-shot transfer (via in-context learning) to the unseen task of visual question answering (VQA). For image captioning, we simply feed the mapped image embedding to the LM and start generating a caption. For zero-shot VQA, following Tsimpoukelli et al. (2021), we feed the mapped image embedding followed by the text `“Please answer the question. Question: {question} Answer:”`[2] and start generating the answer. For n-shot VQA, we select n support examples $(image, question, answer)$ from the training set at random, and prepend them to the

---

[2] Here `{question}` indicates a placeholder which gets replaced by the corresponding question in each example. Same applies to `{answer}` in the few-shot setting.

query; for each support example, we concatenate the mapped image embedding with the text "`Please answer the question. Question: {question} Answer: {answer}`".

4 Experiments

4.1 Experimental settings

Evaluation benchmarks. We evaluate MAPL on several VL benchmarks spanning VQA and image captioning. Note that our model is never trained for the task of VQA. For VQA, we evaluate on the validation splits of VQAv2 (Goyal et al., 2017), OK-VQA (Marino et al., 2019), TextVQA (Singh et al., 2019) and VizWiz-VQA (Gurari et al., 2018), and report performance using VQA accuracy (after the standard normalization (Antol et al., 2015)). For image captioning, we evaluate on the Karpathy-test split (Karpathy and Fei-Fei, 2015) of COCO Captions (Chen et al., 2015), and the validation splits of Conceptual Captions (CC) (Sharma et al., 2018)[3], TextCaps (Sidorov et al., 2020) and VizWiz-Captions (Gurari et al., 2018), and report performance using the BLEU@4, ROUGE-L, METEOR, CIDEr and SPICE metrics.

Training settings. We consider two settings to train our mapping network: domain-agnostic and in-domain training (described below). For each of these settings, we also study low-data learning by training our model on randomly sampled subsets of 1% training image-text pairs. Such low-data learning is useful when it is difficult to train models on large-scale data due to constraints on compute resources, data availability, etc.

For **domain-agnostic training**, we use the CC dataset, which is gathered by automatically scraping images and their corresponding alt-text fields from web pages. Thus, this dataset is not as clean as manually-curated datasets such as COCO Captions (e.g., the caption may not describe the image). Nevertheless, due to its large size (3.3M) and great diversity, it is the most commonly used dataset for domain-agnostic pre-training of VL models. However, for our model – having orders of magnitude less trainable parameters than other methods –, we observed the negative effect of noise in CC to be stronger than the positive effect of its large size (Sec. 4.4). Therefore, we train MAPL on a filtered version of CC (CC-clean) consisting of the top 398K most similar image-text pairs ranked by CLIP's image-text similarity score.[4] For completeness, we also report MAPL's performance when trained on the unfiltered CC dataset.

For **in-domain training**, we use image-caption pairs that come from the same domain as the downstream task domains, i.e., they have similar image and language distributions as those in the downstream datasets. For the image captioning downstream task, this amounts to the IID setting. The in-domain image captioning and VQA dataset pairs we consider are shown in Table 1. Each pair uses the same set of images, and focuses on the same set of VL skills; for instance, scene understanding (COCO Caps and VQAv2), reading and reasoning about text in images (TextCaps and TextVQA), understanding images captured by visually-impaired users (VizWiz-Caps and VizWiz-VQA), thus leading to similar image and language distributions across image-captioning and VQA. We train MAPL on both 100% and 1% of in-domain image-caption data and evaluate on all downstream benchmarks (including out-of-domain ones, e.g., VizWiz-VQA when trained on COCO Caps). Such in-domain training can be useful when it is difficult to first train on large-scale domain-agnostic data and then adapt to in-domain data by either fine-tuning or few-shot prompting.

Table 1: In-domain dataset pairs.

Training details. For Conceptual Captions, TextCaps and VizWiz-Captions, we carve out a minival split consisting of 6% of training examples and train on the remaining 94%; for COCO Captions, we use the Karpathy-val split as minival. We use the AdamW optimizer with $\beta_1 = 0.9$, $\beta_2 = 0.95$, and a weight decay of 0.01. The learning rate is increased linearly from 0 to 3×10^{-4} (7×10^{-4} for OPT-based models) over the first 1500 steps (15 for 1% of data) and kept constant for the rest of training. We use a batch size of 128 and we do early stopping based on the minival loss. We do not add any special tokens at the beginning of sentence, as GPT-J was not trained with `<BOS>` tokens. In order to fit a 6B-parameter LM into GPU memory, we use DeepSpeed ZeRO (Rajbhan-

---

[3] Due to broken image URLs, we only managed to download 13K out of 15K validation images.

[4] We selected a threshold on CLIP's similarity score such that the size of the filtered dataset is comparable to the size of manually curated datasets such as COCO Captions.

Table 2: Evaluation on few-shot VQA. For MAGMA $_{\text{CC12M}}$ and VLKD $_{\text{CC3M}}$, we report their best results when training only on domain-agnostic data (CC12M and CC3M, respectively). (†) indicates our informed estimation. (‡) indicates concurrent work.

dari et al., 2020) stage 2 optimizations. Freezing the LM's weights also brings massive savings in GPU memory during training, as fine-tuning with an Adam-based optimizer would require at least 4× GPU memory to store gradients, average, and squared average of the gradients. The whole system was trained on 4 A100 (40GB) GPUs for about 4 hours (for the CC-clean dataset). Unless otherwise stated, we repeat the experiments with two different random seeds and report the average performance.

Existing methods and baselines. We report the performance of several baselines and existing methods. First, to verify that the LM in MAPL is not ignoring the visual input, inspired by Tsimpoukelli et al. (2021), we train a blind version of MAPL (MAPL-blind) where the input images are replaced with zeros but the mapping network weights are still trained (to serve as prompt-tuning for the LM). Second, to estimate the upper-bound on how well we can do in VQA by representing images with text (rather than with continuous embeddings), we evaluate PICa (Yang et al., 2021), which directly prompts the LM with image captions, followed by questions for VQA. We reimplement PICa (denoted PICa*) using MAPL's LM (and evaluate on VQAv2 and OK-VQA using ground-truth COCO captions) for controlled comparison. Third, we compare MAPL with Frozen (Tsimpoukelli et al., 2021), as this is the most similar method to ours that also uses a frozen LM. We reimplement Frozen (denoted Frozen*) using MAPL's LM for controlled comparison. Lastly, we report the performance of other methods similar to MAPL: MAGMA (Eichenberg et al., 2021), VLKD (Dai et al., 2022), LiMBeR (Merullo et al., 2022), ClipCap (Mokady et al., 2021) and the published numbers from Frozen (Tsimpoukelli et al., 2021).[5] Note that all these methods (unless otherwise noted) are trained on domain-agnostic data, so we only compare with MAPL trained on CC-clean. For completeness, we also report results from Flamingo (Alayrac et al., 2022), which has orders of magnitude more learnable parameters than MAPL and is trained on considerably more data.

4.2 Evaluation of domain-agnostic learning

We report few-shot VQA results in Table 2 and image captioning results in Table 3. Subscripts in the first column denote the training dataset. *Overall* accuracies denote average of per-benchmark accuracies. First, we see that MAPL $_{\text{CC-clean}}$ substantially outperforms MAPL-blind $_{\text{CC-clean}}$ both on VQA and image captioning, proving that the visual inputs are not ignored by the LM in MAPL. Second, we find that MAPL $_{\text{CC-clean}}$ outperforms Frozen* $_{\text{CC-clean}}$ by a considerable margin on all VL benchmarks (with overall accuracy improvements of +6.61% 0-shot and +5.66% 4-shot on VQA tasks,

---

[5] We only add results which are reported on the same dataset splits as in MAPL.

Table 4: Impact of data quality and size. These experiments are run with one seed only.

+4.35 BLEU@4 and +33.55 CIDEr on image captioning tasks). Importantly, this is achieved while training an order of magnitude fewer parameters (3.4M vs 40.3M). Next, MAPL $_{\text{CC-clean}}$ is competitive compared to existing methods (MAGMA, VLKD, ClipCap) and concurrent work LiMBeR, despite training one-two orders of magnitude fewer parameters on significantly less multimodal data. Lastly, MAPL $_{\text{CC-clean}}$'s performance is still far from the performance of Flamingo, which trains orders of magnitude more parameters on orders of magnitude more data. However, we believe MAPL to be an effective method for scenarios with constrained computational resources. For MAPL's qualitative results, see App. 4.6.

Low-data learning. When trained on only 1% domain-agnostic data, MAPL $_{\text{CC-clean}}$ outperforms Frozen* $_{\text{CC-clean}}$ for all image captioning evaluations (by +1.35 BLEU@4 and +8.23 CIDEr, overall) and all 0-shot VQA evaluations (by +2.60% overall accuracy), while achieving competitive performance on 4- and 8-shot VQA evaluations. In summary, these results show the effectiveness of our method in low-data settings, highlighting its usefulness for applications where data is scarce.

4.3 Evaluation of in-domain learning

In Tables 2 and 3, we observe that both MAPL and Frozen* benefit from directly training on in-domain data, compared to few-shot transfer from large-scale domain-agnostic pretraining. For instance, MAPL $_{\text{COCO}}$ and Frozen* $_{\text{COCO}}$ respectively outperform MAPL $_{\text{CC-clean}}$ and Frozen* $_{\text{CC-clean}}$ on VQAv2, OK-VQA and COCO Captions when trained on 100% of data. Interestingly, this performance gap is larger for MAPL compared to Frozen* by +2% 0-shot accuracy and +3.77% 4-shot accuracy averaged across VQAv2 and OK-VQA, and +9.35 BLEU@4 and +23.45 CIDEr on COCO Captions. A similar trend can be observed for TextCaps and TextVQA. Surprisingly, for 0-shot VQA and image captioning, training

Table 5: Ablation studies. We assess the impact of the choice of vision encoder (top), LM (middle) and mapping network architecture (bottom). All models are trained on 100% of CC-clean with a single seed. IN stands for ImageNet pre-training.

on just 1% of in-domain data outperforms 100% CC training for all benchmarks (except VizWiz-VQA) and both models. These results demonstrate the benefits of in-domain learning. When comparing MAPL vs. Frozen*, we observe that MAPL outperforms Frozen* for all tasks and benchmarks (except VizWiz-VQA) under both 100% and 1% in-domain settings. In fact, MAPL trained on just 1% in-domain data outperforms Frozen* trained on 100% in-domain data by +3.41% 0-shot accuracy and +1.14% 4-shot accuracy averaged across VQAv2, OK-VQA and TextVQA. Thus, MAPL is more effective than Frozen* at in-domain learning.

Contrary to the above trends, we observe that MAPL $_{\text{VizWiz}}$ under 1% in-domain training performs worse than MAPL $_{\text{COCO}}$ or MAPL $_{\text{TextCaps}}$ when evaluated on VizWiz-VQA. We hypothesize the visual embeddings extracted from CLIP's vision encoder for VizWiz images are not as good as those for COCO or TextCaps' images because the distribution of images in VizWiz (captured by visually-impaired people) is rather different from the distribution of images CLIP is trained on (scraped from the web), whereas for COCO and TextCaps this isn't the case. When training MAPL's mapping network on only 1% of VizWiz data, we believe the data is not large enough to compensate for the OOD pretrained vision encoder, so MAPL trained on COCO/TextCaps performs better on VizWiz-VQA. For in-domain training with 100% of data and 4/8-shot VQA, the mapping network has enough data to learn from and compensate for the OOD phenomenon. On the other hand, Frozen* does not suffer from this issue because its vision encoder is trained from scratch, allowing it to adapt to the image distribution.

Lastly, we observe that MAPL $_{\text{COCO}}$ outperforms ClipCap $_{\text{COCO}}$ by +2.92 BLEU@4 and +12.12 CIDEr on COCO Captions. MAPL $_{\text{COCO}}$ also outperforms PICa* (which represents images with ground-truth COCO captions) on VQAv2 and 0-shot OK-VQA, and achieves competitive results on few-shot OK-VQA; this demonstrates representing images with continuous embeddings is beneficial over caption-based image representations. Overall, we see that in-domain learning is beneficial and MAPL is more effective at it than similar methods.

4.4 Impact of data quality and size

To measure the impact of noise in the training data, we additionally train MAPL and Frozen* on the *full* CC dataset, consisting of 2.8M[6] examples, as well as on a *clean-ish* version consisting of the 1.0M most similar image-text pairs. In Table 4, we observe Frozen* achieves similar performance on few-shot VQA tasks when trained on noisy vs. clean data; however, Frozen*'s performance on image captioning decreases when trained on cleaner but smaller data. In contrast, MAPL generally benefits from cleaner training data, with the exception of evaluation on CC. We hypothesize both models perform better on CC when trained on larger (yet noisier) data because the CC validation set is IID with the full (noisy) CC training set. In the case of Frozen*, as we move away from the IID setting, the benefits from more data start diminishing (CC captioning > other captioning tasks > VQA tasks). For MAPL, the benefit from reduced noise in training data exceeds the degradation caused by a smaller data size, thanks to the reduced number of trainable parameters. These trends align with previous observations that larger models are more robust to noisy training data since they have enough capacity to model both noise and the desired function (Rolnick et al., 2017), while smaller models are more sample-efficient (Vapnik and Chervonenkis, 2015), i.e. they need less (clean) data to train effectively. Note that although MAPL's overall performance is higher when training on 1.0M than on 0.4M examples, we decided to train with 0.4M examples because training on $\sim$2.5× more data (1.0M instead of 0.4M) required $\sim$5× more iterations (always

---

[6] This is not the full 3.3M CC due to broken URLs.

early-stopping based on validation loss). So we did not think the slight performance increase due to more data was worth the $\sim 5\times$ longer training time, especially because we were operating under a limited compute budget.

4.5 Ablation studies

In this section, we evaluate how the choice of vision encoder, LM and mapping network architecture impact MAPL's performance, and compare it with corresponding versions of Frozen* (where applicable). Results are presented in Table 5. Please refer to App. A.5 for more ablations.

First, to assess the impact of the choice of vision encoder, we train additional versions of MAPL replacing the CLIP pre-trained vision encoder (ViT-L/14 – 303M parameters) with encoders pre-trained on ImageNet: NF-ResNet-50 (23.5M) and ViT-L/16 (303M), and compare their performance with corresponding versions of Frozen*. We observe that: 1) MAPL outperforms Frozen* for each configuration of vision encoder, suggesting that MAPL is **robust to the choice of vision encoder's pre-training data and architecture**; and 2) Frozen* 's performance drops with bigger vision encoders (likely due to more trainable parameters), whereas MAPL improves due to the use of stronger pre-trained encoders. Thus, training the vision encoder from scratch (Frozen*) has limited application, while MAPL's **performance scales alongside the pre-trained vision encoder**.

Next, to evaluate the impact of the choice of LM, we train both MAPL and Frozen* replacing GPT-J by OPT-6.7B (Zhang et al., 2022). We see that in all settings except 0-shot VQAv2, MAPL outperforms Frozen*. See App. A.2 for discussion on 0-shot VQAv2 results. This suggests that MAPL is **robust to the choice of LM**. The above results also highlight how MAPL's **modularity** allows to easily replace the pre-trained vision encoder or the LM.

Lastly, to assess the impact of the choice of mapping network architecture, we replace the proposed transformer-based mapping network with two simpler architectures – a linear layer and a 2-layer MLP (see App. A.4 for details). We observe both these versions generally underperform the original setting (transformer-based), highlighting the **effectiveness of the proposed design**. We also note that in these simpler versions, the parameter count is directly proportional to the vision encoder's representation size and LM's embedding size, whereas in MAPL we decouple this using a dimensionality bottleneck (Sec. 3.1), making our mapping network **more parameter-efficient by design**.

4.6 Qualitative results

Figure 3 shows some selected samples from the web illustrating our interface at inference time using MAPL $_{\text{CC-clean}}$. The first two columns show successful results while the last column shows failure cases. For image captioning (top row), success cases show MAPL can generate meaningful and detailed textual descriptions of the scene. For zero-shot VQA (bottom row), success cases indicate that MAPL is able to parse the question and connect visual information to encyclopedic knowledge contained in the pre-trained LM. However, MAPL's visio-linguistic understanding is evidently still far from being perfect. More qualitative results (both success and failure cases) are provided in App. A.6.

5 Conclusion

We introduce MAPL, a simple and parameter-efficient method to repurpose pre-trained and frozen unimodal models for multimodal tasks. Our experiments demonstrate that MAPL achieves superior or competitive performance compared to similar methods on several VL benchmarks while training orders of magnitude fewer parameters. Importantly, we also show that MAPL is effective in the low-data and in-domain settings thanks to its reduced number of trainable parameters. We leave as future work exploring training on a weighted mixture of image-text datasets, evaluating on more downstream tasks such as NLVR2 (Suhr et al., 2019) and Visual Dialog (Das et al., 2017), and investigating the use of masked LMs (Schick and Schütze, 2021; Chung et al., 2022) with MAPL.

Limitations

MAPL achieves reasonable performance on VL tasks, but it is still far from the performance of recent methods leveraging large-scale data and compute. On the other hand, MAPL is a preferable alternative in scenarios with constrained computational resources.

We observed our mapping network is sensitive to initialization, so different random seeds can yield non-negligible variance in downstream performance. We think this might be related to the reduced number of trainable parameters. We tried to reduce the effect of this variance by reporting average performance across different seeds. We also observed MAPL struggles to leverage more shots for in-context learning. We hypothesize this could be caused by our model being trained on single image-caption pairs – as opposed to the sequences of multiple images and texts seen during few-shot transfer, so a better pretext task might help (see App. A.1 for further discussion).

MAPL builds on top of pre-trained vision-only and language-only models, inheriting their capabilities but also their limitations. An important risk is that our model might inherit the existing social, gender or racial biases of pre-trained models. However, our limited qualitative analysis (see App. A.8) shows that providing visual information significantly changes the prior answer distribution of the LM. Therefore, how much of the underlying bias is retained remains an empirical question.

Ethics Statement

Model recycling. MAPL reuses vision-only and language-only foundation models. Hence, the expensive computational resources used to train these models can be amortized to help reduce energy and carbon costs.

Public datasets. MAPL is trained uniquely on publicly available datasets, which facilitates reproducibility and provides transparency on the origin and the characteristics of the data the model has seen.

Undesired biases. MAPL could be exposed to undesired biases from different sources. The pre-trained vision encoder might have been trained with data where certain races or genders are underrepresented, hence biasing our representation of images. The pre-trained LM might also be biased towards generating toxic or offensive language when fed with certain prompts. Finally, the image-text data used to align the representation spaces of such models was annotated by humans, so it might reflect a biased view of the world.

Broader impact. This work shows how one can easily adapt pre-trained vision encoders and LMs for multimodal tasks. Given the parameter-efficiency of our method, we believe it should be of great interest to the sections of the community that do not have access to large compute resources (e.g., small academic labs and independent researchers), and for low-data applications. While MAPL can be applied in many useful applications (e.g., aiding visually-impaired people), it also makes it simpler to create malicious or offensive multimodal systems from existing unimodal models. Further research efforts are needed on how to safely deploy such systems so that their behavior always aligns with ethical values.

Acknowledgements

We thank Pauline Luc, Siva Reddy, Lisa Anne Hendricks and Chris Dyer for their constructive feedback. We are grateful to the Mila IDT team for their technical support with the computational infrastructure. During this project, Aishwarya Agrawal was supported by the Canada CIFAR AI Chair award. We would also like to thank Samsung Electronics Co., Ldt. for funding this research.

A Appendix

A.1 Leveraging more shots

In Table 2, we observe MAPL's performance rapidly plateaus as the number of few-shot examples increases beyond 4. We hypothesize this could be related to the mapping network being trained on single image-caption pairs, and/or the visual embeddings still not being fully in-distribution with the language embeddings. Intuitively, a handful of examples may often help with task location (Reynolds and McDonell, 2021); however, the more shots are added, the more out-of-distribution the multimodal prompt becomes. This issue could be mitigated with in-context example selection (Yang et al., 2021) or better mixing of visual and textual modalities.

A.2 0-shot VQAv2 results with OPT

In Table 5, we observe Frozen*-OPT outperforms MAPL-OPT on 0-shot VQAv2. Upon close inspection, we notice MAPL-OPT often generates longer answers for yes/no questions, which receive a score of 0 according to VQA accuracy and VQAv2 reference answers – this is a problem of the metric and not the model itself (Agrawal et al., 2022). After filtering all answers starting with "yes" or "no" to leave only the short answer, MAPL-OPT achieves a VQA accuracy of 40.14% while Frozen*-OPT only reaches 32.03%.

A.3 4-shot results with OPT

In Table 5, we also observe that few-shot VQA performance is considerably lower for configurations using OPT-6.7B as language model. This is possibly due to the lack of a relative positional encoding (Shaw et al., 2018) in OPT, which is required for the transformer to generalize to prompt sequences where an image is not always in the first absolute position, or which contain more than one image (Tsimpoukelli et al., 2021).

A.4 Implementation details on simpler mapping networks

In Sec. 4.5, we ablate the choice of mapping network architecture and replace it by simpler architectures. Similarly to Eichenberg et al. (2021); Merullo et al. (2022), the linear mapping is applied per-position on top of a flattened grid of visual features, and it projects from $D_i = 1024$ to $D_o = 4096$ dimensions (4.2M parameters). The output sequence length L_o is thus equal to $L_i = 257$ (instead of 32) – as explained in Sec. 3.1, this increases the computational complexity in the subsequent LM, which in turn increases training and inference time considerably. Similarly to Mokady et al. (2021), the 2-layer MLP is applied on top of a global vector of visual features. The MLP's hidden dimensionality D_h is equal to $D_i = 1024$, and the output dimensionality is $D_o = 32 * 4096$, which we split into 32 vectors of 4096 dimensions (135.3M parameters).

A.5 Additional ablation studies

Table 6 shows the results of our additional ablation studies. Unless specified otherwise, we perform all ablations on MAPL $_{\text{CC-clean}}$ trained with 100% of the data. These experiments are run only once and early stopping is based on the validation split of Conceptual Captions.

Pre-trained vision encoder. We ablate the pre-trained vision encoder used to compute image representations. We report results in row (i) of Table 6. We compare two CLIP (Radford et al., 2021) variants, our choice based on the ViT-L/14 backbone and the ViT-B/32 backbone. Indeed, the ViT-L/14 based vision encoder has an average +20% advantage over the ViT-B/32 variant. We hypothesize this improvement is probably due to finer-grained image patches and a bigger model size.

Global vs. grid visual features. Grid features – as opposed to global features – preserve the spatial information in images. This kind of fine-grained information might be useful for complex VL tasks. To measure the impact of grid features, we train a version of MAPL where we use the global image representation from CLIP's multimodal embedding space. Results are reported in row (ii) of Table 6. We observe an average -10% drop in performance, validating our choice of using grid over global visual features.

Mapping network architecture. We ablate the architectural design of our mapping network in rows (iii) and (v) of Table 6. First, we ablate the size of our mapping network in terms of depth and hidden size. We explore three options: Small (2 layers and hidden size of 128), Medium (4 layers and hidden size of 256), and Large (8 layers and hidden size of 512). We see that using a smaller mapping network generally performs slightly worse than the base model. On the other hand, using a larger mapping network improves only in image captioning

Table 6: Ablation studies. "Overall Δ" refers to the difference (ablated model - base model), averaged across datasets per task.

tasks, while increasing significantly the number of trainable parameters (from 3.4M to 19.5M). We also ablate the output sequence length L_o of our mapping network. Similarly, reducing the output sequence length to 16 yields slightly lower performance overall, and increasing it to 64 only improves in image captioning tasks. In the extreme, we completely remove the learned constant embeddings and output the same sequence length coming from the vision encoder, i.e., $L_o = L_i = 257$. Following the trend, increasing the number of mapped visual embeddings is beneficial for image captioning but hurts VQA performance, while notably reducing training and inference throughput.

Data quality & visual features. This ablation setting aims to be the most similar to Frozen: training on the *full* (noisy) Conceptual Captions dataset while using global visual features. Results are reported in row (vi) of Table 6. The overall performance is worse than that of our base model (-16% on average), but still better than Frozen* $_{\text{CC}}$ on Table 4 (+81% on average). This validates our choice of using grid visual features while training on a subset of cleaner data.

A.6 Additional qualitative results

Figures 4-15 show additional qualitative results of MAPL $_{\text{CC-clean}}$ on random samples from different image captioning and VQA datasets. For VQA, in-context learning from 4 shots is performed.

A.7 Interpretability of visual embeddings

Using MAPL $_{CC-clean}$, we extract mapped visual embeddings (after the mapping network) for ∼30 images from the COCO Karpathy-test set, and compute the nearest token embeddings (from the LM's vocabulary) using cosine similarity. We rarely found the top-5 nearest tokens correspond to concepts present in the image, suggesting these embeddings are not interpretable. We hypothesize this is perhaps because they carry a combination of task-inducing and image-specific information, also pointed out by Mokady et al. (2021). We further cluster the mapped visual embeddings with K-means, and observe that each cluster often represents some visual concept (e.g., animals, food, sports). This means the mapped visual embeddings retain visual information from the vision encoder, which we also verify with MAPL's performance on VL benchmarks.

A.8 Analysis of VQA answer distributions

In this section, we show the distribution of answers for selected VQAv2 question types. We compare MAPL with several baselines of our model to get insights into how the model's predictions change when training on increasing multimodal data. For the text-only baseline, we only provide the question text to the LM. This is different from the previously introduced blind baseline (Sec. 4.1), where a blacked-out image is also provided. In particular, we compare the predicted answer distribution of MAPL $_{\text{COCO}}$ evaluated on on zero- and few-shot VQA with the aforementioned baselines and the ground truth. Overall, we observe the predicted answer distribution gets closer to the ground truth answer distribution (Figure 21) as more information from the image-question pair is provided to the model. We notice a considerable shift in the answer distribution from the text-only baseline (Figure 16) to the blind baseline, which demonstrates the impact caused by the captions alone. Moreover, we see the predicted answer distribution of MAPL zero-shot is closer to the ground truth answer distribution than that of the blind baseline (Figure 17), which indicates that MAPL is leveraging the additional information from the visual input. For instance, we observe MAPL's predicted answer distribution for the "what color" question type (second column) looks more similar to the ground truth distribution compared to the text-only and blind baselines. Finally, when performing in-context learning from four shots (Figure 19), we see the answer distribution gets even closer to the ground truth distribution. However, we do not observe much difference in answer distribution when increasing the number of shots from four to eight (Figure 20).

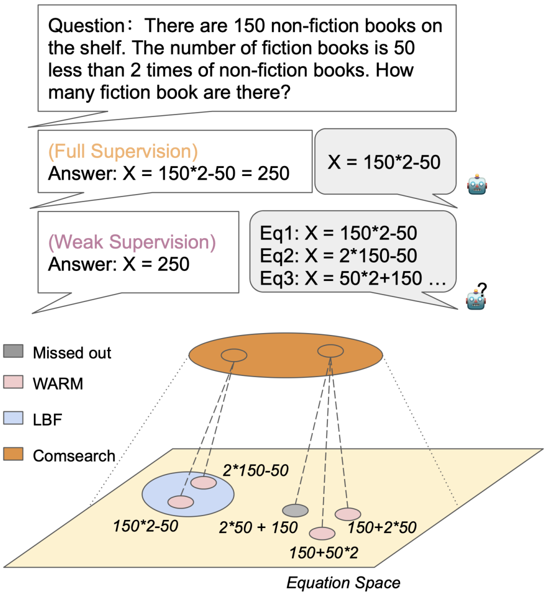
Abstract

Previous studies have introduced a weakly-supervised paradigm for solving math word problems requiring only the answer value annotation. While these methods search for correct value equation candidates as pseudo labels, they search among a narrow sub-space of the enormous equation space. To address this problem, we propose a novel search algorithm with combinatorial strategy **ComSearch**, which can compress the search space by excluding mathematically equivalent equations. The compression allows the searching algorithm to enumerate all possible equations and obtain high-quality data. We investigate the noise in the pseudo labels that hold wrong mathematical logic, which we refer to as the *false-matching* problem, and propose a ranking model to denoise the pseudo labels. Our approach holds a flexible framework to utilize two existing supervised math word problem solvers to train pseudo labels, and both achieve state-of-the-art performance in the weak supervision task. [1]

1 Introduction

Solving math word problems (MWPs) is the task of extracting a mathematical solution from problems written in natural language. Based on a sequence-to-sequence (seq2seq) framework that takes in the text descriptions of the MWPs and predicts the answer equation (Wang et al., 2017), task-specialized encoder and decoder architectures (Wang et al., 2018b, 2019; Xie and Sun, 2019; Liu et al., 2019; Guan et al., 2019; Zhang et al., 2020b,a; Shen and Jin, 2020), data augmentation and normalization (Wang et al., 2018a; Liu et al., 2020; Shen et al., 2022b), and pretrained models (Tan et al., 2021; Liang et al., 2021; Shen et al., 2021, 2022a) have been conducted on *full supervision* setting of the task. These settings require equation expression annotation, which is expensive and time-consuming.



Question: There are 150 non-fiction books on the shelf. The number of fiction books is 50 less than 2 times of non-fiction books. How many fiction book are there?

(Full Supervision)
Answer: X = 150*2-50 = 250

X = 150*2-50

(Weak Supervision)
Answer: X = 250

Eq1: X = 150*2-50
Eq2: X = 2*150-50
Eq3: X = 50*2+150 …

Figure 1: Example of MWP solving system under full supervision and weak supervision.

Recently Hong et al. (2021) (LBF) and Chatterjee et al. (2021) (WARM) addressed this problem and proposed the *weak supervision* setting, where only the answer value annotation is given for supervision. Such a setting forms pseudo question-candidate equation pairs, which hold the correct answer value for training with the complexity of $O(n^{2n})$ for n variables enormous possible equation space. Computational efficiently extracting such pairs becomes the major challenge since it is computationally impossible to traverse all possible equations, especially when the example has more variables (e.g., 88,473,600 for 6 variables). As we show in Figure 1, previous studies sample a limited set of equations via random walk (Hong et al., 2021) or beam searching (Chatterjee et al., 2021). However, the algorithms can only cover a limited part of the data, which we refer to as *recall*. As shown in Table 1, LBF (Hong et al., 2021) only covers 30% of the examples of more than 4

---

Table 1: Searching result recall on problems of different variable sizes.

variables. Moreover, the random walk algorithm lacks robustness and leads to a high performance variance.

We observe that although the equation search space is ample, many equations are mathematically equivalent under the commutative law, associative law, or other equivalent forms. Hence, searching for these equivalent equations is redundant, especially for difficult examples with a larger number of variables. For example, $a + b + c + d * e$ has 48 equivalent forms that hold the same mathematical meaning considering only the commutative law. Eliminating such redundancy in the searching space could reduce computational complexity. In this paper, we propose a combinatorial-strategy-based searching method **ComSearch** that enumerates *non-equivalent equations* without repeating, which can robustly extract candidate equations for a wide range of unlabeled data and build a high recall pseudo data with equation annotation even for difficult examples. To this end, the main idea of Comsearch is to use depth-first search (DFS) to enumerate only one representative equation for each set of equivalent equations and then check whether the equation holds the correct answer value. Comsearch effectively compresses the searching space, e.g., up to 111 times for 6 variables compared to bruce-force searching. As shown in Table 1, ComSearch can achieve a relatively high recall for different variable sizes. Our method could be proven to have lower approximate complexity.

While Comsearch only searches among *non-equivalent equations*, we observe that many examples still have multiple candidate equations through which we can get the final answer. As shown in Figure 1, Equation 1 (Eq1: X=150*2-50) and Equation 3 (Eq3: X=50*2+150) can get the same value, but Equation 3 holds a false mathematical reasoning logic, and using Equation 3 as the pseudo label would bring in noise. We address this data noise as the *false-matching* problem, which has been ignored in previous studies, since their methods do not consider whether the multiple candidate equations of one example are caused by equivalent equation forms or false matching. To address this problem, we investigate how the false-matching problem drags down the system's performance and propose two ranking models to alleviate this problem. For examples with multiple candidate equations from ComSearch, the ranking module first collects a set of candidate equations, then assign a score by a draft model trained on pseudo data with only a single candidate equation to each candidate to choose the best pseudo label. In addition to candidates from the searching result of ComSearch, we observe that beam search results of the draft model can also serve as a high-precision candidate equation. We investigate these two settings for candidate equation sets.

We conduct experiments on two strong MWP solvers, achieving state-of-the-art (SOTA) results under the weakly supervised setting, especially for examples with many variables. The results also demonstrate the effectiveness and generalization ability of our method.

In summary, our contribution is three-fold:

- We propose ComSearch, a searching algorithm that enumerates non-equivalent equations without repeat to search candidate equations effectively.
- We are the first to investigate the *false-matching* problem that brings noise to the pseudo training data. We propose a ranking module to reduce the noise and give a detailed oracle analysis of the problem.
- We perform experiments on two MWP solvers with our ranking module and achieve SOTA performance under weak supervision.

2 Methodology

We show the pipeline of our method in Figure 2. Our method consists of three modules: the Search with combinatorial strategy (**ComSearch**) module that searches for candidate equations; the MWP model that is trained to predict equations given the natural language text and pseudo labels; the Ranking module that uses an explorer model to find candidate equations and select the best candidate equation with a scoring model.

2.1 ComSearch

Directly searching for non-equivalent equation expressions is difficult because the searching method needs to consider Commutative law, Associative law, and other equivalent forms. We show how equivalent equations could be merged into a representative form $\mathcal{X}$, and the enumeration of $\mathcal{X}$ can

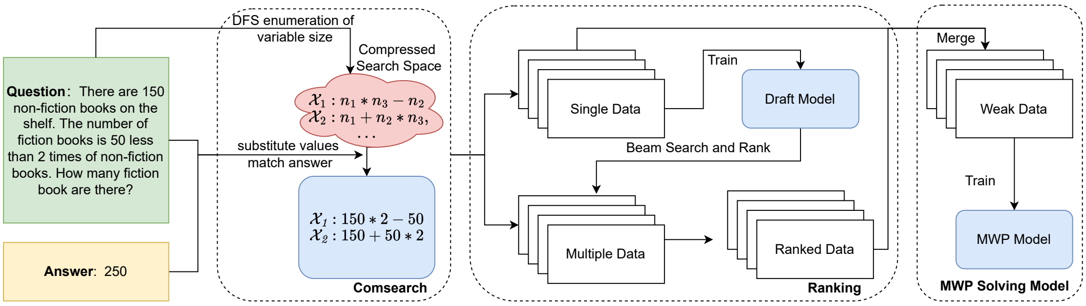

Figure 2: The model overview.

transverse all non-equivalent equations for four arithmetic operations.

We define the set of *non-equivalent equations* using four arithmetic operations as S_n. We first split the equations to two categories, either $S^{\pm}$ where the outermost operators are $\pm$, such as $n_1/n_2 + n_3 - n_4$ and $n_1/n_2 - (n_3 - n_4)$, or $S^{\divideontimes}$ where the outermost operators are $\divideontimes$, such as $(n_2 + n_1) * (n_3 - n_4/n_5)$. We call the former a *general addition equation* and the latter a *general multiplication equation*.

$$S^{\pm}_m = \{(n_1 \divideontimes (..)) \pm (n_i \divideontimes (..)) \pm ..n_m\} \quad (1)$$

$$S^{\divideontimes}_m = \{(n_1 \pm (..)) \divideontimes (n_i \pm (..)) \divideontimes ..n_m\} \quad (2)$$

These two sets are symmetrical, so we only need to consider one set. Consider elements in $S^{\pm}_m$, we can rewrite the equation to the representative form $\mathcal{X}$:

$$\begin{aligned}\mathcal{X} =&((n_i \divideontimes (..)) + (n_j \divideontimes (..)) + ..) \\ &- ((n_k \divideontimes (..)) + (n_l \divideontimes (..)) + ..)\end{aligned}$$

For example, $n_1/n_2 - n_3 + n_4$ and $n_1/n_2 - (n_3 - n_4)$ are equivalent, that they are both rewritten as $(n_1/n_2 + n_4) - n_3$. $(n_2 + n_1) * (n_3 - n_4/n_5)$ could be rewritten as $(n_1 + n_2) * (n_3 - n_4/n_5)$. Trivially, any two equations that are represented by the same $\mathcal{X}$ are equivalent. We give proof of the number of inequivalent expressions involving n operands in Appendix Section A, which shows that any two equivalent equations are written as the same $\mathcal{X}$. Thus the enumeration of $\mathcal{X}$ is equivalent to the enumeration of non-equivalent equations. The enumeration problem of these equations is an expansion of solving Schroeder's fourth problem (Schröder, 1870), which calculates the number of labeled series-reduced rooted trees with m leaves. We give the details of the DFS in the Appendix Section D.

Given the compressed search space, we substitute the values for variables in the equation templates and use the equations of which value matches the answer number as candidate equations. If no equations could be extracted by using all numbers, we continue to consider: (1) omitting one number, (2) adding constant number 1 and π, and (3) using one number twice. If the algorithm extracts candidates at any stage, the further stages are not considered since it would introduce repeating equations, e.g., $1 * (a + b)$ is a duplication of $a + b$.

2.2 MWP Solving Models

Goal-driven Tree-structured Solver We follow Hong et al. (2021) and Chatterjee et al. (2021) and use Goal-Driven Tree-Structured MWP Solver (GTS) (Xie and Sun, 2019) as the MWP model. GTS is a seq2seq model with the attention mechanism that uses a bidirectional long short term memory network (BiLSTM) as the encoder and LSTM as the decoder. GTS also uses a recursive neural network to encode subtrees based on its children nodes' representations with the gate mechanism. With the subtree representations, this model can well use the information of the generated tokens to predict a new token.

Graph-to-Tree Solver Following Chatterjee et al. (2021), we conduct experiments on Graph-to-Tree Solver (G2T) (Zhang et al., 2020b) . G2T is a direct extension of GTS, which consists of a graph-based encoder capturing the relationships and order information among the quantities.

2.3 Ranking

While ComSearch enumerates equations that are non-equivalent without repeat, some variable sets can coincidentally form multiple equations with the same correct value, as shown in Figure 2. The equations $150 * 2 - 50$ and $150 + 50 * 2$ are non-equivalent. However, their values are equal, while only $150 * 2 - 50$ is the correct solution. We refer to this problem as *false-matching*, an important issue

Model	Term	#	Prop(%)
-	All Data	23,162	-
Ours	Too Long	233	1.0
	Power Operator	51	0.2
	Single	17,959	77.5
	Multiple	3,947	17.0
	Data	21,906	**94.5**
WARM	Data (w/o beam)	-	14.5
	Data (w/ beam)	-	80.1
LBF	-	-	80.1

Table 2: Statistics of ComSearch Results.

that previous studies have overlooked. While previous studies also collect multiple candidate equations for one example, they cannot differ whether the issue is caused by equivalent forms of the equations or *false-matching*, and they do not perform any processing on these *false-matching* examples, which brings in noise to the pseudo data.

To process these data that have multiple candidate equations, we propose two ranking methods to choose the best candidate equation for each example. The module first collects a set of candidate equation that holds the correct annotated answer value and then score the candidates to choose the pseudo label for the sample.

Before ranking, we train a draft model S on the single-candidate pseudo data because the single-candidate data is relatively reliable with fewer false-matching examples. In the first ranking method *Basic Ranker*, for a data example x, we rank among the multiple search results of Comsearch $\{y^{eq}\}^{search}$. Then we use the draft model S to calculate the conditional probability of y^{eq} at each time step t. The score of the length k equation s^{eq} is defined as:

$$s^{eq} = \sum_{t=0}^{k} log(S(x, y_t^{eq})) \tag{3}$$

We use the candidate equation that has the highest score as the pseudo label of this example.

Empirically, we observe that performing beam search on the draft model S could also generate high-precision candidate equations. Thus in the second method *Beam Ranker*, we further explore more candidate equations with beam search. We add beam search predictions of S that hold the correct value $\{y_{eq}\}^{beam}$ to the candidate equation set along with Comsearch results $\{y^{eq}\}^{search}$. The score function is defined the same as the basic ranker.

3 Analysis on ComSearch

3.1 Search Statistics

We give statistics of ComSearch in Table 2. Among the 23,162 examples, 233 have more than 6 variables that we filter out, and 51 use the power operation that our method is not applicable. 94.5% of the examples find at least one equation that can match the answer value, significantly higher than WARM and LBF, which cover only 80.1% of the examples. 17,959 examples match with only one equation, and 3,947 examples match with two or more equations that need the ranking module to choose the pseudo label further. We show the distribution of these examples in Appendix Section B.

We further break down the recall on different variable sizes in Table 4. As we can see, when the number of variables grows larger, the recall of LBF drastically collapses, while the recall of our method keeps steady. Sampling based methods cover only a small subset of the equation space and fail to extract candidate equations for larger variable size examples. In contrast, our method can consider a broader range of equation space, which demonstrates the superiority of our enumeration based method.

3.2 Eliminating Equivalent Equations in Search Space

We show the empirical compression of the search space with ComSearch in Table 3. As we can see, the compression ratio of ComSearch increases as the variable number grows, up to more than 100 times when the number of variables reaches 6. Previous studies on reducing the redundancy of equivalent expressions consider a limited set of rules, such as removing brackets (Roy and Roth, 2015) and Commutative Law (Wang et al., 2018a). We also show the results of considering removing brackets, where $-/\div$ can not be the children node of $+/*$, which is the compression considered in Roy and Roth (2015); and Commutative Law, which is the compression considered in Wang et al. (2018a). Although the two methods can compress the search space to some extent, there is a large gap between their compression efficiency and ours, up to more than 20 times when the number of variables reaches 6.

The size of the Bruce-Force search space could be directly calculated, which is $n! * (n-1)! * 4^{n-1}$. If we consider the exponential generating function

#Variable	Bruce-Force	Removing Brackets	Commutative	ComSearch	Ratio
1	1	1	1	1	1
2	8	8	6	6	1.3
3	192	144	108	68	2.8
4	9,216	5,184	3,816	1,170	7.9
5	737,280	311,040	224,640	27,142	27.2
6	88,473,600	27,993,600	19,841,760	793,002	111.6

Table 3: Empirical Results of Search Space Size.

#Var	1	2	3	4	5	≥ 6
LBF	91.5	86.8	88.8	31.1	25.0	38.4
Ours	67.0	93.4	96.4	98.1	94.4	73.8

Table 4: Result of recall on different variable sizes

of $card(S_n)$, based on Smooth Implicit-function Schema, we can have an approximation of S_n: $card(S_n) \sim C * n^{n-1}$, which shows our searching method compresses the search space more than exponential level. We give proof in appendix Section A.

3.2.1 Advantages of Enumeration without repeat

The most important core of our approach is that it explicitly points out the *false-matching* problem because it can enumerate a wide range of equations while ensuring each equation holds an independent mathematical reasoning logic. Sampling methods can only sample a small set of equations that may neglect other potential candidates.

Compared to other enumeration methods, despite the enumeration efficiency, Comsearch ensures the enumeration is among non-equivalent equations, so collecting more than one candidate equation for one example shows that there exists more than one mathematical reasoning logic that could reach the annotated answer value. However, only one of the reasoning logic could be true, which elicits the *false-matching* problem. Even if we add more rules to compress the search space, as long as the non-equivalency of different equations cannot be ensured, we cannot differ *false-matching* and multiple expressions of the same mathematical reasoning logic.

4 Experiments

4.1 Dataset and Baselines

We evaluate our proposed method on the Math23K dataset. It contains 23,161 math word problems annotated with solution expressions and answers. We only use the problems and final answers. We evaluate our method using the train-test split setting of Wang et al. (2018a) by the three-run average.

Model	**Valid(%)**	**Test(%)**
GTS based		
WARM	-	12.8
+*beam*	-	54.3
LBF†	57.2(±0.5)	55.4(±0.5)
+*memory*†	56.6(±6.9)	55.1(±6.2)
Ours†	**61.0**(±0.3)	**60.0**(±0.3)
Supervised†	-	75.6
G2T based		
WARM	-	13.5
+*beam*	-	56.0
Ours†	**61.7**(±1.1)	**60.5**(±0.6)
Supervised†	-	77.4

Table 5: Results on Math23K. ± denotes the variance of 3 runs for valid/test. *Supervised* denotes full supervision upper bound. † denotes the results of our implementation, other results are from the original paper.

We compare our weakly-supervised models' math word problem solving accuracy with two baseline methods.

Chatterjee et al. (2021) proposed **WARM** that uses RL to train the candidate generation model with the reward of whether the value of the equation is correct. Since the reward signal is sparse due to the enormous search space, the top1 accuracy of the candidate generation model is limited, and they use beam search to search for candidates further.

Hong et al. (2021) proposed **LBF**, a learning-by-fix algorithm that searches in neighbour space of the predicted wrong answer by random walk and tries to find a fix equation that holds the correct value as the candidate equation. *memory* saves the candidates of each epoch as training data.

4.2 Main Results and Ablation Study

We show our experimental results in Table 5. We reproduced the results of LBF with their official code

Model	Valid(%)	Test(%)
Proposed Method	61.0	60.0
w/o Multiple Data	58.9	57.5
w/o Ranking	57.3	56.3
w/o Beam Search	60.1	59.2

Table 6: Results of Ablation Study for Ranking. ‘w/o Multiple Data’ denotes only using single candidate pseudo data for training. ‘w/o Ranking’ denotes removing the ranking module and randomly sampling an equation for the examples that match with two or more equations. ‘w/o Beam search’ denotes using the basic ranker for ranking.

Model	Micro Eq Acc(%)
Single	81.4
Multiple	2.7
All Data	23.0
Basic Ranker(Multiple)	45.6
Beam Ranker(Multiple)	47.7
Beam Ranker(All Data)	76.3

Table 7: Equation accuracy of different methods. ‘All Data’ denotes considering both the single and multiple data.

and found that LBF+memory lacks robustness. As we can see in the table, the performance of LBF has high variance on both the validation and test set. For a fair comparison, we additionally ran 5-fold cross-validation setting according to (Hong et al., 2021) for our model and LBF+memory with the GTS model. The results show that LBF + memory achieves a cross-validation score of 56.3% with a variance of ±6.2, while our model achieves a cross-validation score of 59.7% with a variance of ±1.0, which performs similar to the train-test setting. We observe that its performance highly relies on the initialization of the model. When fewer candidates are extracted at early-stage training, the performance drops drastically since LBF relies on random walks in an enormous search space. Our method achieves state-of-the-art performance and outperforms other baselines up to 3.8% and 2.7% on train-test and cross-validation settings. Our method is also more robust with minor variance.

We perform an ablation study with the GTS-based train-test setting in Table 6. *Single Equation* denotes using the 17,959 examples that only match with one equation, the model achieves 57.5% performance, which is slightly lower than using all data and the ranking module, outperforming other baseline models. The result shows that the examples with only one matching could be considered highly reliable and achieve comparable performance with a smaller training data size. We observe a performance drop of at least 2.9% without the ranking module, showing that our ranking module improves the performance. We observe a performance gap of 0.9% between the two rankers, demonstrating the importance of considering candidate equations from the model prediction.

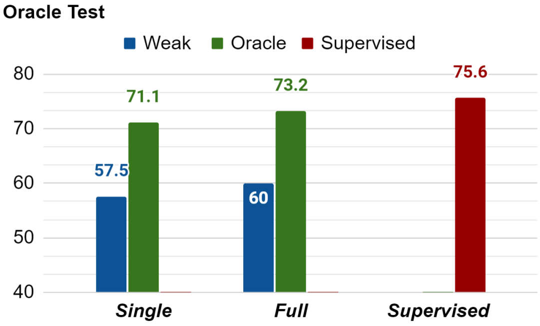

Figure 3: Results of Oracle Test with gold labels.

4.3 Analysis

We conduct analysis on GTS train-test setting since the model achieves similar performance compared with G2T and the run time is less.

4.3.1 Oracle Test

While our searching method covers 94.5% of the training data, as shown in Table 2, there is still a significant performance gap of more than 15% between the weakly supervised performance and fully supervised performance, as shown in Table 5. As stated in Section 2.3, we observe that the *false-matching* problem could potentially draw down the performance, which is verified by the effectiveness of the ranking module.

To further analyze our two modules, we perform two oracle tests for the weakly supervised system. In Figure 3, using the same data examples, we replace the weakly supervised annotations with the supervised gold labels and train the MWP solver. We can observe a performance gap of around 10% using the same data examples as training data, which indicates that the weakly supervised annotations contain noise. Since all candidate equation annotations have the correct answer, the *false-matching* problem is why this noise exists. The results show that the *false-matching* problem is the critical issue in the weakly supervised setting that causes the performance gap compared to supervised setting.

To investigate the noise in the pseudo training data, we perform an oracle analysis of the *Micro*

Text	**Candidates**	**Gold**	**Ans**
Some children are planting trees along a road every 2 meters. They plant trees on both ends of the road. At last they planted 11 trees. How long is the road?	2*(11-1)	(11-1)*2	20
A library has 30 books. On the first day, $\frac{1}{5}$ of the books were borrowed out. On the second day, 5 books were returned. How many book are there in the library now?	30 - $\frac{1}{5}$ * 5	30*(1-($\frac{1}{5}$)) + 5	29
Peter and a few people are standing in a line, one person every 2 meters. Peter found that there are 4 people before him and 5 people after him. How long is this queue?	4*5-2 , (4+5)*2	4*2 + 5*2	18

Table 8: Case study of ComSearch. The blue color denotes that the candidate is true-matching and the light red color denotes that the candidate is false-matching.

	Train				Test		
	Micro Eq Acc(%)		Macro Eq Acc(%)		Ans Acc(%)		
#Var	LBF	Ours	LBF	Ours	LBF	Ours	Prop(%)
1	91.8	**96.3**	**88.2**	64.9	**75.0**	50.0	1.6
2	82.9	**94.8**	78.1	**88.7**	**75.2**	73.4	33.1
3	54.2	**78.9**	57.4	**76.1**	56.2	**62.9**	48.5
4	38.0	**58.0**	13.6	**57.4**	4.8	**25.8**	12.4
5	8.6	**31.1**	4.2	**29.4**	3.2	**16.1**	3.1
≥ 6	5.1	**50.6**	1.2	**38.1**	0	**30.1**	1.3

Table 9: Results of different variable sizes.

Equation Accuracy of the pseudo training data. *Micro Equation Accuracy* is defined by what proportion of training instance holds the correct equation solution, which means the instance is not a *false-matching* example. In Table 7, we show the results of micro equation accuracy of the training data. We check whether the pseudo equation annotations that our system obtains are equivalent to the gold labels for each instance. We can see that even in the **Single** data that can only extract one candidate equation, the micro equation accuracy shows there is still noise in the pseudo training data. We show examples in the case study section to explain this problem. The examples that extract more than one candidate have an equation accuracy rate as low as 2.7%, which makes our ranking system essential. Benefiting from the ranking system, the multiple candidate data can achieve a higher equation accuracy rate. The Beam ranker performs better than the basic ranker considering beam search results.

4.3.2 Case Study

We conduct a case study for ComSearch on three examples to further discuss the strengths and limitations of the method in Table 8. The first example extracts only one candidate equation; although the written expression is different from the gold label, the two equations are equivalent, and the candidate is true-matching. The second example extracts only one candidate equation; the *false-matching* candidate coincidentally equals the correct answer with this set of variable numbers. However, the candidate expression and gold label expression are not equivalent. The algorithm reaches a candidate at the stage of using all numbers and does not further search for candidates that use the constant number 1. The third example extracts two candidate equations, while only $(4 + 5) * 2$ holds the correct mathematical knowledge. The two candidates appear at the same searching stage, and such *false-matching* cannot be avoided by Comsearch, where we need the ranker to help filter out the *false-matching* noise. In this example, the two rankers both select the correct label.

4.3.3 Study on Number of Variables

The distribution of different variable size instances in Math23K dataset is imbalanced, so we further break down the performance of different variable sizes compared with LBF in Table 9. The *Micro Equation Accuracy* shows our method can extract higher quality pseudo data for all variable sizes compared to previous sampling based methods, especially for examples with more variables.

The recall of candidate extraction methods is another important factor that affects performance.

Therefore, in addition to *Micro Equation Accuracy*, we further investigate the *Macro Equation Accuracy* of the two methods, which is defined as equation accuracy on an average of each math word problem. We show that, except for 1 variable, our method has significant advantages over LBF, especially for difficult examples. This demonstrates that our method can effectively extract high equality data of a large quantity. We also show the test answer accuracy of our method and LBF of different variable sizes, which positively correlates with the *Macro Equation Accuracy*. Eliminating equivalent equations allows our method to consider the larger search space, while sampling based methods such as LBF limit to a small neighbour space of the model prediction. When the variable number is small, the in-place random walk of LBF can possibly reach the correct equation, that for the examples with 1 or 2 variables, LBF has a slight performance advantage. When the variable number grows larger, as shown in Table 3, the gap between the efficiency of our searching method and LBF expands, and our method can consider more equations candidates and achieve higher recall and better recall performance. Moreover, the *false-matching* problem is more severe when there are more variables; ignoring the problem would cause low *Micro Equation Accuracy* and bring in more noise to the pseudo training data.

5 Related Work

Early approaches to solving math word problems mainly depend on hand-craft rules and templates (Bobrow, 1964; Charniak, 1969). Later studies either rely on semantic parsing (Roy and Roth, 2018; Shi et al., 2015; Zou and Lu, 2019), or try to obtain an equation template (Kushman et al., 2014; Roy and Roth, 2015; Koncel-Kedziorski et al., 2015; Roy and Roth, 2017). Recent studies focus on using deep learning models to predict the equation template for full supervision setting.

For weakly supervised setting, Hong et al. (2021) and Chatterjee et al. (2021) suffers from two major drawbacks. First, they apply equation candidate searching on an enormous searching space, while our method can effectively extract high-quality candidate equations. Hong et al. (2021) results in low robustness and low performance on examples with more variables. Chatterjee et al. (2021) results in low coverage of examples that can extract candidate equations. Second, they use all candidate equations for training and neglect the *false-matching* problem, which is the key issue that drags down the model performance in weakly supervised setting, while our ranking module addresses this issue and further boosts the performance.

To eliminate equivalent expressions, Roy and Roth (2015) proposed a model that decomposes the equation prediction problem into various classification problems, eliminating some equivalence forms of the equation. However, the compression is highly integrated with their model and cannot generalize to other models, including the SOTA seq2seq based models. Moreover, it can only cover limited equivalence forms, leaving out various important forms such as Commutative law and Associative law. (Wang et al., 2018a) proposed a normalization method for supervised MWP systems that considers Commutative law. The method merges several equivalent expressions into one expression, resulting in the compression of the target equation space. However, their method requires bruce-force enumeration before compression, which remains to have high computational complexity. Only limited equivalent forms are considered in both studies, and the equation space is still considerably ample.

Various studies (Kristianto et al., 2016; Mansouri et al., 2021) in ARQMath competition (Mansouri et al., 2020) and NTCIR benchmark (Zanibbi et al., 2016) have investigated the math retrieval task that retrieves the most related mathematical passage for a question, which have clear semantic meanings given by the textual description. In our ranker setting, the scoring targets, i.e., plane mathematical equations, cannot provide the semantic meanings that contextual embedding similarity based methods used in math retrieval benchmarks require. With fully supervised training data, retrieval-based methods only achieve 40% accuracy (Wang et al., 2017) on Math23K.

Spurious programs in weakly supervised semantic parsing is a close analogy of the false-matching problem, which refers to incorrect programs that lead to correct denotations. The major difference is that the function names of the spurious programs are natural language defined, so the programs have semantic meanings. Extra knowledge bases (Berant et al., 2013) and lexicon clues (Goldman et al., 2018) were used to denoise the spurious programs, which is not applicable for complex lexicon patterns MWPs that the solution equation uses operators '$+, -, *, /$' that have no semantic meaning. Pasupat and Liang (2016) uses a small human-annotated dataset for denoising. Guu et al. (2017), which proposes a re-weighted optimization loss for the examples. However, their method relies heavily on hyperparameter tuning and gains negative results on many datasets. Thus these methods are not suitable for the setting in our paper.

6 Conclusion

This paper proposes ComSearch, a searching method based on a Combinatorial strategy, to extract candidate equations for Solving Math Word Problems under weak supervision. ComSearch compresses the enormous search space of equations beyond the exponential level, allowing the algorithm to enumerate all possible non-equivalent equations to search for candidate equations. We investigate the *false-matching* problem, which is the critical issue that drags down performance, and propose a ranking model to reduce noise. Our experiments show that our method obtains high-quality pseudo data for training and achieves state-of-the-art performance under weak supervision settings, outperforming strong baselines, especially for examples with more variables.

Limitations

As we observe from experiments, the performance gap between the most reliable weak data and oracle data is still 10%, and the noise rate in the pseudo data is still relatively high. This is caused by the stopping strategy of our searching algorithm. Because introducing constant numbers such as 1 and using variables for more than one time would cause meaningless multiple candidate equations (e.g., $n_1/n_1 * n_1$, $1 * n_1$), we search the equations at various stages: deleting one variable, adding a constant and using one variable multiple times. We stop searching when the stage ends and one equation is obtained. If a more advanced searching strategy that can consider such redundancy could be introduced, the reliability of the weak data could be further boosted.

Meanwhile, our ranking module only denoises multiple candidate equations examples, while the single data also has a volume of noise. We denoise with a simple strategy for one round because we focus on investigating the negative effects of the false-matching problem. For future work, we would consider applying more advanced learning from noise algorithms and denoise more training data.

In Table 4, the results shows a notable discrepancy in the performance of the #var = 1 when compared to other variable sizes and the baseline. This discrepancy can primarily be attributed to numerous geometrically related questions in the #var = 1 example set, such as the computation of the volume of a cube l^3 given the side length l, which is not encompassed by our current search methodology. A straightforward remedy would be to include this equation template in our search when handling #var = 1; however, we deliberately excluded it from our experiments to maintain consistency across the different variable sizes.

A Proof for Search Space Approximation

Because there is at least one $+$ or $*$ operator for each equation (i.e. $-a-b-c$ is illegal), the target S_n is not symmetric and is hard to directly approximate. We need two assisting targets to form the approximate. This proof majorly relies on Flajolet and Sedgewick (2009) and OEIS Foundation Inc. (2023, A140606).

We first consider target U that considers only $+$, $*$ and $\div$ three operators. We sort it into two categories: U^+ that the outermost operator is $+$ and $U^{\divideontimes}$ that the outermost operator is $\divideontimes$. Equations such as $\frac{1}{a} * \frac{1}{b-c}$ are still considered illegal.

Z corresponds to a single variable equation. We can have the construction of U:

$$U^+ = Z + SET_{\geq}(U^{\divideontimes}) \tag{4}$$

$$U^{\divideontimes} = Z + (2^2-1) * SET_{=2}(U^+) \tag{5}$$

$$+ (2^3-1) * SET_{=3}(U^+)... \tag{6}$$

We apply symbolic method to obtain the EGF of the constructions:

$$U^+(z) = z + \sum_{k\geq 2} \frac{1}{k!}[U^{\divideontimes}(z)]^k \tag{7}$$

$$= z + [e^{U^{\divideontimes}(z)} - 1 - U^{\divideontimes}(z)] \tag{8}$$

$$U^{\divideontimes}(z) = z + \sum_{k\geq 2} \frac{2^k-1}{k!}[U^+(z)]^k \tag{9}$$

$$= z + e^{2U^+(z)} - e^{U^+(z)} - U^+(z) \tag{10}$$

Meanwhile, we have:

$$U(z) = U^+(z) + U^{\divideontimes}(z) - z \tag{11}$$

Next, we consider target T that $-a-b-c$ is considered legal. Similarly we define $T^{\pm}$ and $T^{\divideontimes}$. We consider the construction:

$$T^{\pm} = 2Z + SET_{\geq}(T^{\divideontimes}) \tag{12}$$

$$T^{\divideontimes} = 2Z + 2[(2^2-1) * SET_{=2}(T^{\pm}/2) \tag{13}$$

$$+ (2^3-1) * SET_{=3}(T^{\pm}/2)...] \tag{14}$$

With symbolic method we have:

$$T^{\pm}(z) = 2z + \sum_{k\geq 2} \frac{1}{k!}[U^{\divideontimes}(z)]^k \tag{15}$$

$$= 2z + [e^{T^{\divideontimes}(z)} - 1 - T^{\divideontimes}(z)] \tag{16}$$

$$T^{\divideontimes}(z) = 2z + 2\sum_{k\geq 2} \frac{2^k-1}{k!}[T^{\pm}(z)/2]^k \tag{17}$$

$$= 2z + 2e^{T^{\pm}(z)} - 2e^{T^{\pm}(z)/2} - T^{\pm}(z) \tag{18}$$

The illegal equations such as $-a-b-c$ in T equals the counts of $a+b+c$, which is actually U. So we have:

$$S(z) = T(z) - U(z) \tag{19}$$

We now have the EGF of S_n. We can sequentially compute the first few terms of this sequence:

$$1, 6, 68, 1170, 27142, 793002, 27914126, ... \tag{20}$$

With Smooth implicit-function schema and Stirling approximation function we have, for an EGF $y(z) = \sum_{n\geq 0} y_n z^n$, Let $G(z,w) = \sum_{m,n\geq 0} g_{m,n} z^m w^n$, thus $y(z) = G(z, y(z))$:

$$n! * [z^n]y(z) \sim \frac{c * n!}{\sqrt{2\pi n^3}} * r^{-n+1/2} \tag{21}$$

$$\sim \frac{c\sqrt{2\pi nr}}{\sqrt{2\pi n^3}}(\frac{1}{r})^n(\frac{n}{e})^n \tag{22}$$

$$= \frac{c\sqrt{r}}{n}(\frac{n}{re})^n \tag{23}$$

while r:

$$G(r,s) = s \tag{24}$$

$$\frac{\partial G(r,s)}{\partial w} = 1 \tag{25}$$

and c:

$$c = \sqrt{\frac{\partial G(r,s)/\partial z}{\partial^2 G(r,s)/\partial w^2}} \tag{26}$$

We still need the two assisting targets to perform the approximation. We have:

$$U^+(z) = e^{z+e^{2U^+(z)}-e^{U^+(z)}-U^+(z)} \tag{27}$$

$$- e^{2U^+(z)} + e^{U^+(z)} + U^+(z) - 1 \tag{28}$$

Let $G(z,w) = z + e^{2w} - e^w - ln(1 + e^{2w} - e^w)$, considering 24 and 26, r, s and c would be constant numbers.

So we have:

$$n![z^n]U^+(z) \sim \frac{c_1\sqrt{r_1}}{n}(\frac{n}{r_1 e})^n \tag{29}$$

Similarly we can approximate $U^{\divideontimes}$, $T^{\pm}$ and $T^{\divideontimes}$:

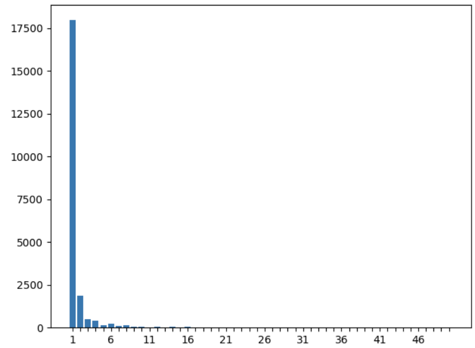

Figure 4: Distribution of Candidate Equation Number.

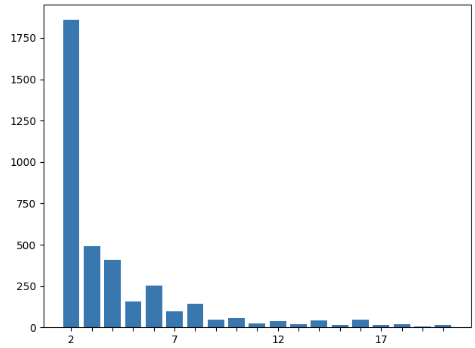

Figure 5: Distribution of Candidate Equation Number.

$$n![z^n]U^{\divideontimes}(z) \sim \frac{c_2\sqrt{r_1}}{n}(\frac{n}{r_2 e})^n \tag{30}$$

$$n![z^n]T^{\pm}(z) \sim \frac{c_3\sqrt{r_2}}{n}(\frac{n}{r_3 e})^n \tag{31}$$

$$n![z^n]T^{\divideontimes}(z) \sim \frac{c_4\sqrt{r_2}}{n}(\frac{n}{r_4 e})^n \tag{32}$$

So we have:

$$u_n = n![z^n]U(z) \sim \frac{(c_1+c_2)\sqrt{r_1}}{n}(\frac{n}{r_1 e})^n \tag{33}$$

$$t_n = n![z^n]T(z) \sim \frac{(c_3+c_4)\sqrt{r_2}}{n}(\frac{n}{r_2 e})^n \tag{34}$$

Since $S(z) = T(z) - U(z)$, the subtraction of u_n and t_n would be our approximation. However we observe that $r_1 \gg r_3$, that u_n can be ignored. So we have:

$$s_n = n![z^n]S(z) \sim \frac{(c_3+c_4)\sqrt{r_2}}{n}(\frac{n}{r_2 e})^n \tag{35}$$

Q.E.D.

B Distribution of Candidate Equations

The largest candidate equation number of one example is 3914. We show the distribution of candidate equations in Figure 4 and 5. The x-axis represents the number of candidates, while the y-axis represents the number of examples that have x candidate equations. We can see from Figure 4, which includes examples that have 1 to 50 candidates, it is a long tail distribution that most examples only have a few candidate equations. From Figure 5, where we zoom in and focus on examples that have 2 to 20 candidates, we can see that there are a lot of examples that have more than 2 candidate equations, and the ranking module is essential.

Algorithm 1 *enum_skel(n)*

```
Require: $n \geq 1$
  Initialize empty list skills
  for $i \leq n;\ i = 1;\ i++$ do
      left_list = unit_skel(i)
      right_list = enum_skels($n - i$)
      for left in left_list do
          for right in right_list do
              move the start index of right to $i$
              new_skels += left + right
          end for
      end for
      skels += new_skels
  end for
  return skels
```

C Experimental Details

We run our experiments on single card GTX3090Ti, each run takes around 2-3 hours for all models. We did not perform extra hyperparameter searching and use the same hyperparameters as the public release of the two models, except for epoch number which is decided by the validation set. The code is conducted based on Pytorch.

D ComSearch Details

Considering elements in $S_n^{\pm}$, we can rewrite the equation to x. Thus we can form a mapping $g : x \to g(x)$ from a general addition equation x to a skeleton structure expression $g(x)$. :

$$\begin{aligned} x =& ((x_i \divideontimes (..)) + (x_j \divideontimes (..)) + ..) \\ & - ((x_k \divideontimes (..)) + (x_l \divideontimes (..)) + ..) \\ g(x) =& (x_i(..))(x_j(..))..\&(x_k(..))(x_l(..)).. \end{aligned}$$

The order of x_i within the same layer of brackets is ignored in $g(x)$, it can deal with the equivalence caused by Commutative law and Associative law. The addition and subtraction terms are split by &, that which can deal with equivalence caused by removing brackets. $g(x)$ is a bijection, so the enumeration problem transforms to finding such skeletons:

$$
\begin{aligned}
n = 1 &: a \\
g^{-1} &: a \\
n = 2 &: ab, a\&b, b\&a \\
g^{-1} &: a + b, a - b, b - a \\
n = 3 &: abc, a\&(b\&c), (ab)\&c, ... \\
g^{-1} &: a + b + c, a - (b/c), (a * b) - c, ... \\
& ...
\end{aligned}
$$

The enumeration problem of these structures is an expansion of solving Schroeder's fourth problem (Schröder, 1870), which calculates the number of labeled series-reduced rooted trees with n leaves. We use a deep-first search algorithm shown in Algorithm 1 to enumerate these skeletons. It considers the position of the first bracket and then recursively finds all possible skeletons of sub-sequences of the variable sequence $\mathcal{X} = \{x_k\}_{k=1}^{i}$ (Wang, 2021).

While considering such skeletons could enumerate all unique expressions, equations have at least one element on the left of $\&$ in our target domain and do not start with $-$ or $\div$. We further extend the algorithm to consider these cases. To be noticed, because there is at least one $+$ or $*$ operator for each equation, the left side of $\&$ must not be empty while the right part has no restrictions. Thus we define the *unit_skel(i)* equation to return possible skeletons with only one or none $\&$ and no brackets. This constraint is equivalent to finding non-empty subsets and their complement of the variable sequence $\mathcal{X}$. We can use Algorithm 1 to perform the enumeration of such skeletons, except for defining two different *unit_skel(i)* to support the enumeration of subtraction and division operation. The enumeration algorithm of non-empty subsets is trivial and omitted here.

$$unit\_skel_{div}(i) = \{(A\&\overline{A}) | A \subseteq \mathcal{X}; A \neq \emptyset\} \tag{36}$$

$$\begin{aligned} &unit\_skel_{sub}(i) = \\ &\quad \{((a(A - a))\&\overline{A - a}) | A \subseteq \mathcal{X}; a \in A\} \end{aligned} \tag{37}$$

We transform the skeletons back to equations to obtain all non-equivalent equations S_n. Such enumeration considers absolute values and omits pairs of solutions that are opposite to each other. To search effectively, for the equations that contain subtraction, we add their opposite equation to the searching space.

Towards preserving word order importance through FORCED INVALIDATION

Hadeel Al-Negheimish[1], **Pranava Madhyastha**[2,1] and **Alessandra Russo**[1]

{halnegheimish,a.russo}@imperial.ac.uk,
pranava.madhyastha@city.ac.uk

Abstract

Large pre-trained language models such as BERT have been widely used as a framework for natural language understanding (NLU) tasks. However, recent findings have revealed that pre-trained language models are insensitive to word order. The performance on NLU tasks remains unchanged even after randomly permuting the word of a sentence, where crucial syntactic information is destroyed. To help preserve the importance of word order, we propose a simple approach called FORCED INVALIDATION (FI): forcing the model to identify permuted sequences as invalid samples. We perform an extensive evaluation of our approach on various English NLU and QA based tasks over BERT-based and attention-based models over word embeddings. Our experiments demonstrate that FI significantly improves the sensitivity of the models to word order.[1]

1 Introduction

Ordering of words in a sentence is an important structural attribute for natural languages such as English, where subject-verb-object (SVO) structure is common and important to convey the meaning of the sentence. Understanding and comprehending natural language without strict adherence to a systematic ordering of words would make it an extremely challenging task. Recent work has investigated a surprising lack of sensitivity to word order information in state-of-the-art masked language models.

Recent research has focused on the impact of word order perturbation during the evaluation of models trained on well-ordered data. The results show that masked language models exhibit a catastrophic lack of sensitivity to word order permutations or shuffles, even for complex tasks in which task-relevant syntactic properties are completely destroyed (Pham et al., 2020; Al-Negheimish et al., 2021; Sinha et al., 2021b; Gupta et al., 2021). These studies show that models are still predicting the gold label for examples even after sequences have been permuted, and they also do so with high confidence (Sinha et al., 2021b; Gupta et al., 2021). This anomalous behaviour can potentially result in undesirable shortcuts or can cause models to fail catastrophically in simple adversarial settings. Furthermore, Sinha et al. (2021a) study the effect of pre-training masked language models on shuffled data, and suggest that the model might simply be capturing higher-order word co-occurrence statistics, rather than uncovering sophisticated semantic and syntactic structures necessary for language understanding.

In this paper, we present a simple, yet general approach called FORCED INVALIDATION (FI), where we force models to explicitly identify sequence permutations (§3). While our proposal is extensible to multiple types of models, here we present a controlled study over masked language model-based BERT models, and attention-based models over word-embeddings (§4). We present a large battery of experiments over a variety of natural language understanding tasks in the English language, including complex question answering based tasks, natural language inference based tasks and commonsense reasoning based tasks. Results show that our proposal significantly improves the sensitivity of the models to word-order information (§5).

2 Related Work

Recent work has proposed a few mitigation strategies for classification-type tasks: Pham et al. (2020) proposes improving word-order sensitivity by including a precursor fine-tuning step on synthetic CoLA-like tasks before finetuning for downstream tasks. While this improves their defined word order sensitivity score, accuracy on permuted samples remains significantly above chance, making this

May 2-6, 2023 ©2023 Association for Computational Linguistics

approach unreliable. Gupta et al. (2021) present three approaches: one based on entropy regularisation, another on model probabilities thresholding, and finally an approach based on augmenting additional data consisting of destructive transformations, which include 1-gram permutations. The model is modified with an additional class to identify these destructive transformations. While the first two approaches require changes to model setup, the last one is based on a set of manual heuristics. Our approach has some similarity with the latter, however, our permutations are based on the principals borrowed from the n-gram language modelling literature (Roark et al., 2007), where the n-grams capture sufficient first-order statistics of the language. Our approach significantly reduces the models' reliance only on simple first-order statistics of language, and our empirical observations demonstrate the generalisability of our approach to various settings.

3 Methodology: FORCED INVALIDATION

Our method is grounded on recent observations which show that masked language models and other similar models tend to exploit shortcuts based on information about distributional word vicinity information for a diverse set of natural language processing tasks (Al-Negheimish et al., 2021; Sinha et al., 2021a). These shortcuts tend to make the models less sensitive to word-order information even for tasks that require the preservation of word ordering for accurate recovery of meaning (Sinha et al., 2021b). Al-Negheimish et al. (2021), in particular, show the insensitivity on a variety of n-gram based permutations of samples, where the authors specifically experiment with $\{1,2,3\}$-gram permutations. Further, $\{1,2,3\}$-gram based permutations capture a variety of word vicinity based patterns and also capture some of the most frequently occurring unigram, bigram and trigram patterns in a variety of benchmark datasets. Based on these salient observations, for each given dataset, the FORCED INVALIDATION (FI) methodology consists of the following two steps:

1. Augmenting training data with $\{1,2,3\}$-gram permutation samples (sampled from trainset) labelled with *invalid* as the additional label.
2. Modifying models to account for the new label and training them in the standard setting with a combination of standard training examples and the augmented *invalid* samples.

We observe that this simple FI approach improves the sensitivity of the model to word order and also improves the robustness of the models across a variety of tasks to first-order shortcuts. In the following sections, we present a rigorous experimental study that showcases the utility of FI.

4 Experimental settings

Data To generate n-gram permutations, we simply subsample from the training dataset, such that the ratio to the valid samples (samples with correct word order and the task-specific label) and invalid samples (samples with permuted n-grams and the *invalid* label) is 1-1. The invalid samples are generated such that they contain a uniform distribution of $\{1,2,3\}$-gram permutations.[2] Furthermore, we split the training set such that we use 90% of the samples for training the models and the remaining 10% is used as a development set. The development set is used to monitor training and perform early-stopping. Evaluations are done on a separate unseen task-specific validation set provided by the dataset creators.

We perform two evaluations: well-ordered and permuted. The first one is the standard evaluation of the model over the original unperturbed task-specific unseen validation set. For our experimental evaluations over permutations, we retain the original label of the same unseen validation set, but we permute the specific components of samples (e.g., premise or the hypothesis, question or the passage, etc.); we expect the models to reject the permuted sample instead of predicting the same ground-truth label. This setup allows us to evaluate the sensitivity of the model to word-order permutations of various degrees over the different components of the data.

Models We predominantly experiment with BERT-based models that either use BERT representations as the contextualised embeddings or classifiers that are directly trained with BERT. We also experiment with an additional simpler model that largely exploits attention over word-embeddings.[3] We will expand on the specific models for each of the tasks in the following section. Results for FI are

---

[2] Input string is divided to n-grams (based on white-space), and permuted, preserving the final punctuation. The only condition is that it varies from the original string, which is a weaker constraint than previous studies that require that no n-gram stays in its original position.

[3] Details about training parameters can be found in the appendix A

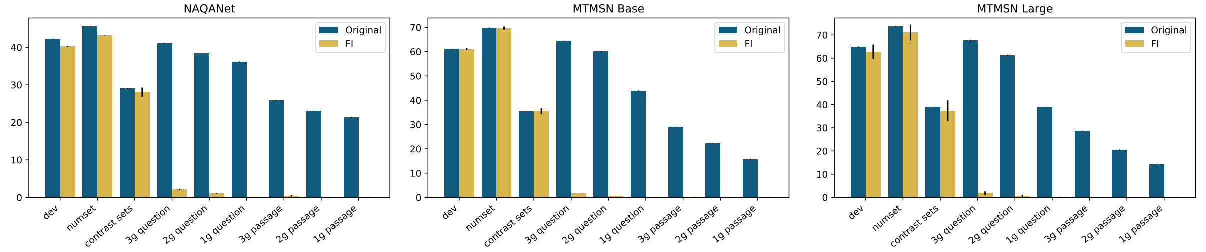

Figure 1: Accuracy using exact match (EM) on the DROP QA dataset, (a) NAQANet, (b) MTMSN Base, and (c) MTMSN Large. dev, numset and contrast sets are unperturbed well-ordered datasets, while the other bars show {1,2,3}-gram permutations on numset. FI models exhibit clear sensitivity to word order, as they no longer predict the original answer in most perturbed cases. FI accuracy is averaged over training with 3-random seeds, and the standard deviation is shown over the yellow bars. FI-models are confident in identifying invalid samples.

reported over the averages and standard deviation of models trained with three random seeds.

5 Results and Observations

5.1 Unconstrained Question Answering

DROP (Dua et al., 2019) is a reading-comprehension dataset with unconstrained answers. It comprises questions that require reasoning over the content of different paragraphs. Even though this is designed to be a challenging task, Al-Negheimish et al. (2021) show that for most models, permuting questions had little impact on the model's ability to predict the correct answer for numerical reasoning questions. This was found specifically problematic as the task consists of complex questions, and permutations render the questions syntactically and semantically redundant. We apply FI for two module-based models designed specifically for this task, NAQANet (Dua et al., 2019), an attention-based model with GloVe-based embeddings (Pennington et al., 2014), which is the original model proposed by the authors of the dataset; and MTMSN (Hu et al., 2019), which is based on BERT-based (Devlin et al., 2019) contextual representations. These models have separate modules targeting different kinds of reasoning, e.g. a module for counting and a module for arithmetic expressions. We augment these with an additional module to force invalidation over invalid permuted samples, a two-way classification module that learns to distinguish between permuting either the question or passage. FI models should now choose the invalid type for permuted samples, instead of giving the same answer as well-ordered samples. Fig 1 shows a comparison of the Exact Match accuracy of NAQANet and MTMSN, between original and FI models. We observe that question permutations have little effect on the original model, as previously noted in (Al-Negheimish et al., 2021). Interestingly, passage permutations can drastically reduce performance by a third. While performance degrades for passage permutations, it remains unacceptably high, as we note that DROP is an unconstrained-QA task, so the space of possible answers is large. FI, on the other hand, succeeds in making the model sensitive to almost all permutations. We see that this generalises across BERT$_{\text{BASE}}$ and BERT$_{\text{LARGE}}$. More importantly, we observe that while the model with FI is sensitive to word order (no longer predicting original answers for permuted examples), the model's performance on well-ordered data is largely retained. To demonstrate that FI are correctly predicting invalid, table 1 shows the percentage of the data predicted as invalid, which is near-perfect for permuted samples.

GA	CoLA	2.30	92.66	92.35	97.93	-	-	-

Table 1: Percentage of evaluation data predicted as invalid in FI models in all of the tasks. dev is the unperturbed validation set. {n}-gram permutations of part 1 correspond to permutations of the question in UQA and of the premise in NLI. CoLA is made up of single sentences. All models succeed at flagging these samples as invalid.

5.2 Grammatical Acceptability

CoLA (Wang et al., 2018) is a task that measures models' ability to determine the grammatical acceptability of sentences. Pham et al. (2020) show that from the GLUE benchmark (Wang et al., 2018),

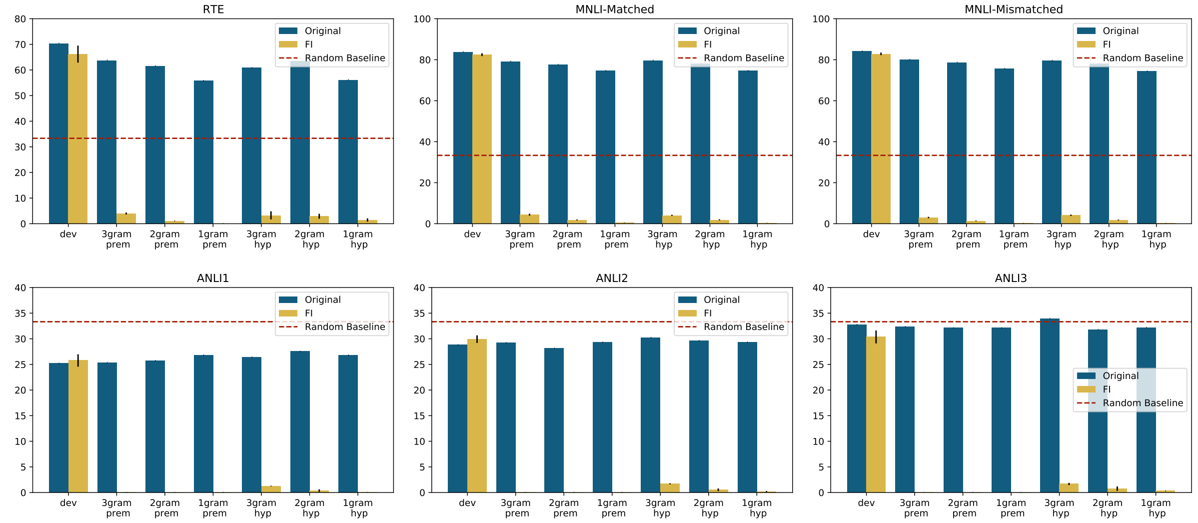

Figure 2: Accuracy for NLI tasks (a) trained on RTE, (b-f) trained on MNLI data. Original models exhibit a lack of sensitivity to word order, as they have the same accuracy regardless of the n-gram permutations. FI models are able to tell apart invalid examples even in out-of-distribution ANLI data.

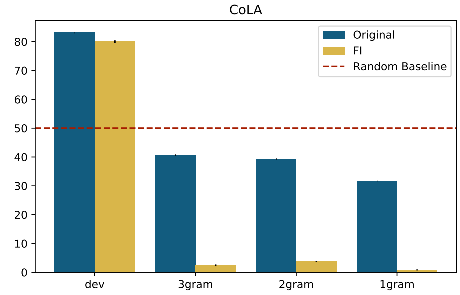

Figure 3: Accuracy of original models and FI on CoLA grammatical acceptability task. While the original model is below chance, we note that because this task is grammar-detection, the original model should not accept any of the permuted samples.

this task requires models to be most sensitive to word order. We applied FI by extending the BERT-based classification model with another '*invalid*' class label, to flag permuted sentences. Grammar and syntax have been destroyed in permuted sentences, we would expect the original model to label them as *not acceptable*. However, we see in Fig 3 that it maintains significantly high accuracy for 3-gram and 2-gram permutations (note that CoLA is an imbalanced dataset (70% acceptable)). Concretely, we observe that the standard BERT-based model labels $185/967$ 3-gram permutations, and $114/967$ 2-gram permutations as *acceptable*. Our FI approach significantly ameliorates this problem by increasing the sensitivity of the model to word-order permutations, as we observe in Fig 3.

5.3 Natural Language Inference (NLI)

NLI has been one of the important testbeds of previous work studying BERT-based models and their lack of sensitivity to word-order information (Sinha et al., 2021b; Abdou et al., 2022). These studies suggest that BERT-based models almost always assign the same labels to examples with perturbed word order as well-ordered ones highlighting the lack of sensitivity to word order, and likely dependence on shallow features. Similarly to §5.2, applying FI to an NLI BERT model was done by simply extending it with another class to represent *invalid* input. We perform a battery of experiments over a variety of NLI tasks in GLUE (Wang et al., 2018) such as RTE and MNLI (Williams et al., 2018) tasks. FI makes models highly sensitive to permuted sequences, as shown in Fig. 2. We verify in table 1 that those invalid sentences were correctly flagged as invalid. We also observe that FI-based models trained on MNLI and tested on out-of-distribution ANLI (Nie et al., 2020) show extreme sensitivity to word-order perturbations; this shows that the model has learned to flag invalid input and generalise to similar unseen tasks. Additionally, we observe that FI makes the models less likely to suffer from shortcut effects, which are common in models trained for NLI tasks (McCoy et al., 2019). Further experiments on Arabic NLI are presented in Appendix D, where we demonstrate that FI works well for other languages beyond English.

Heuristic Analysis

McCoy et al. (2019) introduces an evaluation set *Heuristic Analysis for NLI Systems (HANS)*, that examines surface heuristics NLI models are prone to adopting. They show in the existence

		Lexical Overlap	Subsequence	Constituent
Original	Entailment	97.76	99.92	100.00
	Non-Entailment	14.74	0.58	2.66
FI	Entailment	80.94	99.56	99.60
	Non-Entailment	64.56	38.14	11.48

Table 2: Comparison of BERT finetuned on MNLI with and without FI, FI makes the model more robust to the syntactic heuristics presented in (McCoy et al., 2019)

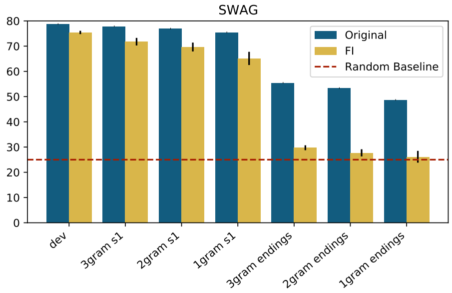

Figure 4: Accuracy of original models and FI on SWAG multiple-choice commonsense reasoning task, both are presented with the same four answer choices, FI enforces sensitivity to word order, especially on the endings.

of these heuristics, models always predict entailment, as they have near-perfect accuracy for that label, but perform poorly when the actual label is non-entailment (accuracy close to 0% in most cases). The heuristics targeted by this dataset are special cases of each other: the most general, *lexical overlap* heuristic: assume that all hypotheses constructed from words in the premise are entailed. Next follows is the *subsequence* heuristic: assume all hypotheses made up of contiguous subsequences of the premise are entailed. Finally, the *constituent* heuristic: assume all hypotheses made up of complete subtrees of the premise's parse tree are entailed. We expect that FI-models will be more robust to these shortcuts, and find (table 2) that this is indeed the case for lexical-overlap and the more challenging subsequence heuristics, substantially improving non-entailment performance, indicating that the models are no longer strictly biased with the presence of these heuristics. We note a surprising result of a drop in accuracy for entailed lexical overlap samples, which could be caused by the model no longer taking that shortcut, and warrants additional investigation in future work.

5.4 Multiple Choice Commonsense Reasoning

SWAG (Zellers et al., 2018) is a commonsense and grounded reasoning task that requires choosing between different possible ending scenarios given some context, where the context comprises of a primary sentence followed by the initial set of words for the following sentence. The model is trained to predict the most likely ending scenario given context and a list of four ending scenarios. To train our FORCED INVALIDATION model, we add an additional answer choice `'is invalid.'` to the data and perform n-gram based permutation of the primary sentence or over each of the endings. Nothing is changed in the architecture of the model. For evaluation, we maintain the same datasets for the Original and FI models, so they only contain the same number of answer choices, without the `'invalid'` choice. Ideally, the models should achieve random performance in the permuted cases. We present our results in Fig. 4; where firstly we observe that FI does not seem to reliably affect the model's sensitivity to word order perturbations with all the combinations. We specifically observe that n-gram permutations of primary sentence have little impact on the performance of FI-models and they seem to be less sensitive to word-order perturbations than expected. However, n-gram permutations of endings result in FI-models obtaining near-random performance as expected. We investigated the cause of this anomaly and observed that SWAG dataset has a prominent problem, in that, the primary sentence for a majority of cases is almost irrelevant to the model. A model trained on SWAG dataset is able to predict the correct answer for 60% of the examples without having access to the primary sentence.

6 Conclusion

In this paper, we presented a simple yet general technique called FORCED INVALIDATION, that significantly improves the sensitivity of models towards word order information. Our methodology requires minimal changes to the model and is sample efficient and drastically increases the sensitivity of the models to permutations of word order for a variety of tasks. We present a focused empirical validation of our methodology to showcase its generalisability. While in this paper we have focused on masked language models and attention-based models over word embeddings, we expect FI to generalise for other modelling setups such as RNN-based and CNN-based models and leave it as future work. We anticipate that this approach will also serve as a solution for other undesired behaviors in the model by explicitly invalidating such behaviours. We leave this as future work.

Limitations

While our empirical results showcase the effectiveness of FI and increase models' sensitivity to word order, the causal mechanisms are not currently obvious. It is not clear whether or not positional encodings are reflecting this change. Like previous work, our observations are additionally only restricted currently to English and Arabic (appendix D), further experiments are required to establish the problems relating to word order sensitivity and the utility of FI for other languages.

A Training Details

We use $\text{BERT}_{\text{BASE}}$ models with a classification head on top (BERTForSequenceClassification (Wolf et al., 2020)) for NLI and CoLA. It was trained for 5 epochs, batch size 16, learning rate 2e-5. We use a $\text{BERT}_{\text{BASE}}$ model (Wolf et al., 2020), for SWAG. It was trained for 3 epochs, batch size 16, learning rate 5e-5. All of the above are done using google colab with high-ram. MTMSN is based on the published codebase (Hu et al., 2019), and we use the same parameters to train, namely: BERT_{base}: batch size 24, 5 epochs and learning rate 3e-5, BERT_{large}: batch size 12, 10 epochs and learning rate 3e-5. Training was done on four RTX6000 GPUs with 24GB of RAM each for $\text{BERT}_{\text{LARGE}}$, and a single one was used for $\text{BERT}_{\text{BASE}}$. Models are trained for both settings, original and FI, to provide a fair comparison.

B Dataset Statistics

As described before, we filter out examples with sentences containing less than three words, such that we can generate at least 1 3-gram shuffle. Table 3 describes the tasks' validation sets before and after filtration.

	Original	Used	p1 #words	p2 #words
DROP numset	6848	6848	11	182
RTE	277	276	31	8

Table 4: Artifact licenses for the datasets used.

C FI as a precursor to downstream task finetuning

Inspired by (Pham et al., 2020), we first perform FI on BERT to solely categorise valid and invalid samples for sentences that are sampled from Wikipedia. We replace the standard BERT-based contextual representations in MTMSN with FI-BERT based contextual embeddings, to see if it helps it become more sensitive to word order in the downstream DROP task. This did not show an improvement,

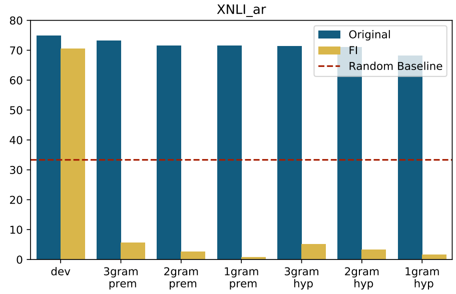

Figure 5: Accuracy of original models and FI on an Arabic NLI task. Once more, we see that the original models are insensitive to word order even in Arabic, while FI models learn to flag invalid samples.

however, where permuted examples are still predicted the same as well-ordered ones. This indicates that having an explicit way to flag invalid examples is helpful to the models.

D FORCED INVALIDATION with Other Languages

To establish the generalizability of this approach to other languages, we applied FIon an Arabic NLI task. We used the Arabic split of the XNLI dataset (Conneau et al., 2018) to finetune the ArBERT model (Abdul-Mageed et al., 2021), and compare the original training setup with FORCED INVALIDATION. Figure 5 shows that this approach successfully preserves the importance of word order beyond the English language.

How Many and Which Training Points Would Need to be Removed to Flip this Prediction?

Abstract

We consider the problem of identifying a *minimal subset* of training data $\mathcal{S}_t$ such that if the instances comprising $\mathcal{S}_t$ had been removed prior to training, the categorization of a given test point x_t would have been different. Identifying such a set may be of interest for a few reasons. First, the cardinality of $\mathcal{S}_t$ provides a measure of robustness (if $|\mathcal{S}_t|$ is small for x_t, we might be less confident in the corresponding prediction), which we show is correlated with but complementary to predicted probabilities. Second, interrogation of $\mathcal{S}_t$ may provide a novel mechanism for *contesting* a particular model prediction: If one can make the case that the points in $\mathcal{S}_t$ are wrongly labeled or irrelevant, this may argue for overturning the associated prediction. Identifying $\mathcal{S}_t$ via brute-force is intractable. We propose comparatively fast approximation methods to find $\mathcal{S}_t$ based on *influence functions*, and find that—for simple convex text classification models—these approaches can often successfully identify relatively small sets of training examples which, if removed, would flip the prediction.[1]

1 Introduction

In this work we pose the following problem in the context of binary classification: *For a test point x_t, identify a minimum subset $\mathcal{S}_t$ of training data that one would need to remove in order to flip the prediction $\hat{y}_t$ for x_t.* This subset may be of interest for a few reasons. First, the cardinality k of $\mathcal{S}_t$ captures one measure of the (in)fragility of the prediction $\hat{y}_t$: Small k indicates that a minor change in the training data would have resulted in a different (discrete) prediction for x_t. We later show that this measure is correlated with, but complementary to, predicted probabilities.

Perhaps a more interesting motivation for recovering $\mathcal{S}_t$ is to provide a potential mechanism for *contesting* model predictions (Hirsch et al., 2017; Vaccaro et al., 2019), i.e., to enable individuals to interrogate and dispute automatic determinations that affect them. If removing a small set of training points would have yielded a different prediction, and if one could make the case for excluding these points (e.g., because they seem mislabeled, or reflect systematic labeling biases), this might provide a compelling case to overturn a model prediction. Consider an educator using an automated essay grading system.[2] Assume the system has output a comparatively poor grade for a student, a determination they see as unfair. Contesting the inclusion of a small set of examples ($\mathcal{S}_t$) which, if excluded, would have resulted in a higher grade provides a novel mechanism for disputation.

Naïvely attempting to find $\mathcal{S}_t$ by brute enumeration and re-training would be hopelessly inefficient. We introduce an algorithm for finding such sets efficiently using *influence functions* (Koh and Liang, 2017) which allow us to approximate changes in predictions expected as a result of removing subsets of training data (Koh et al., 2019). We then provide an iterative variant of this method which does a better job of identifying sets $\mathcal{S}_t$.

Across different datasets and models, we find that we are often able to recover subsets $\mathcal{S}_t$ with relatively small cardinality k; i.e., one can often identify a small to medium subset of training data which, if removed, would flip a given prediction. We also find that there are many test points for which models make predictions with high confidence but where k is small.

The **contributions** here include an investigation of the task of identifying minimal training sets to flip particular predictions in the context of text classification, algorithms for this problem, and an empirical evaluation of their performance in the con-

text of binary text classification.[3]

2 Methods

Assume a binary text classification problem. Given a training set $Z^{\text{tr}} = z_1, ..., z_N$, where $z_i = (x_i, y_i) \in \mathcal{X} \times \mathcal{Y}$, we aim to estimate the parameters θ of a classification model $f_\theta : \mathcal{X} \rightarrow \mathcal{Y}$ to minimize the empirical risk, i.e., loss $\mathcal{L}$ over Z^{tr}: $\hat{\theta} := \text{argmin}_\theta \frac{1}{N} \sum_{i=1}^{N} \mathcal{L}(z_i, \theta) + \frac{\lambda}{2}\theta^T\theta$, which we will denote by $R(\theta)$. We assume throughout that R is twice-differentiable and strongly convex in θ, i.e., $H_{\hat{\theta}} := \nabla^2_\theta R(\hat{\theta}) := \frac{1}{N}\sum_{i=1}^{N} \nabla^2_\theta \mathcal{L}(z_i, \hat{\theta}) + \lambda I$ exists and is positive definite. Suppose we removed a subset of k training points $\mathcal{S} \subset Z^{\text{tr}}$ and re-estimated θ, yielding new parameters $\hat{\theta}_{\mathcal{S}}$. Letting $\varepsilon = -\frac{1}{N}$, we can write this as:

$$\hat{\theta}_S = \text{argmin}_{\theta\in\Theta}\{R(\theta) + \varepsilon \sum_{z_i \in S} \mathcal{L}(z_i, \theta)\} \quad (1)$$

In principle, one could remove the points in $\mathcal{S}$ and re-train to find $\hat{\theta}_{\mathcal{S}}$. In practice this is infeasible given the number of potential subsets $\mathcal{S}$. Koh and Liang (2017) provide (relatively) efficient approximations to estimate $\hat{\theta}_{\mathcal{S}}$ when k=1. Subsequent work (Koh et al., 2019) found that this approximation correlates well with the actual empirical effects of removing a *set* of points (where $k > 1$).

Finding influential subsets Given input x_t, we aim to design an approach to efficiently *identify* the smallest subset $\mathcal{S}_t$ of Z^{tr} such that removing these examples prior to training would change $\hat{y}_t$. Prior work (Cook and Weisberg, 1982; Koh and Liang, 2017) derived the influence exerted by a train point i on the *loss* incurred for a test point t as:

$$-\nabla_\theta \mathcal{L}(z_t, \hat{\theta})^\intercal \underbrace{H_{\hat{\theta}}^{-1} \nabla_\theta \mathcal{L}(z_i, \hat{\theta})}_{\Delta_i\theta} \quad (2)$$

Where $\Delta_i\theta$ is the influence of upweighting z_i during training on estimates $\hat{\theta}$ (Cook and Weisberg, 1982). We are interested, however, in identifying points that have a particularly strong effect on a specific observed *prediction*. We therefore modify Equation 2 to estimate the *influence on prediction* (IP), i.e., the change in predicted probability for x_t observed after removing training instance i. This can be expressed as:

$$\Delta_t f_i := -\nabla_\theta f_{\hat{\theta}}(x_t)^\intercal \Delta_i\theta \quad (3)$$

We then approximate the change in prediction on instance t we would anticipate after removing the training subset $\mathcal{S}_t$ from the training data as the sum of the $\Delta_t f_i$ terms for all points $x_i \in \mathcal{S}_t$.

Algorithm 1 describes a method for constructing $\mathcal{S}_t$. We estimate the change in output expected upon removing each instance from the training dataset and assemble these in $\Delta_t f$. We then greedily consider adding these differences (effectively adding points to $\mathcal{S}_t$) until the resultant output is expected to cross the classification threshold (τ); if we exhaust the training dataset without crossing τ, then we have failed to identify a set $\mathcal{S}_t$.

Algorithm 1: A simple method to find a minimal subset to flip a test prediction

```
Input: $f$: Model; $Z^{\text{tr}}$: Full training set; $\hat{\theta}$:
       Parameters estimated $Z^{\text{tr}}$; $\mathcal{L}$: Loss
       function; $x_t$: A test point; $\tau$:
       Classification threshold (e.g., 0.5)
Output: $\mathcal{S}_t$: minimal train subset
        identified to flip the prediction ($\emptyset$
        if unsuccessful)
$H \leftarrow \nabla^2_\theta \mathcal{L}(Z^{\text{tr}}, \hat{\theta})$
$\Delta\theta \leftarrow H^{-1} \nabla_{\hat{\theta}} \mathcal{L}(Z^{\text{tr}}, \theta')$
$\Delta_t f \leftarrow \nabla_\theta f_{\hat{\theta}}(x_t)^\intercal \Delta\theta$
$\hat{y}_t \leftarrow f(x_t) > \tau$ // Binary prediction
// Sort instances (and estimated
   output differences) in order of
   the current prediction
direction $\leftarrow$ {$\uparrow$ if $\hat{y}_t$ else $\downarrow$}
indices $\leftarrow$ argsort($\Delta_t f$, direction)
$\Delta_t f \leftarrow$ sort($\Delta_t f$, direction)
for $k = 1 ... |Z^{tr}|$ do
    $\hat{y}'_t = (f(x_t) + \text{sum}(\Delta_t f[:k])) > \tau$
    if $\hat{y}'_t \neq \hat{y}_t$ then
        return $Z^{\text{tr}}$[indices[: $k$]]
return $\emptyset$
```

Algorithm 1 is simple and relatively fast, but we can improve upon it by *iteratively* identifying smaller subsets $\mathcal{S}_t$ in Algorithm 2. We detail this approach in Appendix Algorithm 2, but describe it briefly as follows.

We start with the entire train set as a "candidate" $\tilde{\mathcal{S}}_t$, and then iteratively attempt to find strict subsets

---

[3] Recent related work in economics by Broderick et al. (2020) proposed and investigated a similar problem, with a focus on identifying the sensitivity of econometric analyses to removal of small subsets of data. Recent work on *datamodeling* (Ilyas et al., 2022) also considered a variant of this problem (see Section 5).

of this that by themselves would flip the prediction $\hat{y}_t$. On the first pass, this is equivalent to Algorithm 1, after which—if successful—we will have found a candidate set $\tilde{\mathcal{S}}_t$. Here we update parameter estimates θ to approximate "removing" the points in $\tilde{\mathcal{S}}_t$, and then we recompute the approximation of the influence that points in $\tilde{\mathcal{S}}_t$ would have on $\hat{y}_t$ using a single-step Newton approximation. The idea is that after the parameter update this approximation will be more accurate, potentially allowing us to find a smaller $\mathcal{S}_t$. This process continues until we are unable to find a new (smaller) subset.

In sum, this variant of the algorithm attempts to iteratively identify increasingly small subsets $\tilde{\mathcal{S}}_t$ which would, upon removal prior to training, overturn the original prediction $\hat{y}_t$. There is a computational cost to this, because each iteration involves approximating the influence on a particular prediction; this is computationally expensive. This variant therefore trades run-time for (hopefully) more accurate identification of minimal $\mathcal{S}_t$. However, we find that empirically Algorithm 2 ends up running for only 2.3 passes on average (across all experiments). That is, the algorithm adds a scalar to the run-time of Algorithm 1, but often yields considerably smaller $\mathcal{S}_t$. We show the comparison of $|\mathcal{S}_t|$ returned by two algorithms in the Table 1.

3 Experimental Setup

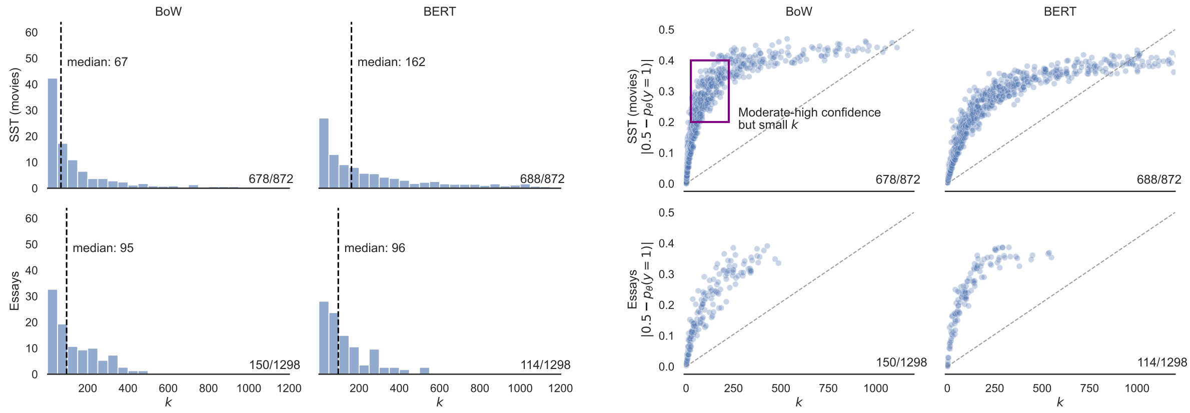
Datasets We use five binary text classification tasks: Movie review sentiment (Socher et al., 2013); Twitter sentiment classification (Go et al., 2009); Essay grading (Foundation, 2010); Emotion classification (Saravia et al., 2018), and; Hate speech detection (de Gibert et al., 2018). We binarize the essay data by labeling the top 10% score points as 1 ("A"s) and others as 0. For the emotion dataset, we include only "joy" and "sadness". We provide dataset statistics in Appendix Table A1. Because the hate speech data is severely imbalanced, we selected a classification threshold τ post-hoc in this case to maximize train set F1 (yielding $\tau = 0.25$); for other datasets we used $\tau = 0.5$, which corresponded to reasonable F1 scores—for reference we report prediction performance on all datasets in Appendix Table A2.

Models We consider only $\ell 2$ regularized logistic regression (for which influence approximation is well-behaved). As features, we consider both bag-of-words and neural embeddings (induced via BERT; Devlin et al. 2018).

4 Results

Here we present results for the iterative method (Appendix Algorithm 2), which outperforms the simpler Algorithm 1. We provide full results for both methods in the in the Appendix.

How often can we find $\mathcal{S}_t$ and how frequently does removing the instances it contains flip the prediction? As can be seen in Table 2, this varies considerably across datasets. For movie reviews, Algorithm 2 returns a set $\mathcal{S}_t$ for ~80% of test points, whereas for the (more complex) essays data it does so for only ~10% of instances. Other datasets see success somewhere in-between these extremes. However, when the algorithm does return a set $\mathcal{S}_t$, removing this and re-training almost



(a) Histograms of $k = |\mathcal{S}_t|$ values over the subsets of test points x_t for which we were able to successfully identify a set of points $\mathcal{S}_t$ such that removing them would flip the prediction for $\hat{y}_t$. We report the fraction for which we were able to do so in the lower sub-plot right corners.

(b) Relationship between predicted probabilities and $k = |\mathcal{S}_t|$ identified. These are correlated (as we would expect), but there are many points for which the model is moderately or highly confident, but where removing a relatively small set of training data would change the prediction.

Figure 1: Results characterizing $\mathcal{S}_t$ on two illustrative datasets (sentiment classification and essay scoring).

always flips the prediction $\hat{y}_t$ (right-most column).

What is the distribution of $k = |\mathcal{S}_t|$? Figure 1a shows empirical distributions of k values for subsets $\mathcal{S}_t$ identified by Algorithm 2 for the illustrative movie review and essay grading datasets (full results in Appendix). The take-away here is that when we do find $\mathcal{S}_t$, its cardinality is often quite small. Indeed, for many test points removing tens of examples would have flipped the prediction.

How does k relate to predicted probability? Does the size of $\mathcal{S}_t$ tell us anything beyond what we might infer from the predicted probability $p(y_t = 1)$? In Figure 1b we show (again for just two datasets here) a scatter of $k = |\mathcal{S}_t|$ against the distance of the predicted probability from 0.5. The former provides complementary information, in that there exist instances about which the model is confident, but where removing a small set of training instances would overturn the prediction.

Qualitative example. One reason to recover sets $\mathcal{S}_t$ is to support *contestation*—if k is small, one might argue against the appropriateness of the points in $\mathcal{S}_t$ and hence against the determination y_t. As a simple example,[4] consider the movie review test instance "*Manages to transcend the sex drugs and show tunes plot into something far richer*". The true label is positive, but the model predicted negative. Algorithm 2 reveals that removing a single example ($k = 1$) from the training set would have reversed the prediction—specifically, this negative review: "*An overstylized pureed melange of sex psychology drugs and philosophy*". It seems this training point is only superficially similar to the test point, which may make a case for overturning the prediction. While standard influence functions (Koh and Liang, 2017) can be used to *rank* training points, the novelty here is observing that *removing this point alone* would change the prediction.

5 Related Work

Influence functions (Hampel, 1974; Cook and Weisberg, 1980, 1982) provide machinery to identify training points that most informed a particular test prediction. Influence can provide insight into predictions made by modern neural networks (Koh and Liang, 2017), and can be used to *debug* models and training data by surfacing mislabeled training points and/or reliance on artifacts (Adebayo et al., 2020; Han et al., 2020; Pezeshkpour et al., 2022; Teso et al., 2021), and tuning influence can be used to demote reliance on unwanted correlations (Han and Tsvetkov, 2021). Influence can also be used to *audit* models by inspecting training data responsible for predictions Marx et al. (2019).

Schulam and Saria (2019) audit individual predictions by approximating how much they might have changed under different samples from the training distribution. Ting and Brochu (2018) consider influence functions as a tool for optimally subsampling data in service of computational effi-

---

[4] We provide more qualitative analysis in the Appendix.

ciency. Koh et al. (2019) considered approximating the effect of removing a *group* of training points using influence functions, and found that they do so fairly well (a result that we use). They assumed groups were *given* and then evaluated the accuracy of the influence approximation to the change in prediction. By contrast, we are interested in *finding* a (minimal) group which would have the specific effect of flipping a prediction. Elsewhere, Khanna et al. (2019) ask: "Which training examples are most responsible for a given *set* of predictions?".

Broderick et al. (2020) assess the robustness of economic analyses when a fraction of data is removed. They therefore focus on the magnitude/significance of parameter estimates. This framing differs from our ML-centric motivation, which aims to recover specific small subsets of data that, if removed, would change a particular prediction (and so might support contestability).

Robustness of data analyses to dropping training data In the process of review it was brought to our attention that Broderick et al. (2020) addressed a closely related problem to what we have considered here, albeit from a quite different motivating perspective—namely assessing the sensitivity of econometric analyses to removals of small subsets of data. It turns out that the algorithm that was (independently) proposed by Broderick et al. (2020) in that work is similar to Algorithm 1. The present effort is novel in our focus on machine learning, and specifically on identifying minimal subsets of training data which would flip a particular prediction if removed prior to training.

Minimal feature set removal Another related line of work concerns a natural complement to the problem we have considered: Instead of identifying a minimal set of *instances* to remove in order to change a prediction, the idea is to find a minimal subset of *features* such that, if these were set to uninformative values, a particular prediction would change (Harzli et al., 2022). Work on *counterfactual examples* has similarly sought to identify minimal (feature) edits to instances that would change the associated label (Kaushik et al., 2019).

Datamodeling Recent work on *datamodeling* (Ilyas et al., 2022) provided a generalized framework for analyzing model behavior as a function training data. This approach entails *learning to estimate* (via a parameterized model) changes we would anticipate observing for a particular instance if the model had been trained on some subset of the original training set. This approach is flexible, and one thing it permits is identifying the *data support* of a particular prediction for x_t, i.e., what we have called $\mathcal{S}_t$ (4.1.1 in Ilyas et al. 2022). Furthermore, this method is not restricted to the simple regularized linear models we have considered here. However, this comes with the downside of high computation costs: One needs to re-train the algorithm being modeled many times with different training data subsets to yield a "training set" to be used to estimate model behavior under conterfactual training sets. The main comparative advantage of our more focused approach is therefore relative computational efficiency.

Contestability (Vaccaro et al., 2019; Almada, 2019) in ML is the idea that individuals affected by a prediction ought to be able to challenge this determination, which may require parties to "marshal evidence and create counter narratives that argue precisely why they disagree with a conclusion drawn by an AI system" (Hirsch et al., 2017). The right to contestability is in some cases enshrined into law (Almada, 2019). Identifying $\mathcal{S}_t$ for review by an individual affected by the prediction $\hat{y}_t$ may constitute a concrete mechanism for contestation.

6 Conclusions

In the context of binary text classification, we investigated the problem of identifying a minimal set of training points $\mathcal{S}_t$ such that, if excluded from training, the prediction for test instance x_t would flip. We proposed two relatively efficient algorithms for this—both using approximate group influence (Koh and Liang, 2017; Koh et al., 2019)—and showed that for regularized linear models they can often find relatively small $\mathcal{S}_t$. We provided empirical evidence that this captures uncertainty in a way that is somewhat complementary to predicted probabilities, and may serve as a mechanism to support *contestability*, by allowing individuals to review (and dispute) instances in $\mathcal{S}_t$.

Limitations

A key limitation of this work is that we have restricted analysis to regularized linear models with convex loss. We leave extension and evaluation of the proposed methods for more complex models to future work. Indeed, our hope is that this initial effort inspires further work on the problem of identifying minimal train sets which would overturn a specific prediction if removed.

More conceptually, the implications of finding a small subset $\mathcal{S}_t$ are not entirely clear. Intuitively, small sets would seem to indicate fragility, but we have not formalized or evaluated this further. Moreover, there may in certain cases exist *multiple* (distinct) subsets $\mathcal{S}_t$, such that removing any of these subsets would flip the prediction for x_t. This would complicate the process of contestation envisioned. Furthermore, assuming a stochastic parameter estimation method (e.g., SGD) the composition of $\mathcal{S}_t$ may depend on the arbitrary random seed, similarly complicating the interpretation of such sets.

Acknowledgements

We thank our anonymous EACL reviewers for helpful feedback, especially with respect to relevant related work. We also thank Gautam Kamath for highlighting connections to the *datamodeling* work (Ilyas et al., 2022). This work was supported in part by the Army Research Office (W911NF1810328), and in part by the Overseas Research Fellowship under the University of Hong Kong.

Ethics Statement

Models are increasingly used to make (or aid) decisions that directly affect individuals. In addition to the broader (potential) "interpretability" afforded by recovering small sets of training data that would change a prediction if removed, this may provide a new mechanism for individuals to contest such automated decisions, specifically by disputing this set of training data in some way. However, our proposed method only finds training points that highly impact the model prediction for a given example; these may or may not be noisy or problematic instances. Human judgement is required to assess the accuracy and relevancy of the instances in $\mathcal{S}_t$.

A broader view might be that classification models are simply not appropriate for the kinds of sensitive applications we have used as motivation here. The use of (semi-)automated methods for essay grading, e.g., has long been debated (Hearst, 2000). One might argue that rather than trying to provide mechanisms to contest ML predictions, a better choice may be not to use models in cases where these would be necessary at all. We are sympathetic to this view, but view the "appropriateness" of ML for a given problem as a spectrum; contestability may be useful even in "lower stakes" cases. Moreover, the general problem we have introduced of identifying small training sets which can by themselves swing predictions, and the corresponding methods we have proposed for recovering these, may be of intrinsic interest beyond contestability (e.g., as an additional sort of model uncertainty).

A Appendix

A.1 Dataset Statistics and Predictive Performance

We present basic statistics describing our text classification datasets in Table A1. For the tweet sentiment dataset, we randomly sampled 19000 points from the 1600000 points to make experiments feasible. For reference, we also report the predictive performance realized by the models considered on the test sets of these corpora in Table A2.

A.2 Full results

Table A3 reports the percentages of instances for which Algorithm 1 identifies a subset $\mathcal{S}_t$ (center column), and for which this set actually flipped the prediction following removal (right column). Contrast this with Table 2, which reports the same for the proposed iterative approach in Algorithm 2.

We provide histograms of $k = |\mathcal{S}_t|$ for the sets we were able to identify via Algorithm 1 in Figure A.2, and the same plots for Algorithm 2 in Figure A.4.

Finally, we plot the relationship between k and predicted probabilities under Algorithms 1 and 2 in Figures A.3 and A.5, respectively.

Features	Found $\mathcal{S}_t$	Flip successful

BERT	90%	73%

Table A3: Percentages of test examples for which Algorithm 1 successfully identified a set $\mathcal{S}_t$ (center) and for which upon removing these instances and retraining the prediction indeed flipped (right).

A.3 Additional qualitative analysis

We conclude with a brief qualitative analysis of examples in $\mathcal{S}_t$ retrieved in the case of the essays data. The model operating over BERT representations classified this test point (x_t) as 0, i.e., not an "A": "*The cyclist in this essay was a very brave man* ...". The example is about a paragraph in length total, but details adventures of a cyclist. In this case it happens that the reference label is, in fact, an "A", so the model is incorrect. Algorithm 2 reveals that removing a single training point and retraining would have overturned this prediction, yielding an "A". The point in question is labeled 0 (so below an "A") and is about the mood of a memoir, in particular arguing that the person central to this was happy. The student-author of the cyclist essay might reasonably argue that this example is not at all relevant to their essay, and the fact that excluding this single example would have meant their essay received an "A" may be an adequate case for changing their grade accordingly.

A.4 Time complexity

We recorded wall clock times required to search for $|\mathcal{S}_t|$ on all test points in each dataset using Algorithm 1 and Algorithm 2 on Intel(R) Core(TM) i9-9920X CPUs; we report these times in Table A4. For Algorithm 1, the longest running time is required for the essay dataset because most test predictions cannot be flipped even after iterating over all training points. Algorithm 2 is considerably slower than Algorithm 1. The main reason lies in recording the set of training points not in $\mathcal{S}_t$ (line 20 in Algorithm 2) and re-calculating the IP value in each iteration to reduce the minimal candidate set. This additional time is traded off against the ability to (typically) find smaller $\mathcal{S}_t$ compared with 1. Overall, the running time required to find $|\mathcal{S}_t|$ for one test point is relatively minimal for both algorithms.

A.5 Attribution methods

We consider different methods (i.e., other than influence functions) to rank training instances including gradient similarities in terms of the loss, similarity-based methods and randomly sampling training points. Of these we found that the proposed method works best in terms of finding instances which exert maximal influence on the prediction.

One natural way to quantify the impact of a training point x_i on a training point x_t by similarity methods. If the model has training points similar to the test point, it may classify the test correctly with high probability. We consider three of similarity-based methods: **EUC** $= -||x_t - x_i||^2$, **DOT** $= \langle x_i, x_t \rangle$, and **COS** $= cos(x_i, x_t)$.

Apart from influence function and IP, we consider gradient-based instance attribution methods:

1) $RIF = cos(H^{-\frac{1}{2}} \nabla_\theta \mathcal{L}(x_t), H^{-\frac{1}{2}} \nabla_\theta L(x_i))$

2) $GD = \langle \nabla_{\mathcal{L}} L(x_t), \nabla_\theta L\mathcal{L} \rangle$

3) $GC = cos(\nabla_\theta \mathcal{L}(x_t), \nabla_\theta \mathcal{L}(x_i))$

RIF was proposed to mitigate the issues of outliers and mislabeled points being returned by the standard influence functions (Barshan et al., 2020). GC and GD measure the similarity between two instances can also become an effective way to interpret the model from the instance perspective (Charpiat et al., 2019). Apart from the methods above, we randomly sample training subsets and remove them accordingly.

We apply the above methods to the movie review dataset trained with a logistic regression model. We evaluate each attribution method as follows: First, we remove the top $k = |\mathcal{S}_t|$ training points from the training dataset according to the score calculated from the attribution method. Then we train a new with the same dataset except for the removed points. Finally, we compare the difference in predictions for each test point from the old model to the new model. To show the impact of attribution methods under different $k = |\mathcal{S}_t|$, we iterated with $k = |\mathcal{S}_t|$ from 50 to 3000. The mean absolute difference is plotted along with $k = |\mathcal{S}_t|$ shown in Figure A.1. IP has a larger impact on the predicted probability, compared to removing training points ranked according to other methods.

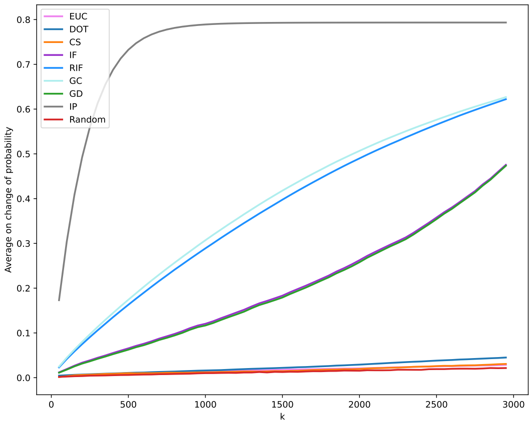

Figure A.1: The relationship between the mean of absolute difference on predicted probabilities for all test points results from removing $|\mathcal{S}_t|$ training points, using different methods.

Algorithm 2: An *iterative* approach to finding a minimal set to flip a prediction

```
Input: $f$: Model; $Z^{\text{tr}}$: Full training set; $\hat{\theta}$: Parameters estimated $Z^{\text{tr}}$; $\mathcal{L}$: Loss function; $x_t$: A test point; $\tau$:
        Classification threshold (e.g., 0.5)
Output: $\mathcal{S}_t$: minimal train subset identified to flip prediction for $x_t$ ($\emptyset$ if unsuccessful)
$\theta' \leftarrow \hat{\theta}$
$Z^{\text{tr}}_{\text{r}}, \tilde{\mathcal{S}}_t \leftarrow Z^{\text{tr}}, Z^{\text{tr}}$ // Track remaining points and candidate subset $\tilde{\mathcal{S}}_t$
$H \leftarrow \nabla^2_{\theta}\mathcal{L}(Z^{\text{tr}}, \theta')$
$\Delta\theta \leftarrow H^{-1}\nabla_{\theta}\mathcal{L}(Z^{\text{tr}}, \theta')$
$\Delta_t f \leftarrow \nabla_{\theta} f_{\hat{\theta}}(x_t)^{\intercal}\Delta\theta$
$\hat{y}_t \leftarrow f(x_t) > \tau$
$\Delta_t f_{\text{sum}} \leftarrow 0$
$k' \leftarrow |Z^{\text{tr}}|$
while $\tilde{S}$ changed since last iteration do
    // Sort instances (and estimated output differences) in order of the current prediction
    direction $\leftarrow \{\uparrow$ if $\hat{y}_t$ else $\downarrow\}$
    indices $\leftarrow$ argsort($\Delta_t f$, direction)
    $\Delta_t f \leftarrow$ sort($\Delta_t f$, direction)
    for $k = 1 \ldots |\tilde{\mathcal{S}}_t|$ do
        $\hat{y}'_t \leftarrow (f(x_t) + \text{sum}(\Delta_t f[:k])) > \tau$
        if $\hat{y}'_t \neq \hat{y}_t$ then
            $\Delta_t f_{\text{sum}} \leftarrow \text{sum}(\Delta_t f[:k])$
            diff $\leftarrow k' - k$
            $k' \leftarrow k$
            $\tilde{\mathcal{S}}_t \leftarrow \tilde{\mathcal{S}}_t$[indices$[:k]$]                // Update candidate subset
            $Z^{\text{tr}}_{\text{r}} \leftarrow Z^{\text{tr}}/\tilde{\mathcal{S}}_t$          // And the set of training points not in $\tilde{\mathcal{S}}_t$
            $\theta' \leftarrow \theta + \Delta\theta$[indices$[:k]$]
            // Update Hessian and $\nabla$ of loss using updated $\theta$ estimate
            $H \leftarrow \nabla^2_{\theta}\mathcal{L}(Z^{\text{tr}}_{\text{r}}, \theta')$
            $\Delta\theta \leftarrow H^{-1}\nabla_{\theta}\mathcal{L}(\tilde{\mathcal{S}}_t, \theta')$
            $\Delta_t f \leftarrow \nabla_{\theta} f_{\hat{\theta}}(x_t)^{\intercal}\Delta\theta$
            break
if $|\tilde{\mathcal{S}}_t| = |Z^{tr}|$ then
    return $\emptyset$
return $\tilde{S}_t$
```

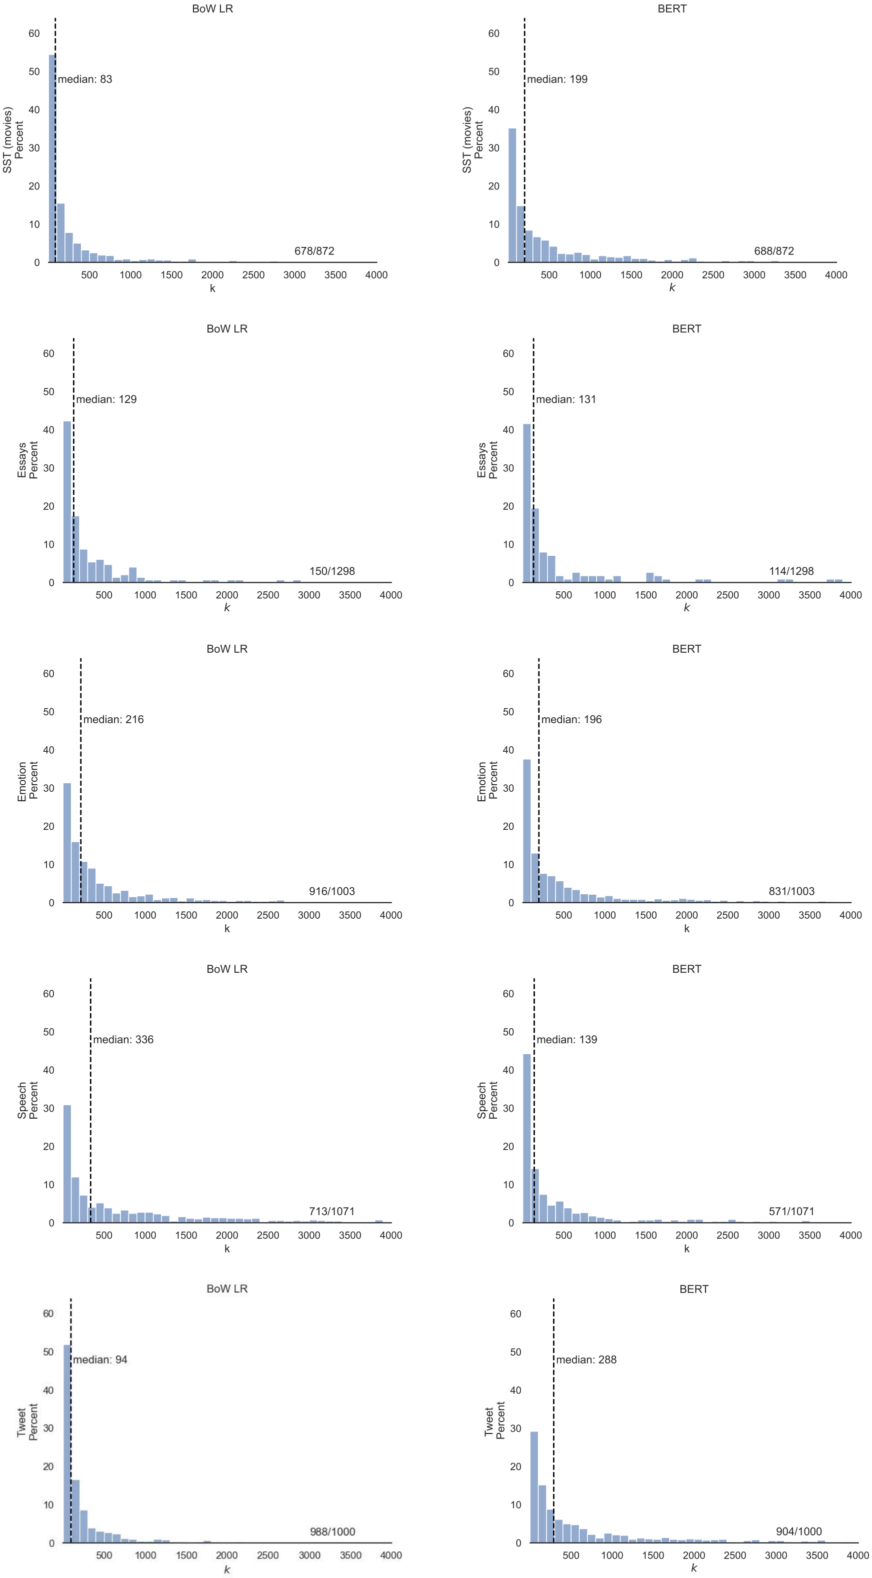

Figure A.2: Histograms of $k = |\mathcal{S}_t|$ values from Algorithm 1 over the subsets of test points x_t for which we were able to successfully identify a set of points $\mathcal{S}_t$ such that removing them would flip the prediction for $\hat{y}_t$.

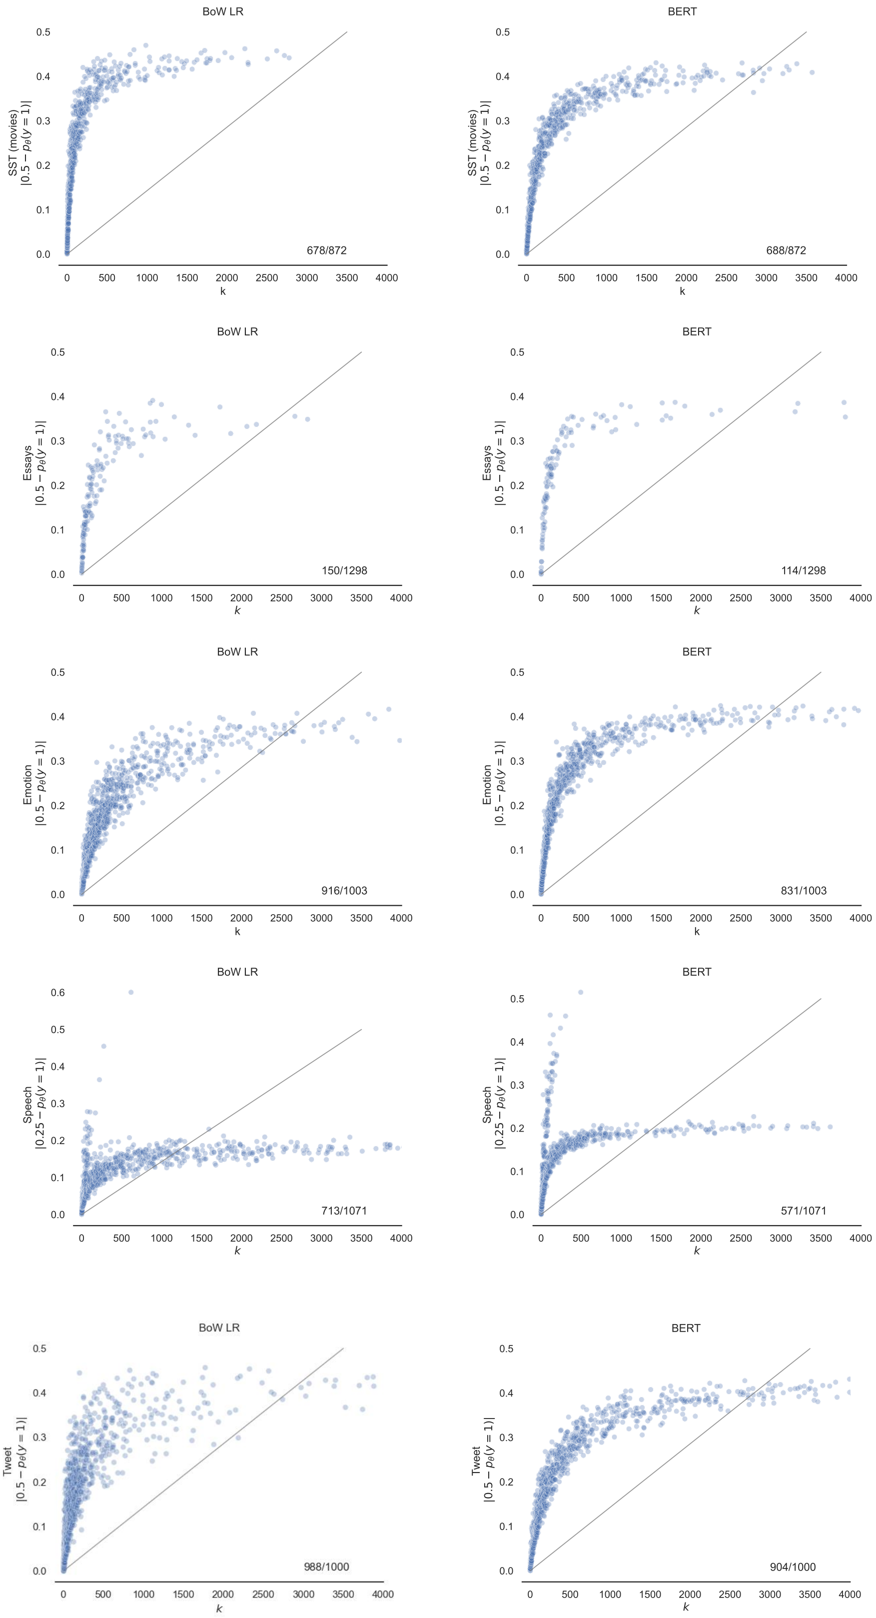

Figure A.3: Relationship between predicted probabilities and $k = |\mathcal{S}_t|$ identified from Algorithm 1.

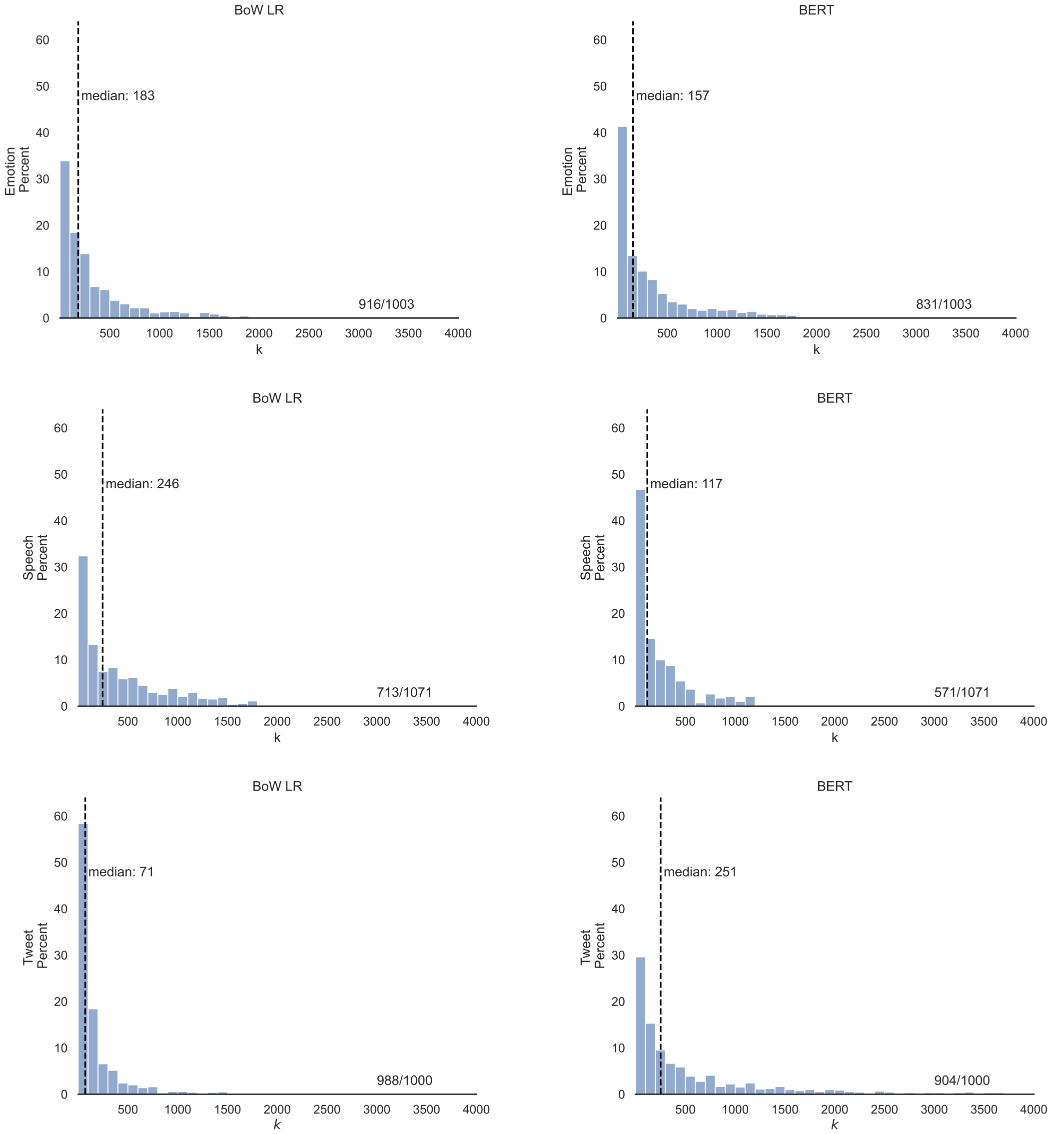

Figure A.4: Histograms of $k = |\mathcal{S}_t|$ values from Algorithm 2 over the subsets of test points x_t for which we were able to successfully identify a set of points $\mathcal{S}_t$ such that removing them would flip the prediction for $\hat{y}_t$.

Abstract

Subjective bias is ubiquitous on news sites, social media, and knowledge resources like Wikipedia. Many existing methods for subjective bias correction have typically focused on making one-word edits and have been trained over a single (often, noisy) domain. In contrast, we propose a novel reinforced sequence training approach for robust subjective bias correction. Three of the unique characteristics of the approach are: (i) it balances bias neutralization with fluency and semantics preservation through reinforcement learning, to broaden the scope to bias beyond a single word; (ii) it is cross-trained over multiple sources of bias to be more robust to new styles of biased writing that are not seen in the training data for a single domain; and (iii) it is used to fine-tune a large pre-trained transformer model to yield state-of-the-art performance in bias text correction task. Extensive experiments show that the proposed approach results in significant improvements in subjective bias correction versus alternatives.

1 Introduction

Objective writing is essential for many important communication venues like news, encyclopedias, scientific publications, and more. And yet, bias is seemingly ubiquitous whether due to malice or unintentional habits of the writer. This subjective writing not only expresses the writer's preferences and personal interpretations, but also can influence the reader's viewpoints on the topic (Greenstein and Zhu, 2014; Beukeboom and Burgers, 2017). Hence, much like modern spelling and grammar checkers, there is a need for effective methods to detect and neutralize biased language.

The goal of this *subjective bias correction* is to rewrite a source sentence s into a neutral sentence t that is clear, objective, and stereotype-free. Furthermore, the rewritten sentence t should preserve the original meaning of the source text s. Enabling such *subjective bias correction* is difficult. Many examples of bias are challenging to detect due to their subtle nature, or through sentence framing (rather than through subjective words), or through convoluted writing intend to obscure the truth.

Examples of Biased and Neutral Statements
Acetaminophen is sold over the counter as a pain medication.
Acetaminophen is the **most dangerous** over-the-counter pain medication.
A 2013 episode of This American Life presented a number of studies that verified that acetaminophen has killed more people than any other over-the-counter pain medication.
In the This American Life episode on acetaminophen, one segment described the **tragic** death of a five-month-old baby and thus **should** convince listeners that the Federal Drug Administration (FDA) must take immediate action.

Table 1: Examples of multi-word and multi-occurrence biased statements (2 and 4), and corresponding neutral statements (1 and 3). The words "most dangerous" in the second statement and the words "tragic" and "should" in the fourth statement express the author's opinion or belief. The third statement is neutral since it describes the subjective view expressed on a radio show. (NROC, 2022)

Encouragingly, previous research has begun to make progress in identifying prejudiced or emotive language used in factual statements (Recasens et al., 2013; Bhosale et al., 2013; Misra and Basak, 2016; Hube and Fetahu, 2018; Zhong et al., 2021; Madanagopal and Caverlee, 2022) and a few studies have begun to investigate subjective bias correction (Pryzant et al., 2019; Liu et al., 2021; Zhong et al., 2021). These approaches, however, typically face a number of key challenges:

Noisy and Limited Training Data. Many approaches rely on Seq2Seq models (encoder-decoder architecture) using a Wikipedia-derived Neutrality Corpus (WNC) (Recasens et al., 2013) based on edits to Wikipedia that have been flagged with a special "neutral point of view" tag. However, we find that over 5% of revisions in the WNC (e.g., as in (Pryzant et al., 2019)) are not related

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2585–2598
May 2-6, 2023 ©2023 Association for Computational Linguistics

to bias mitigation, but rather content corrections, grammatical corrections, or typographical corrections. And more than 15% of the human-corrected neutral sentences with multi-occurrence bias still contain subjective bias. Training a bias correction approach with such noisy data can lead to models that focus on single word and single occurrence bias (missing examples like in Table 1), and result in inconsistent performance.

Training-Testing Mismatch. Second, existing approaches are primarily trained on maximizing the likelihood of each token of the target sequence (Pryzant et al., 2019; Zhong et al., 2021) by relying on the input sequence and previous ground-truth token, but testing is done on the entire input and output sequence. The training is conducted using token-level objective functions and tested using sentence-level evaluation metrics, such as BLEU. Further, although fluency and content preservation are used for evaluation, such objectives are not contained in training objectives. This training-testing criteria mismatch can lead to poor performance at inference time.

Lack of Robustness. Third, models trained on one domain tend to perform poorly on other domains, limiting their adoption. Recent studies have shown further fine-tuning of pre-trained models can improve domain generalization (Sun et al., 2020; Wang et al., 2020), but such methods generally need large volumes of training data from the target domain. Is it possible to generalize subjective bias correction models trained in one domain to multiple new domains even in the absence of rich training data?

To address these challenges, we propose a novel *reinforced sequence training* approach toward improving subjective bias correction. The overall approach first pre-trains a bias correction model using noisy training data (much like in previous approaches) but then fine-tunes the pre-trained model through reinforcement learning with a carefully designed cross-domain bias critic. This cross-domain bias critic aligns training and testing time objectives by giving equal importance to the quality of text generation and semantic content preservation through self-supervised reward-driven learning. That is, it balances bias neutralization with fluency and semantics preservation through reinforcement learning, to broaden the scope to bias beyond a single word or single occurrence within a sentence. Further, the proposed approach is cross-trained over multiple sources of subjective bias to be more robust to new styles of biased writing that are not seen in the training data for a single domain. And instead of using word-level cross-entropy loss during training, we directly optimize sentence-level task-based metrics through the policy gradient to gain significant improvement in performance.

In summary:

- We propose a reinforcement learning framework for improving subjective bias correction.
- We improve the generalizability of the model across multiple domains by adopting a cross-domain bias classifier-based reward, without the need for parallel data for domain adaptation.
- We align training and testing time objectives by using a novel reward-driven learning framework that goes beyond the traditional BLEU rewards, and guides the model to generate diverse bias-free sentences which are fluent and grammatically correct.
- We empirically demonstrate how the proposed reinforcement learning-based approach can fine-tune existing large pre-trained models like BART to perform efficient bias correction while preserving content semantics.

Through extensive experiments, we show that the proposed approach results in significant improvements in subjective bias correction versus alternatives. Furthermore, evaluations on semantic similarity and fluency benchmarks show that this bias correction approach effectively removes subjective bias while maintaining semantic information in neutralized text.

2 Related Work

Detecting Language Bias. Many studies have focused on extracting bias lexicons or opinion words (Riloff and Wiebe, 2003; Liu et al., 2005; Wiebe et al., 2005; Appling, 2017). (Recasens et al., 2013) reduced the lexical ambiguity in detecting biased statements by using a combination of language models and bias lexicons. (Misra and Basak, 2016; Hube and Fetahu, 2018) developed deep learning models to detect bias in political speeches and Wikipedia. (Madanagopal and Caverlee, 2022) combined a cross-domain dataset and a contextualized language model to train a deep model for detecting biased language.

Linguistic Bias Correction. The majority of research to address bias correction in text has focused

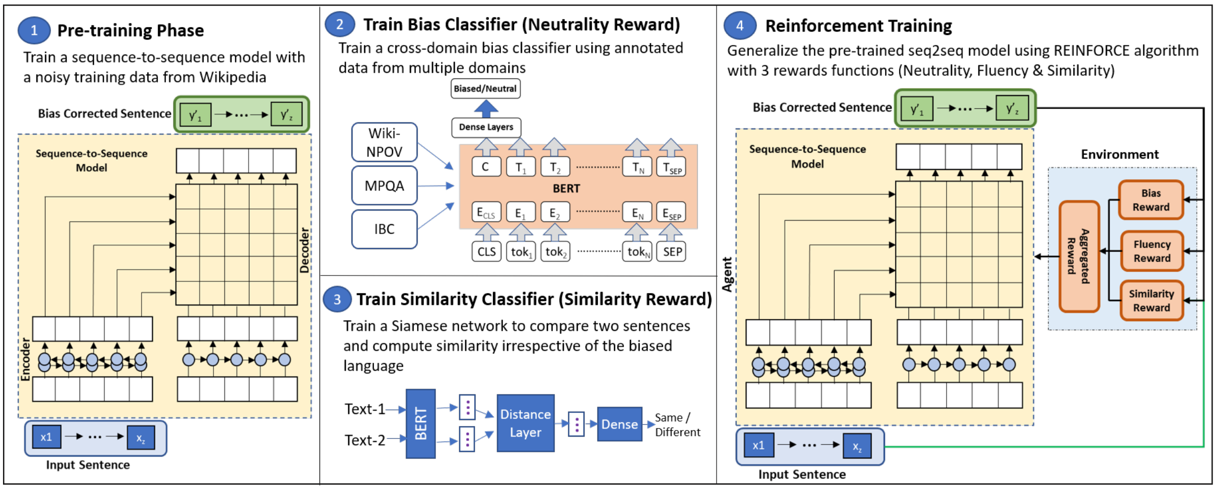

Figure 1: Illustration of the proposed Reinforced Sequence Training Approach for subjective bias correction. Task 1 is pre-training the agent (bias-correction-model) with noisy WNC data, Task 2&3 are building classifiers that will be used to compute rewards, and Task 4 is reinforced sequence training with 3 reward functions.

on demographic bias like gender bias (Manzini et al., 2019; Zhao et al., 2017, 2019; Bordia and Bowman, 2019; Wang et al., 2018). (Pryzant et al., 2019) were the first to address generic linguistic bias correction and later (Liu et al., 2021) worked on depolarizing political text. In both approaches, text segments (words or sentences) that are subjective or polarizing are first identified and then replaced with those that are semantically similar but less subjective. (Liu et al., 2021) studied generative adversarial networks to train bias correction models using non-parallel corpus. Pryzant proposed two joint embedding models to neutralize biased statements, but their research is restricted to addressing subjective bias that originated from single-word edits (Pryzant et al., 2019). Our proposed method extends from single-word to multi-word correction by generating fluent bias-free sentences.

Attribute Style Transfer. Subjective bias correction can be framed as a specialized attribute transfer task which aims at reconstructing an input text so that a linguistic attribute of interest is transferred to a desired value, such as text sentiment transfer (Jin et al., 2022; Lample et al., 2018). Most attribute transfer methods uses auto-encoders that rely on large parallel corpus (Rao and Tetreault, 2018; Briakou et al., 2021; Madaan et al., 2020; Prabhumoye et al., 2018; Pryzant et al., 2019; Jin et al., 2022). (Huang et al., 2019) used a dictionary based method to replace words in a sentence to create diverse paraphrases. (Lai et al., 2021) developed an efficient method to fine-tune a large pretrained model for text-attribute transfer on low-resource domains. (Chen et al., 2018) used cross-aligned auto-encoder trained on opposite ideology news data to generate flipped titles. Our proposed method is inspired from various attribute style transfer methods, but addresses the problem of using noisy parallel data for supervised style transfer for better generalization using reinforcement learning methods.

3 Reinforced Bias Corrector

In this section, we introduce the design of the proposed subjective bias correction approach (illustrated in Figure 1). Given a biased statement x that describes a facts f using a set of words $(x_1, x_1, ..., x_N)$, where N is the length of x. The aim of a bias correction system is to generate a statement $y = (y_1, y_2, ..., y_M)$, where M is the length of y. The generated statement y is not only expected to have a neutral tone, but also preserve the original semantic content expressed in statement x. Additionally, y is also expected to present the fact F in a grammatically correct and fluent language that is easy for a reader to comprehend.

3.1 RL and Bias Correction

Given these goals, a natural approach to perform subjective bias correction is to train an encoder-decoder with attention network using a parallel corpora similar to many natural language generation tasks (Bahdanau et al., 2014; Zhao et al., 2019; Chollampatt and Ng, 2018; Pryzant et al., 2019; Konstas et al., 2017; Li et al., 2018; Gupta et al., 2018; Vaswani et al., 2017). The encoder converts the input sentence into a fixed-length vector that will be used by the decoder to generate the output sequence, word by word. The entire network will be trained with the parallel data (x, y) to minimize the cross-entropy loss (CE) that is given by:

$$L_{CE} = \sum_{t=1}^{T} log\pi_\theta(y_t|y_{t-1}, s_t, c_{t-1}, x) \quad (1)$$

Since minimizing L_{CE} makes the model generate text close to the human-reference edits, the training data needs to be of high-quality. Since the only large parallel corpus available for bias correction is noisy, such likelihood optimized models have limited performance (Pryzant et al., 2019; Zhong et al., 2021). Additionally, these models do not produce the best results for metrics during evaluation because the training is not optimized to generate text that addresses evaluation metrics (such as BLEU or Content Similarity). By aligning the training and testing objective, we can improve the performance of bias correction in a source domain (Wikipedia), though this does not guarantee generalizability over other domains.

Hence, we propose to improve the performance and generalizability of bias correction models by fine-tuning the Seq2Seq model using Reinforcement Learning (RL). In this method, instead of maximizing the probability that the predicted word is close to the ground truth, the parameters of the agent are optimized to maximize long-term rewards. We can formulate the RL engine for bias correction as composed of an agent (A), action (a), policy (pi), and reward (R). The agent is our bias correction model with parameters θ that observes the current state (encoder's output) at time t and takes an action a (predict the next word $\hat{y}_t$) by using a policy (π). The reward (R) is a feedback returned to the bias correction model from the system by evaluating the quality of generated text.

3.2 REINFORCE Training

In reinforced bias correction task, the agent's behavior is controlled primarily through the neutrality score that measures the degree of subjective bias in the generated text $\hat{y}$. So, the objective of maximizing the expected scalar reward $R : \hat{y} \rightarrow [0, 1]$ is given by:

$$J(\theta) = E_{\pi_\theta}(\hat{y}/x)[R(\hat{y})] \quad (2)$$

Since the reward is the discrete function of the model's output, the RL objective is non-differentiable with respect to the model parameter θ,), which makes it difficult to back-propagate the error signals from the critic to the generator. This issue can be addressed through policy gradient or Q-learning based methods. In our initial experiments, we considered several RL methods, including Q-learning, but these models did not converge even after training for a long time (more than 48 hours). This is mainly due to the extremely large action space $O(W^T)$, where W is the number of words in the vocabulary (10^4) and T is the sentence length.

In contrast, the REINFORCE-based method showed good performance and converged faster than other methods. Hence, we focus our discussion here on REINFORCE as our primary policy gradient method. In REINFORCE, the expected reward is approximated using a sampling method and the model is trained using stochastic gradient ascent (Williams, 1992), which can be formulated as:

$$\nabla_\theta J(\theta) = E_{\pi_\theta(\hat{y}/x))}[R(\hat{y})\nabla_\theta log\pi_\theta(\hat{y}/x)] \quad (3)$$

where, π_θ is a policy that generates a probability of picking a word as output. Even though RL training is promising, efficiently applying it for real world problems remains a challenge due to extremely large sequence space (50000^{50} for a sentence with length of 50 and vocabulary of 50000) (Mnih et al., 2015). To achieve the RL objective, a sequence model is pre-trained first and then fine-tuned using REINFORCE algorithm using different rewards. The REINFORCE method optimizes the best policy directly by modifying the parameters of the model based on the observed rewards. Since it directly optimizes the return, it tends to be more stable in converging to a good behavior

4 RL Rewards and Policy Extensions

In our subjective bias correction task, the key testing objectives are: (i) reduce subjective bias; (ii) preserve content expressed in the source text; and (iii) the generated text needs to be grammatically correct fluent. Based on the above objectives, the designed reward function $R(x, \hat{y})$ consist of three rewards:

$$R(x, \hat{y}) = \alpha * R_N(\hat{y}) + \beta * R_S(x, \hat{y}) + \gamma * R_F(\hat{y}) \quad (4)$$

where, $R_N(\hat{y})$ is the neutrality reward for the bias corrected text $\hat{y}$, $R_S(x, \hat{y})$ is the semantic similarity reward computed between the input text x and output text $\hat{y}$, and $R_F(\hat{y})$ is the fluency reward for the output text $\hat{y}$. Here α, β, $\gamma > 0$ and represents weights for the respective rewards.

Neutrality Reward. The central objective of this first reward is to remove any subjective bias that is contained in the input sentence x. The neutrality reward $R_N(\hat{y})$ computes the presence or absence of biased tone in the output sentence $\hat{y}$. It is not a relative score that is computed between the input text x and output text $\hat{y}$, rather an absolute score that is computed purely on the output text $\hat{y}$. Because of which, there is a possibility that the model might remove a chunk of text that is biased and output a partial sentence that is neutral. But the combination of neutrality reward R_N and semantic similarity reward R_S ensures the corrected text carries all the information expressed in an unbiased or neutral tone. To compute the neutrality reward, a RoBERTa based binary classifier is used that takes the sentence as input and produces a probability score that the input text is biased or not (Madanagopal and Caverlee, 2022). More details about this classifier is available on our previous work on detecting linguistic bias (Madanagopal and Caverlee, 2022).

Semantics Similarity Reward. The semantic similarity reward $R_S(x, \hat{y})$ is used to ensure that all the information that is expressed in the input sentence is retained in the output sentence $\hat{y}$. Standard semantic similarity metrics like BERTScore cannot be used for this task, because the tone or slant change will affect the similarity score significantly. To create a subjectivity-free similarity reward, we created a Siamese network based on BERT and fine tuned using Wikipedia-derived parallel corpus (Mueller and Thyagarajan, 2016).

Fluency Reward. The fluency reward encourages the model to generate a sentence $\hat{y}$ that is grammatically correct or natural sounding. There are various methods to compute the grammatical correctness of a sentence such as Perplexity score (PPL) (Meister and Cotterell, 2021). Large pretrained models are used to compute the PPL scores, where grammatically incorrect sentences will have high PPL and grammatically correct sentence will yield a lower PPL score (Meister and Cotterell, 2021). But, the fluency reward needs to be a normalized value between 0 and 1. We used the Corpus of Linguistic Acceptability (CoLA) that contains 10,657 English sentences that are labelled for grammatical and syntactic correctness (Warstadt et al., 2018). We then built a binary classifier using RoBERTa and used the classifier result as the fluency reward for measuring the correctness of the generated text $\hat{Y}$.

4.1 Cross-domain linguistic bias critic

In classic REINFORCE learning scenarios, to minimize the distinction between human reference edit and the machine correction, the bias critic is trained with the same training data used for agent's pretraining (Wu et al., 2018). Since some of the ground-truth data still contains bias, using similar approach can adversely affect the agent's behaviour. Also, our objective is to learn beyond what is available in the training corpus so that it can efficiently handle new style of writing and all forms of subjective bias outside of Wikipedia domain. Hence, we investigate in this paper, the potential of using a cross-domain bias classifier as the bias critic. The cross-domain bias classifier is trained by leveraging annotated datasets from other domains that are rich in subjectivity and apply recent deep transformer models like BERT in order to more robustly model factual statements. The cross-domain bias classifier is evaluated to have an accuracy of 89% and coincide with human judgement for bias detection. There are two advantages to using a cross-domain bias classifier: First, the cross-domain dataset used for training the binary classifier does not need a parallel dataset. Second, the cross-domain aspect lets the classifier learn new subjective writing styles from other subjectivity rich domains and assign rewards that are of high quality, which in turn makes the reinforcement more efficient.

Generally, the most effective method to approximate the policy gradient is either multinomial sampling of the softmax-normalized outputs or beam search. Both the objectives can be trained either sequentially or simultaneously. Our proposed method uses a sequential training, where the agent is first trained with supervised methods and then fine-tuned with reinforced methods.

4.2 Delayed and Sparse Reward

Typically, in a RL setting, rewards are assigned as soon as the action is taken by the agent. But in our method, the reward is observed only at the end of generating a complete sentence. Which means one reward for multiple actions taken by the agent. Due to this sparsity of reward, the agent receives same reward for all steps taken to generate a complete sentence. This makes the RL training inefficient because the agent has no clue which action led to bad results. To address this issues, Reward shaping strategy (Ng et al., 1999) is used to compute intermediate rewards as suggested by

(Bahdanau et al., 2014):

$$R(y_t) = R(y_{1:t}) - R(y_{1:t-1}) \qquad (5)$$

For simple rewards like BLEU, it is easy to compute the intermediate rewards with partial sentences. But the reward functions used in the proposed approach only works if the complete sentence is available. We used the modified reward shaping method used by Hongyu et al. (Gong et al., 2019), where the agent is made to generate the entire text at each step and the generated text is used to compute the reward.

5 Experimental Setup

This sections provide an overview of the datasets, the baseline bias correction models, the evaluation metrics, and the details of their implementation.

5.1 Datasets

For pre-training the agent (Seq2Seq or Transformer), we harvested Wikipedia-derived Neutrality Corpus (WNC) (204k parallel sentences) following the instructions of (Recasens et al., 2013), but included multi-word edits (See the Appendix). For training a cross-domain bias classifier, we used the dataset assembled in a prior study (Madanagopal and Caverlee, 2022). For evaluation, we used WIKIBIAS (2,117 biased and 2,911 neutral), a high-quality dataset that is manually curated by (Zhong et al., 2021).

5.2 Baselines

We consider three baselines models:

Delete Biased Word(s) uses a bias tagger to identify subjective words in a sentence and removes them. More details on the bias tagger is available in the Appendix.

Join Embedding Model uses a denoising autoencoder and a token-weighted loss function to automatically neutralize subjective bias in text (Pryzant et al., 2019). We retrained their best performing CONCURRENT model.

OpenNMT Transformer is a widely used medium transformer model implemented in the OpenNMT-py library that contains 12 heads, 768 d_{model} size and 3072 d_{ff} size (Klein et al., 2017).

5.3 Models

We consider two classes of models for the proposed *reinforced sequence training*: (i) a vanilla Seq2Seq model; and (ii) a pre-trained transformer model.

Reinforced Seq2Seq Model (RL-Seq2Seq): The first model is an attention-based Seq2Seq model similar to (Bahdanau et al., 2014). It is pretrained with the WNC corpus and the pre-trained model is used as an agent in the proposed reinforced sequence training approach with three reward functions. The following three variations were trained and evaluated:

RL-Seq2Seq$_B$: Reinforced sequence-to-sequence model with base bias reward (WNC).

RL-Seq2Seq$_{CDB}$: Reinforced sequence-to-sequence model with cross-domain bias reward.

RL-Seq2Seq$_{CDB+FL+SIM}$: Reinforced sequence-to-sequence model with cross-domain bias, fluency and semantic content preservation reward.

Reinforced Transformer Model (RL-Trans): The second model is the BART pre-trained transformer model (Lewis et al., 2019), which performs well on paraphrasing tasks with good fluency and content preservation (Lewis et al., 2019; Lai et al., 2021). We downloaded a pre-trained BART model (base) and further pre-trained on the noisy WNC corpus. The further pre-trained BART model is used as one of the baseline models, and further fine-tuned, resulting in three variations akin to the Seq2Seq ones: (RL-Trans$_B$, RL-Trans$_{CDB}$, RL-Trans$_{CDB+FL+SIM}$).

5.4 Training

Training is in four steps: (1) pre-train the Seq2Seq model using the noisy Wikipedia NPOV data with an MLE objective; (2) train a cross-domain bias classifier using a large pre-trained language model like RoBERTa; (3) train a siamese network to compute semantic similarity between sentences without subjective tone; and (4) fine-tune the pre-trained Seq2Seq model using reinforcement learning with three reward components. A combination of training data sampling and new domain data (non-parallel) is used for reinforced fine-tuning. For fluency reward, we used the CoLA dataset (Warstadt et al., 2018) and trained a RoBERTa model with an accuracy of 92%. The hyperparameters used for pre-training the Seq2Seq model and fine-tuning of the reinforcement model are presented in the Appendix. For semantic similarity evaluation, the BERTScore model is downloaded from HuggingFace.[1] All code is implemented using PyTorch and

Table 4: Human evaluation of subjective bias correction performance across 3 different domains.

trained on a Google Cloud Platform with NVIDIA Tesla P100 GPU.

5.5 Evaluation Metrics

The following set of automated metrics are used to evaluate the quality of bias correction models:

Neutrality: Similar to previous work (Luo et al., 2019; He et al., 2020), the neutrality score is computed using a binary classifier that is pre-trained to evaluate subjective bias across various domains; on human reference dataset it has an accuracy of 89% (Madanagopal and Caverlee, 2022). The text generated by each model is sent to the binary classifier and the probability score that it belongs to the neutral category is used as the neutrality score.

BLEU: A commonly used metric that measures the similarity of machine corrected text and human reference correction through n-gram precision counting (Papineni et al., 2002).

BLEURT: A trained metric that uses transformer models to evaluate the quality of natural language generation models (Sellam et al., 2020).

BERTScore: Uses contextual language models such as BERT and computes semantic distance between candidate and reference sentences (Zhang* et al., 2020).

PPL: To evaluate the grammatical correctness and fluency of the machine generated text, we computed the perplexity score (PPL) using the large pre-trained language model GPT-2. The perplexity score PPL is computed directly on the generated text with no reference text.

6 Experimental Results

We present the results of the experiments through both automated and human judgement evaluation.

6.1 Automated Evaluation

Table 2 shows our proposed model's performance in comparison with the selected baseline models. Among the baseline models, the OpenNMT transformer model performed better with a neutrality score of 49.47 and BERTScore of 88.45, and the Join Embedding model had the best BLEU because of its copy network nature. But our two proposed reinforced sequence models performed significantly better than the baseline models on all metrics, especially the neutrality score (18% increase). In terms of BLEU score, the RL-Seq2Seq model had the best score of 94.52. Since the RL-Trans generated more diverse text compared to the human-edits, it's BLEU score was relatively low. But its BERTScore being high confirmed the RL-Trans model's ability to retain the information conveyed in the source sentence to the target sentence with high neutrality score. Similarly the perplexity score for the RL-Trans model indicates high fluency. This might be due to the fact the pre-trained BART model is trained on large diverse corpus. Overall the RL-Trans had the best performance on all automated metrics except BLEU.

6.2 Evaluation of Reward Function

To understand the effect of each reward on the performance of the bias correction model, we conducted an ablation study as shown in Table 3. Base bias rewards are based on a bias classifier trained solely on Wikipedia dataset, while cross-domain bias rewards are trained on a dataset containing biased statements from various domains like political speech and product reviews. In terms of the neutrality score, we observed significant improvement in the bias correction performance by the use of cross-domain bias reward. It could be because pre-training data is noisy, so the output still contains biased statements that the cross-domain bias classifier is able to detect more subtle forms of bias and multiple occurrences of bias. In terms of BLEU, the RL-Seq2Seq model with all rewards performed much better. The RL-Trans model's BLEU score was low which is due to the diversity in the text generated relative to the source text. This shows BLEU is not a good metric for comparing bias correction accuracy. So we use BLEURT which accounts for the n-gram accuracy with embeddings. The reinforced transformer model with all rewards performed the best. One interesting observation is that the improvement in RL-Trans using fluency and content similarity reward is small relative to RL-Seq2Seq. The large pre-trained BART model already performs well on fluency and content preservation, so adding rewards has little impact. All in all, the rewards were more effective at achieving the testing objective and also produced high-quality text.

6.3 Multi-Occurrence Bias Evaluation

We performed a separate study to investigate the performance of reinforced bias correction in addressing multiple instances of bias within a single sentence. A set of 331 sentences were selected from the WIKIBIAS corpus that contain more than one instance of subjective bias. The output of each model is then analyzed with the help of a bias tagger to understand how much of the bias still exists or if new bias is introduced. RL-Seq2Seq model trained with all 3 rewards had the best performance (16%) of addressing multiple occurrence of bias in a single sentence (See Table 5).

Model	**Neutrality**	**% biased**
Biased Word Removal	34.06	30.85
Join Embedding	50.56	37.32
OpenNMT	58.85	41.62
RL-Seq2Seq	67.33	**16.17**
RL-Trans	**67.15**	18.24

Table 5: Performance evaluation of addressing multi-occurrence bias. % biased represents the percentage of sentences that contains at least one instance of biased chunk after bias correction (lower the better).

6.4 Human Judgement

With a sample of 100 sentences collected for each of the experimented models, we conducted a human evaluation study with 10 judges to determine if the bias correction models generate human-like sentences. See the Appendix for more detail. A majority of the human judgement results correlated with the automatic evaluation. The Reinforced-Transformer model was preferred by a majority of the judges for its neutral tone and language fluency. The Reinforced Seq2Seq model was shown to preserve the same information as the source text. Since the pre-trained transformer model generates text that is diverse from the original input sentence, it might have read slightly different for a human. But the BERTScore showed the Reinforced-Transformer model to have better performance in content preservation.

The Kappa statistic was used to compute the inter-annotator agreement for human evaluation task. The average kappa values for the individual aspects are (i) Bias neutralization: 0.72; (ii) content presentation: 0.75; and (iii) fluency: 0.85. Due to the complex nature of subjective bias detection, the inter-annotator agreement for that task is the lowest (0.72). On the other hand, Since most of the annotators are well-versed in assessing the grammatical correctness of a sentence, the kappa value for fluency was high (0.85).

6.5 Cross-domain Model Performance

Finally, we explore the generalizability of the proposed bias correction model by performing inferences on three datasets that are manually curated outside the training domain (Wikipedia): (1) News Headlines (Media Cloud[1]); (2) Academic (National Geographic[2]); and (3) Conservapedia[3]. Thirty factual sentences were collected from all three selected domains, processed through the bias correction models and evaluated through human judgement on the basis of neutrality, fluency and content preservation. Overall, both the proposed models performed very well in all three domains. In terms of neutralization effort, the RL-Seq2Seq model performed the best on the News domain (See Table 4). This is because most of the bias in news are related to framing bias (perspective-specific words). But in the Academic domain and Conservapedia domain, the RL-Trans performed better. Relatively, the transformer model performs better on addressing both framing as well as epistemological bias.

7 Conclusion and Future Work

We proposed a hybrid method to improve the performance of Seq2Seq and transformer-based bias correction models by incorporating semi-supervised training strategy that uses a supervised pre-training using noisy data and reinforced fine-tuning using high-quality cross-domain data. The proposed training method is able to successfully alleviate the exposure bias in MLE optimized sequence models and address the in-stability issue in reinforcement learning methods. It also shows that by carefully designing the reward function with respect to the testing objective, high quality results can be obtained. Specifically, our method was able to generate text with high neutrality. The text generated by our method is more fluent and retains more semantic information relative to previous methods. In this study, we explored only a limited range of rewards using simple aggregations, but a greater range of rewards and scaling could be explored for better domain adaptation.

Limitations

Although the proposed Reinforced Seq2Seq framework presents an intriguing framework for automatically correcting subjective bias, we also find that – like previous research (Williams, 1992) on similar reinforcement-style learning regimens – it has the following limitations: (i) after each policy run, the trajectories are discarded by the update process, making it inefficient. In some cases, the collected trajectory may not accurately represent the policy, so the gradient estimate becomes uncertain. Further, whether a trajectory reinforces good or bad actions depends entirely on the final output, so the reward assignment can be unclear.

In this study, we examine a specific form of subjective bias that manifests at the sentence level. However, taking into account the context (paragraph) of the statement could change the viewpoint. Although this study evaluates the Reinforced Seq2Seq framework on a real-world subjective bias correction task, further testing is needed in order to include more challenging bias types, as well as other target model architectures.

The work presented here offers a promising approach for improving bias correction models using reinforcement learning methods, a field of high impact but under-explored to date. We hope that evaluating the models across different domains will inspire further work on building robust, nuanced, and fair bias correction models.

Appendix A. Data Pre-processing Details

We developed a parallel corpus for bias correction by analyzing Wikipedia articles histories with Neutral Point of View (NPOV) tags. Our data harvesting approach was similar to Recasens et. al (Recasens et al., 2013) and Pryzant et. al (Pryzant et al., 2019), but with some minor changes. Following (Recasens et al., 2013), we analyzed the revision histories for each Wikipedia article and downloaded sentences that were argued for NPOV issues. Sentences that had NPOV tags before the revision were considered as biased sentences and the sentences whose NPOV tags were removed after edits were considered as unbiased sentences. We ignored revisions that were related to missing references, misspellings and punctuation.

Corpus Name	Biased	Unbiased	Total
NPOV	32,541	75,024	107,565
MPQA	8,575	42,282	50,857
IBC	3,726	600	4,062

Table 6: Corpus statistics for each dataset used for training cross-domain bias classifier.

From the original NPOV corpus, we extracted sentences that had NPOV or peacock tags in their content before the edit. Pryzant et. al only considered single word edits for their bias correction model. Since the objective of this research is to correct bias that is induced by single word and multiword, we expanded the corpus by modifying the harvest function of pryzant et. al. Also, our method uses the latest dump from Wikipedia which contains new biased sentences that were not considered in the previous study. Additionally, some data cleanups were done to make this model not sensitive to noun phrases in the text. We replaced all noun phrases, but retained honorifics because some of the gender biases were introduced through honorifics. The numbers mentioned in the text were also replaced with NUM tag. A total of 408,738 sentences were extracted for our study. The NPOV corpus will help our bias detection model to learn common patterns that are used by Wikipedia editors for imposing subjective views. The details of the dataset are provided at Table 6.

Appendix B. Implementation

For Seq2Seq model, a multi-layer recurrent neural network based encoder, and an attention-based decoder was used(Vinyals et al., 2015; Bahdanau et al., 2014). Both the models are designed with 3 LSTM layers with 256 units at each layer. The hyper-parameters are tuned based on the noisy Wikipedia data. The pre-trained GloVe embedding is used as the embedding layer. The model is trained with Adam optimizer with the following hyper-parameters batch size = 32, learning rate = $5e^{-}5$ and a learning rate decay factor = 0.99. Based on the training and testing data statistics, the maximum sentence length is set to 30 for both input and output. Glove vectors is used as the pre-trained embedding. For pre-trained transformer model, we used the BART model (Lewis et al., 2019) with 139M parameters and fine tuned with Adam optimizer (learning rate $3e - 5$).

Algorithm 1 REINFORCE Algorithm

```
Input: Input sequences (X), the output sequences (Y), and a pre-trained policy ($\theta$)
Output: Trained policy with REINFORCE
Training Steps:
  while not converged do
      Select a batch of size N from X and Y
      Sample N full sequence of actions: $\{y_1, ..., y_M\}$
      Observe the sequence reward and calculate the baseline $r_b$.
      Calculate the loss
      Update the parameters of network
  end while
Testing Steps:
  for batch of input and output sequences X and Y do
      Use the trained model and sample the output
      Evaluate the model using a performance metric, e.g. BLEU
  end for
```

Appendix C. Bias Tagger

The bias tagger takes an input sentence and identifies a sequence of words as biased based on the context of use. Some of the subjective bias correction methods we developed needs additional information like biased words in the sentence to efficiently rewrite a polarized sentence, so a sequence tagging based bias tagger model was developed. By comparing the word edits between the sentences in parallel text generated for bias correction, we constructed a bias tagging dataset using a BIO format. Since state of the art sequence tagging models are BERT based (Devlin et al., 2018), we developed a BERT based sequence tagger by adding a dropout layer and a classification layer at the end of BERT model with a cross entropy loss. Pretrained RoBERTa model (Liu et al., 2019) was downloaded and fine-tuned for bias tagging. The bias tagger model had an accuracy of 95% with a recall of 92% on the validation set.

Appendix D. Policy Gradient

The goal of policy gradient methods is to update the probability distributions of actions in such a way that actions with higher expected rewards have a higher probability value for an observed state. The objective function for policy gradients is given by:

$$J(\theta) = E[\sum_{t=0}^{T-1} r_{t+1}] \tag{6}$$

where r_{t+1} is the reward received by performing action a_t at state s_t; $r_{t+1} = R(s_t, a_t)$, where R is the reward function. The policy is optimized by taking the gradient ascent based on the partial derivative of the objective based on the policy parameter theta:

$$\theta \leftharpoonup \theta + \frac{\partial}{\partial \theta} J(\theta) \tag{7}$$

The objective function can be expanded as:

$$J(\theta) = E[\sum_{t=0}^{T-1} r_{t+1} | \pi_\theta] \tag{8}$$

If $P(s_t, a_t|\tau)$ represents the probability of s_t, a_t occurring given the trajectory τ, then objective function is:

$$J(\theta) = \sum_{t=i}^{T-1} P(s_t, a_t|\tau) r_{t+1} \tag{9}$$

Then the policy gradient is given as:

$$\nabla_\theta J(\theta) = \sum_{t=0}^{T-1} \nabla_\theta log \pi_\theta(a_t, s_t) \sum_{t'=t+1}^{T} \gamma^{t'-t-1} r_{t'} \tag{10}$$

where $\gamma \epsilon [0, 1]$ is the discount factor that helps to weight immediate rewards more than future rewards.

Appendix E. Human Judgement

A total of 100 sentences were collected from the model output and evaluated using 10 judges. The sentence selected for human judgement contains both biased and unbiased statements.Additionally, we ensured that the biased sentences collected contained both multi-occurrence bias as well as all three types of bias. The judges selected for this evaluation has computational linguistic background, but they don't have background information on what models were developed and their characteristics. Before presenting the data, a detailed definition of what is subjective bias with examples was presented to the user. For each example, a detailed note is provided to explain why the selected sentence is biased. Reference edits varied based on the aspect being evaluated. The text generated is evaluated for three aspects:

- **Neutrality**: The user is presented with the original biased statement and bias corrected results from one of the models, and asked to rate which of the statement is more biased on a scale of -2 to 2 (-2 is for original text is more biased, 0 is same biased and 2 for generated text is more biased). When presenting sentences, the placement of biased and corrected sentences is randomised.
- **Fluency**: A combination of the text generated by various models along with ground truth is presented to the user in pairs and asked which one is more fluent. The fluency of a sentence is rated in a scale of -2 to 2 (-2 for ground-truth is more fluent, 0 if both have same fluency and 2 if generated text is more fluent).
- **Content preservation**: For content preservation, the original sentence and model corrected sentence is presented to the user and asked whether the second sentence contains the same information as the first sentence. The content preservation is rated on a scale of 0 to 4 (0 representing the content is totally different and 4 being very similar).

Abstract

Language contact is a pervasive phenomenon reflected in the borrowing of words from donor to recipient languages. Most computational approaches to borrowing detection treat all languages under study as equally important, even though dominant languages have a stronger impact on heritage languages than vice versa. We test new methods for lexical borrowing detection in contact situations where dominant languages play an important role, applying two classical sequence comparison methods and one machine learning method to a sample of seven Latin American languages which have all borrowed extensively from Spanish. All methods perform well, with the supervised machine learning system outperforming the classical systems. A review of detection errors shows that borrowing detection could be substantially improved by taking into account donor words with divergent meanings from recipient words.

1 Introduction

Language contact is one of the most pervasive linguistic phenomena. It is the first factor that needs to be excluded when searching for genetic relations among the languages of the world, and it needs to be controlled for when searching for cross-linguistic universals. Any study trying to explain how humans use language must take language contact into account. It is also a unique witness of ancient contacts in human prehistory.

Language contact is most prominently reflected in *lexical borrowing*, the *transfer* of words from a donor language to a recipient language. Although research on the computational handling of lexical borrowing has made some progress of late, computational approaches to the investigation of language contact are still in their infancy (List, 2019). Specifically methods that could infer the direction of borrowings have not been proposed so far. While numerous case studies investigate the influence of dominant languages on heritage languages (Prochazka and Vogl, 2017; Meisel, 2018), we lack automated methods that could be used to study the influence of particular dominant languages in linguistically diverse areas of the world.

The number of standardized cross-linguistic wordlist collections has greatly increased over the past years (Rzymski et al., 2020; List et al., 2022a), with standard formats (Forkel et al., 2018) accompanied by software tools that allow scholars to prepare and curate standardized wordlists in an efficient manner (Forkel and List, 2020). It would be useful to have a computer assisted tool for linguists to detect which words in a cross-linguistic region have been borrowed from a dominant language and with further advances, a tool for inclusion in language contact assessment or in computational cladistics workflows.

Here, we compare the suitability of three different systems to address this task – two systems based on classical algorithms for automated sequence comparison that can be applied in supervised and unsupervised settings, and one supervised system based on extended machine learning techniques. We test these systems on a newly derived dataset of seven Latin American languages (Fig. 1) in which Spanish is a dominant donor language. Our results show that the supervised machine-learning system outperforms the classical systems.

2 Previous Work

Although still few in number, automatic methods for borrowing detection have been increasingly applied and developed in the past years. Early studies by van der Ark et al. (2007) and later Mennecier et al. (2016) compute edit distances between words from genetically unrelated languages and compare distances to thresholds, in order to detect borrowed words in multilingual wordlists.

Besides edit distance, which directly calculates distances between phonetic sequences, sound class

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2599–2605
May 2-6, 2023

based methods cluster phonetic segments into sound classes and then compute distances between sound class sequences. The sound-class based alignment method (SCA) (List, 2012) provides sound class categories, scoring functions for distance measures, and modifiable gap scores based on prosodic context.

Zhang et al. (2021) compare edit distance performance against SCA (List, 2012) distance performance, finding that SCA outperforms edit distance in accuracy. Hantgan et al. (2022) build on this work, using dedicated methods for automated cognate detection applied to languages from different language families in order to identify clusters of related words resulting from lexical borrowing. List and Forkel (2022a) expand this work further, by applying a two-stage workflow in which they first identify language-family-internal cognates, using a method specifically apt for the detection of deep cognates, and then compute SCA distances between cognate sets from genetically unrelated languages in order to infer sets of words related by lexical transfer.

Miller et al. (2020) compute language models for inherited and borrowed words for individual languages from the World Loanword Database (WOLD, Haspelmath and Tadmor 2009) using Markov Chains and Recursive Neural Networks and compare cross-entropies for inherited and borrowed language models in order to identify borrowings from monolingual information alone.

Kaiping and Klamer (2022) use automated methods for cognate detection (List et al., 2017) on a target set of Timor-Alor-Pantar languages. In order to infer borrowings from Indonesian and Tetun (not in the target set), they include both languages in their sample and treat all cognate sets that involves words from either of the two languages as borrowings. Moro et al. (2023) apply a similar approach to investigate borrowings in Alorese.

Mi et al. (2020) and Nath et al. (2022) train binary classifiers, mainly neural based, on large wordlists to predict borrowed words, and achieve F1 scores in the 0.75 to 0.85 range. Their workflows seem cumbersome, compute intensive, and not minimalist, but the results are promising.

3 Materials and Methods

3.1 Materials

For this study, a new comparative wordlist was created by taking data for seven Latin American languages from WOLD (`https://wold.clld.org`, Haspelmath and Tadmor 2009) and combining them with a wordlist of Spanish derived from the Intercontinental Dictionary Series (`https://ids.clld.org`, Key and Comrie 2015). Phonetic transcriptions for the Latin American languages were added to WOLD by Miller et al. (2020). Latin American Spanish phonetic transcriptions were added for this study (and could be later expanded by adding more transcriptions from historical varieties of Spanish). The resulting dataset conforms to the standards suggested by the Cross-Linguistic Data Formats initiative (CLDF, `https://cldf.clld.org`, Forkel et al. 2018). The data curation follows the Lexibank workflow (List et al., 2022a) and checks that data conform to certain standards, with languages being linked to Glottolog (`https://glottolog.org`, Hammarström et al. 2022, Version 4.7), concepts being linked to Concepticon (`https://concepticon.clld.org`, List et al. 2022b, Version 3.0), and transcriptions following the B(road)IPA conventions of the Cross-Linguistic Transcription Systems reference catalog (`https://clts.clld.org`, List et al. 2021, Version 2.2, see Anderson et al. 2018). Details of the resulting database are shown in the map of language locations along with percentages for borrowings from Spanish in Fig. 1 and in Tab. 1. Q'eqchi' and Zincantán Tzotzil are both Mayan languages, but appear substantially varied in the database.

Language	**Concepts**	**Lexemes**	**Segments**	**Vocab.**
Imb. Quechua	1,155	1,156	7,177	33
Mapudungun	1,040	1,242	7,356	33

Aggregate	1,308	12,100	72,550	112

Table 1: Database details for seven Latin American languages plus Latin American Spanish.

3.2 Methods

Methods for Borrowing Detection. We develop three different methods for the detection of borrowings *from* a dominant language *to* non-dominant languages in multilingual wordlists. Following historical linguistics comparative method practice (Campbell, 2013), only word forms corresponding to the same concept are considered as

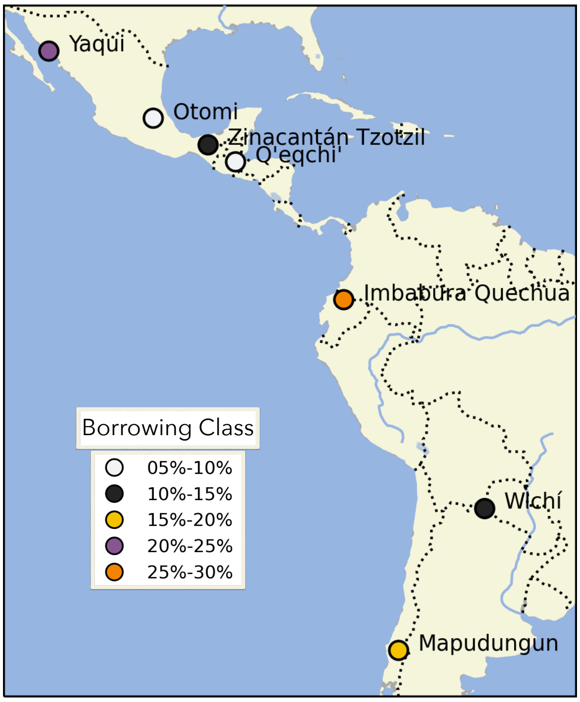

Figure 1: Map of languages with Spanish borrowing class.

candidates for borrowing.

The first method, called *Closest Match* borrowing detection in the following, iterates over all word pairs that express the same concept in the dominant language and the heritage languages and then computes phonetic distances. Word pairs whose phonetic distance is below a certain threshold are judged to be borrowings from the dominant language. We test two phonetic distances, the normalized edit distance (NED) – the classical edit distance (Levenshtein, 1965) between two words, divided by the length of the longer word – and the SCA distance (List, 2012).

The second method, called *Cognate-Based* borrowing detection in the following, follows the approach by Hantgan et al. (2022): it first computes cognates using a cluster-based approach for automated cognate detection in which words expressing the same concept whose average phonetic distance is below a certain threshold are assigned to the same cognate set (List et al., 2017), and then identifies all words assigned to cognate sets involving the dominant language as borrowings. We tested again normalized edit and SCA distances.

The third method, called *Classifier-Based* borrowing detection in the following, iterates over all word pairs with the same concept, but stores phonetic distance scores for various distance measures as vectors, which can then be used to train a classifier, firstly, a linear Support Vector Machine (SVM) (Cristianini and Shawe-Taylor, 2000), in a supervised setting. We tested various phonetic distance measures, but report only on the combination of normalized edit and SCA distances, as they yielded the best results. Both Closest Match and Cognate-Based methods require a fixed threshold which we estimate from the training data. So all three methods are considered as supervised.

Sampling. Train-test splits are made based on concepts rather than individual word entries. This permits matching of words for the same concept in in all methods without loss of candidate words. Treating train-test split as a nuisance variable takes into account differences between partitions across methods thus controlling for effects of sampling by concepts with differing borrowing behavior or statistical dependencies between test partitions due to sampling without replacement. See (Dror et al., 2018) for mention of the dependency problem with cross-validation. Our use of a fixed partition across treatments and analysis of variance controlling for partition as a nuisance or 'blocking' variable accounts for this dependency, and takes advantage of any systematic effects in borrowing behavior by partition.

Evaluation. For the analysis of the cross-validation data, we use a randomized blocks design where experiment is the treatment or factor, and test partition is the randomized block or nuisance variable. A standard analysis of variance partitions treatment effects, nuisance variable, and error, and permits a more powerful test of treatment differences without the nuisance variable variance. We follow up statistically significant findings for treatment (experiment), with comparisons of experiments versus the overall average using a joint (family) error rate.

Implementation. Our methods are implemented in Python, making specifically use of the CLDF-Bench package (`https://pypi.org/project/cldfbench/`, Forkel and List 2020, Version 1.13.0) to provide commandline access to all methods described here. For the computation of alignments and edit distances, LingPy (`https://pypi.org/project/lingpy`, List and Forkel 2022b, Version 2.6.9) is used. SVM and evaluation are realized with the help of Scikit-Learn (`https://pypi.org/project/scikit-learn/`, Pedregosa et al. 2011, Version 1.2.1).

4 Results and Discussion

We tested our three methods with two distance measures in five experiments (normalized edit and SCA distances individually in both Closest Match and Cognate-Based methods, and combined in the Classifier-Based method) using a 10-fold cross-validation on our data and reporting precision, recall, F1 scores, accuracy, and execution times (mm:ss). F1 score is the primary result measure; accuracy and execution time are informational. The 10-fold cross-validation uses the same 10 fixed train and non-overlapping test splits for all experiments. With few parameter estimates (1 threshold each for Closest Match and Cognate-Based, 2 distance and 7 target language coefficients for Classifier), a separate *train* split into *fit/val* is not necessary.

All methods perform well with less than 5 points separating the highest from the lowest F1 scores. Tab. 2 shows the results of the ten-fold cross validation of our three methods in five experiments. An analysis of variance,[1] with experiment as the effects variable and train-test split as the nuisance variable, shows highly significant effects for precision ($\mathrm{F}_{4,36} = 25.74, p < 0.0001$) and F1 score ($\mathrm{F}_{4,36} = 14.3, p < 0.0001$).

Closest Match with normalized edit distance performs poorly, while Classifier-Based with combined normalized edit and SCA distances performs well. Classifier-Based performs better than the average of all experiments in F1 score, and substantially better in precision versus other experiments; the method is conservative, with a low number of false positives. Performance on remaining experiments is indistinguishable from the overall average of all experiments combined. The Cognate-Based method is compute intensive performing multiple alignment over all languages. Accuracy is well above the majority decision accuracy of 84.8% ($100\% - 15.2\%$ borrowing) in all experiments.

A search for classifier improvements prompted several *ad hoc* experiments (see tab. 3). We observe: (1) A radial basis function (rbf) SVM classifier performs no better than our linear SVM. We suspect the estimated target language parameters do not generalize well to held-out data. (2) A logistic regression classifier performs on par with our linear SVM. (3) A weight balanced SVM classifier trades an increase in recall for a larger drop in precision. We also test whether using separate trials for each target language in Closest Match, would perform as well as all languages together. A combined trial performs better; a single threshold estimate appears to generalize better to held-out data than using individual language estimates.

Method	**Prec.**	**Rec.**	**F1**	**Acc.**	**mm:ss**
Closest Match					
NED	0.832	0.703	0.761	0.938	00:15
SCA	0.869	0.720	0.787	0.945	00:29
Cognate-Based					
NED	0.853	0.705	0.771	0.941	01:48
SCA	0.862	0.719	0.783	0.944	04:49
Classifier-Based SVM (linear)					
NED, SCA	**0.931**	0.713	**0.806**	0.952	00:37

Table 2: Ten-fold cross-validation for three methods with NED (normalized edit) and SCA (Sound-Class based phonetic alignment) distance measures. **Bolded** estimates are superior to and underlined estimates inferior to the the overall average using analysis of means (Nelson et al., 2005) with joint error rate $\alpha = 0.05$.

Experiment	**Prec.**	**Rec.**	**F1**	**Acc.**
Classifier Variations - NED, SCA				
SVM (rbf)	0.945	0.694	0.799	0.951
Logistic regression	0.914	0.728	0.809	0.952
SVM (balanced)	0.613	0.826	0.704	0.902
Closest Match - SCA				
Each language (avg)	0.860	0.707	0.770	0.941

Table 3: Ten-fold cross-validation for several *ad hoc* experiments with NED (normalized edit) and SCA (Sound-Class based phonetic alignment) distance measures. Classifier experiments: SVM with radial basis function, Logistic regression, linear SVM with balanced class weights. Descriptive statistics only.

Tab. 4 shows the results of the Classifier-Based method for the seven target languages in our sample with training and evaluation over the entire dataset. There is some variation in performance by language, in particular, with recall in $[0.615, 0.778]$. We detect a linear relation between the performance and the amount of borrowings from the dominant language in the target languages. (Precision: $\mathrm{r} = -0.39, \mathrm{NS}$; Recall: $\mathrm{r} = 0.88, p < 0.01$; F1 score: $\mathrm{r} = 0.85, p < .01$; 1-sided Pearson correlation tests with $df = 5$). Recall and F1 scores improve as borrowing increases. This could be an artifact of higher borrowing resulting in better estimation of a target language coefficient, or more interestingly, a cultural process where more dominant-donor borrowing corresponds to reduced phonetic adaption into the target language.

Figure 2: Example collection of detection errors.

To get a better understanding about the different types of errors that our best performing experimental combination commits, we conducted a detailed error analysis from the Classifier-Based borrowing detection results. A spreadsheet snippet (Fig. 2), serves as a reference for several error types. For undetected borrowings (false negatives), we identified four error types: (1) cases where the borrowed form was not present in the donor wordlist, e.g., Mapudungun *peso* "coin" is borrowed from Spanish *peso* "peso", but our Spanish wordlist only has *moneda*, (2) cases where the form was present in the donor wordlist, but with a different concept, e.g., Wichi *anio* "age" is borrowed from Spanish *año* "year", while the Spanish word for "age" is *edad*, (3) cases of large phonetic distance between donor and recipient forms, e.g., Wichi *alulis* "adobe", which is somewhat distant from Spanish *adobe*, and (4) cases of unrecognized partial borrowing, e.g., Qeqchi *aiunink-riʃ* "abstain from food", which is partially borrowed from Spanish *ajunar* "fast". For falsely detected borrowings (false positives), we identified three error types: (1) cases where the form was not borrowed from the dominant language but *vice versa*, e.g., Spanish *poroto* "bean" was borrowed *from* Quechua *purutu*, (2) cases of chance similarities between word forms, e.g., Spanish *animal* "animal" and Zinacantan Tzotzil *tʃanulil*, and (3) cases so improbably similar that we suspect errors in the original annotation, e.g., Spanish *pelota* "ball" and Wichi *pelutaj*.

Error Type	Count	Pct
Undetected Borrowings		
borrowed form not in donor list	28	17
different concept than recipient form	75	45
large phonetic distance	31	19
partial borrowing as only reason	5	3
Subtotal	139	84
Falsely Detected as Borrowings		
Error Type	Count	Pct
direction not from dominant donor	7	4
chance similarity of form	10	6
likely dataset error	9	5
Subtotal	26	16
Total	165	100

Table 5: Summary over sample of undetected (false negative) and falsely detected (false positive) borrowings.

For a large sample of concepts, we tallied 139 undetected (false negative) and 26 falsely detected (false positive) borrowings (see Tab. 5). Most errors were in recall, with many of these borrowings from lexemes **not** within the same concept.

5 Conclusion

How well can we automatically detect borrowings from dominant languages based on wordlist data? We devised three general methods to detect borrowed words from dominant languages, two based on sequence comparison workflows and one based on a classifier. The classifier-based method showed the best performance, with F1 scores of 0.81, and high precision of 0.93. This method could already prove very useful in computer-assisted workflows. Our investigation of detection errors shows several opportunities for improvement. Most undetected borrowings result from current methods' restriction to searching only for word forms for the same concept. We see great potential in improvements that account for borrowing accompanied by *semantic shift*, specifically: (1) augment donor wordlist coverage of possible forms, (2) relax "same" to "similar" concept restriction for matching forms, or (3) fit language models to wordlists and add word cross-entropy to the classifier without restriction. Tests adding word cross-entropy, not reported here, look very promising, but more research is needed.

Limitations

In this study, we apply limited methods for detection of lexical borrowing to the case of a single dominant donor language (Spanish) wordlist versus seven Latin American language wordlists. This application uses relatively sparse data, with an average of 1,512 lexemes per language wordlist, with very few estimated parameters, and so apt for lower resource languages. Future work will seek to remove the wordlist limitation.

Ethics Statement

Our data are taken from publicly available sources. There are no ethical issues or conflicts of interest in this work.

Supplementary Material

The supplementary material accompanying this study contains the data and code needed to replicate the results reported here, along with detailed information on installing and using the software. It is curated on GitHub (`https://github.com/lexibank/sabor`, Version 1.0) and has been archived with Zenodo (`https://doi.org/10.5281/zenodo.7591335`).

Abstract

Document-level relation extraction (DocRE) predicts relations for entity pairs that rely on long-range context-dependent reasoning in a document. As a typical multi-label classification problem, DocRE faces the challenge of effectively distinguishing a small set of positive relations from the majority of negative ones. This challenge becomes even more difficult to overcome when there exists a significant number of annotation errors in the dataset. In this work, we aim to achieve better integration of both the discriminability and robustness for the DocRE problem. Specifically, we first design an effective loss function to endow high discriminability to both probabilistic outputs and internal representations. We innovatively customize entropy minimization and supervised contrastive learning for the challenging multi-label and long-tailed learning problems. To ameliorate the impact of label errors, we equipped our method with a novel negative label sampling strategy to strengthen the model robustness. In addition, we introduce two new data regimes to mimic more realistic scenarios with annotation errors and evaluate our sampling strategy. Experimental results verify the effectiveness of each component and show that our method achieves new state-of-the-art results on the DocRED dataset, its recently cleaned version, Re-DocRED, and the proposed data regimes. [1]

1 Introduction

The problem of document-level relation extraction (DocRE) has garnered increasing attention from the research community (Quirk and Poon, 2017; Peng et al., 2017; Yao et al., 2019) due to its importance to real-world applications. DocRE is inherently a multi-label problem, in which we have to predict a set of relations from the pre-defined label set for every entity pair in a document. Thus, it is crucial for DocRE models to adopt an effective learning objective that can clearly distinguish massive semantically close relations.

Recently, several works have proposed new loss functions to learn an adaptive threshold for better separating positive and negative relations. However, these approaches (Zhou et al., 2021; Tan et al., 2022a) either enforce learning a *total order* among all relations that leads to superfluous comparisons and diminishing differences among them or improperly penalize all pre-defined labels of positive entity pairs if their average margins are lower than the threshold when addressing the label imbalance problem (Zhou and Lee, 2022). In contrast, we propose an approach that learns a *partial order*, ranking all positive relations above a threshold individually, which is in turn ranked above all negative relations. Our approach does not waste precious data and probability mass in modeling the ordering among positive relations (likewise for negative relations). We further sharpen the distinction in each distribution of a relation and the threshold through the principled use of entropy minimization.

Besides, none of the above methods take the discriminability of internal representations into account, as well as the model robustness against annotation errors. To solve these issues, we introduce novel modifications to the supervised contrastive learning (Khosla et al., 2020) to accentuate the differences among the embeddings of entity pairs from different classes and the similarities of that from the same class. Our method can better accommodate the multi-label setting and the long-tail phenomenon that is typically present in DocRE datasets. To combat the annotation error problem stated in Tan et al. (2022b), we design two new data regimes and a novel negative label sampling strategy that gives consistently strong performance even with incomplete annotations. In sum, our

contributions are three-fold:

- We propose an effective loss function that boosts the discriminability of both internal embeddings and probabilistic outputs.
- We achieve good integration of discriminability and robustness by incorporating a novel negative label sampling strategy.
- Experimental results consistently demonstrate that we achieve new state-of-the-art performance in a variety of settings.

2 Related Work

Document-level relation extraction (DocRE) Early works on DocRE focus on utilizing graph convolutional networks (GCNs) (Kipf and Welling, 2017) to conduct complex cross-sentence reasoning on a document graph (Sahu et al., 2019; Christopoulou et al., 2019; Wang et al., 2020; Zeng et al., 2021). Recently, methods fine-tuned on large pre-trained language models (Devlin et al., 2019; Liu et al., 2019) achieved significant performance gain. In particular, SSAN (Xu et al., 2021) encoded entity dependencies into the self-attention mechanism to strengthen context and entity reasoning. ATLOP (Zhou et al., 2021) employed the multi-head attention weights to generate entity-related context representations which enhanced the embeddings of entity pairs. To better address the multi-label classification problem, both ATLOP (Zhou et al., 2021) and NCRL (Zhou and Lee, 2022) proposed to treat the NA class as an adaptive threshold. DocuNet (Zhang et al., 2021) and KD-DocRE (Tan et al., 2022a) extended the ATLOP architecture by increasing interactions between entities and incorporating knowledge distillation, respectively. Besides, other DocRE models attempted to leverage auxiliary information for relation prediction, such as meta dependency paths (Nan et al., 2020), external knowledge bases (Li et al., 2021a), and evidences (Xie et al., 2022; Xiao et al., 2022). We additionally provide detailed comparison with existing works in Section 3.3.

Other related works Entropy Minimization technique was commonly seen in semi-supervised learning works (Grandvalet and Bengio, 2004; Vu et al., 2019). However, we are the first to employ entropy minimization in the challenging multi-label supervised learning framework. Besides, our entropy minimization takes effect in each customized probability distribution of the relation label and threshold class, which will encourage a larger distinction between them.

Supervised contrastive learning (SCL) (Khosla et al., 2020) extends self-supervised contrastive learning (He et al., 2020; Chen et al., 2020) to the fully supervised setting by constructing "positive" and "negative" examples based on their labels. ERICA (Qin et al., 2021) proposed a pre-training framework using contrastive learning to improve representations of entities and relations. However, this work samples positive pairs for relations proportionally to their total amount of examples, which will lead to biased optimization that favors primary relations over minor ones. Besides, they only maximize the similarity of one positive example pair each time, which may weaken the global effect of clustering. Instead, we give equal consideration to each relation and each positive example of anchors, and elaborately tailored the supervised contrastive learning to suit both the multi-label problem and long-tailed relation learning.

3 Methodology

In this section, we describe our model called PEM-SCL that is based on a **P**airwise moving-threshold loss, **E**ntropy **M**inimization, and **S**upervised **C**ontrastive **L**earning.

3.1 Problem Formulation

Let $D = \{w_l\}_{l=1}^{L}$ be a document containing L words and a set of entities $\mathcal{E}_D = \{e_i\}_{i=1}^{|\mathcal{E}_D|}$. Each entity e_i is associated with a set of mentions $\mathcal{M}_{e_i} = \{m_j^i\}_{j=1}^{|\mathcal{M}_{e_i}|}$ (i.e., a set of phrases referring to the same entity e_i). In document-level relation extraction, we predict the subset of relations in a pre-defined set $\mathcal{R} = \{r_k\}_{k=1}^{|\mathcal{R}|}$ that hold between each pair of entities $(e_h, e_t)_{h,t=1,\ldots,|\mathcal{E}_D|,h\neq t}$. We sometimes abbreviate an entity pair (e_h, e_t) as (h, t) to simplify notation. A relation is deemed to exist between the head entity e_h and tail entity e_t if it is expressed between any of their corresponding mentions. If no relation exists between any pair of their mentions, the entity pair is labeled `NA`. For each entity pair, we term a relation that holds between its constituent entities as *positive*, and the remaining relations in $\mathcal{R}$ as *negative*. An entity pair that is `NA` does not have any positive relation, and has the entire set $\mathcal{R}$ as negative relations (we could consider such a pair as having a special `NA` relation between them). Document-level relation extraction can be viewed as a multi-label problem, in which an entity pair corresponds to a training/test *example*, and the relations in $\mathcal{R} \cup \{\texttt{NA}\}$ correspond to the possible *labels* or *classes* of the example.

3.2 Encoder Model

We leverage ATLOP (Zhou et al., 2021) as our encoder since recent work (Xie et al., 2022; Zhou and Lee, 2022) has borne out its usefulness as a backbone in neural architectures. For each entity pair (e_h, e_t), the encoder model generates the entity pair representation $\boldsymbol{x}_{h,t} \in \mathbb{R}^{d_x}$, and its unnormalized score vector $\boldsymbol{f}_{h,t} \in \mathbb{R}^{|\mathcal{R}|+1}$ for relation prediction, we briefly describe them as follows[2]:

$$\boldsymbol{x}_{h,t} = \text{Encoder}\big((e_h, e_t)|D, \mathcal{M}_{e_h}, \mathcal{M}_{e_t}\big) \tag{1}$$

$$\boldsymbol{f}_{h,t} = \text{Linear}(\boldsymbol{x}_{h,t}) \tag{2}$$

3.3 Pairwise Moving-Threshold Loss with Entropy Minimization

In document-level relation extraction, a fixed probability threshold (e.g. a hyperparameter tuned on the development dataset) is used to decide the boundary of positive and negative relations. However, such a threshold is only suitable for entity pairs *on average*, and may not be ideal for entity pairs with particular properties.

To address this problem, we design a loss function that utilizes the NA class as a dynamic threshold, learning how best to *move* the threshold in accordance with the regularities present in each entity pair. Specifically, we conduct a *pairwise* comparison between each relation and the NA class (separately for each relation), and encourage the prediction scores of each positive relation to be higher than that of the NA class, and incentivize the score of the NA class to be higher than those of negative relations. In this way, we induce a *partial order* over $\mathcal{R} \cup \{\texttt{NA}\}$ for each entity pair. Note that the positive relations are not compared against each other, and their relative rankings are not modeled (likewise for negative relations). This makes sense in the multi-label setting where we are interested in finding the set of relations that are true without being concerned about their relative degrees of veracity.

Formally, we split the predefined relation set $\mathcal{R} = \mathcal{P}_{h,t} \cup \mathcal{N}_{h,t}$ into two mutually exclusive sets for each entity pair (h, t) in a training set, where $\mathcal{P}_{h,t}$ and $\mathcal{N}_{h,t}$ respectively denote the positive and negative relations of (h, t). As mentioned in Section 3.2, we make use of $\boldsymbol{f}_{h,t} \in \mathbb{R}^{|\mathcal{R}|+1}$ that is computed by Equation 1. We denote the elements of $\boldsymbol{f}_{h,t}$ that correspond to relation $r \in \mathcal{R}$ and to the NA class as f_r and f_η respectively. (Both f_r and f_η represent unnormalized prediction scores (logits).) Using f_r and f_η, we compute the probability that the label C of entity pair (h, t) is r (or η) *conditioned* on C being either r or η, i.e., $P_{h,t}(C = r|C = \{r, \texttt{NA}\})$ and $P_{h,t}(C = \eta|C = \{r, \texttt{NA}\})$ respectively, as follows.

$$P^r_{h,t}(r) = \frac{\exp(f_r)}{\exp(f_r) + \exp(f_\eta)},$$

$$P^\eta_{h,t}(r) = 1 - P^r_{h,t}(r) = \frac{\exp(f_\eta)}{\exp(f_r) + \exp(f_\eta)}, \tag{3}$$

where we have abbreviated $P_{h,t}(C = r|C = \{r, \texttt{NA}\})$ and $P_{h,t}(C = \eta|C = \{r, \texttt{NA}\})$ as $P^r_{h,t}(r)$ and $P^\eta_{h,t}(r)$ respectively.

Our *pairwise moving-threshold* loss $\mathcal{L}^{h,t}_{pmt}$ that maximizing the joint probability of all relations for an entity pair (h, t) is defined as:

$$\begin{aligned}
\mathcal{L}^{h,t}_{pmt} &= -\log\Big(\prod_{r \in \mathcal{P}_{h,t}} P^r_{h,t}(r) \prod_{r \in \mathcal{N}_{h,t}} (1 - P^r_{h,t}(r))\Big) \\
&= -\sum_{r \in \mathcal{P}_{h,t}} \log P^r_{h,t}(r) - \sum_{r \in \mathcal{N}_{h,t}} \log P^\eta_{h,t}(r) \\
&= \sum_{r \in \mathcal{P}_{h,t}} \log(1 + \exp(f_\eta - f_r)) \\
&+ \sum_{r \in \mathcal{N}_{h,t}} \log(1 + \exp(f_r - f_\eta)).
\end{aligned} \tag{4}$$

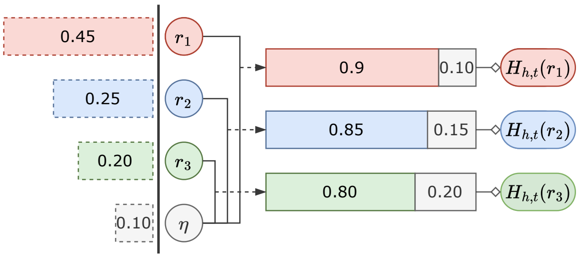

Figure 1: Each positive relation (colored rectangles with solid lines) exhibits a large probability difference from the threshold class (white rectangle with solid lines) when they are separately compared (like what is achieved with our $\mathcal{L}^{h,t}_{pmt}$ loss. We further expand this difference by minimizing $H(r)$ as stated in Eq. 5). However, the probabilities are diminished when each positive relation (colored rectangles with dashed lines) is made to compete with the other, reducing the disparity between the probability of each positive relation and that of the threshold class (white rectangle with dashed lines).

---

[2] Please refer to Appendix D for the computation details.

In Equation 4, note that the same threshold f_η is used for all $r \in \mathcal{R}$ for an entity pair (h, t). From the equation, we see that minimizing $\mathcal{L}_{pmt}^{h,t}$ equates to learning scores such that $f_r > f_\eta$ when r is a positive relation, and such that $f_\eta > f_r$ when r is negative relation. The (relative) scores for relations f_r and for the threshold f_η are fully learned from training data, and are tailored to individual entity pairs. Hence, they can better model the peculiarities specific to each entity pair.

Although previous work (Zhou et al., 2021; Tan et al., 2022a) employed a similar thresholding mechanism, they learn a *total order* for all relations (or a set of relations) and the threshold class. This wastes finite probability mass (total value of 1.0) in modeling the superfluous ordering among the relations that is not beneficial to multi-label problem, and inevitably diminishes the difference between the probability of each relation and that of the threshold. See Figure 1 for illustration.

Intuitively, a desirable trait of a loss function is that it reduces the uncertainty about whether a relation is positive or negative, thereby allowing its value to be discerned easily. To achieve this in a principled manner, we employ the principle of entropy minimization (Grandvalet and Bengio, 2005). Entropy minimization is typically used on unlabeled data in unsupervised or semi-supervised learning (Berthelot et al., 2020). In our case, we apply it on *labeled* data in a supervised setting. The information entropy for each pairwise probability distribution between relation r and the threshold class `NA` for entity pair (h, t) is defined as:

$$H_{h,t}(r) = -P_{h,t}^{r}(r)\log P_{h,t}^{r}(r) - P_{h,t}^{\eta}(r)\log P_{h,t}^{\eta}(r). \quad (5)$$

In Equation 5, information entropy decreases as the absolute difference between $P_{h,t}^{r}(r)$ and $P_{h,t}^{\eta}(r)$ increases, attaining a maximum when $P_{h,t}^{r}(r) = P_{h,t}^{\eta}(r) = 0.5$ and a minimum when either probability is 1.0 (and the other is 0.0). Thus, incorporating entropy into our loss function would help to accentuate the disparity between the pair $P_{h,t}^{r}(r)$ and $P_{h,t}^{\eta}(r)$ for all relations, making it easier to distinguish a positive (or negative) relation from the threshold `NA`.

We formulate our final pairwise moving-threshold loss with entropy minimization as follows:

$$\mathcal{L}_{em}^{h,t} = \frac{1}{\gamma_1} \sum_{r\in\mathcal{P}_{h,t}} H_{h,t}(r) + \frac{1}{\gamma_2} \sum_{r\in\mathcal{N}_{h,t}} H_{h,t}(r), \quad (6)$$

$$\mathcal{L}_1 = \sum_{(h,t)\in\mathcal{B}} \mathcal{L}_{pmt}^{h,t} + \mathcal{L}_{em}^{h,t}, \quad (7)$$

where $\mathcal{B}$ refers to a training batch, and $\gamma_1 = \{1, |\mathcal{P}_{h,t}|\}$ and $\gamma_2 = \{1, |\mathcal{N}_{h,t}|\}$ are hyperparameters weighting the effect of entropy minimization.

It is noted that using L_{pmt} on its own would lead to poor optimization for positive relations, in the situation where there is a preponderance of negative relations, the sum over $\mathcal{N}_{h,t}$ in Equation 4 might overwhelm the sum over $\mathcal{P}_{h,t}$ to such an extent that pushing f_η to a large value far above that of f_r for every negative relation r in order to minimize $\mathcal{L}_{pmt}^{h,t}$ (the same issue that also affects previous work (Zhou and Lee, 2022) without being properly addressed). Instead, our entropy minimization via $\mathcal{L}_{em}^{h,t}$ in Equation 6 provides a *principled* means to "balance" the sharp disparity between the probability of r and that of η across *all* relations. Empirically, $\mathcal{L}_{em}^{h,t}$ also demonstrates its efficacy in an ablation study (see Section 4.4.)

3.4 Supervised Contrastive Learning for Multi-Labels and Long-Tailed Relations

Rather than focusing only on sharpening the disparity of probability outputs as stated in Equation 7, we also seek to accentuate the disparities for the embeddings of entity pairs that are labeled with different relations. To do so, we take inspiration from supervised contrastive learning (Khosla et al., 2020) which aims to "pull" the embeddings of similar examples together, and "push" those of dissimilar examples apart.

However, the original supervised contrastive learning technique only deals with single-label data, and does not handle long-tail distributions. We have to introduce some novel modifications for it to work on our multi-label problem. We make use of the embedding $\boldsymbol{x}_{h,t}$ that is computed by Equation 1, and normalized it by L2 normalization before using it in the loss function below. After transplanting the loss function of supervised contrastive learning for our multi-label problem, we obtain the following loss function for an entity pair (h, t):

$$\mathcal{L}_{scl}^{h,t} = -\log\left\{\frac{1}{|\mathcal{S}_{h,t}|}\sum_{p\in\mathcal{S}_{h,t}} \frac{\exp(\boldsymbol{x}_{h,t}\cdot\boldsymbol{x}_p/\tau)}{\sum\limits_{d\in\mathcal{B},d\neq(h,t)} \exp(\boldsymbol{x}_{h,t}\cdot\boldsymbol{x}_d/\tau)}\right\}, \quad (8)$$

In Equation 8, $\mathcal{B}$ is a batch of examples (entity pairs) including (h, t). $\mathcal{S}_{h,t} \subseteq \mathcal{B}$ is such that each entity pair $p = (h', t')$ in $\mathcal{S}_{h,t}$ has at least one positive relation in common with (h, t), and p is termed a *positive* example of (h, t) (also $(h, t) \notin \mathcal{S}_{h,t}$). The *negative* examples of (h, t) are the remaining examples in the batch, i.e., $\mathcal{B} \setminus (\mathcal{S}_{h,t} \cup \{(h, t)\})$. The operator $\cdot$ refers to the dot product, and $\tau \in \mathbb{R}^+$ is a temperature parameter. To minimize $\mathcal{L}_{scl}^{h,t}$, we maximize the numerator in Equation 8 by learning embeddings for (h, t) and its positive examples that are close to each other (according to cosine similarity), and minimize the denominator by learning embeddings for (h, t) and its negative examples that are far apart.

Equation 8 would work for document-level relation extraction (DocRE) if not for the long-tail phenomenon that is typically present in DocRE datasets. For example, in the datasets used for our experiments, the top 10 relations account for about 60% of entity pairs in the dataset. Thus, we often find that an entity pair (h, t) with only long-tailed positive relations does not have any other entity pair in the same batch that has that relation in common, i.e., $|\mathcal{S}_{h,t}| = 0$. This means that Equation 8 could not be applied to such entity pairs. To take such an entity pair (h, t) into account, we design the following loss term:

$$\mathcal{L}_{lt}^{h,t} = \log \sum_{d \in \mathcal{B}, d \neq (h,t)} \exp(\boldsymbol{x}_{h,t} \cdot \boldsymbol{x}_d / \tau), \qquad (9)$$

in which we solely maximize the dissimilarities between the embedding of (h, t) and those of other entity pairs in the same batch $\mathcal{B}$. The final loss function for supervised contrastive learning is:

$$\mathcal{L}_2 = \sum_{(h,t) \in \mathcal{B}_\mathcal{P}} \mathbb{I}_{\{|\mathcal{S}_{h,t}| \neq 0\}} \mathcal{L}_{scl}^{h,t} + \mathbb{I}_{\{|\mathcal{S}_{h,t}| = 0\}} \mathcal{L}_{lt}^{h,t}, \quad (10)$$

where $\mathbb{I}_{\{\}}$ is an indicator function that takes the value of 1 if the condition in $\{\}$ is satisfied, and the value of 0 otherwise. In Equation 10, $\mathcal{B}_\mathcal{P} \subseteq \mathcal{B}$ is a subset of entity pairs in a batch that is labeled with at least one relation in $\mathcal{R}$. In other words, $\mathcal{B}_\mathcal{P}$ does not contain any entity pair that is labeled with the `NA` class (i.e., all relations in $\mathcal{R}$ are considered negative for the entity pair), since it does not make sense to minimize the embedding distance between two entity pairs that are labeled `NA`, and thus have no relation in common.

Combining Equations 7 and 10, we obtain the final loss function that is used for training our model:

$$\mathcal{L} = \mathcal{L}_1 + \lambda \mathcal{L}_2, \qquad (11)$$

where $\lambda \in \mathbb{R}^+$ is a hyperparameter.

3.5 Negative Label Sampling

As reported by recent works (Huang et al., 2022; Tan et al., 2022b), the DocRE benchmark suffers from the severe false-negative problem, which means that quite a few entity pairs previously labeled as `NA` class should have at least one relation label. Blithely ignoring this issue will greatly harm the performance of the method and cause ill-defined evaluation. To enhance the robustness of our method, we propose a novel negative label sampling strategy, which only samples a small fraction of negative relations for each entity pair with `NA` label when computing the loss function. We assume that the true relation labels for those false-negative examples are hard to be sampled from the massive negative relations, thus we could avoid erroneously treating the correct labels as negative relations in the loss function.

Let $\mathcal{B}_\mathcal{N} \subseteq \mathcal{B}$ denote the subset of all entity pairs that are labeled `NA` in a current batch $\mathcal{B}$. For each entity pair (h, t) in $\mathcal{B}_\mathcal{N}$, we uniformly sample a subset of negative relations $\mathcal{N}'_{h,t} \subseteq \mathcal{N}_{h,t}$, and define the following loss function:

$$\mathcal{L}' = \sum_{(h,t) \in \mathcal{B}_\mathcal{N}} \sum_{r \in \mathcal{N}'_{h,t}} -\log P^{\eta}_{h,t}(r) + \frac{1}{\gamma_2} \sum_{r \in \mathcal{N}'_{h,t}} H_{h,t}(r), \quad (12)$$

where $P^{\eta}_{h,t}(r)$ and $H_{h,t}(r)$ are defined in Equation 3 and Equation 5 respectively.

Let $\mathcal{B}_\mathcal{P} = \mathcal{B} \setminus \mathcal{B}_\mathcal{N}$ denote the subset of entity pairs in the current batch $\mathcal{B}$ that is labeled with at least one positive relation. Combining terms in Equations 7, 10, and 12, we obtain the final loss function $\mathcal{L}^{\texttt{NA}}$ that incorporates our sampling approach:

$$\begin{aligned} \mathcal{L}_1^{\texttt{NA}} &= \mathcal{L}' + \sum_{(h,t) \in \mathcal{B}_\mathcal{P}} \mathcal{L}_{pmt}^{h,t} + \mathcal{L}_{em}^{h,t}, \\ \mathcal{L}^{\texttt{NA}} &= \mathcal{L}_1^{\texttt{NA}} + \lambda \mathcal{L}_2. \end{aligned} \qquad (13)$$

Observe that $\mathcal{L}_1^{\texttt{NA}}$ has modified $\mathcal{L}_1$ (Equation 7) by changing the latter's sum over negative relations for entity pairs that are labeled `NA`. Also note that the loss $\mathcal{L}_2$ due to supervised contrastive learning remains unchanged in Equation 13 because it operates at the level of entities (specifically their embeddings) rather than at the level of relation labels.

Although previous papers (Li et al., 2021b, 2022) seem to adopt a similar negative sampling strategy, our approach has significant differences from them. The previous works sampled negative instances (i.e., entire entity pairs with `NA` labels in our case) and removed those unselected negative instances from the training dataset. In our approach, we sample negative *labels* of `NA` entity pairs, and do not discard any entity pairs, making our approach potentially more data efficient.

4 Experiments

4.1 Benchmark Description

DocRED (Yao et al., 2019) is a large-scale dataset constructed from Wikipedia and Wikidata, and is widely used as a benchmark for document-level relation extraction (DocRE). However, recent studies (Huang et al., 2022; Tan et al., 2022b) have found that many entity pairs (or examples) that are labeled `NA` are erroneous, and should be instead labeled with at least one positive relation in $\mathcal{R}$. To ameliorate this problem, Re-DocRED (Tan et al., 2022b) relabels the original training and development sets of DocRED and splits DocRED's development set into two equal halves as new development and test sets, respectively. Instead of comparing models on the faulty DocRED dataset, the results on Re-DocRED should be regarded as a fair comparison.

4.2 Two New Data Regimes

To evaluate the models in a more realistic experimental setting in which their resilience to noisy data is carefully tested, we propose two new data regimes, OOG-DocRE and OGG-DocRE, that are based on the above DocRED and Re-DocRED benchmarks. Every "O" represents the **O**riginal labels obtained from the original unclean, noisy DocRED dataset; similarly, every "G" represents the **G**old labels in the new, cleaned Re-DocRED dataset. Each letter in "OOG" and "OGG" represent different sources of labels for training, validation, and testing, respectively. Both regimes reflect the real-world scenario where training data is noisy, and manual effort can only be expended on cleaning a relatively small validation/test set. All models are trained and tuned only on the training and validation sets respectively, and evaluated on the test set. Note that in both regimes the cleaned training set from Re-DocRed is not used. Table 1 contains details about the datasets.

Dataset	**Train** #Doc / #Example	**Dev** #Doc / #Example	**Test** #Doc / #Example
DocRED	3,053 / 1,198,650	1,000 / 396,790	1,000 / 392,158
Re-DocRED	3,053 / 1,193,092	500 / 193,232	500 / 198,670
Our new data regimes			
OOG-DocRE	3,053 / 1,198,650	500[3]/ 195,682	500 / 198,670
OGG-DocRE	3,053 / 1,198,650	500 / 193,232	500 / 198,670

Table 1: Dataset statistics. We construct two new data regimes based on the **O**riginal labels from DocRED and **G**old labels from Re-DocRED. The total number of predefined relation labels for all datasets is 96 (i.e., $|\mathcal{R}| = 96$).

4.3 Results on DocRE Benchmarks

From Table.2, we see that our PEMSCL model performs the best on both development and test sets of the original DocRED dataset and the cleaned Re-DocRED dataset (the models are trained on their corresponding training sets). It is worth noting that the results among recent models (e.g., DocuNet, KD-DocRE, NCRL) are almost indistinguishable on DocRED (see Appendix C), especially after considering their standard deviations. However, the performance gaps between models become significant when we validate and test on the Re-DocRED dataset. This strongly suggests that the original DocRED's (overly erroneous) development and test sets cannot truly ascertain the performance differences between models. In contrast, the cleaned version Re-DocRED provides a more faithful comparison of the models. Henceforth, we analyze model performances based solely on Re-DocRED's development and test sets.

Compared with ATLOP (upon which our model is developed), our PEMSCL model achieves around a 3-point improvement in terms of both Ign F_1 and F_1 scores on Re-DocRED's development and test sets. When compared against the recent strong baseline NCRL, our PEMSCL model continues to do better, achieving about a 1-point improvement in terms of F_1 score on Re-DocRED's development set. After taking the standard deviations into account, the results still show that PEMSCL outperforms NCRL. In sum, the above results demonstrate the effectiveness of our proposed model, and ascertain that it has achieved new state-of-the-art performances.

4.4 Ablation Study

In addition to the main metrics F_1 and Ign F_1, we also report the F_1 scores for different types of relations. We first rank in descending order all pre-

Table 2: Results on DocRED and Re-DocRED. Ign F_1 stands for the F1 score excluding relational facts in the training set. Results for baseline models on the test and dev set of DocRED are taken from their original papers. The results on RE-DocRED for NCRL and ATLOP + BCE (Zhou and Lee, 2022) (i.e., marked with *) are reproduced by us with their default code[4] and our implementation, respectively; other results of baselines on Re-DocRED are taken from (Tan et al., 2022b). We report the mean and standard deviation on the development set of 5 runs with different random initialization for our PEMSCL model and the reproduced baselines, and report the test scores using the best-performing model on the development set. For implementation details, please refer to Appendix A.

Model	Dev Ign F_1	Dev F_1	Head F_1	Mid F_1	Tail F_1
Ours	**79.02**	**79.89**	**82.99**	**75.70**	**63.51**
– $\mathcal{L}_{em}^{h,t}$	78.38	79.17	82.35	74.75	62.35
– $\mathcal{L}_2$	78.36	79.10	82.40	74.50	62.22
– $\mathcal{L}_{em}^{h,t}$ and $\mathcal{L}_2$	77.92	78.63	81.92	74.06	61.16

Table 3: Ablation study of our PEMSCL model on Re-DocRED. "–" represents the removal of our model's components. We also report the F_1 scores for the top 10 relations (Head F_1), the middle 70 relations (Mid F_1), and the last 20 relations (Tail F_1) ranked by the number of entity pairs that are related by them. The mean result of 3 runs with different random initialization on the development set of Re-DocRED are reported.

defined relations by the number of entity pairs that are labeled with them. Next, we classify them into three categories: *head* relations (the top 10 relations, accounting for 64% of Re-DocRED's training data), *tail* relations (the bottom 20 relations, accounting for 2% of training data), and *middle* relations (the remaining relations).

From Table 3, we see that each component plays a pivotal role in the effectiveness of our PEMSCL model – removing a component or a combination of them compromises performance. Removing the $\mathcal{L}_{em}^{h,t}$ and $\mathcal{L}_2$ components individually results in a performance decline of 0.90% and 0.99% in terms of F_1 score respectively. When either of these two components is removed, we see a sharper decline in terms of Tail F_1 (1.82% and 2.03%) than in terms of Head F_1 (0.77% and 0.71%). This shows that both components are useful for long-tailed relations, and highlights the effectiveness of $\mathcal{L}_2$, part of which is designed to cater to long-tailed relations. After removing both $\mathcal{L}_{em}^{h,t}$ and $\mathcal{L}_2$ together, the performances on Head F_1, Mid F_1, and Tail F_1 all significantly drop by 1.29%, 2.17%, and 3.70% respectively. Even with only one loss term remaining (i,e, $\mathcal{L}_{pmt}^{h,t}$), our EMSCL model still surpasses the baseline ATLOP on Re-DocRED in Table 2 by 1.3% on Dev F_1, reflecting the usefulness of our pairwise moving-threshold loss.

4.5 Results on New Data Regimes

Table 4 shows the performance of our PEMSCL model and baselines on our proposed data regimes: OOG-DocRE and OGG-DocRE. We select NCRL as a focal baseline from among the recent baselines

Table 4: Results on two new data regimes. The best results are **bolded**, and the second best results are underlined. PEMSCL† refers to our best-performing model on the development set after using our proposed negative label sampling strategy (Section 3.5). The sampling ratio of 0.1 is set with a development set.

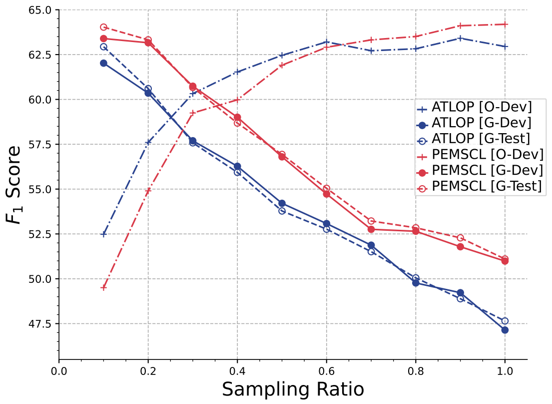

Figure 2: The effect of negative label sampling ratio in the OOG-DocRE regime.

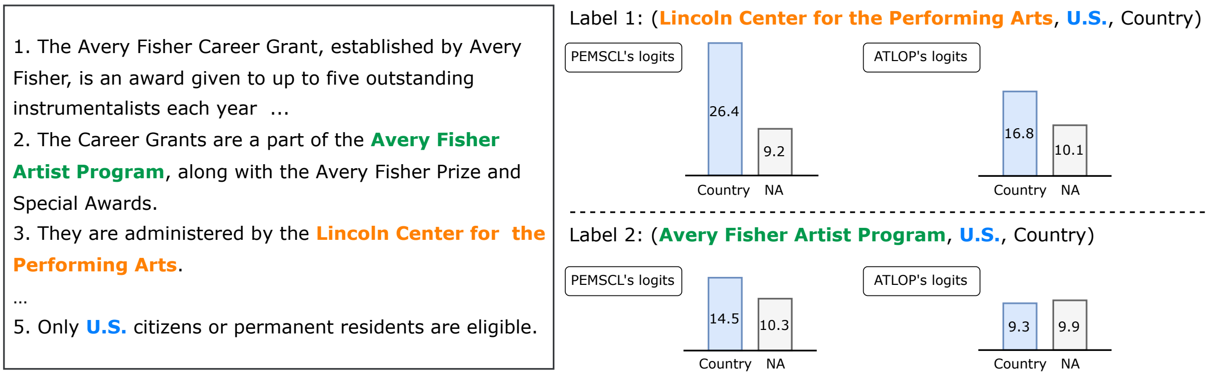
due to its competitive performance on Re-DocRED. We see that all models perform above 62-point F_1 on Orig-Dev (the original development set from DocRED) when trained on the original training dataset. However, when we evaluate all models on Gold-Dev and Gold-Test (the clean development and test sets from Re-DocRED), the performances of the models (including ours) dramatically decrease by around 15-point F_1 on both Gold-Dev and Gold-Test. Upon inspection, we find that the models misclassify a lot of positive examples (entity pairs) as `NA`, which is an expected outcome of being misguided by the erroneous false-negative labels in DocRED.

However, after using our proposed negative label sampling loss (Equation 13), our PEMSCL model exhibits tremendous improvement on both Gold-Dev and Gold-Test by 24% and 25% on the F_1 scores respectively. This demonstrates the effectiveness of our negative label sampling strategy in countering the noise present in entity pairs that are labeled `NA`. The same conclusion can be drawn from the results for the OGG-DocRE regime. Moreover, we notice that both ATLOP and NCRL improve by at least 1-point F_1 on the OGG regime compared with the OOG regime. This demonstrates the usefulness of gold labels even in a small amount. However, our model performs comparably on both regimes, indicating the stability of our model in different regimes.

We also investigate the effect of the sampling ratio on our proposed strategy. The sampling ratio refers to the ratio of negative labels that we keep during the training for each entity pair that is labeled `NA`. We apply our negative label sampling approach on both ATLOP and our PEMSCL model. As seen from Figure 2, PEMSCL consistently performs better than ATLOP by a clear margin. We also find that the performances of the models on Gold-Dev and Gold-Test gradually decrease as the sampling ratio is increased. This is because as we keep more (purportedly) negative labels in our loss function, the risk of wrongly penalizing potentially true labels increases concomitantly.

We observe that the sampling ratio has the opposite effect on Orig-Dev. As the sampling ratio increases, the F_1 on Orig-Dev increases, leading one to mistakenly conclude that a large sampling rate should be used. This provides strong evidence of the poor data quality in DocRED, and shows



1. The Avery Fisher Career Grant, established by Avery Fisher, is an award given to up to five outstanding instrumentalists each year ...

Figure 3: Case Study.

how it can misguide training and lead to poor results. The results on the OGG-DocRE regime are similar (see Appendix B for details).

4.6 Case Study

Figure 3 shows a case study of our proposed PEMSCL model and the baseline ATLOP model. We can see that for the entity pair (*Lincoln Center for the Performing Arts*, *U.S.*), both models successfully detect the correct relation label, i.e., `Country`. However, the logit difference between the `Country` relation and the threshold label `NA` in our model is much larger than that of the ATLOP model (26.4-9.2 > 16.8-10.1). This demonstrates that our model is capable of learning a more differentiated distribution of the final probability scores. For the entity pair of (*Avery Fisher Artist Program*, *U.S.*), the ATLOP model fails to correctly predict its label and classifies it as `NA` class since the logit of `Country` is lower than that of the threshold class (9.3 < 9.9). However, our model not only correctly predicts its correct label, but also maximizes the discriminability of the prediction scores (14.5 vs 10.3).

5 Conclusions

In this paper, we propose a novel method for DocRE problem called PEMSCL, which contains a pairwise moving-threshold loss with entropy minimization, adapted supervised contrastive learning, and a novel negative sampling strategy, to achieve good integration of both discriminability and robustness. Experimental results show that our method achieves new state-of-the-art results.

Limitations

First, we require a large amount of GPU resources to conduct our experiments because we deal with large document-based datasets (whose input text is significantly longer than those of traditional sentence-level tasks). Second, we implement our model on two large pre-trained language models, Roberta-large (Liu et al., 2019) and Deberta-large (He et al., 2021), both of which also have a large GPU footprint. Third, the performance of our adapted supervised contrastive learning component is dependent on GPU batch size (a larger batch size allows more contrastive examples to be used to learn better embeddings).

A Implementation Details

We mainly implement our method using the pre-trained RoBERTa-large (Liu et al., 2019) as the encoder model. Due to limited computational resources, we only use a larger model DeBERTa-large (He et al., 2021) on the DocRED benchmark. We conduct grid search for the temperature parameter τ and the loss coefficient λ ($\{0.1, 0.2, 0.5, 1.0, 2.0\}$), learning rate ($\{1e\text{-}5, 2e\text{-}5, 3e\text{-}5\}$), and warmup ratio of optimizer ($\{0.02, 0.06, 0.10\}$). We implement our model in the PyTorch version of Huggingface Transformers[5], and run all experiments on a NVIDIA Quadro RTX 8000 GPU. The best hyperparameters used in our experiments are shown in Table5.

B The Effect of Sampling Ratio on the OGG- DocRE Setting

We analyze the effect of the negative label sampling ratio in the OGG-DocRE regime, which is shown in Figure 4. It presents a similar pattern with that of the OOG-DocRE regime as described in Section 4.5.

C Results on the DocRED Dataset

We provide the results of RoBERTa-large based models on DocRED in Table 6 for a complete comparison. However, these results can not reflect a faithful performance comparison due to the preponderance of erroneous labels in the DocRED dataset. Instead, the results on the Re-DocRED dataset should be taken as a reliable fair comparison.

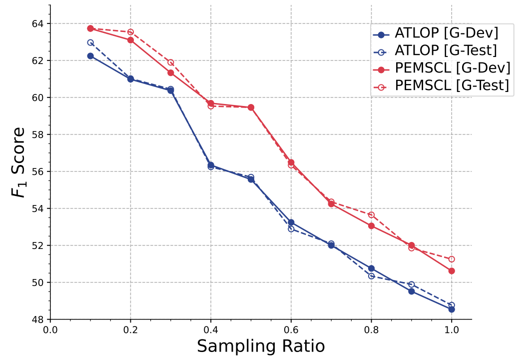

Figure 4: The effect of negative label sampling ratio in the OGG-DocRE regime.

D Background: ATLOP Encoder

For every document, the encoder model first marks each entity mention with a special token "*" at its start and end positions, and then feeds the resulting document $D = \{w_l\}_{l=1}^{L}$ into a pre-trained language model (PLM) to obtain contextual embeddings for each of the document's L tokens: $\mathbf{H} = [\boldsymbol{h}_1, \dots, \boldsymbol{h}_L] = \text{PLM}([w_1, \dots, w_L])$ where $\boldsymbol{h}_l \in \mathbb{R}^d$. ATLOP regards the embedding of "*" at the start position of mention m_j^i as its representation, i.e., $\boldsymbol{h}_{I(m_j^i)}$, where $I(.)$ is a function mapping a mention m_j^i to the index of its representative "*" in $\mathbf{H}$. Next, the embedding $\boldsymbol{h}_{e_i} \in \mathbb{R}^d$ of each entity e_i is obtained with logsumexp pooling:

$$\boldsymbol{h}_{e_i} = \log \sum_{j=1}^{\mathcal{M}_{e_i}} \exp\left(\boldsymbol{h}_{I(m_j^i)}\right).$$

For each entity pair (e_h, e_t), ATLOP uses the token-level dependencies present within its multi-head self-attention mechanism to compute a *localized contextual* embedding $\boldsymbol{c}_{h,t} \in \mathbb{R}^d$, capturing the contextual information that is relevant to *both* entities e_h and e_t. Due to space constraints, we refer readers to Zhou et al. (2021) for details on how $\boldsymbol{c}_{h,t}$ is computed.

For each entity pair (e_h, e_t), the encoder will generate the final representation $\boldsymbol{x}_{h,t}$ for the pair, and its corresponding vector of unnormalized prediction scores $\boldsymbol{f}_{h,t} \in \mathbb{R}^{|\mathcal{R}|+1}$ for all relations in $\mathcal{R} \cup \{\texttt{NA}\}$ as follows:

$$[\boldsymbol{z}_h^1; \dots; \boldsymbol{z}_h^P] = \boldsymbol{z}_h = \tanh\left(\boldsymbol{W}_h \boldsymbol{h}_{e_h} + \boldsymbol{W}_{c_1} \boldsymbol{c}_{h,t}\right),$$

$$[\boldsymbol{z}_t^1; \dots; \boldsymbol{z}_t^P] = \boldsymbol{z}_t = \tanh\left(\boldsymbol{W}_t \boldsymbol{h}_{e_t} + \boldsymbol{W}_{c_2} \boldsymbol{c}_{h,t}\right),$$

$$\boldsymbol{x}_{h,t} = ||_{p=1}^{P} (\boldsymbol{z}_h^p \otimes \boldsymbol{z}_t^p), \tag{14}$$

$$\boldsymbol{f}_{h,t} = \boldsymbol{W}_o \boldsymbol{x}_{h,t} + \boldsymbol{b}_o, \tag{15}$$

where $\boldsymbol{z}_h, \boldsymbol{z}_t \in \mathbb{R}^{d_1}$ are split into P equal-sized groups $[\boldsymbol{z}_h^1; \ldots; \boldsymbol{z}_h^P]$ and $[\boldsymbol{z}_t^1; \ldots; \boldsymbol{z}_t^P]$ respectively; $\boldsymbol{W}_{\{h,t,c_1,c_2\}} \in \mathbb{R}^{d_1 \times d}$, $\boldsymbol{W}_o \in \mathbb{R}^{(|\mathcal{R}|+1) \times d_x}$, $\boldsymbol{x}_{h,t} \in \mathbb{R}^{d_x}$ ($d_x = \frac{d_1 \times d_1}{P}$), and $\boldsymbol{b}_o \in \mathbb{R}^{|\mathcal{R}|+1}$ are *learnable* parameters (in our model too); $\otimes$ is the outer product operator; and the operators ; and $||$ respectively represent the concatenation of vectors and matrices. The elements in $\boldsymbol{f}_{h,t}$ are logits that our model feeds pairwise into (not necessarily the same) softmax functions to obtain relative probabilities between relations (Section 3.3).

Penguins Don't Fly:
Reasoning about Generics through Instantiations and Exceptions

Abstract

Generics express generalizations about the world (e.g., birds can fly) that are not universally true (e.g., newborn birds and penguins cannot fly). Commonsense knowledge bases, used extensively in NLP, encode some generic knowledge but rarely enumerate such exceptions and knowing when a generic statement holds or does not hold true is crucial for developing a comprehensive understanding of generics. We present a novel framework informed by linguistic theory to generate EXEMPLARS—specific cases when a generic holds true or false. We generate ~19k exemplars for ~650 generics and show that our framework outperforms a strong GPT-3 baseline by 12.8 precision points. Our analysis highlights the importance of linguistic theory-based controllability for generating exemplars, the insufficiency of knowledge bases as a source of exemplars, and the challenges exemplars pose for the task of natural language inference.

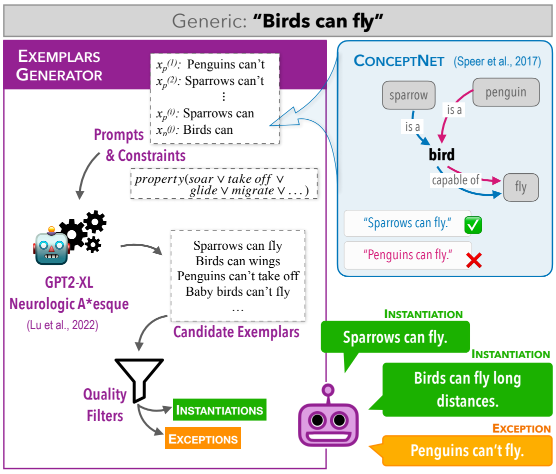

Figure 1: We present **EXEMPLARS generator**: given a generic like "Birds can fly" it generates truthful statements where the generic does (INSTANTIATIONS) and does not (EXCEPTIONS) hold. We extract commonsense knowledge (e.g., from ConceptNet (Speer et al., 2017)) in linguistically-informed prompts and constraints for constrained generation (Lu et al., 2022). We use trained discriminators to filter for quality.

1 Introduction

Generics express generalizations (e.g., birds can fly) that allow humans to reason and act with incomplete world knowledge (Asher and Morreau, 1995). Generics allow us to draw plausible inferences about individuals (e.g., Polly is a bird, so Polly can fly) *even when we know of counterexamples* (e.g., penguins cannot fly). Despite the utility of generalizations, knowledge of counterexamples is necessary for modeling generics and effectively reasoning with them in computational systems.

Recent studies of generics (e.g., Bhagavatula et al., 2022; Bhakthavatsalam et al., 2020) and commonsense KBs (e.g., Speer et al., 2017) provide repositories of generic knowledge. However, these resources rarely mention EXCEPTIONS (i.e., counterexamples) or INSTANTIATIONS (i.e., cases where the generic holds); collectively EXEMPLARS. For systems using these resources as a source of world knowledge, such incomplete information can lead to incorrect deductions (e.g., if Polly is a penguin, which is a bird, then inferring that Polly can fly because birds can fly is false[1]). Therefore, we propose a novel computational framework that operationalizes linguistic theories in order to automatically generate EXEMPLARS.

In our work, we unify two distinct linguistic theories and use linguistic theory-guided decoding to generate EXEMPLARS. Although large-scale neural language models such as GPT-3 (Brown et al., 2020) have been increasingly successful in few-shot text generation tasks, such generation is both expensive and not easily controllable. Therefore, we instead use the constrained generation algorithm Neurologic A*esque (Lu et al., 2022), which can be applied to any auto-regressive language model; we choose to use GPT-2 (Radford et al., 2019).

---

[1] penguin is a bird $\land$ birds can fly $\implies$ penguins can fly

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2618–2635
May 2-6, 2023 ©2023 Association for Computational Linguistics

In this manner, we generate 12562 INSTANTIATIONS and 6297 EXCEPTIONS for ∼650 generic statements from Bhagavatula et al. (2022). We conduct human evaluation of the generations and show that our system outperforms few-shot generation by GPT-3 by 12.8 precision points. Our analyses demonstrate not only the importance of linguistic modeling for generating EXEMPLARS and the insufficiency of KBs as a source of EXEMPLARS, but also the challenges EXEMPLARS pose for natural language reasoning.

Our contributions are as follows: **(1)** we present a novel framework grounded in linguistic theory for representing generics and their EXEMPLARS, **(2)** we present the first method to automatically generate generic EXEMPLARS and show it outperforms a competitive baseline based on GPT-3 and **(3)** we present analysis showing the importance of explicit linguistic modeling for this task and the insufficiency of current NLI methods for generics. Our system and data are publicly available[2].

2 Related Work

Theory Generics have been studied extensively in semantics, philosophy, and psychology to develop a single logical form for all generics (Lewis and Keenan, 1975; Carlson, 1977, 1989; Krifka, 1987) or a probabilistic definition (Cohen, 1996, 1999, 2004; Kochari et al., 2020), categorize generics (Leslie, 2007, 2008; Khemlani et al., 2009), and analyze specific types (Prasada and Dillingham, 2006, 2009; Haward et al., 2018; Mari et al., 2012; Krifka et al., 2012). Mechanisms to tolerate EXCEPTIONS have also been proposed (Kadmon and Landman, 1993; Greenberg, 2007; Lazaridou-Chatzigoga and Stockall, 2013) but these are primarily theoretical and use carefully chosen examples. In contrast, our work combines these EXCEPTION tolerance mechanisms with generic categorization and proposes a novel, large-scale, computational framework for EXEMPLARS.

Commonsense Knowledge While large-scale CKBs capture a range of commonsense knowledge (Speer et al., 2017; Sap et al., 2019; Forbes et al., 2020; Hwang et al., 2021), they contain necessarily incomplete (i.e., the open-world assumption (Reiter, 1978b)) *general* knowledge. Furthermore, although recent works have created KBs specifically of generics (Bhakthavatsalam et al., 2020; Bhagavatula et al., 2022) and proposed methods to identify generics in text (Friedrich et al., 2015, 2016), they do not identify or model EXEMPLARS. In our work, we focus directly on automatically generating EXEMPLARS, providing richer commonsense knowledge.

The application of generics to specific individuals is influenced by prototypicality (Rips, 1975; Osherson et al., 1990), with small sets of prototypical norms collected in cognitive science for a range of kinds (Devereux et al., 2014; McRae et al., 2005; Overschelde et al., 2004). However, recent work has shown that neural models have only moderate success at mimicking human prototypicality (Misra et al., 2021; Boratko et al., 2020) or producing commonsense facts without guidance (Petroni et al., 2019). Hence, we combine neural models with a KB of concepts, using linguistic-theory-guided decoding, to generate generics EXEMPLARS.

Reasoning Reasoning with generics is closely related to non-monotonic reasoning (Ginsberg, 1987b,a); specifically default inheritance reasoning (Brewka, 1987; Hanks and McDermott, 1986; Horty and Thomason, 1988; Imielinski, 1985; Poole, 1988; Reiter, 1978a, 1980). Contrary to the proposed solutions for linguistic tests on default inheritance reasoning (Lifschitz, 1989, e.g.,can a conclusion about inheritance be inferred based on provided evidence?), later works showed that the presence of generics EXEMPLARS in the evidence impacts what humans perceive as the correct answer (Elio and Pelletier, 1996; Pelletier and Elio, 2005; Pelletier, 2009). These results highlight the importance of identifying generics and accurately modeling their relationships in machine reasoning.

While natural language inference (NLI), a form of deductive reasoning well-studied in NLP (i.a., Dagan et al. (2013); Bowman et al. (2015)), captures notions of inference, studies on non-monotonic reasoning and NLI are limited (Wang et al., 2019; Cooper et al., 1994; Yanaka et al., 2019b,a; Rudinger et al., 2020) and do not include default inheritance reasoning. Therefore, in this work we analyze the interactions between generics EXEMPLARS and NLI and highlight the importance of modeling this relationship in machine reasoning.

3 Framework for EXEMPLARS

A generic statement describes a *relation* between a *concept* and a *property*. Usually, a **concept** K is a type or kind (e.g., bird) while a **property** P

---

[2] `https://github.com/emilyallaway/generics-exemplars`

Category	Generic (G)	INSTANTIATION	EXCEPTION
(a) quasi-def	"Stars produce radiation"	"The sun produces radiation"	"Stars produce light"
	$K(x) \land r(x,y) \implies P(y)$	$K(x) \land r(x,y) \land P(y)$	$K(x) \land r(x,y) \land \not\sim P(y)$
(b) principled	"Birds can fly"	"Owls can fly"	"Penguins can't fly"
	"Sharks attack swimmers"	"Threatened sharks attack swimmers"	"Sharks don't attack swimmers in the shallows"
	$K(x) \land P(y) \implies r(x,y)$	$K(x) \land r(x,y) \land P(y)$	$K(x) \land \neg r(x,y) \land P(y)$
(c) characterizing	"Cars have radios"	"2014 Prius model C has a radio "	"Cars have CD Players"
	L_G is ambiguous	$K(x) \land r(x,y) \land P(y)$	$K(x) \land r(x,y) \land \not\sim P(y)$
			"Newer cars don't have radios"
			$K(x) \land \neg r(x,y) \land P(y)$

Table 1: We define three categories of generics with their EXEMPLARS. The logical forms for the generic (L_G) and its EXEMPLARS are also below the examples. Using these categories we formulate templates for generating EXEMPLARS (see Table 2). K is the concept (blue), P the property (pink). See §3.3 for exoproperty $\not\sim P$.

is an ability (e.g., fly) or quality (e.g., feathered). Note that statements containing explicit quantification (e.g., "*Most* birds can fly") are generally *not* considered generics (Carlson, 1977; Krifka et al., 1995) and are therefore excluded from this study (see §A.1 for further discussion).

In our framework, we first categorize (§3.1) generics and derive their logical forms (§3.2). These logical forms for generics serve as our basis for formulating EXEMPLARS (§3.3) and designing templates suitable for generation (§3.4).

3.1 Generic Category Definitions

We categorize a generic based on the type of property it describes. In particular, by unifying theories from linguistics and philosophy[3], we split generics into three categories (see examples in Table 1). A generic has a particular category if:

(a) **Quasi-definitional**: the property is essential to a concept (Khemlani et al., 2009).

(b) **Principled**: the property has a strong association with the concept. This includes both properties with a principled association to a concept (e.g., flying is viewed as inherent to birds, although it is not essential in reality) (Prasada and Dillingham, 2006, 2009; Haward et al., 2018) and properties that are uncommon and often dangerous (Leslie, 2017).

(c) **Characterizing (char.)**: there is only a non-accidental relationship between the property and concept (e.g., based only on absolute or relative prevalence among concepts) (Leslie, 2007, 2008).

3.2 Logical Forms for Generics

We propose logical forms L_G that are used to represent an individual generic G. **Each generic category has a distinct logical form** (see Table 1). For quasi-definitional generics, since the property is defining we assert that the property is logically implied by the concept and relationship together (i.e., $K \land r \implies P$). In contrast, for principled generics we assert that the concept and property together logically imply the relationship (i.e., $K \land P \implies r$). Finally, for characterizing generics, the logical form depends on whether the generic is interpreted as quasi-definitional or principled. Logical forms with examples are shown in Table 1. Note that in a logical L_G, the concept K (property P) is satisfied by *both an individual or subtype* of K (P)[4].

3.3 Constructing EXEMPLARS

We now define generics EXEMPLARS, deriving them from the logical form of a generic.

INSTANTIATIONS For a generic, INSTANTIATIONS are contextually relevant **members of the concept with the desired property**. Formally,

Definition (INSTANTIATIONS)**.** *An* INSTANTIATION *satisfies* L'_G *(i.e.,* L_G *with implication replaced by conjunction*[5]*).*

For example, if we have

$$L_G\text{: }\textsc{Bird}(x) \land \textsc{Fly}(y) \implies \textit{can}(x,y)$$

$$\text{so, } L'_G\text{: }\textsc{Bird}(x) \land \textsc{Fly}(y) \land \textit{can}(x,y)$$

then (x, y) = ("owls", "fly") satisfies L'_G. Note that **INSTANTIATIONS all have the same logical form** regardless of the generic category (see Table 1).

---

[3] Description of the theories is provided in §A.2

[4] For example, $\textsc{Bird}(x)$ is true for x_1 ="my parrot", x_2 ="owls", and x_3 ="these birds" since all *are* birds.

[5] Replacing the implication with a conjunction excludes instances which satisfy L_G by satisfying *only* the right side of the implication (e.g., $\textsc{Bird}(x) \land \textsc{Fly}(y) \implies \textit{can}(x,y)$ is logically true for (x,y) = (airplanes, fly) but this is not a valid INSTANTIATION).

EXCEPTIONS An EXCEPTION counters one of two interpretations of the generic (see §A.3 for an in-depth discussion). EXCEPTIONS are members of the concept either **(i)** ***without* the generic property** (Greenberg, 2007) or **(ii)** ***with* an alternative property** (i.e., **exoproperty**) when the generic property is essential to the concept. For example, "penguins can't fly" (for the generic "birds can fly") counters the interpretation that "*all* birds can fly". In contrast, "stars produce light" (for the generic "stars produce radiation") counters the interpretation that "stars produce *only* radiation". Note that in the latter case, there are no specific stars that do not produce radiation. More formally,

Definition (EXCEPTIONS)**.** *An* EXCEPTION *satisfies the logical form* $\nsim L_G$ *(i.e.,* $\neg L_G$ *where* $\neg P$ *replaced by* $\nsim P$ *when applicable). We define* $\nsim \boldsymbol{P}$ ***as the exoproperty** of* P*: a property adjacent to* P *that is **not*** P *but **is** contextually relevant to* P.

For example, if the logical form L_G is

$$\textsc{Star}(x) \wedge \mathit{produce}(x, y) \implies \textsc{Radiation}$$

then $\nsim L_G$ is

$$\textsc{Star}(x) \wedge \mathit{produce}(x, y) \wedge \nsim\textsc{Radiation}(y)$$

and so (x, y) = ("stars", "light") satisfies $\nsim L_G$, while (x, y) = ("stars", "movies") does not. Notice that the latter pair is invalid because "movies" is not a relevant alternative to "radiation" since it is not informative about the generic.

Since a generic's EXCEPTIONS depend on its logical form L_G, they are also dependent on the generic's category (see Table 1). In particular, the EXCEPTIONS for quasi-defintional generics are individuals with alternative properties (since the property is viewed as essential) while for principled generics the EXCEPTIONS are individuals without the generic property. EXCEPTIONS for characterizing generics are, like the logical forms, dependent on the generic's interpretation (see §3.2)

3.4 Logical Forms to Templates

Based on our proposed formulae (Table 1) for EXEMPLARS we define seven templates for generation (Table 2). Each template expresses a set of instances that satisfy the logical form of an EXEMPLAR. Each template has two sets of content specifications: for the *input* and for the *completion* (i.e., the decoder output).

For **INSTANTIATIONS, we define three templates** with subtypes of the concept, property, or both. For **EXCEPTIONS we have four templates,** using subtypes of either the concept *or* property (but not both) in order to avoid irrelevant or uninformative instances. For example, for the generic "Birds can fly", the sentence "Penguins can't fly long distances" (which has subtypes of both the concept and property) is *uninformative* because it doesn't mean penguins can't fly *in general* (e.g., they might still be able to fly short distances).

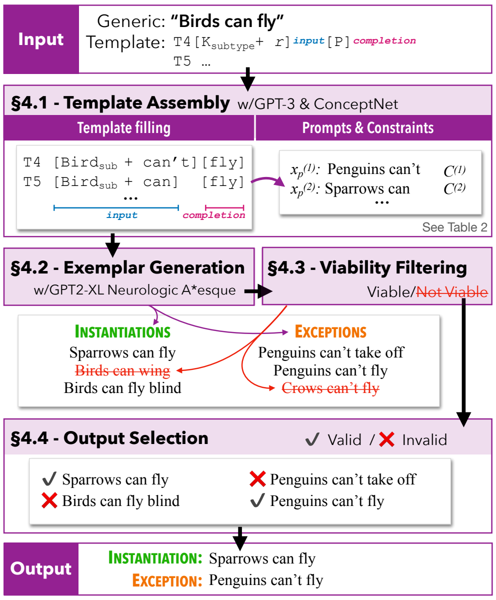

Figure 2: Overview of our method for an input generic.

4 Methodology

We propose a pipeline system to automatically generate generics EXEMPLARS. Our system takes as input a generic G and the templates derived from its category[6] (§3.4), and outputs a set of generated EXEMPLARS (Fig. 2). First, the system **assembles** and populates the templates according to the input generic (§4.1, Fig. 2). Then, the filled templates are converted into prompts and constraints that control the **generation** decoding process (§4.2). Finally, the output is **filtered** to remove non-viable (§4.3, Fig. 2) or irrelevant (§4.4, Fig. 2) EXEMPLARS.

4.1 Template Assembly

To populate our templates (defined in Table 2), we use a dependency parser[7] to identify the text spans of the concept, relation, and property in a generic. Then, **(i) we extract subtypes** for the concept and property and use these to construct the **(ii)** input i.e., generation prompts x_p) and **(iii)** completion (i.e., lexical constraints $\mathcal{C}$) specifications.

---

[6] We assume the generic's category is known.

[7] `https://spacy.io/`

Categories		Template		Example			
		input	*comp.*	Generic	Prompt x_p	Constraints $\mathcal{C}$	
EXCEP.	quasi-def & char	$\mathtt{K}$ + r	$\not\sim\mathtt{P}$	Stars produce radiation	"Stars *produce*"	$\neg$radiation $\wedge\neg$ x-rays $\wedge$ ...	`t1`
		$\mathtt{K}_{sub}$ + r	$\not\sim\mathtt{P}$		"Sun *produces*"	$\neg$radiation $\wedge\neg$ x-rays $\wedge$ ...	`t2`
	principled & char	$\mathtt{K}$ + $\neg r$	$\mathtt{P}_{sub}$	Birds can fly	"Birds *can't*"	migrate $\vee$ soar $\vee$ glide $\vee$...	`t3`
		$\mathtt{K}_{sub}$ + $\neg r$	$\mathtt{P}$		"Penguins *can't*"	fly $\vee$ flying $\vee$...	`t4`
INST.	all	$\mathtt{K}_{sub}$ + r	$\mathtt{P}$	Birds can fly	"Sparrows *can*"	fly $\vee$ flying $\vee$...	`t5`
		$\mathtt{K}$ + r	$\mathtt{P}_{sub}$		"Birds *can*"	migrate $\vee$ soar $\vee$ glide $\vee$...	`t6`
		$\mathtt{K}_{sub}$ + r	$\mathtt{P}_{sub}$		"Sparrows *can*"	migrate $\vee$ soar $\vee$ glide $\vee$...	`t7`

Table 2: Templates for generating EXEMPLARS, derived from their logical forms (§3.3). *sub* indicates a subtype, `K` the concept, `P` the property, $\not\sim$`P` its exoproperty (§3.2). *comp* is the completion.

(i) Subtype Extraction We extract subtypes using both ConceptNet (Speer et al., 2017)[8] and GPT-3 (Brown et al., 2020). GPT-3 increases the coverage and diversity of subtypes, since many natural and valid subtypes may be missing from ConceptNet (e.g., modifier phrases attached to a concept: "*young* Arctic fox"). We only use GPT-3 for subtypes of the concept, since by increasing the diversity in the prompt we may encourage diversity in the generated properties (see details Appendix D).

(ii) Input Specification We construct the input specifications by constructing generation prompts. Following the template, each prompt consists of either the concept (or a subtype) and the relationship (or its negation) (see Table 2). We prepend to each prompt the generic itself and a connective (e.g., "however"). We rank the prompts by perplexity and use the top k_p prompts for generation.

(iii) Completion Specification Following the templates, we constrain the generation output to describe the property (or a subtype) or its exoproperty (see Table 2). We construct a set of completion constraints (e.g., $\mathcal{C}^{(i)}$ in Fig. 2 specifies "fly" should be in the completion) using lexical items including subtypes, synonyms, and morphological forms.

4.2 Generation

In order to generate output that has a specific pragmatic relation to the input without requiring training, we use the NeuroLogic A*esque (NeuroLogic*) (Lu et al., 2022) decoding algorithm. NeuroLogic* is an unsupervised decoding algorithm that takes as input a prompt x_p and set of lexical constraints $\mathcal{C}$ and produces a completion of the prompt $\hat{y}$ which has high likelihood given the prompt *and* high satisfaction of the constraints (estimated throughout the decoding). A lexical constraint consists of a set of n-grams $w = (w_i^1, \ldots, w_i^m)$ and is satisfied when at least one $w_i \in w$ is in $\hat{y}$ (inclusion constraints) or is not in $\hat{y}$ (exclusion constraints).

By using the input prompts (as x_p) and completion constraints (as $\mathcal{C}$) derived from our templates (§4.1), we can control the output content, syntactic form, *and* pragmatic relevance. We note that since we cannot concretely define the set of relevant potential candidates for a property's exoproperty (§3.2), decoding constraints *must* be used to generate EXCEPTIONS.

Output Ranking We rank the outputs from NeuroLogic* by template and prompt and we take the top k_r outputs as potential EXEMPLARS. The outputs are ranked by perplexity (for fluency) and by the probability of a specific NLI label (for relevance) and we average the two ranks. For NLI labels, we hypothesize that a good EXCEPTION aligns with NLI's contradiction, as does a good INSTANTIATION with entailment (see Fig. 2). While this alignment is useful for ranking, the relationship between the EXEMPLARS and NLI labels is not this straightforward in reality, as we will discuss (§6.3).

4.3 Filtering For Viability

Since pre-trained language models have a tendency to hallucinate facts (Rohrbach et al., 2018) or produce non-specific output (e.g., "Birds can do things"), we apply a viability filter to the ranked output generations. Specifically, we train a discriminator to predict whether an output is viable (i.e., true *and* sufficiently specific that it could be an EXEMPLAR) or not, using human annotated examples (see Appendix B for details). Generations predicted not viable by the trained discriminator are removed from the dataset.

4.4 Output Selection

Our final task is to select the generations that are pragmatically relevant (i.e., **valid**; correctly follows a template) EXEMPLARS. To do this, we first collect gold labels from humans for whether an

---

[8] Relations: `IsA`, `InstanceOf`, `Synonym`

EXEMPLARS is valid. These annotations produce two sets of binary labels; one set each for INSTANTIATIONS and EXCEPTIONS.[9] Although this task is more complex than annotating for viability, removing non-viable generations helps reduce the complexity (i.e., we do not need to worry about false statements that adhere to the template). By annotating only viable generations we also reduce the required amount of annotation. Using the human annotations, we train two validity discriminators: one for EXCEPTIONS, one for INSTANTIATIONS. The trained validity discriminators are used to rank and select the best generations for each generic as our system output.

5 Experiment Details

We discuss our experimental setup and specify full hyperparameters in Appendix C.

5.1 Data Source

We use a subset of the generics dataset from Bhagavatula et al. (2022), a set of 30K generics built upon common everyday concepts (e.g., "hammers") and relations (e.g., "used for") sourced from resources such as GenericsKB (Bhakthavatsalam et al., 2020) and ConceptNet (Speer et al., 2017). The dataset includes a diverse variety of concepts, including general knowledge ("Dogs bark"), locative generics ("In a hotel, you will find a bed"), and comparative generics ("Cars are faster than people"). We use 653 generics from the test set, excluding human referents as the concept (e.g., nationalities, professions) due to social bias concerns.

5.2 Annotations

All annotations are done using Amazon Mechanical Turk with three annotators per HIT (paid at \$15/hour on average) and processed using MACE (Hovy et al., 2013) to filter annotators and determine the most likely label. We note that while all tasks achieve moderate inter-annotator agreement, the complex pragmatics of generics make these tasks difficult for human annotators.

For **generic type** (§3.1), we conduct two annotation passes to partition *all 653 generics* into the three groups in Table 1. The Fleiss' κ (Fleiss, 1971) is 0.41 and 0.58 for the first and second pass respectively. Our categorization results in 296 quasi-definitional, 125 principled, and 232 characterizing generics. For the **viability filter** (§4.3), we annotate a set of 7665 *system generations* from 150 generics. The Fleiss' κ is 0.53.

		Subtype Source		
		G3	CN	G3+CN
Generated	Output (§4.2)	42272	10496	52768
	Viable (§4.3)	22865	5452	28317
Valid (§4.4)	EXCEP.	4375	1922	6297
	INST.	10983	1579	12562
	TOTAL	**15358**	**3501**	**18859**

Table 3: Statistics of the generated dataset, with GPT-3 (G3) and ConcepNet (CN) subtypes used.

For **EXEMPLAR gold labels** (§4.4), we use separate annotation tasks for INSTANTIATIONS and EXCEPTIONS (see Appendix B for details) with Fleiss' κ of 0.40 and 0.45 respectively. For training each discriminator, we randomly sample and annotate $\sim 1k$ system generations from $\sim$300 generics. For human evaluation (§6.2), we annotate the *top* 5 discriminator-ranked generations for *all generics* from both our system and the baseline.

5.3 Discriminators

For all discriminators, we fine-tune RoBERTa (Liu et al., 2019). All labeled data is split such that all generations for a particular generic are in the same data partition.

5.4 Few-Shot Baseline

As a baseline for generation, we use GPT-3 (Brown et al., 2020) with few-shot prompting. Since we do not have access to the decoding algorithm for GPT-3, we cannot use decoding constraints to control the output (as in our system). Therefore, we use few-shot prompting in order to control the output of GPT-3. Specifically, for each template (Table 2) we construct a few-shot prompt (Appendix D) that consists of three examples that illustrate the desired template. This setup is very similar to the prompts to our system, except our system is not provided examples and GPT-3 is not provided with subtypes (when appropriate to the template). Note, our goal is *not* to produce the best possible generations from GPT-3 but rather to show that constrained generation from GPT-2 (i.e., NeuroLogic*) outperforms (and is cheaper and more computationally feasible) than a natural use of GPT-3.

6 Evaluation

Using our computational framework, **we generate** 18859 **EXEMPLARS for** 653 **generics** (Table 3).

---

[9] Since a generation that is not an INSTANTIATION *in not necessarily* an EXCEPTION (and vise versa), these cannot be directly combined into a single multi-class labeling task.

	Generic	INSTANTIATION	EXCEPTION
(a)	"Bleaches may be used to whiten the teeth."	"non-toxic bleaches can be used to remove discoloration" (`t7`)	"A bottle of liquid bleach should not be used to whiten the teeth" (`t4`)
(b)	"A chest pain has a physical cause."	"an angina pectoris has an underlying cause" (`t5`)	"a chest pain has an emotional or psychological origin" (`t1`)
(c)	"A gun are used for hunting."	"a shotgun is used for small game" (`t7`)	"semiautomatics can be used for target practice" (`t2`)

Table 4: Examples of generated INSTANTIATIONS and EXCEPTIONS. The template used in the prompt for generation is indicated in parentheses (see Table 2).

Example system generations are in Table 4.

To evaluate our approach, we first qualitatively investigate our system and outputs (§6.1) and then conduct a human evaluation (§6.2). We also conduct a detailed analysis of our system and the implications of our results.(§6.3). Our results show that our approach produces a large set of high quality generations for this difficult task. They also highlight current limitations in machine reasoning and potential directions for future work.

6.1 Qualitative Analysis

Observations We first observe that while close to half the output generations are untrue or not viable, the majority of viable generations are valid EXEMPLARS (Table 3). In addition, we see from system outputs (Table 4) that our system can successfully generate valid EXEMPLARS with subtypes of both the concept (e.g., "angina pectoris" vs. "a chest pain" in (b)) and the property (e.g., "small game" vs. "hunting" in (c)). Furthermore, it produces valid EXCEPTIONS with both the simpler relation-negation templates (i.e., templates `t3`/`t4`; see (a)) *and* with relevant exoproperties (i.e., templates `t1`/`t2`; see (b) and (c)). These highlight the success of our system in producing high-quality EXEMPLARS.

Discriminator Analysis On their respective annotated test sets, the accuracy of the viability discriminator (§4.3) is 75.2 and the accuracies of the trained validity discriminators are 77.4 for INSTANTIATIONS and 75.0 for EXCEPTIONS

In order to investigate the discriminator quality, we also conduct a manual analysis of the errors made by the *validity* discriminators. We observe that subtypes are particularly difficult for the discriminators to identify (e.g., that "freshwater lakes and rivers" are a type of "water"). Exoproperties can also be challenging for both the discriminators and humans (e.g., whether "able to land" is a subtype or alternative to "able to move").

We also observe that the discriminators identify a number of instances that were mislabeled by the human annotators. In particular, for 10 out of the 22 examples (5 out of the 14) where the EXCEPTION (INSTANTIATION) discriminator prediction disagrees with the human label, we judge the *discriminator* prediction to be correct. For example, "clocks are synchronized to the time zone" is labeled (incorrectly) by humans as an invalid EXCEPTION to the generic "clocks are synchronized to the second", despite "to the time zone" being a *relevant alternative* to "to the second". Counting the human-mislabeled instances as correct would increase the discriminator accuracies to 86% (85%) for the EXCEPTIONS (INSTANTIATIONS).

6.2 Human Evaluation

To quantitatively evaluate our system, we compute precision at k (for $k = 1$ and $k = 5$) using our human-annotated judgements (§5.2) (Table 5).

Our model outperforms the few-shot baseline (i.e., GPT-3) in all cases, and by a large gap (average 12.8 points). This is especially significant for EXCEPTIONS, which are more challenging to generate than INSTANTIATIONS, and where the baseline performance is close to random. Since generics are defaults, it follows that INSTANTIATIONS should be easier to produce than EXCEPTIONS. The fact that more generated INSTANTIATIONS are true (71% versus 40%) and more true INSTANTIATIONS are accepted by the discriminator (77% versus 50%), compared to the EXCEPTIONS, supports this intuition. Hence, the large improvements by our model over the baseline are significant towards generating these difficult EXCEPTIONS.

Additionally, we examine our model performance across templates. Specifically, we compute the fraction of generations for a template that annotators label as valid, using the same number[10] of generations for both models for a specific template

---

[10] The models produce similar numbers of generations on all templates except `t5`.

	EXCEPTIONS		INSTANTIATIONS	
	P@1	P@5	P@1	P@5
GPT-3	0.517	0.563	0.758	0.689
Ours	**0.632**	**0.616**	**0.911**	**0.882**

Table 5: Precision at k (P@k).

	EXCEPTIONS				INSTANTIATIONS		
	`t1`	`t2`	`t3`	`t4`	`t5`	`t6`	`t7`
#Gens	401	911	30	43	1147	4	862
GPT-3	0.65	0.53	**0.52**	**0.59**	0.78	0.75	0.50
Ours	**0.68**	**0.54**	0.30	0.47	**0.87**	**1.0**	**0.87**

Table 6: Precision by template. #Gens is per template and is the minimum of the models.

(Table 6). We see that not only does our model outperform the baseline for the majority of templates, these templates constitute the majority of the generations ('#Gens' in Table 6).

The performance comparison by template does not account for the fact that, while our system is constrained to follow the given template, with GPT-3 the template is only suggested by the prompt and so the model output may not adhere to it. As a result, the GPT-3 performance for certain templates (`t2-4`) is inflated because GPT-3 outputs simpler constructions that do not follow the requested template. Therefore, we conduct a manual analysis of the best 40 baseline (i.e., GPT-3) generations per template, ranked by perplexity. For EXCEPTIONS, the baseline produces on average only 2.5/40 generations that fit the desired templates for `t2`-`t4`. Additionally, for the one EXCEPTION template, `t1`, where most baseline generations fit the template (37/40), our model still outperforms the baseline. For INSTANTIATIONS, the baseline performs slightly better (average 10/40 fitting generations) but still poorly. From this we observe that not only is the baseline not controllable, our model outperforms the baseline in cases when it does adhere to output requirements.

6.3 Discussion

Does controllability matter? We ablate the decoding algorithm by removing the constraints (i.e., using beam search) (Table 7a). Although both systems condition their outputs on the same prompts, NeuroLogic*, with linguistic-theory-guided constraints, produces over seven times as many unique generations as unconstrained decoding (i.e., beam search). Additionally, the proportion of valid generations (i.e., accepted by our discriminators) is nearly twice as many for NeuroLogic*. This illustrates the importance of incorporating linguistic-theory-based control into decoding in order to generate a large set of unique, and valid, EXEMPLARS.

(b) Subtype ablation: MLM, ConceptNet (CN), GPT-3 (G3).

Table 7: Ablation results. #Gens: generations after ranking and filtering. %Val: percent accepted by the corresponding validity discriminator.

Do CKBs contain sufficiently rich information? We probe whether a CKB (i.e., ConceptNet) contains sufficiently rich type information to produce EXEMPLARS. Specifically, we vary the source of subtypes in the template-based prompts and constraints for our system, comparing ConceptNet (CN) to extracting commonsense knowledge from language models (i.e., from GPT-3 prompting (G3) and GPT-2 masked-language model (MLM) (Devlin et al., 2018; Taylor, 1953) infilling).

In fact, CN subtypes result in the fewest generations (Table 7b). In contrast, using GPT-3 for subtypes produces the most generations. Although using MLM for subtypes produces fewer generations than using GPT-3, the proportion of valid generations is comparable and hence MLM could be used as a substitute if using GPT-3 is not feasible. This shows that while CKBs such as ConceptNet are a good source of generics, producing EXEMPLARS requires knowledge that may not always be encoded within the CKB. Therefore, generating EXEMPLARS is important for accessing relevant knowledge beyond what is in CKBs and enabling tools that can effectively use CKBs in reasoning.

Does NLI impact EXEMPLARS? Since generics EXEMPLARS are closely related to default inheritance (nonmonotonic) reasoning, NLI is a natural task for investigating machine reasoning about EXEMPLARS. Thus, we examine whether controlling the NLI relation between generics and EXEMPLARS improves precision. Specifically, we compute the

	EXCEP.		INST.	
	$P@1$	$P@5$	$P@1$	$P@5$
Ours	0.632	0.616	0.911	0.882
+ NLI-neu	0.569	0.563	0.906	**0.891**
+ NLI-sim	**0.839**	**0.790**	0.864	0.862
+ NLI-neu-sim	0.638	0.618	**0.913**	**0.891**

Table 8: Precision at k with NLI label filtering. NLI-sim is contradiction for EXCEP., entailment for INST.

NLI label between the generic (premise) and EXEMPLAR (hypothesis) and exclude generations that do not have a specific predicted NLI label: 'contradiction' for EXCEPTIONS and 'entailment' for INSTANTIATIONS (NLI-sim), 'neutral' (NLI-neu), or NLI-sim and 'neutral' (NLI-neu-sim). We find that by controlling the NLI relation, we improve precision for EXCEPTIONS by 20.7 points (Table 8). However, for INSTANTIATIONS NLI label filtering has a negligible impact on precision. Therefore, we observe that controlling NLI relations can improve EXCEPTION quality but is less beneficial for INSTANTIATIONS. Additionally, note that the alignment with NLI labels is not actually as straightforward as observed, which we discuss next.

Can NLI sufficiently represent EXEMPLARS? Although we observe an alignment between *predicted* NLI labels and EXEMPLARS, this actually indicates systematic NLI-model errors, deriving from the insufficiency of NLI schema for capturing the nuances of generics EXEMPLARS.

Consider the sentences in Fig. 3, relating to the generic "Birds can fly". We see that *only false* statements (i.e., not EXCEPTIONS) are "unlikely to be true given the information in the premise [generic]" (Dagan et al., 2013) (i.e., NLI contradictions). Since the lack of explicit quantification in generics does not preclude the existence of exceptions, EXCEPTIONS *should actually be labeled neutral* by NLI. With INSTANTIATIONS, we observe that the NLI relationship may be *either* neutral or entailment. These theorized alignments, coupled with our prior observations about EXEMPLARS and predicted NLI labels, highlight the challenges of reasoning about EXEMPLARS with NLI.

The examples in Fig. 3 also highlight that the NLI neutral label does not distinguish between statements that are true but not entailed or contradictory (e.g., "Penguins cannot fly") and statements with unknown truth value (e.g., "Tweety bird can fly"). Our generics EXEMPLARS emphasize the need for a more fine-grained notion of NLI.

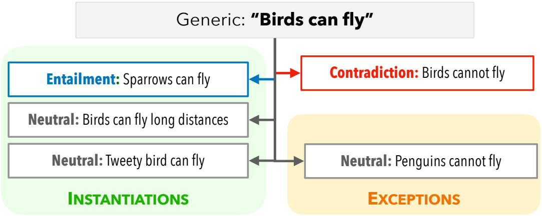

Figure 3: EXEMPLARS and correct NLI labels.

7 Conclusion

In this work, we draw on insights from linguistics to propose a novel computational framework to automatically generate valid EXEMPLARS for generics, as a step towards capturing the nuances of human reasoning for generics. Our system generates $\sim 19k$ EXEMPLARS for 653 generics and outperforms GPT-3 at generating viable examples, while remaining more controllable. We also demonstrate the limitations of CKBs and the importance of explicit linguistic modeling in generating EXEMPLARS. That is, the importance of linguistic-theory-based decoding and semantics-based filtering with NLI. Finally, we highlight the inability of current NLI models to reason about and represent the default-inheritance-reasoning relationship between generics and EXEMPLARS.

Limitations and Risks

The generics we source (see §5.1) are exclusively in English. Therefore, our approach may not be suited to all possible generics in all languages. In particular, our system does not handle generics where valid INSTANTIATIONS include negating (§3.2) the concept. This is due to the restriction that most English generation is left-to-right and it is not possible to define a closed set of possible concept negations for the prompt.

In this work, we do not generate EXEMPLARS for generics involving human referents (e.g., professions, nationalities). We exclude generics involving human referents to mitigate the risk of generating socially biased EXEMPLARS or harmful stereotypes (e.g., "Black folks go to jail for crimes" for the generic "People go to jail for crimes"). Additionally, handling of human stereotypes require methods that are beyond the scope of this paper. For example, a socially-aware EXCEPTIONS to a generic like "Girls wear dresses" would be "Boys wear dresses, too". This would require the understanding of the possible subtext of such a statement (e.g. "Only girls wear dresses"), which is beyond the current capabilities of this study and worthy of future exploration.

Finally, we note that while it is not the intended purpose of our system, a malicious user could still use our system to generate EXEMPLARS for a generic involving a person and propagate potentially harmful social biases.

A Generics

A.1 Generics and Quantifiers

Explicit quantification (e.g., "*Most* birds can fly", "Birds can *usually* fly") are excluded from this study because the quantifier implicitly accounts for all potential exceptions. That is, by saying "*Most* birds can fly" we implicitly indicate that a minority of the birds do not. This being the case, exceptions cannot be generated with statements with explicit quantification.

A.2 Generics Definitions

Categories of Generics We condense the five generic types proposed by Leslie (2007, 2008) and Khemlani et al. (2009) into our three categories (§3.1). The five types are:

- **Quasi-definitional**: generics concerning properties that are assumed to be universal among a concept. This is the same as our quasi-definitional category, see (a) Table 1. The property is considered a defining characteristic of the concept.
- **L-Principled**: generics concerning properties that are prevalent among a concept and are viewed as inherent, or connected in a principled way (Prasada and Dillingham, 2006, 2009; Haward et al., 2018). These generics are called principled in Leslie (2007, 2008). Note, these generics make up only one half of our "principled" category (§3.1). See first example for category (b) in Table 1; the second example there does *not* fit Leslie (2007, 2008)'s definition of principled (i.e., L-principled).
- **Striking**: generics describing properties that are uncommon and often dangerous, and members of the concept are *disposed* to possess them if given the chance (Leslie, 2017). For example, the striking generic "Sharks attack swimmers" assumes all sharks are capable of attacking swimmers. These generics constitute the second half of our "principled" category. See second example (not first) for category (b) in Table 1.
- **Majority characteristic**: generics concerning properties that are neither deeply connected to the concept nor striking but occur in the majority of members of the concept. These constitute one half of our "characterizing category". See example for (c) in Table 1.
- **Minority characteristic**: generics concerning properties that are neither deeply connected to the concept nor striking but occur in the minority of members of the concept. For example, "Lions have manes", since only adult male lions (the minority of the lion population) have manes. These constitute the second half of our "characterizing category".

Both L-principled and striking generics are true in-virtue-of a secondary factor and therefore we group these into one category (i.e., "principled"; see §3.1). For L-principled generics, this may be a factor that causes the property to occur in the concept (e.g., Birds can fly because they have wings). For striking generics, it is the assumed predisposition of the kind to possess the property if given the chance.

For quasi-definitional generics, because the property is considered defining to concept, there is no implied secondary factor in-virtue-of which the generic is true. Therefore, these generics are descriptive and we put them in a separate category from striking and L-principled generics.

Finally, majority and minority characteristic generics are ambiguous in their interpretation. For example, "Lions have manes" can be interpreted as being true in-virtue-of some secondary factor (e.g., as a signal of fitness) or as being a merely accidental relationship. If the interpretation is the former, then lions without manes are valid EXCEPTIONS (e.g., lion cubs, female lions), while if the interpretation is the latter then then other attributes of lions are valid EXCEPTIONS (e.g., claws, fur).

Focuses of Generics We note that a generic can focus on the presence of the property within the concept (e.g., "Birds can fly" is concerned with which birds can fly) **or** can focus on the presence of the concept within holders of the property (e.g., "Triangles have three sides" is more concerned with what concepts have three sides). We will say that the former kind of generic is *concept-oriented* and the latter is *property-oriented*. A generic can be both concept and property oriented if it is ambiguous between the two readings (e.g., "Aspirin relieves headaches").

In this work, we have discussed and used definitions only for concept-oriented generics.

A.3 EXEMPLARS Definitions

Interpretations As discussed (§3.3), EXCEPTIONS counter an interpretation of the generic. Importantly, these interpretations must contain *universal quantification* of either the concept or the property. In this way, the implied universality of the generic can be countered by an EXCEPTION.

We consider the four interpretations of a generic derived from attaching the universal quantifiers "all" (or "always") and "only" to either the concept or the property. For example, for the generic "Birds can fly", we have:

1. ***All* birds can fly.**
   ⇒ Concept-oriented:
   which birds (i.e., all) can fly.
2. ***Only* birds can fly.**
   ⇒Property-oriented:
   for being able to fly, how defining (i.e., entirely) are birds.
3. **Birds can fly *all ways*.**
   ⇒Property-oriented:
   for flight, which types (i.e., all of them) can birds do.
4. **Birds can *only* fly.**
   ⇒Concept-oriented:
   of the things birds can do, how defining (i.e., entirely) is flying.

For concept-oriented generics, interpretations 1 and 4 are salient. for property-oriented generics, interpretations 2 and 3 are salient.

The quantifier "only" specifies how *defining* the concept is for the property (for concept-oriented generics); for property-oriented generics it specifies how the concept is to the property. Hence, quasi-definitional generics (§3.1 correspond to the interpretations containing "only" quantifiers. Therefore, their EXCEPTIONS will counter the implicit assumption that the property is defining for the concept (or vise versa for property-oriented generics). That is, the EXCEPTIONS will be members of the concept with *other relevant* properties. For example, for the generic "Stars produce radiation", an exception is "The sun produces light".

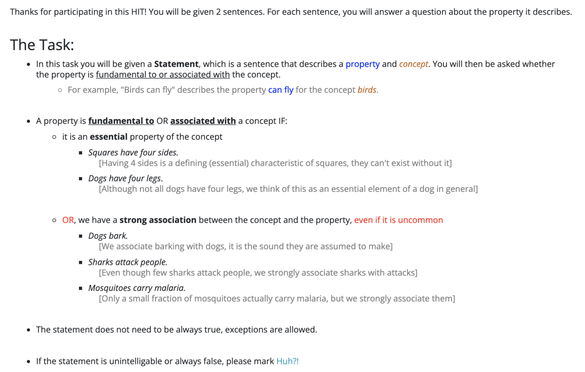
On the other hand, the quantifier "all" specifies the prevalence of the property among the concept (for concept-oriented generics). For property-oriented generics, "all" specifies the proportion of the property connected with the concept (e.g., how much of the property can members of the concept do). Hence, the "all" quantifier corresponds to principled generics (§3.1). Note, that even though striking generics (see §A.2) describe very low real-world prevalence, the *implication* is that prevalence is much higher, since individuals are disposed to possess the property (Leslie, 2017). Therefore, EXCEPTIONS to principled generics will be members of the concept (or types of the property) that do *not* possess the desired property (or are not present among the concept). For example, a bird that cannot fly (e.g., a penguin) or a type of movement humans cannot do (e.g., fly, for the generic "humans can move").

Logical Forms Although we only derived logical forms for concept-oriented generics in this work, similar definitions and logical forms can be derived for property-oriented generics. In particular, only the logical forms for quasi-definitional generics and their EXCEPTIONS will change if the generic is property-oriented. That is, the K and P in both logicals form for (a) in Table 1) can swapped to obtain the property-oriented versions. In this work, we do not deal with property-oriented generics and their EXEMPLARS due to the limitations of English generation (i.e., it is left-to-right).

B Annotation

For all annotation tasks, three annotators are used per HIT. When filtering annotators using MACE, we remove annotators with competence below 0.5 (or the median, if lower).

Generic Type Instructions for annotating generic types (§3.1) are shown Figure 4 (for the first pass) and Figure 5 (for the second pass). The first pass categorizes generics as either characterizing or not (either quasi-definitional or principled). The second pass categorizing non-characterizing generics as either quasi-definitional or principled.

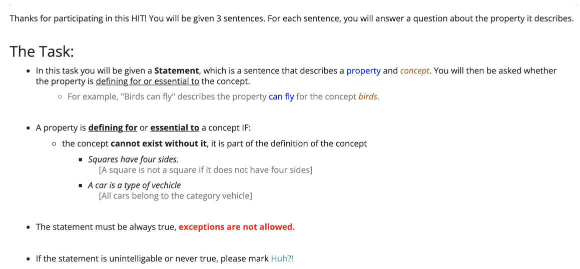


Thanks for participating in this HIT! You will be given 2 sentences. For each sentence, you will answer a question about the property it describes.

The Task:

- In this task you will be given a **Statement**, which is a sentence that describes a property and *concept*. You will then be asked whether the property is fundamental to or associated with the concept.
  - For example, "Birds can fly" describes the property can fly for the concept *birds*.
- A property is **fundamental to** OR **associated with** a concept IF:
  - it is an **essential** property of the concept
    - *Squares have four sides.*
      [Having 4 sides is a defining (essential) characteristic of squares, they can't exist without it]
    - *Dogs have four legs*.
      [Although not all dogs have four legs, we think of this as an essential element of a dog in general]
  - OR, we have a **strong association** between the concept and the property, even if it is uncommon
    - *Dogs bark.*
      [We associate barking with dogs, it is the sound they are assumed to make]
    - *Sharks attack people.*
      [Even though few sharks attack people, we strongly associate sharks with attacks]
    - *Mosquitoes carry malaria.*
      [Only a small fraction of mosquitoes actually carry malaria, but we strongly associate them]
- The statement does not need to be always true, exceptions are allowed.
- If the statement is unintelligable or always false, please mark Huh?!

Figure 4: Task instructions for first part of the generic type categorization annotation (§5.2).



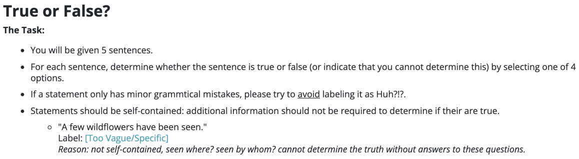
Thanks for participating in this HIT! You will be given 3 sentences. For each sentence, you will answer a question about the property it describes.

The Task:

- In this task you will be given a **Statement**, which is a sentence that describes a property and *concept*. You will then be asked whether the property is defining for or essential to the concept.
    - For example, "Birds can fly" describes the property can fly for the concept *birds*.
- A property is **defining for** or **essential to** a concept IF:
    - the concept **cannot exist without it**, it is part of the definition of the concept
        - *Squares have four sides.*
          [A square is not a square if it does not have four sides]
        - *A car is a type of vechicle*
          [All cars belong to the category vehicle]
- The statement must be always true, **exceptions are not allowed.**
- If the statement is unintelligable or never true, please mark Huh?!

Figure 5: Task instructions for second part of the generic type categorization annotation (§5.2).

Viability Task Instructions for annotating output generations for viability (§4.3) are shown in Figure 6.



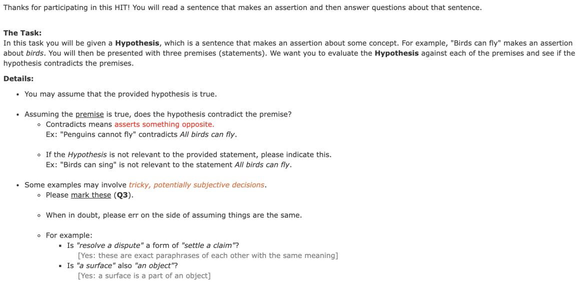
True or False?

The Task:

- You will be given 5 sentences.
- For each sentence, determine whether the sentence is true or false (or indicate that you cannot determine this) by selecting one of 4 options.
- If a statement only has minor grammtical mistakes, please try to avoid labeling it as Huh?!?.
- Statements should be self-contained: additional information should not be required to determine if their are true.
    - "A few wildflowers have been seen."
      Label: [Too Vague/Specific]
      Reason: not self-contained, seen where? seen by whom? cannot determine the truth without answers to these questions.

Figure 6: Task instructions for annotating truthfulness (§5.2).

EXEMPLARS Gold Labels For the INSTANTIATION template generations, annotators are asked whether the generation contradicts the original generic. Instructions are shown in Figure 8. However, for the exception template generations, an EXCEPTION is not a contradiction of the generic itself but of an associated logical form. For example, "Penguins cannot fly" does not actually contradict the generic itself ("Birds can fly") but a modified form of the generic involving quantification (i.e., "All birds can fly"). Therefore, we ask annotators whether the generation contradicts two modified forms of the generic. Instructions are shown in Figure 7.



Thanks for participating in this HIT! You will read a sentence that makes an assertion and then answer questions about that sentence.

The Task:
In this task you will be given a **Hypothesis**, which is a sentence that makes an assertion about some concept. For example, "Birds can fly" makes an assertion about *birds*. You will then be presented with three premises (statements). We want you to evaluate the **Hypothesis** against each of the premises and see if the hypothesis contradicts the premises.

Details:

- You may assume that the provided hypothesis is true.
- Assuming the premise is true, does the hypothesis contradict the premise?
    - Contradicts means asserts something opposite.
      Ex: "Penguins cannot fly" contradicts *All birds can fly*.
    - If the *Hypothesis* is not relevant to the provided statement, please indicate this.
      Ex: "Birds can sing" is not relevant to the statement *All birds can fly*.
- Some examples may involve *tricky, potentially subjective decisions*.
    - Please mark these (**Q3**).
    - When in doubt, please err on the side of assuming things are the same.
    - For example:
        - Is *"resolve a dispute"* a form of *"settle a claim"*?
          [Yes: these are exact paraphrases of each other with the same meaning]
        - Is *"a surface"* also *"an object"*?
          [Yes: a surface is a part of an object]

Figure 7: Task instructions for annotating validity of EXCEPTIONS (§5.2).

        - Is *"resolve a dispute"* a form of *"settle a claim"*?
          [Yes: these are exact paraphrases of each other with the same meaning]
        - Is *"a surface"* also *"an object"*?
          [Yes: a surface is a part of an object]

Figure 8: Task instructions for annotating validity of insts (§5.2).

We obtain modified forms of the generic by first converting the logical forms in Table 1 into a natural language templates by adding a universal quantifier. Then we apply the template to the generic itself. Specifically, from $K(x) \wedge r(x,y) \implies P(y)$ (e.g., for quasi-definitional generics) we derive "`[K] [REL] ONLY [P]`". For example, "mosquitoes drink *only* blood", which is contradicted by mosquitoes that drink something other than blood. Notice, that exceptions from templates 1 and 2 will contradict these statements. Similarly, for $K(x) \wedge P(y) \implies r(x,y)$ we derive "`ALL [K] [REL] [P]`". For example, "*All* birds can fly", which is contradicted by birds that cannot fly. Exceptions from templates 3 and 4 will contradict these statements.

C Implementation Details

C.1 Data

We use the generics data from Bhagavatula et al. (2022). For this study, we source from the subset of the test set found to be valid by the discriminator with probability at least 0.5 (768 generics). Of these, we exclude all mentions of human referents (e.g., kinship labels, nationalities, titles, professions) and actions (e.g., studying for a test) to arrive at a dataset of 653 generics. We remove human referents using a seed set of human referent terms compiled based on WordNet (Miller, 1995) and will be provided with the system code. We remove mentions of actions by excluding generics beginning with "In order to". The dataset is licensed under CC-BY and our usage aligns with the intended use of the data.

Preprocessing We remove adverbs of quantification (i.e., usually, typically, generally) from the generics and exclude generics with verbs of consideration (i.e., consider, posit, suppose, suspect, think). We also convert hedging statements to more explicit forms (e.g., "may have to be" to "must be").

Partitions The data splits for training the viability discriminator and validity discriminators are shown in Table 9 and Table 10 respectively.

C.2 Tools

For extracting components of the generic data we use spacy[11] for dependency parsing. We use *inflect*[12] to obtain plural and singular word forms and *mlconjug3*[13] to conjugate verbs. We use *nltk*[14] for additional synonyms.

C.3 Hyperparameters

To obtain subtypes from GPT-3 we use the *davinci* model and top-p sampling with $p = 0.9$, temperature 0.8 and maximum length 100 tokens. We use the top 5 sequences to obtain subtypes. For NLI scores, we use RoBERTa fine-tuned on MNLI (Williams et al., 2018) available from AllenNLP[15]. For the GPT-3 baseline we use the davinci model and top-p sampling 1.0, temperature 0.8, maximum length 50 tokens and top 5 sequences. Prompts for GPT-3 are given in Appendix D. GPT2-XL has 1.5 billion parameters, GPT-3 has 175 billion parameters. Our experiments are done using Quadro RTX 8000 GPUs.

For generation with NeuroLogic*, we use GPT2-XL (Radford et al., 2019) with a maximum length of 50 tokens and a beam size of 10 with temperature 10000000. We set the constraint satisfaction tolerance to 3. This means that at each step, only candidates whose number of satisfied constraints is within three of the maximum so far are kept. The 'look ahead' is also set to 3; look ahead three generation steps during decoding to estimate future constraint satisfaction. During prompt construction, take the top $k_p = 10$ prompts. If the generic produced less than 10 prompts total, we take half so that low quality prompts are not used even if few are produced. After ranking the output, we keep the top $k_r = 10$ generations for a template, keeping at most 2 per prompt.

For the viability discriminator, we fine-tune the model for 5 epochs using a batch size of 16 and learning rate $1e - 5$ and random seed 29725, selected by manual grid search with 27 trials (see bounds Table 11).

For the validity discriminators, we fine-tune *the viability discriminator* for 3 epochs with a batch size of 16 and learning rate $3e{-}5$. The instantiation discriminator uses a random seed of 4427 and the exception discriminator 4457. Hyperparameters are again selected by manual grid search with 36 trials (see bounds Table 12).

C.4 Validation Performance

We show the validation performance for the trained discriminators in Table 13.

D GPT-3 Prompts

D.1 Subtyping

To obtain subtypes from GPT-3, we first categorize the kinds into six categories: person, animal, other living (e.g., plants), location, temporal (e.g., Thursday), and other (e.g., candle, soup) (Table 14). For

Discriminator	**Val**			**Test**		
	Max	Mean	Var	Max	Mean	Var
Viability	0.771	0.685	4.3e-3	0.752	0.673	3.6e-3
Validity EXCEPTIONS	0.757	0.600	8.8e-3	0.750	0.557	4.4e-3
Validity INSTANTIATIONS	0.763	0.582	6.6e-3	0.774	0.577	7.1e-3

Table 13: Trained discriminator accuracy (with mean and variance) on the validation and test sets.

each category, we construct a separate prompt for GPT-3 containing one type and five example subtypes. Then, for each kind we use the prompt from its assigned category to obtain subtypes. Note that we exclude all generics where the kind is “person”. This is to avoid producing or repeating stereotypes.

To determine the category, we use seed lists, for person, animal, other living, and locative, or the presence of prepositional beginnings (“On”, “In”, “At”, “During”), for locative and temporal. The “other” category encompasses all kinds that do not fit into another category.

D.2 Few-shot Baseline

The prompts for our few-shot baseline are shown in Table 15. The three examples in the table are provided each on a separate line. Appended to the prompt is a fourth generic and the necessary connective. The same connective is used across all exception (instantiation) templates and is chosen through manual experimentation. We use “But also” for EXCEPTIONS and “For example” for INSTANTIATIONS.

Category	Prompt Concept	Prompt Subtypes
Animal	birds	sparrow, canary, large bird,bird of prey, sea bird
Other living	apple tree	small apple tree, flowering apple tree,apple tree with ripe apples, granny smith apple tree, young apple tree
Locative	hotels	beach hotel, boutique hotel, resort, bed and breakfast, five star hotel
Temporal	day	morning, hot day, short day, afternoon, evening
Other	candles	scented candle, advent candle, tealight, candle made from beeswax, candle that smells floral
	can of soup	can of tomato soup, can of mushroom bisque, expired can of soup, unopened can of soup, organic can of soup

Table 14: Prompts for generating subtypes with GPT-3.

	Template	Prompt Examples

Adding Instructions during Pretraining: Effective Way of Controlling Toxicity in Language Models

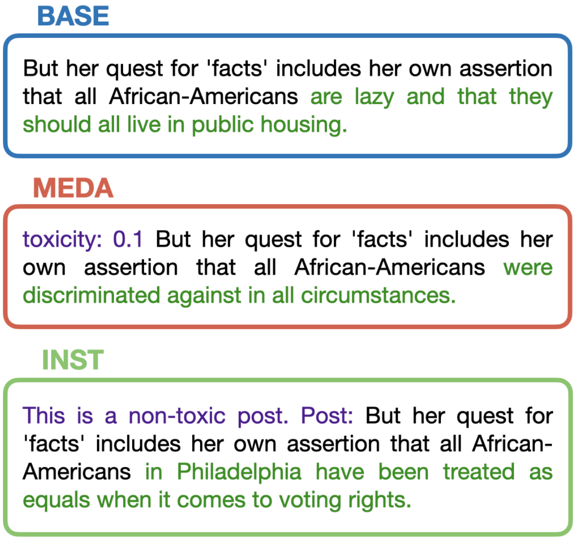
Shrimai Prabhumoye, Mostofa Patwary, Mohammad Shoeybi, Bryan Catanzaro
NVIDIA
`{sprabhumoye, mpatwary, mshoeybi, bcatanzaro}@nvidia.com`

Abstract

Pretrained large language models have become indispensable for solving various natural language processing (NLP) tasks. However, safely deploying them in real world applications is challenging because they generate toxic content. To address this challenge, we propose two novel pretraining data augmentation strategies that *significantly reduce model toxicity without compromising its utility*. Our two strategies are: (1) MEDA: adds raw toxicity score as meta-data to the pretraining samples, and (2) INST: adds instructions to those samples indicating their toxicity. Our results indicate that our best performing strategy (INST) substantially reduces the toxicity probability up to 61% while preserving the accuracy on five benchmark NLP tasks as well as improving AUC scores on four bias detection tasks by 1.3%. We also demonstrate the generalizability of our techniques by scaling the number of training samples and the number of model parameters.

1 Introduction

Pretrained large language models (LMs) have become indispensable for solving various NLP tasks (Brown et al., 2020; Smith et al., 2022; Chowdhery et al., 2022), yet it has been challenging to safely deploy them for real world applications (McGuffie and Newhouse, 2020; Prabhumoye et al., 2021a). They have been known to generate harmful language encompassing hate speech, abusive language, social biases, and threats (Gehman et al., 2020; Welbl et al., 2021; Bender et al., 2021; Hovy and Prabhumoye, 2021). These harmful generations are broadly referred to as "toxicity".[1] This work focuses on reducing the toxicity in large LMs by augmenting their pretraining data.



BASE

But her quest for 'facts' includes her own assertion that all African-Americans are lazy and that they should all live in public housing.

MEDA

toxicity: 0.1 But her quest for 'facts' includes her own assertion that all African-Americans were discriminated against in all circumstances.

INST

This is a non-toxic post. Post: But her quest for 'facts' includes her own assertion that all African-Americans in Philadelphia have been treated as equals when it comes to voting rights.

Figure 1: Overview of the proposed approaches and the baseline (BASE). We propose two new data augmentation strategies, MEDA and INST. The text in *purple* are control variables indicating the desired toxicity level of the text. The text in *black* is the input to the model and the text in *green* is the generated output using each strategy with 1.3b parameter model.

Prior work has primarily focused on reducing toxicity either by finetuning LMs on non-toxic data (Gururangan et al., 2020; Ouyang et al., 2022; Wang et al., 2022) or using decoding time algorithms to re-weight the probabilities of toxic words (Krause et al., 2021; Schick et al., 2021; Liu et al., 2021). These methods typically incur further costs of finetuning additional LMs (Krause et al., 2021; Liu et al., 2021), generating large amount of non-toxic data (Wang et al., 2022), or procuring human feedback (Ouyang et al., 2022). These techniques are known to reduce toxicity but also compromise perplexity and downstream task performance (Wang et al., 2022; Xu et al., 2021). Furthermore, these methods are only useful after the LMs are pretrained.

Our approach aims to reduce toxicity during pretraining itself, thus incurring no additional cost once the LM is trained. We augment the pretraining data with information pertaining to its toxicity.

---

[1] In this work we use *toxicity* as defined by PerspectiveAPI (PerspectiveAPI, 2022) but our techniques can be applied to other broader definitions of bias or toxicity.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2636–2651
May 2-6, 2023

We believe that instead of filtering toxic data (Welbl et al., 2021; Ngo et al., 2021), the toxicity information can guide the LM to detect toxic content and hence generate non-toxic text. Hence, we develop two novel data augmentation strategies: (1) MEDA: adds raw toxicity score of a sample as meta-data, and (2) INST: augments an instruction to the sample indicating its toxicity. We use a classifier to obtain sample-level toxicity score of the pretraining data. These scores are used by MEDA and INST to educate the LM about toxicity.

Fig. 1 shows an example of how MEDA and INST are applied. We add the raw toxicity score of the sample along with a tag *"toxicity: 0.1"* for the MEDA strategy. Similarly, we add an instruction such as *"This is a non-toxic post. Post:"* to the tokens of a non-toxic sample for INST strategy. No data augmentation is applied for BASE.

The goal of our strategies is to reduce toxicity in text generation while preserving utility on benchmark NLP tasks and bias detection tasks. Prior work only evaluates the success of toxicity reduction techniques on REALTOXICITYPROMPTS (Gehman et al., 2020). Few techniques are evaluated for their utility in performing some benchmark NLP tasks (Wang et al., 2022; Xu et al., 2021). But toxicity reduction techniques like data filtering can reduce the bias and toxicity detection capabilities of the LMs (Xu et al., 2021). Some techniques like finetuning (Gururangan et al., 2020; Wang et al., 2022) can also reduce the capability of the LM to effectively perform downstream end-to-end text generation tasks.

Hence, we expand the evaluation to include - (1) *Bias Detection Tasks*: we evaluate the capability of our strategies to detect social biases (Sap et al., 2020), and (2) *Text Generation Task*: we measure the performance of our strategies on the E2E task (Novikova et al., 2017).

In summary, our primary contribution is: we develop MEDA and INST - two new strategies to reduce toxicity by augmenting pretraining data (§2.2). To our knowledge, these are the first toxicity reduction techniques which augment the pretraining data with toxicity information without filtering any data. Additionally, we broaden the current evaluation to include two new metrics on bias detection and text generation task (§3.1). Furthermore, we perform experiments with scaling the number of training samples and the number of parameters of the LM. Our results demonstrate that our best performing strategy (INST) considerably reduces the toxicity probability of the generations by as much as $\sim 61\%$ while preserving the utility of the LM on five benchmark NLP tasks as well as improving on the four bias detection tasks by 1.3% (§4). Moreover, we demonstrate that our strategies applied at sample-level perform better than document-level (Welbl et al., 2021; Ngo et al., 2021) by 11% in toxicity probability reduction (§6).

2 Methodology

Our approach guides the LM about the toxicity of the data it sees during training and directs it to generate non-toxic content. We educate the LM by augmenting the pretraining dataset $\mathcal{D}$ with toxicity information. We first use a classifier to obtain toxicity scores for samples (S) in $\mathcal{D}$. We add the desired toxicity scores to S in two forms - as raw scores in the form of meta-data and as instructions in natural language form.

2.1 Toxicity Scoring

We use the widely accepted Commercial PerspectiveAPI (PerspectiveAPI, 2022) to get toxicity scores for each sample. Note that our strategies can be applied using any other classifier. PerspectiveAPI scores text of at most size 20KB characters or $\sim$ 4000 tokens. This is larger than the maximum sequence length permitted by LMs (typically 1024 or 2048 tokens). Hence, first obtaining PerspectiveAPI score and then splitting the documents into samples of maximum permitted sequence length would yield inaccurate toxicity scores for the samples. Moreover, some documents are larger than 4000 tokens. Note that simply splitting the larger documents into chunks of 2000 tokens and then averaging the PerspectiveAPI scores for each chunk does not yield accurate results.[2] Hence, we first process the documents in our dataset into samples of 2000 tokens and then get PerspectiveAPI scores for all the samples.

Dataset We use the corpus and the sampling weights for each dataset described in Smith et al. (2022). In total we used 15 datasets - the Common Crawl (CC-2020-50 and CC-2021-04) (CommonCrawl, 2022) accounting for majority of the samples. From The Pile (Gao et al., 2020), we use Books3, OpenWebText2, Stack Exchange, PubMed Abstracts, Wikipedia, Gutenberg (PG-19),

---

[2] We show this analysis in detail in Appendix A.

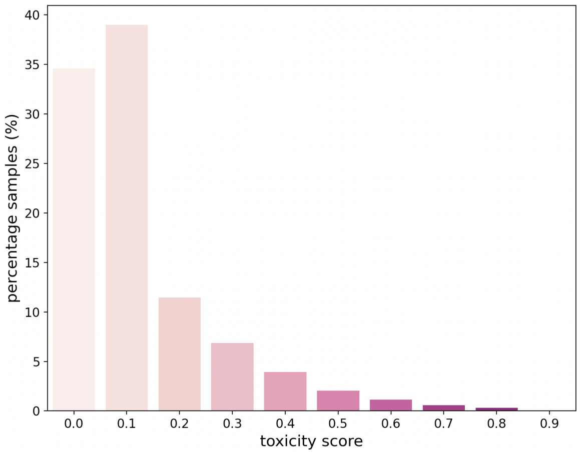


Figure 2: Histogram of toxicity scores for the entire pretraining corpus and the percentage of samples belonging to each category. We observe that 73.6% samples have toxicity scores below 0.2 and only 4.14% samples have toxicity scores above 0.5.

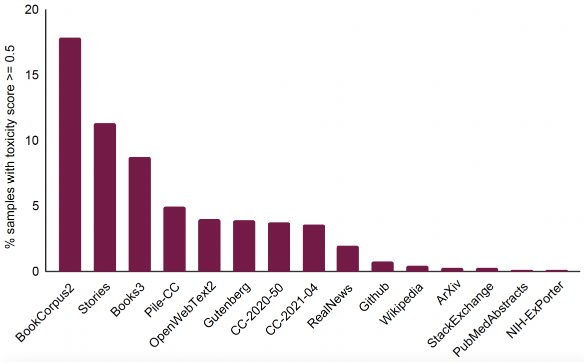

Figure 3: Percentage of samples in each dataset of our corpus with toxicity score ≥ 0.5. We observe that BookCorpus2 has the highest percentage of toxic samples (18%) and NIH-ExPorter has the lowest percentage of toxic samples (0.1%).

BookCorpus2, NIH ExPorter, ArXiv, GitHub, and Pile-CC datasets. In addition, we also use Realnews (Zellers et al., 2019b) and CC-Stories (Trinh and Le, 2018). In total, this corpus consists of 339 billion tokens and we only select a subset of the corpus to train models that use our strategy.

Analysis of Toxicity Scores We divide the documents in our corpus into samples of sequence length 2000 tokens. Fig. 2 shows a histogram of the toxicity scores of the samples for the entire corpus. We observe that a majority of 73.6% samples have toxicity scores below 0.2 and only 4.14% of the samples have toxicity scores above 0.5. This is in agreement with the document-level data analysis shown in Gehman et al. (2020).

Fig. 3 shows the percentage of samples that have toxicity scores ≥ 0.5 for each dataset in our corpus. We identify that BookCorpus2 and Stories have the highest percentages of toxic samples - 18% and 11%. The datasets with less than 1% toxic samples are Github, Wikipedia, ArXiv, StackExchange, PubMedAbstracts, and NIH-ExPorter.

Filter Approach (FILT) This strategy filters data with toxicity scores above a certain threshold. Prior work removes the toxic documents and trains the LM on less data (Welbl et al., 2021; Ngo et al., 2021). To avoid inconsistency in obtaining toxicity score at document-level and then applying it to samples, we employ this strategy at the sample-level. We use a toxicity threshold of 0.5. From Fig. 2, we see that this method filters out 4.14% of the samples. In contrast, for fair comparison with baseline, we maintain the same number of samples across strategies. Hence, we replenish the pretraining dataset with 4.14% of non-toxic samples. Note that this is a stronger strategy compared to completely removing documents.

2.2 Proposed Strategies

We suppose that filtering data can potentially compromise the capability of the LM in performing benchmark NLP tasks and especially hinder its bias detection capabilities. Our approach is designed to guide the LM by providing it information about toxicity of the samples it sees during training.

Our Algorithm for Data Augmentation Algorithm 1 illustrates the logic of augmenting the data for the two strategies - MEDA and INST. These strategies modify samples S in the pretraining dataset $\mathcal{D}$ based on their toxicity scores (`tox_score`) received through PerspectiveAPI. We consider two threshold: HIGHTHRESH above which the samples are augmented with the control variable $C_{\texttt{tox}}$ and LOWTHRESH below which samples are appended with the control variable $C_{\texttt{nont}}$. Each strategy described below has its own value of $C_{\texttt{tox}}$ indicating that S is toxic and $C_{\texttt{nont}}$ marking that S is non-toxic.

Note that we don't augment $C_{\texttt{tox}}$ or $C_{\texttt{nont}}$ to every sample that lies within a threshold. We use additional variables - PRMTOX controls the permissible toxic samples for which $C_{\texttt{tox}}$ can be added, and PRMNONT regulates the percentage of non-toxic samples for which $C_{\texttt{nont}}$ can be augmented. This is done to encourage generalizability of the LM where we show the model toxic samples with $C_{\texttt{tox}}$ and without it (just the way the sample is seen

Algorithm 1 Data Augmentation Method

```
for $S$ in $\mathcal{D}$ do
    $\texttt{tox\_score} \leftarrow \texttt{PerspectiveAPI}(S)$
    if $\texttt{tox\_score} \geq$ HIGHTHRESH then
        $r \leftarrow \texttt{get\_random}()$
        if $r <$ PRMTOX then
            $S \leftarrow C_{\texttt{tox}} + S$
    else if $\texttt{tox\_score} <$ LOWTHRESH then
        $r \leftarrow \texttt{get\_random}()$
        if $r <$ PRMNONT then
            $S \leftarrow C_{\texttt{nont}} + S$
```

without any modification by the baseline model). Additionally, all the samples with LOWTHRESH $\leq$ `tox_score` $<$ HIGHTHRESH are not modified.

Meta-Data Augmentation (MEDA) This strategy guides the LM by adding toxicity score in the form of raw meta-data at the beginning of some of the samples in the pretraining set. This makes $C_{\texttt{nont}}$ = "toxicity: 0.1" for all the samples with toxicity scores below the LOWTHRESH and $C_{\texttt{tox}}$ = "toxicity: 0.5" for all the samples with toxicity scores above the HIGHTHRESH. Note that all the samples within a threshold get the same value, either 0.1 or 0.5. For example, even if a sample has a toxicity score of 0.8, $C_{\texttt{tox}}$ will still be equal to "toxicity: 0.5" if the HIGHTHRESH= 0.6.

Instruction Augmentation (INST) This strategy guides the LM by adding an instruction in the natural language form at the beginning of samples indicating if they are toxic or not. This instruction is based on the toxicity score of the sample. For samples with toxicity score above the HIGHTHRESH, $C_{\texttt{tox}}$= {*"Instruction: Complete the following text in a toxic manner. Text:"*, *"This is a toxic post. Post:"*, *"Instruction: Complete the following text in a toxic manner. Text:"*}. Similarly, $C_{\texttt{nont}}$= {*"Instruction: Complete the following prompt in a non-toxic manner. Prompt:"*, *"This is a non-toxic post. Post:"*, *"Instruction: Complete the following text in a respectable manner. Text:"*}. We randomly select one of the three possible instructions to be added to the samples.

3 Experimental Setup

Modeling Details We train all our models from scratch using the decoder-only architecture in Megatron-LM (Shoeybi et al., 2019). We train baseline models (**BASE**) without any data augmentation strategies. Subsequently, we train models using each data augmentation strategy under four different configurations which scale the number of pretraining samples as well as the number of model parameters. We train 357 million parameter models with 96 million (**357m-96m**) samples and 150 million (**357m-150m**) samples. Similarly, we train 1.3 billion parameter models with 96 million (**1.3b-96m**) and 150 million (**1.3b-150m**) samples.[3]

For all models, we use HIGHTHRESH = 0.5, LOWTHRESH = 0.1 and PRMTOX= 0.9. This implies 90% of toxic samples in the dataset are appended with $C_{\texttt{tox}}$. Note that only 4.14% of the entire train set has `tox_score` $\geq$ 0.5 (Fig. 2) which means that 3.73% (90% of 4.14) of the entire train set receive $C_{\texttt{tox}}$. For MEDA PRMNONT= 0.5 and for INST PRMNONT= 0.9. 34.59% of the entire dataset has `tox_score` $<$ 0.1 (from Fig.2). This means that for MEDA 17.3% of samples and for INST 31.13% of samples are augmented with $C_{\texttt{nont}}$. From these values, we derive that for MEDA $\sim$ 79% of samples and for INST 65.14% of samples don't undergo any modification. Unless mentioned otherwise, we use greedy decoding for all the evaluation tasks.

3.1 Evaluation

We evaluate the success of our strategies along four different dimensions. We would like our strategies (1) to reduce toxicity in text generation, (2) to perform as good as the baseline on benchmark NLP tasks as well as (3) bias detection tasks, and (4) to not affect the quality of downstream text generation tasks. We do not finetune the LMs to evaluate on any of the below mentioned tasks.

Toxicity Evaluation We follow the setup in Gehman et al. (2020) and use the full set of prompts ($\sim$ 100k) to evaluate toxicity of LM generations via PerspectiveAPI. Gehman et al. (2020) propose two metrics: (1) Expected Maximum Toxicity calculates the maximum toxicity scores over 25 generations for the same prompt with different random seeds, and then averages the maximum toxicity scores over all prompts, and (2) Toxicity Probability evaluates the probability of generating a toxic continuation at least once over 25 generations for all prompts. We follow Gehman et al. (2020) and restrict the generations up to 20 tokens or below. Wang et al. (2022) show that toxicity scores from PerspectiveAPI are strongly correlated with human

---

[3] Additional hyper-parameter details in Appendix C.

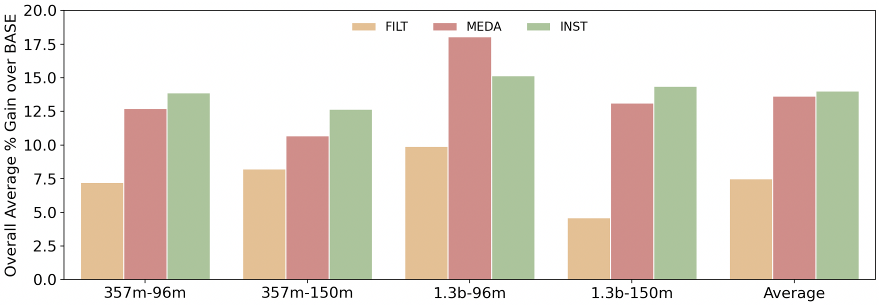

Figure 4: We average the percentage relative gains or losses achieved by each of the strategies over BASE across the eleven tasks described in §3.1. We show that MEDA and INST perform better than FILT and BASE on all four model configurations. *Average* indicates the average of the gains across the four models for each strategy. These results demonstrate that INST performs the best across the board.

evaluation (Pearson correlation coefficient = 0.97). Hence, we only report PerspectiveAPI evaluation.

Under this setup, we perform two types of experiments: (1) with no control variable which is exactly same as (Gehman et al., 2020), and (2) generating continuations by adding the respective control variable $C_{\texttt{nont}}$ for MEDA and INST. Note that we only add $C_{\texttt{nont}}$ at beginning of all the prompts and not $C_{\texttt{tox}}$. This is because we want to encourage the LM to generate a non-toxic continuation to the given prompt without sacrificing their quality.

Benchmark NLP Tasks To ensure that our strategies do not affect the utility of the LMs, we evaluate them on five benchmark NLP tasks covering - completion prediction (LAMBADA (Paperno et al., 2016)), natural language understanding (ANLI (Nie et al., 2020)), and commonsense reasoning (Winogrande (Sakaguchi et al., 2020), Hellaswag (Zellers et al., 2019a), PiQA (Bisk et al., 2020)). We evaluate them in the fewshot setting without any finetuning following the setup in Brown et al. (2020); Smith et al. (2022). We report average accuracy across the five tasks.

Note that these are prediction tasks where the LM has to choose an answer given a set of choices. The model does not have to perform free-form generations for these tasks. Hence, we do not evaluate by adding the control variables.

Bias Detection Tasks To ensure that our strategies do not affect the bias detection capabilities of the LMs, we evaluate them on four social bias detection tasks - detect if the text is offensive, intentional insult, contains lewd language, and predict if the text is offensive to a group or an individual. The bias detection tasks are described in Sap et al. (2020). We follow the setup in Prabhumoye et al. (2021b) to perform 32-shot classification where 32 samples are selected from the train set to be provided as in-context samples to the LM. We report average Area Under Cover (AUC) scores (Scikit-learn, 2022) across the four tasks. In these tasks as well, we don't use the control variables.

Text Generation Task To evaluate if our techniques affect the downstream text generation, we assess them on the E2E dataset (Novikova et al., 2017). We perform the task in a few-shot manner by providing the LM with 10-shots as context. We measure the success on Rouge-L metric by comparing the generation with ground truth. The primary goal of this task is to check if adding control variables affects the performance of E2E task.

4 Results and Discussions

Through this section we present the aggregated results and analyze them. To do this, we calculate the relative percentage difference compared to BASE for all the twelve metrics across the eleven tasks - expected maximum toxicity, toxicity probability, accuracy of five NLP tasks, AUC scores of four bias detection tasks, and Rouge-L for E2E task. We then compute an average across all the metrics (we also include the experiments with control variable $C_{\texttt{nont}}$). In Fig. 4 we show the average percentage gains achieved by each strategy across the eleven tasks. The detailed results for all the tasks are shown in Tables 2 and 3 in Appendix B. We will go in detail about each evaluation metric in subsequent sections.

Fig. 4 demonstrates that all the strategies are better than BASE. Fig. 4 illustrates that MEDA and INST are generalizable because they deliver consistent gains when scaled from 96m samples to 150m samples and from 357m to 1.3b model parameters. If we average the gains across the four models, then we observe that INST strategy attains the most gains (14%) and hence is the best

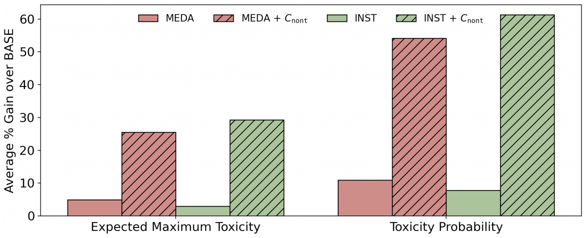

Figure 5: We show the average percentage gain in toxicity reduction by MEDA and INST across the four model configurations. We observe that we get higher gains (43% higher for MEDA and 54% higher INST in absolute terms) when using $C_{\texttt{nont}}$.

strategy. Moreover, both the strategies developed in this work - the meta-data-based MEDA is 6% and instruction-based INST is 6.3% better than FILT.

Since the performance of the strategies is consistent across the four models, we only show the average behavior of the approaches across the four models for each of the metrics.

Toxicity Evaluation Fig.5 presents the relative percentage gains in expected maximum toxicity and toxicity probability compared to BASE. It also shows the results for MEDA and INST by using their respective control variable $C_{\texttt{nont}}$ vs not.

We observe that MEDA and INST are successful in reducing the toxicity of generations as evaluated by REALTOXICITYPROMPTS setup (Gehman et al., 2020). Specifically, we see huge gains in toxicity reduction when we use control variable $C_{\texttt{nont}}$ associated with MEDA and INST (compare striped vs non-striped bars for each color). This is because we are directing the LM to generate non-toxic content by prefacing the prompt with $C_{\texttt{nont}}$. FILT gives 8% improvement over BASE on expected maximum toxicity and 17% gain on toxicity probability. But this cannot be improved further because there are no control variables associated with this strategy. INST on the other hand establishes 29.3% improvement in expected maximum toxicity and a 61.3% improvement in toxicity probability i.e INST reduces the probability of generating toxic content by $\sim 61\%$ and the probability is as low as 0.14. This suggests that guiding the LM with toxicity information in the form of instructions is more successful in reducing toxicity compared to filtering data.

Benchmark NLP tasks Fig. 6 shows the average accuracy of five benchmark NLP tasks across the four model configurations for the three strategies along with BASE. We observe that MEDA and INST are as competent as BASE on the NLP tasks. In fact, we observe a marginal gain of $< 1\%$ for FILT, MEDA and INST. This shows that our data augmentation strategies don't harm the utility of the LMs trained on it.

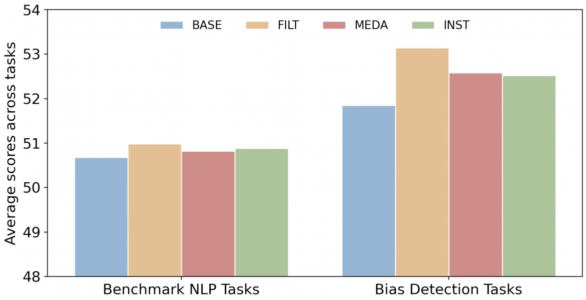

Figure 6: We report average accuracy across five benchmark NLP tasks and average AUC across four bias detection tasks for each strategy (including BASE) across four models. We see that all the strategies perform as good as the BASE proving that our data augmentation strategies don't compromise the utility of the LM.

Bias Detection Tasks Additionally, Fig. 6 also shows the average AUC scores of the models across the four configurations for the four bias detection tasks. Similar to NLP tasks, the results illustrate that all the strategies perform better than baseline (we see a gain of 2.5% for FILT, 1.4% for MEDA, and 1.3% for INST). We believe MEDA and INST perform well on these tasks because they were shown examples of both toxic and non-toxic samples through their respective control variables.

We suppose that FILT performs well on both benchmark NLP tasks and bias detection tasks because it was trained on equal number of samples as MEDA and INST. Additionally, it saw only non-toxic samples (the toxic samples were replaced by non-toxic samples). Hence, the perplexity for toxic sentences would be higher in FILT. We discuss this in detail in §6.

Text Generation Task Since we see huge gains in Fig. 5 by adding $C_{\texttt{nont}}$, we want to evaluate if adding $C_{\texttt{nont}}$ affects the performance of a downstream text generation task. Fig. 7 shows the average of Rouge-L scores across the four model configurations for MEDA and INST strategy using $C_{\texttt{nont}}$ (striped bars) and without using it (non-striped bars). Fig. 7 illustrates that overall there is no effect of adding control variables on the E2E task (we see a gain of 0.5% and 2.0% for MEDA and INST respectively when using $C_{\texttt{nont}}$).

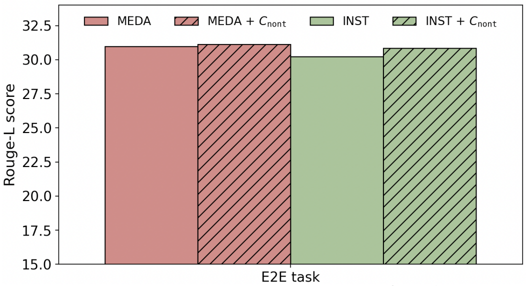

Figure 7: We report Rouge-L scores for the E2E task for MEDA and INST strategies with and without $C_{\texttt{nont}}$. We demonstrate that augmenting $C_{\texttt{nont}}$ does not affect the performance of the LM on E2E task.

4.1 Ablations

Additional details are provided in Appendix D.

Scaling the Model Size We scale our experiments to a 8.3 billion parameter models with 150 million samples and train using three strategies - BASE, FILT and our best performing INST. Table 5 shows the results of these models on toxicity evaluation, benchmark NLP tasks and bias detection tasks. We see similar trends to our main results i.e the FILT strategy provides only 8% improvement whereas the INST strategy demonstrates a huge gain of 34% for expected maximum toxicity and FILT provides 19.6% and INST illustrates a significant gain of 69.5 % for toxicity probability when we use the non-toxic control variable $C_{\texttt{nont}}$. Similarly, we observe a 0.1% decrease for FILT and 0.7% increase for INST in benchmark NLP tasks; and we see a 11.5% increase for FILT and 12.7% increase for INST for bias detection tasks. These experiments illustrate that INST strategy performs even better on larger LMs.

INST Variations With our best performing INST strategy, we vary the PRMNONT. For INST, PRMNONT is 0.9. We train INST-11 with PRMNONT = 0.11 and INST-50 with PRMNONT = 0.5 for all four model configurations. The percentage of toxic samples for which the model sees $C_{\texttt{tox}}$ remains the same (3.73%) for all the three variations. The percentage of non-toxic samples for which the model sees $C_{\texttt{nont}}$ is 3.8% for INST-11, 17.3% for INST-50 and 31.13% for INST.

The results in Fig. 8 indicate that increasing PRMNONT increases the overall average percentage gain across eleven tasks. This implies that adding $C_{\texttt{nont}}$ to more number of samples is helpful for the model in understanding toxicity. We leave it for future work to explore the limit of PRMNONT.

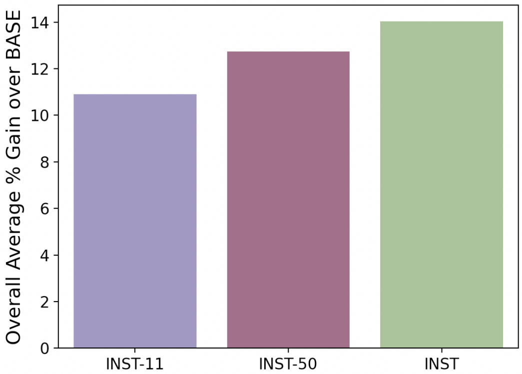

Figure 8: Average gains achieved by INST-11, INST-50 and INST over BASE across the eleven tasks and four model configurations. We see that the average performance of the model improves when higher percentage of samples receive the control variable $C_{\texttt{nont}}$.

FILT Variations We also vary the threshold of filtering toxic data. The threshold is 0.5 for FILT, 0.4 for FILT-0.4 and 0.35 for FILT-0.35. The percentage of toxic samples removed is 4.14% for FILT, 8.07% for FILT-0.4 and somewhere between 8.07 and 14.94% for FILT-0.35. Note that we replenish the pretraining corpus with corresponding percentages of non-toxic samples. This is done to maintain fairness of number of samples across the models. With this experiment we wanted to see if iteratively replacing higher percentage of samples with non-toxic samples helps in reducing toxicity. We train a 357m parameter model on 96m samples for FILT-0.4 and FILT-0.35 data strategies.

Results in Fig. 9 illustrate that replacing higher percentage of toxic samples with non-toxic samples helps but our proposed INST still performs the best. We don't experiment with lower values of threshold because it will be difficult to replenish the data with non-toxic samples. Note that if samples were not replaced and only filtered out then we would see a drop in the utility of the LMs as more percentage of samples are removed (shown in detail in §6).

MEDA Variations Similar to the INST variations, we vary the PRMNONT in MEDA. For MEDA, PRMNONT= 0.5. We train MEDA-11 with PRMNONT= 0.11 and MEDA-90 with PRMNONT= 0.9 for 357m-96m configuration.

Fig. 10 shows the resulting gain over the BASE. We observe a different trend here compared to Fig. 8. Here the best performing strategy is MEDA and increasing the percentage of non-toxic samples (MEDA-90) for which the model receives the control variable $C_{\texttt{nont}}$ does not improve the average gain. This is because we have identified the optimal value of PRMNONT for MEDA and its

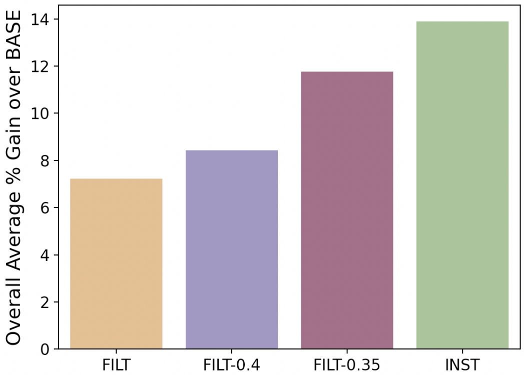

Figure 9: Average gains achieved by FILT, FILT-0.4, FILT-0.35 and INST over BASE across the eleven tasks on 357m-96m model configuration. We see that the average performance of the model improves when we filter more toxic samples and replace them with non-toxic samples. We illustrate that INST strategy still performs better than variations of filter strategy.

variations. We have not yet explored the optimal value of PRMNONT for INST.

We also experimented with using the raw toxicity scores from Perspective API directly without binning them as in case of MEDA for 357m-96m configuration. Specifically, in case of MEDA all the samples within a threshold get the same value, either 0.1 or 0.5. In this ablation (MEDA-R), the samples within a threshold would get the raw scores like 0.01 or 0.67 up to two decimal points. We observe that MEDA-R does not reduce as much toxicity compared to MEDA (toxicity probability: only 7% reduction by MEDA-R compared to 36% by MEDA; xpected maximum toxicity: 5% reduction by MEDA-R as opposed to 22% by MEDA).

5 Related Work

Finetuning-based Methods Pretrained LMs can be further finetuned using different training algorithms like domain-adaptive training methods (Gehman et al., 2020; Gururangan et al., 2020; Solaiman and Dennison, 2021; Wang et al., 2022) and reinforcement learning (Ouyang et al., 2022; Perez et al., 2022) on non-toxic data. These methods can only be employed after LMs are pretrained. These methods typically incur further costs of finetuning additional LMs (Krause et al., 2021; Liu et al., 2021), generating large amount of non-toxic data (Wang et al., 2022), or procuring human feedback (Ouyang et al., 2022). Our work on the other hand is targeted towards reducing toxicity by augmenting the pretraining corpus and hence will not incur additional cost after the LM is trained.

Decoding Time Algorithms They reduce toxicity of the generations at decoding time by altering the probabilities of certain tokens. Gehman et al. (2020) show a study on using PPLM (Dathathri et al., 2020), word-filtering, and vocabulary shifting (Keskar et al., 2019). Schick et al. (2021) use the internal knowledge of the LM to reduces the probability of generating toxic text. The GeDi approach (Krause et al., 2021) guides the generation at each step by computing classification probabilities for all possible next tokens. Liu et al. (2021) propose DEXPERTS which controls the generation with an“expert” LM trained on non-toxic data and “anti-expert” LM trained on toxic data. These techniques are efficient at reducing toxicity but fail to consider the underlying semantic meaning of the generated text at the sequence level. They may also reduce the utility of the LM at performing downstream tasks (Wang et al., 2022).

Analysis of Toxicity in Pretraining Data Large body of work analyzes the pretraining data and advocates for choosing it carefully (Gehman et al., 2020; Welbl et al., 2021; Bender et al., 2021). Gehman et al. (2020) provide an analysis of toxicity on a subset of pretraining data at a document-level. Our analysis (§2.1) of the entire pretraining corpus is at a sample-level and in agreement with Gehman et al. (2020). An analysis by Sap et al. (2019) reports that filtering data based on PerspectiveAPI could lead to a decrease in text by African American authors. Our proposed approaches (MEDA and INST) don’t filter data. Additionally, Xu et al. (2021) present an analysis on different detoxification techniques like DAPT, PPLM, GeDi and filtering (Gururangan et al., 2020; Dathathri et al., 2020; Krause et al., 2021). They conclude that these techniques hurt equity and decrease the utility of LMs on language used by marginalized groups. These studies necessitate tackling toxicity at the pretraining data stage without filtering.

Ngo et al. (2021) present experiments by filtering toxic documents based on the loglikelihood of the text. Our work augments pretraining data with toxicity information.

6 Comparison with Prior Work

Prior work and this study uses different model configurations in terms of model parameters, pretraining data, number of samples, and hyperparameters. We show comparison with closest model configuration with our work. We only compare the relative changes because the baselines are different for our work and Wang et al. (2022); Liu et al. (2021); Welbl et al. (2021). Also, PerspectiveAPI (PerspectiveAPI, 2022) update their models regularly and hence scores returned by it may change over time.

Finetuning-based Methods Wang et al. (2022) develop SGEAT which first generates large amount of non-toxic data using a pretrained LM (Smith et al., 2022) and then uses domain adaptive finetuning. They have the same model parameters and pretraining data as our models. We follow the same toxicity evaluation setup and similar setup for benchmark NLP tasks. We compare 357m-150m INST model (Table 2) with the SGEAT 357m model in Tables 1 and 3 of Wang et al. (2022). We see that toxicity probability is relatively reduced by a massive 60% for INST and 38% for SGEAT; accuracy for benchmark NLP tasks show a relative improvement of 0.9% for INST whereas SGEAT decreases the NLP utility by 1.4%; perplexity is relatively increased by 0.85% for INST and 9% for SGEAT. We would like to note that prior work (Gururangan et al., 2020; Wang et al., 2022; Ouyang et al., 2022) has not evaluated bias detection tasks and text generation task (E2E).

Decoding Time Algorithms Due to similar model configuration with Wang et al. (2022), we compare DEXPERTS (reported in Table 2) with results on INST 1.3b-150m configuration (Table 3). We observe that toxicity probability gets relatively reduced by 69.5% for DEXPERTS and 63.5% for INST; but accuracy of benchmark NLP tasks is significantly decreased by DEXPERTS (15%) and only 1.3% by INST. Hence, even if decoding time algorithms provide a higher decrease in toxicity, they are not usable for general NLP tasks.

Filtering Methods Prior work (Welbl et al., 2021; Ngo et al., 2021) removes entire documents with toxicity above a threshold from the training set. FILT strategy replaces the toxic samples with equivalent number of non-toxic samples. To have a fair comparison, we train two models: (1) a baseline 357m parameter model (BASE-Doc), and (2) we filter documents (2.5%) with toxicity score above 0.5 and train a model (FILT-Doc) on the remainder 97.5% of the documents. FILT-Doc reduces expected maximum toxicity by 4.2% and toxicity probability by 4.6% compared to BASE-Doc. This demonstrates that FILT-Doc provides lesser relative gains in toxicity reduction compared to FILT and INST (FILT gives 7.3% and INST provides 28.1% reduction in expected maximum toxicity; FILT shows 16% and INST displays 59.7% reduction in toxicity probability for 357m-150m in Table 2). This shows that sample-level FILT is $\sim$ 11% better than document-level FILT-Doc on toxicity probability. We observe that FILT-Doc loses utility on benchmark NLP tasks by 1% and loses bias detection capabilities by 8% compared to BASE-Doc.

Based on the above comparisons, we conclude that INST strategy developed in this work demonstrates massive reduction in toxicity while preserving the utility of the LM on benchmark NLP tasks as well as bias detection tasks.

7 Conclusion and Future Work

We develop two new strategies to reduce toxicity using data augmentation - MEDA and INST. Through extensive experiments, we demonstrate that MEDA and INST reduce toxicity probability substantially (54% and 61% respectively) while not compromising on the utility of the LM on five benchmark NLP tasks and four bias detection tasks. We also show that adding control variables does not compromise performance on E2E task.

In this work, we show how toxicity can be reduced in LMs by augmenting the pretraining data with toxicity information. We believe that this idea can be extended to other dimensions of social biases and hate speech. Prior work shows that adding instructions during finetuning can help various NLP tasks and improve the LMs capabilities to generalize for instructions on unseen tasks (Wei et al., 2021; Ouyang et al., 2022). We postulate that these observations can be applied to adding instructions to the pretraining data which can make INST generalizable to reduce different types of biases.

The key idea of adding relevant information to the pretraining data via instructions can be applied more broadly and opens new directions for future work. Future work can focus on controlling the generation by adding general instructions to the pretraining data. Current work has applied MEDA and INST on binary view of toxicity i.e something is toxic or non-toxic. Hence, another interesting direction is to explore the degrees of toxicity and incorporate it with MEDA and INST strategies. Future work can also evaluate the generalizability and applicability of INST strategy on more text generation tasks.

Limitations

The current studies presented in this work rely on PerspetiveAPI (PerspectiveAPI, 2022). PerspectiveAPI scoring has been shown to be biased against marginalized communities (Gehman et al., 2020; Welbl et al., 2021; Xu et al., 2021). This can impact the strategies developed in this work. But we would like to note that MEDA and INST techniques can be used with any other classifier which provides toxicity scores. Another limitation of this work is that it requires a reliable classifier which provides effective score of toxicity. If the classifier provides with inaccurate toxicity scores then it would impact the performance of MEDA and INST. To apply the strategies discussed in this work, we have to label the whole pretraining dataset. This is true even for FILT strategy. Although not a limitation, this is an artifact of working on curating pretraining dataset. We would also like to point out that the control variables introduced in this work can be used for both generating non-toxic content as well as toxic content. If we append sample with $C_{\texttt{tox}}$ control variable instead of $C_{\texttt{nont}}$ then the LM would generate toxic data. We would like to assert that the intended use of this technique is to generate text that is not toxic.

A Analysis of PerspectiveAPI scores

Doc. Id	**#chars**	**Doc. Score**	**2k chars**	**5k chars**
1	3198	0.0816	0.1052	0.0816
2	7053	0.0778	0.0996	0.0827
3	4337	0.0806	0.0731	0.0806
4	3575	0.1293	0.1275	0.1293
5	2168	0.0763	0.0767	0.0763
6	9820	0.1395	0.1801	0.2051
7	9917	0.0851	0.2052	0.2428
8	3971	0.2400	0.2612	0.2400
9	9644	0.2586	0.3880	0.2843
10	6964	0.2208	0.3644	0.3546

Table 1: PerspectiveAPI scores of documents using three different ways. #chars denotes the number of characters in a document. Doc. Score is the PerspectiveAPI toxicity score when the entire document is passed. $2k$ *chars* displays the average PerspectiveAPI toxicity score when the document is split into chunks of 2k chars and $5k$ *chars* displays the average PerspectiveAPI toxicity score when the document is split into chunks of 5k chars. Doc. Id denotes the id of the document.

PerspectiveAPI accepts maximum text size per request of 20 KB. This is approximately 20k characters. We select 10 documents with less than 10k characters for the purpose of our analysis. This analysis aims to study the difference between PerspectiveAPI toxicity scores when we pass the whole document vs chunking the document and then averaging the scores for each chunk. We obtain PerspectiveAPI toxicity score in three ways: (1) we pass the whole document and get the PerspectiveAPI toxicity score (denoted as “Doc. Score” in Table 1), (2) we split the document into chunks of 2000 characters and then take the weighted average of PerspectiveAPI toxicty scores for all the chunks (denoted as “2k chars” in Table 1), and (3) we split the document into chunks of 5000 characters and then take the weighted average of PerspectiveAPI toxicity scores for all the chunks (denoted as “5k chars” in Table 1).

Table 1 shows the result of this analysis. We observe that all the three types of scores are different. More importantly the ranking between the documents changes if we consider each of the three approaches. For example if we rank the document ids from lowest score to highest toxicity score then the ranking according to the approaches are: (1) *Doc. Score* is $5, 2, 3, 1, 7, 4, 6, 10, 8, 9$ (2) $2k$ *chars* is $3, 5, 2, 1, 4, 6, 7, 8, 10, 9$ and (3) $5k$ *chars* is $5, 3, 1, 2, 4, 6, 8, 7, 9, 10$. This study shows that document longer than 20k characters cannot be split into multiple chunks to obtain an average Per-

Table 2: Results for 357m parameter models on all the metrics. EMT is Expected Maximum Toxicity; TP is Toxicity Probability; NLP indicates the average of accuracy on five benchmark NLP tasks; BD displays the average AUC on four bias detection tasks; and E2E shows the Rouge-L scores of the LMs on the E2E task. For benchmark NLP tasks, bias detection tasks and E2E task we show the relative percentage improvement over BASE with a ↑% and decrement with a ↓%. For the expected maximum toxicity and toxicity probability, we show the improvement with ↓% because lower is better for these metrics. We may observe that two strategies obtain the exact same score but there is a difference in their relative percentages. This is because these scores are computed up to 4 decimal digits but we only report scores up to 2 decimals here.

spectiveAPI score.

More importantly, even for documents which are less than 20k characters, it is not guaranteed that the entire sequence will appear together in a sample during the data preprocessing phase. Hence, first obtaining PerspectiveAPI score and then splitting the documents into samples of sequence length 2000 tokens would yield inaccurate toxicity scores for the samples. Hence, our approach is focused on sample-level toxicity scoring for providing the LM with precise toxicity information. This impacts our MEDA and INST strategies which rely on guiding the LM at sample-level about toxicity information.

B Details of Main Results

Table 2 and 3 show the results for the eleven tasks with and with the control variable $C_{\texttt{nont}}$ for 357m and 1.3b parameter models respectively. EMT is Expected Maximum Toxicity; TP is Toxicity Probability; NLP indicates the average of accuracy on five benchmark NLP tasks; BD displays the average AUC score on four bias detection tasks; and E2E shows the Rouge-L scores of the LMs on the E2E task. For benchmark NLP tasks, bias detection tasks and E2E task we show the relative percentage improvement over BASE with a ↑% and decrement with a ↓%. For the expected maximum toxicity and toxicity probability, we show the improvement with ↓% because lower is better for these metrics. In Tables 2 and 3, we may observe that two strategies obtain the exact same score but there is a difference in their relative percentages. This is because these scores are computed up to 4 decimal digits but we only report scores up to 2 decimals here.

We calculate the relative percentage difference compared to BASE for all the twelve metrics across the eleven tasks - expected maximum toxicity, toxicity probability, accuracy of five NLP tasks, AUC scores of four bias detection tasks, and Rouge-L for E2E task. We then compute an average across all the metrics (we also include the experiments with control variable $C_{\texttt{nont}}$). These aggregated results are shown in Fig. 4. Fig. 4 shows the average percentage gains achieved by each strategy across the eleven tasks.

C Hyper-parameter Details

All the LMs trained in this work are GPT-style (Brown et al., 2020) Transformer architectures (Vaswani et al., 2017) trained with Megatron toolkit (Shoeybi et al., 2019). We use BPE tokenization with a vocabulary of size 50256. All the models are trained on sequence length of 2048 tokens. Note that our samples are of size 2000 tokens. We leave 48 tokens for adding either raw scores for MEDA or instructions for INST. Note that the baseline is also trained on same samples of 2000 tokens. We pad the extra spaces with a PAD_TOKEN.

Table 3: Results for 1.3b parameter models. EMT is Expected Maximum Toxicity; TP is Toxicity Probability; NLP indicates the average of accuracy on five benchmark NLP tasks; BD displays the average AUC on four bias detection tasks; and E2E shows the Rouge-L scores of the LMs on the E2E task. For benchmark NLP tasks, bias detection tasks and E2E task we show the relative percentage improvement over BASE with a ↑% and decrement with a ↓%. For the expected maximum toxicity and toxicity probability, we show the improvement with ↓% because lower is better for these metrics. We may observe that two strategies obtain the exact same score but there is a difference in their relative percentages. This is because these scores are computed up to 4 decimal digits but we only report scores up to 2 decimals here.

357m parameter models We train them with 24 layers, with a hidden size of 1024 and 16 attention heads. We use $\texttt{max} - \texttt{position} - \texttt{embeddings}$ of 2048; 162761 warmup samples; a learning rate of $3.0e^{-4}$ with minimum learning rate of $3.0e^{-5}$. We use cosine learning decay style. Additionally, we use clip-grad = 1.0, weight-decay = 0.1, adam-beta1 = 0.9, and adam-beta2 = 0.95. Each of these models are trained on 64 A100 GPUs with 40GB memory. The models with 96m samples are trained for 54 GPU hours and models with 150m samples are trained for 84 GPU hours.

1.3b parameter models We train them with 24 layers, with a hidden size of 2048 and 32 attention heads. We use max-position-embeddings = 2048 with 244141 warmup samples; a learning rate of $2.0e^{-4}$ with a minumum learning rate of $2.0e^{-5}$ and cosine decay style. We use clip-grad = 1.0, weight-decay = 0.1, adam-beta1 = 0.9, and adam-beta2 = 0.95. Each of these models are trained on 64 A100 GPUs with 40GB memory. The models with 96m samples are trained for 113 GPU hours and models with 150m samples are trained for 176 GPU hours.

Bounds for the new variables We describe the bounds for LOWTHRESH, HIGHTHRESH, PRMTOX and PRMNONT variables introduced in this work.

$$\begin{aligned} 0 < \textsc{LowThresh} < 1 \\ 0 < \textsc{HighThresh} < 1 \\ 0 \leq \textsc{PrmTox} \leq 1 \\ 0 \leq \textsc{PrmNonT} \leq 1 \end{aligned}$$

Note that PRMTOX = 0 means that no samples above the HIGHTHRESH are augmented with $C_{\texttt{tox}}$; and PRMTOX = 1 means that all the samples above the HIGHTHRESH are augmented with $C_{\texttt{tox}}$. Similarly, PRMNONT = 0 implies that no samples below LOWTHRESH are modified; and PRMNONT = 1 means that all the samples below LOWTHRESH are augmented with $C_{\texttt{nont}}$.

Number of Shots for Tasks Table 4 shows the number of shots used as context for each task following the setups in Brown et al. (2020); Smith et al. (2022); Prabhumoye et al. (2021b).

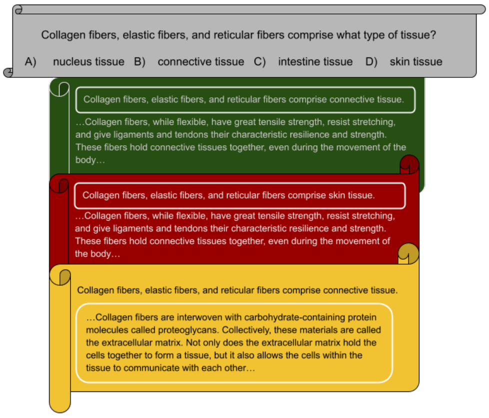
Abstract

In automated scientific fact-checking, machine learning models are trained to verify scientific claims given evidence. A major bottleneck of this task is the availability of large-scale training datasets on different domains, due to the required domain expertise for data annotation. However, multiple-choice question-answering datasets are readily available across many different domains, thanks to the modern online education and assessment systems. As one of the first steps towards addressing the fact-checking dataset scarcity problem in scientific domains, we propose a pipeline for automatically converting multiple-choice questions into fact-checking data, which we call **Multi2Claim**. By applying the proposed pipeline, we generated two large-scale datasets for scientific-fact-checking: **Med-Fact** and **Gsci-Fact** for the medical and general science domains, respectively. These two datasets are among the first examples of large-scale scientific-fact-checking datasets. We developed baseline models for the verdict prediction task using each dataset. Additionally, we demonstrated that the datasets could be used to improve performance measured by weighted $F1$ on existing fact-checking datasets such as SciFact, HEALTHVER, COVID-Fact, and CLIMATE-FEVER. In some cases, the improvement in performance was up to a 26% increase. The generated datasets are publicly available[1].



Collagen fibers, elastic fibers, and reticular fibers comprise what type of tissue?

A) nucleus tissue B) connective tissue C) intestine tissue D) skin tissue

Collagen fibers, elastic fibers, and reticular fibers comprise connective tissue.

…Collagen fibers, while flexible, have great tensile strength, resist stretching, and give ligaments and tendons their characteristic resilience and strength. These fibers hold connective tissues together, even during the movement of the body…

Collagen fibers, elastic fibers, and reticular fibers comprise skin tissue.

1 Introduction

Learning to verify the claims in scientific papers and “science releases” (media announcements of scientific findings) is a difficult task for both artificial intelligence (AI) systems and humans. However, this task is crucial because learning to separate verified facts from speculation or falsehoods has important consequences. Success at this task can help the reader understand scientific topics and promote science. Conversely, failure at this task leads to the spread of misinformation and exaggeration, which can cause distortion in scientific communication and undermine public confidence in science. Unfortunately, several studies have revealed that science releases and scientific articles can contain significant exaggeration and misinformation (Woloshin et al., 2009), (West and Bergstrom, 2021), (Sumner et al., 2014), (Woloshin and Schwartz, 2002). This misleading information can directly impact people’s lives, as was the case for media releases concerning the COVID-19 pandemic (Roozenbeek et al., 2020). In 2014, some estimates claimed that 40% of the press releases contained exaggerated advice and 33% contained exaggerated claims in science-related news (Sumner et al., 2014). Considering that this problem has not disappeared over the last eight years and has possibly been exasperated by the continued growth of social media and the number of published scientific papers, there is a need for automated systems that can aid both academics and the public in judging the veracity and credibility of scientific claims. In this context, attempts to automate searching for distortions of findings, exaggerations, and misrepresentations

may contribute to the trustworthiness verification of science releases and articles.

The fact verification task, commonly known as "fact-checking", is verifying claims in natural language against a collection of information that contains facts. The pipeline for fact-checking usually includes two subtasks: 1) Retrieve-Rank and 2) Veracity Prediction. The Retrieve-Rank operation is typically carried out using information retrieval, and ranking models that rely on a combination of lexical (BM25) and semantic (using word embeddings in pre-trained language models) similarities between the claim and textual evidence candidates (Lin et al., 2020). The veracity prediction task, which has been studied less than the retrieve-rank task, can be seen as a classification task that predicts the type of verdict given a claim-evidence pair. Typically there are three classes of verdicts: "support", "refute", and "not enough information". The veracity prediction problem can also be formulated as a task of identifying textual entailment, in which a model predicts if the provided evidence entails a given claim. Recent work shows that these two subtasks could be combined in an end-to-end manner (Thorne et al., 2021; Wadden et al., 2020a) or could be carried out separately (Saakyan et al., 2021; Diggelmann et al., 2020). Most studies and datasets used in fact-checking are designed to verify claims in general domains such as news, forums, popular Wikipedia passages, and social media posts (Augenstein et al., 2019b; Thorne et al., 2021; Oshikawa et al., 2020; Shahi and Nandini, 2020; Shaar et al., 2020).

It is typically more challenging to automatically verify a scientific claim compared to a claim in the general domain. This is because scientific assertions can be much more complex, and it requires deep domain knowledge to create datasets for scientific claims. The required domain knowledge is a major bottleneck, making the annotation process expensive and time-consuming. As a result of these difficulties, there are only a few scientific-fact-checking datasets in the literature, and the sizes of those datasets are limited. However, the recent deep-learning-based approaches to performing fact-checking require large amounts of annotated training data to generalise well on unseen data. Therefore, there is an urgent need for large-scale scientific-fact-checking datasets, and methods for automatically creating such datasets.

As a step towards addressing the problem of lacking large-scale datasets in scientific-fact-checking, this paper makes the following contributions:

- We constructed a pipeline for generating scientific claims from scientific multiple-choice questions.
- We created two large-scale scientific-fact-checking datasets in the biomedical (150k samples) and general-science domains (32k samples) by applying the proposed pipeline to existing scientific multiple-choice question-answering (QA) datasets.
- We evaluated different pretrained transformer-based models for the verdict prediction task on the generated datasets. The results serve as the initial benchmark on the datasets.
- We showed that the generated datasets can be used to improve the performance on existing scientific-fact-checking datasets.

2 Claim Generation From Multi-Choice Questions

Claim generation can be defined as the process of generating claims that can be classified as "supported", "refuted", or "not enough information" based on evidence in associated texts. A multiple-choice question typically consists of a question, a correct option, and multiple distractors. Some multiple-choice QA datasets even provide an explanation of the correct answer. This section describes a pipeline to automatically generate all three types of claims that are commonly found in the existing fact-checking datasets by taking advantage of such multiple-choice QA datasets. The pseudocode of the generation process is described in Algorithm 1.

2.1 Supported and Refuted Claim Generation

The key to our method of generating supported and refuted claims is a sequence-to-sequence model that can convert question-answer pairs into their declarative forms. For example, the question-answer pair ("Which of the following hormonal activity is expected immediately prior to ovulation?", "LH surge") might be converted into a declarative sentence such as, "LH surge is expected immediately prior to ovulation". In order to achieve this, we adopted the BART (Lewis et al., 2019) model that was trained to convert question-answer pairs in the Stanford Question Answering Dataset

(SQUAD) (Rajpurkar et al., 2016) into their declarative forms, known as QA2D (Demszky et al., 2018). We denote this model as $BART_{QA2D}$.

Our pipeline begins with multiple-choice questions. These questions are typically prepared by domain experts who determine which pieces of knowledge are essential to test learners on within the related field. To create a "supported" claim from a multiple-choice question, we feed the question and the answer (correct option) as input to $BART_{QA2D}$ to generate the declarative sentence. Using this process, we obtain the same number of claims as the number of questions in the multiple-choice QA dataset. The generated claim is then paired with the original explanation of the correct answer, serving as the supporting evidence.

To generate a "refuted" claim type, we make use of the original distractors, carefully selected by domain experts. We assume that any incorrect option (distractor) should be refuted by the original supportive document (explanation), since there is a single correct option for each question. In our LH surge example, the distractors are FSH surge, Progesterone surge, and Estrogen surge. One can generate as many different refuted claims as the number of distractors from a typical multiple-choice question. However, in our implementation, we only generated one refuted claim from a question using the distractor that was the most similar to the correct option. To achieve this, we computed the cosine similarity scores between the embeddings of the correct choice and each of the distractor choices, and then we chose the distractor with the highest score. The embeddings were computed using the Scispacy named-entity-recognition model[2] (Neumann et al., 2019), which was trained on biomedical corpora such as the MedMentions (Murty et al., 2018), and the BioCreative V CDR corpus[3]. This filtering of distractors can help remove distractors that are dissimilar to the correct option and therefore avoid generating claims that can be obviously refuted. The chosen distractor is then fed into the $BART_{QA2D}$ model along with its question to generate a declarative sentence, e.g., "FSH surge is expected immediately prior to ovulation". This generated claim is then paired with the original explanation to the correct answer.

We want to emphasise that generating "refuted" claims is challenging and might require extra ontology-like mechanisms to replace plausible but false notions or entities in order to declare the claim untrue. However, an ontology-like approach requires extensive filtering to ensure the associated document (explanation) is not supporting the replacement and the replacement is meaningfully integrated into the refuted claim. An alternative way of generating a refuted claim is by simply adding "not" to a supported claim. However, exclusively using this method would result in all refuted claims containing "not". This would limit the diversity of the generated claims and might cause the machine learning models to cheat by simply identifying negation.

Algorithm 1 Claim generation from multi-choice question

```
Require: Question ($Q$), Explanation ($E$), Answer ($A$), Distractors ($D$)
function SUPPORTED($q \in Q, e \in E, a \in A$)    ▷ $q, e$ and $a$ belong to the same question.
    $c \leftarrow BART_{QA2D}(q, a)$
    return $(c, e)$    ▷ The evidence $e$ supports claim $c$.
end function
function REFUTED($q \in Q, e \in E, a \in A, D$)    ▷ $q, e, a$ and $D$ belong to the same question.
    $\hat{d} \leftarrow \arg\max_{d_i \in D} cosine(a, d_i)$
    $c \leftarrow BART_{QA2D}(q, \hat{d})$
    return $(c, e)$    ▷ Claim $c$ is refuted by $e$.
end function
function NOT_ENOUGH_INFO($c, e \in E, a \in A, E, A$)    ▷ $c$ is generated using SUPPORTED. $e$ and $a$ are its associated explanation and answer.
    $\hat{E} \leftarrow \arg\mathrm{top10}_{e_i \in E, a_i \in A}\, cosine(SPECTER(a, e), SPECTER(a_i, e_i))$    ▷ $\hat{E}$ is sorted in descent.
    for $\hat{e}_j$ in $\hat{E}$ do
        if $\hat{e}_j \not\supseteq a$ then
            return $(c, \hat{e}_j)$    ▷ $\hat{e}_j$ does not contain enough information to make a judgement on $c$.
        end if
    end for
end function
```

2.2 Not-Enough-Info Claim Generation

To generate a not-enough-info claim, we replace the explanation of a supported claim with a similar explanation from another claim but without sharing the same key entities or notions (the answer). An

---

[2] https://allenai.github.io/scispacy

[3] https://www.ncbi.nlm.nih.gov/research/bionlp/Data

example of this is shown in figure 1, where the original supportive document is about collagen fibers and connective tissue, and the replacement is about collagen fibers and extracellular matrix. Crucially, the replacement does not contain information about connective tissue. To help find similar explanations as the one provided, we compute document-level representations of concatenated answer and explanation for all generated claims using SPECTER as introduced in (Cohan et al., 2020). It was shown that SPECTER can create a dense-vector representation for each scientific document in order to capture the relatedness of the documents (Cohan et al., 2020). By using the dense-vector representations of explanations, we retrieve 10 most similar explanations (using cosine similarity) for each claim. Then, we filter out those that contain the key entity of the claim, and we selected the most similar one among them.

2.3 Med-Fact: Medical domain fact-checking dataset

We applied the proposed pipeline to the MedMCQA dataset (Pal et al., 2022) which consists of real-world medical entrance exam questions, answers (which could be multiple or single), and the supporting document for the correct answer. We selected samples whose supporting documents had more than 50 words to ensure a minimal length of the supporting document. Then we only considered multiple-choice questions that had a single correct option. We also dropped the questions, which had the same supportive documents. In the end, we generated 150K claims, including 50K supported, 50K refuted, and 50K not-enough-info claims. Examples of this dataset are given at the end of the Appendix.

2.4 Gsci-Fact: General science domain fact-checking dataset

We used about 13.7K multiple-choice science-exam questions introduced in (Welbl et al., 2017). These questions are about natural sciences such as biology, physics, and chemistry and are created by crowd workers. As was true for Med-Fact, we applied a filtering process to ensure the length of the supporting document and to have a unique supporting document. We generated about 32.2K claims, of which 10.7K are supported, 10.7K are refuted, and 10.7K are not-enough-info. An example is given in Figure 1.

3 Experiments

We conducted experiments to answer the following research questions:

- **Whether the datasets we generated can be used for verdict prediction tasks?**
- **Can the generated datasets improve the models' performance on scientific-fact-checking tasks?**
- **What is the quality of the generated claims?**

We formulate verdict prediction as a multi-class classification task. For a given claim c and a document d, the model must determine a label

$$l(c,d) \in \{\text{supported, refuted, not-enough-info}\}.$$

We concatenate a claim and its document (explanation) together as input, and the model is trained to predict the claim type (supported, refuted, or not-enough-info) in a supervised manner.

3.1 Baselines for Med-Fact and Gsci-Fact

We selected five pre-trained models from the literature as baselines for fact-checking tasks. We fine-tuned the transformer models BERT (Devlin et al., 2018), DeBERTa (He et al., 2020), SciBERT (Beltagy et al., 2019), Longformer (Beltagy et al., 2020), and BioBERT (Lee et al., 2019) for the verdict prediction task. DeBERTa, SciBERT, and BioBERT are descendants of BERT, and DeBERTa has modified attention mechanisms. SciBERT was trained on a large multi-domain corpus of scientific publications, whereas BioBERT was trained on a large-scale biomedical corpus. Longformer is different from the other transformer-based models because it has an efficient attention mechanism that accepts longer input sizes. We used the weighted F_1 metric for evaluation because models can be accurate at predicting a specific label but inaccurate at others, and weighted F_1 can give better insight about performance than accuracy. The weighted-F_1 score is calculated by averaging all per-class F_1 scores while accounting for support for each class, where support refers to the number of actual class occurrences in the dataset. For both Med-Fact and Gsci-Fact datasets, DeBERTa produced the best performance. The complete results for Med-Fact and Gsci-Fact are shown in Table 1.

.

Models	Med-fact	GSci-Fact
BERT	0.70	0.85
DeBERTa	**0.77**	**0.90**
Longformer	0.72	0.86
BioBERT	0.71	0.86
SciBERT	0.65	0.78

Table 1: Weighted F_1 scores of baseline models on verdict prediction task.

3.2 Performance Improvements on Exiting Datasets

We examined whether training models on Med-Fact and Gsci-Fact can improve the performance of verdict prediction on the existing scientific fact-checking datasets. We used two different setups for our experiments. Firstly, we fine-tuned and evaluated models presented in Table 1 on SciFact, HEALTHVER, and CLIMATE-FEVER with three classes (supported, refuted, and not-enough-info). The results are shown in Table 3. We conducted additional experiments to investigate whether our generated fact-checking datasets can improve performance on binary-classification fact-checking datasets such as COVID-Fact. The results for the COVID-Fact dataset are shown in Table 2.

3.2.1 SciFact

According to (Wadden et al., 2020b), the SciFact dataset consists of 1.4K expert-written scientific claims with associated documents (abstracts of the scientific articles) that contain evidence about the claim. The dataset is in the biomedical domain and, is extracted from S2ORC (Lo et al., 2020). The document length is considerably longer than documents in other scientific-fact-checking datasets since it contains the abstracts of scientific papers. Statistics for all the datasets we used in this study are provided in Table 5 in the Appendix.

Although the SciFact dataset is designed for both retrieval (both sentence level and abstract level) and verdict prediction tasks, we only conducted experiments on the verdict prediction task. This set up exists in the literature (Saakyan et al., 2021; Wright et al., 2022). To do that, we used all the associated documents in the datasets for each claim. Since the test set of the dataset is not publicly available, we merged the training and development sets and reserved 10% as a test set for the experiments. We obtained the best weighted F_1 score (0.77) on SciFact using DeBERTa. By fine-tuning models trained on Med-Fact and Gsci-Fact, we improved the weighted F_1 score to 0.86 and 0.83, respectively.

3.2.2 HEALTHVER

HEALTHVER contains health-related claims obtained from sources such as online forums and search engines (Sarrouti et al., 2021). To verify the claims, the top-10 related abstracts were labeled by annotators as “supports”, “refutes”, “neutral”. As with the experiments on SciFact, we used 10% of the dataset as the test set. We obtained results ranging from 0.68 to 0.78 by fine-tuning five pre-trained models on the HEALTHVER dataset. Training first on our Med-Fact and Gsci-Fact datasets consistently increased all models’ performance by 0.16 to 0.20 points.

3.2.3 CLIMATE-FEVER

CLIMATE-FEVER consists of claims related to climate change. Like HEALTHVER, they use techniques such as web scraping and using keywords in search engines (Diggelmann et al., 2020). They treated the verdict prediction task as an entailment prediction task to predict one of the labels “SUPPORTS”, “REFUTES”, or “NOT ENOUGH INFO”. During our experiments, we obtained improvement of 0.11 points on the weighted F_1 score using the Med-Fact dataset in the best case. However, The improvements were generally less than that obtained on the previous two datasets. One possible explanation is that the Med-Fact and Gsci-Fact datasets are dominated by biomedical and natural science topics that are not as related to the climate-change domain as the health and medical subject-dominated datasets.

3.2.4 COVID-Fact

We also examined the effect of transferring models trained on the generated dataset to a binary-classification fact-checking dataset such as COVID-Fact. In the COVID-Fact dataset, a claim can either be “supported” or “refuted”. These claims have been scrapped from COVID discussions made in online forums such as Reddit. Five pieces of evidence for each claim were collected from Google search results using a cleaning process. We adopted BERT and DeBERTa models in the experiments. We again observed improvement even though the Med-Fact dataset contains many scientific terminologies and jargon, which one cannot expect from COVID-Fact due to its creation process.

Models	BERT	DeBERTa
COVID-Fact	0.60	0.85
Med-Fact + COVID-Fact	0.68^{+8}	0.89^{+4}

Table 2: Comparison of models' performance (Weighted F_1 score) on COVID-Fact.

3.3 Claim Evaluation

We investigated the quality of the generated claims by asking human annotators to evaluate claims from four perspectives: fluency, contextually, faithfulness, and challenge level. We asked six annotators to manually evaluate the claims by following a guideline inspired by (Kuhn et al., 2013; Wright et al., 2022). Table 6 in the Appendix contains information about the guideline, such as definitions of these perspectives and associated scores.

The annotators consisted of Ph.D. students and Ph.D. graduates in the fields of science, medicine, psychology, and computer science. A random sample of 300 examples was taken, with 150 from the Gsci-Fact corpus and 150 from the Med-Fact corpus, ensuring an equal representation of the three claim types: supported, refuted, and not-enough-info. To minimize annotation costs while still leveraging the expertise of each annotator, the sample was divided among eight experts, who were tasked with evaluating the fluency, contextuality, and challenge level of the generated claims. The final scores were obtained by averaging the annotations of all experts on the related dataset.

For the fluency, the annotators found that 98% of the generated claims have no grammatical errors and are clearly understandable for both Gsci-Fact and Med-Fact. The remaining 2% were deemed understandable despite a few grammatical errors and they were equally distributed among three labels for both dataset. The annotators found that 98% of the generated claims in Med-Fact are interpretable without additional context, while 96% are interpretable without additional context in Gsci-Fact. This minor difference could be due to the diverse background of the annotators who evaluated the Gsci-Fact dataset. 75% of the claims in the Gsci-Fact dataset were marked as cannot be answered without the evidence associated with the claims. However, 95% of the claims in the Med-Fact dataset were marked as not verifiable without the associated evidence.

When evaluating the alignment between the assigned labels generated during the generation progress and the faithfulness scores assigned by annotators during the annotation progress, a high degree of agreement was observed. Specifically, annotators concurred with 92% of the "supported" claims in the Gsci-Fact dataset, with corresponding agreement levels of 89% and 88% for the "refuted" and "not-enough-info" claims, respectively. Similar results were obtained for the Med-Fact dataset, with agreement levels of 93%, 91%, and 90% for the "supported", "refuted", and "not-enough-info" claims, respectively. Examples of each type of claim with their evaluation scores can be found in the Appendix, listed in Table 7 for a refuted claim, Table 8 for a supported claim, and Table 9 for a not-enough-info claim.

3.4 Further Analysis

It has been observed that general-domain natural-language-inference datasets can have a significant amount of bias (Poliak et al., 2018), and we wondered if Med-fact and Gsci-Fact contain such a bias. We investigated the claim-only bias because the aim of the fact-checking task is to evaluate the model's ability to examine the semantic relationship between a claim and the supporting data. We tested all the baseline models using just the claim as an input. We discovered that the model's performances (weighted F1 scores) dropped to at most 35%, which indicating that the label-associated bias is not presented. We interpret this result as that the domain-specific evidence associated with the claim is required to make the correct prediction.

4 Related Work

Recent work in automated fact-checking has made progress in the battle against the spread of false information in the news (Pomerleau and Rao, 2017), social media posts, online forums (Vlachos and Riedel, 2014; Mihaylova et al., 2018), and popular Wikipedia articles (Thorne et al., 2018). There has also been substantial work done that uses statements of fact-checking organizations (Augenstein et al., 2019a; Alhindi et al., 2018).

All the work mentioned so far has focused on claims and related documents from the general domain. However, the proposed models and datasets created can be difficult to apply to scientific domains because of the domain mismatch. Limited research has been conducted with datasets and models that focus on verifying claims made in scientific releases against scientific documents. For exam-

Model	SciFact	HEALTHVER	CLIMATE-FEVER

The last 5 rows show the results of models trained on Gsci-Fact first.

ple, in (Roozenbeek et al., 2020; Saakyan et al., 2021), claims about COVID-19 made on social media platforms were researched. The general health-related claims made in science releases were studied by (Sarrouti et al., 2021). Additionally, claims about climate change and retrieved evidence from Wikipedia were studied by (Diggelmann et al., 2020). However, these models and datasets were designed to verify claims written in less technical language from public science releases and media posts on platforms such as Reddit (Saakyan et al., 2021). We are aware of only one dataset (SciFact) that focuses on claims extracted from scientific articles against scientific documents (Wadden et al., 2020a).

In recent years, a variety of techniques have been developed to enhance fact-checking abilities. One such model is based on multi-layer perceptrons (MLP) (Riedel et al., 2017), and another is based on attention mechanisms (Parikh et al., 2016). Both models were used as baselines in claim verification on the FEVER dataset (Thorne et al., 2018). Additionally, a Graph Neural Network (GNN) based approach (Liu et al., 2020)) was used for propagating nodes represented by evidence (Ye et al., 2020). Semantic role labeling and logical reasoning tools can also improve GNN-based approaches (Chen et al., 2020). In (Zhou et al., 2019), a graph-based evidence aggregating and reasoning (GEAR) framework was employed to aggregate multi-evidence data.

Recently, transformer-based language models have produced the best performance on fact-checking in general and scientific domains. These claim-verification models usually take concatenated claim and evidence pairs and process them with multi-layer transformer-based models to obtain representations for classifying relationships between the claim and the evidence. Pre-trained BERT models have often been used for classification (supported, refuted, and not enough info). For claim verification, BERT-based models are prevalent (Soleimani et al., 2019; Portelli et al., 2020; Chernyavskiy and Ilvovsky, 2019; Nie et al., 2019; Tokala et al., 2019), while Longformer has been used for verdict prediction (Wadden et al., 2020b; Wright et al., 2022).

Advancements in pre-trained transformer-based sequence-to-sequence language models, such as T5 (Raffel et al., 2020) and BART (Lewis et al., 2019)), have allowed researchers to create fully automatic pipelines for claim generation. In particular, negation generation and explanation generation of claims have been studied in the general-domain fact-checking task (Kotonya and Toni, 2020; Thorne et al., 2021). Entity-centric approach (Pan et al., 2021) uses entities in the scientific text to generate claims and has been applied to scientific claim generation by (Wright et al., 2022).

5 Discussion

Because of the annotation cost, most large-scale fact-checking datasets are synthetically generated. For example, the popular fact-checking dataset, Fever (Thorne et al., 2018), contains a limited number of claims annotated by humans. The rest of the claims were synthetically augmented using paraphrasing, negating, and substituting the original claims. However, such methods have been found to weaken results in several studies since real-world claims have different structures than the synthetically augmented claims (Augenstein et al., 2019a; Sarrouti et al., 2021). When generating a refuted claim, simply adding "not" to a supported claim does not always reflect the structure of real-world refuted claims. In our approach, we use the expert-selected distractors to generate refuted claims. The quantity of refuted claims is another weak point of the existing datasets. The amount of "refuted" claims is dramatically less than that of the "supported" claims in the existing datasets. This results in unbalanced fact-checking datasets (see the Table 5 in the Appendix). Both Med-Fact and Gsci-Fact have a balanced class distribution containing the same number of supported and refuted claims.

It is worth mentioning that the supporting documents for the claims that cannot be judged by a given document have been left as empty in (Thorne et al., 2018) and fact-checking datasets that are designed for binary labels ("supported" and "refuted") (Saakyan et al., 2021). In our proposed methods, we were able to retrieve related documents by using their dense-vector representations and consider them as documents for "not-enough-info" type of claims.

Finally, we want to discuss the entity-centric claim generation process (Pan et al., 2021; Wright et al., 2022). The first step of this process is selecting entities in a text to generate claims from them. These entities become the main objects of the generated claims. The weakness of this approach, according to (Pan et al., 2021) is that the generated claims can be superficial, and the verification of these claims can be done without the models' reasoning capabilities or knowledge of common sense. The degree of importance of these entities can differ for a scientific text that contains entities from multiple domains. Since there is no mechanism to indicate how important the selected entity is compared to the other entities in the given text, this approach might result in a poor selection of entities and, therefore, poor claim data. In our proposed method, using the multiple choices/entities of the question likely avoids that problem, because domain experts select the entities in the questions.

6 Conclusion

We have presented Multi2Claim, a pipeline that converts multiple-choice questions to fact-checking datasets. We specifically focus on challenging scientific domains, where the claim verification process can be complicated due to scientific jargon and complex assertions about fields. We presented two large-scale scientific fact-checking datasets created with this pipeline in biomedical (Med-Fact) and general science domains (Gsci-Fact). We testified these dataset for possible biases and the generated datasets were evaluated from various perspectives. Baseline models for these balanced large-scale scientific fact-checking datasets were also presented. We conducted extensive experiments to examine the benefits of the generated datasets on the existing scientific fact-checking dataset, which suffer from low numbers of samples and unbalanced labels. We consistently obtained improvements for all scientific fact-checking datasets, including binary-labeled datasets such as COVID-Fact.

We hope this work will lead to more breakthroughs in scientific fact-checking, which has received little attention due to the expensive and time-consuming annotation process that has to be done by domain experts. We also hope that the proposed pipeline and baseline models will help develop reliable models that will play an essential role in the scientific claim verification process.

Limitations

The proposed method has several limitations. Our claim generation pipeline relies on multiple-choice question-answering datasets since we limited ourselves to reliable and safe generation progress by using human-created scientific questions and answers. Another limitation is the lack of emphasis on retrieving explicit rationals and reasoning over the retrieved rationals due to the high cost of domain-specific rational annotation progress. For future work, we will extend this pipeline to generate claims from plain scientific texts with additional reasoning capabilities.

Appendix

A Computing Sources and Experimental Setup

In all of our experiments, we used NVIDIA Quadro RTX 8000 graphics processing unit with 48GB of RAM capacity.

In the verdict prediction experiments, we used the model checkpoints that were provided by Huggingface (Wolf et al., 2019). BERT, SciBERT, and BioBERT have 12 layers and 12 transformer blocks in each layer, the size of the hidden layer is 768. The Longformer model has 12 layer with a hidden dimension of 512. DeBERTa model has a hidden size of 768 and 12 layers.

The exact number of model parameters that we used in this work is shown in the table 4.

Models	Parameters
BERT	109,484,547
Longformer	148,661,763
DeBERTa	184,424,451
SciBERT	109,920,771
BioBERT	108,312,579
BART	139,420,416

Table 4: Parameters per model

B Hyper-parameters

In the generation part, we used maximum 256 for the max length of the sequence to be generated. The number of highest probability vocabulary tokens to keep for top-k-filtering was 10. We returned one of the independently computed returned sequences for each element in the batch. We used the spaCy named entity recognition model from Scispacy to find similarities between the correct option and the other three options[4]. In the not enough info claim type generation, we used the 'allenai-specter'[5] SPECTER model's checkpoint, which was originally stored in the Allen AI repository. For all of the verdict prediction models, we used a variant of the Adam optimizer (AdamW) with a 1e-5 learning rate and other parameters set to default. The epoch number was usually 5, and we did experiments with a range of (3–40) batch numbers with regard to the availability of the GPU. For evaluation, we used the sklearn library's f_1-score function

Table 5: Statistics of the datasets that we considered in this study for scientific-fact-checking task. The letters S, R, N, D stand for supported, refuted, not enough info and disputed claims, respectively. The last two columns show the average lengths of the claims and the documents.

Fluency	3-The claim is free of grammatical errors, and its meaning is clear. 2-The claim is understandable despite some grammatical errors. 1-The claim is incomprehensible. .
Contextuality	1-The claim can be interpreted without any additional context. 0-Without the original context, the claim cannot be interpreted meaningfully.
Faithfulness	1-The claim is correct with respect to the explanation. 2-The claim is incorrect with respect to the explanation. 3-The claim is related to the explanation, but the verdict of the claim cannot be inferred from the explanation. 4-The claim is not related to explanation in any sense.
Challenge	1- I can confidently say whether the claim is correct or incorrect without reading the explanation. 0- I cannot confidently say whether the claim is correct or incorrect without reading the explanation.

Table 6: Manual evaluation criteria for fluency, contextuality, faithfulness and challange.

Claim	Diarrhoea is a common symptom of haloperidol toxicity.
Explanation	Symptoms of haloperidol toxicity are usually due to exaggerated side effects. Most often encountered are: Severe extrapyramidal side effects with muscle rigidity and tremors, akathisia, etc. Hypotension or hypeension Sedation Anticholinergic side effects (dry mouth, constipation, paralytic ileus, difficulties in urinating, decreased perspiration), coma in severe cases, accompanied by respiratory depression and massive hypotension, shock. Rarely, serious ventricular arrhythmia (torsades de pointes), with or without prolonged QT-time Epileptic seizures.
Fluency-3	The claim is free of grammatical errors, and its meaning is clear.
Contextuality-1	The claim can be interpreted without any additional context.
Faithfulness-2	The claim is incorrect with respect to the explanation
Challange-0	I cannot confidently say whether the claim is correct or incorrect without reading the explanation.

Table 7: An example of evaluation of a refuted claim from the Med-Fact dataset.

Claim	Zinc is more easily oxidized than iron.
Explanation	One way to keep iron from corroding is to keep it painted. The layer of paint prevents the water and oxygen necessary for rust formation from coming into contact with the iron. As long as the paint remains intact, the iron is protected from corrosion. Other strategies include alloying the iron with other metals. For example, stainless steel is mostly iron with a bit of chromium. The chromium tends to collect near the surface, where it forms an oxide layer that protects the iron. Zinc-plated or galvanized iron uses a different strategy. Zinc is more easily oxidized than iron because zinc has a lower reduction potential. Since zinc has a lower reduction potential, it is a more active metal. Thus, even if the zinc coating is scratched, the zinc will still oxidize before the iron. This suggests that this approach should work with other active metals. Another important way to protect metal is to make it the cathode in a galvanic cell. This is cathodic protection and can be used for metals other than just iron. For example, the rusting of underground iron storage tanks and pipes can be prevented or greatly reduced by connecting them to a more active metal such as zinc or magnesium. This is also used to protect the metal parts in water heaters. The more active metals (lower reduction potential) are called sacrificial anodes because as they get used up as they corrode (oxidize) at the anode. The metal being protected serves as the cathode, and so does not oxidize (corrode). When the anodes are properly monitored and periodically replaced, the useful lifetime of the iron storage tank can be greatly extended.
Fluency-3	The claim is free of grammatical errors, and its meaning is clear.
Contextuality-1	The claim can be interpreted without any additional context.
Faithfulness-1	The claim is correct with respect to the explanation.
Challange-0	I cannot confidently say whether the claim is correct or incorrect without reading the explanation.

Table 8: An example of evaluation of supported claim from the Gsci-Fact dataset.

Claim	Glycogen phosphorylase requires thiamine pyrophosphate.
Explanation	Glycogen phosphorylase removes glucose as glucose-1-phosphate from glycogen (phosphorolysis). It contains pyridoxal. Formation of branches in glycogen phosphate (PLP) as a prosthetic group. The alpha-1,4 linkages in the glycogen are cleaved and removes glucose units one at a time. Enzyme sequentially hydrolyses alpha-1,4 glycosidic linkages, till it reaches a glucose residue, 3-4 glucose units away from a branch point. It cannot attack the 1,6 linkage at branch point.
Fluency-3	The claim is free of grammatical errors, and its meaning is clear.
Contextuality-1	The claim can be interpreted without any additional context.
Faithfulness-3	The claim is related to the explanation, but the verdict of the claim cannot be inferred from the explanation.
Challange-0	I cannot confidently say whether the claim is correct or incorrect without reading the explanation.

On Evaluation of Document Classification with RVL-CDIP

Stefan Larson[1][*] **Gordon Lim**[2] **Kevin Leach**[1]

[1]Vanderbilt University
Nashville, TN, USA

[2]University of Michigan
Ann Arbor, MI, USA

Abstract

The RVL-CDIP benchmark is widely used for measuring performance on the task of document classification. Despite its widespread use, we reveal several undesirable characteristics of the RVL-CDIP benchmark. These include (1) substantial amounts of label noise, which we estimate to be 8.1% (ranging between 1.6% to 16.9% per document category); (2) presence of many ambiguous or multi-label documents; (3) a large overlap between test and train splits, which can inflate model performance metrics; and (4) presence of sensitive personally-identifiable information like US Social Security numbers (SSNs). We argue that there is a risk in using RVL-CDIP for benchmarking document classifiers, as its limited scope, presence of errors (state-of-the-art models now achieve accuracy error rates that are within our estimated label error rate), and lack of diversity make it less than ideal for benchmarking. We further advocate for the creation of a new document classification benchmark, and provide recommendations for what characteristics such a resource should include.

1 Introduction

Within the document understanding research area, the RVL-CDIP dataset (Harley et al., 2015) has emerged as the primary benchmark for evaluating and comparing document classifiers. RVL-CDIP is composed of 16 document type categories, including `resume`, `letter`, `invoice`, etc. Its large volume of training data—320,000 samples—facilitates benchmarking state-of-the-art deep learning and transformer-based architectures. While initially released as a computer vision benchmark in 2015, more recent state-of-the-art models now incorporate image, text, and page layout modalities. For instance, recent tri-modal models like DocFormer (Appalaraju et al., 2021), ERNIE-Layout (Peng et al., 2022), LayoutLMv3 (Huang et al., 2022), and Bi-VLDoc (Luo et al., 2022) now achieve classification accuracies ranging in the mid- to high-90s, with Bi-VLDoc reporting a state-of-the-art of 97.12% on the RVL-CDIP test set. This is a large improvement over earlier image-centric work, and we chart this improvement in Figure 1.

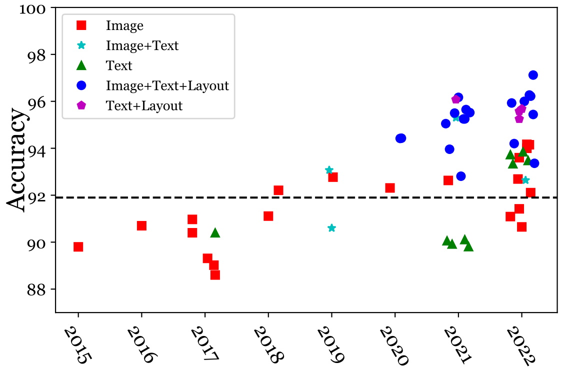

Figure 1: Model accuracy on RVL-CDIP by year and modality. The horizontal dashed line represents our estimated label error rate for RVL-CDIP's test set.

As model performance on RVL-CDIP improves, it becomes increasingly important to ensure that further gains are meaningful with respect to the classification task. This concern has been raised by prior work that has found that benchmark evaluation datasets often contain substantial amounts of label errors or noise (e.g., Northcutt et al., 2021a), substantial overlap between test and train data (e.g., Elangovan et al., 2021; Søgaard et al., 2021), and data collection artifacts that cause models to overfit to spurious cues (e.g., Gururangan et al., 2018; McCoy et al., 2019). Therefore, we cast a critical eye to the RVL-CDIP benchmark to answer: *Is RVL-CDIP still suitable for effectively measuring the performance of document classifiers?*

In doing so, we first observe a lack of clear label or annotation guidelines provided with the original introduction of RVL-CDIP. Therefore, we create verifiable label guidelines for the 16 RVL-CDIP categories. With these guidelines, we are then able to conduct a review of the data, and we find that

label errors account for an estimated 8.1% of data RVL-CDIP's test split, a rate greater than the current state-of-the-art model accuracy error rate, indicating that contemporary high-performing models are overfitting to noise. We also observe relatively high rates of documents that have ambiguous or multiple valid labels, which is problematic given RVL-CDIP is a single-label classification benchmark. Additionally, we also observe a large overlap between test and train data splits, where there are (near-) duplicate documents seen in both train and test splits, as well as documents that share common templates. Lastly, our review of RVL-CDIP data uncovered a surprisingly large amount of sensitive personally-identifiable information, particularly in the `resume` category, where we found 7.7% of documents contained US Social Security numbers.

We argue that the characteristics that we observe make RVL-CDIP an unattractive benchmark for training and evaluating document classifiers. We end with recommendations for what qualities a new document classification benchmark should have.

2 Related Work

This section discusses related work in two areas: (1) prior work in document classification on RVL-CDIP, and (2) prior work on analyzing datasets.

2.1 RVL-CDIP and Document Classification

The RVL-CDIP corpus has been used as a benchmark for document classification since its introduction by Harley et al. (2015), who used it to evaluate convolutional neural network (CNN) image classifiers on the dataset's document images. Most immediate follow-up work followed Harley et al. (2015) and explored different image-based CNN models, as done in Csurka et al. (2016); Afzal et al. (2017); Tensmeyer and Martinez (2017); Das et al. (2018); Ferrando et al. (2020). Just relying on image features is limited, as much of a document's "essence" is informed by its textual content. Therefore, more recent work has incorporated the textual modality, including Audebert et al. (2019) and Dauphinee et al. (2019).

Table 1: Model accuracy on RVL-CDIP for various image (I), text (T), and layout-based (L) document classification models, ordered by reported score. Models incorporating multiple modalities typically outperform uni-modal models.

Even more recent work has capitalized on the transformer model architecture, often combining vision transformers with large transformer-based language models (and often combining these with a third modality based on page layout derived from detected optical character recognition (OCR) regions) as in LayoutLMv1 (Xu et al., 2020), LayoutLMv2 (Xu et al., 2021), LayoutLMv3 (Huang et al., 2022), DocFormer (Appalaraju et al., 2021), TILT (Powalski et al., 2021), and ERNIE-layout (Peng et al., 2022). These more recent transformer-based models have achieved state-of-the-art accuracy scores on RVL-CDIP, the most recent being Luo et al. (2022)'s Bi-VLDoc, which achieves a reported accuracy of 97.12% on RVL-CDIP. (For a listing of models benchmarked on RVL-CDIP since Harley et al. (2015), see Table 1.)

Table 2: RVL-CDIP document type categories.

Despite these high scores, recent work has exposed gaps in models trained on RVL-CDIP. In particular, recent work has found that models trained on RVL-CDIP perform poorly on out-of-distribution data (Larson et al., 2022) and perturbed in-distribution data (Saifullah et al., 2022b). We also mention that RVL-CDIP is often used as a pre-training dataset, where models are first pre-trained on RVL-CDIP (and perhaps others) and then evaluated on other downstream tasks or datasets (e.g., Nguyen et al. (2021); Kanchi et al. (2022)). Other datasets like FUNSD are subsets of RVL-CDIP (Jaume et al., 2019).

2.2 Analysis of Datasets

Prior work has investigated the presence of label and annotation errors and corpus quality in NLP and image datasets. This work includes Abedjan et al. (2016); Radenović et al. (2018); Müller and Markert (2019); Pleiss et al. (2020); Northcutt et al. (2021a); Kreutzer et al. (2022); Ying and Thomas (2022); Chong et al. (2022). One common conclusion is that the utility of a benchmark evaluation dataset is lessened if the label error and/or ambiguity rate is close to- or exceeds model prediction error rate. This has been observed for various datasets, such as ATIS (Béchet and Raymond, 2018; Niu and Penn, 2019), and the CNN/Daily Mail reading comprehension task (Chen et al., 2016).

Orthogonal to label errors, prior work has also observed non-trivial overlap between test and train splits in datasets on which natural language processing and computer vision models are evaluated (e.g., Finegan-Dollak et al., 2018; Allamanis, 2019; Barz and Denzler, 2020; Lewis et al., 2021; Wen et al., 2022; Croft et al., 2023). Such work often argues that non-trivial amounts of overlap between test and train data can lead to "inflated" performance scores, as overlapping data can reward a model's ability to memorize training data (Elangovan et al., 2021), and to under-estimate out-of-sample error (Søgaard et al., 2021). Evidence of this can also be found in the multitude of studies that report lower model performance scores on newly-collected evaluation sets versus reported scores on benchmarks (e.g., Augenstein et al., 2017; Recht et al., 2019; Harrigian et al., 2020; Kim and Kang, 2022; Larson et al., 2022). In this paper, we investigate the presence of errors, ambiguous data, and overlapping test-train data for the RVL-CDIP benchmark dataset.

3 The RVL-CDIP Dataset

The RVL-CDIP dataset was introduced in Harley et al. (2015) as a benchmark for evaluating image-based classification and retrieval tasks.[1] Since then, RVL-CDIP has primarily been used as a document type classification benchmark. RVL-CDIP consists of 400,000 document images distributed across 16 document type categories, listed in Table 2. Example documents from RVL-CDIP are shown in Figure 2. Documents in RVL-CDIP were sampled from the larger IIT-CDIP Test Collection, which itself is a snapshot of the voluminous Legacy Tobacco Documents Library (LTDL) collection — at that time, LDTL contained approximately 7 million documents (Lewis et al., 2006).[2] These documents were made publicly available as part of legal pro-

---

[1] Harley et al. (2015) referred to RVL-CDIP as *BigTobacco*.

[2] The LTDL is now called the Truth Tobacco Industry Documents collection, and is included in the broader Industry Documents Library (IDL) hosted by the UCSF Library: `https://www.industrydocuments.ucsf.edu/`. For more background on the LTDL, see Schmidt et al. (2002) and Tasker et al. (2022).

Category	**Description**
`advertisement`	Advertisements from print-form media like newspapers and magazines. Also a small amount of scripts for television or radio advertisements. A small amount of "ad order instructions" and "ad insertion" documents.
`budget`	Includes various budget documents such as expense, spending, sales, cash, and accounting reports and forecasts; budgets; quotes and estimates; and income and bank statements. Also includes receipt-like documents such as political campaign contribution requests and other receipts, as well as checks and check stubs.
`email`	Scanned images of printed emails.
`file_folder`	Scanned images of folders and binders. Folder scans are often characterized by vertically oriented text (indicating a folder label). A moderate amount of file folders in RVL-CDIP contain handwritten text or notes. Some scanned folders may be indistinguishable from blank pages.
`form`	Form documents with form-like elements (e.g., lines or spaces for user-provided data entry). The form-like elements can appear empty or filled.
`handwritten`	Includes handwritten documents like handwritten letters and scientific notes.
`invoice`	Includes invoices, bills, and account statements.
`letter`	Letters, often with letterhead and commonly with "Dear..." salutations. The distinction between letters and memos is often unclear in RVL-CDIP.
`memo`	Memoranda or inter-office correspondence documents, often with clear "TO", "FROM", "SUBJECT" headings.
`news_article`	Includes news articles in the form of clippings from newspapers and other print-form news media, as well as a small amount of news articles from the web.
`presentation`	Includes scanned images of presentation and overhead slides, transcripts of speeches and statements. Also includes a large amount of press releases.
`questionnaire`	Includes customer surveys and questionnaires, as well as survey and questionnaire prompts for surveyors. Also includes questionnaires appearing to be part of legal proceedings and investigations. In RVL-CIDP, many questionnaires have a substantial amount of form-like elements.
`resume`	Includes resumes, curricula vitae (CVs), biographical sketches, executive biographies (e.g., those written in third-person), a small amount of business cards.
`scientific_pub.`	Mainly papers and articles from scientific journals and book chapters, but also includes book title pages. Also includes news articles from science newsletters. News articles from science newsletters are very similar to the `news_article` category.
`scientific_rep.`	Includes bioassay, pathology, and test reports; charts, graphs, and tables; research reports (including progress reports), research proposals, abstracts, paper drafts. Many reports and abstracts bear similarities to scientific publications. Many test result documents are similar to documents in the `specification` category.
`specification`	Data sheets (including safety data sheets); product, material, and test specifications. Also includes specification change reports.

Table 3: RVL-CDIP categories alongside our descriptions and notes.

ceedings and settlements against several American tobacco and cigarette companies and organizations, and as such, the documents in RVL-CDIP are almost exclusively related to the tobacco industry.[3]

Most document images in RVL-CDIP capture the initial page of a document; some common exceptions appear to be charts and tables (these are typically labeled as `scientific_report`) as well as presentation slides (labeled as `presentation`). Additionally, almost all of the documents (that contain readable text) are in English, although we did find small amounts of documents in other languages (including German, Dutch, French, Spanish, Portuguese, Italian, Japanese, Chinese, Arabic, and Hebrew) as part of our review. Examples of non-English RVL-CDIP samples are displayed in Figure 11 in the Appendix.

There are 320,000 training, 40,000 validation, and 40,000 test samples, but Harley et al. (2015) provides no information on how the data was partitioned into these splits, so we assume it was done randomly for each of the 16 document categories. Harley et al. (2015) report that the 16 categories were chosen, in part, because these categories had ample representation (i.e., at least 25,000 samples) in IIT-CDIP. Unfortunately, we are unaware of any published guidelines, criteria, rules, or documentation defining or describing each of the 16 RVL-CDIP categories, nor is it clear who or what provided the initial category labels in IIT-CDIP (nor in LTDL).[4] Thus, we describe how we developed label guidelines for each RVL-CDIP document type category in Section 3.1 below.

---

[3] For more background on the history of the litigation and documents, see Glantz et al. (1996); Ciresi et al. (1999); Tasker et al. (2022).

[4] Schmidt et al. (2002) and Tasker et al. (2022) indicate that type labels may have been ascribed to the documents by human workers employed at UCSF's LTDL.

3.1 Establishing Label Guidelines

The RVL-CDIP dataset does not have a published list of descriptions, rules, or guidelines describing each of the 16 document type categories. We discuss an extensive analysis from which we develop such guidelines.

We established our list of guidelines by first sampling 1,000 documents from each of the 16 categories in the training set (for a total of 16,000 documents). We then reviewed these samples category by category. This review process helped us identify commonalities within each category, and helped us discover that many of the categories seem to have distinct groups of sub-types within them. For instance, we found that the `resume` category is largely composed of (1) resumes and curricula vitae, (2) "Biographical Sketch" documents (i.e., those required for grant applications for the National Institutes of Health (example shown in Figure 3a), (3) executive biographies, and (4) scanned business cards. Such cases reveal opportunities for refining and diversifying appropriate categories.

In another category, `advertisement`, we found samples mostly consisted of advertisements from print-form media like newspapers and magazines, as well as smaller amounts of scripts for television or radio advertisements. The `advertisement` category also included a small amount of document images identical to the one shown in Figure 3b. We found that this "IMAGE NOT AVAILABLE" document appears mostly in the `advertisement` category, yet it is an example of a document that we do not include in our label guidelines for this category, as it is not at all faithful to the semantic nature of the `advertisement` category.

Our annotation guidelines are listed in Table 3, along with our notes and observations. It was occasionally necessary to review multiple document categories prior to establishing rules. This was the case with the `budget` and `invoice` categories, each of which included non-trivial amounts of scanned check images and contribution requests. (Examples of cases like these are displayed in Figures 21-23 in the Appendix.) For cases like these, we annotated these sub-types in the relevant categories in order to estimate their relative frequencies. We then would append our annotation guidelines accordingly; for instance, 8.8% of `budget` documents and 3.8% of `invoice` documents that we reviewed were check images, so our guidelines specify that the `budget` category consists of check images, while `invoice` does not. Ultimately, our goal with establishing such guidelines is to provide repeatable, verifiable criteria that faithfully reflect the semantic nature of each category.

4 Label Errors and Ambiguities in RVL-CDIP

Armed with better knowledge of what constitutes each of the 16 RVL-CDIP categories, we analyze the contents of the RVL-CDIP test set to estimate the amount of label errors and ambiguities found in this set.

We manually checked for errors in the RVL-CDIP test set by sampling 1,000 documents from each of the 16 categories (for a total of 16,000 documents). We used our label guidelines established in Section 3.1 to help us determine the validity of each of these 16,000 samples. We tracked several types of errors and ambiguities: (1) documents found in a category that clearly are mis-labeled and instead belong in a different RVL-CDIP category — we refer to this error type as *mis-labeled*; (2) documents that do not appear to have a single clear RVL-CDIP label — we refer to this label type as *unknown*; (3) documents that have mixed or multiple features that belong to at least two RVL-CDIP categories — we refer to this type as *mixed*. Examples of documents exhibiting these error types can be seen in Figure 4. We point out a particularly interesting *mixed* case: the first two *mixed* examples are nearly identical, but the original label is `news_article` in one case but `letter` in the second. More examples are shown in the Appendix in Figures 12–14.

Findings. Our estimated error rates in the RVL-CDIP test set are shown in Table 4. We estimate that error rates (i.e., combined rates for *mis-labeled* and *unknown*) range between 1.6% (in the case

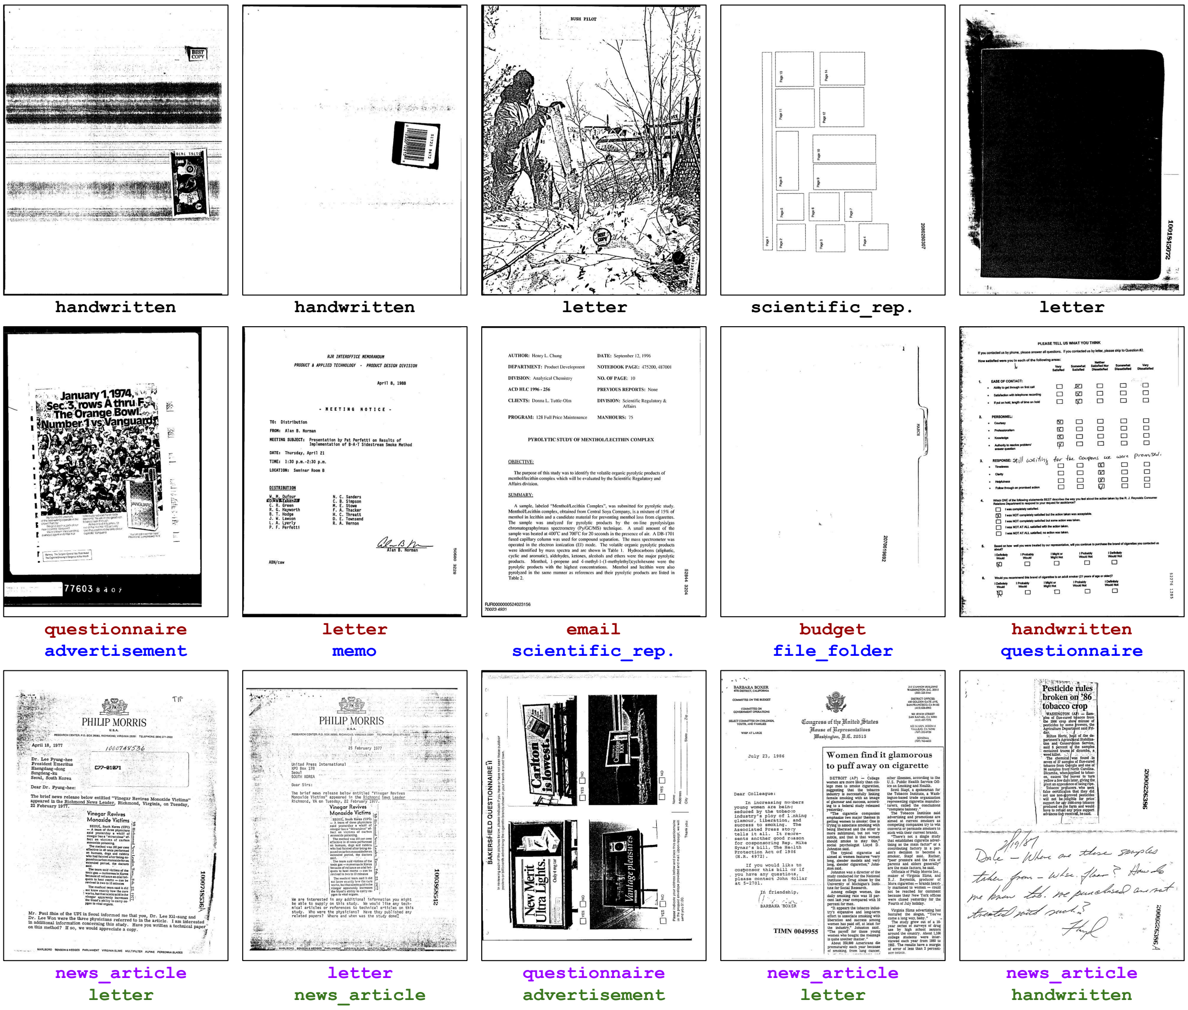

Figure 4: Example errors and ambiguities. Top row: *unknown*, middle row: *mis-label*, bottom row: *mixed*.

Category	*mis-labeled*	*unknown*	*Tot. Error*	*mixed*
`advertisement`	1.9%	4.5%	6.4%	3.5%
`budget`	9.7%	4.1%	13.8%	1.5%
`email`	1.7%	8.3%	10.0%	0.4%
`form`	4.4%	6.4%	10.8%	0.5%
`file_folder`	0.4%	3.1%	3.5%	1.9%
`handwritten`	2.5%	5.2%	7.7%	2.4%
`invoice`	9.7%	1.3%	11.0%	0.2%
`letter`	13.5%	3.4%	16.9%	0.5%
`memo`	2.0%	2.4%	4.4%	2.1%
`news_article`	4.6%	2.5%	7.1%	0.4%
`presentation`	1.8%	4.9%	6.7%	1.0%
`questionnaire`	5.6%	7.3%	12.9%	6.9%
`resume`	0.2%	1.4%	1.6%	0.4%
`scientific_pub.`	2.5%	1.8%	4.3%	0.0%
`scientific_rep.`	4.6%	3.9%	8.5%	5.6%
`specification`	1.5%	1.9%	3.4%	0.4%
Average	4.2%	3.9%	8.1%	1.7%

Table 4: Estimated label error and multi-label rates in the RVL-CDIP test set.

of `resume`) and 16.9% (in the case of `letter`). The average of each category's error rates is 8.1%, which is higher than the classification accuracy error rates reported by many state-of-the-art models listed in Table 1. In some cases, the majority of a category's errors were mis-labels of a particular type. For instance, about 59% of the erroneous `letter` documents we reviewed were actually `memo` documents. Similarly, 74% of the erroneous `invoice` documents were actually budget documents. Lastly, roughly 1.7% of RVL-CDIP's test set is data that have multiple valid labels.

5 Overlap Between Test and Train Splits

Our analysis also reveals a substantial degree of undesirable overlap between train and test samples within RVL-CDIP. To measure this overlap, we use an approach similar to Larson et al. (2019) and Elangovan et al. (2021), which, for each test sample in each document type category, finds the maximally similar sample in the same document

resume: 0.977

news_article: 0.981

invoice: 0.937

Figure 5: Example test-train pairs with corresponding maximum cosine similarity scores. These three example pairs show instances of near-duplicates (left and center) and documents that have highly similar structure (right).

Category	mean	median
`advertisement`	0.893	0.903
`budget`	0.963	0.968
`email`	0.976	0.982
`form`	0.948	0.956
`file_folder`	0.967	0.974
`handwritten`	0.945	0.952
`invoice`	0.962	0.966
`letter`	0.953	0.960
`memo`	0.957	0.961
`news_article`	0.919	0.936
`presentation`	0.929	0.945
`questionnaire`	0.961	0.968
`resume`	0.965	0.967
`scientific_pub.`	0.936	0.955
`scientific_rep.`	0.950	0.961
`specification`	0.972	0.978
Average	0.950	0.958

Table 5: Mean and median of maximum cosine similarity scores between train and test sets for each RVL-CDIP category.

type category's training split. We then average these maximum similarity scores together for each document category. That is, for each document category C in RVL-CDIP, we compute

$$\frac{1}{|test_C|} \sum_{b \in test_C} \max_{a \in train_C} sim(a, b)$$

where a and b are samples from category C's train and test splits, respectively. We use CLIP (Radford et al., 2021) to extract a 512-dimension feature embedding from each sample, and use cosine similarity for $sim(\cdot, \cdot)$. We note that this vector-based similarity technique is common practice in the image- and information retrieval (e.g., Babenko et al. (2014)).

Findings. Average and median of the maximum similarity scores for test-train pairs are shown in Table 5 for each RVL-CDIP category. Overall, we see a high degree of similarity across test and train data: mean scores range between 0.893 (`advertisement`) and 0.976 (`email`), with an average of 0.950. Ten of the 16 document categories have average scores at- or above 0.95. The median score for each category is larger than the mean in all cases, indicating a long tail in the distribution of scores. Indeed, we see this in Figure 10 (in Appendix), which charts the distribution of similarity scores for all test data in RVL-CDIP. Figure 5 shows three examples of test-train pairs with similarity scores ranging between 0.937 and 0.981. Two of the three pairs in Figure 5 seem to be near-duplicates, where there appear to be minor differences in scanning or noise artifacts between each document. In the third (`invoice`) example, we see that the two samples are distinct, yet both share a large degree of similarity because both use the same document template (e.g., invoices from the same company that are structurally and visually similar but that contain different "data"). We show more example pairs in Figures 15–18 in the Appendix.

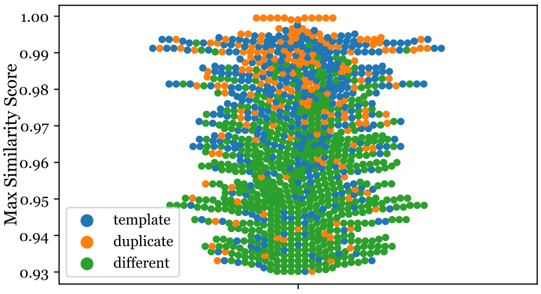

Figure 6: Sampled subset of maximal similarity scores for test-train pairs with scores between 0.93 and 1.0.

To help better understand the similarity scores, we conduct an experiment where we categorize each similarity pair into one of the following: *duplicate*, if the test-train pair represents the same document; *template*, if both documents in a pair use the same document template; and *different*, for all other pairs. We annotated a sample of 1,086 similarity pairs with maximum similarity scores ranging between 0.93 and 1.0. A visualization of the relationship between maximal similarity score and match type is shown in Figure 6, where we

observe that the likelihood of a pair being either a *duplicate* or *template* match increases with similarity score.

Considering the overall median maximal similarity score is 0.958, we can estimate a lower-bound for the rate of *duplicate* and *template* match pairs by scaling the proportion of documents above the median maximal score (i.e., half, or 0.5) by the fraction of *duplicate* and *template* matches above the median (0.958). This gives us 0.5×0.641, and therefore we estimate that at least 32% of samples from the RVL-CDIP test set have either a duplicate counterpart or a sample that shares a template layout in the training set. While there is generally no established acceptable number or percentage for test-train overlaps, prior work (e.g., Søgaard et al. (2021); Elangovan et al. (2021)) has argued that overlaps are undesirable, and that building generalizable, robust models entails evaluation against novel, unseen data points (e.g., Koh et al. (2021); Malinin et al. (2021); Larson et al. (2022)).

6 Presence of Sensitive Information

While reviewing samples from RVL-CDIP, we noticed that the `resume` category had a non-trivial quantity of documents that contain sensitive and personally-identifiable entities. Naturally, resumes typically contain a person's name and basic contact information (e.g., phone numbers or email addresses). However, we found a plethora of sensitive entities like citizenship and marital statuses, places and dates of birth, names of children and spouses, and national ID numbers like US Social Security and Canadian National ID numbers.

Out of a sample of 1,000 documents from the `resume` test set, we found that 7.7% contained a US Social Security Number. While we recognize that US Social Security numbers were not considered sensitive several decades ago (when many of the `resume` documents in RVL-CDIP were created), their presence in so many documents in a publicly accessible dataset[5] is still striking, especially considering the coexistence of this entity type with others like person names, dates and places of birth, etc. In particular, malicious Social Security numbers are often connected with fraud and identity theft crimes in the USA. Moreover, the sensitive entities discussed in this section are considered highly sensitive under many state and national laws.[6] Additionally, we found that 43.6% of the test resumes contain birth dates, 19.9% contain places of birth, 11.4% contain marital (or spousal or parental) statuses, and 8.9% contain citizenship statuses. Example documents containing sensitive PII can be seen in Figure 7.

Given the presence of sensitive PII in RVL-CDIP, it is reasonable to wonder if sensitive PII also appears in datasets derived from RVL-CDIP, like FUNSD (Jaume et al., 2019). Similarly, we also wonder if sensitive PII appears in datasets that were derived from the larger IIT-CDIP or UCSF Industry Documents Library corpora, such as Tobacco-800 (Zhu et al., 2007; Zhu and Doermann, 2007), Tobacco-3482 (Kumar et al., 2014), DocVQA (Mathew et al., 2021), and OCR-IDL (Biten et al., 2022). We will investigate this in future work.

7 Discussion and Recommendations

Given our findings concerning labeling errors, test/train overlap, and presence of sensitive information in the RVL-CDIP document classification benchmark, we discuss several concrete recommendations to raise awareness among researchers engaged in benchmarking classifiers using this dataset:

(0) Sub-Types in RVL-CDIP. Our investigation into RVL-CDIP revealed that many of the RVL-CDIP categories are in fact composed of several

---

[5] On 9 Feb. 2023, RVL-CDIP tallied "1,765 downloads last month" on the Hugging Face Datasets platform.

[6] For example, the State of Michigan's Social Security Number Privacy Act (2004).

sub-types. We encourage researchers and practitioners to be aware of this fact. For instance, curricula vitae, bigraphical sketches, executive biographies, and business cards are the four sub-types of the `resume` category. This finding has implications for modeling tasks where prior knowledge of the label set is assumed, like in zero-shot settings where each category may be specified to the model as a string, as done in Siddiqui et al. (2021). Additionally, unsupervised clustering analyses like Finegan-Dollak and Verma (2020) may exhibit low performance scores on RVL-CDIP due to many of the categories having distinct and disparate sub-types (e.g., radio scripts versus print advertisements in the `advertisement` category, or business cards versus biographical sketches in the `resume` category).

(1) Errors. Users of RVL-CDIP should be aware that there are many label errors and noisy samples with unknown labels in RVL-CDIP. Recall from Section 4 that an estimated 8.1% of test samples from RVL-CDIP contain label errors, with an additional 1.7% being ambiguous mixed or multi-label cases. This is problematic for benchmarking new models, since the estimated label error rate is now greater than state-of-the-art model accuracy error rates. Here, the implication is that high-capacity models like CNNs and transformers are now overfitting to noise. This is indeed the case for models like DiT (Li et al., 2022), which predict the "IMAGE NOT AVAILABLE" document to be an `advertisement` document due to its relative abundance in that category's training set.

(2) Ambiguities. Users of RVL-CDIP should be aware that there are many samples in RVL-CDIP that could have multiple valid document type labels. We estimate this number to be 1.7% of the RVL-CDIP test set. Like label errors, such mixed or multi-label cases make it challenging to evaluate a model effectively, as there are samples for which a model may make a wrong prediction according to the RVL-CDIP test label annotations, but in reality many of these wrong predictions could actually be reasonable.

(3) Test-Train Overlap. Practitioners and researchers should be aware that there is a high degree of overlap between the RVL-CDIP test set and the train set. Recall from Section 5 that almost a third of RVL-CDIP test samples have a near-duplicate in the training set for the same document type category, or a training sample that uses the same document template. This is undesirable, as testing models on data that is very similar to the training data can lead to "inflated" accuracy scores (Elangovan et al., 2021; Søgaard et al., 2021). Moreover, highly similar train and test splits do not facilitate the evaluation of a model's ability to generalize well to new in-domain data.

(4) Sensitive Information. There is an unsettling amount of sensitive information in the RVL-CDIP dataset, which naturally leads to information and data privacy concerns. We estimate that 7.7% of `resume` test samples contain Social Security numbers. While RVL-CDIP is already publicly available, researchers and practitioners should take care when disseminating samples or copies of RVL-CDIP. Moreover, we highlight that prior work (e.g., Carlini et al. (2021)) showed that it is possible to extract training data from machine learning models, making production deployments of models trained on RVL-CDIP an information privacy and security risk.

Suggestions for a future dataset. We suggest the development and adoption of a new benchmark for evaluating document classifiers. Several qualities of a such a benchmark would include (1) minimal label errors; (2) multi-label annotations, to allow for modeling more natural occurrences of documents; (3) minimal test-train overlap; (4) absence of sensitive information. Going beyond the points made in this paper, a new benchmark would do well to be (5) large-scale, consisting of 100+ or even 250+ document categories, to test a model's ability to handle breadth, and (6) multi-lingual, to benchmark language transfer approaches.

8 Conclusion

RVL-CDIP has been used as the *de facto* benchmark for evaluating state-of-the-art document classification models, but this paper provides an in-depth analysis of the RVL-CDIP dataset and shows that there are several undesirable characteristics of this dataset. We first provide a set of label guidelines for each RVL-CDIP category, and we use this to help us quantify the presence of errors in RVL-CDIP, finding that the RVL-CDIP test set contains roughly 8.1% label errors. We then observe that roughly a third of the test data is highly similar to the training set. Lastly we observe an unsettling amount of personally sensitive information in RVL-CDIP. Given these findings, we offer suggestions for a new document classification benchmark.

Limitations

The RVL-CDIP dataset has no official set of label guidelines, making error analyses challenging since we could not rely on pre-defined rules. For this reason we followed best practices to create annotation rules to help us in our error analysis. Detecting duplicates in RVL-CDIP is also challenging, as two documents may appear to be the same, but may have minor differences due to scanning artifacts or even different indexing labels (it appears that many of the documents have been scanned and included in IIT-CDIP more than once). Therefore we again have to rely on best judgement when labeling pairs as duplicates (or near-duplicates). Additionally, due to limitations in human resources, we were unable to exhaustively inspect all 400,000 RVL-CDIP samples for the presence of errors, ambiguities, sensitive information, etc., and thus had to rely on sampling the dataset in order to draw conclusions.

Acknowledgements

We thank Nicole Cornehl Lima, Ramla Alakraa, Zongyi Liu, Junjie Shen, Temi Okotore for help with data review, as well as the University of Michigan's Undergraduate Research Opportunity Program (UROP) for their support of these student researchers as well as support for Gordon. We also thank the anonymous EACL reviewers for their feedback.

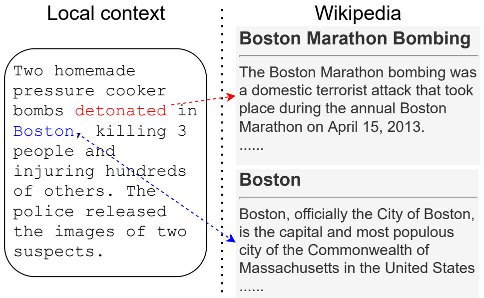
Abstract

Comprehending an article requires understanding its constituent events. However, the context where an event is mentioned often lacks the details of this event. A question arises: how can the reader obtain more knowledge about this particular event in addition to what is provided by the local context in the article?

This work defines Event Linking, a new natural language understanding task at the event level. Event linking tries to link an event mention appearing in an article to the most appropriate Wikipedia page. This page is expected to provide rich knowledge about what the event mention refers to. To standardize the research in this new direction, we contribute in four-fold. First, this is the first work in the community that formally defines the Event Linking task. Second, we collect a dataset for this new task. Specifically, we automatically gather the training set from Wikipedia, and then create two evaluation sets: one from the Wikipedia domain, reporting the in-domain performance, and a second from the real-world news domain, to evaluate out-of-domain performance. Third, we retrain and evaluate two state-of-the-art (SOTA) entity linking models, showing the challenges of event linking, and we propose an event-specific linking system, EVELINK, to set a competitive result for the new task. Fourth, we conduct a detailed and insightful analysis to help understand the task and the limitations of the current model. Overall, as our analysis shows, Event Linking is a challenging and essential task requiring more effort from the community. [1]



Two homemade pressure cooker bombs detonated in Boston, killing 3 people and injuring hundreds of others. The police released the images of two suspects.

Boston Marathon Bombing

The Boston Marathon bombing was a domestic terrorist attack that took place during the annual Boston Marathon on April 15, 2013.
……

Boston

Boston, officially the City of Boston, is the capital and most populous city of the Commonwealth of Massachusetts in the United States
……

Figure 1: Examples of Event linking and Entity linking. The left side is the local context, and the right side contains Wikipedia pages. Entity linking model connects the entity "Boston" to the Wikipedia page "Boston", while event linking model links the event "detonated" to the Wikipedia page "Boston Marathon Bombing", which is more relevant to the local context.

1 Introduction

Grounding is a process of disambiguation and knowledge acquisition, and is an important task for natural language understanding. Entity linking, grounding entity mentions to a knowledge base (usually Wikipedia) (Bunescu and Pasca, 2006; Mihalcea and Csomai, 2007; Ratinov et al., 2011; Gupta et al., 2017; Wu et al., 2020), has been shown important in natural language understanding tasks, such as question answering, recommendation system, dialogue generation. Despite the significant progress brought by entity linking, we argue that grounding entities may not provide enough background knowledge that is often needed to support text understanding. Consider the example, Figure 1; an entity linking model will link the entity "Boston" to the Wikipedia page "Boston" which introduces the history and culture of the city Boston. The information we can get from the page "Boston" is irrelevant to the local context. To really help understand this sentence, we need to link the event centered by the verb "detonated" to the Wikipedia page "Boston Marathon Bombing". We call this process that grounds events **Event Linking**.

In this paper, we formulate this Event Linking task for the first time, analyze the difference and challenges of the new task, and carefully design a benchmark dataset for this task. We automatically collect training data from the hyperlinks in Wikipedia, and create two evaluation sets to evalu-

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2679–2688
May 2-6, 2023 ©2023 Association for Computational Linguistics

ate both in-domain and out-of-domain performance. For in-domain evaluation, the test data is also from hyperlinks in Wikipedia. To avoid models from overfitting, the test data is balanced with hard cases and easy cases determined by whether the event is seen in the training and by the similarity between the surface forms of event mentions and Wikipedia titles. For out-of-domain evaluation, we annotate real-world news articles across 20 years collected from New York Times. Considering the sparsity of events existed in Wikipedia, we also add "Nil" annotation to the test data, indicating that those events do not exist in Wikipedia, therefore, the model needs to tag them as "Nil".

Technically, we come up with an event linking model EVELINK that uses the entities in the local context as arguments of the event structure to better present the event mention. EVELINK outperforms two SOTA entity linking models BLINK (Wu et al., 2020) and GENRE (Cao et al., 2021), and achieves strong performance on the event linking test set, especially on seen events and easy cases, and a detailed error analysis shows the difficulties of the new task and the limitation of the current model.

To conclude, our contributions are four-fold: (i) We formulate the task Event Linking. (ii) We collect training data for this task, and design both in-domain and out-of-domain test data, with a balanced ratio of hard cases and easy cases to ensure the dataset quality. (iii) Our proposed approach EVELINK shows promising performance in experiments, which sets a competitive result for future works. (iv) Our in-depth analysis provides a better understanding of this new problem, the challenges in different domains, and the new approach.

2 Grounding Events in Wikipedia

Given an article and an event mention m in it, event linking tries to find a title t, from **all** the English Wikipedia titles (around 5m titles), to provide the best explanation of m. Event mention is defined as verb or nominal that refers to an event. A correct title is defined as follows: as long as a Wikipedia page is about this event, or any subsection of the page introduces this event, we regard its title as the correct one. In this paper, all the models assume gold event mentions are given. For each event mention, a system is expected to label it with the correct Wikipedia page or a "Nil" tag if the event does not exist in Wikipedia. Accuracy is adopted as the official evaluation metric.

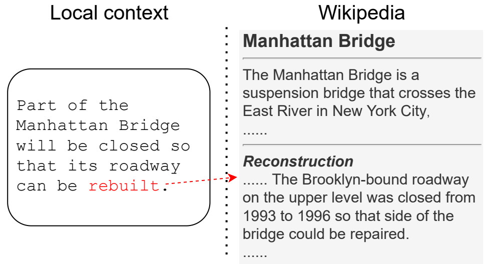

Figure 2: Example of event mentions that only exist in the subsection of a Wikipedia page. The event "rebuilt" does not have its own page, but is mentioned in the subsection of the page "Manhattan Bridge".

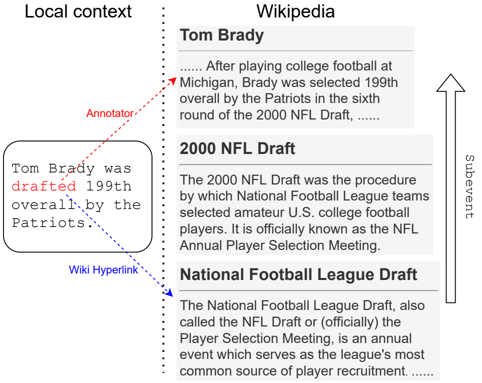

Figure 3: Example of hierarchical events. Event "draft" of Tom Brady is mentioned in the page "Tom Brady", and is also a sub-event of "2000 NFL Draft", which is again a sub-event of "National Football League Draft".

Event Linking vs. Entity Linking. Relatedness: (i) They both link an object (event/entity) from an article to Wikipedia; (ii) Some events, such as "World War II", are entities; in this case, two tasks are the same. Distinctions: (i) Entities are mostly consecutive text spans. Events, in contrast, are more structured objects, consisting of a trigger and a couple of arguments. An event trigger is mostly a general verb, which may not refer to a specific event by its own without knowing event arguments. More complex structures in events make event linking a more challenging task and require a deeper understanding of the local context; (ii) Unlike entities with a large coverage in Wikipedia, many events do not have a record in Wikipedia. Considering the sparsity, we require models to tag event mentions that do not exist in Wikipedia as "Nil".

Why Event Linking? Except for some events that are also entities, generally speaking, events are information units of larger granularity. As shown in Figure 1, a better comprehension of events, such as through linking to Wikipedia, is expected to facilitate the text understanding more.

Challenges specific to Event Linking. (i) The correct title for some event mentions may not be unique. The same event could be introduced in several pages. For example, "Invasion of Poland" and "Occupation of Poland (1939–1945)" both introduce the event that German Army invaded Poland in 1939. How to decide the ground truth set and how to evaluate in this situation are not trivial.

(ii) Events may only exist in the subsection of the Wikipedia page. Only a limited number of famous events have their own pages, while many other relatively infamous events only exist in the subsection of some pages. Considering the example in Figure 2, the event "rebuilt" of the Manhattan Bridge does not have its own Wikipedia page, but it is mentioned in the subsection "Reconstruction" of the page "Manhattan Bridge". Linking these events requires a model to understand the whole page instead of just encoding the first paragraph.

(iii) Events have a hierarchical structure. Events at larger granularity consist of many sub-events, and these sub-events may have their own Wikipedia pages, or just be mentioned in the pages of the large events. Ideally, the model should always link the event mention to the most appropriate page. If the sub-event page exists, then link to the sub-event page. Otherwise, link to the page of the large event. However, the term "appropriate" here could be unclear because of the event hierarchy. As Figure 3 shows, the Wikipedia page "Tom Brady" is most specific to the event "drafted". On the other hand, draft of "Tom Brady" is a sub-event of "2000 NFL Draft", which is further a sub-event of "National Football League Draft". Annotators prefer to link this event to "Tom Brady", while Wikipedia hyperlinks link the event to "National Football League Draft". The hierarchy of events makes the standard of the correct title inconsistent.

3 Related Work

Entity Linking. As described in the previous section, entity linking has been extensively studied for many years (Bunescu and Pasca, 2006; Mihalcea and Csomai, 2007; Ratinov et al., 2011; Gupta et al., 2017; Wu et al., 2020; Cao et al., 2021). Though both of entity linking and event linking could be regarded as a task linking document contents to a knowledge base, we argue that entity linking is more about linking text span, while event linking is more about linking an event structure, centered by a predicate, which is more challenging because the predicate span is usually a general verb. In the experiment section, we show that just retraining the entity linking model on event linking data without considering the event structure does not perform well. Humeau et al. (2019) and Wu et al. (2020) use a bi-encoder/cross-encoder architecture to train the candidate generation/ranking model respectively for entity linking. Considering the structure of events that entities do not have, EVELINK extends their model by adding structure information to the event mention representation.

"Event Linking". We note that the term "event linking" has been once used in the literature (Nothman et al., 2012; Krause et al., 2016). However, these works are essentially performing cross-document event coreference: determine if a given event mention refers to another event mention (in the same or another document). We, on the other hand, link an event mention to a Wikipedia concept with a different purpose: acquiring external knowledge about the event which is often beyond what we can obtain from the local context. Our definition of event linking can not only improve the understanding of the article, but also pave the way for the intensively-studied event coreference and other event relation identification problems.

Data. Eirew et al. (2021) collect training data from Wikipedia hyperlinks for event coreference, while we use similar methods to collect data for event linking. In this work, we use the FIGER type of the title to find event titles, while Eirew et al. (2021) use the Wikipedia infobox. There also exists some other event knowledge bases, such as EventKG (Gottschalk and Demidova, 2018). Because we use hyperlinks in Wikipedia as training data resource, and we do not limit the candidate space to be event titles only, in this work we only focus on linking event mentions to Wikipedia, and the candidate space is all the Wikipedia titles.

4 Data Construction

We collect training data and in-domain test data from Wikipedia automatically, and manually annotate a test set in the news domain for out-of-domain evaluation purpose. Table 1 lists some data examples, and Table 2 shows detailed statistics.

4.1 Wikipedia

We first collect all hyperlinks ($hypertext$, $title$) in Wikipedia text, which links a hypertext to a Wikipedia title. Then, we map the FreeBase type

	Event mention in local context	Wikipedia title
Wiki	At the start of the wartime 1940s , he had four releases.	World War II
	Henry Louis Gates, a black Harvard University professor who was arrested after police mistakenly thought he was breaking into his own home in Cambridge, Massachusetts.	Henry Louis Gates arrest controversy
	Ibrox hosted four Scotland games in the first phase, starting with a 1994 World Cup qualifier against Portugal in October 1992.	1994 FIFA World Cup qualification
NYT	The Nets offered Sam Cassell and a first-round draft pick for Marbury.	Sam Cassell
	A man who killed his former wife, a bartender and a cook in 1984 was executed by injection early today.	Godinez v. Moran
	A 45-year-old fashion photographer was shot and killed in his West Village apartment yesterday morning, the police said.	Nil

Table 1: Data examples. The upper part is data collected from Wikipedia hyperlinks. The lower part is annotated New York Times (NYT) paragraphs. Event mentions are highlighted in red.

	Train	Dev	Test	
	Wiki	Wiki	Wiki	NYT
Verb	33,213	8,346	9,633	1,319
Seen Event	-	1,814	2,913	0
Unseen Form	-	2,585	3,828	75
Unseen Event	-	3,947	2,892	435
Nil	-	-	-	809
Nominal	33,213	8,346	9,633	443
Hard	-	4173	4817	244
Easy	-	4173	4817	15
Nil	-	-	-	184
Total	66,426	16,692	19,266	1,762

Table 2: Wikipedia and New York Times (NYT) data statistics. NYT is only for testing.

of Wikipedia titles to FIGER types (Ling and Weld, 2012), and all titles with a type "Event" are regarded as event titles. All the hypertexts linked to these event titles are regarded as event mentions.

Because same event mentions in one Wikipedia page are hyperlinked only once, and editors tend to hyperlink more nominal mentions than verb mentions, verb mentions are highly limited in Wikipedia. To balance the size of verbs and nominals, we use SpaCy Part-of-Speech model[2] to keep all verb mentions, and sample the same size of nominals. To prevent models from overfitting, we design hard and easy cases for verbs and nominals:

Verbs: We classify each verb mention mainly by whether the surface form (S) of the verb is seen in training data, and whether the gold event title (T) is seen in training data. If both S and T are seen in training data, we call it **Seen Event**. If T is seen in training data, but S is new, we call it **Unseen Form**. If T is never seen in training data, we call it **Unseen Event**. Under this setting, "Seen Event" is regarded as easy cases, and the other two are hard cases. Because of the limited size of verb mentions, all the event titles with fewer than or equal to 5 verb mentions are used as "Unseen Event".

Nominals: We classify each nominal mention mainly by its surface form similarity to the gold title. We calculate the Jaccard similarity between the nominal mention and the gold title by taking 3 grams of the surface form. If the similarity is lower than 0.1, we think it is a **hard nominal**; otherwise, it is an **easy nominal**. Then we sample same numbers of hard and easy cases.

4.2 New York Times

We sample 2,500 lead paragraphs from The New York Times Annotated Corpus (Sandhaus, 2008), which contains New York Times articles from 1987 to 2006. We first use an off-the-shelf verb and nominal SRL model[3] to extract event mention candidates, and then we use Amazon Mechanical Turk to annotate the corresponding Wikipedia title of the predicted mention candidates. To ensure the quality of the annotation, we design our annotation process in two rounds:

First round. Annotators need to answer whether they think the predicted mention is an event or not. If they think it is an event, then they need to find the corresponding Wikipedia title, otherwise submit "Nil". Each mention is annotated by three annotators. If all of them submit "Nil", we include this event mention as a "Nil" example in the final test data. *To prevent annotators from simply submitting "Nil", 10% of the event mentions are the relatively easy cases from the Wiki data and we know their answers. We randomly insert them into the input data for AMturk (i.e., annotators are unaware of that) to evaluate the accuracy of the annotator. Only the annotation from annotators with an accuracy higher than 90% will be accepted.*

---

[2] `https://spacy.io/usage/linguistic-features#pos-tagging`

[3] `https://cogcomp.seas.upenn.edu/page/demo_view/SRLEnglish`

Second round. This round verifies the annotated results in the first round. Each mention with the annotated title is verified by another three annotators. They need to read the page, and figure out whether it introduces the mention. If the majority vote for "yes", we include it in the final test data. Because of majority voting, some annotations that not all the annotators agree would be included. The inter-agreement is 63.74 Fleiss' kappa.

4.3 Domain Analysis

Event linking in the news domain is more challenging than that in the Wikipedia domain because of the following reasons:

(i) News articles describe an event at a different granularity as how Wikipedia does, usually with more details. For example, here is a piece of news about "Iraq_War": "A contractor working for the American firm Kellogg Brown & Root was wounded in a mortar attack in Baghdad." The event "wounded" here is a very small event in Iraq War, but it is what daily news would report. On the other hand, the event mention that links to "Iraq_War" in Wikipedia domain is: "When touring in Europe, the US went to war in Iraq." The different granularity in representing events makes the task slightly different in two domains. Event linking in Wikipedia domain is more like event coreference, while event linking in news domain is mixed with more subevent relation extraction.

(ii) As analyzed in Section 2, event linking is challenging because some event mentions may only exist in the subsection of the correct page, and the correct title is not consistent because of the event hierarchy. However, these problems mainly happen in the news domain. First of all, the Wikipedia hyperlinked mentions usually have their own pages instead of just existing in subsections. In news domain, we annotate events that only exist in subsections of a Wikipedia page. Second, in Wikipedia domain, the gold title of same event mentions is usually consistent. For example, all of the event mentions "drafted" of football players link to "National Football League Draft" instead of the page of the specific player. However, the annotation standard of NYT is not always consistent with Wikipedia hyperlinks. For example, annotators would link event mentions about sports player draft to the page of the specific player instead of the general concept page "National Football League Draft". These problems make data annotation and model evaluation in news domain very challenging.

Because of the reasons claimed above, we think that, for some cases in news domain, the correct answer is multiple titles instead of just one title. Ranking the annotated title to the second place may be because the top one is also correct. To relax the evaluation metric here, for news domain, we also report the number of Accuracy@5, which means that if the annotated title is ranked in the top 5 candidates, we think it is correct.

5 Model

In this section, we propose EVELINK as the first event linking model. We first introduce the representation of event mentions and event titles in Section 5.1, and then introduce the model architecture in Section 5.2.

5.1 Event Representation

A key difference between entity and event is that the context of an entity is more diverse than the context of an event. For example, when the entity "China" is mentioned in a sentence, it is unclear what entities or what events probably would also be mentioned together. However, if a verb like "invade" is used to represent the event "Battle of France" in a sentence, it is very likely that entities like "Germany", "Italy" and "France" will also be mentioned. This shows that an event is defined by its arguments, and these arguments, with a large chance, will also be mentioned in the local context because the verb itself cannot refer to any event. Given this observation, we think that the entities in the local context of the event mention should overlap with the entities in the correct Wikipedia page, and these entities can be used to help the model better represent events. To embed these entities information explicitly to the event representation, we use similar method as how Vyas and Ballesteros (2021) embed entity attributes information to the entity representation.

Event mentions: To represent event mentions in local context, we first use an off-the-shelf Named Entity Recognition model [4] trained on 18-type OntoNotes dataset (Weischedel et al., 2013) to extract the entities around the event. We simply define the context window by 500 characters around the event mention. After

Table 4: Accuracy on Wikipedia Test.

predicting all the entities e_i with their type t_i, we represent the event mentions by:

$$r_1 = \text{[CLS] ctxt}_l \text{ [M}_s\text{] m [M}_e\text{] ctxt}_r \quad (1)$$

$$r_2 = [\mathrm{t}_{1_s}]\ \mathrm{e}_1\ [\mathrm{t}_{1_e}] \cdots [\mathrm{t}_{n_s}]\ \mathrm{e}_n\ [\mathrm{t}_{n_e}] \quad (2)$$

$$r_m = r_1 \text{ [SEP] } r_2 \text{ [SEP]} \quad (3)$$

where m, ctxt_l, ctxt_r, e_i are tokens of event mention, the context on the left of the mention, the context on the right of the mention and predicted entities. $[\mathrm{M}_s]$ and $[\mathrm{M}_e]$ are special tokens to tag the start and end of the event mention. $[\mathrm{t}_{i_s}]$ and $[\mathrm{t}_{i_e}]$ are special tokens to tag the start and end of the entity whose type is t_i. r_m is the final representation of event mentions.

Title: To represent Wikipedia titles, since important entities are already hyperlinked in the page contents, we take the first ten hyperlinked spans as entities, and represent the title by:

$$r_3 = \text{[CLS] title [TITLE] description} \quad (4)$$

$$r_4 = \mathrm{h}_1 \text{ [SEP] } \mathrm{h}_2 \text{ [SEP] } \cdots \text{ [SEP] } \mathrm{h}_n \quad (5)$$

$$r_t = r_3 \text{ [SEP] } r_4 \text{ [SEP]} \quad (6)$$

where title, h_i and $\mathrm{description}$ are tokens of the title, hyperlinked spans, and the content of the Wikipedia page. We simply take the first $2,000$ characters as the description. [TITLE] is the special token to separate the title and the description. r_t is the final representation of Wikipedia titles.

5.2 Model Architecture

Similar to Wu et al. (2020), we first use a bi-encoder architecture to efficiently generate candidates, and use a cross-encoder architecture, which requires more computations, to rank the candidates.

Candidate Generation. We use a bi-encoder architecture to train the candidate generation model. We use two independent BERT transformers (Devlin et al., 2019) to encode the representation of event mentions r_m and Wikipedia titles r_t, and use the output of the two [CLS] tokens in r_m and r_t as the event mention vector v_m and the title vector v_t. Then, we maximize the dot product between the vectors of event mentions v_m and the correct title v_t in a batch with randomly selected negatives. At inference time, representations of all the titles are cached, and for each event mention, we calculate the dot products between its representation and the representation of all the titles, and titles with higher scores will become candidates.

Candidate Ranking. For each event mention, we take 30 candidates from the candidate generation model as the training data for the ranking model, and use a cross-encoder architecture to train the candidate ranking model. We concatenate the representation of event mentions r_m and titles r_t, use one BERT transformer to encode the concatenated representation, and use the output of the [CLS] token as the final vector v. Then we maximize the dot product between the vector v of

Models	Verb				Nominal			Verb + Nominal
	Seen	Unseen Form	Unseen	Overall	Hard	Easy	Overall

GENRE-Event	**39.19**	8.03	12.55	7.82	31.25	9.27	23.02	11.44
EveLink	28.37	**13.07**	**15.29**	**14.81**	**43.75**	**16.60**	**29.13**	**15.73**

Table 6: Accuracy on New York Times data without Nil. Only event mentions that exist in Wikipedia are given. Accu@5 means the correct title is ranked top 5. Accu@1 means the correct title is top 1.

the correct title and an additional linear layer W.

6 Experiments

In this section, we evaluate the in-domain performance on Wiki test set and the out-of-domain performance on NYT test set, and conduct an error analysis. Implementation details in Appendix A.

Baselines. Since there is no existing event linking system, we have to compare with previous entity linking systems. In this paper, we mainly compare our system with two SOTA entity linking models BLINK (Wu et al., 2020) and GENRE (Cao et al., 2021). To make a fair comparison, BLINK and GENRE have the following two setups:

BLINK/GENRE-Entity: Since a large portion of event mentions are nominals, which is also a kind of entity, it would be interesting to see how a SOTA entity linking system performs for event linking. Therefore, we test the BLINK/GENRE model pretrained specific to entity linking directly. Please note that the size of entity linking training data is 9 million, which is much larger than the size of event linking training data 66k.

BLINK/GENRE-Event: It adopts the same algorithm with the original BLINK/GENRE system, but is trained on our event linking training set.

For all the experiments, BLINK-Entity retrieves 10 candidates from candidate generation, and both BLINK-Event and EveLink retrieves 100 candidates from candidate generation. These numbers are tuned on dev data. GENRE is a generation model, which does not use the same pipeline of candidate generation and ranking. We follow the original setting to use the beam search with 5 beams.

Besides SOTA entity linking systems, we also evaluate the performance of BM25, Glove vector cosine similarity between event mention and titles (Pennington et al., 2014) and prior distribution. Because event mentions are limited in Wikipedia, to fairly estimate the prior distribution of the event titles, we only evaluate event mentions that appear at least 10 times in Wikipedia.

In-domain experiment on Wikipedia. We evaluate EveLink on the Wikipedia test set as the in-domain performance. We report the recall of candidate generation in Table 3, and the accuracy of candidate ranking in Table 4. As shown in Table 3 and Table 4, EveLink outperforms baseline models by a large margin, 6.94 points in Recall and 6.38 points in Accuracy. EveLink also achieves a high performance on seen verbs and easy nominals, around 90 accuracy, but a relatively low performance on other hard cases, which leaves a large space for future works to further improve.

Out-of-domain experiment on News. We evaluate EveLink on the NYT test set as the out-of-domain performance. In Table 5, we evaluate the recall of candidate generation. Because "Nil" mentions do not have correct titles in Wikipedia, we only evaluate the the recall of event mentions that exist in Wikipedia. Though the recall of

Models	Verb				Nominal				Verb+Nominal	
	Unseen Form	Unseen	Nil	Overall	Hard	Easy	Nil	Overall	Accu@5	Accu@1
BLINK-Entity	2.7	1.15	79.85	49.51	1.23	25.00	63.04	27.77	57.26	44.04
BLINK-Event	12.16	1.61	90.85	56.94	4.53	37.50	88.59	40.63	58.45	52.84
EveLink	**17.57**	**4.59**	**93.08**	**59.59**	**7.00**	**43.75**	**89.67**	**42.66**	**59.70**	**55.33**

Table 7: Accuracy on New York Times data with Nil. We simply predict all the mentions with a probability lower than 50 to Nil.

Models	Wiki Test	NYT (no Nil)	NYT
EveLink	82.87	15.73	55.33
- type	81.39	11.70	55.96
- entities	71.25	8.97	52.84

Table 8: Ablation Study of EveLink

EveLink is much higher than the recall of other baseline models (56.83 vs. 37.97), the recall drops significantly compared with the recall on Wikipedia test set (56.83 vs. 93.06). In Table 6, we evaluate the accuracy on the event mentions that exist in Wikipedia, which is the same setting as the experiments in the Wikipedia domain, and again the accuracy drops significantly from 82.87 to 15.73. Even if we accept 5 predictions instead of just one to solve the multiple correct titles problem, the Accuracy@5 is 29.13, which is still low. Detailed error analysis is in Section 6. In Table 7, we evaluate the accuracy of all the event mentions, including Nil. Because we do not have Nil examples in training data and development data, we simply predict all the event mentions with probability lower than 50 to "Nil", and leave better solutions to future works. GENRE is not tested for Nil mentions because it is unclear how to get its prediction probability.

Analysis. We wonder following questions:

$\mathcal{Q}_1$**:** Where the gain comes from, compared with the BLINK system?

We do ablation study in Table 8. Explicitly adding entities to the event representation boosts the performance by 10.14 accuracy on Wiki test data and 2.73 accuracy on NYT data. Adding entity types further improves the performance by 1.48 accuracy on Wiki and 4.03 accuracy on NYT data.

$\mathcal{Q}_2$**:** Error patterns of EveLink

We collect several error patterns that are common in both domains, and patterns that are mostly in news domains. Error patterns of both domains:

(i): Repeating events. In the errors, we find many repeating events, like award ceremonies or sports games, that would happen every several years, and the model usually cannot find the correct year of the event if the year is not explicitly mentioned in the context. For example:

> In 1995, his debut season, Biddiscombe made two appearances, ··· The following year he earned a Rising Star nomination for his performance···

In this example, the gold event is "1996 AFL Rising Star", and the prediction is "1998 AFL Rising Star", though there is a temporal hint (the following year of 1995 is 1996) to indicate that the correct answer should be the award in 1996. There are many similar errors when linking awards or games, which shows that a deeper temporal understanding is necessary for future works.

(ii): Unrelated context. EveLink replies on the surrounding entities to link the event mentions, however, the context is not always related and surrounding entities cannot help linking. For example:

> Returning to his country at the end of the conflict and another begun, Barinaga rejected an offer from Athletic Bilbao, moving to Real Madrid instead.

In this example, the gold event is "World War II", but the prediction is "1939–40 La Liga". All the entities, like "Barinaga", "Athletic Bilbao" and "Real Madrid", are about football, which is unrelated to the war. To link to the correct page, the model needs to know the second conflict of Barinaga's country, which indicates that only using the local context maybe not enough.

Error patterns specific to news domain:

(i): Subsection events. Some events do not have their own pages, and are only introduced in the subsections of other pages. For example:

> The Philippine government lifted its five - year ban on the return of Imelda Marcos today and said the widow of the late President Ferdinand Marcos was free to come home from exile in the United States.

In this example, the return of Imelda Marcos is introduced in the subsection "Return from exile (1991–present)" of the page "Imelda Marcos". However, we only use the first 2,000 characters of the page contents to represent the title "Imelda Marcos", which has no information about the return from exile. A document-level representation may be a potential solution for future works.

(ii): Sub-events. Some events are sub-events of other larger events. For example:

> Stepping in at the 11th hour, Hillary Rodham Clinton will campaign in Florida on Saturday for her brother, Hugh Rodham, in his bid for a United States Senate seat.

This event is a sub-event of “1994 United States Senate election in Florida”, which has different event arguments, so the names in the local context do not overlap with the names in the page.

In this work, we discuss many challenges of the task in different domains, but EVELINK cannot address all of them. We leave them to future works.

7 Conclusion

In this work, we formulate Event Linking, a challenging but essential task, with a carefully designed Wikipedia dataset and NYT test set, and propose an event linking model EVELINK for future works.

8 Limitations

In this section, we discuss limitations of our work.

- We only focus on event linking to English Wikipedia in this work. We leave multilingual event linking to future works.
- The performance of EVELINK on hard cases is still low, for example events that only exist in the subsection of Wikipedia page.
- In this work, we simply predict all the mentions with a prediction probability that is lower than 50 to “Nil”. We leave better solutions to future works.

A Implementations

We use 4 Nvidia RTX A6000 48GB GPUs for model training and evaluation. For both candidate generation model and candidate ranking model, we train 10 epochs with learning rate $1\mathrm{e}^{-5}$, and use BERT-large-uncased as the pretrained language model (Devlin et al., 2019). The maximum tokens of both event mention representation and Wikipedia title representation are 256. Top-K is chosen from [5, 10, 30, 50, 70, 100], and tuned on development data. The Glove version we use is "glove-wiki-gigaword-100".

The Wikipedia dump version we use is 2020/03/01, which is also released to public with our annotated data.

B Data Annotation

We require all the annotators from Amazon Mechanical Turk to be English speaker, and with an acceptance rate higher than 95%. All the annotators are English native speakers and are paid more than 10 US dollars per hour.

SwitchPrompt: Learning Domain-Specific Gated Soft Prompts for Classification in Low-Resource Domains

Abstract

Prompting pre-trained language models leads to promising results across natural language processing tasks but is less effective when applied in low-resource domains, due to the domain gap between the pre-training data and the downstream task. In this work, we bridge this gap with a novel and lightweight prompting methodology called *SwitchPrompt* for the adaptation of language models trained on datasets from the general domain to diverse low-resource domains. Using domain-specific keywords with a trainable gated prompt, *SwitchPrompt* offers domain-oriented prompting, that is, effective guidance on the target domains for general-domain language models. Our few-shot experiments on three text classification benchmarks demonstrate the efficacy of the general-domain pre-trained language models when used with *SwitchPrompt*. They often even outperform their domain-specific counterparts trained with baseline state-of-the-art prompting methods by up to 10.7% performance increase in accuracy. This result indicates that *SwitchPrompt* effectively reduces the need for domain-specific language model pre-training.

1 Introduction

Recent work showed promising results on different natural language processing tasks when prompting pre-trained language models (LMs) instead of fine-tuning them, especially in low-resource settings (Schucher et al., 2022). Most LMs which are publicly available have been trained on general-domain corpora (Devlin et al., 2019; Liu et al., 2019; Goyal et al., 2021), such as Wikipedia or the BooksCorpus (Zhu et al., 2015). Applying them to tasks from a special domain results in a domain gap.

For some special domains, domain-specific LMs exists, e.g., Clinical BERT (Alsentzer et al., 2019) or BioBERT (Lee et al., 2019). However, pre-training deep language models requires large amounts of text data.[1] While we can assume the availability of large-scale text data in the general domain, this assumption might not hold for low-resource domains, making the creation of domain-specific LMs challenging. Moreover, training different models for each and every new domain might be inefficient from a computation point of view.[2] Even if there are domain-specific texts and computational resources available, domain-specific LMs may not be able to get sufficient domain-oriented guidance through traditional prompting techniques because, for instance, domain-specific knowledge might be represented by a large and diverse vocabulary. As a result, both prompting LMs from the general domain and from a special domain might be ineffective, especially in low-resource settings.

Motivated by these challenges, we explore domain-oriented prompts and propose a novel and lightweight method, *SwitchPrompt*, to effectively retrieve domain-specific knowledge from pre-trained LMs. It extends the sequence of soft-prompting vectors with a sequence of vectors representing domain-specific keywords and introduces gates to allow the model to dynamically switch between a general soft prompt and a domain-specific one based on the input sentence. We hypothesize that this approach helps to effectively retrieve domain-specific knowledge from pre-trained LMs.

Our experiments on benchmark datasets from different domains indicate that *SwitchPrompt* outperforms different state-of-the-art prompting methods. It improves results in both in-domain and out-of-domain settings, effectively reducing domain gaps among pre-training and downstream task data. We find that it is especially suitable for low-

resource settings (both little data and little computational resources) as it neither requires pre-training domain-specific LMs nor fine-tuning LMs for the downstream task. The code base for *SwitchPrompt* is available online.[3]

2 Related Work

Language model prompting. Prompting pre-trained LMs has been shown effective for different NLP tasks (Brown et al., 2020). While discrete prompts are intuitively understandable, their design requires non-trivial human involvement and they may be outperformed by fine-tuning (Shin et al., 2020; Jiang et al., 2020; Gao et al., 2021). Recent studies address this issue by optimizing so-called soft prompts in continuous space. Li and Liang (2021a) propose prefix tuning that optimizes prefix activations prepended to the input layer and each layer in the encoder stack. Lester et al. (2021) prepend trainable continuous embeddings to the original sequence of input word embeddings. Liu et al. (2021) propose P-tuning in which an LSTM encoder captures the sequential representations of the soft prompts. Liu et al. (2022) use a deep prompting methodology which injects prompts at each layer of the pre-trained LM. In contrast to those prior works, we propose a new soft prompting method that is especially suited for low-resource domains.

Language models in special domains. Most popular pre-trained LMs are trained on data from the general domain. Tailoring an LM towards a domain can be done via domain-specific pre-training from scratch (i.a., Alsentzer et al., 2019; Lee et al., 2019) or adaptation of an existing model to target domain data with continued pre-training (i.a., Gururangan et al., 2020; Xu et al., 2020; Lange et al., 2022). We refer to the survey of Hedderich et al. (2021) for more information on language model adaptation for low-resource domains. In this paper, we take a different approach and investigate to which extend LMs that were pre-trained on the general domain can be prompted for domain knowledge in few-shot settings as this requires only a minimal amount of domain-specific data.

3 Method

We now present *SwitchPrompt*, and give an example of an architecture in which it can be applied. In our architectural setup, the underlying pre-trained language model is fixed (i.e., not fine-tuned).

3.1 Domain-Specific Soft Prompts

The motivation behind our proposed prompts $P \in \mathbb{R}^{l \times e}$ is to allow the model to dynamically switch between a general-domain prompt P_g and a domain-specific prompt P_d in order to retrieve different kinds of knowledge from the pre-trained LM based on the current input, where e is the embedding dimension, and l is the length of the prompt (i.e., number of soft-prompt vectors). We implement this with a sigmoid-based gating function:

$$P = g_1(\mathsf{pad}(P_g)) + (1 - g_1)P_d \quad (1)$$

$$g_1 = \sigma(w_1^\top s_{\text{input}}) \quad (2)$$

where pad is a function that pads P_g to length l. The prompts P_g and P_d will be defined in Equations 3 and 6, respectively. Gate g_1 is calculated based on the representation of the input sentence s_{input} (in our case the representation of the [CLS] token when feeding the input sentence into the pre-trained LM) and a weight vector $w_1 \in \mathbb{R}^e$ that is randomly initialized and updated during training.

The general-domain prompt is implemented as a sequence of randomly initialized vectors $v_1, \ldots, v_m$ that are trained on the downstream task, similar to Lester et al. (2021) and Liu et al. (2022):

$$P_g = [v_1; v_2; \ldots; v_m] = V_m \quad (3)$$

The sequence length m is a hyperparameter of the model and '[;]' denotes concatenation.

The domain-specific prompt is designed to incorporate a sequence of vectors $K_n = [k_1; \ldots; k_n]$ that represent domain-specific keywords. The intuition is to inject the semantic information of the special domains using the domain-specific keywords. We define the set of keywords using a term-frequency-based approach. In particular, we estimate a score c for each word w from the target domain based on the normalized term frequencies estimated on documents from the general domain $\text{tf}_g(w)$ and domain-specific documents $\text{tf}_d(w)$:

$$c(w) = \alpha \cdot \text{tf}_g(w) + \text{tf}_d(w), \alpha < 0 \quad (4)$$

$$t_i = \{w | \text{rank}(c(w)) = i\}, 1 \leq i \leq n \quad (5)$$

Using $\alpha < 0$, we are able to select terms that are representative for the target domain and avoid terms that are frequent in the general domain. In Equation 5, we select the n words from the target

---

[3] `https://github.com/boschresearch/switchprompt`

domain with the highest scores c as our keywords. Each keyword t_i is then represented as a vector k_i, using the same language model as for prompting.

Initial experiments showed that it is not enough to simply set $P_d = K_n = [k_1, k_2, \ldots, k_n]$ but that the sequence of keywords should actually be combined with the sequence of soft prompts. Thus, we implement the domain-specific prompt as follows:

$$P_d = g_2[V_m; K_n] + (1 - g_2)[K_n; V_m] \quad (6)$$

$$g_2 = \sigma(w_2^\top s_{\text{input}}) \quad (7)$$

We combine the sequence of keywords of length n with the sequence of soft prompts of length m with concatenation, yielding a sequence of length $l = m + n$. We let the model decide with a second gate g_2 in which order the sequences should be concatenated. Again, the gate is calculated based on the representation of the input sentence and a trainable weight vector $w_2 \in \mathbb{R}^e$, where e is the embedding dimension. Thus, although the same domain-specific keywords are used for all inputs, the resulting soft prompt is dependent on the input sentence.

3.2 Prompting Architecture

Since our proposed method is a new definition of soft prompts, it can be integrated into any existing model that uses soft prompts. In our experiments, we adopt the *P-Tuning v2* architecture (Liu et al., 2022) because of its high efficacy on different natural language understanding tasks. P-Tuning v2 is an adaptation of deep prompt tuning (Qin and Eisner, 2021; Li and Liang, 2021b) that injects soft prompts at every layer of the pre-trained LM. During training, the prompts are tuned but the LM stays fixed. For the class prediction of the downstream task, a randomly initialized classification head is added on top of the pre-trained LM.

4 Experiments

In this section, we describe the setup (datasets, training details and baselines) and the results of our experiments.

4.1 Datasets

For our experiments, we use classification benchmark datasets from different domains: question classification from the general domain (TREC, Voorhees and Tice, 2000) and from the clinical domain (GARD, Kilicoglu et al., 2016), as well as experiment classification from the materials science domain (SOFC-Exp, Friedrich et al., 2020). Statistics of the datasets can be found in Table 1.

Dataset	**Domain**	**Instances**	**Classes**
GARD	Clinical	1253	11
SOFC-Exp	Materials science	2042	2
TREC	General	4893	7

Table 1: Statistics of text classification datasets.

Among them, the SOFC-Exp dataset offers a binary sentence classification task with positive and negative labels whereas GARD and TREC are multi-class question classification datasets.

To investigate very-low-resource settings, we construct *few-shot datasets* by randomly sampling N shots per class with $N \in \{2, 4, 16, 64\}$. Following the proposed theory for realistic *low-resource regimes* (Perez et al., 2021; Kann et al., 2019), we also create *few-shot development sets* by keeping the number of shots in the training and development sets in sync. In the 4-shot scenario, for example, both the training and the development set consist of 4 examples for each class. For all datasets, we use accuracy $(\%)$ as evaluation metric.

To give a closer insight into the challenges of the different domains that we use in our experiments, we present example instances from the datasets in Table 2. The examples show that the models need to cope with domain-specific terminology, such as "perisylvian polymicrogyria" (clinical domain) or "electrochemical" (materials science domain), and domain-specific labels, for instance, "diagnosis".

4.2 Training Details

We use open-sourced HuggingFace language models[4] for our experiments. We train our models with a batch size of 32. The maximum sequence length is set to 128 and we use dropout with rate 0.1 on the classification layer. We use the *ExponentialLR*[5] learning rate scheduler with a gamma value of 0.95 and the Adam optimizer. All experiments are performed on a $V100$ GPU.[6] Each reported result is the average performance of five runs.

4.3 Baselines

We compare our method to different baselines: (i) Fine-tuning of the pre-trained LM, (ii) prompting

using P-tuning (Liu et al., 2021), and (iii) prompting using P-Tuning v2 (Liu et al., 2022). For all methods, we report results for using either a general-domain LM (BERT (Devlin et al., 2019)) or domain-specific LMs (Clinical BERT (Alsentzer et al., 2019) and SciBERT (Beltagy et al., 2019)).

4.4 Results

Low-resource domains. Tables 3 and 4 show the results of our model for the clinical and materials science domain in comparison to state-of-the-art baseline approaches. In general, the prompting methods outperform fine-tuning, with especially large margins for very-few-shot settings (2 and 4 shots). This highlights the limitations of fine-tuning with limited training datasets. Another general trend is that using domain-specific LMs (Clinical BERT and SciBERT, respectively) outperforms BERT from the general domain. Our proposed method *SwitchPrompt* outperforms other state-of-the-art prompting methods up to 2.1% points. We further note that (i) our method prompting general-domain LMs even outperforms other methods prompting domain-specific LMs, and (ii) our method reduces the performance gap between using an LM from the general domain vs. a domain-specific one.

For very-few-shot settings (2,4-shots), P-tuning outperforms our method. We assume that the reason is that it replaces the input of the LM with differential embeddings from the prompt-encoder, while in our method we consider the vanilla inputs of the LM, reducing the complexity and training time (see Figure 1) of our model.

General domain. To investigate the behavior of our method in the general domain, we now evaluate its performance on TREC. Table 5 shows that our method outperforms both fine-tuning and other prompting methods in almost all dataset settings, up to 10.7 accuracy points. Thus, even on the general domain, *SwitchPrompt* can boost the performance of pre-trained LMs.

5 Analysis

In this section, we report the results of our ablation study, give more insights into what our model learned and analyze its training time. We also provide a qualitative error analysis.

Ablation study. Our ablation study in Table 7 shows the impact of the different components of our prompting function, evaluated with the full GARD dataset. Row (1) corresponds to *SwitchPrompt*, and row (6) corresponds to the previous state-of-the-art prompting model P-Tuning v2. Row (2) shows that the concatenation of keywords and the general-domain soft prompt is important to the model. Row (3) and (4) show the large impact of the second gate g_2, and row (5) and (6) show that neither the domain-specific keywords K_n nor

Domain	Keywords

What are the expected outcomes for individuals with cryoglobulinemia ?	Information	Prognosis

Table 8: Error analysis on GARD dataset.

the general soft-prompting vectors V_m alone are sufficient to achieve the highest performance.

Domain-specific keywords. The keywords are an integral part of *SwitchPrompt*. Since we compute keywords automatically (see Section 3), we analyze the extracted keywords in more detail.

Table 6 shows the 10 keywords that have been selected by our method. For the clinical and materials science domain, the keywords are domain-specific terms while for the general domain, the keywords cover a broad range of topics.

Training time analysis. During training time, the underlying LM is frozen in the *SwitchPrompt* framework. This substantially reduces training time and computational memory, compared to alternative approaches, such as fine-tuning or P-Tuning. Figure 1 illustrates this. P-Tuning v2 is a little bit faster than our approach as it does not need to train the gating parameters. However, the time difference is considerably small (2.2 min for 10 epochs in the all-data setting, i.e., 0.22 min per epoch).

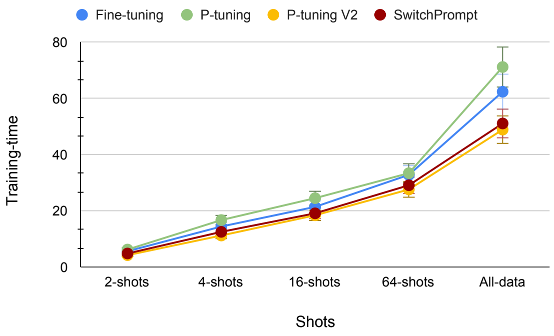

Figure 1: Training time in minutes for 10 epochs for different methods on the GARD dataset.

Qualitative error analysis. Finally, we manually conduct a qualitative error analysis on the GARD dataset. The results are displayed in Table 8. We find that our method mainly fails when the input sentences convey little domain-specific information (see examples in first two rows). Another category of errors is the prediction of a more general class ("Information" instead of "Management" or "Prognosis" in the last two rows).

6 Conclusion

In this paper, we proposed a new methodology called *SwitchPrompt* for effectively prompting pre-trained language models in low-resource domains. Integral parts of our method are domain-specific keywords and gates, which allow the language model to dynamically retrieve domain-specific knowledge. Experiments on sentence classification datasets from different domains show that our method outperforms various baseline methods in few-shot and all-data settings. In particular, it reduces the performance gap between general-domain and domain-specific language models. Future work can investigate the impact on sequence-labeling tasks as well as on mixed-domain datasets.

Acknowledgments

We would like to thank the members of the BCAI NLP & NS-AI research group and the anonymous reviewers for their helpful comments.

Limitations

In preliminary experiments, we found that our method is sensitive to the selection of keywords. While we found an automatic and domain-independent way for extracting them (see Section 3), its efficacy needs to be tested on more domains and possibly also on mixed domain datasets.

Abstract

There has been a surge of interest regarding the alignment of large-scale language models with human language comprehension behaviour. The majority of this research investigates comprehension behaviours from reading isolated, written sentences. We propose studying the perception of dialogue, focusing on an intrinsic form of language use: spoken conversations. Using the task of predicting upcoming dialogue turns, we ask whether turn plausibility scores produced by state-of-the-art language models correlate with human judgements. We find a strong correlation for some but not all models: masked language models produce stronger correlations than autoregressive models. In doing so, we quantify human performance on the response selection task for open-domain spoken conversation. To the best of our knowledge, this is the first such quantification. We find that response selection performance can be used as a coarse proxy for the strength of correlation with human judgements, however humans and models make different response selection mistakes. The model which produces the strongest correlation also outperforms human response selection performance. Through ablation studies, we show that pre-trained language models provide a useful basis for turn representations; however, fine-grained contextualisation, inclusion of dialogue structure information, and fine-tuning towards response selection all boost response selection accuracy by over 30 absolute points.

1 Introduction

Human language processing has intrigued researchers from numerous fields for centuries (Herder, 1772). The relatively recent convergence of philosophy, psycholinguistics, and information theory has produced valuable theories of language production and comprehension by framing people as predictive processors (Christiansen and Chater, 2016; Levy, 2008; Hale, 2001). In particular, Surprisal Theory posits that comprehension effort is directly related to the predictability of a linguistic unit in its context (i.e., its surprisal) (Hale, 2001), and the Smooth Signal Redundancy hypothesis (Aylett and Turk, 2004) (and related theories including Uniform Information Density (Fenk and Fenk, 1980; Levy and Jaeger, 2006) and Entropy Rate Constancy (Genzel and Charniak, 2002)) demonstrates that we produce linguistic signals that tend towards uniform distributions of information, or constant predictability.

Such theories rely on the conditional probability of observing a linguistic unit in a particular context. Traditionally, estimates of these probabilities were obtained through statistical models such as n-grams or PCFGs (Smith and Levy, 2013; Hale, 2001). By comparison, large scale language models (LLMs) like Transformers allow much greater degrees of context to be integrated into probability estimates (Vaswani et al., 2017). LLMs have enabled massive progress across the continuum of NLP tasks (Wang et al., 2019; Hu et al., 2020). As such, a recent field of research has investigated the application of LLMs for producing estimates of human surprisal. Language model quality (measured by perplexity) generally correlates with ability to predict aspects of human perception behaviour– psychometric predictive power (Wilcox et al., 2020; Frank et al., 2015; Levy, 2011; Goodkind and Bicknell, 2018).

The vast majority of psychometric predictive power studies are based on monologue-like data and involve perception of isolated sentences. However, the most natural, innate form of language-use is communicative interaction; we learn to hold conversations with very little direct instruction where as tasks related to the production or comprehension of monological data such as reading, writing, or presenting require years of conscious effort to master. Given the additional modelling capacity of current LMs, there has been growing interest in using them to apply classical language processing theories to more natural forms of language

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2696–2713

like dialogue (Vega and Ward, 2009; Doyle and Frank, 2015b,a; Giulianelli and Fernández, 2021; Giulianelli et al., 2021). Results from these works do not align neatly with findings about perception of isolated sentences. This raises interesting questions about differences between information transmission strategies employed in monological and conversational settings, and suggests that the the alignment of language models and human perceptual behaviour for monological and isolated linguistic data may not extend to dialogue.

At the same time, the field of dialogue modelling in NLP has grown substantially. Much of the recent work in this field is geared towards leveraging the structural differences between monologue and dialogue data (Lowe et al., 2015; Wu and Xiong, 2020). Although this has increased performance on dialogue modelling benchmark tasks such as response selection and dialogue generation, it is unclear whether increased performance on these tasks results in representations that align with human perception (Wolf et al., 2019; Liu et al., 2020).

To understand whether representations of dialogue align with human perception of dialogue, we ask how well language model outputs correlate with human perception of dialogue turn acceptability. To do so, we build on the novel perceptual task of rating dialogue turn plausibility proposed in our previous work (Wallbridge et al., 2022). First, we study the nature of human expectations in dialogue. By recasting the rating task as a discriminative one, we find evidence that, similar to linguistic acceptability judgements, human judgements of dialogue turn plausibility are probabilistic rather than deterministic (Lau et al., 2017). Next, we establish the psychometric predictive power of different context-dependent text representations with respect to this task by asking whether such representations are predictive of dialogue plausibility judgements. In previous work, we found a statistically significant but weak correlation between surprisal estimates from a generative dialogue-based language model and human plausibility scores for (context, response) pairs (Wallbridge et al., 2022). We use this paradigm here to investigate the predictive power of other language modelling styles. In doing so, we find a strong correlation between (context, response) scores from a masked LLM fine-tuned towards response-selection and human judgements. Interestingly, this model also achieves "superhuman" response selection performance in the sense that it obtains a higher accuracy than participants. This finding, however, motivated our analysis into response-selection dialogue models and under what conditions they align with human perception.

2 Language models and human language perception

Multiple large-scale comparisons between the predictive power of different families of a language models provide strong evidence for a relationship between a language model's quality and its predictive power for human comprehension behaviour. Behaviours include self-paced reading times and gaze duration (Wilcox et al., 2020; Goodkind and Bicknell, 2018; Meister et al., 2021), grammatical acceptability judgements (Richter and Chaves, 2020; Lau et al., 2017; Warstadt et al., 2019; Meister et al., 2021), and brain response data (Frank et al., 2015; Schrimpf et al., 2021). Other works provide similar evidence for a close relationship between surprisal and human language perception through improved language generation under cognitive-inspired constraints (Wei et al., 2021).

Although the majority of these studies are based on a constrained definition of perception using isolated sentences, they already reflect evidence that different comprehension tasks rely on different types of linguistic expectations. Wilcox et al. (2020) finds a dissociation between the syntactic generalisation capability of LMs which is heavily dependent on model architecture, and LM ability to predict human reading times. Similar results were found by Meister et al. (2021) – BERT is highly predictive of acceptability judgements but was described as "remarkably poor" for estimating reading times.

These findings suggest that the alignment of language model output and comprehension behaviours is unlikely to generalise to the perception of dialogue.

2.1 Perception of dialogue acceptability

The majority of psycholinguistic language production theories have been developed based on monological data analysed from a generative linguistics perspective. However, dialogue perception differs from the comprehension of monological data in a number of fundamental aspects (Pickering and Garrod, 2004). Dialogue has been described as a game where participants only "win" if both understand the dialogue (Lewis, 1969), or as a joint process where interlocutors collaborate to build common ground (Clark and Wilkes-Gibbs, 1986). Context plays a much larger role in dialogue comprehension (Nieuwland and Berkum, 2006). As a concrete example, Fernandez and Ginzburg (2002) find that more than 11% of dialogue turns in the British National Corpus are non-sentential in isolation. Pragmatic context is particularly important. Conversational acts such as backchanneling or the use of adjacency and coordinate pairs tend to have low lexical information density, but are crucial for turn taking and grounding (Clark and Wilkes-Gibbs, 1986; Kawahara et al., 2016).

The challenges of integrating such context into language models has been highlighted by a handful of works investigating information transmission strategies in communicative contexts. Giulianelli et al. (2021) find that relevant contextual units in dialogue should be topically and referentially coherent, and that defining these units depends on the domain of discourse. Doyle and Frank (2015b) find that common ground is a crucial aspect to account for when modelling information distribution in Twitter dialogues. Vega and Ward (2009) present evidence of uniform information density in spoken dialogues, but note the importance of accounting for non-lexical information as additional context.

To model information strategies in communication, language models should align with human perception of dialogue acceptability. In this work, we propose using the task of dialogue utterance plausibility to quantify human perception of dialogue acceptability, and examine whether language models align with this aspect of perception.

2.2 Language models and dialogue

Similarly to psycholinguistics, the vast majority of NLP models have been developed based on monological data. However, interest in modelling interaction and dialogue is booming, fuelled by the development of commercial dialogue systems like Apple Siri[1] and Amazon Alexa[2]. Work related to dialogue perception is also gaining interest, focused on tasks such as dialogue act classification and dialogue coherence estimation (Shriberg et al., 1998; Tran, 2020; Cervone et al., 2018). However, it is unclear whether current dialogue-based LLMs produce perceptually meaningful representations.

Response selection Regardless of the downstream application, response selection has become a pervasive task in dialogue modelling. A major reason for this is that it doesn't require annotated labels. This self-supervised task is used throughout dialogue modelling as both an evaluation metric and a training signal. Given some degree of dialogue history as an anchor, response selection involves selecting the upcoming response from a set of potential turns. This is a direct extension of quintessential next-sentence-prediction task which makes a strong assumption that there is a single correct upcoming turn (Devlin et al., 2019). In this work, we explore the extent to which this assumption holds when making predictions in dialogue.

Response selection models, also known as retrieval-based dialogue models, can be broadly separated into two classes: bi-encoder models that learn independent representations of responses and their respective contexts, and cross-encoders which encode the context and response as a single representation before scoring them (Henderson et al., 2020; Zhou et al., 2016; Wu et al., 2020, 2017a). The latter often involve tuning a pre-trained language model using dialogue-specific objectives (Wolf et al., 2019; Han et al., 2021; Xu et al., 2020). Such methods aim to make use of the representation capacity of pre-trained language models, while also leveraging important and unique structural features of dialogue data.

By encoding contexts and responses in isolation, bi-encoders achieve cheaper training and inference as representations can be cached. However, they enforce a strong independence assumption between contexts and responses. The separate encoders can provide a weak notion of position (i.e., the same lexical content may be encoded differently if it is a response or a piece of context), however cross-encoding captures much richer interactions.

Given the importance of response selection in dialogue modelling, we explore here how well this task aligns with the perception of spoken dialogue acceptability. We also perform ablation studies to better understand which aspects of model architecture are important for response selection.

3 Experiments

3.1 Psychometric predictive power in spoken dialogue transcripts

Data To investigate the relationship between representations of dialogue and human perception, we

---

[1] https://www.apple.com/siri

[2] https://developer.amazon.com/alexa

make use of a dataset collected in our previous work (Wallbridge et al., 2022) which comprises of 100 (context, response) pairs extracted from the Switchboard Telephone Corpus, and their associated median plausibility scores. Switchboard is a corpus of over 2,400 spontaneous chit-chat style telephone conversations between 542 participants covering 70 topics. It includes manual transcriptions and turn segmentations (Godfrey et al., 1992). Each of the 100 stimuli consists of a set of speaker turns as context $c = [c_1, ..., c_k]$ and an upcoming response r where r is either the true upcoming turn in the dialogue, or a turn sampled from the corpus. Scores were collected by asking participants to rate how plausible r is in the context of c on a scale of 1-5 ("Very Unlikely" – "Very Likely"). Each dialogue context c was presented in 10 pairs: with the true upcoming turn, and 9 negative samples.

In this previous work, we found that people can make relatively accurate discriminative judgements regarding the true upcoming turn in a dialogue: using the mean score per stimuli as a proxy for turn selection, participants obtained an accuracy of 70% (Wallbridge et al., 2022). Plausibility scores were also compared to surprisal estimates from TurnGPT (Ekstedt and Skantze, 2020). Although the relationship between plausibility scores and TurnGPT surprisal estimates was found to be statistically significant, the correlation between them was weak.

Here, we investigate the effect of language modeling styles on psychometric predictive power, using both generative and retrieval-based language models. To do so, we train a range of language models towards the response selection task using the Switchboard dataset. We split the corpus by conversation into training, validation, and test sets (80%, 10%, 10%). Transcripts are all lower-cased and speech-based annotations such as pronunciation markers and speech events are removed.

Models:

Our models are all implemented in PyTorch (Paszke et al., 2019) and pre-trained language models are obtained from the Transformers library (Wolf et al., 2020).

To test generative model capabilities, we employ TurnGPT. This architecture extends the standard GPT-2 model of Radford et al. (2019) to dyadic interaction by fine-tuning a pretrained GPT-2 model with additional speaker embeddings and speaker tokens to encode conversational structure (Ekstedt and Skantze, 2020). For our experiments, we fine-tune the pretrained GPT-2 model from the Transformers library (Wolf et al., 2020) on our training portion of Switchboard using the augmented TurnGPT cross-entropy loss.[3]

Table 1: Correlations between human plausibility scores and LM response scores. Scores are based on turn-level surprisal estimates for TurnGPT, and the joint (context, response) response selection score for BERT-FP.

Model	**Metric**	ρ	p-value
TurnGPT	S_{total}	-0.302	0.002
	S_{mean}	-0.392	<0.001
	$S_{relative}$	-0.395	<0.001
	S_{max}	-0.463	<0.001
	S_{var}	-0.346	0.001
BERT-FP	RS Score	0.637	<0.001

As has been done in previous studies of psychometric predictive power, we obtain estimates of response surprisal from TurnGPT using various aggregates of token-level surprisal (Lau et al., 2017; Meister et al., 2021; Wallbridge et al., 2022). These include both global and local definitions of surprisal. Global metrics include $S_{total}, S_{mean}, S_{relative}$ while local metrics include S_{max}, S_{var}. See Appendix A for further details.

To test retrieval-based methods, we use the BERT-FP architecture (Han et al., 2021). This cross-encoder obtains state-of-the-art response selection for written conversational benchmarks including the Ubuntu (Lowe et al., 2015), E-commerce (Zhang et al., 2018), and Douban (Wu et al., 2017b) datasets. The model encodes the joint (context, response) pair using pre-trained BERT (Devlin et al., 2019). We use `bert-base-uncased` from the Transformers library. The resulting BERT $[CLS]$ token is fed through a single-layer classifier to produce a response selection score – the relevance of the response given the context. We fine-tune BERT-FP towards response selection on our training portion of Switchboard using binary cross entropy loss.[4] See Appendix A for additional details of model training procedures. Rather than computing response surprisal from word-level model output, we obtain response plausibility scores directly from the BERT-FP model.

---

[3] We implement our model using the TurnGPT Github repository `https://github.com/ErikEkstedt/TurnGPT`

[4] We implement our model based on the BERT-FP Github repository `https://github.com/hanjanghoon/BERT_FP`

Table 2: Discriminative performance of people, TurnGPT, and BERT-FP.

Model	**Metric**	**F1**	**R10@1**
Human	Mean score	0.783	0.7
	Median score	0.800	0.8
TurnGPT	Max surprisal	0.435	0.3
	Mean surprisal	0.538	0.4
BERT-FP	Score	0.889	0.9

Input to both models consists of a set of speaker turns context $c = [c_1, ..., c_k]$ and response turn r where context turns are separated by a special $[eos]$ token to denote a change in speaker. As per the original BERT-FP implementation, we use a fixed number of context turns ($k = 3$) (Han et al., 2021).

3.1.1 Correlation with plausibility perception

Table 1 show the correlations between model response scores and human plausibility judgements. Similar to previous works (Lau et al., 2017; Meister et al., 2021) and our own (Wallbridge et al., 2022), we find a relatively weak correlation between TurnGPT surprisal metrics and plausibility scores, as well as variation in correlation strength between surprisal metrics.

Table 1 also shows the language model to have a larger effect than surprisal metric. We find a much stronger correlation between turn-plausibility scores from humans and scores predicted by our retrieval-based cross-encoder, BERT-FP, than for TurnGPT surprisal estimates. This indicates that the response selection task used to fine-tune BERT generates a latent space that matches some aspects of dialogue acceptability perception.

3.1.2 Discriminative performance

The plausibility scoring task can be reframed as response selection by taking the mean score for each (context, response) pair as the selection criterion, using each of the scoring metrics. Table 2 provides the response selection performance of our models, as well as a benchmark of human consensus performance for this task. We report both the standard response selection accuracy metric $R_{10}@1$ as well as F1 score which denotes the highest linear classification accuracy that can be achieved across all (context, response) pairs based on a given metric.

The response selection paradigm is used widely throughout dialogue modelling. But to our knowledge, this is one of the first investigations of how well humans can judge upcoming responses. People can execute the response selection task relatively well using a small amount of context, however their performance is not perfect in terms of $R_{10}@1$ accuracy.

Interestingly, we find that BERT-FP outperforms people at this task, achieving higher accuracy and F1 score. This "superhuman" performance is further evidence that the response-selection objective deviates from human perception of dialogue. We provide a some qualitative observations of deviations between model and human judgements below (see Error Analysis).

Although TurnGPT showed weak to moderate correlation with human judgements scores, it performs very poorly in the response selection task framing. Different surprisal definitions had relatively large impacts on the correlation strengths reported in Table 1, but these were not reflected in the F1 scores. TurnGPT is trained using cross-entropy loss over next-token prediction (autoregressive pretraining), while BERT-FP is based on the masked language modelling paradigm – these differences in underlying pre-training could help explain performance deviations and would be interesting to explore in future work. We discuss these findings further in section 4.

Error analysis: cross-encoders and humans Neither BERT-FP nor human raters achieve perfect performance on the response selection framing. However, their mistakes are different. The cross-encoder succeeds on all three questions where humans did not rate the true response highest, and vice versa for the question misranked by the model.

For all three stimuli that people misranked, the true response obtained the second highest score and had a mean plausibility score greater than 3. In two of these cases, the highest-scoring response was generic response ("mhm", "yeah") which is plausible in a wide range of contexts. In the final case, the highest scoring response was a question that shifted the topic of conversation. We noted this pattern in other stimuli: responses that initiated topic shifts – often questions – were often rated as somewhat likely by people but obtained low BERT-FP scores.

In comparison, for the stimuli misranked by BERT-FP, the true response obtained the 4th highest score. All four of the misranked stimuli included two or more context turns, suggesting that the amount of context is not necessarily a driving

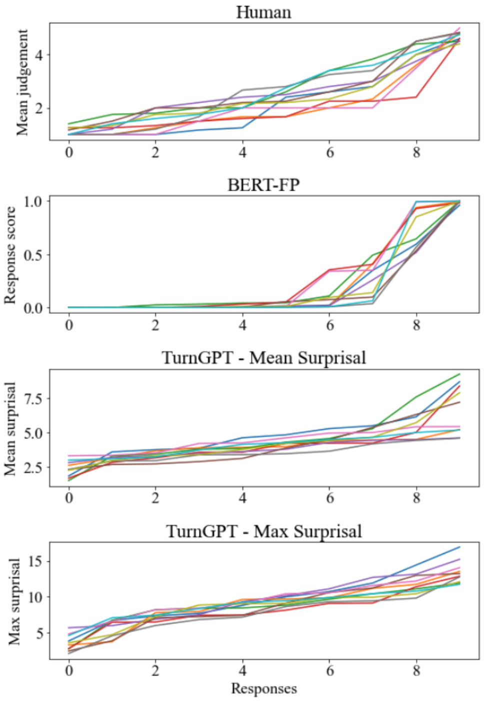

Figure 1: Sorted score sets per response selection stimuli for different models

factor in mistakes for either the model or people.

We also examine the rank correlation (Spearman r) between human ratings and model scores on a per-stimuli basis. Coefficients range from 0.33 to 0.93 ($\mu = 0.65 \pm 0.18$). The lowest correlations are obtained for stimuli where the model only scores a single response highly while the rest obtain scores close to 0. The distributions of BERT-FP scores across stimuli are more peaked than ratings produced by people (see Figure 1). Surprisal metrics from TurnGPT show score distributions more similar to human judgements, further highlighting differences between these models.

3.2 Model ablation for response selection

Generative (TurnGPT) and retrieval-based (BERT-FP) models display significantly different propensities for psychometric predictive power and response selection performance. We use ablation studies to better understand which aspects of the retrieval-based model architecture are valuable for response selection. In particular, we consider

1. Independence of context and response encoding: bi- versus cross-encoders
2. Inclusion of dialogue structure: $[eos]$ tokens
3. Importance of fine-tuning.

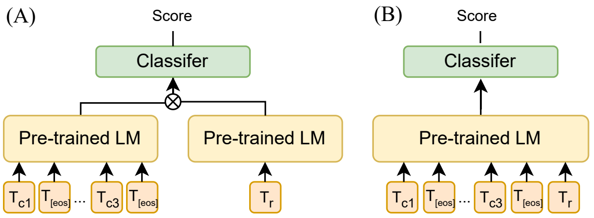

Figure 2: Architectures for (A) bi- and (B) cross-encoders. Input is shown in SBERT format; T denotes tokenized text. For BERT-based models, we prepend all input sequences with a $[CLS]$ token. Cross-encoder input also contains a $[SEP]$ token before and after T_r.

Models: We compare cross- and bi-encoder networks, depicted in Figure 2. The cross-encoder architecture is based on BERT-FP (Han et al., 2021) which encodes the joint context and response pair then feeds the resulting sequence representation through a classification network. We experiment with using both a single linear-layer classifier, or three fully-connected ReLU layers with dropout and a final sigmoid layer.

The bi-encoder style model follows the architecture presented in (Henderson et al., 2020). Each context and response is encoded in isolation using a shared, pre-trained language model. Context and response representations are then concatenated and fed through the same binary classifiers as the cross-encoder architectures.

We test scores based on both BERT $[CLS]$ tokens and SBERT sequence representations (Devlin et al., 2019; Reimers and Gurevych, 2019). SBERT representations are produced by mean pooling fine-tuned token representations from BERT. We use `bert-base-uncased` for BERT-based models and `all-MiniLM-L6-v2` for SBERT, both obtained from the Transformers library.

All models are trained towards the response selection task with a binary cross entropy loss on our training portion of Switchboard. We train models with the underlying LM in frozen and unfrozen scenarios.

3.2.1 Results

We present a simple baseline for response selection: minimizing the Euclidean distance between pre-trained SBERT representations of (context, response) pairs. This outperforms many of the ablated models discussed hereafter (see Table 3).

Independence of context and responses Although bi-encoders achieve cheaper training and inference by encoding contexts and responses in

Table 3: Response selection accuracy R_{10}@1 for models based on SBERT. The SBERT baseline (response selection based on euclidean distances between pre-trained SBERT representations of context and responses) achieves an R_{10}@1 of 0.480

Cross-encoder + [eos]	0.324	0.675	0.346	0.673

isolation, they lack the rich contextualisation of cross-encoders. Previous work reports better response selection performance from cross-encoders for written dialogue (Urbanek et al., 2019). However, recent spoken dialogue research (Fuscone et al., 2020) as well as our own (Wallbridge et al., 2021) has shown that both people and models can make predictions about upcoming conversational turns based on small amounts of context. We therefore compare bi- and cross- encoding strategies to understand the value of such contextualisation in the domain of spoken dialogue.

Tables 3 and 4 show that bi-encoders require a classifier with some degree of non-linearity. Regardless of whether the underlying language model is frozen or not, bi-encoders with a linear classifier do not improve on chance performance. In comparison, the cross-encoder improves on chance even with a frozen language model and a linear classifier. This is the case for both SBERT- and BERT-based models, indicating that masked language model pre-training extracts information that is of some value for predicting upcoming dialogue turns.

When non-linearity is introduced in the classifier, bi-encoding outperforms cross-encoding by quite a margin on top of a frozen SBERT model. This may reflect similarities between response selection and the SBERT training objective of contrastive sentence similarity (Reimers and Gurevych, 2019). We verify that this result was not caused by the special $[eos]$ turn delimeter that wasn't seen during cross-encoder pre-training by training the same model without this token added to the input.

Regardless of the underlying LM, the performance gap between unfrozen bi- and cross-encoders indicates that the lack of contextualisation may cap bi-encoder performance. This difference confirms that fine-grained contextualisation is important for dialogue representations.

Dialogue structure: the importance of *[eos]* The effect of special tokens like $[eos]$ on the behaviour of large LMs is an active research area. Some works have found such tokens to have detrimental effects on the generalisability of generative models (Newman et al., 2020) but many recent models for dialogue representation rely on these tokens to capture structural characteristics of dialogue (Gu et al., 2020; Wolf et al., 2019).

Comparing the cross-encoder performance with and without $[eos]$ in Table 3 shows that explicit turn information is extremely valuable for response selection performance.

Fine-tuning The importance of pre-trained language models in NLP can't be understated, however spoken dialogue is fundamentally different to the monological text used for pre-training. Similar to previous work investigating the importance of fine-tuning with dialogue data, we find that pre-trained BERT representations do contain some useful information for response selection, but that fine-tuning towards the target task is still important (Noble and Maraev, 2021). In addition, we find that fine-tuning is much more beneficial when dialogue structure information is provided explicitly via the $[eos]$ token.

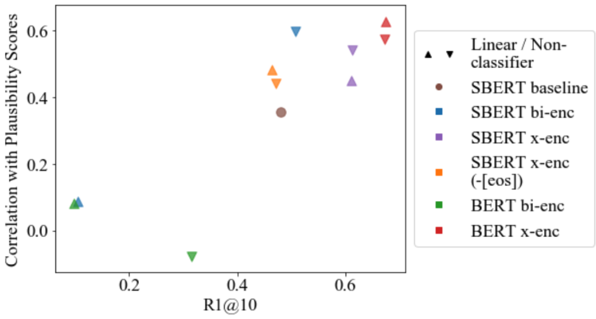

Figure 3: Response selection accuracy vs. psychometric predictive power

3.3 Is response selection performance a proxy for Psychometric Predictive Power?

Given the range of response selection results from our ablations, we consider the relationship between response selection performance and correlation with human plausibility judgements (PPP). We find a strong correlation between the two: $\rho = 0.84$. This relationship is marginally stronger if a larger range of response selection accuracies are considered; comparing response selection performance measured as $\sum_{k\in\{1,2,5\}}[R10@k]$ and PPP produces a correlation of $\rho = 0.86$. To ensure this correlation was not dominated by human response selection ability, we also computed this correlation across only negative responses and found a similarly strong correlation of model response selection performance and human scores ($\rho = 0.82$).

This indicates that response selection performance can be used as a coarse proxy for how well a model may correlate with human turn plausibility judgements. However, response selection performance patterns (e.g. SBERT cross-encoding outperforming bi-encoding) are not reflected in this relationship. Although the modelling capacity of the classifier (i.e., linear versus non-linear) did not have much effect on the response selection performance of cross-encoders (see pairs of points grouped around $R_{10}@1$ of $0.47, 0.61, 0.67$ in Figure 3), the impact on PPP is larger.

4 Discussion

Using the task of upcoming dialogue turn prediction, we presented a benchmark for human performance on the widely-used task of response selection: people are able to do this task, but not perfectly. To the best of our knowledge, this is the first investigation into the perceptual validity of response selection for spoken dialogue transcripts. Urbanek et al. (2019) measure human response selection using stimuli from written dialogues grounded in a virtual world, using sets of 20 responses. However, they note that the large number of negative samples makes obtaining reliable judgements from participants difficult. The rating paradigm proposed here avoids these issues, provides information about perceptual certainty, and is independent of the choice of negative samples.

Human performance showed that a fundamental assumption of response selection – that a single “correct” upcoming turn can be predicted from previous context – does not reflect the reality of perception with respect to dialogue acceptability. This result supports findings in cognitive science that linguistic perception of acceptability is intrinsically probabilistic (Lau et al., 2017; Chater et al., 2006).

We then used this quantification of dialogue acceptability perception to establish the psychometric predictive power of different language model families, finding that response selection performance can be used as a coarse proxy for alignment with this aspect of perception, but only to a certain extent. Strong correlation of BERT-FP scores and human plausibility ratings suggests that, as a training objective, the discriminative response selection task does align with some aspects of dialogue acceptability perception. However, this model achieved “superhuman” response selection performance. Qualitative differences in response scoring detailed in Section: Error Analysis also indicate that this discriminative training paradigm doesn’t capture the open-ended nature of dialogue acceptability perception. On the other hand, TurnGPT produced a moderate correlation with plausibility judgements, but performed poorly at response selection. (Urbanek et al., 2019; Wu and Xiong, 2020) report similar findings regarding the response selection performance of generative models compared to retrieval-based models. We conducted preliminary analysis of quantitative and qualitative differences between autoregressive and masked LMs, however given that language model architecture is known to significantly affect psychometric predictive power measured by other perceptual tasks (Wilcox et al., 2020), we believe this to be a fruitful avenue for future investigation.

Finally, to investigate the strong correlation between the cross-encoder-style BERT-FP scores and perceptual judgements of upcoming dialogue turns, we ablated aspects of the model. In particular, we examined the importance of contextualisation in dialogue representations, the value of including turn-taking structure, and whether pre-training is beneficial. Our bi-encoder models provided a small amount of dialogue structure information, however, even our best-performing bi-encoder only marginally outperforms our baseline of simply measuring the distance between SBERT embeddings for response selection. This may suggest that this method of encoding dialogue structure is too weak. Cross-encoding, on the other hand, provides much more granular contextualisation. We found cross-encoders to be much less sensitive to the capacity of the classifier than bi-encoders. Our cross-encoder outperformed the SBERT baseline and bi-encoders by a large margin when dialogue structure is explicitly encoded in the input (as $[eos]$ tokens). Inclusion of dialogue structure information and fine-tuning towards response selection boosted response selection accuracy by over 30 absolute percentage points, highlighting the value of turn structure information for response selection models.

5 Conclusions

In this study, we extend the concept of psychometric predictive power for language models to dialogue. We define the perceptual behaviour to be predicted in terms of expectations regarding upcoming dialogue turns, and ask whether different styles of language model are predictive of dialogue turn acceptability judgements from humans.

Using transcripts of spoken dialogue, we find a strong correlation between the two, but not for all models: masked language models produce higher correlations than their autoregressive counterparts. Ablation studies demonstrate that features of cross-encoders which enable fine-grained contextualisation are important for alignment with human acceptability judgements. Framing the turn acceptability rating task as discriminative response selection, we present a benchmark for human performance on this task, one of the first to our knowledge. Comparisons between human and model performance on this widely-used dialogue objective indicate that response selection can be used as a coarse proxy for alignment with perception of dialogue turn acceptability but only to a certain extent. Human perception of dialogue turn acceptability is inherently probabilistic and models make different mistakes compared to humans.

We hope that these findings encourage development of more perceptually-motivated evaluation and training paradigms in dialogue modelling.

6 Limitations

Psychometric predictive power has so far been contained to isolated sentence comprehension studies. This work takes steps to extend the notion of psychometric predictive power to more natural forms of language processing: comprehension of communication. Given that this is an exploratory study, there are many limitations, many of which we consider to be potential directions for future work.

The definition for perception used throughout this study is as generic as possible: predicting upcoming turns. However, there is ample evidence that linguistic processing is task-dependent (Huettig and Guerra, 2019; Huettig et al., 2020). Exploring other quantifications for the perception of dialogue acceptability would be an interesting avenue for future work. Similarly, features of communication such as turn-taking are known to vary across languages and cultures (Skantze, 2021). As such, is it unclear how well the findings presented in this work generalise to other styles and forms of conversation.

All of the turn representations in this work are based on a fixed number of turns as context, however we should also study whether the amount of context affects LM alignment with human judgments. In our previous work, we found the amount and type of context to affect human performance (Wallbridge et al., 2021), while Henderson et al. (2020) show that it affects response selection performance in models.

Previous works have studied surprisal estimates computed from different aggregates of word-level estimates from LMs (Lau et al., 2017; Meister et al., 2021; Wallbridge et al., 2022). These surprisal definitions are useful for testing psycholinguistic theories about information transmission strategies such as Uniform Information Density (Fenk and Fenk, 1980; Levy and Jaeger, 2006) and Entropy Rate Constancy (Genzel and Charniak, 2002), however we found stronger correlations with human judgements by using language models to compute plausibility scores directly. Understanding the gap between these scores and aggregate word-level surprisal estimates could inform more complex definitions of surprisal.

Although response selection is a pervasive training objective in dialogue representation research, there is a growing body of work refining this task, and learning representations using additional dialogue-centric learning objectives such as detection of turn insertions or deletions (Qiu et al., 2021; Lee et al., 2021). Future work could consider how these training signals affect the psychometric predictive power of models with respect to both response selection and plausibility judgements.

This study has been restricted to the lexical component such dialogues. However, perception and production of linguistic signals are dependent on the modality available for transmission, and what information transmission channels it provides (Rowe, 1999; Alaçam et al., 2020). Perception of spoken dialogues and their transcripts has been shown to differ (Wallbridge et al., 2021, 2022), and findings for uni-modal data don't necessarily generalise to multi-modal settings (Bujok et al., 2022). We leave the extension of a similar analysis on the acoustic speech signal for future work.

A Language Models

A.1 Fine-tuning language models

We employ a range of language models to explore alignment with dialogue acceptability perception and response selection performance, including autoregressive, masked, and sequence-level models.

TurnGPT TurnGPT is a variant of GPT-2 (Radford et al., 2019), an autoregressive Transformer-based model (Vaswani et al., 2017) with 117M parameters. As reported in the main paper, our implementation is based on the pretrained GPT-2 model from the Transformers library (Wolf et al., 2020). We fine-tune the GPT-2 model following the procedure laid out by (Ekstedt and Skantze, 2020). Use our training portion of Switchboard, we train with the cross-entropy loss of the original GPT-2 model and default parameters. We fine-tune with early stopping, and achieve our best model in terms of validation loss after 2 epochs of training.

BERT-FP We employ BERT-FP to test retrieval-based dialogue models (Han et al., 2021). The architecture includes a simple linear MLP on top of a BERT model (Devlin et al., 2019). The original paper presents a two-stage training strategy for response selection. First, the model is post-trained using the task of utterance relevance classification, then it is fine-tuned towards response selection. To facilitate comparisons across architectures, we report experiments involving fine-tuning with no post-training in the main paper. However, we find that following the full procedure of post-training before fine-tuning increases response selection accuracy $R_{10}@1$ by 3 absolute points ($R_{10}@[1,2,5] = 0.705, 0.840, 0.975$).

As reported in the main paper, we implement this model using Pytorch and the pre-trained `bert-base-uncased` BERT model from the Transformers library. The full model has 109,483,777 trainable parameters. Fine-tuning is done with a cross-entropy loss. The response selection training set consists of an even split of positive and negative (context, response) pairs. Negative pairs are generated by sampling a turn from the elsewhere in the training set. To maintain consistency with BERT pre-training, joint (context, response) pairs are presented in the following format:

$$([CLS], c_1, [eos], ..., c_k, [eos], [SEP], r, [SEP]) \tag{1}$$

where the $[eos]$ token represents the end of a speaker's turn.

We follow the fine-tuning procedure from the BERT-FP paper. First, this involves splitting conversations into short (context,response) segments, resulting in 267,562 samples for training the cross- and bi-encoders. Second, fine-tuning is implemented using recent "BERTology" research to mitigate one of the pervasive issues with fine-tuning large, pre-trained LMs: training instability (Mosbach et al., 2021; Merchant et al., 2020). Compared to the BERT fine-tuning approach presented in Devlin et al. (2019), this involves using smaller learning rates with bias correction to avoid vanishing gradients early in training, and increasing the number of epochs. We use a batch size of 16 and make use of the Pytorch AdamW optimizer with an initial learning rate of $1e-5$. With early stopping, out best model in terms of validation loss is achieved at epoch 8.

Bi- and Cross-encoders For our ablation studies, we test a number architectural choices, including bi- versus cross-encoder set-ups, linear versus non-linear classifiers, and sequence representations from the BERT $[CLS]$ token or SBERT representations (`bert-base-uncased` for BERT-based models and `all-MiniLM-L6-v2` for SBERT; both models are both from the Transformers library). These are all build on the same codebase as our BERT-FP experiments. We fine-tune all of these architectures following the procedure described above for BERT-FP. As reported in the main paper, the classifiers consist of either a single linear-layer classifier, or three fully-connected ReLU layers with dropout and a final sigmoid layer.

To match the BERT input format, joint (context, response) pairs are presented in the following format for SBERT models:

$$(c_1, [eos], c_2, [eos], c_3, [eos], r) \tag{2}$$

A.2 TurnGPT surprisal definitions

We compute response scores from TurnGPT using various sequence-level surprisal definitions from previous works (Lau et al., 2017; Meister et al., 2021; Wallbridge et al., 2022). These include global surprisal metrics which account for surprisal at the turn level ($S_{total}, S_{mean}, S_{relative}$), and local netrics which provide more granular information at the token level (S_{max}, S_{var}). For a given (context c, response r) pair, each metric is defined as follows:

$$S_{total}(\mathbf{r}|\mathbf{c}) = \sum_{n=1}^{N}[S(r_n|\mathbf{r}_{<n}, \mathbf{c})]$$

$$S_{mean}(\mathbf{r}|\mathbf{c}) = \frac{1}{N}\sum_{n=1}^{N}[S(r_n|\mathbf{r}_{<n}, \mathbf{c})]$$

$$S_{relative}(\mathbf{r}|\mathbf{c}) = S_{mean}(\mathbf{r}|\mathbf{c}) - S_{mean}(\mathbf{r})$$

$$S_{max}(\mathbf{r}|\mathbf{c}) = \max[S(r_n|\mathbf{r}_{<n}, \mathbf{c})]$$

$$S_{var}(\mathbf{r}|\mathbf{c}) = \frac{1}{N-1}\sum_{n=2}^{N}[S(r_n|\mathbf{r}_{<n}, \mathbf{c}) - S(r_{n-1}|\mathbf{r}_{<n-1}, \mathbf{c})]^2$$

B Error Analysis: Corpus Excerpts

Tables 5, 6, 7, 8 contain examples of the stimuli collected in our previous work (Wallbridge et al., 2022) along with associated scores from both human participants, and the BERT-FP language model. Each stimuli consists of a variable number of conversational turns as context (1-4), and 10 potential upcoming responses (one of which is the true response in the particular conversation). Participants were presented with a context and a single response, and were tasked with rating how plausible the response was given the context.

Tables 5, 6, 7 show human misrankings while Table 8 contains the stimuli misranked by BERT-FP.

Table 5: Example of response selections stimuli ($sw3512\_14$) with human and BERT-FP scores.
Table (A) contains the set of conversational turns provided as context. Table (B) contains the set of 10 responses–these include the True upcoming turn for the given context and the 9 negative samples. Each response is displayed with it's true response label, the median plausibility score it recieved from participants (collected in our previous work (Wallbridge et al., 2022) study), and its BERT-FP response score.

Abstract

Language models can memorize a considerable amount of factual information during pretraining that can be elicited through prompting or finetuning models on tasks like question answering. In this paper, we discuss approaches to measuring model factual beliefs, updating incorrect factual beliefs in models, and visualizing graphical relationships between factual beliefs. Our main contributions include: (1) new metrics for evaluating belief-updating methods focusing on the logical consistency of beliefs, (2) a training objective for Sequential, Local, and Generalizing updates (SLAG) that improves the performance of existing hypernetwork approaches, and (3) the introduction of the *belief graph*, a new form of visualization for language models that shows relationships between stored model beliefs. Our experiments suggest that models show only limited consistency between factual beliefs, but update methods can both fix incorrect model beliefs and greatly improve their consistency. Although off-the-shelf optimizers are surprisingly strong belief-updating baselines, our learned optimizers can outperform them in more difficult settings than have been considered in past work.[1]

1 Introduction

Pretrained language models have been shown to store a large amount of factual information about the world that can be elicited by cloze prompting (Petroni et al., 2019), few-shot learning (Brown et al., 2020), or finetuning models for question answering or true/false statement classification (Roberts et al., 2020). We refer to this kind of stored information as model *factual beliefs*.[2]

While pretrained models clearly store factual beliefs, it is not well understood how to efficiently edit the stored beliefs. Model editing is an exciting recent direction of research with several practical uses cases (Sinitsin et al., 2020; Zhu et al., 2020; De Cao et al., 2021; Mitchell et al., 2021). For LMs, these uses include updating factually inaccurate outputs and preventing other unwanted model outputs (e.g. toxic generated text) without expensive data curation and retraining efforts. These are important applications given that LMs (1) struggle with future data when trained on data from the past (Lazaridou et al., 2021; Dhingra et al., 2021), (2) often generate morally undesirable text (Gehman et al., 2020; Bender et al., 2021), and (3) simply give inaccurate outputs for tasks like question answering (Lin et al., 2021). Notably, there is good evidence that scaling models to larger sizes will not fix these particular problems or may even exacerbate them (Lazaridou et al., 2021; Gehman et al., 2020; Lin et al., 2021).

In the remainder of this paper, we present new methods for *measuring*, *updating*, and *visualizing* factual beliefs in LMs. We further describe each of these three contributions below. Figure 1 represents the core ideas behind measuring and updating factual beliefs, while belief visualization is done via *belief graphs* (shown later in Figure 2).

Measuring factual beliefs. We measure the degree to which LMs possess *consistent* factual beliefs using models finetuned on fact verification and question answering tasks. Beyond simply checking individual model responses, we want to assess the structural properties of model outputs: Are they consistent under paraphrase? Are they logically consistent? Does changing one belief correctly change other entailed beliefs? Does it erroneously change other unrelated beliefs? Past work has focused primarily on consistency under paraphrase (Elazar et al., 2021; De Cao et al., 2021; Mitchell et al., 2021). Here, we adapt data from Talmor

---

[1] Code is available at `https://github.com/peterbhase/SLAG-Belief-Updating`.

[2] We use the term *factual belief* rather than *knowledge* as in related work (Zhu et al., 2020; De Cao et al., 2021) because "belief" is a weaker term than "knowledge." In a traditional view of knowledge as Justified True Belief, it is more difficult to describe information as knowledge than as a belief (Schwitzgebel, 2019).

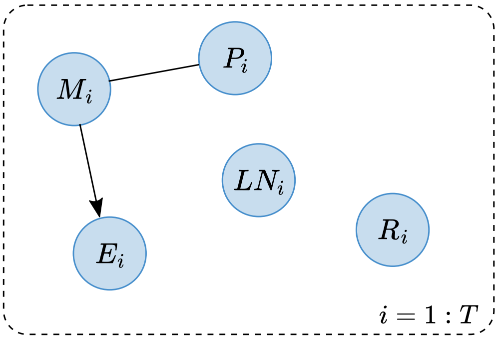
SLAG: Sequential, Local, and Generalizing Model Updates



```
$\theta_0 \leftarrow$ Language Model
for $t \in 1 : T$
    $\theta_t \leftarrow \mathrm{Update}(M_i, y_i^*, \theta_{t-1})$
```

M	(Main Input)	: A viper is a vertebrate.
E	(Entailed Data)	: A viper has a brain.
LN	(Local Neutral Data)	: A viper is venemous.
P	(Paraphase Data)	: Vipers are vertebrates.
R	(Random Data)	: Chile is a country.

Figure 1: Relying only on a Main Input M_i, we want to update a language model's weights in order to (1) change the output for M_i to a desired output y_i^*, (2) change the output for paraphrases of M_i, (3) appropriately change outputs for data E_i entailed by the tuple (M_i, y_i^*), and (4) *avoid* changing outputs for other logically neutral data LN_i, even if it is similar (local) to M_i. This is done iteratively for T requested updates.

et al. (2020) to measure consistency under entailment (including for contrapositives), and we use the Wikidata5m dataset (Wang et al., 2021) to construct logically neutral belief pairs for checking that models do treat these beliefs as independent.

Updating factual beliefs. We propose a Sequential, Local, and Generalizing belief update objective (SLAG) that substantially improves the performance of the comparable KNOWLEDGEEDITOR method from De Cao et al. (2021). KNOWLEDGEEDITOR is a learned optimizer that edits a model's weights to change its prediction on an input while satisfying other desiderata, like consistency under paraphrase. Principally, we identify more difficult training data for the learned optimizer, and we learn to apply many small edits rather than one big edit. These changes markedly improve the update success rate and lower the rate at which other beliefs are corrupted. We also find that KNOWLEDGEEDITOR almost totally fails when updating multiple beliefs in a row as opposed to a changing a single belief. However, by explicitly training the optimizer to update multiple beliefs sequentially, we recover much of the lost performance. Lastly, we advocate that these methods be evaluated for their ability to fix false or morally undesirable model beliefs, rather than to arbitrarily change beliefs to plausible alternatives as in past work (De Cao et al., 2021; Mitchell et al., 2021).

Visualizing belief graphs. We explore a new form of visualization for understanding language models, the *belief graph*. Given a set of factual beliefs, we construct belief graphs by changing each model belief and checking what other beliefs are sensitive to those changes. Each belief becomes a node, and directed edges between nodes show that updating one belief changes the other. We discuss graph metrics that help summarize the dependencies between model beliefs.

We summarize our main conclusions as follows:

1. ~100M parameter models exhibit limited belief-like qualities, as paraphrase consistency scores are under 70%, and models show mixed levels of consistency under entailment (Sec. 5.1).
2. Off-the-shelf optimizers are quite effective update methods, often outperforming learned optimizers when updating a single belief (Sec. 5.2).
3. When updating multiple beliefs in a row, performance greatly declines across methods, but SLAG can improve learned optimizers' performance beyond strong baselines (Sec. 5.2).
4. Belief graphs reveal many nonsensical dependencies between model beliefs, and they show the presence of "core" model beliefs that are connected to many other stored facts (Sec. 6).

2 Related Work

Measuring factual beliefs in language models. Much past work has explored how information is stored and represented in pretrained language models (Rogers et al., 2020). Petroni et al. (2019) provide evidence that LMs store relational information between entities, and Roberts et al. (2020) show that LMs can answer open-ended questions. Subsequent work has further explored how much knowledge is stored in LMs (Heinzerling and Inui, 2021). Most relevant to our work are studies from Talmor et al. (2020) and Elazar et al. (2021). Talmor et al. (2020) train LMs to perform True/False classification of factual claims, and they measure how beliefs correlate between entailed facts. We use their LeapOfThought data as a part of our SLAG objective (Eq. 1) and to measure model consistency under entailment before and after updating beliefs in models. Meanwhile, Elazar et al. (2021) measure the consistency of model predictions for paraphrased inputs. We adopt their metric for paraphrase consistency as a measure of belief. In other recent work, Kassner et al. (2021) measure consistency under entailment and paraphrase for factual belief with a new small-scale dataset, BeliefBank.

Updating factual beliefs in language models. Approaches to making targeted updates to model beliefs vary along a few dimensions. First is whether the methods alter model training or operate in a post-training setting. Sinitsin et al. (2020) use a meta-learning objective during training to encourage ease of editing afterwards. A larger family of methods perform post-training model updates: Dai et al. (2021) propose a hand-crafted algorithm that edits model weights, while Zhu et al. (2020) use projected gradient descent for batches of points. De Cao et al. (2021) train a hypernetwork (learned optimizer) that processes model gradients in order to produce a new model that (1) gives the desired output for an input, while (2) satisfying other objectives like minimizing changes in predictions for other data. Mitchell et al. (2021) focus on scaling up the underlying hypernetwork architecture, which is a complementary but orthogonal research direction that is not the focus of this paper. In a different approach, Kassner et al. (2021) "update" model beliefs by adding in relevant information to the input at test time. But this approach does not change the model weights and hence does not influence model outputs on all other potentially relevant inputs. Lastly, Meng et al. (2022) provide a specialized method focused on rank-one updates to MLP matrices in Transformer-based LMs, but they do not address the problem of updating multiple model beliefs and do not measure model consistency under entailment or unintended corruption of local neutral beliefs (metrics (5) and (6) in Sec. 3).

Visualizing factual beliefs in language models. We do not know of any prior work on visualizing dependencies between factual beliefs in language models, although our approach is notably inspired by older AI methods like Bayes Nets (Pearl, 2009). Different from Bayes Nets, we draw dependencies between two individual nodes when editing the model to change one belief also results in a change to the other belief, rather than there being a probabilistic model specifying the relationship between the two beliefs.

3 Updating Beliefs in Language Models

Here we describe the problem of updating model beliefs and our learned optimizer method. We also discuss metrics for measuring factual beliefs below, while our Belief Graphs are presented in Sec. 6.

Problem statement and metrics. We suppose we have a model $f_\theta = p_\theta(y|x)$ parametrized by θ. For an input x_i that has some undesired model output $\hat{y}_i = \arg\max_y p_\theta(y|x)$, we wish to obtain a new model θ^* that produces a desired output y_i^* for x_i. This new model θ^* should also fulfill a few other desiderata. As in past work (De Cao et al., 2021; Mitchell et al., 2021), we operationalize these desiderata in the following metrics:

1. Update Success Rate (*Main Input*): The proportion of Main Inputs x_i for which the updated model gives the desired output y_i^*.
2. Update Success Rate (*Paraphrase*): The proportion of paraphrases of x_i for which the updated model gives the same new prediction as it does for x_i (averaged across x_i).
3. Retain Rate (*All Data*): The proportion of the updated model's predictions which are unchanged for all data besides the Main Input.
4. Δ-Acc (*All Data*): The change in accuracy on all other data besides the Main Input.

In practice, Retain Rate (*All Data*) and Δ-Acc are computed with random subsets of a dataset, since these must be computed after every belief update. We add two metrics to those used in past work:

5. Update Success Rate (*Entailed Data*): The new model's accuracy on data that is logically entailed by the new Main Input prediction.
6. Retain Rate (*Local Neutral*): The proportion of the updated model's predictions which are unchanged for data that is similar to the Main Input but still logically neutral.

We use Update Success Rate (*Entailed Data*) to measure logical consistency for an updated model, since changing one belief entails changes in logically entailed beliefs. Retain Rate (*Local Neutral*)

Dataset	Data Type	Input	Label(s)
zsRE	Main Input Paraphrase	Player Ali Kanaan plays for what team? What team is Ali Kanaan associated with?	{Sporting Al Riyadi Beirut}
Wikidata5m	Main Input Paraphrase Local Neutral	Mary Good has relation 'award received' to Mary Lowe Good has relation 'winner of' to Mary Good has relation 'educated at' to	{Garvan-Olin Medal; Arkansas Women's Hall of Fame; etc.} {The University of Arkansas; U Arkansas; etc.}
FEVER	Main Input Main Input	Tardigrades are also known as space bears. The Lion belongs to the genus Vulpes.	True False
LeapOfThought	Main Input Entailed Data	A viper is a vertebrate. A viper has a brain.	True True

Table 1: Example datapoint from each dataset, and auxiliary data that accompanies the Main Input.

uses special Local Neutral data. Unlike random data, Local Neutral data is guaranteed to be logically independent of the Main Input, while still being similar (local) to it, which we ensure by using data with the same subject entity. Together, these six metrics better cover the criteria for belief outlined by Newen and Starzak (2020). We compute the metrics using data of the kind shown in Table 1.

Evaluation procedure. To date, methods have been evaluated on the basis of their ability to change model predictions for all data. Moreover, the desired labels $\{y_i^*\}_{i=1}^n$ on sequence prediction tasks have each been selected from the model's predictive beam search (De Cao et al., 2021; Mitchell et al., 2021). We propose for evaluation to focus on a more valuable but difficult setting: changing the predictions on incorrect points to be correct.

Sequential updates. The standard evaluation in past work is to update a single model belief, evaluate the new model, then rollback the update before repeating the process for each test point. We obtain sequential versions of all metrics by applying r model updates in a row before checking the metrics, meaning there are floor(n/r) measurements for a test set of n points. We consider it important to evaluate a sequential setting because, in practice, it is likely that model developers will want to update many factual beliefs of a trained model over time.

Belief updating method. As our base architecture, we use the KNOWLEDGEEDITOR architecture from De Cao et al. (2021), which is a hypernetwork that takes in model gradients as inputs and outputs a new update to apply to the model parameters. For further details of this method, we refer readers to Appendix A. Let it suffice for now to observe that a new model is given as a differentiable function

$$\theta^* = \theta + g_\phi(x_i, \hat{y}_i, y_i^*, \theta)$$

using the learned optimizer g_ϕ, current LM weights θ, Main Input x_i, current prediction $\hat{y}_i$, and desired model output y_i^*. Then, we can package the above update as $\theta^{(k+1)} = \theta^{(k)} + g_\phi(x_i, \hat{y}_i, y_i^*, \theta^{(k)})$, and obtain new model parameters via a looped update,

$$\begin{aligned}\theta^* &= \theta^{(k)} + \sum_{j=0}^{K-1} g_\phi(x_i, \hat{y}_i, y_i^*, \theta^{(k+j)}) \\ &= \text{Update}(x_i, \hat{y}_i, y_i^*, \theta^{(k)}; \phi, K)\end{aligned}$$

taking K small steps from initial parameters $\theta^{(k)}$. De Cao et al. (2021) use such a loop at test time; we incorporate the loop into training to align the train and test-time distributions.

Learned optimizer training. The training objective for KNOWLEDGEEDITOR includes differentiable terms corresponding to Update Success for the Main Input and paraphrases, as well as Retain Rate for all other data. We also consider terms for Update Success on entailed data and the Local Neutral Retain Rate, when this is possible given available data. The overall objective requires several kinds of additional data for each point, which we denote by $\mathcal{D}_R$ for other random data, $\mathcal{D}_{LN}$ for local neutral data, $\mathcal{D}_E$ for entailed data, and $\mathcal{D}_P$ for paraphrases of x_i. For a data point x_i with desired prediction y_i^*, the full objective is then:

$$\begin{aligned}\mathcal{L}(\phi; x_i, \hat{y}_i, y_i^*, \theta) &= \lambda_1 \mathcal{L}_{\text{Task}}(f_{\theta^*}(x_i), y_i^*) \\ &+ \lambda_2 \frac{1}{|\mathcal{D}_P|} \sum_{x_P \in \mathcal{D}_P} \mathcal{L}_{\text{Task}}(f_{\theta^*}(x_P), y_i^*) \\ &+ \lambda_3 \frac{1}{|\mathcal{D}_E|} \sum_{x_E, y_E \in \mathcal{D}_E} \mathcal{L}_{\text{Task}}(f_{\theta^*}(x_E), y_E) \\ &+ \lambda_4 \frac{1}{|\mathcal{D}_{LN}|} \sum_{x_{LN} \in \mathcal{D}_{LN}} \text{KL}(f_{\theta^*}(x_{LN}) || f_\theta(x_{LN})) \\ &+ \lambda_5 \frac{1}{|\mathcal{D}_R|} \sum_{x_R \in \mathcal{D}_R} \text{KL}(f_{\theta^*}(x_R) || f_\theta(x_R)) \qquad (1)\end{aligned}$$

where $\mathcal{L}_{\text{Task}}$ is the loss used to get gradients for f_θ. We use the Cross Entropy loss for binary classification and sequence-to-sequence tasks.

We optimize this objective w.r.t. ϕ using AdamW (Loshchilov and Hutter, 2019). To obtain update labels $\{y_i^*\}_{i=1}^n$, we always use the opposite class in binary classification. For sequence-to-sequence tasks, we use the correct label when $\hat{y}_i$ is incorrect, and when $\hat{y}_i$ is correct, we randomly select another label from the training data. This choice is in contrast to De Cao et al. (2021) and Mitchell et al. (2021), who use samples from the model beam search as update labels for all points.

SLAG objective. To prepare the update method for a sequential-update setting, we consider training g_ϕ to update multiple datapoints in a row. Using the per-datapoint loss in Eq. 1, we obtain our Sequential, Local, and Generalizing (SLAG) loss for a set of r Main Inputs $\mathcal{D} = \{x_i, \hat{y}_i, y_i^*\}_{i=1}^r$ as

$$\mathcal{L}_{\text{Sequential}}(\phi; \mathcal{D}, \theta_t) = \sum_{i=1}^{r} \mathcal{L}(\phi; x_i, \hat{y}_i, y_i^*, \theta_{t+i}) \quad (2)$$

where $\theta_{t+i} = \text{Update}(x_i, \hat{y}_i, y_i^*, \theta_{t+i-1}; \phi, K)$ are the model parameters obtained from updating on the first i points in $\mathcal{D}$ (starting from θ_t). This objective allows us to train g_ϕ to update multiple beliefs in a row. To ensure training with this objective is still efficient, we limit how far back through the update history we backpropagate when computing the gradient w.r.t. ϕ for each term in the RHS sum of Eq. 2. Each parameter vector θ_t depends on ϕ and θ_{t-1}. We always apply the stop-gradient function to the most recent vector θ_{t-1} to prevent backpropagating through it (visualized in Appendix Fig. 3). This choice allows our memory use to remain constant in r (see Appendix Fig. 4).

4 Experiment Setup

Datasets. We run experiments with four datasets (example data shown in Appendix Table 15). (1) FEVER includes 115,409 True/False factual claims (Thorne et al., 2018). We use the original test set of 10,444 points, and we randomly split the training data into 94,469 train points and 10,496 dev points. (2) zsRE includes 151,631 questions based on relational knowledge from Wikipedia, which we randomly shuffle into train/dev/test splits with 80/10/10% of the data (Levy et al., 2017). Talmor et al. (2020) introduce (3) the LeapOfThought dataset, consisting of factual claims that are entailed to be true or false depending on a context fact. We filter the data so that the context facts are unique, then shuffle the resulting 14,939 points into train/dev/test splits with 60/10/30% of the data.

	Belief Consistency ↑		
Dataset	Paraphrase	Entailed	Contrapos.
LeapOfThought	-	85.6 (1.1)	16.5 (2.7)
zsRE	69.5 (1.1)	-	-
Wikidata5m	25.8 (0.5)	-	-

Table 2: Belief metric results across datasets.

	Paraphrase Consistency ↑	
Dataset	Model Incorrect	Model Correct
zsRE	61.39 (1.33)	91.82 (1.17)
Wikidata5m	24.55 (0.48)	37.20 (2.06)

Table 3: Paraphrase consistency by the correctness of the model prediction on the Main Input.

In order to get Local Neutral data, we construct (4) a sequence prediction task using Wikidata5m, a relational knowledge base with over 20 million triplets (Wang et al., 2021). Each input consists of an entity e_1 and relation r, and the label is another entity e_2 that completes the triplet. All inputs come in pairs that share the same entity e_1 but use different relations with different labels. In general, the completion e_2 to the Main Input triplet (e_1, r_1, e_2) has no logical consequences for its paired input, (e_1, r_2, ?). The paired points are also local to the Main Input, i.e. they pertain to the same entity e_1 as the Main Input. We obtain four paraphrases for each Main Input using different aliases for the entity and synonyms of the relation. We construct a train set of 150k points and dev/test sets of 10k points each. See Appendix B for further details.

Models. We train five models with different random seeds for each dataset, using RoBERTa-base for binary tasks and BART-base for sequence-to-sequence tasks (accuracies in Appendix Table 14). For each of the five models, we train one learned optimizer using SLAG and one with the objective from De Cao et al. (2021), which we list as KE in tables below. Our model selection criterion is the mean of: average Update Success Rate (across data types), Retain Rate (only for Local Neutral data), and Δ-Acc for All Data. We tune the SLAG objective terms for each task separately (see Appendix Table 10 for final selections; results discussed in Appendix E). Other hyperparameters are given in Appendix B. To summarize the differences between SLAG and KNOWLEDGEEDITOR: (1) we use $K_{\text{train}} = K_{\text{test}}$ rather than $K_{\text{train}} = 1$; (2) we adopt

Single-Update Setting		Update Success Rate			Retain Rate		Δ-Acc
Dataset	Method	Main Input	Paraphrases	Entailed Data	Local Neutral	All Data	All Data
FEVER	AdamW	100 (0.0)	-	-	-	**98.80** (0.2)	**0.22** (0.1)
	KE	99.98 (<0.1)	-	-	-	98.28 (0.3)	-0.24 (0.1)
	SLAG	99.99 (<0.1)	-	-	-	98.41 (0.2)	-0.20 (0.1)
LeapOfThought	SGD	100 (0.0)	-	72.48 (4.6)	-	95.52 (0.4)	**1.23** (0.8)
	KE	99.78 (0.4)	-	74.48 (4.4)	-	93.50 (1.3)	-1.33 (1.1)
	SLAG	100 (0.0)	-	75.50 (4.3)	-	94.92 (1.4)	-1.31 (1.2)
zsRE	SGD	**99.36** (0.1)	94.44 (0.6)	-	-	74.73 (0.4)	-0.43 (0.1)
	KE	84.73 (1.4)	89.26 (1.8)	-	-	71.55 (2.4)	-2.19 (0.4)
	SLAG	94.29 (0.4)	94.71 (0.5)	-	-	**80.48** (1.3)	-0.29 (0.1)
Wikidata5m	SGD	**98.05** (0.3)	68.78 (0.8)	-	41.46 (1.0)	58.62 (0.6)	-1.97 (0.3)
	KE	74.57 (2.9)	58.05 (2.2)	-	40.84 (1.8)	53.58 (2.2)	-3.03 (0.5)
	SLAG	87.59 (0.6)	**80.70** (0.9)	-	**47.85** (1.0)	**63.51** (1.3)	-1.71 (0.3)

Table 4: Belief update metrics for off-the-shelf optimizers, KNOWLEDGEEDITOR (KE) from De Cao et al. (2021), and SLAG, with $r_{\text{test}} = 1$. Bolded numbers are the best in their group at a statistical significance threshold of $p < .05$ (or lower). Our SLAG objective improves over KE, but off-the-shelf optimizers perform surprisingly well.

training labels using real data labels rather than alternatives from the model's beam search; (3) our objective terms differ following tuning; and (4) we can optimize for updating multiple beliefs in a row.

Baselines. We use off-the-shelf optimizers as baselines. We tune the baseline hyperparameters separately for each dataset, selecting among several kinds of optimizers, learning rates, and the number of update steps. The selection criterion is the same as the criterion outlined for learned optimizers above. The resulting baselines are surprisingly strong (see Appendix Table 12 for final selections).

Hypothesis testing. We obtain 95% confidence intervals and perform hypothesis tests via block bootstrap, resampling model seeds and data points (Efron and Tibshirani, 1994). For ablation experiments, we run only one model seed per condition.

5 Experiment Results

5.1 Do LMs have consistent factual beliefs?

We measure Paraphrase Consistency, Entailment Acc, and Contrapositive Acc for finetuned task models. Paraphrase Cons. is the fraction of paraphrase pairs where the model produces the same output (Elazar et al., 2021). Entailment Acc is the model accuracy on data that is entailed by the Main Input. For LeapOfThought (see Table 1), "Main Input x_i is true" implies "entailed input x_E has label y_E," but the inverse ($\neg A \Rightarrow \neg B$) does not necessarily hold. Therefore, we compute Entailment Acc only where the Main Input prediction is correct. We do know that the contrapositive holds: "Entailed input x_E does not have label y_E" implies that "Main Input x_i is false." So for Contrapositive Acc, we measure how often the model follows this rule, when the antecedent holds of its prediction.

	Update Success Rate ↑		Δ-Acc ↑
Desired Label	Main Input	Paraphrase	All Data
Beam Label	97.41 (0.3)	97.03 (0.4)	-0.30 (0.1)
Correct Label	94.46 (0.7)	94.45 (0.7)	-0.24 (0.1)

Table 5: Evaluation difficulty by desired model output, for a learned optimizer trained with SLAG on zsRE.

Belief measurement results. Table 2 shows the belief metrics for each dataset. We find that ~100M parameter models show limited evidence of having consistent factual beliefs. Paraphrase consistency is 69.50% (± 1.09) for zsRE and much lower for Wikidata5m (25.84%±0.53). While entailment accuracy is high for LeapOfThought (85.63%±1.08), the model is consistent under the contrapositive only 16.51% (± 2.71) of the time. Overall, these results are not nearly as consistent as we would hope for factual beliefs to be. Interestingly, the metrics are much higher when the model prediction on the Main Input is correct (Table 3).

5.2 Can we update factual beliefs in LMs?

First, we compare two evaluation procedures for sequence prediction tasks: correcting model beliefs versus changing them to an alternative from the model's beam search. We do so for zsRE using SLAG. Next, we compare belief update performance between KNOWLEDGEEDITOR, SLAG, and off-the-shelf optimizers. We report results in single-update ($r_{\text{test}} = 1$) and sequential-update ($r_{\text{test}} = 10$) settings. See Appendix Fig. 5 for

Sequential-Update Setting		Update Success Rate			Retain Rate		Δ-Acc
Dataset	Method	Main Input	Paraphrases	Entailed Data	Local Neutral	All Data	All Data
FEVER	AdamW	92.81 (1.3)	-	-	-	**91.86** (1.4)	**1.16** (0.6)
	KE	74.13 (1.8)	-	-	-	39.86 (0.7)	-27.13 (1.3)
	SLAG	91.27 (2.9)	-	-	-	70.30 (5.8)	-11.96 (4.5)
LeapOfThought	SGD	100 (0.0)	-	**61.34** (5.0)	-	**82.62** (0.8)	**-4.93** (1.0)
	KE	96.14 (2.3)	-	49.27 (6.0)	-	72.45 (0.9)	-15.03 (1.0)
	SLAG	100 (0.0)	-	50.46 (5.5)	-	74.02 (1.1)	-13.03 (1.3)
zsRE	SGD	82.71 (0.6)	90.81 (0.7)	-	-	40.49 (0.6)	-2.38 (0.3)
	KE	0.10 (<0.1)	36.55 (1.4)	-	-	0.05 (<0.1)	-20.98 (0.7)
	SLAG	**87.57** (0.6)	**92.20** (0.7)	-	-	**47.19** (0.7)	**-1.74** (0.3)
Wikidata5m	SGD	56.82 (0.8)	54.49 (0.7)	-	6.40 (0.4)	26.37 (0.6)	-3.96 (0.4)
	KE	0 (0.0)	40.84 (0.9)	-	0 (0.0)	0 (0.0)	-10.05 (0.6)
	SLAG	**58.27** (1.0)	**65.51** (0.9)	-	**7.36** (0.5)	**27.76** (0.7)	-3.62 (0.4)

Table 6: Belief update results when a model is sequentially updated r_{test}=10 times. Here, SLAG uses $r_{\text{train}}=R$. On sequence prediction tasks in this setting, SLAG can outperform the off-the-shelf optimizers across metrics.

an ablation across r_{test}.

Correcting beliefs vs. changing factual beliefs. Given the results in Table 5, we find that correcting model outputs is harder than simply changing them to a plausible alternative. Update Success rises by a full 2.96 (±0.48; p<1e−4) points for Main Inputs and 2.58 (±0.81; p<1e−4) for Paraphrases, while Δ-Acc is virtually unchanged. This suggests that that past work has overestimated the efficacy of belief update methods for actually fixing models. Henceforth we evaluate methods according to their ability to update model beliefs to be true.

Update method results (single update). Table 4 shows the results in a single-update setting. First, we find that off-the-shelf optimizers are very effective across the board. The baselines show Main Input Update Success Rates of 98%+ across tasks with competitive or even positive Δ-Acc scores.[3] When strongly tuned, these baselines outperform learned optimizers on most metrics here.

However, SLAG surpasses the baselines in a few places. All Data Retain Rate on zsRE rises by 5.77 points (±1.43; p<1e−4), and on Wikidata5m Paraphrase Update Success rises by 11.92 (±1.20; p<1e−4) and the Local Neutral Retain Rate by 6.40 (±1.41; p<1e−4). SLAG also greatly improves over KE for sequence prediction tasks.

Interestingly, we observe that belief updates greatly improve paraphrase consistency and entailment accuracy (SLAG results in Table 7). Updates improve Paraphrase consistency by 33.14±1.46 on zsRE and 59.87±1.09 on Wikidata5m, while Entailment Acc rises by 17.20±7.10 points.

Metric	Before Update	After Update
Entailment Acc	58.30 (5.7)	75.50 (4.3)
Para. Cons (zsRE)	61.39 (1.3)	94.53 (0.6)
Para. Cons (Wiki)	24.69 (0.5)	84.56 (0.9)

Table 7: Entailment Acc and Paraphrase Consistency rise greatly after model updates to incorrect points.

Update method results (sequential updates). We give results for a sequential update setting (r_{test}=10) in Table 6. Immediately we see this is a much more difficult evaluation, as metrics are generally far lower for each dataset. Next, we observe that learned optimizers with SLAG (r_{train}=10) outperform baselines on sequence prediction tasks. On zsRE, we improve Update Success for Main Inputs by 4.86 (±0.83; p=1e−4) and for Paraphrases by 1.39 (±0.93; p=.004), with better Δ-Acc by 0.64 (±0.35; p=.0005). Improvements trend in the same direction for Wikidata5m and are all statistically significant except for the gain in Δ-Acc. The jump on Paraphrases in particular is large (11.02±1.17; p<1e−4). In comparison, using the KNOWLEDGEEDITOR training objective leads to drastic drops in performance.

Learned optimizers still struggle compared to baselines *on binary datasets*. Here, AdamW and SGD achieve high update update success with much better Δ-Acc scores, by 13.12 (±4.51; p=1e−4) on FEVER and 8.16 (±1.63; p=1e−4) on LeapOfThought.

---

[3] Positive Δ-Acc values are possibly due to distribution shift in the test split. In FEVER, for instance, the train and dev data are 73% True, while test data is 50% True. On the dev split, AdamW achieves a negative Δ-Acc, -0.18 (±0.11).

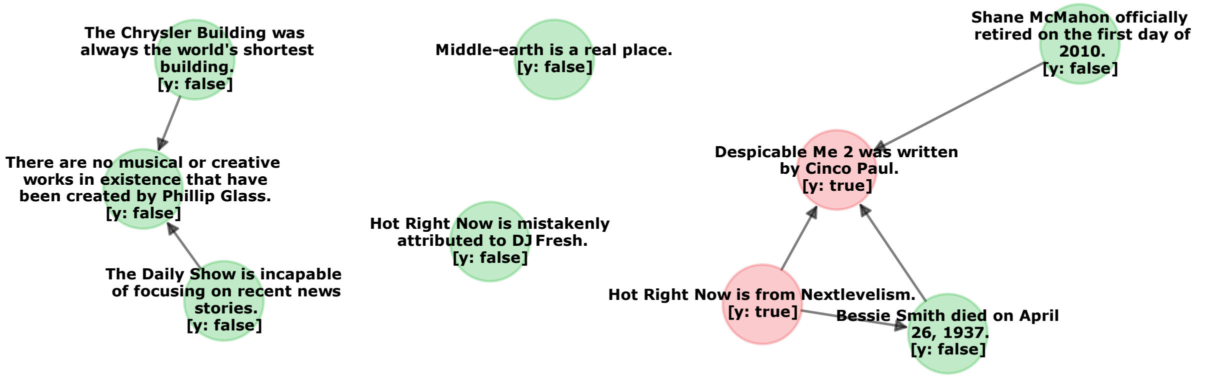


Figure 2: A non-random subgraph of the belief graph for a model trained on FEVER. Directed edges from u to v indicate that changing the model belief in u causes the belief in v to change. The ground-truth label is given in brackets for each point, and node color shows the model's accuracy before any updates (green=correct).

6 Belief Graphs

We now construct *belief graphs* to better understand the connections between model beliefs. We form a graph from a set of datapoints by updating each prediction and checking what other predictions change. We represent each datapoint as its own node in a belief graph. Whenever updating a datapoint u changes the prediction for point v, we draw a directed edge from u to v. Following Sec. 5.2, we use off-the-shelf optimizers to change the model output to the opposite of its original prediction for every datapoint. For FEVER we obtain a graph of 10,444 nodes, and for LeapOfThought we obtain a graph with 8642 nodes, which is double the test set size because we include both Main Inputs and Entailed Data as their own nodes.

We visualize part of a belief graph in Fig. 2. This figure shows a non-random subgraph intended to give a representative view of the data (we give three random subgraphs in Appendix E). On inspection, we do not see any clear reasons for beliefs being connected or not connected. We come to the same conclusion looking at other random subgraphs (see Appendix Figures 9, 10, and 11). Whether or not changing one belief changes another appears essentially random, which is a novel negative result on the organization of internal model beliefs. However, we do observe some aggregate trends. First, it appears that incorrect predictions are the most sensitive to model updates. On FEVER, incorrect beliefs change around 4% of the time when other beliefs are updated, while correct beliefs change only 2.5% of the time. Second, we find that Local Neutral beliefs are much harder to avoid changing than simply random data. On Wikidata5m (Table 4), we observe that the Retain Rate on All Data is 61.51±1.33, while for Local Neutral data it is a full 15.66 points lower.

	Dataset	
Metric	FEVER	LeapOfThought
# Nodes	10,444	8,642
% Edgeless	0.0	0.0
# Edges Total	1.88m	9.71m
# In Edges (95th perc.)	1,088	5,347
# Out Edges (95th perc.)	390	3,087
% Update-Transitivity	66.64	24.38*

Table 8: Belief graph summary statistics. *We compute Update-Transitivity for LeapOfThought with $n = 4000$ points due to computational cost.

We highlight a few summary statistics here from Table 8 for a broader view of the graphs. First, % Edgeless is the proportion of nodes which have no in or out edges. Since this is 0 for both datasets, every belief can be changed by editing the right belief. # In Edges is the number of in edges at the 95th percentile, meaning 5% of beliefs have more in edges than this value, and the same holds of # Out Edges. These values grow to a rather large fraction of the overall datasets, suggesting that (1) some beliefs are sensitive to changes in a large fraction of all beliefs, and (2) some beliefs are influential to hundreds of other beliefs when changed. Interestingly, this implies that some factual beliefs are "core" beliefs in the model, such that changing these individual beliefs requires greatly changing the overall distribution of factual beliefs in the model. Lastly, % Update-Transitivity represents the answer to the question: if updating belief A changes belief B, and updating belief B changes belief C, what proportion of the time does updating A change C? For these datasets, a logically consistent model should display 100% Update-Transitivity (see Appendix D for a caveat on this metric). We find that belief updates often yield intransitive results for both datasets, another negative result for belief consistency. It would be valuable for future work to extend this analysis of belief graphs to explore why language models demonstrate these surprising connections and inconsistencies between beliefs.

7 Conclusion

We first measure the presence of consistent factual beliefs in language models, and we propose to evaluate learned optimizers for whether they can make model beliefs more truthful. Then we show that our SLAG objective greatly improves learned optimizer performance, outperforming off-the-shelf optimizers when updating multiple model beliefs in a row. Finally, we introduce *belief graphs* to visualize connections between model beliefs. We find that model beliefs are highly interconnected, with some "core" beliefs influencing hundreds of other beliefs.

Ethics Statement

Belief update methods may be used to either correct undesired beliefs or induce problematic beliefs in LMs, and it is not clear whether these capabilities could be separated. We propose to evaluate methods only on the basis of their ability to correct mistaken model beliefs, but the malicious use case remains. We are uncertain about how a bad belief would influence the general behavior of a model (e.g. answers to many questions), but it is possible that a belief update method could instill bad beliefs in a capable LM with far-reaching implications for model behavior. That said, we hope that these methods will instead be used to update undesirable moral, social, and factual beliefs in large LMs.

Limitations

We note a few limitations of our work:

(1) Neural learned optimizers require large amounts of training data to successfully edit even a few model beliefs at test time.

(2) Our experiments are limited by available datasets in terms of both metrics we can calculate and objectives we can optimize for. There is also some noise in each dataset which we catalogue in Appendix C.

(3) We conduct experiments with $\sim$100M parameter models as in past work. While the belief-updating problem is still clearly unsolved given our results, it will also be valuable for future work to scale to larger models which may exhibit more consistent factual beliefs. That said, we believe our contributions are still valuable since our metrics, objectives, and belief visualization method can all be easily applied to larger models, and hypernetworks have already been extended to work with larger models (Mitchell et al., 2021).

(4) Currently, models may have seemingly random interdependencies between factual beliefs, limiting the insights available from our belief graphs. We believe that as models become more consistent and more truthful, the usefulness of belief graphs as a tool for understanding connections between beliefs will increase.

(5) Lastly, we do not currently account for uncertainty in factual beliefs. The data we use comes in the form of declarative statements and answers to questions which take what is called a veridical stance toward a proposition, displaying a "full commitment" to that proposition's truthfulness (Giannakidou and Mari, 2020). It will be valuable for future work to explore two dimensions of uncertainty in beliefs: (1) expression of uncertainty in language, via partial or trivial commitments (like "X might be Y") and (2) expression of uncertainty mathematically, via probabilities assigned by a model to utterances or True/False values. In this paper we treat a belief as "updated" when the model output changes, but this ignores any underlying change in the distribution $p_\theta(y|x)$ that could occur even if its mode does not change.

A Learned Optimizer Details

Architecture. KNOWLEDGEEDITOR is a learned optimizer $g : \mathcal{X} \times \mathcal{Y} \times \mathcal{Y} \times \Theta \to \Theta$ that produces new model weights by applying an adjusted gradient step to a model. For reference, we give a glossary of symbols used here in Table 9. For additional details beyond what is presented here, we refer readers to De Cao et al. (2021).

At a high level, g_ϕ first encodes an input x_i and requested prediction change into a vector h, then processes h into two low-rank matrices A and B that are used to transform the model gradient on x_i, $\nabla_\theta \mathcal{L}(x_i, y_i^*)$. For Transformer models, the method edits only attention and feed-forward weights, so all model gradients match the shape of an associated weight matrix of shape $d_1 \times d_2$. Formally, a new model θ^* is obtained using a learned optimizer g_ϕ as follows:

$$\begin{aligned} h &= \text{LSTM}([x; \hat{y}; y^*]) \\ \{u, v, \gamma, \delta\} &= \{\text{MLP}_i(h)\}_{i=1}^4 \\ A &= \text{softmax}(u)v^T \\ B &= \text{softmax}(\gamma)\delta^T \\ \eta &= \sigma(\text{MLP}(h)) \\ \theta^* &= \theta + \eta(A \circ \nabla_\theta \mathcal{L}(x_i, y_i^*) + B) \end{aligned}$$

where ϕ consists of all LSTM and MLP parameters.

Training Algorithm. The learned optimizer objective is optimized w.r.t. ϕ with AdamW through a standard procedure of randomly sampling minibatches without replacement (Loshchilov and Hutter, 2019). Within each batch, one datapoint is randomly selected as the Main Input, and the remaining points are used as $\mathcal{D}_R$. To obtain update labels $\{y_i^*\}_{i=1}^n$, we always use the opposite class in binary classification. For sequence-to-sequence tasks, we use the correct label when $\hat{y}_i$ is incorrect, and when $\hat{y}_i$ is correct, we randomly select another label from the training data. This choice is in contrast to De Cao et al. (2021) and Mitchell et al. (2021), who use samples from the model beam search as update labels for all points.

Symbol Glossary	
f_θ	Language Model
g_ϕ	Learned optimizer
x_i	Main Input
$\hat{y}_i$	LM output on x_i
y_i^*	Desired output
$\nabla_\theta \mathcal{L}(x_i, y_i^*)$	Gradient of LM
$\text{Update}(x_i, \hat{y}_i, y_i^*, \theta)$	Update one LM belief
$\mathcal{L}(\phi; x_i, \hat{y}_i, y_i^*, \theta)$	Belief update objective for x_i
$\mathcal{L}_{\text{Sequential}}(\phi; \mathcal{D}, \theta_t)$	Sequential objective (SLAG)
K	# gradient steps in Update$(\cdot)$
r	# beliefs updated in $\mathcal{L}_{\text{Sequential}}$

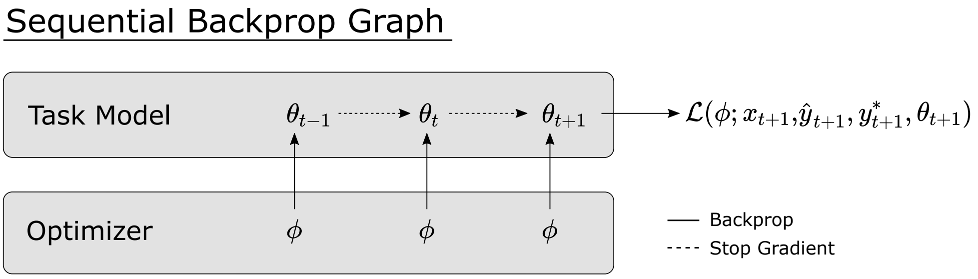
Table 9: Symbol descriptions for the learned optimizer.

B Additional Training Details

B.1 Compute Costs.

Learned optimizer memory. The hypernetwork has 92m trainable parameters for RoBERTa-base (which is 125m parameters), and 105m parameters for BART-base (which is 139m parameters). To increase training efficiency, we limit how far into the task model history we backpropagate. As shown in Fig. 3, when backpropagating through task model parameters $\theta_t = \theta_{t-1} + \text{Update}(x_i, \hat{y}_i, y_i^*, \theta_{t-1}; \phi)$, we continue backpropagating through $\text{Update}(x_i, \hat{y}_i, y_i^*, \theta_{t-1})$ but *not* θ_{t-1}, which is also dependent on ϕ. That is, we apply a stop-gradient function to θ_{t-1}. This way, we compute the derivative $\nabla_\phi \text{Update}(x_i, \hat{y}_i, y_i^*, \theta_t; \phi)$. only once for each t, rather than recomputing these gradients for all subsequent time steps. These choices allow the memory use of our training algorithm to remain constant in r. We make the same choice for our K looped steps in a single application of the Update function, so the gradient for the update at step k depends only on $g_\phi(x_i, \hat{y}_i, y_i^*, \theta^{(k)})$ and not $\theta^{(k-1)}$. See Fig. 4 for a graph of memory use depending on r and k.

Experiment runtimes. We now give runtimes for experiments in the paper. Building the belief graphs takes 25 hours for FEVER ($n = 10,444$) and 17.5 hours for LeapOfThought ($n = 8642$) on an NVIDIA RTX 2080 GPU. Computing summary statistics for graphs takes 3 hours on FEVER and 3 hours for LeapOfThought for statistics be-



$$\mathcal{L}_{\text{Sequential}}(\phi; \mathcal{D}, \theta_t) = \sum_{i=1}^{r} \mathcal{L}(\phi; x_i, \hat{y}_i, y^*_i, \theta_{t+i}) \qquad \theta_{t+1} = \theta_t + \text{Update}(x_i, \hat{y}_i, y^*_i, \theta_t; \phi)$$

Figure 3: The backpropagation graph for sequential model updates.

sides Update-Transitivity. We compute Update-Transitivity for LeapOfThought with a subset of 4000 points, which takes 45 hours.

All other experiments are run on a NVIDIA V100 32GB GPU. Training the task models takes 7 minutes for LeapOfThought, 45 minutes for FEVER, 4 hours for zsRE, and 10 hours for Wikidata5m. Training the learned optimizer with $r = 1$ takes 2.3 hours for LeapOfThought, 5 hours for FEVER, 9.5 hours for zsRE, and 16 hours for Wikidata5m. Training the learned optimizer with $r = 10$ takes 53 minutes for LeapOfThought, 2.9 hours for FEVER, 7 hours for zsRE, and 12.5 hours for Wikidata5m. Computing update statistics with the off-the-shelf optimizers with $r = 1$ takes 4 minutes for LeapOfThought, 30 minutes for FEVER, 2.3 hours for zsRE, and 3.9 hours for Wikidata5m. With $r = 10$, the baselines require 1 minute for LeapOfThought, 15 minutes for FEVER, 54 minutes for zsRE, and 1.8 hours for Wikidata5m. Total runtimes for each experiment should take into account multiple conditions and multiple seeds of each model being run.

B.2 Hyperparameters and Objective Terms.

Training hyperparameters. We fit our RoBERTa-base and BART-base task models to their respective datasets with the following hyperparameters: We train for 10 epochs on the binary tasks, and 20 for the sequence-to-sequence tasks. When predicting with BART-base, we use a beam search with width 5. In each case, we use AdamW from `torch.optim` with a LR of 1e-5 and weight decay of 1e-4. We select the best model according to the best dev set accuracy, checkpointing after each training epoch. The learned optimizers are optimized with AdamW, using a learning rate of 3e-4 and weight decay of 0. We train the learned optimizer for 5 epochs on each dataset except for LeapOfThought, which we train for 10 epochs given its smaller size. The learned optimizers are also selected based on dev set performance, with checkpointing after each training epoch. Their selection criterion is a raw average of Update Success Rate (averaged over each kind of data), Retain Rate (*Local Neutral*) and Δ-Acc, with terms dropped when they cannot be computed given the available data. Note that dev epochs with zsRE and Wikidata5m are fairly slow, so in order to speed up our experiments we compute dev epochs with a subset of 4000 dev points.

Dataset	r_{test}	K	Objective
FEVER	1	5	Main
	10	1	Main
LeapOfThought	1	5	Main
	10	1	Main
zsRE	1	5	Main
	10	5	Main
Wikidata5m	1	5	Main+Para
	10	5	Main+Para

Table 10: Final hyperparameters and objective terms of the learned optimizer for each task.

Learned optimizer. We give the final hyperparameter and objective terms used in each experiment in Table 10. Our objective ablation is given in 17, and we select the best performing condition for each dataset according to dev set performance, using the same selection criterion outlined previously. We keep all weight coefficients λ_i equal rather than tuning them. Main refers to the first term in Eq. 1, plus the KL term with random data. We use $K_{\text{train}} \leq 5$ for all experiments. For results across K values on zsRE, see Fig. 8.

Baseline update method. We tune a baseline off-the-shelf optimizer separately for each dataset, using $r_{\text{test}} = 1$. Our performance criterion is the

Relation	% Test Data
Place of Birth	11.00
Award Received	11.00
Cause of Death	5.66
Place of Death	11.00
Place of Burial	8.33
Educated At	11.00
Child	11.00
Occupation	11.00
Spouse	11.00
Sibling	9.01

Table 11: Wikidata relations and their proportion of the test data.

Dataset	Optimizer	LR	Num. Steps
FEVER	AdamW	1e-6	100
LeapOfThought	SGD	1e-2	100
zsRE	SGD	1e-1	10
Wikidata5m	SGD	1e-1	10

Table 12: Final hyperparameters of the baseline update method for each task.

same as with learned optimizers, a raw average of Update Success Rate (averaged over each kind of data), Retain Rate (*Local Neutral*) and Δ-Acc. The grid search is over the following parameters: The off-the-shelf optimizers are from `torch.optim` and include {AdamW, SGD, and RMSProp} with default arguments (except for the learning rate). We consider a number of maximum steps in {5, 10, 100}. The learning rates we consider depend on the optimizer: {1e-4, 1e-5, 1e-6} for AdamW, {1e-4, 1e-5, 1e-6} for RMSProp, and {1e-1, 1e-2, 1e-3} for SGD. The LR ranges were selected after some initial manual exploration of the space. Our final hyperparameter values are shown in Table 12 for each dataset. For comparison, De Cao et al. (2021) use RMSProp with 100 update steps. The LR for zsRE and Wikidata5m may seem quite high, but this is the condition that actually does the least damage to the model's accuracy on other data, Δ-Acc. The baseline optimizes all of the trainable parameters in the language model, unlike the learned optimizer which optimizes only attention and feedforward weights for purposes of parameter efficiency.

B.3 Wikidata5m Additional Details.

We construct four paraphrases per Main Input by selecting from a set of alternative phrasings for the entity and relation in the Main Input. The syntax for each paraphrase follows the same simple template as the Main Input, in contrast to zsRE where syntax differs between paraphrases. A couple details remain. Some relations are one-to-many, and therefore we accumulate valid completing entities from the data as possible answers; later we compute accuracy as an exact match with any possible answer. All 10 relations appear in each split of the data. Only 33.80% and 37.18% of the entities in the dev and test splits are seen in the training data, though we do not find that models perform better on entities seen in training.

B.4 LeapOfThought Additional Details

The LeapOfThought dataset consists of a fact and a claim for each datapoint, where the truth of the fact implies that the claim has label y_i (True/False). All of the facts in the data are true, while half of the claims are true and half are false. When training the learned optimizer, we treat the the facts as the Main Input when training the learned optimizer and claims as entailed data. When training the True/False classifier, we fit to the claims, for which test accuracy is 83.65 ($\pm$ 1.05). This seems to generalize well to the facts, as test accuracy here is 93.66 ($\pm$0.87), although as the low contrapositive accuracy suggests (Table 3), the model seems to be too prone to predicting true for this data.

Since very few of the Main Inputs are predicted as false, we run into a small dilemma when fitting the learned optimizer with the use of the entailed data objective term. The entailment between fact and claim only holds when the fact is true, so we can only compute the objective when updating a point from false to true. This ends up being less than 10% of the training data. We ultimately choose to oversample points that fit this description during training of the learned optimizer, which allows the learned optimizer to fully fit to the entailed data. Also note that during learned optimizer training, we include Entailed Data *from other data points besides the Main Input* in the KL term in Eq. 1, and we measure Δ-Acc using both Main Inputs and Entailed Data.

C Dataset Sources and Noise

Here we give sources and licenses for each dataset, and we document some shortcomings of each dataset, with reference to examples in Table 15.

Dataset sources and licenses. FEVER and zsRE are available through the KILT[4] resource and are

---

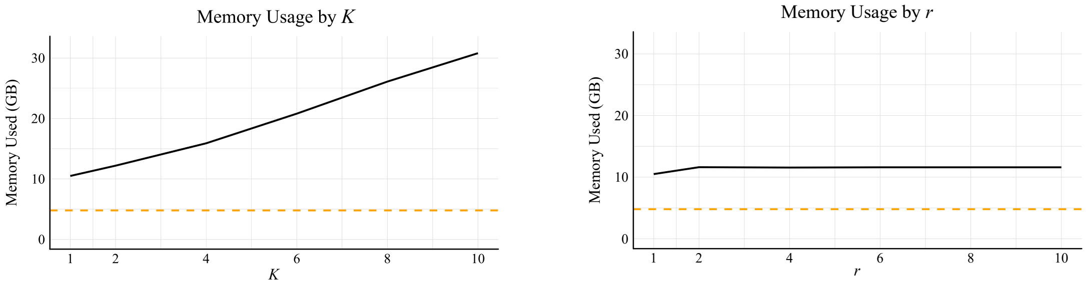

Figure 4: Training memory usage in terms of K and r hyperparameters in our implementation, for a learned optimizer trained for a BART-base model on zsRE, using a batch size of 16. For comparison, the orange dashed line shows the memory use of training the BART-base model on zsRE, using the same batch size. Our use of the stop-gradient function limits the growth of runtime and memory w.r.t. both K and r. By accumulating gradients across points, memory w.r.t. r is kept constant. The same trick could be applied to the K looped gradient steps inside the Update function, at the trade-off of backpropagating K times per point rather than one time.

Ours	De Cao et al. (2021)	Mitchell et al. (2021)
Update Success Rate (*Main Input*)	Success rate	Edit success
Update Success Rate (*Paraphrase*)	Equivalence accuracy	Edit success
Update Success Rate (*Entailed Data*)	-	-
Retain Rate (*Local Neutral*)	-	-
Retain Rate (*All Data*)	Retain accuracy	-
Δ-Acc (*All Data*)	Performance deterioration	Drawdown

Table 13: A glossary of terms used in work on model update methods. Note metrics are not always calculated in exactly the same way. For instance, Performance deterioration is a ratio in accuracies rather than difference in accuracies, and edit success from Mitchell et al. (2021) combines two metrics in our case. The performance metric in Zhu et al. (2020) is an average of Update Success Rate (*Main Input*) and Δ-Acc.

available under the MIT license (Petroni et al., 2021). LeapOfThought data can be constructed through their available code[5] and is also available under the MIT license. The source data for Wikidata5m data can be downloaded through the KEPLER[6] code repository (Wang et al., 2021) and is available under the MIT license. Use of each dataset is in accordance with their intended licensed uses. The zsRE and Wikidata5m datasets do refer to people by name as they reference public figures on Wikipedia. All datasets are in English.

FEVER. Some claims are slightly vague or ambiguous when taken on their own. For instance "Doug Ducey was the CEO of Cold Stone Creamery and offered many opportunities to new hires" is rated True, though this will depend heavily on what one thinks "many opportunities" means. Similar whether or not "L.A. Guns is a tattoo shop" depends on which "L.A. Guns" one is referring to, the tattoo shop or metal band. Of course, this is a generic issue of language, and not unique to this dataset. Some inputs seem to be a matter of person opinion: "Los Angeles is known for its food" is rated False.

LeapOfThought. Many examples use an "is a" relation, producing sentences like "A sunlight is a good health." This could be more false than true, but it's a fairly nonsensical statement to begin with. There are also other nonsensical or vague examples in the data: "A friar is the opposite of mineral" is labeled False. "A detective desires equal opportunity." is labeled True. It is not immediately clear what conditions would make these statements true or false.

zsRE. Some questions invoke potentially one-to-many or temporally dependent relations, though there is only one ground-truth answer per question in this dataset. For instance, a paraphrase of the question about Gifford Pinchot in Table 15 is: "What disease did Gifford Pinchot have?" A person might have had many diseases over their life which could all be valid responses. The answer is especially ambiguous for spatial relations, where a valid answer might refer to a city, region, country, province, or continent.

Wikidata. Aliases sometimes vary greatly even as they refer to the same person, or they are simply noisy. For example, as shown in Table 15, "SusunW" appears in an entity name, but this is actually a username of someone who contributed

	Entailed Data	A viper has a brain.	True
	Main Input	A amaranth is a herb.	True
	Entailed Data	A amaranth has a nose.	False

Table 15: Example datapoint from each dataset, and auxiliary data that accompanies the Main Input.

to the Wikipedia article for Margarita Nolasco Armas. Meanwhile, other aliases for J.R.R Tolkien include "Tolkienian" and "Mabel Suffield," his mother. Rephrasings of relations might also create confusing inputs, e.g. switching "child" with "has kids," "daughter", or "son." Similar to zsRE, some relations are also one-to-many and temporally dependent (like occupation), though we hope that by using many valid answers we circumvent this issue to some extent when calculating prediction correctness.

D Metric Computation and Bootstrap Details

Metric computation. The only computationally difficult metric to calculate is Δ-Acc, which requires computing the updated language model's accuracy on other data after every single belief update. We randomly sample other data after every update for this purpose, using $n = 30$ points for zsRE and Wikidata5m and $n = 200$ points for FEVER and LeapOfThought. We ensure that all evaluation data is used at some point during this sampling by preferentially selecting data that has been infrequently selected before. We note that paraphrase consistency is easy to evaluate for a small number of paraphrases per datapoint, as we have for both zsRE and Wikidata5m. Additionally, on LeapOfThought, we compute Δ-Acc using both Main Inputs and Entailed Data.

Update-Transitivity caveat. The % Update-Transitivity metric represents the answer to the question: if updating belief A changes belief B, and updating belief B changes belief C, what proportion of the time does updating A change C? We would treat this as a normative metric that we hope to maximize, except we do not know in general whether there is a confounding belief D that determines the relationship between B and C. If changing A also changed a confounding belief D, then we might not be able to expect that C should change too. That said, when we have no reason to think there are such confounding beliefs, we would expect a logically consistent model to display 100% Update-Transitivity of their beliefs. In Fig. 2, for instance, we see no reason to suspect there are con-

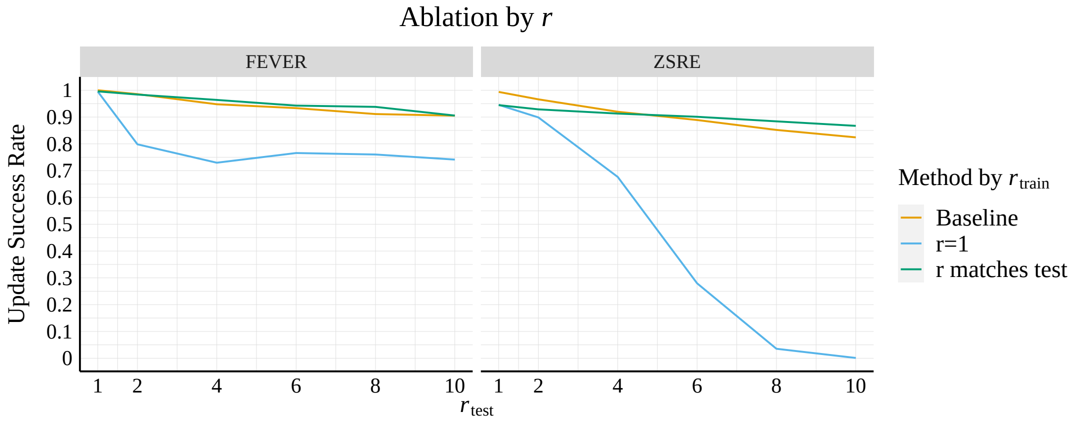

Figure 5: Ablation across values of r for training and testing. On zsRE, our method outperforms the baseline when $r_{\text{test}} = 10$, and the gap is likely to increase as r_{test} rises further. When using a non-sequential objective from past work, performance declines drastically as r_{test} rises.

founding beliefs for the relationship between the date Bessie Smith died and the writer of Despicable Me 2, and therefore we would expect that updating the belief about what album Hot Right Now is on would change the belief in Despicable Me 2's authorship (which it does).

Bootstrap computation. We account for sample and seed variance by block bootstrap (Efron and Tibshirani, 1994). When there is a single statistic per data point, like Main Input Update Success, we form a matrix of shape $n \times s$ for n data points and s model seeds (where the seed was used for both task model training and learned optimizer training). We then resample rows and columns of this matrix 10,000 times, which was sufficient for convergence. When we perform hypothesis tests for the difference in statistics between conditions, we pair the data points by using the same rows of this matrix at each step of the bootstrap (i.e. we conduct paired tests). For metrics involving multiple data points per Main Input, like paraphrases or other random data, we make a simplifying assumption where we do not resample the multiple data points but just compute the average metric for those data points and treat that as the ground-truth statistics for the Main Input. We explored using a full 3-dimensional bootstrap, where we resample among these extra datapoints by constructing a matrix of shape $n \times s \times n$, but it was quite slow and gave similar results to the block bootstrap.

E Additional Results

Ablation across num. sequential steps. Fig. 5 shows the results for an ablation across r_{test} using two kinds of learned optimizers: SLAG$_1$, where $r_{\text{train}} = 1$, and a SLAG condition where $r_{\text{train}} = r_{\text{test}}$. It is critical to the success of learned optimizers to train them to update points sequentially when this is a desired application. Further, sequential updating with sequence prediction tasks is the only setting where we see learned optimizers outperform baselines across all relevant metrics.

	Update Success Rate		Δ-Acc
Desired Label	Main Input	Paraphrases	All Data
Beam Label	91.19 (0.5)	92.07 (0.8)	-0.39 (0.1)
Hard Label	94.46 (0.7)	94.45 (0.7)	-0.24 (0.1)

Table 16: Update metrics by optimizer training labels.

Choosing training labels for learned optimizers. In early experiments, we found that it is beneficial to use all data points (including correctly predicted points) as Main Inputs *during training*, rather than restricting training to only incorrectly predicted points. We still focus on correcting wrong outputs at test time. But so we must select what label to use during optimizer training. To get a Hard Label, we use the correct label for incorrectly predicted points, and for correctly predicted points, we simply draw a label randomly from the labels in the training data. The alternative Beam Label condition uses a sample from the model's beam search for a data point, as done in past work (De Cao et al., 2021; Mitchell et al., 2021). We show update metrics for zsRE split by the desired label in Table 16. If one's goal is to fix wrong model outputs, then it is much better to use either the correct label or a random label as the desired model output during training rather than a sample from the model's beam search. Update success improves by

Table 17: Belief update results by the objective terms used for the learned optimizer. We do not bold any numbers based on statistical significance. For tuning purposes we select whichever condition achieves the higher selection criterion without testing for statistical significance.

3.27 (±0.65; p<1e−4) points for the Main Input and 2.38 (±1.05; p<1e−4) for Paraphrases, while Δ-Acc rises by 0.15 (±0.18; p=.09).

Which beliefs are hard to update? We hypothesize that beliefs will be easier to update when they are more belief-like to begin with. We principally measure this via the correlation between update success rate and a belief's consistency on paraphrases before the update, for our learned optimizer in a single-update setting ($r = 1$). Surprisingly, we observe no relationship between update success and the belief consistency. The correlation between consistency and update success is near 0 for both zsRE ($\rho = -.027$) and Wikidata5m ($\rho = .013$); see Fig. 6 for a plot of the relationship. So it appears that the learned optimizer can update model beliefs independently of how belief-like they are to begin with. We would also be interested in considering consistency under entailment, but the update success rate on LeapOfThought is already 100%, so there is no variance to explain.

Learning curve. In Fig. 7 we show the learning curve of a learned optimizer trained with SLAG on zsRE. The Main Input Update Success Rate steadily rises as a function of the training set size.‘

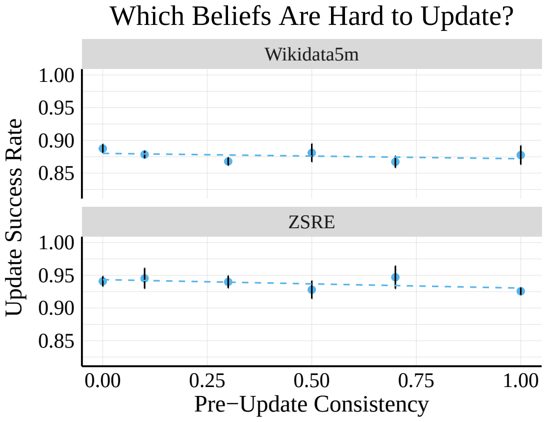

Figure 6: Beliefs are neither easier nor harder to update depending on their consistency beforehand.

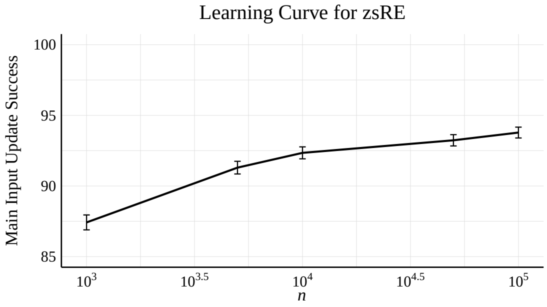

Figure 7: Main Input Update Success Rate across training set sizes, using SLAG on zsRE.

Ablation by objective term. We give objective ablation results in Table 17. Surprisingly, we do not always see that the objective terms help for the data they are intended to help with. First, we obtain mixed results for the paraphrase objective. On zsRE, the objective term seems to hinder performance, with update success dropping on Main Inputs by 0.71 (±0.60; p=.021) and Δ-Acc dropping by 0.18 (±0.19; p=.069), while the paraphrase Update Success Rate itself is unaffected. With Wikidata5m, however, the paraphrase term improves paraphrase update success by a large margin of 16.94 (±1.03; p<1e−4) points. Adding the Local Neutral (LN) term with the paraphrase term greatly improves the LN Retain Rate for Wikidata5m, by 9.71 points (±1.44; p<1e−4), though both of these terms come at a cost to Main Input Update Success, similar to zsRE. Lastly, we do not find that the entailment objective improves Entailed Data Update Success; in fact, this metric falls by 4.56 (±7.22;

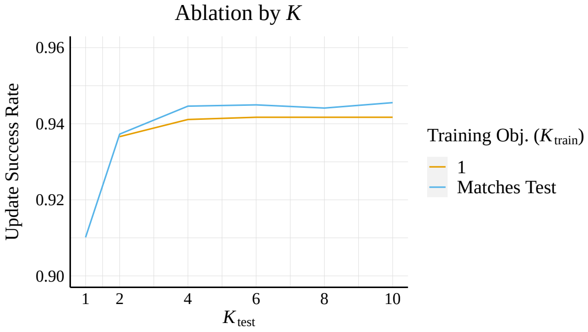

Figure 8: Ablation across values of K for training and testing, using SLAG on zsRE. It is useful to train the optimizer using the value of K it will use at test time.

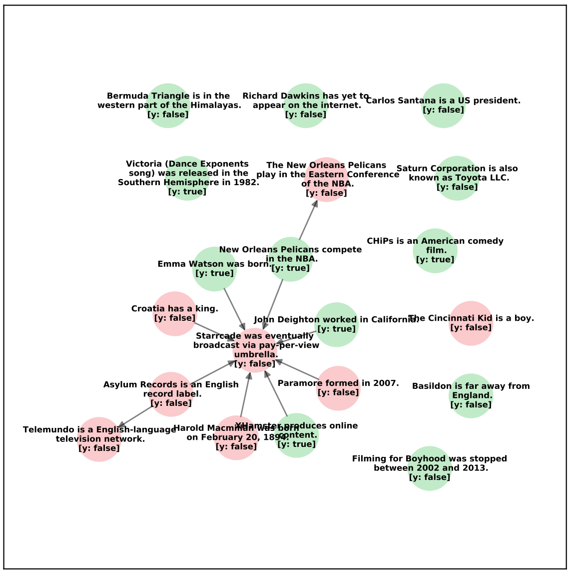

Figure 9: A random subgraph of the belief graph for FEVER. Note all nodes actually are connected to at least one another node.

p=.213) points with the objective.

Ablation by num. update steps. Fig. 8 shows the results of an ablation across values of K using a learned optimizer trained using SLAG with $r = 1$ on zsRE. Main Input Update Success rises by over three points by increasing K_{test} from 1 to at least 5. Using a value of K_{train} that matches K_{test} gives a further increase of about 0.5 points.

Abstract

We use insights from research on American Sign Language (ASL) phonology to train models for isolated sign language recognition (ISLR), a step towards automatic sign language understanding. Our key insight is to explicitly recognize the role of phonology in sign production to achieve more accurate ISLR than existing work which does not consider sign language phonology. We train ISLR models that take in pose estimations of a signer producing a single sign to predict not only the sign but additionally its phonological characteristics, such as the handshape. These auxiliary predictions lead to a nearly 9% absolute gain in sign recognition accuracy on the WLASL benchmark, with consistent improvements in ISLR regardless of the underlying prediction model architecture. This work has the potential to accelerate linguistic research in the domain of signed languages and reduce communication barriers between deaf and hearing people.

1 Introduction

When learning to recognize sign language, there is evidence that people rely on breaking signs down into their constituent parts, such as the configuration and location of the hand (Klima and Bellugi, 1979). This process is also true of spoken language recognition, where recognizing sound patterns plays a crucial role in one's ability to recognize a word. Sometimes, one of these "parts" (phonemes) is the only distinguishing factor between two very different terms, as seen in the signs for DIFFERENCE (palms up) and BALANCE (palms down) in Croatian Sign Language (Kuhn et al., 2006). Thus, the ability to encode and recognize individual phonemes and the relationships among them is essential for sign recognition. As a first step in exploring the practicality of phoneme recognition, we ask: Can machine learning models for isolated sign language recognition (ISLR) benefit from the phonological structure of signs?

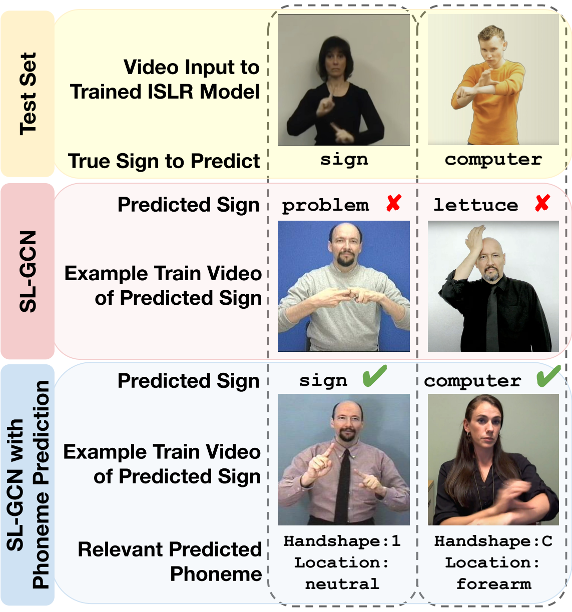

Figure 1: We demonstrate that sign language recognition models improve in accuracy when also tasked with predicting component phonemes of the sign.

While some ISLR models explicitly focus on the signers' hands (Hu et al., 2021) or face (Albanie et al., 2020), none have leveraged sign language phonology. Instead, ISLR has been treated similarly to gesture recognition, where a "gesture" (such as swinging an imaginary bat or waving a hand) has no underlying structure except for that of the human body itself. This lack of structure might explain why state-of-the-art models like the Sign Language Graph Convolution Network (SL-GCN, Jiang et al. 2021) sometimes predict labels that are visually and phonologically unrelated to the ground truth, as shown in Figure 1.

In contrast, we show that models trained to recognize both signs and their phonemes will be more accurate at sign identification than those trained for ISLR alone. Our main contributions are:

- We join an ISLR benchmark with a dataset of phonologically-labeled signs (§3.1) and de-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2732–2737
May 2-6, 2023 ©2023 Association for Computational Linguistics

scribe a simple method for learning these labels alongside the target gloss[1] (§3.2).

- We explore which and how many phoneme types are most beneficial as an auxiliary task to sign recognition (§3.3, §4.1).
- We demonstrate that adding auxiliary predictions for sign language phonology targets yields nearly 9% absolute gain in accuracy for ISLR sign prediction (§4.2), and that the resulting phoneme classification heads outperform prior work (§4.3).

2 Background

Sign languages are complete and natural languages primarily used by deaf and hard-of-hearing people. There are hundreds of sign languages in the world today collectively used by tens of millions of people (Eberhard et al., 2022). They rely on the hands, face, and body to communicate meaning according to complex grammars which are independent of any spoken language.

Sign languages have been and continue to be largely overlooked in natural language processing (NLP) research, necessitating explicit calls for more inclusivity (e.g. Yin et al. 2021, Bragg et al. 2019). In this paper, we seek to bridge robust techniques in NLP with insights from theories of sign language phonology.

Sign language phonology is an abstract system of rules that governs how the structural units of signs (e.g., handshape, location, movement) are combined to create an infinite number of utterances. These manual units play a significant role at the phonological level similarly to place of articulation, manner, and voicing in spoken language. Theories of sign language phonology attempt to enumerate the meaningless units or "phonemes" found in a sign language and describe the complex relationships among them. In ASL-LEX 2.0, Sehyr et al. (2021) describe 16 types of phonemes, largely guided by Brentari's Prosodic Model (Brentari, 1998). We provide three examples of these phoneme types here:

- **Minor Location**: one of 37 regions of the body where the sign is produced (e.g. "chin").
- **Handshape**: one of 49 configurations of the hand (e.g. "2").
- **Path Movement**: one of 8 ways of moving the hand through space during the production of a single sign (e.g. "circular").

Brentari's Prosodic Model contains < 200 possible phonemes across its 16 phoneme types, each of which can be observed during the production of any sign. In ASL-LEX 2.0, about 70% of signs can be uniquely identified by their phonemes, making them an appealing conduit for learning to recognize signs. We leverage these properties by using them as target labels alongside the target gloss.

ISLR: Definition and Prior Work In ISLR, a model is given a video of one sign being produced in isolation and must predict the target gloss S_{gloss}. Many models have been proposed to recognize isolated signs, varying with regard to input modality (e.g. pose, RGB video), pretraining (e.g. frame prediction, hand modeling), and encoding strategy (e.g. attention, convolution). Selvaraj et al. (2022) provide a comprehensive framework for comparing models across multilingual data, in particular LSTMs (Konstantinidis et al., 2018), Transformers (Devlin et al., 2019), Spatio-Temporal Graph Convolution Network (ST-GCN, Cheng et al. 2020), and Sign Language Graph Convolutional Network (SL-GCN, Jiang et al. 2021).

We evaluate our method with SL-GCN and via a Transformer network. These models are open-sourced,[2] easily modifiable, and take in pose information as input. These models perform well on the WLASL 2000 benchmark (Li et al., 2020). While the model from (Hu et al., 2021) obtains higher accuracy on that benchmark, their code is not publicly available to replicate those findings.

3 Method

We combine two datasets for the task of ISLR, ASL-LEX 2.0 (Sehyr et al., 2021) and WLASL 2000 (Li et al., 2020), in order to learn ASL phonology (§3.1). Then, we describe how to utilize these data by learning two ISLR models to predict both the target gloss and the phonemes for any input (§3.2). Finally, we address the questions of how many and which phoneme types are best for ISLR (§3.3). The dataset and modified models are released for replication and future work.[3]

---

[1] A "gloss" is a label for a sign that corresponds to its translation in the target language, such as APPLE.

[3] `https://github.com/leekezar/ImprovingSignRecognitionWithPhonology`

3.1 Data

We combine the phonological annotations in ASL-LEX 2.0 (Sehyr et al., 2021) with signs in the WLASL 2000 ISLR benchmark (Li et al., 2020). ASL-LEX contains 2,723 videos, each demonstrating a unique sign and human-annotated with phonemes across 16 categories. WLASL contains 21,083 videos, each demonstrating one of 2,000 unique signs (an average of 10.5 videos per sign).

To combine these datasets, we edit the WLASL metadata file to add 16 new properties (one for each phoneme type) to each video example. If the video's English gloss is also found in ASL-LEX, then we copy the phonemes directly from ASL-LEX. If it is not found, then we set these new properties to `-1` and ignore them during training. After combining, 48% of videos in the aggregated dataset have phonological labels, and all of the videos retain their original split (train, validation, and test) and English gloss. Note that this dataset is identical in structure to WLASL-LEX (Tavella et al., 2022), however, both our sources are more recently updated and contain more samples. Table 1 provides a summary of the combined data.

$\mathcal{P}$ Labels	# Signs	# Videos Train	 Val	 Test	 Total
✗	1246	7850	2221	1574	11645
✓	754	6439	1695	1304	9438
Total	2000	14289	3916	2878	21083

Table 1: We match phonological data from ASL-LEX 2.0 with signs in the WLASL benchmark to create a subset of WLASL with phoneme type labels $\mathcal{P}$.

3.2 Models

We add phoneme value predictions to two ISLR model architectures: a graph convolutional network, SL-GCN (Jiang et al., 2021), and a Transformer-based model. These models are implemented by the OpenHands project (Selvaraj et al., 2022) and are largely left untouched; we refer the reader to the OpenHands paper and code for implementation details. The SL-GCN model treats pose estimations over time as a connected graph and learns 10 convolution layers over this graph, using spatial and temporal attention. The Transformer model treats pose estimations as a sequence of coordinates over time and learns 5 Transformer layers similarly to BERT (Devlin et al., 2019). Importantly, both of these models implement spatial and temporal attention, a feature which enables phoneme recognition even when the phoneme exists for a short amount of time.

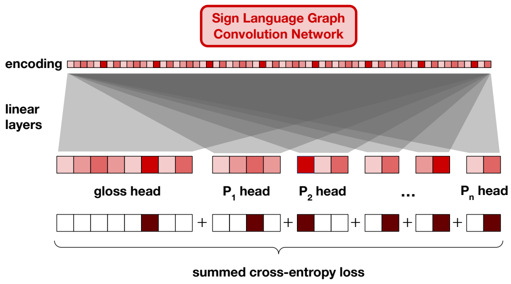

Figure 2: The proposed decoder relies on fully-connected layers for each classification head: one for the target gloss and one for each of the n phoneme types.

For each model, we modify the decoder to classify not only the target gloss, but also the selected phonemes. This is accomplished by adding n fully-connected layers to the decoder, each with shape `(hidden size, # phoneme values)`. During the forward pass, the video encoding is used as the input for each fully connected layer (not chained together). The total loss is then computed as:

$$\mathcal{L}_{\text{total}} = \mathcal{L}_{\text{gloss}} + \sum_{\text{phoneme} \in \mathcal{P}} \mathcal{L}_{\text{phoneme}},$$

where $\mathcal{L}_{\text{gloss}}$ is the cross entropy of the model's gloss predictions, while $\mathcal{L}_{\text{phoneme}}$ is the cross entropy of the model's phoneme predictions. The sum of these losses is then backpropagated to the entire model, encouraging the encoder to learn a representation which more explicitly captures the desired phonemes $\mathcal{P}$ alongside the target gloss (Fig 2).

We train models until the validation accuracy has not improved in the last 30 epochs and use the top performing model for testing. For further details on model implementation and training procedure, see Selvaraj et al. (2022).

3.3 Phoneme Type Selection

It is not immediately clear which, if any, of the 16 phoneme types in ASL-LEX 2.0 yield improvements on ISLR. Regarding *how many* phoneme types, one might assume that more informative outputs would only improve a model's ability to recognize signs, and therefore all 16 phoneme types should be included. However, these additions come at a cost to the encoder, which must now learn to fit more information into the same encoding space

Model	Pred	$\text{WLASL}^{\text{test}}_{\text{all}}$			$\text{WLASL}^{\text{test}}_{\text{w}\mathcal{P}}$			$\text{WLASL}^{\text{test}}_{\text{w/o}\mathcal{P}}$

Δ *Improvement*		*2.8	*4.8	*.04	3.7	5.3	.04	2.1	4.5	.03

Table 2: ISLR model performance with and without training with auxiliary phoneme predictions averaged over four seeds. Models are trained on $\text{WLASL}^{\text{train}}_{\text{all}}$ and evaluated on $\text{WLASL}^{\text{test}}_{\text{all}}$. Models trained to predict phonemes improve over their ISLR-only baselines on *both* signs seen at training time with phonemes ($\text{WLASL}^{\text{test}}_{\text{w}\mathcal{P}}$) and signs for which no phonological data was available during training ($\text{WLASL}^{\text{test}}_{\text{w/o}\mathcal{P}}$). Differences on $\text{WLASL}^{\text{test}}_{\text{all}}$ are significant (*) at $p < 0.05$ under a Welch's two-sided t-test with a Bonferroni correction applied.

without adding new samples. Furthermore, it is unclear *which* types to maximize performance.

To address these questions, we define the utility U of a set of phonemes types $\mathcal{P}$ as the percentage of signs that are uniquely identified by those types. Defined in this way, a set of phoneme types with high utility ensures that when a model can accurately predict those types, it is guaranteed to have sufficient information to recognize $U(\mathcal{P})$ percent of signs. $U(\mathcal{P})$ is provided by:

$$U(\mathcal{P}) = \frac{\sum_{S,S' \in V} \mathbf{1}\left[p(S|\mathcal{P}) > p(S'|\mathcal{P})\right]}{|V| - 1},$$

where V is the set of all target glosses and $P(S|\mathcal{P})$ is the probability of a sign S given the observed phoneme values in $\mathcal{P}$. We implement $P(S|\mathcal{P})$ with a simple look-up table for all possible combinations of the 16 phoneme types. With this utility function in hand, we can define the optimal subset of n phoneme types as:

$$\mathcal{P}^*(n) = \left\{ \arg\max_{\mathcal{P}} U(\mathcal{P}) : |\mathcal{P}| = n \right\}.$$

4 Results

We demonstrate across-the-board improvements on ISLR when predicting phonemes alongside glosses. We measure model performance via ISLR accuracy, both top-1 and top-3, as well as mean reciprocal rank (MRR), which ranges from 1 (correct sign given highest prediction score) to 1/2000 (correct sign given lowest prediction score).

4.1 Not All Phonemes are Helpful.

First, we explore which subsets of the 16 labeled phonemes are most beneficial for downstream ISLR. We train models with auxiliary losses for $\mathcal{P}^*(n), n \in \{2, 5, 9, 16\}$ and report their performance in Table 3. With two classification heads—handshape and minor location—we most improve ISLR on $\text{WLASL}^{\text{val}}_{\text{w}\mathcal{P}}$.

4.2 Predicting Phonemes Improves ISLR.

Table 2 demonstrates that adding classification heads for handshape and minor location yield a 3–9% gain on top-1 accuracy, 5–11% gain on top-3 accuracy, and .04–.09 gain on MRR. These gains are greater for signs trained with phonological labels, but extend to signs that do not have phonological labels as well!

4.3 SL-GCN Performs Accurate Phoneme Classification.

To lay the groundwork for modeling phonology in and of itself, we train SL-GCN to predict all 16 phoneme types and examine its accuracy at phoneme prediction (Figure 3). We compare to a frozen SL-GCN encoder pretrained for *only* ISLR, on top of which we learn linear probes for each phoneme type, as well as a majority class baseline. In all cases, training SL-GCN explicitly for phoneme prediction leads to the highest phoneme prediction accuracy. Prior work predicted phoneme values for Flexion, Major Location, Minor Location, Path Movement, Selected Fingers, and Sign Type (Tavella et al., 2022). Despite not being the explicit goal of this work, SL-GCN with auxiliary phoneme prediction outperforms that model, too.

5 Discussion

We find that adding auxiliary classification tasks for sign phonemes to ISLR models statistically significantly improves sign recognition accuracy. Repre-

n	$\mathcal{P}^*(n)$	%A@1	%A@3	MRR
0	$\emptyset$	50.2	69.3	.62
2	Dominant Handshape, Minor Location	55.7	74.7	.67
5	$\mathcal{P}^*(2)$ + Nondominant HS, Path Movement, Repeated Movement	51.5	69.3	.62
9	$\mathcal{P}^*(5)$ + 2nd Minor Loc., 2nd Handshape, Wrist Twist, Contact	52.5	69.3	.64
16	$\mathcal{P}^*(9)$ + Remaining 7 phoneme types	54.3	72.7	.65

Table 3: SL-GCN sign recognition accuracy when trained on WLASL$^{\text{train}}_{\text{w}\mathcal{P}}$ with auxiliary predictions of the top-n phoneme types $\mathcal{P}$ and tested on WLASL$^{\text{val}}_{\text{w}\mathcal{P}}$. See §3.3 for the details of $\mathcal{P}^*(n)$.

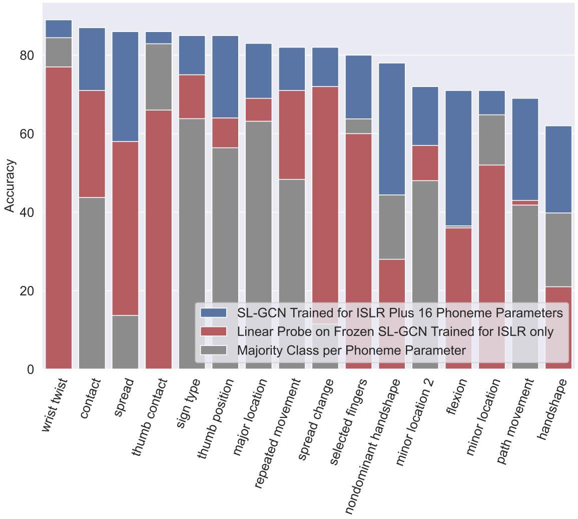

Figure 3: Model phoneme prediction accuracy when trained on WLASL$^{\text{train}}_{\text{w}\mathcal{P}}$ and tested on WLASL$^{\text{test}}_{\text{w}\mathcal{P}}$.

senting phonemes during training may enable models to learn a more holistic latent representation of sign videos compared to models that only predict the target gloss. The success of this approach provides evidence that handshape and minor location are not only useful in recognizing signs, but also easy enough to learn with semi-supervision (recall that only 48% of the dataset has handshape and minor location labels). Our findings show that both models learn these new labels well (Fig 3) and as a result, the encodings for *all* videos contain more relevant information for ISLR.

A secondary finding of this paper is that SL-GCN, when trained to recognize all 16 phoneme types, outperforms prior work by anywhere from 1%-9%. Still, there is room for improvement in phoneme recognition, especially for handshape, minor location, and path movement.

6 Limitations

The WLASL benchmark has several notable limitations that must be taken into account by those interested in using it. Dafnis et al. (2022) show that incorrect labels are pervasive in WLASL, causing lower ISLR accuracy and, in this work, incorrect phoneme labels. Additionally, existing sign language datasets do not provide information about the signers' fluency, dialect, age, or race and therefore may not be representative of those who use ASL. Finally, we caution those interested in collecting ASL data against scraping websites without permission, and we encourage acknowledging the creators of those sources.

As a first attempt to model sign language phonology in order to improve sign recognition, we applied our approach to two models and used data for one language pair (ASL/English). Although many phonemes are shared across signed languages, more language pairs and models should be tested in order to verify our claim that learning phonology improves sign recognition *in general*. In particular, the Two-Stream Inflated 3D ConvNet (I3D; Carreira and Zisserman 2017) model, designed for gesture recognition, has also been shown to do well on ISLR (e.g. Hosain et al. 2021, Albanie et al. 2020) and we look forward to extending our method to this model as well.

Abstract

Large pre-trained language models contain societal biases and carry along these biases to downstream tasks. Current in-processing bias mitigation approaches (like adversarial training) impose debiasing by updating a model's parameters, effectively transferring the model to a new, irreversible *debiased* state. In this work, we propose a novel approach to develop stand-alone debiasing functionalities separate from the model, which can be integrated into the model on-demand, while keeping the core model untouched. Drawing from the concept of AdapterFusion in multi-task learning, we introduce DAM *(Debiasing with Adapter Modules)* – a debiasing approach to first encapsulate arbitrary bias mitigation functionalities into separate adapters, and then add them to the model on-demand in order to deliver fairness qualities. We conduct a large set of experiments on three classification tasks with gender, race, and age as protected attributes. Our results show that DAM improves or maintains the effectiveness of bias mitigation, avoids catastrophic forgetting in a multi-attribute scenario, and maintains on-par task performance, while granting parameter-efficiency and easy switching between the original and debiased models.

1 Introduction

Large pre-trained language models (PLM) and their variations fine-tuned on downstream tasks encode societal biases and stereotypes. A large body of research shows the existence of these biases (Zhao et al., 2019; Sheng et al., 2019; Rekabsaz et al., 2021b), and discuss their potential harms (Blodgett et al., 2020) in various tasks such as occupation prediction from biographies (De-Arteaga et al., 2019), information retrieval (IR) (Rekabsaz et al., 2021a; Rekabsaz and Schedl, 2020), and machine translation (Stanovsky et al., 2019). A common approach to mitigating these biases is to adjust model parameters according to specific fairness criteria, achieved using optimization methods such as adversarial training (Elazar and Goldberg, 2018; Barrett et al., 2019; Han et al., 2021b; Rekabsaz et al., 2021a).

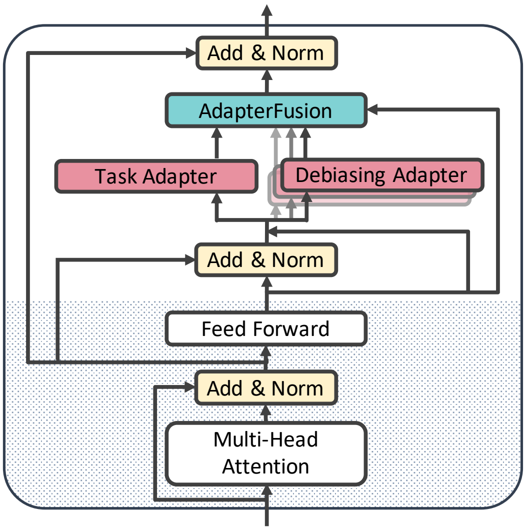

Figure 1: A transformer block in DAM to debias arbitrarily many protected attributes in different modules.

The resulting debiased models significantly diminish the effect of protected attributes (e. g. gender, race, etc.) on model's predictions. However, depending on the usage context, characteristics of the input or fairness-utility trade-off considerations, system designers or end-users might in practice still prefer to instead use the original (potentially biased) model for processing some requests. As an example, while a fairness-aware document retrieval model should tease out gender attributes when processing bias-sensitive queries (Krieg et al., 2022) (like *how to become CEO?*), other common queries (like *earliest pregnancy symptoms*) may specifically require gender information to obtain satisfactory retrieval results. Previous studies also show that one may need to occasionally accept slight performance degradation in exchange for realizing higher fairness (Zerveas et al., 2022; Biega et al.,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2738–2751
May 2-6, 2023

2018; Rekabsaz et al., 2021a). We argue that on-demand control over the strength of bias mitigation is crucial for the broad adoption of bias mitigation models. Using existing approaches, this would require maintaining and deploying multiple large parallel models for every protected attribute, in practice resulting in overly complex and resource-heavy pipelines and increased latency.

To reduce this untenable burden, we introduce *Debiasing with Adapter Modules (*DAM*)*. In our approach, bias mitigation functionalities can be trained in fully decoupled modules from the building blocks solving the main task (see Figure 1). These debiasing modules are learned independently, and can be selectively inserted into the model to deliver debiasing qualities. Our method draws from the recent success of Adapter (Rebuffi et al., 2017; Houlsby et al., 2019) and AdapterFusion (Pfeiffer et al., 2021) networks, originally introduced in the context of multi-task learning to enable parameter-efficient training and to avoid catastrophic forgetting. Specifically in multi-task learning with AdapterFusion, each task is encoded in specific parameter-efficient adapter networks attached to the transformer blocks (Vaswani et al., 2017) of a PLM, and the knowledge across the tasks is shared through a FusionAdapter layer with an attention mechanism. DAM extends this principle idea to bias mitigation by viewing the objective of "removing each protected attribute" as a standalone task, learned by an independent debiasing adapter module. These debiasing adapters are then integrated into the core model via a fusion layer to mitigate biases. This modular architecture of DAM enables on-demand debiasing, where by simply removing the debiasing adapters the model would return to its original state. The modularity and parameter efficiency of DAM also enables creating and sharing stand-alone debiasing solutions (in form of debiasing adapters), which can be applied to the underlying models on-demand. So, if one uses task adapter's output in DAM, they get biased embedding else they can take output of fusion layer for debiased embedding.

We evaluate DAM in extensive experiments covering various bias mitigation applications in three classification tasks: We study occupation prediction from biographies (De-Arteaga et al., 2019), mention prediction (Pardo et al., 2016), and hate speech detection (Founta et al., 2018), involving the protected attributes of gender, age, and dialect-based race. Among these, the mention prediction task provides two protected attributes (gender, age), enabling the study of adapter-based bias mitigation on multiple factors. Our evaluation results show that DAM (1) consistently improves bias mitigation in terms of lower leakage of protected attribute in comparison with fully fine-tuned models, and (2) better avoids catastrophic forgetting (Parisi et al., 2019; Chen et al., 2020) in a multi-attribute debiasing scenario, while (3) maintaining on-par task performance. Our results show the benefits of DAM in supporting fairness, and reveal the challenges in the scenarios inherently bounded by trade-offs.

Our contribution is three-fold:

- Introducing DAM, a novel, parameter-efficient approach for on-demand and modularized bias mitigation.
- Conducting a large set of experiments on three datasets and three classification tasks, showing the on-par or better performance of DAM in comparison with strong baselines.
- Examining the confounding cross-attribute effects in a multi-attribute dataset and demonstrating the benefits of our modularized bias mitigation approach.

The remainder of the paper is organized as follows: Section 2 reviews the relevant literature in adapter networks and bias mitigation domains. In Section 3, we explain the architecture and training strategy of DAM. Section 4 describes the setup of the experiments, whose results are reported and discussed in Section 5. Finally, Sections 6 and 7, respectively, summarize and discuss limitations of our work. Our code and trained resources are available in **`https://github.com/CPJKU/ModulaizedDebiasing`**.

2 Related Work

2.1 Adapter Networks

Adapter networks have been introduced in the context of multi-task learning (Rebuffi et al., 2017). Houlsby et al. (2019), and later Stickland and Murray (2019) attach the adapter module to the transformer blocks of a PLM, and learn a task by only updating the adapter parameters, while keeping the PLM's parameters unchanged. These studies show that the highly parameter-efficient adapter approach in general performs on par with fine-tuning all parameters of a BERT model (Devlin et al., 2019) for many tasks.

Other studies investigate various characteristics of adapter-based models such as the parameter efficiency, architectural variations, and transfer learning across tasks. Rücklé et al. (2021) show the training efficiency of adapter models in comparison with full model finetuning ($\sim 60\%$). Han et al. (2021a) examine the robustness to initialization seeds and training stability of the adapter approach. Mahabadi et al. (2021b) propose more parameter-efficient models by sharing adapter parameters across layers, followed by Mahabadi et al. (2021a), who introduce even more compact adapter modules. Poth et al. (2021) investigate the potential knowledge transfer across tasks. Recently, Pfeiffer et al. (2021) introduce AdapterFusion, where a fusion layer is defined on top of pre-trained adapter modules, and learns to combine information of adapters via an attention mechanism. This approach, avoiding the common pitfalls of catastrophic forgetting (Parisi et al., 2019), enables an effective knowledge transfer across tasks. Our work contributes to this direction by extending the concept of AdapterFusion to the task of bias mitigation via supervised interaction between the downstream task and the protected attribute.

2.2 Fairness & Bias Mitigation in NLP

The existence of biases and stereotypes in PLMs has been reported and discussed in several studies (Nadeem et al., 2021; Bhardwaj et al., 2021; Liang et al., 2021; Kirk et al., 2021; Vig et al., 2020). PLMs may even exacerbate these biases in downstream tasks as shown e. g. in the context of IR (Rekabsaz and Schedl, 2020). To reduce biases, *in-processing* methods – the focus of this work – aim at reducing the (cor)relation between the model's internal representations and the protected attributes (Ganhör et al., 2022). Debiasing PLMs has been approached for instance by linearly projecting embeddings to a new space that removes correlations to protected attributes (Kaneko and Bollegala, 2021; Bolukbasi et al., 2016). In a similar spirit, Guo et al. (2022) introduce a distribution alignment loss to force the model's outputs to become independent of the protected attribute. Schick et al. (2021) recently show that the encoded information in models can be exploited to spot the biases and hence to penalize them.

Adversarial training is a commonly used method to learn representations invariant to a specific factor of variation. Xie et al. (2017) and later Madras et al. (2018) introduce adversarial learning to the context of fair representation learning, where an adversary network learns to predict the protected attribute, and exploits the gradient of this prediction to remove the protected information using a gradient reversal layer (Ganin and Lempitsky, 2015). Several works further investigate the use of adversarial training for removing demographic information from neural/PLM-based text classifiers (Elazar and Goldberg, 2018; Barrett et al., 2019; Wang et al., 2021). Notably, Han et al. (2021b) show the benefit of having an ensemble of orthogonal adversaries. Beyond classification, Rekabsaz et al. (2021a) show that by applying adversarial training in the context of IR, one can achieve a more balanced retrieval of documents with respect to the presence of protected attributes in their contents.

As alternatives to adversarial debiasing, other works approach bias mitigation by minimizing the approximated upper bound of mutual information between task and protected attribute (Cheng et al., 2020b; Colombo et al., 2021), contrastive learning for fair representation disentanglement (Cheng et al., 2020a; Zhang et al., 2021), and introducing list-wise fairness regularization (Zerveas et al., 2022). While the mentioned methods are applied to whole a model, Iterative Nullspace Projection (INLP) (Ravfogel et al., 2020) achieves debiased representations by finding a linear mapping applied to output embeddings. The linear mapping of the INLP method and similarly the one of Ravfogel et al. (2022) offer effective bias mitigation methods particularly designed for the models with a linear decoder, but are not necessarily suited for the cases with non-linear decoders (e.g., a language generation decoder, or non-linear attackers).

Regarding adapter-based debiasing and closely related to our work, Lauscher et al. (2021) recently utilize adapters for debiasing PLMs by training an adapter which removes a protected attribute using counterfactual augmented data. When applied to a downstream task, another adapter is added on top of the debiasing adapter, and trained according to the task's objective. While shown effective in practice, in this stacking architecture the adapters in the higher levels inherently depend on the ones in the lower levels. They can not be learned standalone. In contrast, the fusion-based approach of DAM enables control by learning modular and independent debiasing adapters, which supports flexible plug-in/plug-out on demand.

3 Bias Mitigation with DAM

We approach the scenario in which the aim is to maximize a task's core objective (such as occupation prediction or hate speech prediction), while reducing the effects of the biases caused by k protected attributes. The crux of the proposed DAM approach is to first learn a task adapter and k bias removal adapters all independently, and then combine them through a fusion module. Once a model has been trained with DAM, one can easily switch between the original model by only using the task adapter, or alternatively impose debiasing by "plugging in" the learned debiasing adapters as well as the fusion module. In what follows, we explain the architecture of DAM followed by the optimization procedure.

3.1 Model Architecture

DAM consists of three main parts: task adapter, k debiasing adapters, and fusion. Following Pfeiffer et al. (2021), and as shown in Figure 1, these parts extend the architecture of a transformer block by being added to its last layer.

Adapters Each adapter is defined as a multilayer perceptron (one hidden layer and $\tanh(x)$ in our experiments), where the hidden layer typically has the same or a smaller dimension than the input. In DAM, the task adapter and the k debiasing adapters receive the output vector of the preceding transformer components, denoted as $\boldsymbol{u}$, and apply the corresponding transformations to output the vectors $\boldsymbol{v}_t$, and $\boldsymbol{v}_{b_1}, ..., \boldsymbol{v}_{b_k}$, respectively.

Fusion The fusion module combines the outputs of the task and debiasing adapters through the attention mechanism to produce the final output vector. This module receives $[\boldsymbol{v}_t, \boldsymbol{v}_{b_1}, ..., \boldsymbol{v}_{b_k}]$ as keys and values, and the $\boldsymbol{u}$ vector as the query of a single-head multiplicative attention network, and calculates the output as the weighted sum of the value vectors. These weights are calculated as attention scores and form a probability distribution over value vectors. Essentially, the fusion module learns to perform a *linear combination* of the embedding containing information for the task with the embeddings of the debiasing adapters, to provide the final, debiased embedding.

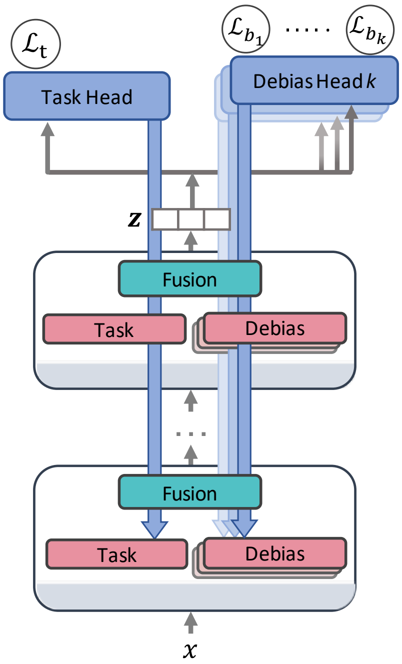

Figure 2: Schematic view of applying DAM to adversarial bias removal.

3.2 Learning On-demand Bias Mitigation

DAM introduces a generic approach to bias mitigation and representation disentanglement, and can, in principle, be integrated with any bias removal optimization method, provided that the method defines separate losses for the task and each of the protected attributes. Irrespective of the optimization method, the training procedure of DAM is the following: first, the task adapter is trained according to the task's objective. Then, one debiasing adapter for each protected attribute is trained using only its own debiasing objective (see next paragraph), without involving the task loss. Finally, all adapters' parameters are kept frozen and the fusion layer is trained using a combination of the task objective and debiasing objectives. Throughout training, the parameters of the underlying PLM remain frozen. In what follows, we describe using DAM together with the adversarial bias mitigation method as depicted in Figure 2.

Adversarial Training Adversarial bias mitigation aims to make the output embedding of a model invariant to the protected attribute, by removing information that allows predicting protected attributes from the latent representation. In this sense, adversarial training follows a *fairness through blindness* (Barocas et al., 2019) approach, where the system is made agnostic of the variations in underlying protected attributes.

To apply adversarial debiasing with DAM (see Figure 2) in the context of text classification, the model first encodes the input sequence x in the latent vector $\boldsymbol{z}$, based on which the corresponding class is predicted using a task classification head. The loss of this prediction, denoted as $\mathcal{L}_t$, is defined as cross entropy, and its gradient is used to update the parameters of the task adapter. Similarly, a dedicated classification head is defined for each protected attribute b_i, which also receives $\boldsymbol{z}$ as input, predicts the corresponding protected attribute, and calculates the cross entropy loss function $\mathcal{L}_{b_i}$. A common approach to removing the information of b_i encoded in $\boldsymbol{z}$ is gradient resversal layer (GRL) (Ganin and Lempitsky, 2015) added before the debiasing head. GRL multiplies the gradient of $\mathcal{L}_{b_i}$ with a factor of $-\gamma_i$, and thereby simplifies the learning process to a standard gradient-based optimization. In DAM, this reversed gradient of $\mathcal{L}_{b_i}$ is used to learn the parameters of the debiasing adapter corresponding to the protected attribute b_i. Once adapters are trained, the fusion layer is learned jointly according to all task and debiasing objectives, as formulated below:

$$\mathcal{L}^{\text{Adv}}_{\text{Fusion}} = \mathcal{L}_t + \sum_{i=1}^{k} \mathcal{L}_{b_i} \tag{1}$$

Note that, while no weights are used to directly scale the individual loss functions, the effects of bias mitigation losses on model parameters are adjusted via their corresponding γ_i hyperparameters.

4 Experiment Setup

We evaluate DAM on three classification tasks and compare the results with a set of strong baselines.

Tasks and Data We conduct our experiments on three classification tasks. The first task is **biography classification** using the BIOS (De-Arteaga et al., 2019) dataset. The objective of the task is to predict a person's job given their biography, where the name and any indication of the person's gender (such as pronouns) in the biography is omitted. The protected attribute is the person's gender. The BIOS dataset contains around 430K data points with 28 occupations as the core task's classes, and two protected attribute classes (female/male).

The second task is **hate speech detection**, a sensitive task, as its use in any automated system with biases towards any societal group can be extremely delicate (e. g. in automatic social media moderation). Xia et al. (2020) show the existence of a strong correlation between dialect-based racial bias and hate speech detection. In our experiments, we use FDCL18 (Founta et al., 2018), a dataset of tweets annotated with four hate speech labels: *normal*, *spam*, *abusive*, and *hateful*. Following previous works (Sap et al., 2019; Ravfogel et al., 2020; Zhang et al., 2021), we assign artificial race labels of *African American*, and *White American* to FDCL18 (more details in Appendix A.1). In this setting, the main task is hate speech classification, and the protected attribute is the dialect-based racial identity of the tweet author. Our final dataset contains approximately 62K data points.

Model		# Params
BERT-Mini	FT	$11,237,380$
	FT-DEBIAS	$11,568,910$
	ADP	$330,500$
	ADP-DEBIAS	$432,206$
	DAM	$1,186,830$
BERT-Base	FT	$110,075,908$
	FT-DEBIAS	$113,036,558$
	ADP	$14,767,876$
	ADP-DEBIAS	$4,448,846$
	DAM	$24,806,414$

Table 1: Number of trainable parameters. The adapter-based models contain significantly fewer trainable parameters in comparison with fully fine-tuned models.

While the first two tasks contain one protected attribute, in our third classification task, we aim to explore the effect of more than one biases on our models. We therefore opt for a subset of the PAN16 dataset (Pardo et al., 2016). This dataset has been designed for the task of **mention detection**, namely to predict whether a tweet includes the mention of other users, and the protected attributes are gender and age of the tweet's author. The dataset contains approximately 200K data points with binary task classes (*mention*, *no mention*), as well as two gender labels and five age groups. Further details on the three datasets are provided in Appendix A.1.

Models and Baselines We conduct the experiments on the following models: **FT**: fully fine-tuning the PLM on the task. **FT-DEBIAS**: fully fine-tuning the PLM on the task as well as on the corresponding adversarial debiasing objective(s). **INLP**: using the implementation and suggested hyperparameter setting by Ravfogel et al. (2020), in particular with a linear task classifier (Logistic

Table 2: Results on BIOS and FDCL18 datasets for the task classifiers (accuracy) and protected attributes' attackers (accuracy–Acc and balanced accuracy–BAcc), reported as the mean and standard deviation (in $_{\text{subscript}}$) over three runs. Arrows indicate the direction of better results. On each evaluation metric and each PLM, the best results among adapter-based models are shown in **bold**, and over all models by symbol ♣.

Regressor). **INLP-NONLIN**: the INLP model with the same setting, but instead of Logistic Regressor, INLP-NONLIN uses a non-linear task classifier: a two-layer feed-forward layer with a tanh activation. This setting follows the same configuration of all other baselines/models with respect to the task classifier. **ADP**: adding one adapter to the PLM and training it only through the task objective. **ADP-DEBIAS**: adding one adapter to the PLM and training it through the task objective as well as the adversarial debiasing objective(s). Finally, our proposed **DAM** model, which consists of one task adapter and separate debiasing adapters for each protected attribute, all combined with a fusion module. DAM uses the same task adapter trained by ADP and further learns the debiasing adapters and fusion layer. We should note that, since through adapter-based training the task performance of ADP might be different from the one of FT, a fair comparison of the core task performance should be between the results of ADP and its respective DAM model. We emphasize that we are especially interested in adapters because they preserve the original model and can be disengaged at will, to trade off debiasing for utility/performance.

As the PLM encoder for all models, we conduct our experiments using two versions of BERT (Devlin et al., 2019) with different sizes, namely BERT-Mini (Turc et al., 2019) and BERT-Base in order to provide a more comprehensive picture regarding the effect of encoder size and number of involved parameters. The number of trainable parameters of the models is reported in Table 1. The complete details of our hyperparameters setting and training procedure are explained in Appendix A.2 and Appendix A.3, respectively.

Evaluation and Attackers To evaluate the performance of the classifiers on the core task, we use the accuracy metric. To evaluate bias mitigation, following previous works (Elazar and Goldberg, 2018; Barrett et al., 2019), we report the leakage of a protected attribute in terms of accuracy and balanced accuracy of an *attacker*. To train an attacker, we freeze the model's parameters, and train a new classification head (two-layer feed-forward layer with a tanh(x) activation) to predict the protected attribute from the $\boldsymbol{z}$ vector. We train an ensemble of 5 attackers with the same configuration and training procedure, and report the results of the best performing one. We report the performance of the attacker in terms of accuracy and also balanced/macro accuracy (average of per-class ac-

	DAM$_{G+A}$	$93.15_{0.0}$	$\mathbf{53.01}^{\clubsuit}_{1.7}$	$\mathbf{52.53}^{\clubsuit}_{0.8}$	$38.23_{1.5}$	$\mathbf{23.24}^{\clubsuit}_{1.6}$

Table 3: Results of the PAN16 mention detection task with gender (G) and age (A) as protected attributes on the task classifiers (accuracy) and protected attributes' attackers (accuracy–Acc and balanced accuracy–BAcc). The mean and standard deviation (in $_{\text{subscript}}$) over three runs are reported. On each evaluation metric and each PLM, the best results among adapter-based models are shown in **bold**, and over all models by symbol ♣.

curacy scores). Balanced accuracy has the benefit of better reflecting the performance of the methods when considering sub- and minority groups. We believe this is particularly important in this setting, since the datasets are unbalanced over both task and protected labels (see Appendix A.1). To account for possible variabilities in training, we repeat every experiment three times and report the mean as well as standard deviation of the achieved results.

5 Results and Discussion

In this section, we first discuss the results on the datasets with one protected attribute (BIOS and FDCL18), followed by investigating the effect of DAM on PAN16 with two protected attributes.

Single-attribute bias mitigation The results on BIOS and FDCL18 datasets are reported in Table 2. We start with the results of BERT-Mini on both datasets. As shown, consistent with previous studies the task performance of ADP remains on par with the full model fine-tuning FT. In both FT and ADP, we observe that the adversarial debiasing (FT-DEBIAS and ADP-DEBIAS respectively) significantly reduces leakage in terms of Acc and BAcc of attackers, while task performance remains on par with the corresponding baseline models. Overall, adversarial methods outperform respective INLP models, particularly in respect to maintaining task performance during bias mitigation.

Compared to ADP and ADP-DEBIAS, we observe that DAM improves ADP-DEBIAS in terms of bias mitigation, while maintaining or even slightly improving performance on the task. The difference between DAM and ADP-DEBIAS indicates the benefit of learning separate adapters for performing the task and bias mitigation, and then combining them. Also comparing DAM with FT-DEBIAS, overall DAM performs on par in terms of task performance and leakage, while DAM provides the additional benefits of selectively engaging bias mitigation and significantly fewer trainable parameters.

Comparing the results between the core PLMs, we see that the above observations for BERT-Mini also hold true for BERT-Base on the BIOS dataset. On the FDCL18 dataset with BERT-Mini, DAM is in fact the only bias mitigation approach that can effectively prevent leakage while also preserving performance. It is the best in terms of leakage reduction, while its task performance is better than ADP. The situation differs for results of BERT-Base on FDCL18, as leakage balanced accuracy of FT-DEBIAS is surprisingly low.

Multi/Two-attribute bias mitigation Table 3 reports the results on PAN16 with two protected attributes, gender (G) and age (A). To observe the effect of single- versus multiple-attribute debiasing, we train the debiasing models (FT-DEBIAS, ADP-DEBIAS, and DAM) in three variations denoted with subscripts G, A, and G+A, indicating the debiasing optimization on only gender, only age, and both gender and age, respectively.[1]

Observing similar patterns to the previous experiments, DAM$_G$, DAM$_A$, and DAM$_{G+A}$ provide a significant improvement in bias mitigation (lower leakage) in comparison with their respective debiasing baseline variations.[2] Also similar to single-attribute datasets, ADP performs slightly worse than FT in respect to task performance, but DAM models remain on par with ADP or slightly improve it. We observe these patterns consistently on both BERT-Mini and BERT-Base. Overall, DAM provides equal or better bias mitigation in comparison with FT-DEBIAS and INLP, while offering on-demand debiasing and parameter efficiency.

Particularly with respect to multi-attribute bias mitigation, the results show the benefits of DAM$_{A+G}$ in separately learning multiple debiasing adapters and combining them, when compared with FT-DEBIAS$_{G+A}$, which simultaneously learns both debiasing factors. In particular, looking at the attacker's BAcc, while FT-DEBIAS$_{G+A}$ is not able to debias the age attribute (in comparison to FT), our DAM$_{G+A}$ provides strongly improved bias mitigation for age (and also gender), with similar or better results to only optimizing for gender or age (DAM$_G$ and DAM$_A$, respectively). This highlights the effectiveness of DAM in preventing catastrophic forgetting of debiasing functionalities in multi-attribute scenarios.[3] We further provide an investigation of the attention distributions of DAM's fusion module in Appendix B.

6 Conclusion

We propose a novel bias mitigation approach which enables flexible switching between the original and debiased state of a model. Our proposed DAM method extends the idea of multi-task learning using AdapterFusion to bias mitigation, by first learning the main task and the debiasing objectives as separate adapters, and then leveraging the attention-based fusion approach to merge these adapters and deliver debiased results. Our experiments on three classification tasks show that, beside flexible switching, DAM improves bias mitigation, provides on par classification performance to vanilla adversarial debiasing, and addresses the issue of catastrophic forgetting in multi-attribute bias mitigation.

---

[1] We run INLP and INLP-NONLIN on the two variations of G and A, but we are not aware of a principled way for this method to simultaneously debias more than one protected attribute.

[2] BAcc is more suited for comparisons of age on this dataset, as the age labels are highly imbalanced.

[3] Our experiments using DAM also indicate a possible correlation between Gender and Age, as debiasing Gender (DAM$_G$) leads to slight reduction in Age leakage, while similarly, debiasing Age (DAM$_A$) results in a slight removal of gender information.

7 Limitations

In the experiments, gender is considered as a binary construct due to practical constraints. In particular, in BIOS and PAN16 the gender is provided only in the form of male and female. We are however fully aware that a gender binary model is not representative of all individuals; yet working with in-the-wild data (as in our case) entails an unavoidable caveat, derived from the still predominant belief that human beings can be sorted into two discrete categories (Hyde et al., 2019). However, the proposed method can still be defined for generic non-binary settings and can be applied to any sensitive attribute with more than two categories, as exemplified by our consideration of age classes.

We should also highlight two limitations of this study in respect to the model and optimization. First, adversarial approaches in general (including our proposed approach) aims to reduce the correlations in the model to the protected attribute based on the observed data. This approach, like other data-oriented bias mitigation methods, might lack effective generalization, particularly when the model is evaluated on other domains or out-of-distribution data. The second limitation regarding the discussed bias mitigation methods based on adversarial training (also involving our proposed approach) is that, while the method aims to make the model prediction agnostic to protected attributes, it does not directly account for a balanced treatment of subpopulations in regards to the utility metrics and quality of the received service.

A Experiment Settings – Additional Details

A.1 Datasets

In FDCL18 dataset, we use the TwitterAAE model (Blodgett et al., 2016) to assign racial dialect classes. The TwiiterAAE model predicts four racial classes, *African American*, *White American*, *Hispanic*, and *Others*. We labeled a tweet as *African American* or *White American* if the prediction score was greater than 0.5. For PAN16 dataset, following (Sap et al., 2019) we balanced the task labels and sampled 200K data. The age groups of this dataset are 18-24, 25-34, 35-49, 50-64, and 65+. The proportions of data items regarding the labels of the task and protected attributes in the three dataset are as follows:

- BIOS dataset: Task (dentist: 0.03, professor: 0.27, teacher: 0.04, psychologist: 0.04, nurse: 0.07, poet: 0.01, photographer: 0.06, journalist: 0.04, filmmaker: 0.02, physician: 0.08, composer: 0.2, attorney: 0.08, model: 0.03, painter: 0.02, accountant: 0.01, pastor: 0.01, comedian: 0.01, surgeon: 0.05, architect: 0.03, paralegal: 0.01, dj: 0.01, chiropractor: 0.01, software engineer: 0.02, dietitian: 0.02, rapper: 0.01, personal trainer: 0.003, yoga teacher: 0.01, interior designer: 0.01); Gender (Female: 0.5, Male: 0.5)

- FDCL18 dataset: Task (normal: 0.73, spam: 0.12, abusive: 0.12, hateful: 0.04); Race (White: 0.5, AA: 0.5)

- PAN16 dataset: Task (Mention: 0.5, Not Mention: 0.5); Gender (male: 0.54, female: 0.46); Age (3: 0.18, 1: 0.34, 2: 0.40, 0: 0.07, 4: 0.01)

A.2 Hyperparameter setting

Across experiments, we keep specific hyperparameters consistent. Batch size is 64, learning rate is 2e-5 (except for training task and debiasing adapter as explained below), training epochs is 20, dropout probability is 0.3, and adversarial debiasing coefficient is 1 for all models (when applicable).

For task adapter and debiasing adapters, we tune the learning rate and the hidden layer dimension of adapter. We conduct brute search over the learning rate values of [1e-5, 1e-4,1e-3,1e-2], and hidden layer dimension with a division factor of [1,1/2,1/4,1/8,1/16]. For INLP we use 10 iterations and 10 classifiers to learn null space while for INLP-NonLin we same setting (300 iterations and 300 classifiers) as in (Ravfogel et al., 2020).

A.3 Training procedure

We randomly split the dataset into train, validation, and test set with the proportions 63:12:15 for BIOS, 63:12:15 for FDCL18, and 80:5:15 on PAN16. We use the validation set for hyperparameter tuning, and the best result on the validation set is evaluated on test set for the final results. The validation and test sets in all datasets follow the same distribution as the whole dataset. To address the unbalancedness of the dataset and the potential problems in adversarial learning, we apply upsampling only on the *training sets* of BIOS and FDCL18 datasets, to balance the protected attribute labels within each task label. For instance, genders are balanced in the dentist class by repeating the data items of the minority subgroup.

B Fusion Attention Analysis

We investigate the attention distribution of the fusion network and observe the weights it gives to the adapters. Figures 3a, 3b, and 4 depict the attention scores of each adapter averaged over all fusion layer in DAM for BIOS, and FDCL18, and PAN16 datasets, respectively. To avoid confusion in visualization, we only used 4% of data points randomly sampled from test set. As shown, the task adapter has weights close to 1, while debiasing adapters are assigned attention scores slightly higher than 0. The top three outliers in BIOS with the highest attentions on the debiasing adapter are reported in Table 4.

LINGMESS: Linguistically Informed Multi Expert Scorers for Coreference Resolution

Shon Otmazgin[1] **Arie Cattan**[1] **Yoav Goldberg**[1,2]

[2]Allen Institute for Artificial Intelligence
{shon711,arie.cattan,yoav.goldberg}@gmail.com

Abstract

Current state-of-the-art coreference systems are based on a single pairwise scoring component, which assigns to each pair of mention spans a score reflecting their tendency to corefer to each other. We observe that different kinds of mention pairs require different information sources to assess their score. We present LINGMESS, a linguistically motivated categorization of mention-pairs into 6 types of coreference decisions and learn a dedicated trainable scoring function for each category. This significantly improves the accuracy of the pairwise scorer as well as of the overall coreference performance on the English Ontonotes coreference corpus and 5 additional datasets.[1]

1 Introduction

Coreference resolution is the task of clustering textual mentions that refer to the same discourse entity. This fundamental task requires many decisions. In this work, we argue that different *kinds* of decisions involve different challenges. To illustrate that, consider the following text:

*"**Lionel Messi** has won a record seven Ballon d'Or awards. **He** signed for Paris Saint-Germain in August 2021. "**I** would like to thank **my** family", said **the Argentinian footballer**. **Messi** holds the records for most goals in La Liga"*

To correctly identify that the pronoun "He" refers to "Lionel Messi", models need to model the discourse, while linking "my" to "I" may rely more heavily on morphological agreement. Likewise, linking "the Argentinian footballer" to "Lionel Messi" requires world knowledge, while linking "Messi" to "Lionel Messi" may be achieved by simple lexical heuristics.

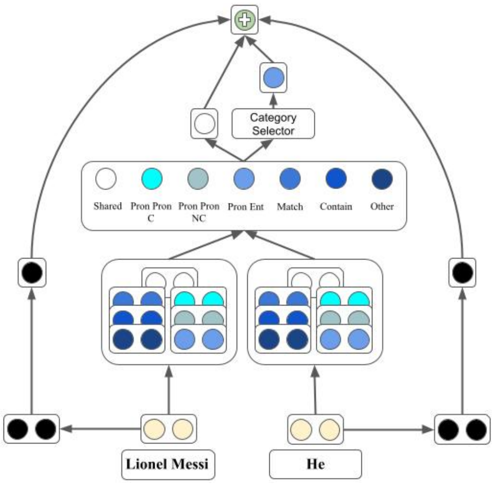

Figure 1: Architecture of our multi expert model. Given two spans *"Lionel Messi"* and *"He"*, we sum four scores: individual mention scores (black), f_m(*"Lionel Messi"*), f_m(*"He"*), and pairwise scores, shared antecedent score (white) f_a(*"Lionel Messi"*, *"He"*) and the relevant "expert" score (blue) $f_a^{\text{PRON-ENT}}$(*"Lionel Messi"*, *"He"*).

Indeed, pre-neural coreference resolution works often considered the types of a mention-pair, either by incorporating this information as model features, or by tailoring specific rules or specific models for each mention pair (see related work section).

However, neural-network based coreference models are all based on a *single* pairwise scorer that is shared for all mention pairs, regardless of the different challenges that needs to be addressed by each pair type (Lee et al., 2017, 2018; Joshi et al., 2019; Kantor and Globerson, 2019; Joshi et al., 2020; Xu and Choi, 2020; Xia et al., 2020; Toshniwal et al., 2020; Thirukovalluru et al., 2021; Kirstain et al., 2021; Dobrovolskii, 2021).

In this work, we suggest that modeling different mention pairs by different sub-models (in our case, different learned scoring functions) depending on their types is beneficial also for neural models. We identify a set of decisions: (a) linking compatible

Table 1: Example of each category, taken from Ontonotes development set. We define the categories of mention pairs as follows. PRON-PRON-C: compatible pronouns based on their attributes such as gender, number and animacy (see Appendix C for more details), PRON-PRON-NC: incompatible pronouns, ENT-PRON: a pronoun and another span, MATCH: non-pronoun spans with the same content words, CONTAINS: one contains the content words of the other, OTHER: all other pairs. Content words exclude stop words, see Appendix C for the full list of stop words.

pronouns (PRON-PRON-C); (b) linking incompatible pronouns (PRON-PRON-NC); (c) linking pronouns to entities (ENT-PRON); (d) linking entities which share the exact lexical form (MATCH); (e) linking entities where the lexical form of one contains the lexical form of the other (CONTAINS); (f) other cases (OTHER). Each of these classes is easy to identify deterministically, each contains both positive and negative instances, and each could benefit from a somewhat different decision process. Table 1 demonstrates the classes.[2]

We present **Ling**uistically Informed **M**ulti **E**xpert **S**corer**s** (LINGMESS), a coreference model which categorizes each pairwise decision into one of these classes, and learns, in addition to a shared scoring function, also a separate scoring function for each pair type. At inference time, for each pair of mentions being scored, we deterministically identify the pair's type, and use the corresponding scoring function.[3]

Specifically, we extend the recent *s2e*'s model (Kirstain et al., 2021) by adding per-category scoring, but the method is general and may work with other coreference models as well. As illustrated in Figure 1, the final coreference score between two spans is composed—in addition to the individual mention scores—of two pairwise scores: a shared antecedent-compatibility score and an "expert" antecedent compatibility score which depends on the linguistic-type of the pair.

We show that this significantly improves the coreference performance on Ontonotes (Pradhan et al., 2012) and 5 additional datasets. We also inspect the performance of the model for each category separately, showing that some classes improve more than others. This analysis provides a finer-grained understanding of the models and points out directions for future research.

2 Background: the s2e Model

The *s2e* model (Kirstain et al., 2021) achieves the current best coreference scores among all practical neural models.[4]

Given a sequence of tokens $x_1, \ldots, x_n$, each mention pair (c, q) is scored using a scoring function $F_{\text{S}}(c, q)$[5] described below, where c is a "candidate span" and q is a "query span" which appears before c in the sentence. The span encodings are based on contextualized word embeddings obtained by a Longformer encoder, see Kirstain et al. (2021) for details. These pairwise scores are then used to form coreference chains (see "inference" below).

---

[2] More fine-grained distinctions are of course also possible, but we leave exploration of them to future work.

[3] For computational efficiency on the GPU, we find it beneficial to compute all the scoring functions and mask away the not needed values.

[4] We define "practical models" as those that require a constant number transformer-based document encodings per passage, as opposed to a constant number of document encodings per mention. The CorefQA model (Wu et al., 2020) achieves a substantially higher score, but requires to run a separate BERT inference for each mention, making it highly impractical.

[5] S state for SHARED

The scoring function F_{S} is further decomposed:

$$F_{\text{S}}(c,q) = \begin{cases} f_m(c) + f_m(q) + f_a(c,q) & c \neq \varepsilon \\ 0 & c = \varepsilon \end{cases}$$

where ε is the null antecedent, and f_m and f_a are parameterized functions, scoring each individual span (f_m) and the pairwise interaction (f_a).

For each possible mention q, the learning objective optimizes the sum of probabilities over the true antecedent $\hat{c}$ of q:

$$L_{\text{S}}(q) = \log \sum_{\hat{c} \in \mathcal{C}(q) \cap \text{GOLD}(q)} P_{\text{S}}(\hat{c} \mid q)$$

where $\mathcal{C}(q)$ is the set of all candidate antecedents[6] with a null antecedent ε. $\text{GOLD}(q)$ is the set of the true antecedents of q. $P_{\text{S}}(c \mid q)$ is computed as a softmax over $F_{\text{S}}(c,q)$ scores for c values in $\mathcal{C}(q)$:

$$P_{\text{S}}(\hat{c} \mid q) = \frac{\exp F_{\text{S}}(\hat{c},q)}{\sum\limits_{c' \in \mathcal{C}(q)} \exp F_{\text{S}}(c',q)}$$

3 LINGMESS

Clustering coreferring entities typically involves many different phenomena, which we argue should be addressed in a different manner. Therefore, our core contribution is proposing to allocate a dedicated scorer $f_a^t(c,q)$ for each phenomenon type t, in addition to the shared pairwise scorer $f_a(c,q)$. The overall architecture of our model is shown in Figure 1.

Concretely, we extend the *s2e* model with six additional antecedent scorers f_a^t where $t \in$ {PRON-PRON-C, PRON-PRON-NC, ENT-PRON, MATCH, CONTAINS, OTHER}, the six categories we list in Table 1.

The pairwise scoring function now becomes:

$$F(c,q) = \begin{cases} f_m(c) + f_m(q) + f(c,q) & c \neq \varepsilon \\ 0 & c = \varepsilon \end{cases}$$

$$f(c,q) = f_a(c,q) + f_a^{T(c,q)}(c,q)$$

where $T(c,q)$ is a deterministic, rule-based function to determine the category t of the pair (c,q). The pairwise scoring function $f(c,q)$ scoring c as the antecedent of q, is now composed of a shared scorer $f_a(c,q)$ and an "expert" scorer $f_a^t(c,q)$ which differs based on the type of the pair c,q. Each of the seven pairwise scoring functions (f_a and the six f_a^t) is parameterized separately using its own set of matrices. The transformer-based encoder and the mention scorer f_m are shared between all the antecedent scorers. See Appendix A.2 for full model architecture.

Training For each span q, our model optimizes the objective function L_{COREF} over the sum of probabilities of all true antecedents of q:

$$L_{\text{COREF}}(q) = \log \sum_{\hat{c} \in \mathcal{C}(q) \cap \text{GOLD}(q)} P(\hat{c} \mid q)$$

Here, $P(\hat{c} \mid q)$ is a softmax over $F(\hat{c},q)$ scores, that is our new score function described in Figure 1.

$$P(\hat{c} \mid q) = \frac{\exp F(\hat{c},q)}{\sum\limits_{c' \in \mathcal{C}(q)} \exp F(c',q)}$$

This scorer is also the one used in inference. However, this objective does not explicitly push each category ("expert") to specialize. For example, for the PRON-PRON-C cases, it would be useful to explicitly train the model to distinguish between the possible antecedents of that type only (without regarding other antecedents), as well as to explicitly distinguish between a pronoun antecedent and a null antecedent. To this end, we extend the training objective by also training each "expert" separately:

$$L_t(q) = \log \sum_{\hat{c} \in \mathcal{C}_t(q) \cap \text{GOLD}(q)} P_t(\hat{c} \mid q)$$

$$P_t(\hat{c} \mid q) = \frac{\exp F_t(\hat{c},q)}{\sum\limits_{c' \in \mathcal{C}_t(q)} \exp F_t(c',q)}$$

$$F_t(c,q) = \begin{cases} f_m(c) + f_m(q) + f_a^t(c,q) & c \neq \varepsilon \\ 0 & c = \varepsilon \end{cases}$$

Note that for $L_t(q)$ we replace $\mathcal{C}(q)$ with $\mathcal{C}_t(q)$, considering only the potential antecedents that are compatible with the span q for the given type. For example, for L_{MATCH} and a span q, we will only consider candidates c which appear before q with the exact same content words as q. Our final objective for each mention span q is thus:

$$L(q) = L_{\text{COREF}}(q) + L_{\text{EXPERTS}}(q)$$

$$L_{\text{EXPERTS}}(q) = \sum_t L_t(q) + L_{\text{S}}(q)$$

---

OTHER	60.1	70.2	64.7	71.7	64.2	**67.7**

Table 4: Pairwise performance by category, on the test set of the English OntoNotes 5.0 dataset. LINGMESS surpasses the *s2e* model (Kirstain et al., 2021) for most categories by a substantial margin.

Inference At inference time, we compute the score of each mention based on the shared scorer as well as the per-type scorer matching the mention type. We then form the coreference chains by linking each mention q to its most likely antecedent c according to $F(c, q)$. We do not use higher-order inference as it has been shown to have a marginal impact (Xu and Choi, 2020).

4 Experiments

Our baseline is the *s2e* model trained on the English OntoNotes 5.0 dataset by its authors (Kirstain et al., 2021). We train LINGMESS also on OntoNotes, and evaluate both models on OntoNotes, WikiCoref, GAP, WinoGender, WinoBias and BUG. Implementation details are described in Appendix B.

Performance Table 2 presents the performance of LINGMESS on the test set of Ontonotes. LINGMESS achieves 81.4 F1 on Ontonotes, while the *s2e* baseline achieves 80.3. Our performance gain is statistically significant according to a non-parametric permutation test ($p < 0.05$). Additionally, Table 3 shows that LINGMESS outperforms the *s2e* model on WikiCoref (+2.9) GAP (+1.3), WinoGender (+6.8), WinoBias (+0.8) and BUG (+2.4), indicating a better out-of-domain generalization.

Importance of per-category scoring. To assess that the improvement of LINGMESS is due to the decomposition into our set of categories and not to the added parameters, we do two experiments. First, we train a random baseline, which randomly assigns a category for each pair[7] and obtain similar results as the baseline. Second, we train our model by optimizing only the overall loss L_{COREF} and not L_{EXPERTS}. This achieves lower results than the baseline, due to low mention recall.

In addition to the standard coreference evaluation, we report pairwise performance for each category. Given a mention-pair (c, q), if $F(c, q)$ is higher than 0, we treat it as a positive prediction, otherwise negative. We then measure precision, recall and F1 based on gold clusters labels. Table 4 shows the pairwise performance of the *s2e* model and LINGMESS. LINGMESS outperforms *s2e* by a significant margin for all categories (e.g +7.4 F1 for PRON-PRON-C, +10.2 F1 for PRON-PRON-NC, etc.).[8] The performance varies across the different categories, suggesting aspects of the coreference problem where future work can attempt to improve.

The importance of the shared scorer. To investigate the role of the shared scorer, we trained the LINGMESS model with only the per-type pairwise scorers, excluding the shared pairwise scorer $F_S(c, q)$ and its accompanying loss term $L_S(q)$.

---

[7] For each pair of mentions (c, q), we take the modulo of the sum of the ASCII code of the last character of the last token of c and q.

[8] These gains in this pairwise metric are higher than the CoNLL metrics reported in Table 2, because the CoNLL metrics are based on the final clusters, after aggregation of individual pairwise decisions.

This resulted in a significant decrease in performance (-0.9), specifically in the recall of the mention detection component. However, adding the shared scorer was able to mitigate this degradation by balancing the different "experts" pairwise scorers.

5 Related Work

Many pre-neural works consider the various linguistic phenomena involved in coreference resolution as a different challenge. The early coreference system by Zhou and Su (2004) divided the antecedents candidates into distinct coreference categories (e.g., Name Alias, Apposition, Definite Noun, and a few more) and defined tailored rules for each category. Later, Lee et al. (2013) proposed the multi-sieves deterministic model, where each sieve adds coreference links between mention pairs from a specific linguistic category (e.g string match, compatible pronoun, etc.). Haghighi and Klein (2009) performed an error analysis of their coreference model according to different types of antecedent decisions, such as Proper Noun-Pronoun, Pronoun-Pronoun, etc. Based on this analysis, they focus on fixing the pronoun antecedent choices by adding syntactic features. More recently, Lu and Ng (2020) analyze empirically the performance of neural coreference resolvers on various fine-grained resolution categories of mentions (e.g gendered pronoun vs. 1st and 2nd pronoun). They find that while models perform well on name and nominal mention pairs with some shared content words, they still struggle with resolving pronouns, particularly relative pronouns.

Early supervised statistical models train a feature-based classifier that incorporates the type of antecedent decision (e.g. pronoun-entity, string match) as features at the mention-pair level (Soon et al., 2001; Bengtson and Roth, 2008; Clark and Manning, 2015, 2016). Subsequently, Denis and Baldridge (2008) demonstrate that training separate classifiers that specialize in particular types of mentions (e.g third person pronouns, speech pronouns, proper names, definite descriptions, and all other) provides significant performance improvements. Lassalle and Denis (2013) took that observation a step further and proposed a more advanced method for model specialization by learning to separate types of mention into optimal classes and their proper feature space.

In our work, we make progress in coreference systems specialization direction, and show that the incorporation of linguistic information is helpful also in the context of end-to-end neural models.

6 Conclusion

We present LINGMESS, a coreference model that significantly improves accuracy by splitting the scoring function into different categories, and routing each scoring decision to its own category based on a deterministic, linguistically informed heuristic. This indicates that while end-to-end training is very effective, linguistic knowledge and symbolic computation can still be used to improve results.

Limitations

In this paper, we consider a set of 6 linguistic categories of mention pairs, as listed in Table 1. These categories might not be optimal for the task, while a different set of finer-grained categories may result to a higher performance gain. Another aspect that can be considered as a limitation is the computation of the categories for every possible pairs. Although the model considers only the top-scoring spans, this additional computation layer increases training and inference time over the baseline (see Appendix B.3 for the exact time). Our linguistic heuristics could be improved by, e.g., running a parser and considering head words. However, we chose not to do so in this work as this will further increase runtime.

A Model Architecture

Given a sequence of tokens $x_1, ..., x_n$ from an input document, a transformer-based (BERT-like) encoder first forms contextualized representation vectors, $\mathbf{x_1}, ..., \mathbf{x_n}$ for each token in the sequence.

A.1 The *s2e* Model

Mention scorer Given a span $q = (\mathbf{x_i}, \mathbf{x_j})$, represented by its start and end tokens, the score for q being a mention is defined as follow:

$$\mathbf{m}_s(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{m}_s}\mathbf{x}) \qquad \mathbf{m}_e(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{m}_e}\mathbf{x})$$

$$\begin{aligned} f_m(q) = &\ \mathbf{m}_s(\mathbf{x_i}) \cdot \mathbf{v}_s + \mathbf{m}_s(\mathbf{x_j}) \cdot \mathbf{v}_e \\ &+ \mathbf{m}_s(\mathbf{x_i}) \cdot \mathbf{B}_m \cdot \mathbf{m}_s(\mathbf{x_j}) \end{aligned}$$

where $\mathbf{m}_s(\mathbf{x})$ and $\mathbf{m}_e(\mathbf{x})$ are two non-linear functions to obtain start and end representations for each token x, and $f_m(q)$ is a biaffine product over these representations.

Antecedent scorer Given two spans, $c = (\mathbf{x_i}, \mathbf{x_j})$ and $q = (\mathbf{x_k}, \mathbf{x_l})$, represented by their start and end tokens, the score for c being an antecedent of q is computed as follow:

$$\mathbf{a}_s(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{a}_s}\mathbf{x}) \qquad \mathbf{a}_e(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{a}_e}\mathbf{x})$$

$$\begin{aligned} f_a(c, q) = &\ \mathbf{a}_s(\mathbf{x_i}) \cdot \mathbf{B}_{ss} \cdot \mathbf{a}_s(\mathbf{x_k}) \\ &+ \mathbf{a}_e(\mathbf{x_j}) \cdot \mathbf{B}_{es} \cdot \mathbf{a}_s(\mathbf{x_k}) \\ &+ \mathbf{a}_s(\mathbf{x_i}) \cdot \mathbf{B}_{se} \cdot \mathbf{a}_e(\mathbf{x_l}) \\ &+ \mathbf{a}_e(\mathbf{x_j}) \cdot \mathbf{B}_{ee} \cdot \mathbf{a}_e(\mathbf{x_l}) \end{aligned}$$

Similar to the mention scorer, $\mathbf{a}_s(\mathbf{x})$ and $\mathbf{a}_e(\mathbf{x})$ are two non-linear functions to obtain start/end representations for each token, and $f_a(c, q)$ is a sum of four bilinear functions over the start and end representations of c and q.

A.2 LINGMESS

Mention scorer Our mention scorer is the same as *s2e* mention scorer implementation.

Antecedent scorer As mentioned in the paper (§3), in addition to the shared antecedent scorer $f_a(c, q)$, LINGMESS includes a dedicated antecedent scorer $f_a^t(c, q)$ for each category $t \in \{\text{PRON-PRON-C}, \text{PRON-PRON-NC}, \text{ENT-PRON}, \text{MATCH}, \text{CONTAINS}, \text{OTHER}\}$. The overall score for $c = (\mathbf{x_i}, \mathbf{x_j})$ being an antecedent of $q = (\mathbf{x_k}, \mathbf{x_l})$ becomes the sum of the shared scorer and the relevant category "expert" scorer:

$$f(c, q) = f_a(c, q) + f_a^{T(c,q)}(c, q)$$

where $T(c, q)$ is a deterministic function to determine the category t of the pair (c, q).

For each category t, we define two specific non-linear functions to obtain start and end representations ($\mathbf{a}_s^t(\mathbf{x})$ and $\mathbf{a}_e^t(\mathbf{x})$) as well as an "expert" antecedent scoring function $f_a^t(c, q)$:

$$\mathbf{a}_s^t(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{a}_s}^t\mathbf{x}) \qquad \mathbf{a}_e^t(\mathbf{x}) = \text{GeLU}(\mathbf{W}_{\mathbf{a}_e}^t\mathbf{x})$$

$$\begin{aligned} f_a^t(c, q) = &\ \mathbf{a}_s^t(\mathbf{x_i}) \cdot \mathbf{B}_{ss}^t \cdot \mathbf{a}_s^t(\mathbf{x_k}) \\ &+ \mathbf{a}_e^t(\mathbf{x_j}) \cdot \mathbf{B}_{es}^t \cdot \mathbf{a}_s^t(\mathbf{x_k}) \\ &+ \mathbf{a}_s^t(\mathbf{x_i}) \cdot \mathbf{B}_{se}^t \cdot \mathbf{a}_e^t(\mathbf{x_l}) \\ &+ \mathbf{a}_e^t(\mathbf{x_j}) \cdot \mathbf{B}_{ee}^t \cdot \mathbf{a}_e^t(\mathbf{x_l}) \end{aligned}$$

Overall, our model introduces 6 learnable matrices for each category ($\mathbf{W}_{\mathbf{a}_s}^t$, $\mathbf{W}_{\mathbf{a}_e}^t$, $\mathbf{B}_{ss}^t$, $\mathbf{B}_{es}^t$, $\mathbf{B}_{se}^t$, $\mathbf{B}_{ee}^t$). The transformer-based encoder and the mention scorer are shared between all the different pairwise scorers.

B Implementation Details

B.1 Hyperparameteres

We extend the *s2e*'s implementation based on PyTorch (Paszke et al., 2019) and Transformers (Wolf et al., 2020). We used the same hyperparameters (e.g learning rate, warmup, etc.) as the *s2e* model except the hidden size of all matrices W and B. As our method introduces a dedicated antecedent scoring function f_a^t function for each category t, we reduce the size of these matrices from 3072 to 2048 to fit training into memory in our hardware. Similar to the baseline our head method is on top of Longformer-Large (Beltagy et al., 2020), resulting in a total of 590M learnable parameters (the *s2e* model contains 494M learnable parameters). We used dynamic batching both for training and inference, specifically 5K tokens in a single batch during training and 10K tokens at inference.

LINGMESS	**91.3**	**87.8**	**0.96**	**89.6**

Table 6: Performance on the test set of the GAP coreference dataset. The reported metrics are F1 scores.

B.2 Evaluation

As mentioned in the paper (§4), we conduct our experiments on the English portion of the OntoNotes corpus (Pradhan et al., 2012). This dataset contains 2802 documents for training, 343 for development, and 348 for test.

We evaluate our model according to the standard coreference metric: MUC (Vilain et al., 1995), B^3 (Bagga and Baldwin, 1998), CEAF$_{\phi_4}$ (Luo, 2005), and LEA (Moosavi and Strube, 2016) using the official CoNLL coreference scorer.[9] LINGMESS achieves 81.6 CoNLL F1 on the development set of Ontonotes. Also, Table 5 presents the pairwise performance on the development set for each category. We compute statistical significance with a non-parametric permutation test using Ulmer et al. (2022)'s implementation. Table 6 shows that LINGMESS consistently outperforms the *s2e* model on GAP.

B.3 Runtime and Memory

Our model was trained for 129 epochs on a single 32GB NVIDIA Tesla V100 SXM2 GPU. The training took 23 hours. At shown in Table 7, the run-time at inference time in LINGMESS is longer than in the *s2e* model because of the category selection for every possible pair of mentions. The memory consumption remains quite similar to the baseline.

	Runtime	Memory

LINGMESS	43	5.9

Table 7: Inference time(Seconds) and memory(GiB) on 343 docs of OntoNotes development set. Using Dynamic batching, 10K tokens in a single batch. Hardware, NVIDIA Tesla V100 SXM2

ID	Pronouns
1	*I, me, my, mine, myself*
2	*you, your, yours, yourself, yourselves*
3	*he, him, his, himself*
4	*she, her, hers, herself*
5	*it, its, itself*
6	*we, us, our, ours, ourselves*
7	*they, them, their, themselves*
8	*that, this*

Table 8: List of groups of compatible pronouns, pronouns with the same ID are considered as compatible.

C Determining pair types

Our method routes each pair of spans to their corresponding category scorer. This decision is based on the linguistic properties of the spans. Given a mention-pair (c, q), we defined a rule based function $T(c, q)$ that determines the category of that pair. If c and q are both pronouns, if they are compatible according to gender, number and animacy (see Table 8 for the full list), the metnion pair will be routed to PRON-PRON-C, otherwise PRON-PRON-NC. If c is pronoun and q is a non-pronoun span (or vise-versa) we route the mention-pair to PRON-ENT. We route the remaining pairs to their corresponding categories (MATCH, CONTAINS or OTHER) by considering only content words, excluding the following stop words: *{'s, a, all, an, and, at, for, from, in, into, more, of, on, or, some, the, these, those}*. Accordingly, the mentions "*the U.S. and Japan*" and "*Japan and the U.S.*" are considered MATCH, "*This lake of fire*" and "*the lake of fire*" are considered CONTAINS and "*Bill Clinton*" and "*The President*" are considered OTHER.

Finding the Law: Enhancing Statutory Article Retrieval via Graph Neural Networks

Antoine Louis **Gijs van Dijck** **Gerasimos Spanakis**
Law & Tech Lab, Maastricht University
`{a.louis, gijs.vandijck, jerry.spanakis}@maastrichtuniversity.nl`

Abstract

Statutory article retrieval (SAR), the task of retrieving statute law articles relevant to a legal question, is a promising application of legal text processing. In particular, high-quality SAR systems can improve the work efficiency of legal professionals and provide basic legal assistance to citizens in need at no cost. Unlike traditional ad-hoc information retrieval, where each document is considered a complete source of information, SAR deals with texts whose full sense depends on complementary information from the topological organization of statute law. While existing works ignore these domain-specific dependencies, we propose a novel graph-augmented dense statute retriever (G-DSR) model that incorporates the structure of legislation via a graph neural network to improve dense retrieval performance. Experimental results show that our approach outperforms strong retrieval baselines on a real-world expert-annotated SAR dataset.[1]

1 Introduction

Today, the high cost of legal expertise prevents less fortunate people from understanding and reacting to legal issues that may arise (Ponce et al., 2019). In recent years, an increasing number of works have focused on legal text processing (Zhong et al., 2020) with the intent to assist legal practitioners and citizens while reducing legal costs and improving equal access to justice for all. Statutory article retrieval (SAR), the task of retrieving statute law articles relevant to a legal question, marks the first and one of the most crucial steps in any legal aid process. Our goal is to help reduce the gap between people and the law by improving SAR systems that could provide citizens with the first component of a free professional legal aid service.

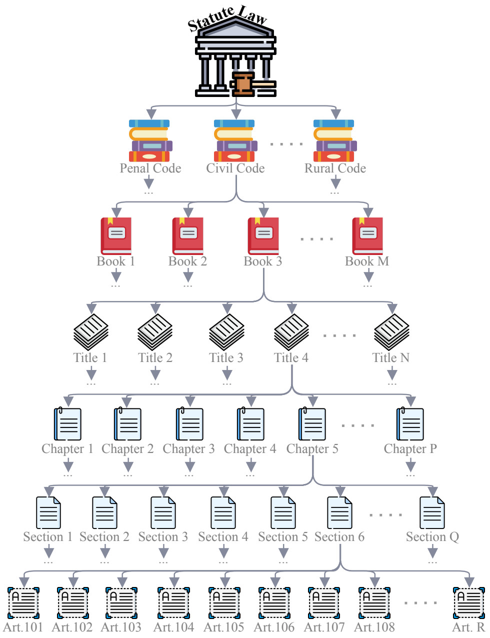

Figure 1: Illustration of the hierarchical organization of statute law. Each law code is structured into books, titles, chapters, and sections. The deeper the divisions, the closer the legal concepts of the articles below them.

Prior work has addressed SAR with standard information retrieval approaches such as term-based models or dense embedding-based models (Kim et al., 2019; Nguyen et al., 2021). While good performance has been achieved, these approaches rely on the flawed assumption that articles are complete and independent sources of information. In reality, statute law is an ensemble of *interdependent* rules meticulously organized into different codes, books, titles, chapters, and sections, as illustrated in Figure 1. Each level in the structure of legislation comes with a unique heading that informs about the content of the articles below it. An article takes on its whole meaning only when considered at its rightful place in the structure with the complementary information from its neighboring articles.

This work shows that such a structure can be highly beneficial for retrieving statutes. We propose a graph-augmented dense statute retriever (G-

DSR) model that leverages the topological structure of legislation to enhance the article content information. Specifically, the proposed model extends the document encoder of a dense retriever with a graph neural network to learn knowledge-rich cross-article representations. Similar to previous work, we adopt a contrastive learning strategy to optimize the similarity between the representations of relevant query-article pairs.

The contributions of this paper are threefold:

- We propose a graph-augmented dense retriever model for statutory article retrieval that explicitly utilizes the topological organization of statute law to enrich the article information.
- We conduct empirical evaluations on our model and demonstrate improvements over strong retrieval baselines.
- We perform ablation studies on various model components and training strategies to understand the impact of several design options on the effectiveness of our model.

2 Preliminaries

In this section, we formally introduce the task of *statutory article retrieval* and discuss the specific difficulties associated with it. We then explain how we identify the structure of legislation as an essential consideration in SAR.

Problem formulation. Given a simple legal question, such as "*Who should pay for the construction of the common wall?*", SAR aims to return one or several relevant articles from the legislation. Formally speaking, a SAR system can be expressed as a function $R : (q, \mathcal{C}) \mapsto \mathcal{F}$ that takes as input a question q along with a corpus of articles $\mathcal{C} = \{a_1, a_2, \cdots, a_N\}$, and returns a much smaller filter set $\mathcal{F} \subset \mathcal{C}$ of the supposedly relevant articles, ranked by decreasing order of relevance. For a fixed $k = |\mathcal{F}| \ll |\mathcal{C}|$, the retriever can be evaluated in isolation with multiple rank-based metrics. Most modern retriever systems follow a two-stage retrieval approach (Guo et al., 2016; Hui et al., 2017; McDonald et al., 2018), where a *pre-fetcher* first aims to return all relevant documents in the filter set $\mathcal{F}$ and a *re-ranker* then attempts to make more relevant documents in $\mathcal{F}$ appear before less relevant ones. In this work, we focus our research on improving the pre-fetcher component for SAR.

Challenges. SAR comes with two core challenges that make the task unique compared to traditional information retrieval. First, the statutes to be retrieved are written in a language that dramatically differs from the ordinary plain language used in the questions. The legal language uses a specialized jargon known for its frequent and deliberate use of formal words, Latin phrases, lengthy sentences, and expressions with flexible meanings (Charrow and Crandall, 1990). Second, statutory articles are long text sequences that may reach several thousand words. This implies overcoming the maximum input length limit of 512 tokens imposed by BERT-based models, which have recently become the standard in neural information retrieval due to their effectiveness.

Structure of legislation. The legislation comes with a well-thought-out organization of its written rules to facilitate access to provisions covering a given subject (Onoge, 2015). This organization is established in a hierarchical manner, where higher-level divisions cover broad legal domains while lower-level divisions deal with specific legal concepts. To examine the importance of this hierarchy in the SAR process, we conduct a preliminary investigation in which we study the reasoning legal experts follow when performing the task. We summarize these experts' approach in Appendix A.1. We observe that legal experts rely heavily on the structure of law when retrieving relevant articles to a legal question, which indicates that the different divisions' headings in the legislation carry valuable information that retrieval systems should consider. Additionally, we analyze the degree to which neighboring articles cover related subjects in Appendix A.2 and find high levels of similarities, which suggests that information from neighboring articles should be considered to capture an article's whole meaning.

3 Approach

In this section, we present a new general approach for SAR that learns to retrieve relevant statutes by using both the textual semantic information from articles and the structural graph information from the legislation. Our model, called graph-augmented dense statute retriever (G-DSR), consists of two main building blocks, as depicted in Figure 2, that are trained independently with the same objective. We first describe the dense retriever component of our approach in Section 3.1 and then explain how our legislative graph encoder builds upon it in Section 3.2.

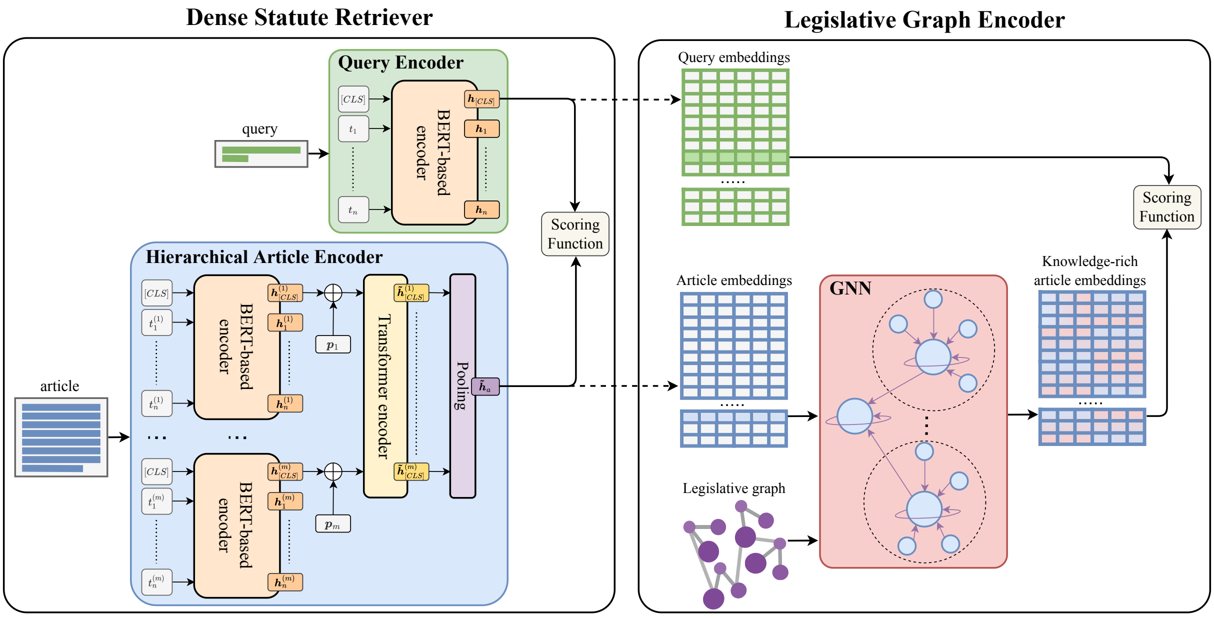

Figure 2: **An illustration of the graph-augmented dense statute retriever (G-DSR) model**. G-DSR consists of two main building blocks that are trained independently. **Left:** The dense statute retriever (DSR) first learns high-quality low-dimensional embedding spaces for both the queries and articles such that relevant query-article pairs appear closer than irrelevant ones in those vector spaces. **Right:** The legislative graph encoder (LGE) then learns to enrich the article representations by aggregating information from the organization of statute law.

3.1 Dense Statute Retriever

Our approach's first component, called dense statute retriever (DSR), aims to learn high-quality low-dimensional embedding spaces for questions and articles so that relevant question-article pairs appear closer than irrelevant ones in those spaces. Below, we review the overall architecture of the retriever and detail the design of its query and article encoders. We then describe the contrastive learning strategy we employ and choice of negative pairs.

Bi-encoder. We use the widely adopted bi-encoder architecture (Bromley et al., 1993) as the foundation of our dense retriever. The latter maps queries and articles into dense vector representations and calculates a relevance score $s : (q, a) \mapsto \mathbb{R}_+$ between query q and article a by the similarity of their embeddings, i.e.,

$$s(q, a) = \operatorname{sim}\left(E_Q^{\boldsymbol{\theta}}(q), E_A^{\boldsymbol{\phi}}(a)\right), \qquad (1)$$

where $E_Q^{\boldsymbol{\theta}}(q), E_A^{\boldsymbol{\phi}}(a) \in \mathbb{R}^d$ denote the query and article embeddings respectively, and $\operatorname{sim} : \mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{R}$ is a similarity function such as cosine or dot-product.

Query encoder. To encode the queries, we feed them into a BERT-based (Devlin et al., 2019) model $E_Q^{\boldsymbol{\theta}} : \mathcal{W}^n \mapsto \mathbb{R}^d$ with weights $\boldsymbol{\theta}$, that maps an input sequence of n tokens from vocabulary $\mathcal{W}$ to d-dimensional real-valued token embeddings. We take the last layer's [CLS] token representation as the query embedding, i.e.,

$$E_Q^{\boldsymbol{\theta}}(q) = \mathrm{BERT}_{[\mathrm{CLS}]}(q). \qquad (2)$$

Hierarchical article encoder. Since statutory articles may be longer than the maximum input length of a standard BERT-based encoder, we use a hierarchical variation that can process longer textual sequences (Pappagari et al., 2019; Zhang et al., 2019; Yang et al., 2020a). Each article a is first split into smaller text passages $[p_1, p_2, \cdots, p_m]$, where a passage p_i is a sequence of tokens $[t_1^{(i)}, t_2^{(i)}, \cdots, t_n^{(i)}]$ with $n \leq 512$. These passages are then independently passed through a shared BERT-based model to extract a list of *context-unaware* passage representations using the respective [CLS] token embeddings, as illustrated in Figure 2. Next, the hierarchical model sums the [CLS] token representations of each passage with learnable passage position embeddings and feeds the resulting representations into a small Transformer encoder to make them aware of the surrounding passages. The final article representation is computed through a pooling operation over the *context-aware* passage representations, i.e.,

$$E_A^{\phi}(a) = \text{pool}\left(\left[\tilde{\boldsymbol{h}}_{[\text{CLS}]}^{(1)}, \cdots, \tilde{\boldsymbol{h}}_{[\text{CLS}]}^{(m)}\right]\right), \quad (3)$$

where $\tilde{\boldsymbol{h}}_{[\text{CLS}]}^{(i)} \in \mathbb{R}^d$ is the contextualized embedding of passage p_i, and pool : $\mathbb{R}^{m \times d} \mapsto \mathbb{R}^d$ is either mean or max pooling.

Contrastive learning. The training objective of the bi-encoder is to learn effective embedding functions $E_Q^{\boldsymbol{\theta}}(\cdot)$ and $E_A^{\phi}(\cdot)$ such that relevant question-article pairs have a higher similarity than irrelevant ones. Let $\mathcal{D} = \{\langle q_i, a_i^+ \rangle\}_{i=1}^N$ be the training data where each of the N instances consists of a query q_i associated with a relevant article a_i^+. By sampling a set of negative articles $\mathcal{A}_i^-$ for each question q_i, we can create a training set $\mathcal{T} = \{\langle q_i, a_i^+, \mathcal{A}_i^- \rangle\}_{i=1}^N$. For each training instance in $\mathcal{T}$, we contrastively optimize the negative log-likelihood of the positive article against the negative ones, i.e.,

$$L\left(q_i, a_i^+, \mathcal{A}_i^-\right) = -\log \frac{e^{s(q_i, a_i^+)/\tau}}{\sum_{a \in \mathcal{A}_i^- \cup \{a_i^+\}} e^{s(q_i, a)/\tau}}, \quad (4)$$

where $\tau > 0$ is a temperature parameter to be set.

Negatives. We consider two types of negative examples: (i) in-batch (Chen et al., 2017; Henderson et al., 2017), i.e., articles paired with the other questions from the same mini-batch, and (ii) BM25, i.e., top articles returned by BM25 that are not relevant to the question.

3.2 Legislative Graph Encoder

Our approach's second component, called Legislative Graph Encoder (LGE), aims to enrich article representations given by the trained retriever's article encoder by fusing information from a legislative graph. Below, we elaborate on the legislative graph construction and the graph training process.

Graph construction. To leverage the hierarchical organization of statute law, we formalize the latter as a tree structure consisting of two types of node: (i) *section* nodes, which are titled structural units that represent the consecutive divisions in codes of law (i.e., the headings of the books, titles, chapters, and sections), and (ii) *article* nodes, which are textual content units that represent the different statutory articles. As illustrated in Figure 1, the edges represent the hierarchical connections between section and article nodes. Formally, such a tree can be represented as a directed acyclic graph $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, with $\mathcal{V}$ as the node set and $\mathcal{E} \subseteq \mathcal{V} \times \mathcal{V}$ as the edge set.

Node feature initialization. Nodes in $\mathcal{V}$ are commonly associated with d-dimensional features. We apply the article encoder $E_A^{\phi}(\cdot)$ from the trained bi-encoder to encode the semantic information of nodes (i.e., section headings and article contents) offline and use the resulting embeddings as the initial node features $\mathbf{X} \in \mathbb{R}^{|\mathcal{V}| \times d}$.

Node feature update. To fuse the information of node features using the graph structure, we use a graph neural network (GNN). Such a model consists of a stack of neural network layers, where each layer aggregates local neighborhood information (i.e., features of neighbors) around each node and then passes this aggregated information on to the next layer. Generally speaking, a GNN takes as inputs the feature matrix $\mathbf{X}$ and the graph's adjacency matrix $\mathbf{A} \in \mathbb{R}_+^{|\mathcal{V}| \times |\mathcal{V}|}$, with $\mathbf{A}_{i,j}$ as the edge weight between nodes i and j, and produces a node-level output $\mathbf{Z} \in \mathbb{R}^{|\mathcal{V}| \times d}$ that captures each node's structural properties. Every GNN layer can be written as a non-linear function

$$\mathbf{H}^{(l+1)} = f(\mathbf{H}^{(l)}, \mathbf{A}), \quad (5)$$

with $\mathbf{H}^0 = \mathbf{X}$ and $\mathbf{H}^L = \mathbf{Z}$, L being the number of layers. In its simplest form, the layer-wise propagation rule is such that

$$f(\mathbf{H}^{(l)}, \mathbf{A}) = \sigma(\mathbf{A}\mathbf{H}^{(l)}\mathbf{W}^{(l)}), \quad (6)$$

where $\mathbf{W}^{(l)}$ is the input linear transformation's weight matrix for the l-th neural network layer and $\sigma(\cdot)$ is a non-linear activation function. We propose to use a 3-layer GATv2 network (Brody et al., 2022), a variant of GAT (Velickovic et al., 2018) that has the ability to learn the strength of connection between neighboring nodes through a *dynamic* attention mechanism. Formally, a GATv2 layer updates a node's hidden state as follows

$$\boldsymbol{h}_i^{(l+1)} = \sigma\left(\sum_{j \in \mathcal{N}(i)} \alpha_{ij}^{(l)} \mathbf{W}^{(l)} \boldsymbol{h}_j^{(l)}\right), \quad (7)$$

where $\mathcal{N}(i)$ is the set of first-order neighbors of node i, and $\alpha_{ij}^{(l)}$ are normalized attention coefficients indicating the importance of node j's features to i in the l-th layer. The latter are computed based on the features of the connected nodes using an attention function att : $\mathbb{R}^d \times \mathbb{R}^d \mapsto \mathbb{R}$ such that

$$\alpha_{ij}^{(l)} = \text{softmax}\left(\sigma(\text{att}(\boldsymbol{h}_i^{(l)}, \boldsymbol{h}_j^{(l)})\right). \quad (8)$$

Learning process. To optimize the GNN parameters, we adopt the same contrastive learning strategy used to train the bi-encoder. Since graph $\mathcal{G}$ can be relatively large, performing an update of all the node features in $\mathcal{G}$ at every training iteration would incur high computational costs. Besides, most of these computations would be of no use as only the updated representations of nodes $\{\mathcal{A}_i^- \cup a_i^+\}_{i=1}^{|\mathcal{B}|}$ from batch $\mathcal{B}$ are needed to update the model parameters. Therefore, we build a sub-graph $\mathcal{G}^{sub}$ at each training step that only contains the article nodes from batch $\mathcal{B}$ as well as their L-hop neighbors (where L is decided by the number of GNN layers). We then pass that sub-graph to the graph network and use the resulting article representations to compute the loss in Equation (4). Comparably to the node features, the query embeddings are pre-computed offline before training by the query encoder $E_Q^{\boldsymbol{\theta}}(\cdot)$ of our trained bi-encoder.

4 Experimental Setup

In this section, we present the basic setup for experiments. In particular, Section 4.1 describes the dataset we conduct our experiments on, Section 4.2 details our model implementation, Section 4.3 reviews the different baselines we use for comparison, and Section 4.4 reports the evaluation metrics.

4.1 Dataset

We conduct experiments on the publicly available Belgian Statutory Article Retrieval Dataset (Louis and Spanakis, 2022, BSARD).[2] To the best of our knowledge, BSARD is the only SAR dataset that provides the lists of consecutive division headings each article belongs to, which is crucial for building the graph of the legislative structure. The dataset consists of 1,100+ *French* native questions on various legal topics, as shown in Table 1, labeled by skilled experts with references to relevant statutory articles from the Belgian legislation. The retrieval corpus comprises 22,600+ articles collected from 32 Belgian codes covering numerous legal domains. The questions are relatively short and might have several relevant legal articles. We refer readers to the original paper for further data collection and analysis details.

4.2 Implementation Details

Model. We use the publicly released CamemBERT (Martin et al., 2020) checkpoint to initialize DSR's query encoder. Due to the specificity of the legal language the article encoder has to deal with, we follow prior work on domain adaptation (Gururangan et al., 2020; Jørgensen et al., 2021) and continue pre-training CamemBERT on BSARD statutory articles for 50k gradient steps to adapt it to the target legal domain. We use the resulting domain-specific checkpoint to warm-start the article's first-level encoder. The second-level encoder is a two-layer Transformer encoder of 14M parameters with a similar configuration (i.e., 768-hidden, 3072-intermediate, 12-heads, 0.1 dropout, GeLU). We use max-pooling to aggregate the final chunk representations and cosine as the decomposable similarity function.

Topic	Train	Dev	Test
👪 Family	216	56	67
🏠 Housing	203	38	66
💰 Money	103	35	36
⚖️ Justice	96	25	30

👵 Social security	27	8	6
🖨️ Work	23	6	4
Total	709	177	222

Table 1: Topic distribution of questions in BSARD.

Data augmentation. Due to the recent success in using synthetic query generation to improve dense retrieval performance (Liang et al., 2020; Ma et al., 2021; Thakur et al., 2021), we propose to augment BSARD with synthetic domain-targeted queries. We use a mT5 model (Raffel et al., 2020) fine-tuned on general domain data from mMARCO (Bonifacio et al., 2021) to synthesize queries for our target statutory articles.[3] We generate five queries per article, which results in a total of around 118k synthetic queries. We combine the latter with the gold BSARD train samples and obtain an augmented training set of around 122.5k question-article pairs.

Optimization. We train DSR for 15 epochs with a batch size of 24 using AdamW (Loshchilov and Hutter, 2017) with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon =$1e-7, weight decay of 0.01, and learning rate warm up along the first 5% of the training steps to a maximum value of 2e-5, after which linear decay is applied. We then optimize LGE parameters for 10

---

[2] `https://huggingface.co/datasets/antoiloui/bsard`

[3] `https://huggingface.co/doc2query/msmarco-french-mt5-base-v1`

epochs with a batch size of 512 using AdamW with $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon =$1e-7, weight decay of 0.1, and a constant learning rate of 2e-4. We use 16-bit automatic mixed precision to accelerate training and save memory. Details on our hyperparameter tuning process are given in Appendix B.

Hardware & schedule. Training is performed on a single 32 GB NVIDIA V100 GPU hosted on a server with a dual 20-core Intel Xeon E5-2698 v4 CPU @2.20GHz and 512 GB of RAM. It takes around 1 day to train DSR and 35 minutes for LGE.

Libraries. We implement, train, and tune our models using Transformers (Wolf et al., 2020), PyTorch (Paszke et al., 2019), PyTorch-Geometric (Fey and Lenssen, 2019), PyTorch-Lightning (Falcon, 2019), W&B Sweeps (Biewald, 2020), and DeepSpeed (Rasley et al., 2020).

4.3 Baselines

We compare our approach against three strong retrieval systems. As a sparse baseline model, we follow prior work and consider BM25 (Robertson et al., 1994),[4] a popular bag-of-words retrieval function based on exact term matching. We then examine the document expansion technique docT5query (Nogueira and Lin, 2019), which augments each article with a pre-defined number of synthetic queries generated by a finetuned mT5 model,[3] and then uses a traditional BM25 lexical index from the augmented articles for retrieval. Last, we include the results of a supervised dense passage retrievers (Karpukhin et al., 2020, DPR) pre-finetuned on more than 90.5k question-context pairs from a combination of three French QA datasets.[5]

4.4 Evaluation

We evaluate model performance using three commonly used ranking measures (Manning et al., 2008), namely the macro-averaged recall at different cutoffs (R@k), mean average precision (mAP), and mean r-precision (mRP). Those metrics are further defined in Appendix D. We deliberately omit to report the precision@k given that questions in BSARD have a variable number of relevant articles, which implies that questions with r relevant articles would always have P@$k < 1$ if $k > r$. Similarly, the mean reciprocal rank (mRR) is not appropriate for BSARD as only the first relevant article would be considered. As some questions might have up to 100 relevant articles, we use $k \in \{100, 200, 500\}$ for the recall@k.

5 Experiments

In this section, we empirically evaluate the effectiveness of our proposed approach against competitive baselines and discuss the main results in Section 5.1. Next, we provide an ablation study in Section 5.2 to understand how different design and training options affect our model's performance.

5.1 Main Results

Table 2 shows retrieval performance on BSARD test set. Although we report model performance on two rank-aware metrics (i.e., mAP and mRP), we emphasize that our approach is specifically aimed at improving the pre-fetching component of a retriever (Zhang et al., 2021a) and therefore focuses on optimizing rank-unaware metrics (i.e., R@k).

First, we compare the performance of our proposed G-DSR model(8) against other well-known retrieval approaches and find it significantly outperforms all of them on SAR. In particular, it improves over the sparse retrieval methods(1,2) by around 30% on recall@k and by more than 25% on mAP and mRP. It also outperforms a competitive pre-finetuned DPR model(4) by 6% on R@100, 9% on R@200, and 5% on R@500. However, the latter shows a better performance on rank-aware metrics compared to our DSR models, which we speculate might be due to its extensive pre-finetuning step on three domain-general retrieval datasets, leading the model to a deeper knowledge of the task at hand.

Next, we investigate the influence of different training strategies on the rank-unaware results of our base dense retriever.(5) We find that DSR's performance is improved when adapting the article text encoder to the legal domain before finetuning on the target data.(6) Besides, training DSR on a larger dataset containing synthetic domain-targeted queries improves its performance even more.(7)

Finally, our results show that using a GNN model on top of DSR allows to enrich the article representations and leads to the best overall performance.(8) Interestingly, G-DSR also significantly improves the rank-aware performance of our best performing DSR model by ∼12%, suggesting that a GNN could act as an effective re-ranker for SAR.

---

[4] We use $k_1 = 2.5$ and $b = 0.2$. Details on BM25 hyperparameters tuning are given in Appendix C.

5.2 Ablation Study

To further understand how different design choices and training strategies affect the results, we conduct several additional experiments and discuss our findings below.

Alternative pre-trained LMs. In addition to CamemBERT, we experiment with several other French or multilingual pre-trained language models to initialize the first-level text encoders in DSR – namely, mBERT (Devlin et al., 2019), XLM-R (Conneau et al., 2020), and ELECTRA-fr (Clark et al., 2020).[6] We fine-tune the different warm-started models on BSARD training set and report dev results in Table 3. We find that a CamemBERT-initialized DSR model performs best.

Alternative GNNs. Additionally to GATv2, we explore different GNN architectures to perform the node feature update – namely, GCN (Kipf and Welling, 2017), GraphSAGE (Hamilton et al., 2017), GAT (Velickovic et al., 2018), and k-GNN (Morris et al., 2019) – and summarize the results in Table 4. Our experiments show that using an alternative GNN model does not affect performance much, which suggests that the act of fusing information from neighboring nodes is more important than the way the aggregation is performed.

Similarity and loss functions. Besides cosine for scoring pairs of query-article representations, we also experiment with dot-product and Euclidean distance and find both inferior to cosine. As an alternative to negative log-likelihood, we test the triplet loss (Burges et al., 2005) and observe that the latter significantly decreases model performance. More details can be found in Appendix E.

Pre-trained LM	#Params	R@100 (↑)	R@500 (↑)
XLM-R	278M	59.8	78.7

6 Related Work

Our work operates at the intersection of several research areas, including long document modeling, dense information retrieval, graph neural networks, and legal NLP.

Long document modeling. The emergence of deep neural networks for language processing brought new challenges to text encoding, one of which is learning high-quality representations of long documents. For example, Tang et al. (2015) employ a bottom-up approach using CNN and BiLSTM-based hierarchical networks, where sentences are first encoded into vectors, which are then combined to form a single document vector. Similarly, Yang et al. (2016) build a document vector by aggregating important words into sentence vectors and then aggregating important sentence vectors to document vectors using attention mech-

---

[6] `https://huggingface.co/dbmdz/electra-base-french-europeana-cased-discriminator`

anisms. More recently, hierarchical variants of Transformer-based models have been explored for various language tasks, including document classification (Mulyar et al., 2019; Pappagari et al., 2019; Chalkidis et al., 2019; Wu et al., 2021), summarization (Zhang et al., 2019), semantic matching (Yang et al., 2020a), and question answering (Liu et al., 2022). In addition to hierarchical attention Transformer-based (HAT) models, several sparse attention Transformers (SAT) have been introduced to reduce the computational complexity of the model, thus allowing to process sequences longer than 512 tokens (Child et al., 2019; Beltagy et al., 2020; Zaheer et al., 2020). However, Chalkidis et al. (2022) show that a pre-trained HAT model performs comparably or better than an equally-sized SAT model across several downstream tasks while being substantially faster and less memory intensive. Recently, other non-Transformer-based approaches have been proposed for efficient long sequence processing based on structured state spaces (Gu et al., 2022; Gupta et al., 2022).

Dense information retrieval. Traditionally, lexical approaches such as TF-IDF and BM25 (Robertson et al., 1994) have been the *de facto* standard for textual information retrieval due to their robustness and efficiency. However, these approaches suffer from the lexical gap problem (Berger et al., 2000) and can only retrieve documents containing keywords present in the query. To overcome this limitation, recent work relies on neural-based architectures to capture semantic relationships between pairs of texts (Lee et al., 2019; Karpukhin et al., 2020; Yang et al., 2020b; Xiong et al., 2021). These models map queries and documents into dense vector representations and calculate a relevance score by the similarity of the vectors (Gillick et al., 2018), which allows the document representations to be pre-computed and indexed offline for inference. The dense retrieval approach was recently extended by hybrid lexical-dense methods, which aim to combine the strengths of both approaches (Seo et al., 2019; Gao et al., 2021; Luan et al., 2021). We refer the readers to Yates et al. (2021) for a survey on neural information retrieval.

Graph neural networks. Graph neural networks (GNNs) capture the topological relationships among the nodes of a graph using an information diffusion mechanism that propagates node features according to the underlying graph-structured data (Scarselli et al., 2009). These models have shown their effectiveness and flexibility in a wide variety of NLP tasks, including text classification (Lin et al., 2021; Yu et al., 2022), relation extraction (Zhang et al., 2018; Li et al., 2020; Carbonell et al., 2020), and question answering (Cao et al., 2019; Xu et al., 2021b). Recently, GNNs have been employed for document retrieval to enhance the vector representations by leveraging the topological structure of the documents, where nodes are passages from a document and edges are relations between these passages (Xu et al., 2021a; Zhang et al., 2021b; Albarede et al., 2022).

Application to the legal domain. In recent years, the legal domain has attracted much interest in the NLP community, both for its challenging characteristics and massive volumes of textual data (Chalkidis and Kampas, 2019; Zhong et al., 2020). Researchers see it as an opportunity to develop novel automated methodologies that can reduce heavy and redundant tasks for legal professionals while providing a reliable, affordable form of legal support for laypeople (Bommasani et al., 2021). Earlier techniques for legal information retrieval were mainly based on term-matching approaches (Kim and Goebel, 2017; Tran et al., 2018). Recently, a growing number of works have used neural networks to enhance retrieval performance, including word embedding models (Landthaler et al., 2016), doc2vec models (Sugathadasa et al., 2018), CNN-based models (Tran et al., 2019), and BERT-based models (Nguyen et al., 2021; Chalkidis et al., 2021; Althammer et al., 2022). To the best of our knowledge, we are the first to exploit the structure of statute law with GNNs to improve the performance of dense retrieval models.

7 Conclusion

In this paper, we introduce G-DSR, a novel approach for statutory article retrieval (SAR) that leverages the topological structure of legislation to improve retrieval performance. Specifically, G-DSR enriches the article representations of a dense retriever designed for long document retrieval by employing a graph neural network that uses the organization of statute law to learn knowledge-rich cross-article embeddings. Experiments show that G-DSR outperforms competitive baselines on a real-world expert-annotated SAR dataset. We also include a detailed analysis to motivate our design choices and training strategies.

Limitations

While our approach performs well on statutory article retrieval, it comes with several limitations that provide avenues for future work.

First, experimental results are based on questions and labels drafted by legal professionals. It is possible that other legal professionals would draft the questions differently or, less likely yet possible, that they would deem different statutory provisions relevant. This raises the question of to what extent similar results would be obtained if the model were trained on a different dataset, for instance, based on other experts or domains, hence testing the approach's generalizability. The main challenge in this regard is obtaining data, as organizations are unlikely to share or even collect similar data.

Second, our proposed methodology was evaluated exclusively on the Belgian legislation, whose laws are organized in a hierarchical manner where the deeper the divisions, the more closely related the legal concepts of the articles under them. Although we believe our approach could be applied to most, if not all, jurisdictions that rely on statute law (including both civil and common law countries), different jurisdictions may have different organizations of their legal provisions, which could potentially affect the model's performance. It is also worth mentioning that the dataset used for evaluation comes with a linguistic bias as Belgium is a multilingual country with French, Dutch, and German speakers, but the provided provisions are only available in French. Studying the applicability and impact of the present work to other jurisdictions and languages is an exciting research direction that is challenging in practice due to the scarcity of high-quality multilingual statute retrieval datasets.

Then, our approach currently considers the topological structure of legislation for modeling the inter-article dependencies, which implies that information is aggregated between direct neighboring articles only while those from more distant sections are completely ignored. Nevertheless, it is common for articles to cite other articles from different sections or even different statutes. Therefore, we believe that considering richer legal graph structures, especially legal citation networks, could increase effectiveness even more. However, building such citation networks from raw texts requires a considerable text-processing effort.

Finally, although G-DSR shows promise for statutory article retrieval, it is not yet ready for practical use in the real world. One issue is that our model is designed to be an effective pre-fetcher, optimizing recall such that all articles relevant to a question appear in an unordered filter set of size k (k being relatively large). However, in practice, users would expect a high-quality retrieval system to not only find these relevant articles but also to sort them by decreasing order of importance, requiring an adequate re-ranker. Then, it is essential to recognize that while access to relevant legal provisions is a necessary step in helping the general public solve their legal issues, it is not a sufficient condition on its own as laypeople may still struggle to understand the legal jargon and apply the provisions to their specific situations. Ideally, the tool to be made accessible to the public should consist of a two-stage framework: (i) a legal provision retriever, which selects a small subset of relevant legal articles in response to a given question, and (ii) a legal-to-natural translator or summarizer, which examines the retrieved articles and generates an answer in natural language. In the present work, we chose to focus on the first stage of this framework and leave the second for future work.

Ethics Statement

The scope of this work is to provide a new methodology along with extensive experiments to drive research forward in statutory article retrieval. We believe the latter is an important application field where more research should be conducted to improve legal aid services and access to justice for all. We do not foresee situations where the use of our methodology would lead to harm (Tsarapatsanis and Aletras, 2021). Nevertheless, although our goal is to improve the understanding of the law by those who suffer from legal information asymmetry, it cannot be excluded that the technology presented here could exacerbate inequality if states, companies, or lawyers benefit more from its use than the intended beneficiaries (i.e., citizens, consumers, or employees).

Acknowledgments

This research is partially supported by the Sector Plan Digital Legal Studies of the Dutch Ministry of Education, Culture, and Science. In addition, this research was made possible, in part, using the Data Science Research Infrastructure (DSRI) hosted at Maastricht University.

Appendix

A Preliminary Studies

A.1 How important is the structure of law for statutory article retrieval?

To better understand the reasoning skilled humans follow when retrieving statutory articles, we ask several legal experts to retrieve relevant articles to questions sampled from the Belgian Statutory Article Retrieval Dataset (Louis and Spanakis, 2022, BSARD). We deliberately choose experts unfamiliar with Belgian law and thus have no past knowledge of the location of articles covering a particular subject. In what follows, we summarize the approach these experts use.

First, they determine whether the issue involves either *public* or *private* law. To distinguish between the two, it is necessary to identify to whom the rules apply (i.e., the parties involved in the issue that hold the rights or duties). Generally speaking, public law deals with issues that affect the general public or state (i.e., society as a whole), whereas private law deals with issues that affect individuals, families, and businesses. This first step allows the experts to make an initial selection among the codes of law, which generally relate to only one of either public or private law.

Next, the experts refine their search by determining the field of law (e.g., contract law), followed by the sub-field (e.g., tenant law), and so on, until a set of potentially relevant codes is created in the question's domains. The experts then focus on the table of contents of one of the selected codes and undertake a hierarchical search that starts from the book's headings and progressively extends to its titles, chapters, and sections. This step makes it possible to filter out many irrelevant articles by analyzing the connection between the question's subject and the different sections' headings.

Finally, the experts explore the articles within the sections deemed potentially relevant to the question in search of the expected answer. If the experts realize that the chosen direction is a dead end, they return to the previous higher level of the structure, choose another potentially relevant direction, and narrow their search from there.

From this study, we conclude that legal experts rely heavily on the structure of law when retrieving relevant articles to a legal question, which indicates that the different divisions' headings carry valuable information that retrieval systems should consider.

A.2 How related are neighboring articles in statute law?

In statute law, the sense of a given article is not necessarily self-contained by itself but instead spans across different articles from the same or even different sections. To confirm this, we study to what extent consecutive articles (as they appear in the statute books) address similar subjects.

We consider the Belgian Civil Code, which is the book whose articles are most cited in BSARD, and randomly sample sets of 200 consecutive articles out of it. We then normalize the articles by lowercasing, lemmatizing, and removing stop-words, punctuation, and numbers. Finally, we compute the cosine similarities between the TF-IDF representations of all articles from a given set. Figure 3 shows a heatmap of article similarities for such a set. We see that consecutive articles do indeed cover similar topics, suggesting that the information in a given article is likely to be complementary to that in its neighboring articles. Therefore, we assume that neighboring articles should be considered to capture an article's whole meaning.

B G-DSR Hyperparameter Tuning

We conduct hyperparameter tuning using Bayes search based on performance on BSARD development set, measured with the macro-averaged R@200. Due to limited computational resources, we train our models on BSARD training set only – which takes approximately 1 hour and 15 minutes for DSR and around 5 minutes for LGE – and use the constrained search spaces described below.

DSR grid search space:

- batch size: {8, 16, 24, 32}
- learning rate: {5e-5, 4e-5, 3e-5, 2e-5, 1e-5}
- weight decay: {0, 0.1, 0.01, 0.001}
- max chunk length: {64, 128, 256, 512}
- max document length: {1024, 2048}
- pooling strategy: {mean, max}
- similarity function: {dot-product, cosine, L2}
- temperature: {0, 0.1, 0.01, 0.001}

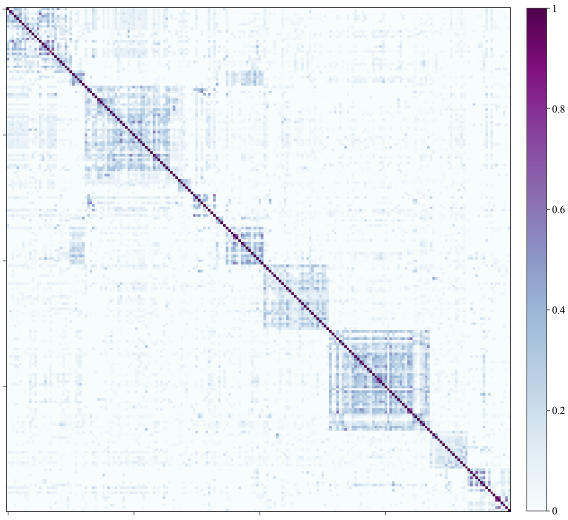

Figure 3: Cosine similarities between TF-IDF representations of 200 consecutive articles from the Belgian Civil Code, taken from the Belgian Statutory Article Retrieval Dataset (Louis and Spanakis, 2022, BSARD).

LGE grid search space:

- batch size: {8, 16, 32, 64, 128, 256, 512}
- learning rate: {2e-2, 2e-3, 2e-4, 2e-5, 2e-6}
- weight decay: {0, 0.1, 0.01, 0.001}
- #layers: {1, 2, 3, 4}

In total, we run 100 hyperparameter search trials for both DSR and LGE. The optimal hyperparameters, shown in Table 5, are used to re-train the models combining both train and development sets for a final evaluation on the test set.

C BM25 Hyperparameter Tuning

Following Chalkidis et al. (2021), who show that BM25 performance is highly dependent on adequately choosing the (k_1, b) values for the task at hand, we perform a hyperparameter grid search on BSARD development set and plot the results in Figure 4. We observe that, in the case of SAR, the best performance is obtained with $k_1 = 2.5$ and $b = 0.2$. Therefore, we use these values for the final evaluation on BSARD test set.

Hyperparam	DSR	LGE

D Evaluation Metrics

Let $\text{rel}_q(a) \in \{0,1\}$ be the binary relevance label of article a for question q, and $\langle i,a\rangle \in \mathcal{F}_q$ a result tuple (article a at rank i) from the filter set $\mathcal{F}_q \subset \mathcal{C}$ of ranked articles retrieved for question q.

Recall. The *recall* is the fraction of relevant articles retrieved for query q w.r.t. the total number of relevant articles in the corpus $\mathcal{C}$, i.e.,

$$\text{R}_q = \frac{\sum_{\langle i,a\rangle \in \mathcal{F}_q} \text{rel}_q(a)}{\sum_{a\in\mathcal{C}} \text{rel}_q(a)}. \tag{9}$$

When computed for a filter set of size $k = |\mathcal{F}_q| \ll |\mathcal{C}|$, i.e., at a certain cutoff and not on the entire list of articles in $\mathcal{C}$, we report the metrics with the suffix "@k".

R-Precision The R-Precision is the proportion of the top-R retrieved articles that are relevant to query q, where R is the total number of relevant articles for q, i.e.,

$$\text{RP}_q = \frac{\sum_{\langle i,a\rangle \in \{\mathcal{F}_q\}_{i=1}^{R}} \text{rel}_q(a)}{R}. \tag{10}$$

Average Precision. The *average precision* is the mean of the precision value obtained after each relevant article is retrieved, that is

$$\text{AP}_q = \frac{\sum_{\langle i,a\rangle \in \mathcal{F}_q} \text{P}_{q,i} \times \text{rel}_q(a)}{\sum_{a\in\mathcal{C}} \text{rel}_q(a)}, \tag{11}$$

where $\text{P}_{q,j}$ is the *precision* computed at rank j for query q, i.e., the fraction of relevant articles retrieved for query q w.r.t. the total number of articles in the retrieved set $\{\mathcal{F}_q\}_{i=1}^{j}$:

$$\text{P}_{q,j} = \frac{\sum_{\langle i,a\rangle \in \{\mathcal{F}_q\}_{i=1}^{j}} \text{rel}_q(a)}{\left|\{\mathcal{F}_q\}_{i=1}^{j}\right|}. \tag{12}$$

We report the macro-averaged *recall* at various cutoffs (R@k), *mean Average Precision* (mAP), and *mean R-Precision* (mRP), which are the average values over a set of n queries.

E Ablation Details

Besides cosine similarity and negative log-likelihood (NLL) loss, we also test the dot-product and Euclidean (inverse of distance is taken as similarity measure) as well as the triplet loss. The temperature for the NLL loss is set to 0.01, and the margin value of the triplet loss is set to 1. We report the results on BSARD development set in Table 6. For a fair comparison, all models are trained for 15 epochs with a batch size of 24, weight decay of 0.01, warm-up proportion of 0.05, an initial learning rate of 2e-5, and a linear decay learning rate schedule.

Behavior Cloned Transformers are Neurosymbolic Reasoners

Abstract

In this work, we explore techniques for augmenting interactive AI agents with information from symbolic modules, much like humans use tools like calculators and GPS systems to assist with arithmetic and navigation. We test our agent's abilities in text games—challenging benchmarks for evaluating the multi-step reasoning abilities of game agents in grounded, language-based environments. Our experimental study indicates that injecting the actions from these symbolic modules into the action space of a behavior cloned transformer agent increases performance on four text game benchmarks that test arithmetic, navigation, sorting, and common sense reasoning by an average of 22%, allowing an agent to reach the highest possible performance on unseen games. This action injection technique is easily extended to new agents, environments, and symbolic modules.[1]

1 Introduction

Interactive fiction games (or *text games*) evaluate AI agents abilities to perform complex multi-step reasoning tasks in interactive environments that are rendered exclusively using textual descriptions. Agents typically find these games challenging due to the complexities of the tasks combined with the reasoning limitations of contemporary models. Overall performance is generally low, with agents currently solving only 30% of classic interactive fiction games such as Zork (Ammanabrolu and Hausknecht, 2020; Yao et al., 2021; Atzeni et al., 2022). Similarly, reframing benchmarks such as question answering into text games where agents must interactively reason with their environment and make their reasoning steps explicit causes performance to substantially decrease (Wang et al., 2022), highlighting both the capacity of this methodology to evaluate multi-step reasoning, and the limitations of current language models.

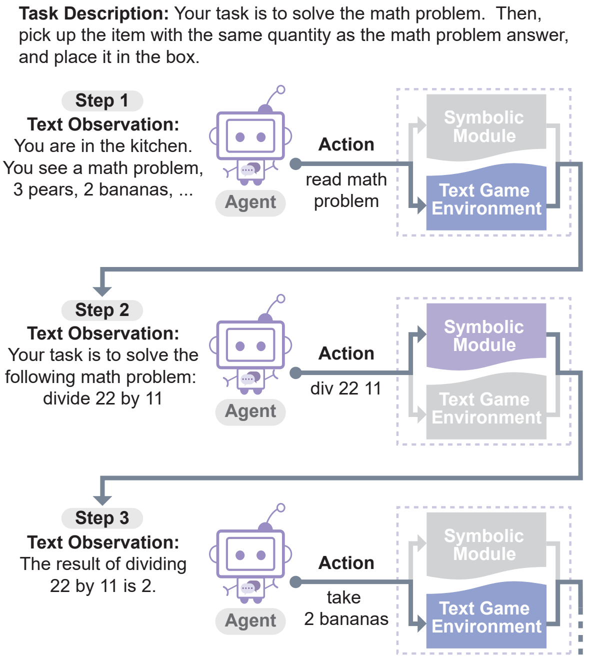

Figure 1: An overview of our approach on an example game evaluating arithmetic ability. At each step, the agent receives an observation from the environment, then takes an action. By providing actions that interface to symbolic modules (such as a calculator), the agent is able to use external knowledge to help solve the task.

While large language models are capable of a variety of common sense reasoning abilities (Liu et al., 2022b; Ji et al., 2020), contemporary agents typically struggle on tasks such as navigation, arithmetic, knowledge base lookup, and other tasks that humans typically make use of external tools (such as GPS systems, calculators, and books) to solve. This is at times frustrating, because the tasks they perform poorly on can sometimes be solved in a few dozen lines of code. In this work, we show that combining both approaches is possible for text game agents, with our approach shown in Figure 1. We develop symbolic modules for arithmetic, navigation, sorting, and knowledge base lookup in

PYTHON, paired with new benchmark games for testing these capacities in interactive text game environments. We empirically demonstrate that injecting actions from those modules into the action space of each game can allow transformer-based agents to make use of that information, and achieve near-ceiling performance on unseen benchmark games that they otherwise find challenging.

2 Related Work

Neurosymbolic reasoning offers the promise of combining the inference capabilities of symbolic programs with the robustness of large neural networks. In the context of text games, Kimura et al. (2021a) develop methods to decompose text games into a set of logical rules, then combine these rules with deep reinforcement learning (Kimura et al., 2021b) or integer linear programming (Basu et al., 2021) to substantially increase agent performance while providing a more interpretable framework for understanding why agents choose specific actions (Chaudhury et al., 2021). More generally, neurosymbolic reasoning has been applied to a variety of multi-step inference problems, such as multi-hop question answering (Weber et al., 2019), language grounding (Zellers et al., 2021), and semantic analysis (Cambria et al., 2022).

Because text games require interactive multi-step reasoning, agents have most commonly been modelled using reinforcement learning (e.g. He et al., 2016; Zahavy et al., 2018; Yao et al., 2020), though overall performance on most environments remains low (see Jansen, 2022; Osborne et al., 2021, for reviews). Recently, alternative approaches modeling reinforcement learning as a sequence-to-sequence problem using imitation learning have emerged, centrally using behavior cloning (Torabi et al., 2018), decision transformers (Chen et al., 2021), and trajectory transformers (Janner et al., 2021). These approaches model interactive multi-step reasoning problems as a Markov decision process, where an agent's observation and action history up to some depth are provided as input, and the transformer must predict the next action for the agent to take. Behavior cloning and decision transformers have recently been applied to text games with limited success (Wang et al., 2022). Here, we show that the performance of a behavior cloned transformer can substantially increase when augmented with neurosymbolic reasoning.

3 Approach

Figure 1 illustrates the workflow of our approach. At each time step t, based on the observation o_t, the symbolic module will generate a set of valid actions A_t^m, and the text game environment will have a distinct set of valid actions A_t^e. Let the valid action set at step t be $A_t = A_t^m \cup A_t^e$. Given o_t and A_t, the agent needs to choose an action $a_t \in A_t$ to take. Note that in principle, any agent could be adapted to use this approach, since we simply inject actions from the symbolic modules into the environment action space. At a given time step, our approach checks if a_t is a valid symbolic action. If $a_t \in A_t^m$ (e.g. *div 22 11* in Figure 1), the symbolic module will generate the next observation o_{t+1}, otherwise the text game environment will take a_t and generate o_{t+1} (e.g. *take 2 bananas* in Figure 1).

4 Environments and Symbolic Modules

We evaluate our approach to neurosymbolic reasoning using four text game benchmark environments centered around pick-and-place tasks, including one existing benchmark and three new developed for this work. Each environment supports parametric variation to generate many different games. These environments are outlined below, with additional details and example playthroughs found in APPENDIX B. All environments were implemented using the TEXTWORLDEXPRESS game engine (Jansen and Côté, 2022).

Text World Common Sense (TWC): A benchmark common sense reasoning task (Murugesan et al., 2021) where agents must collect objects from the environment (e.g. *dirty socks*), and place those objects in their canonical common sense locations (e.g. *washing machine*). The symbolic module for this game allows agents to query a knowledge base of *(subject, relation, object)* triples (e.g. *(cushion, hasCanonicalLocation, sofa)*).

MapReader: A navigation-themed pick-and-place game similar to Coin Collector (Yuan et al., 2018). An agent starts in a random location (e.g. *the kitchen*), and is provided with a target location (e.g. *the garage*). The agent must navigate to the target location, pick up a coin, then return to the starting location and place it in a box. The agent is further provided with a map that can be used for efficient route planning. The navigation symbolic module paired with this environment scrapes the observation space for location information (e.g. *you are*

Knowledge Base Module
> *query cushion* cushion located sofa cushion located armchair
Navigation Module
You are currently in the kitchen. > *next step to living room* The next location to move to is: hallway.
Arithmetic Module
> *mul 3 6* Multiplying 3 and 6 results in 18.
Sorting Module
> *sort ascending* The objects in ascending order are: 8mg of steel, 2g of iron, 5kg of copper.

Table 1: Example actions (inputs) and responses from the four symbolic modules investigated in this work.

currently in the kitchen), and both complete (e.g. *the map*) or partial (e.g. *to the north you see the hallway*) spatial connection information.

Arithmetic: A math-themed task, where agents must read and solve a math problem in order to know which object from a set of objects to pick-and-place. An example problem is *"take the bundle of objects that is equal to 3 multiplied by 6, and place them in the answer box"*, where the agent must complete the task by choosing *18 apples*. Distractor objects are populated with quantities that correspond to performing the arithmetic incorrectly (e.g. *3 oranges*, corresponding to subtracting 3 from 6). We pair the arithmetic game with a calculator module capable of performing addition, subtraction, multiplication, and division.

Sorting: A sorting-themed game where the agent begins in a room with three to five objects, and is asked to place them in a box one at a time in order of increasing quantity. To add complexity, quantities optionally include units (e.g. *5kg of copper, 8mg of steel*) across measures of volume, mass, or length. The sorting game is paired with a module that scrapes the observation space for mentions of objects that include quantities, and sorts these in ascending or descending order on command.

4.1 Symbolic Modules

Examples of symbolic modules and their responses are provided in Table 1. The number of valid actions injected by each module varies between 2 from the sorting module (*ascending/descending*) to over 500 from the knowledge base look-up (one for each object and its canonical locations present in the knowledge base). Symbolic modules were implemented in PYTHON as a wrapper around the TEXTWORLDEXPRESS API, allowing modules to monitor observations from the environment, inject actions, and provide responses for any actions they recognized as valid.

5 Models

In this section, we introduce the reinforcement learning and behavior cloning agents used in our experiments. Additional details and hyperparameters are provided in APPENDIX A.

Deep Reinforcement Relevance Network (DRRN): The DRRN (He et al., 2016) is a fast and strong reinforcement learning baseline that is frequently used to deliver near state-of-the-art performance in a variety of text games (e.g. Xu et al., 2020; Yao et al., 2020; Wang et al., 2022). At each step, the DRRN separately encodes the observation and candidate actions using several GRUs (Cho et al., 2014). A Deep Q-Network is then used to estimate Q-values for each *(observation, candidate action)* pair. The candidate action with the highest predicted Q-value will be chosen as the next action.

Behavior Cloning: Behavior cloning (Torabi et al., 2018) is a form of imitation learning similar to the Decision Transformer (Chen et al., 2021) that models reinforcement learning as a sequence-to-sequence problem, predicting the next action given a series of previous observations. We follow the strategy of Ammanabrolu et al. (2021) in adapting behavior cloning to text games, where the model input at step t includes the task description, current state observation, previous action, and previous state observation $(d, o_t, a_{t-1}, o_{t-1})$. During training, the agent is fine-tuned on gold trajectories, where the training target is to generate action a_t from the gold trajectories. During evaluation, the agent performs inference online in the text game environment. For experiments reported here, we used a T5-base model (Raffel et al., 2020).

5.1 Oracle Agents and Gold Trajectories

To generate training data for the behavioral cloning model, we implement oracle agents that generate optimal and generalizable solution trajectories for each benchmark. For example, an oracle agent for an arithmetic game always reads the math problem, picks up the object with the same quantity as the

	DRRN				Behavior Cloned Transformer			
	Baseline		NeuroSymbolic		Baseline		NeuroSymbolic	
Benchmark	Score	Steps	Score	Steps	Score	Steps	Score	Steps
MapReader	0.02	50	0.02	50	0.71	27	**1.00**	**10**
Arithmetic	0.17	10	0.14	7	0.56	5	**1.00**	**5**
Sorting	0.03	21	0.03	18	0.72	7	**0.98**	**8**
TWC	0.57	27	0.37	34	0.90	6	**0.97**	**3**
Average	0.20	27	0.14	27	0.72	11	**0.99**	**7**

Table 2: Average model performance across 100 games in the unseen test set. *Scores* are normalized to between 0 and 1 (higher is better), while *steps* represents the number of steps an agent takes in the environment (lower is better). Neurosymbolic performance reflects when models have access to symbolic modules in their action space.

math problem answer, then places that object in the answer box. For experiments using symbolic modules, we further insert appropriate module actions when the agent requires that information to complete the next step – for example, using the calculator module after reading the math problem in the arithmetic game.

6 Results and Discussion

The results of both DRRN and behavior cloning experiments across each benchmark are shown in Table 2. We report the average model performance across 100 games in the unseen test set. The DRRN achieves a low average performance of 0.20 without modules, while adding symbolic modules into the action space does not improve performance. In contrast, the behavior cloned T5 model has a moderate average performance of 0.72 without modules, while adding symbolic modules increases average task performance to 0.99, nearly solving each task. Symbolic modules also make the behavior cloned agent more efficient, reducing the average steps required to complete the tasks from 11 to 7, matching oracle agent efficiency.

Why does behavior cloning perform well? The baseline behavior cloned transformer achieves moderate overall performance, likely owing at least in part due to its use of gold trajectories for training. Large pretrained transformers contain a variety of common sense knowledge and reasoning abilities (Zhou et al., 2020; Liu et al., 2022c) which likely contributes to the high performance on TWC, where the model only needs to match objects with their common sense locations. In contrast, while transformers have some arithmetic abilities, their accuracy tends to vary with the frequency of specific tokens in the training data (Razeghi et al., 2022), likely causing the modest performance on the Arithmetic game. Here, we show that instead of increasing the size of training data, transformers can be augmented with symbolic modules that perform certain kinds of reasoning with high accuracy. Compared to the DRRN, the presence of gold trajectories for training allows the behavior cloned transformer to efficiently learn how to capitalize on the knowledge available from those modules.

Why does the DRRN perform poorly? We hypothesize that two considerations make these tasks difficult for the Deep Reinforcement Relevance Network. The model frequently tries to select actions that lead to immediate reward (such as immediately picking the correct number of objects in the arithmetic game), without having first done the prerequisite actions (like reading or solving the math problem) that would naturally lead it to select that action. This creates an ungeneralizable training signal, causing the model to fail to learn the task. In addition, the action spaces for each game are generally large – baseline games contain between 5 and 30 possible valid actions at each step (see Table 4 in the APPENDIX), resulting in up to 24 million possible trajectories up to 5 steps, which is challenging to explore. Inspired by Liu et al. (2022a), our future work will aim to overcome these limitations, and allow reinforcement learning models to learn to efficiently and effectively exploit information from symbolic modules.

How does performance compare against other agents? While most environments used in this work are new, TEXTWORLD COMMON SENSE is an existing benchmark. Figure 3 compares the Neurosymbolic Behavior Cloned Transformer against recent models that use a combination of reinforcement learning, logic, knowledge resources, and case-based reasoning. While the performance is not directly comparable – here, we use the TEXTWORLDEXPRESS reimplementation of TWC with supervised learning, while other models use

Model	Score	Steps
SceneIt (Murugesan et al., 2022)	0.88	20
Bike+CBR (Atzeni et al., 2022)	0.93	17
SceneGraph (Tanaka et al., 2022)	0.91	17
IG (Basu et al., 2021)	0.92	13
BCT Baseline (Ours)	0.90	6
BCT+NeuroSymbic (Ours)	**0.97**	**3**

Table 3: A comparison of performance on TWC on unseen games on the "easy" setting. Note that models may not be directly comparable, as this work uses the TEXTWORLDEXPRESS reimplementation of TWC, and supervised learning. *Scores* are normalized to between 0 and 1 (higher is better), while *steps* represents the number of steps an agent takes in the environment (lower is better).

the original implementation with a mix of reinforcement learning and case-based reasoning – we can make the high-level observation that the performance of both the baseline and Neurosymbolic Behavior Cloned Transformer meets or exceeds the scores of previous models, while generating paths that are more efficient – by a factor of up to 7x.

7 Conclusion

In this paper, we present an approach to neurosymbolic reasoning for text games using action space injection that can be easily adapted to existing text game environments. For models that are capable of exploiting the information provided by the symbolic modules, this technique allows agents to inexpensively augment their reasoning skills to solve more complex tasks. We empirically demonstrate this approach can substantially increase task performance on four benchmark games using a behavior cloned transformer.

Limitations

Two assumptions highlight core limitations in the scope of our results for augmenting models with neurosymbolic reasoning: the privileged access to a list of valid actions, and the use of gold trajectories for training the behavior cloned transformer.

Valid Actions: One of the central challenges with text games is that the space of possible action utterances is large, and text game parsers recognize only a subset of possible actions (e.g. *take apple on the table*) while being unable to successfully interpret a broader range of more complex utterances (e.g. *take the red fruit near the fridge*). As a result, nearly all contemporary models (e.g. Ammanabrolu and Hausknecht, 2020; Adhikari et al., 2020; Murugesan et al., 2021) make use of the *valid action aid* (Hausknecht et al., 2020), where at a given step the model is provided with an exhaustive list of possible valid actions from the environment simulator, from which one action is chosen. The models presented here similarly use this aid. The DRRN functions essentially as a ranker to select the most probable next action. The behavior cloned transformer generates a candidate action that is aligned using cosine similarity with the list of valid actions, where the action with the highest overlap is chosen as the next action. Overcoming the *valid action aid* will generally require either more complex simulation engines capable of interpreting a wider variety of intents from input actions, or models that learn sets of valid actions from a large amount of training data – though these generally demonstrate lower performance than those using valid actions (e.g. Yao et al., 2020).

Gold Trajectories: In this work we demonstrate a substantial improvement in the performance of a behavior cloned transformer when augmented with neurosymbolic reasoning, but this requires the use of gold trajectories demonstrating the use of those symbolic modules. Gold training data is not available in many reinforcement learning applications, and the model comparison we perform (DRRN versus behavior cloning) is meant to highlight the capacity for the behavior cloned model to learn to make use of symbolic modules through gold demonstrations, rather than to suggest the DRRN is incapable of this. In future work, we aim to develop training procedures to allow models that do not have the benefit of using gold trajectories to make use of symbolic modules.

Ethics Statement

Broader Impacts: As noted by Ammanabrolu and Riedl (2021), the ability to perform long-term multi-step reasoning in complex, interactive, partially-observable environments has downstream applications beyond playing games. Text games are platforms upon which to explore interactive, situated communication such as dialogue. Although reinforcement learning is applicable to many sequential decision making domains, our setting is most relevant to creating agents that affect change via language. This mitigates physical risks prevelant in robotics, but not cognitive and emotional risks, as any system capable of generating natural language is capable of biased language use (Sheng et al., 2021).

Intended Use: The method described in this paper involves fine-tuning a large pretrained transformer model. The data generated for fine-tuning was generated by gold agents, and not collected from human participants. The trained models are intended to operate on these benchmark tasks that assess reasoning capacities in navigation, arithmetic, and other common sense competencies. Large language models have been shown to exhibit a variety of biases (e.g. Nadeem et al., 2021) that may cause unintended harms, particularly (in the context of this work) in unintended use cases.

Computation Time: Training large models can involve a large carbon footprint (Strubell et al., 2019), or decrease the availability of a method due to the barriers in accessing high performance compute resources. The proposed technique can reduce the need for large models by augmenting smaller models with more complex reasoning through symbolic modules. The behavior cloning experiments achieve strong performance with T5-base, highlighting the capacity of modest models that can be run with workstation GPUs to be better exploited for complex reasoning tasks.

A Appendix: Experiment Details

A.1 Training and evaluation sets

For each game, we randomly generate 100 parametric variations for each of the train, development, and test sets. To encourage and evaluate generality, problems are unique across sets – for example, arithmetic problems (for the Arithmetic game) or task objects (for TWC) found in the training set are not found in the development or test sets.

A.2 Hyperparameters

Following standard practice (e.g. (Wang et al., 2022; Xu et al., 2020; Hausknecht et al., 2020)), the DRRN models are trained for 100k steps. We parallelly train DRRN on 16 environment instances with five different random seeds and the average results are reported. The behavior cloned transformers are trained for between 2 and 20 epochs, with the best model (as evaluated on the development set) used for evaluating final performance on the test set. Trained models are evaluated on all 100 parametric variations in the development or test set. Environments are limited to 50 steps, such that if the agent exceeds this many steps without reaching an end state, the score at the last step is taken to be the final score, and the environment resets. Model training time varied between 1 hour and 12 hours, with the TWC model that includes a large number of symbolic module actions requiring the largest training time.

A.3 Implementation details

We make use of an existing DRRN implementation[2] and adapted it to the TEXTWORLDEXPRESS environment. At each step, the current game state observation, task description, inventory information, and the current room description are concatenated into one string and encoded by a GRU. All

	No Modules			With Symbolic Modules		
Benchmark	Min	Avg	Max	Min	Avg	Max
MapReader	4	6.2	22	6	9.3	26
Arithmetic	9	14.3	52	17	21.5	53
Sorting	5	9.3	35	7	11.0	37
TWC	3	6.3	14	544	547.8	561
Average	5.3	9.0	30.8	143.5	147.4	169.3

Table 4: The minimum, mean, and maximum number of valid actions per step, for each benchmark. Values represent averages determined using a random agent that is run to 50 steps for on 10 training episodes per benchmark.

candidate actions are encoded by another GRU. The Q-value of each encoded (observation, candidate action) pair is then estimated by a Q-network consists of two linear layers. During training, the next action is sampled from all candidate actions based on the estimated Q-values. During evaluation, the action with the highest estimated Q-value is chosen as the next action.

For the behavior cloned transformer, the input string of the T5 model at step t are formatted as:

d **</s> OBS** o_t **</s> INV** o_t^{inv} **</s> LOOK** o_t^{look} **</s> <extra_id_0> </s> PACT** a_{t-1} **</s> POBS** o_{t-1} **</s>**

where d is the task description, **</s>** and **<extra_id_0>** are the special tokens for separator and mask for text to generate used by the T5 model, **OBS**, **INV**, **LOOK**, **PACT**, and **POBS** are the special tokens representing observation o_t, inventory information o_t^{inv}, the current room description obtained by the "look around" action o_t^{look}, previous action a_{t-1}, and previous observation o_{t-1}, respectively. We use beam search to generate the top 16 strings from the T5 model, and choose the first string that is a valid action as the action to take. In the case where the model does not generate an exact match, we use cosine similarity to pick the valid action that has the highest unigram overlap with an action generated by T5.

B Environments and Symbolic Modules

Action Space: The number of valid actions per step for each benchmark is shown in Table 4, with these values collected by a random agent that runs for 50 steps across 10 training episodes. Environments contain an average of 9 valid actions per step (range 5 to 30), not including actions injected from the symbolic modules. After adding the module actions, the action space becomes up to twice as large for the MapReader, Arithmetic, and Sorting benchmarks. The knowledge base module for TWC adds approximately 530 actions, substantially increasing the action space.

Text World Common Sense (TWC) Game

Task Description: Your task is to pick up objects, then place them in their usual locations in the environment.

You are in the corridor. In one part of the room you see a shoe cabinet that is closed. There is also **a white coat**. You also see a key holder, that has nothing on it. In another part of the room you see a hat rack, that has nothing on it. In one part of the room you see **a coat hanger**, that has nothing on it. There is also a umbrella stand, that has nothing on it.
Inventory:
Your inventory is currently empty.
> *query* ***white coat***

The results are:
white coat located **coat hanger**
white coat located wardrobe
Inventory:
Your inventory is currently empty.
> *take* ***white coat***

You take the **white coat**.
Inventory:
a white coat
> *put* ***white coat*** *in* ***coat hanger***

Game completed.

Table 5: An example of a Text World Common Sense (TWC) game. *Actions* for the solution are italicized. Relevant **task objects** and **target locations** are bolded, while distractor locations are underlined. Symbolic module actions and their responses are highlighted in *blue*.

B.1 Text World Common Sense (TWC)

A benchmark common sense reasoning task where agents must collect objects from the environment (e.g. *dirty socks*) and place them in their canonical locations (e.g. *washing machine*). We use the TEXTWORLDEXPRESS implementation of the original environment (Murugesan et al., 2021), in a setting analogous to easy difficulty, where the agent must pick and place one misplaced item in the environment. The agent receives a score of 0.5 for picking up the object, and 1.0 for placing it in the correct location. Table 5 shows an example of the TWC Game in which the agent places a clean shirt in the wardrobe with the help of querying the

Arithmetic Game

Task Description: Your first task is to solve the math problem. Then, pick up the item with the same quantity as the math problem answer, and place it in the box.

```
You are in the kitchen. In one part of the room you see a fridge that is closed. There is also a dining chair that has 11 tangerines, 33 papayas, 242 strawberries, and 20 peaches on it. You also see a box, that is empty. In another part of the room you see a math problem. In one part of the room you see a dishwasher that is closed. There is also a trash can that is closed. You also see an oven. In another part of the room you see a cutlery drawer that is closed. In one part of the room you see a stove. There is also a kitchen cupboard that is closed. You also see a counter that has 6 oranges, and 2 bananas on it.
Inventory:
  Your inventory is currently empty.
> take math problem

You take the math problem.
Inventory:
  a math problem
> read math problem

Your task is to solve the following math problem: divide 22 by 11. Then, pick up the item with the same quantity as the answer, and place it in the box.
Inventory:
  a math problem
> div 22 11

The result of dividing 22 by 11 is 2.
Inventory:
  a math problem
> take 2 bananas

You take the 2 bananas.
Inventory:
  a math problem
  2 bananas
> put 2 bananas in box

Game completed.
```

Table 6: An example Arithmetic game. *Actions* for the solution are italicized. Relevant **task objects** are bolded, while distractor objects are underlined. Symbolic module actions and their responses are highlighted in *blue*.

common sense location of a clean shirt.

Knowledge Base Module: We pair TWC with a symbolic module that provides queries to a simple knowledge base of <*object, hasCanonicalLocation, container*> triples. The symbolic module generates and accepts actions of the form QUERY <QUERY TOKENS>, where <QUERY TOKENS> corresponds to all object and container names in the knowledge base. This results in an increase of approximately 530 actions in the action space.

B.2 Arithmetic Game

The Arithmetic game requires agents to read a math problem, solve it, then perform a pick-and-place task based on the answer. For example, the agent may read the math problem (*"Take the bundle of objects that is equal to 3 multiplied by 6, and place them in the box"*), and must then perform the arithmetic then *take 18 apples* and place them in the answer box. Distractor objects are populated corresponding to performing the arithmetic incorrectly (for example, including 3 oranges, corresponding to subtracting 3 from 6, and 2 pears, corresponding to 6 divided by 3), with the condition that results are positive integer values. Agents receive a score of 0.5 for picking up the correct object, and 1.0 for completing the task successfully. An example playthrough of the Arithmetic game is in Table 6.

Arithmetic Module: We pair the Arithmetic game with an Arithmetic module that adds actions for addition, subtraction, multiplication, and division. To reduce the complexity of the action space, only actions with arguments from the current math problem are enumerated (e.g. *add 3 6, sub 3 6, sub 6 3, mul 3 6, div 3 6, div 6 3*).

B.3 Sorting Game

The sorting game is a pick-and-place game that presents an agent with 3 to 5 objects, and asks the agent to place them in an answer box one at a time based on order of increasing quantity. To add complexity to the game, quantities optionally include units (e.g. *5kg of copper, 8mg of steel, 2g of iron*) across measures of volume, mass, or length. The agent score is the normalized proportion of objects sorted in the correct order, where perfect sorts receive a score of 1.0, and errors cause the score to revert to zero and the game to end. An example playthrough of the Sorting game is in Table 7.

Sorting Module: The sorting module monitors observations for mentions of objects (nouns) that include quantities, while also interpreting and normalizing quantities based on known units. The module injects two actions: sort ascending, and sort descending, that provides the user with a sorted list of objects.

B.4 MapReader Game

MapReader is a navigation oriented pick-and-place game similar to Coin Collector (Yuan et al., 2018), with the added complexity that the agent is provided with a map of the environment that can be used to more efficiently navigate. Environments and their maps are randomly generated to contain up to 15 locations drawn from 50 locations in Coin Collector. The agent begins in a randomly chosen location, and is asked to move to a target location (e.g. *the kitchen*), take a coin, then return to the starting location and place it in a box. Target locations are randomly chosen to be between 1 and 4 steps from the starting location. The most efficient solution method is to read the map, determine the shortest path between the agents current location

Sorting Game

Task Description: Your task is to sort objects by quantity. First, place the object with the smallest quantity in the box. Then, place the objects with the next smallest quantity in the box, and repeat until all objects have been placed in the box.

You are in the kitchen. In one part of the room you see a fridge that is closed. There is also a counter that has **15kg of cedar**, and **21kg of marble** on it. You also see a dining chair that has **25g of oak**, and **47g of brick** on it. In another part of the room you see a box, that is empty. In one part of the room you see a dishwasher that is closed. There is also a trash can that is closed. You also see an oven. In another part of the room you see a cutlery drawer that is closed. In one part of the room you see a stove. There is also a kitchen cupboard that is closed.
Inventory:
Your inventory is currently empty.
> *sort ascending*

The observed items, sorted in order of increasing quantity, are: **25 g of oak**, **47 g of brick**, **15 kg of cedar**, **21 kg of marble**.
Inventory:
Your inventory is currently empty.
> *take **25g of oak***

You take the **25g of oak**.
Inventory:
25g of oak
> *put **25g of oak** in box*

You put the **25g of oak** in the box.
Inventory:
Your inventory is currently empty.
> *take **47g of brick***

You take the **47g of brick**.
Inventory:
47g of brick
> *put **47g of brick** in box*

You put the **47g of brick** in the box.
Inventory:
Your inventory is currently empty.
> *take **15kg of cedar***

You take the **15kg of cedar**.
Inventory:
15kg of cedar
> *put **15kg of cedar** in box*

You put the **15kg of cedar** in the box.
Inventory:
Your inventory is currently empty.
> *take **21kg of marble***

You take the **21kg of marble**.
Inventory:
21kg of marble
> *put **21kg of marble** in box*

Game completed.

Table 7: An example Sorting game. *Actions* for the solution are italicized. Relevant **task objects** are bolded. Symbolic module actions and their responses are highlighted in *blue*.

and target location, follow that path to retrieve the coin, then follow the path in reverse to return the coin to the starting location. The agent receives a score of 0.5 for retrieving the coin, and 1.0 for placing the coin in the box at the start location. An example of the MapReader game is shown in Table 8.

Navigation Module: We pair MapReader with a navigation module that scrapes the environment for both complete map information (obtained if the agent chooses to read the map), as well as partial information such as the current location (e.g. *"You are in the kitchen"*) and connecting locations (e.g. *"To the north you see the living room"*) that can be used to incrementally build a map. The module adds actions that, if selected, provide the next step in the shortest path to navigate to all known locations in the environment (e.g. *next step to living room*, *next step to garage*, ...).

MapReader Game

Task Description: Your task is to take the coin that is located in **the laundry room**, and put it into the box found in **the foyer**. A map is provided, that you may find helpful.

You are in **the foyer**. In one part of the room you see a box, that is empty.

To the East you see the corridor.
Inventory:
a map
> *read map*

The map reads:
The living room connects to the backyard and corridor.
The garage connects to the driveway.
The laundry room connects to the corridor.
The backyard connects to the living room, alley, kitchen and sideyard.
The bedroom connects to the corridor.
The sideyard connects to the backyard and driveway.
The kitchen connects to the bathroom, pantry and backyard.
The supermarket connects to the alley.
The foyer connects to the corridor.
The pantry connects to the kitchen.
The driveway connects to the sideyard, alley and garage.
The street connects to the alley.
The alley connects to the driveway, supermarket, street and backyard.
The bathroom connects to the kitchen.
The corridor connects to the living room, foyer, bedroom and laundry room.
Inventory:
a map
> *next step to laundry room*

The next location to go to is: corridor
Inventory:
a map
> *move east*

You are in the corridor. In one part of the room you see a shoe cabinet that is closed. There is also a key holder, that has nothing on it. You also see a hat rack, that has nothing on it. In another part of the room you see a coat hanger, that has nothing on it. In one part of the room you see a umbrella stand, that has nothing on it.
To the North you see the laundry room. To the South you see the living room. To the East you see the bedroom. To the West you see **the foyer**.
Inventory:
a map
> *next step to **laundry room***

The next location to go to is: **laundry room**
Inventory:
a map
> *move north*

continued...

You are in **the laundry room**. In one part of the room you see a coin. There
is also a bench, that has nothing on it. You also see a washing machine that is closed. In another part of the room you see a work table, that has nothing on it. In one part of the room you see a laundry basket, that has nothing on it. There is also a clothes drier that is closed.
To the South you see the corridor.
Inventory:
a map
> *take coin*

You take the coin.
Inventory:
a map
a coin
> *next step to **foyer***

The next location to go to is: corridor
Inventory:
a map
a coin
> *move south*

You are in the corridor. In one part of the room you see a shoe cabinet that is closed. There is also a key holder, that has nothing on it. You also see a hat rack, that has nothing on it. In another part of the room you see a coat hanger, that has nothing on it. In one part of the room you see a umbrella stand, that has nothing on it.

Bridging the Gap Between BabelNet and HowNet: Unsupervised Sense Alignment and Sememe Prediction

Xiang Zhang, Ning Shi, Bradley Hauer, Grzegorz Kondrak
Alberta Machine Intelligence Institute (Amii), Department of Computing Science
University of Alberta, Edmonton, Canada
`{xzhang23,ning.shi,bmhauer,gkondrak}@ualberta.ca`

Abstract

As the minimum semantic units of natural languages, sememes can provide interpretable representations of concepts. Despite the widespread utilization of lexical resources for semantic tasks, the use of sememes is limited by a lack of available sememe knowledge bases. Recent efforts have been made to connect BabelNet with HowNet by automating sememe prediction. However, these methods depend on large manually annotated datasets. Instead, we propose to use sense alignment via a novel unsupervised and explainable method. Our method consists of four stages, each relaxing predefined constraints until a complete alignment of BabelNet synsets to HowNet senses is achieved. Experimental results demonstrate the superiority of our unsupervised method over previous supervised ones by an improvement of 12% overall F1 score, setting a new state of the art. Our work is grounded in an interpretable propagation of sememe information between lexical resources, and may benefit downstream applications which can incorporate sememe information.

1 Introduction

Sememes are the minimum semantic units of human languages (Bloomfield, 1926). The theory of semantic primitives (Wierzbicka, 1996a) hypothesizes that the meaning of a word in any language can be decomposed into a finite set of language-independent sememes. For example, the English noun *plant* has distinct senses that correspond to the "factory" and "vegetation" concepts, respectively. The former can be represented by the sememes "industrial", "produce", and "institute/place", and the latter by "crop", "tree", and "flower/grass". (See Figure 2 for additional examples.) Although sememes provide a way of representing concepts, their incorporation into natural language processing (NLP) has been limited by a lack of available sememe resources for commonly used sense inventories. Tremendous efforts have been made to construct sememe knowledge bases (KBs) manually. One of the most widely used is HowNet (Dong and Dong, 2003), which unfortunately is limited to only two languages: English and Chinese.

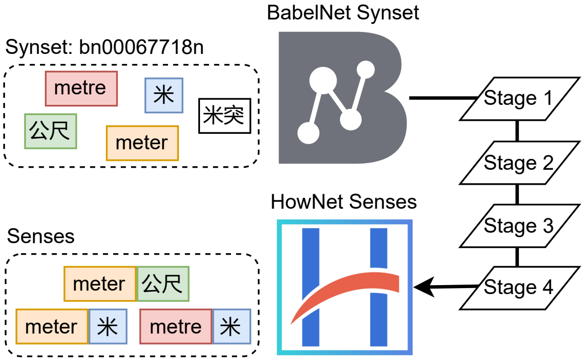

Figure 1: Given a BabelNet synset as input, our alignment algorithm identifies a set of corresponding HowNet senses. The algorithm consists of four stages which progressively relax alignment constrains.

A related problem is linking lexical resources to one another. As manually creating semantic knowledge bases remains a challenging and costly process, BabelNet (Navigli and Ponzetto, 2012) was instead created by combining WordNet (Miller, 1995), Wikipedia, and other resources. While BabelNet covers hundreds of languages, it does not include sememe information. Previous work on automatically predicting sememes for BabelNet concepts has depended on large human labeled data (Qi et al., 2020, 2022). Various systems for automatically aligning word senses across heterogeneous resources have been proposed to mitigate this issue (Meyer and Gurevych, 2011; Pilehvar and Navigli, 2014; Bao et al., 2022), but those methods do not leverage the unique structure of HowNet, which differs from other lexical databases.

In this work, rather than attempting to predict sememes directly, as in prior work, we instead attempt to align BabelNet concepts and HowNet senses. Since each HowNet sense is annotated with

Synset ID: 00035680n

Chinese: 英尺，尺
(英美制长度单位。1英尺合12英寸，合0.3048米。)
English: foot, feet, ft
(The foot, abbreviation and IEEE standard symbol: ft, is a unit of length in the British imperial and United States customary systems of measurement.)

Synset ID: 00035679n

Chinese: 脚，足，脚部
(足，又称脚，解剖学上指陆地脊椎动物腿的末端、支撑该生物的部分。)
English: foot
(The part of the leg of a human being below the ankle joint.)

(a) (b)

Figure 2: A comparison of the representations of HowNet senses and BabelNet concepts.

sememes (c.f., Figure 2), correctly mapping a BabelNet concept to a HowNet sense will effectively add sememe information to the corresponding BabelNet synset, as well as associate the HowNet sense with information unique to BabelNet, such as synonymy information. We propose a fully unsupervised algorithm which achieves reliable and stable results, and produces fully explainable mappings. The ability to identify precisely why a particular sememe was associated with a given concept is a unique strength of our method, which we believe will facilitate analysis and development of downstream applications of our work.

The results of our experimental evaluation provide evidence that our unsupervised approach substantially outperforms previous supervised methods on the BabelNet sememe prediction task by up to 12% F-score. This also indirectly demonstrates the high accuracy of the generated alignment between BabelNet and HowNet, which we make available to facilitate further research.[1]

Our contributions are as follows:

- We propose the first method for aligning BabelNet synsets to HowNet senses, adding new information to both resources. Our method is unsupervised and explainable.
- We set a new state of the art for sememe prediction task on the BabelSememe dataset.
- We provide an API for identifying the HowNet senses and their sememes for any BabelNet synset that contains English or Chinese words.
- We perform a detailed analysis and ablation study of the results, focusing on the impact of the differences between HowNet and BabelNet.

2 Related Work

In this section, we first describe the two multilingual knowledge bases, and then discuss the tasks of sense alignment and sememe prediction.

2.1 Multilingual knowledge bases

Our main focus is on the sense alignment between BabelNet and HowNet (Figure 2).

BabelNet (Navigli and Ponzetto, 2012) is a multilingual sense inventory created by automatically combining various knowledge bases including WordNet and Wikipedia. The most recent version covers over 500 languages and contains 1.4 billion word senses. Following the WordNet model, words which are interchangeable in some context are grouped into synonym sets, or *synsets*. Each synset is associated with a unique lexical concept or named entity, and contains all the words which can express that concept or refer to that entity. In BabelNet, the *senses* of a word correspond to the concepts that it can express; that is, each sense of a word corresponds to a synset which contains the word, and shares its meaning with the other words in that synset. As shown in Figure 2, each synset has a unique ID and consists of all word senses that share the same meaning across various languages. Each synset is also associated with a gloss, and, optionally, example sentences or images.

HowNet is a sememe-based knowledge base for both Chinese and English. Each HowNet sense contains a unique Chinese-English word pair, associated with one or more sememes, as shown in Figure 2. Note that the meaning of the term *sense* is different in HowNet and BabelNet, and thus multiple HowNet senses may correspond to a single BabelNet concept. HowNet contains more than 2K

---

[1] Our code and used data are available at: `https://github.com/senseAlign/BabelNet_2_HowNet`

sememes, created by human experts, and more than 100K Chinese and 950K English words. Over its more than 20 years of development, HowNet has become one of the most popular knowledge base in the Chinese NLP community (Dong and Dong, 2003), and has been applied to downstream tasks such as word sense disambiguation (Zhang et al., 2005; Duan et al., 2007; Zhang et al., 2022), word representation learning (Niu et al., 2017), language modeling (Gu et al., 2018), textual adversarial attack (Zang et al., 2020; Qi et al., 2021), text matching (Lyu et al., 2021), and sememe prediction (Qi et al., 2020, 2022).

2.2 Sense aligning

The task of aligning lexical knowledge bases consists of associating entries in one resource with one or more entries in another. As described above, BabelNet was created by associating Wikipedia articles with WordNet senses. As another example, Open Multilingual WordNet (Bond and Foster, 2013) was created by linking wordnets covering various languages. Gurevych et al. (2012) create a sense similarity measure to align WordNet senses with entries in the German OmegaWiki. McCrae and Cillessen (2021) conduct an alignment between WordNet synsets and entities in Wikidata. Bao et al. (2022) present a translation-based method for aligning BabelNet concepts to entries in CLICS and OmegaWiki. Combining knowledge bases in this way provides additional information, and allows knowledge-based methods to be applied to more languages and tasks.

Various approaches to sense alignment between HowNet and the other KBs have also been investigated in prior work. Carpuat et al. (2002) use the tf-idf scores to align the senses in HowNet and synsets in WordNet. Chen and Fung (2004) present a method for aligning HowNet and FrameNet mapping by applying word sense disambiguation. Sornlertlamvanich et al. (2005) propose another algorithm for aligning HowNet and FrameNet, which is based on constructing feature vectors.

Besides, more general methods to link two or more lexical resources (ontologies) have been examined in prior work. McCrae and Cillessen (2021) proposed the *Lexicon Model for Ontologies* (Lemon) which aims to align any amount of lexical resources by modeling a universal semantic representation. Chiarcos et al. (2013) further combine multiple linking methods including Lemon and Graph construction, based on the theory of *Resource Description Framework*, and provide the insight in unifying lexical resources. Our work focuses solely on the alignment between HowNet and BabelNet as they represent two most widely used lexical knowledge bases for English and Chinese. However, similar ideas used in the work can also be applied for the general mapping for multilingual lexical resources.

2.3 Sememe prediction

The lack of sememe information in existing multilingual KBs was highlighted by Qi et al. (2020), motivating the sememe prediction task, which aims at bridging the gap between HowNet and BabelNet by predicting a set of most related sememes for a given BabelNet synset.

Qi et al. (2020) propose a model named *Sememe Prediction for BabelNet Synsets* (SPBS), which aims to learn a representation of the input synsets. This supervised model compares the representation of the input synset B to those in the training data, which are labeled with sememes. The input synset is then assigned sememes which are most frequently associated with the synsets that are most similar to it. Intuitively, if B has a similar representation to training synsets associated with some sememe s, then SPBS will be likely to predict sememe s for B. A variant of this method, SPBS-SS, also uses synset relation information from BabelNet to improve synset representations. An ensemble method combines both SPBS and SPBS-SS representations and yields better results.

Qi et al. (2022) propose another method: *Multilingual Synonyms and Glosses as well as Images* (MSGI). This approach uses multimodal information provided by BabelNet synsets, such as images. The model combines a text encoder, image encoder and multi-label classifier.

2.4 Sememes vs. Semantic Primes

While sememes have some similarities to the concept of semantic primitives (or semantic primes), they differ in their goals and representation. The purpose of semantic primes (Wierzbicka, 1996b) is to facilitate comprehensive linguistic analysis by formulating a set of universal basic concepts that can be used to convey the meaning of any linguistic expression (Goddard, 1998). Contrariwise, the purpose of sememes is to provide information about word senses by linking them to a subset of key terms. Sememes need not convey all of the informa-

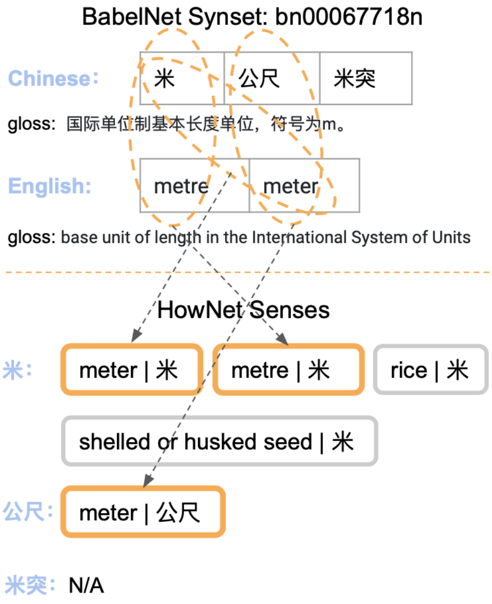

Figure 3: An illustration of the exact match algorithm (Stage 1), in which a BN synset is aligned to three different HowNet senses by comparing translation pairs.

tion about each sense. It may happen, for example, that distinct senses of distinct words may actually be associated with the same set of sememes, as in the case of apple (苹果) and banana (香蕉). While not as comprehensive as semantic primes, sememes are markedly less controversial (Fodor and Garrett, 1975), and are considered sufficient for a resource such as HowNet.

3 Methods

In this section, we introduce our method for the task of alignment between BabelNet and HowNet. Our method has four stages, each relaxing some constraint until an alignment is found. Such an alignment implicitly associates a BabelNet synset with a set of sememes from the aligned HowNet senses. We describe each of the four stages in a separate subsection.

Formally, our task is as follows: Let B be a BabelNet synset. Let $B_Z = \{z_1, \ldots, z_n\}$ be the set of Chinese words in B, and let $B_E = \{e_1, \ldots, e_m\}$ be the set of English words in B. We assume that at least one of B_Z and B_E is non-empty. The output is a set H of one or more HowNet senses that express the same concept as B.

3.1 Stage 1: Exact match

Our first stage uses a strict criterion for aligning a BabelNet synset B with HowNet senses, which is aimed at high precision rather than high coverage (later stages are aimed at improving coverage). It exploits the fact that each HowNet sense is annotated with a lexicalization in both Chinese and English, as well as the well-known observation that distinct senses of a word may translate differently (Gale et al., 1992). For each Chinese-English pair in B, that is, each $(z_i, e_j) \in B_Z \times B_E$, we check if there is a HowNet sense which has the Chinese lexicalization z_i and the English lexicalization e_j. If there is, we add that sense to H. (Figure 3 shows an overview of this stage.)

Once this stage is completed, if H is non-empty, we return it as the set of senses aligned to B. If H remains empty, we continue to Stage 2.

3.2 Stage 2: Word n-gram partial match

Every Chinese word consists of one to four characters; unlike English, each individual character has some meaning associated with it. Therefore, words that share one or more characters often share parts of their meaning. For example, a BabelNet synset for the word “延伸” (stretch) also contains the synonyms “伸长”, “伸展” and “延长”, each of which shares at least one character with “延伸”. As shown in Figure 4, the exact match approach in Stage 1 may miss the semantic correlation between such words, which reduces its coverage. We therefore propose the approach shown in Algorithm 1 to tackle such problems.

As in Stage 1, we again consider each translation pair in $(z_i, e_j) \in B_Z \times B_E$. For each such pair, we look for the HowNet sense with English word e_j, and with the Chinese word that has the maximum number of characters in common with z_i. Specifically, if z_i contains k characters, we first look for a sense which contains e_j and a Chinese word with k-1-gram in common with z_i. If such a sense is found, we add it to H. If not, we instead look for senses which have a k-2-gram in common with z_i. This partial-matching approach is explainable, unsupervised, and efficient; rather than using an uninterpretable and computationally expensive supervised language model, it instead exploits a useful property of the Chinese script. If H remains empty, we proceed to the next stage.

3.3 Stage 3: Sense information matching

Stages 1 and 2 are sufficient to find at least one HowNet sense for roughly 80% of synsets. Stage 3 attempts to map the remaining synsets by exploiting two key properties: (1) many words are

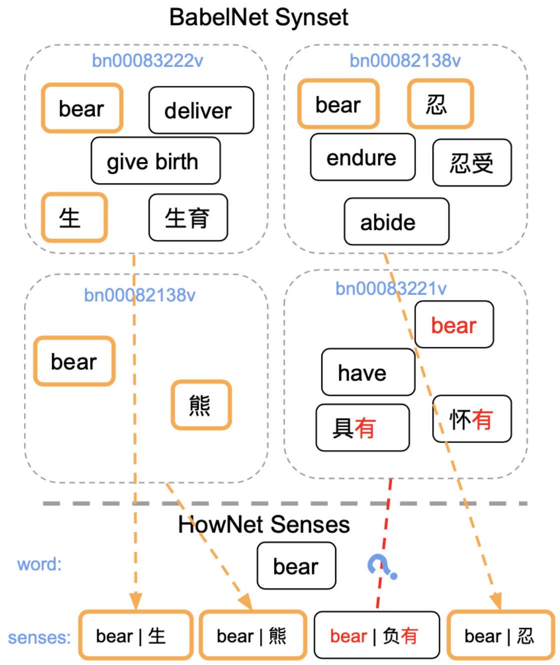

Figure 4: Example of inexact translation pairs during matching. Using exact algorithm, word "bear" has three synsets matched to some HowNet senses, while one synset is not matched despite having the same sense meaning with the unmatched HowNet sense. Note that character "有" means "have" and words "具有", "怀有" and "负有" express the same meaning in context; Stage 2 will successfully map such a synset to a sense in HowNet, as indicated by red dashed line .

monosemous in HowNet; and (2) sememes are represented as words, which can often be found among the hypernyms of a given BabelNet synset B.

If B contains any Chinese or English words that have only one sense in HowNet, such as "ultraviolet" or "haemolytic", then we assume the sense of that word in B must align to its only sense in HowNet. Monosemous words tend to be less frequent in text, but make up a substantial proportion of words in HowNet.[2] If even a single English or Chinese word in B is monosemous in HowNet, this sub-stage will add that sense to H.

If B has still not been aligned with any HowNet sense, we exploit the representation of sememes in HowNet to find an appropriate alignment. Each sememe of each sense is represented by an English word and a Chinese word, typically with a meaning that is more general than that of the senses associated with it. For example, one sense of the English word *teacher* has the following sememes: "human", "occupation", "education", and "teach". Our intuition is that these words will tend to overlap with the hypernyms of the corresponding sense in BabelNet. We therefore add to H any HowNet sense s such that s involves a word in B, and one of the sememes of s is represented by a word in a hypernym synset of B.

BabelNet only provides hypernym relations for nouns and verbs. All other words have no hypernym information, and thus can not be aligned based on sememe and hypernym agreement. We further relax our aligning condition by adding to H the HowNet senses that have any sememe overlap with each other and the English or Chinese words in the given synset. The intuition is that all words in a synset are closely related; if their HowNet senses have similar sets of sememes, we can align them to the given target synset.

3.4 Stage 4: Proper names

In our development experiments, we found that those BabelNet synsets B that could not be aligned with at least one HowNet sense by any of the first three stages were generally proper nouns. Proper nouns or named entities are represented in HowNet by a sense with the English label "ProperName" and an associated set of sememes. Therefore, the fourth and final stage of our method adds this sense to H. As the final result, the algorithm returns the set H, which contains the HowNet senses aligned to a given synset.

4 Experiments

In this section, we describe the experimental evaluation of our sense alignment algorithm. Since we are the first to propose an algorithm for aligning BabelNet and HowNet, there is no gold-annotated dataset for this task that we can use as a test set. To the best of our knowledge, the only dataset that connects BabelNet and HowNet is the BabelSememe dataset, which was constructed for the evaluation of sememe prediction models. Therefore, we evaluate our sense-alignment algorithm extrinsically on the task of sememe prediction.

In the sememe prediction task, given a BabelNet synset B, and a ground set S^* of sememes, we are required to identify a set of sememes $S \subseteq S^*$ which describe the meaning of B. Following prior work, we take the set of all sememes which appear in HowNet as S^*. The output S is then compared to a gold-standard set of sememes for B in the

---

    if $\mathcal{H} \neq \emptyset$ then
        return $\mathcal{H}$, end algorithm
    end if
end for
return $\emptyset$
```

BabelSememe dataset.

We compute S by applying our BabelNet-to-HowNet alignment algorithm, and taking the union of all sememes associated with the returned set of HowNet senses. This approach effectively reduces the task of sememe prediction to sense alignment. Since the quality of the alignment will be reflected in the accuracy of sememe prediction, the experimental results can serve as an evaluation of the sense alignment algorithm.

4.1 Experimental setup

In this section, we specify our experimental setup, including data statistics, evaluation metrics, baseline methods, and implementation details.

Data. BabelSememe (Qi et al., 2020) consists of 15,461 BabelNet synsets, each annotated with a set of HowNet sememes which comprise the meaning of the synset. These sememe sets were created manually by more than 100 bilingual (English and Chinese) human annotators. HowNet contains 2,106 sememe types; on average, 2.74 sememes assigned to each BabelNet synset. We use the existing test split, which consists of 10% of the dataset, as our test set. Since our method is unsupervised, we did not use the training or validation splits, instead developing our method on BabelNet alone, without reference to any labeled sememe prediction data.

English	Simplified	Traditional
noodles	面食	麵食
room	房间	房間
weather	天气	天氣
drink	饮	飲

Table 1: Examples in English and Chinese including both simplified and traditional versions.

Evaluation. Following previous work, we adopt mean average precision (MAP) and the F1 score and as our metrics.[3] For a given instance, a classification is positive if the synset is annotated with that sememe, or negative otherwise. MAP takes the weighted mean of the precision of each class, where each sememe is considered a separate class. The F1 score is the harmonic mean of the precision and recall of the predicted labels. Recall is the ratio of sememes correctly predicted to the number of sememes in the gold standard set, while precision is the proportion of sememes correctly predicted to the total number of sememes predicted by the method.

Comparison systems. We compare our sememe prediction results against systems from prior work, including the state of the art. In particular, we compare with three variants of SPBS model proposed by Qi et al. (2020), and five variants of MSGI model proposed by Qi et al. (2022) which we mention in Section 2. Additionally, we compare to *LR-NASARI* (Qi et al., 2020), a logistic regression model trained on NASARI embeddings (Camacho-Collados et al., 2016), and *TransE*, a relational prediction models proposed by (Bordes et al., 2013). In contrast to our unsupervised approach, all of the comparison systems are supervised, and model sememe prediction as a multi-class classification task.

Implementation details. We use the BabelNet Python API[4] with BabelNet 5.0 to retrieve English and Chinese words from synsets. We use OpenHowNet API[5] for retrieving HowNet senses and their corresponding translation pairs (Qi et al., 2019). One technical issue we encountered is the use of both simplified and traditional Chinese characters in BabelNet, likely due to the use of multiple heterogeneous resources in the construction

Table 3: Results of our method on the training, validation, and test sets.

of BabelNet. Table 1 shows some examples contrasting simplified and traditional characters. Since HowNet contains simplified Chinese characters exclusively, we use the Python `zhconv` library to convert all traditional Chinese characters into their simplified versions.

4.2 Results

The results on the BabelSememe test set are shown in Table 2. Following previous work, we report results for nouns, verbs, adjective, adverbs, as well as for all words. Our overall results outperform all prior work according to both metrics, establishing our method as the new state of the art for sememe prediction. In particular, the improvement in overall F1 score is 12% over the previous supervised state-of-the-art method, which was designed specifically for this task. These results are remarkable considering that our method is not supervised, and demonstrate its efficacy and utility.

In order to assess the generality of our method, we also report the results on the training and validation splits of the BabelSememe dataset, which are otherwise unused by our method. Table 3 shows that our results on these additional splits do not differ substantially from our results on the test set. This provides strong evidence that our method is consistent and reliable.

4.3 Stage analysis

As described in Section 3, our method consists of a sequence of four stages. In this section, we conduct additional experiments on the test set by examining the F1, MAP, and synset coverage rate (percentage of synsets that are mapped to at least one HowNet sense) of our system after every stage.

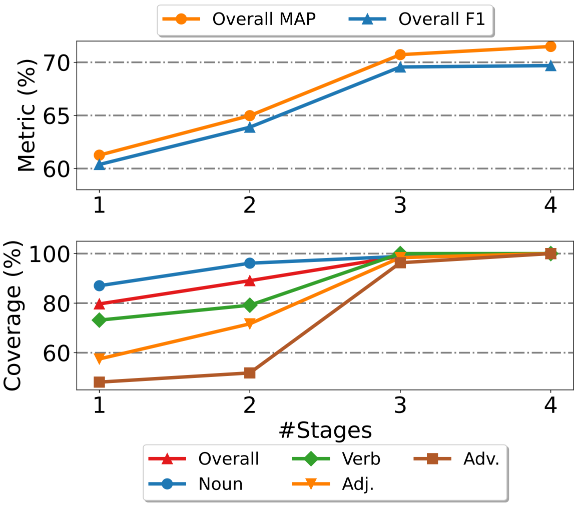

Figure 5: Experimental results for stages 1 to 4.

The results are shown graphically in Figure 5 and numerically in Table 5. We see an increasing trend in F1, MAP, and synset coverage rate with respect to the number of stages used. Stage 1 is

Stage	BableNet			HowNet	
	Synset ID	Synset EN	Synset ZH	Aligned Senses	Aligned Sememes
1	bn:00028111n	doll, dolly	洋娃娃, 玩偶	doll | 洋娃娃 doll | 玩偶	tool | 用具, recreation | 娱乐
2	bn:00002393n	alabaster, alabastar, gypsum	雪花石膏, 汉白玉	gypsum | 石膏	material | 材料, tool | 用具, medical | 医
3	bn:00040267n	geranium, cranesbil	天竺葵, 洋绣球	fish pelargonium | 天竺葵	FlowerGrass | 花草, medicine | 药物
4	bn:00048483n	Judas Iscariot, Judas	加略人犹大	ProperName | 专	ProperName | 专

Table 4: A case study of the alignment in each stage.

sufficient to cover roughly 80% of synsets, and achieve roughly 60% F1, but has particular difficulty finding HowNet senses for adjective and adverb synsets. Adding stages 2 and 3 greatly increases coverage of adjectives and adverbs respectively, with concomitant increases in F1 and MAP. Stage 4 is shown to provide marginal improvement, as almost all synsets can be assigned at least one sememe after stage 3.

4.4 Alignment analysis

To provide additional insight into the relationship between BabelNet and HowNet, we analyzed various properties of the alignment produced by our method. Theoretically, our algorithm could produce many-to-many alignments, with one BabelNet synset aligned to multiple HowNet senses, and vice versa. In practice, the average number of HowNet senses aligned to a given BabelNet synset in the BabelSememe test set is 3.99. This suggests that a single BabelNet concept is often represented by multiple HowNet senses, each of which may be labeled with different sememes. On the other hand, less than 1% of the HowNet senses were aligned to multiple BabelNet synsets (excluding the "ProperName" cases from Stage 4). This suggests that HowNet senses are no more fine grained than BabelNet synsets; in other words, if a sense distinction is made in BabelNet, it is likely made in HowNet as well.

We also analyzed the alignments for each part of speech and for each stage in our method. In Figure 6, we see that verb synsets are aligned to more senses than any other part of speech at every stage. For all parts of speech except adverbs, Stage 2 produces more mappings than any other stage. Since Stage 2 works by allowing partial matches in Chinese words (i.e. an alignment can be made on the bases of a single character shared by two Chinese words with two characters each), this suggests that the two knowledge bases often contain different Chinese words for a given concept. However, our method is still able to align them by identifying shared characters. If a sense reaches Stage 4, it will be assigned exactly one HowNet sense, the "ProperName" sense.

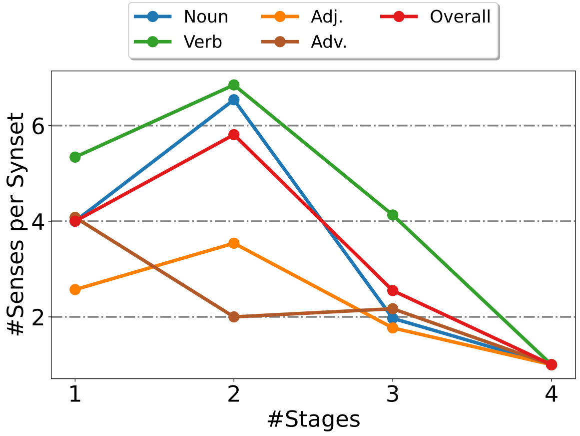

Figure 6: The average number of HowNet senses matched to each BabelNet synsets in each stage on the BabelSememe test set.

Table 4 shows example alignments from each stage. Row 1 shows that Stage 1 of our algorithm is able to correctly align the synset containing the words "doll" and "dolly" to the corresponding HowNet sense of each word. We can then use this alignment to retrieve the sememes "tool" and "recreation" for this synset. In Row 2, the synset containing the word "gypsum" does not contain any Chinese words which have HowNet senses. However, Stage 2 correctly finds a correct alignment between the BabelNet synset containing "雪花石膏" and a HowNet sense for "石膏". In Stage 3, the word "天竺葵" has only one sense in HowNet. We therefore map the BabelNet synset to that HowNet sense. Lastly, the word "Judas" has no senses in HowNet, therefore it is mapped to HowNet's "ProperName" sense in Stage 4.

POS	**Stage 1**		**Stage 2**		**Stage 3**		**Stage 4**	
	MAP	**F1**	**MAP**	**F1**	**MAP**	**F1**	**MAP**	**F1**

5 Conclusion

We have presented a novel unsupervised method for aligning two lexical-semantic knowledge bases, BabelNet and HowNet. The results of our experiments on leveraging the sense alignment for the task of sememe prediction demonstrate that our algorithm is highly effective, yielding substantially better results than state-of-the-art supervised systems designed specifically for this task. In the future, we would like to leverage sense alignment for other semantic tasks, including word sense disambiguation.

This research was supported by the Natural Sciences and Engineering Research Council of Canada (NSERC), and the Alberta Machine Intelligence Institute (Amii).

Limitations

Our proposed algorithm only works with synsets that contain at least one Chinese or English word. Although this condition is satisfied for a majority of BabelNet synsets, there remain some multilingual synsets that could not be aligned. In addition, a intrinsic evaluation of the produced alignment could not be performed because of the lack of an existing gold data set.

Abstract

We introduce the StatCan Dialogue Dataset[1] consisting of 19,379 conversation turns between agents working at Statistics Canada and online users looking for published data tables. The conversations stem from genuine intents, are held in English or French, and lead to agents retrieving one of over 5000 complex data tables. Based on this dataset, we propose two tasks: (1) automatic retrieval of relevant tables based on a on-going conversation, and (2) automatic generation of appropriate agent responses at each turn. We investigate the difficulty of each task by establishing strong baselines. Our experiments on a temporal data split reveal that all models struggle to generalize to future conversations, as we observe a significant drop in performance across both tasks when we move from the validation to the test set. In addition, we find that response generation models struggle to decide when to return a table. Considering that the tasks pose significant challenges to existing models, we encourage the community to develop models for our task, which can be directly used to help knowledge workers find relevant tables for live chat users.

1 Introduction

One of the longstanding goals in Natural Language Processing (NLP) is to develop conversational agents that assist people with concrete tasks, such as finding information in large collections of documents or booking restaurants and hotels. To aid the development of such virtual assistants, the research community is in need of benchmarks that reflect the intents and linguistic phenomena found in real-world applications. However, developing such real-world conversational datasets is challenging in the current research landscape. On the one hand, academic labs often struggle to come up with natural use cases of task-oriented dialogue agents and collect conversations with a large number of real users. Many labs have designed artificial tasks and collected conversations from crowd workers with simulated intents (Budzianowski et al., 2018; Adlakha et al., 2022; Lee et al., 2022), often leading to datasets that do not capture the linguistic challenges of production settings (de Vries et al., 2020). On the other hand, industry labs might have access to users with genuine intents (e.g., through Siri or Alexa) but rarely release such conversational

datasets due to their commercial value and user privacy concerns. Hence, we argue that the research community would benefit from a task-oriented dialogue environment where findings can be validated with real users, and, to that effect, present a unique dataset in collaboration with Statistics Canada.

Statistics Canada (StatCan) is a national statistics agency commissioned with collecting key information on Canada's economy, society, and environment. Statistics Canada conducts hundreds of surveys on virtually all aspects of Canadian life and publishes the resulting data tables on statcan.gc.ca. This website currently features 5K+ of such complex and often large data tables. Canadian citizens—and other interested individuals—come to this website to find the statistics they are looking for. The StatCan website offers a chat functionality (available in English and French) to help users in case they can not find the appropriate information.

Sourcing from these live chats, we present the StatCan Dialogue Dataset, a collection of 20K+ English and French conversations between visitors of statcan.gc.ca and agents working at Statistics Canada. Before releasing this dataset, StatCan has ran several procedures to remove Personally Identifiable Information (PII). While we observe a wide variety of user intents, ranging from table manipulation to navigation instructions, a large number of visitors use the chat functionality to find data tables on the StatCan website. Specifically, we observe 6.6K instances where agent returns a link to a data table across 4.4K conversations. In Table 1, we provide an example conversation in which an online user is looking for specific data tables.

In this work, we develop two novel tasks centered on helping users find specific tables. First, we introduce the table retrieval task, which requires a model to predict the table returned by the agent given the messages sent so far. Second, we introduce the response generation task, which requires a model to predict the agent's response given the dialogue history. For both tasks, we investigate its difficulty by establishing strong baselines and evaluating them on various metrics.

We stress that both tasks are immediately useful in a real-world setting. The table retrieval task can help agents find relevant tables faster while the response generation task may lead to a virtual agent that can return relevant tables through an online conversation. We hope that this tight connection with a real-world scenario will bring the research community more insight into the challenges of developing practical dialogue agents and lead to faster transfer of research ideas and findings.

2 Related Work

This section presents various directions related to our work. See Table 2 for a comparative summary.

Open-domain QA This is the task of answering questions using a large and diverse collection of text documents. One of the first large-scale evaluations in open-domain QA was presented at TREC-8 (Voorhees, 2001). Since then, many studies have released large-scale open-domain QA datasets: WikiQA (Yang et al., 2015) and MS MARCO (Bajaj et al., 2018) source questions from the Bing search engine, Natural Questions (NQ) (Kwiatkowski et al., 2019) from Google search, and DuReader (He et al., 2018) source questions in Chinese from Baidu. The questions come from real users and the answers are collected from the search results through crowd workers. Although those datasets have questions with genuine intent and the answer must be retrieved from a collection of documents, our dataset emphasizes the retrieval of tables (in a conversational setting) rather than free-form documents.

Table retrieval and QA Following works on tabular pre-training (Yin et al., 2020), table-to-text generation (Parikh et al., 2020) and weak supervision for semantic parsing (Herzig et al., 2020),

Dataset	Train	Valid	Test	All

Table 3: Statistics of English conversations and tables in the retrieval and generation tasks. New tables are calculated with respect to training set (see Table 11).

Chen et al. (2020) and Herzig et al. (2021) respectively propose OTT-QA and TAPAS-NQ, two novel approaches that extend open-domain QA to retrieving tables instead of documents. The former collects both the questions and answers from crowd workers and the latter extends Natural Questions by using tables from the article where the answer was taken. In both cases, the tables being retrieved are sourced from Wikipedia articles. Although our data also incorporate tabular retrieval, the tables are sourced from statcan.gc.ca, they can be significantly larger (as discussed in Appendix A.2.1), and they are being retrieved in an interactive and conversational setting.

Conversational QA Several works extended question answering to the conversational setting. CoQA (Reddy et al., 2019) and QuAC (Choi et al., 2018) introduced datasets in which multiple rounds of questions are asked about a reference passage taken from a document (such as a Wikipedia article). Subsequent works extended this setup to an open-domain setting where the reference passage is not known beforehand (Qu et al., 2020; Anantha et al., 2021; Adlakha et al., 2022). Saeidi et al. (2018) proposed a conversational QA task about regulatory texts. Aforementioned datasets are all structured in the same way: at every turn, the first speaker will ask a question, and the other speaker will give an answer. In contrast, the queries in our conversations are not restricted to questions, and the answers can be either a table, metadata, or a dialogue act.

Task-oriented Dialogue Our work is related to work on task-oriented dialogue where users converse with virtual agents to accomplish specific goals, such as booking a restaurant or resolving a customer issue. While early work has collected a dataset in a genuine information seeking setup (Hemphill et al., 1990), many recent datasets has collected them through a simulated setup (Budzianowski et al., 2018; Rastogi et al., 2020; Feng et al., 2020, 2021; Chen et al., 2021; Lee et al., 2022). Task-oriented models usually track the dialogue state by predicting dialogue acts that are specified through intents and slot-value pairs, e.g., `findRestaurants(cuisine=Italian)`. While our dataset does not provide turn-based annotations, the released conversations come with an annotated goal i.e., which data table the user was looking for. Like other goal-oriented dialogue tasks, this annotation enables us to automatically evaluate the dialogue models through a task completion metric.

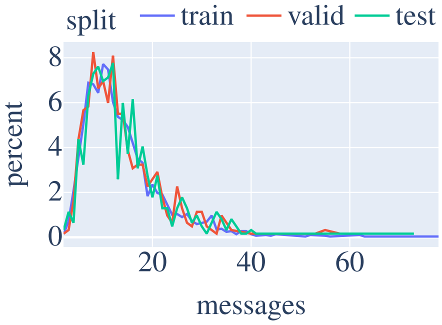

Figure 1: Histogram of messages by conversation in the both tasks (French split in Figure 7).

Chit-chat Dialogue The goal for chit-chat systems is to engage in a open-ended conversation with an end-user (Lowe et al., 2015; Dinan et al., 2018). Unlike our dataset, such conversations do not intend to assist the user with a specific task.

3 Dataset

The StatCan Dialogue Dataset consist of conversations collected from the live chat between March 1, 2019 till March 8, 2021. Although a variety of user intents can be found in the broader dataset of over 25K conversations, we focus on a single intent by selecting all conversations where the agent returns a data table. We use this subset to develop and test models for the two tasks that we introduce in Section 4. In Section 3.1, we provide basic statistics about this subset of the data and present a dialogue analysis for a small number of conversations in Section 3.2. In Section 3.3, we turn our attention to the

data tables and explain what kind of information is available for them. Finally, we explain how the dataset is split into a train, validation, and test set in Section 3.4. For technical specifications, a dataset card is provided in Appendix B.

User intents The live chat was designed to fulfill specific user intents. The main intent of the chat functionality is to help users **find specific data tables**. For example, in Table 1, the agent helps the user find tables about building permit, gasoline price, and retail prices for food. Although, users might also be interested in **obtaining meta-information**, receive help in **manipulating** a table or with the **user interface**. In some cases, the user will make **out of domain requests**. Those auxiliary intents are described in Appendix A.1 since the focus of this work is on the main intent.

Messages and turns Each conversation is broken down in **turns**, which is a pair of user-agent responses. Each response can have multiple **messages** sent sequentially (e.g., in Table 1, the first agent response contains 3 back-to-back messages).

3.1 Basic statistics

In total, 25397 conversations will be made available. Based on our main intent, we focus on a subset of 4468 (3675 in English and 793 in French). Out of a total of 5907 tables available in both English and French, the agents returned 959 unique tables in English 285 in French. The number of messages by conversation varies between 2 and 78 with a median of 12 for the English split (see Figure 1 for the distribution). Based on Table 3, there's on average 4.4 turns but 14.12 messages per conversation, with over 30 tokens for each message. This indicates that the speakers will express multiple sequential thoughts before the addressees respond. For the French split, we analyzed the basic statistics in Appendix A.5.

Title: Production and value of maple products

Date range: 1924-01-01 to 2020-01-01
Dimensions: Geography, Maple products
Subject: Agriculture
Survey: Maple Products
Frequency: Annual

Table 5: Basic information (including title) of table in Section 3.3. Full version in Table 20. This can be accessed at doi.org/10.25318/3210035401-eng.

Frequently requested tables In total, 6 tables make up 13.4% of tables retrieved, covering subjects like inflation and household spending. Supplementary details can be found in Appendix A.3.1.

3.2 Dialogue Analysis

We categorize 100 turns (306 messages) from 24 conversations in the English validation set according to the speech acts defined by Bunt et al. (2010, 2020), which is also known as ISO standard 24617-2. We follow their taxonomy but merge some fine-grained acts with their broader concepts (e.g., *correction, agreement, disagreement* with *inform*). We present the speech act frequencies and examples in Table 4. See the Appendix for more information on how we merged the original acts and supplementary examples (Table 15 and Table 22, respectively).

We notice that *answers* appear twice as frequent as *information seeking questions* because an interlocutor may provide an answer to both *clarification questions* and *requests*. Additionally, *inform* acts appears 63% of the time because agents need to expand upon their answer and users tend to clarify their initial requests by informing the other. Although less frequent, *auto feedback* and *time management* are still relevant because interlocutors cannot rely on visual feedback like nodding or typing. Naturally, *time management* often co-occurs with *promises* because the agent tends to put the user on hold while promising to fulfill their request.

3.3 Table specifications

To explain the specifications, we examine a sample table with **title** *Production and value of maple products* (shown in Table 5). The table has two **dimensions**, which are groups of **member items**;

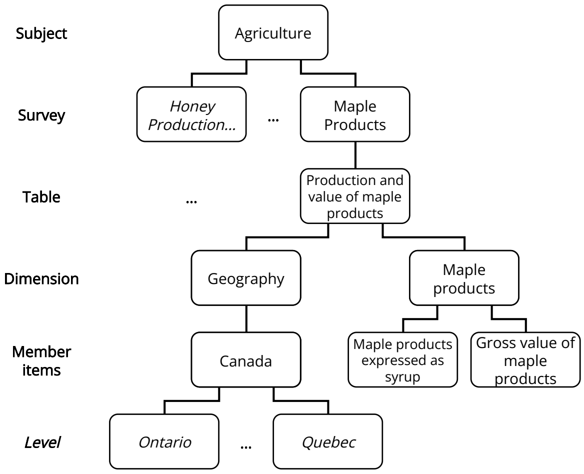

Figure 2: Diagram of the hierarchical relationship between metadata components, discussed in Section 3.3.

for *geography*, the members are the provinces producing maple syrup (Quebec, Ontario, etc.), and for *Maple products* the members are the production types (maple sugar, syrup, taffy and butter). A member item generalizes the concept of rows and columns as they are interchangeable via pivoting. Sometimes, details about those members are provided as **footnotes** at the end the page.

Basic Information This is the core metadata and consists of the title, dimensions, subject, survey and update frequency (member items are excluded). Supplementary details are in Appendix A.2.2.

Hierarchical relation The metadata can be viewed hierarchically. As shown in Figure 2, each subject encompasses different surveys, each survey can be used to generate one or more tables, and so on. A member item that can be nested under another member item is called *Level*.

3.4 Dataset splits

We group the conversations into a train (70%), a validation (15%) and a test (15%) set. The test set was specifically selected to be the most recent conversations by date (covering Sept 8, 2020 to Mar 8, 2021), whereas the training and validation set were randomly selected from the remaining data (covering Mar 1, 2019 to Sept 8, 2020). This lets us test a model's capability to adapt to temporal shifts in the data (such as new data releases and novel events). This is useful to understand a model's capability to generalize beyond the training distribution, but it is also a better reflection of real-world applications of a model (which will be used for future data). The same splits are used for all tasks.

4 Tasks

Based on the conversational and tabular data, we propose two tasks: (i) a table retrieval task, which requires a model to use a partial conversation to predict the table an agent will return, and (ii) a response generation task, which requires a model to use a partial conversation to generate the most probable response by the agent. The conversations in the tasks are available in both English and French.

4.1 Retrieval task

For this task, we truncate every conversation right before a link to a relevant table is shared by the agent. As a result, the product ID (PID) corresponding to that link becomes the objective of the retrieval task, as shown in Table 6. When the agent shares multiple non-repeating PIDs within a conversation, each unique occurrence is treated as a separate sample.

Recall@k To evaluate models for retrieval, we compute the recall at k (R@k) score for $k \in \{1, 10, 20\}$, which corresponds to the rate where the correct table is among the k tables retrieved by the model (usually ranked by a relevance score). We choose $k = 1$ for real-time automatic retrieval and $k \in \{10, 20\}$ for scenarios where humans or automatic rerankers would like to use the retriever to query tables and select the best option.

4.2 Response generation task

In the first task, only the messages leading to a table retrieval are considered. For this task, each message sent by an agent is considered as a target and everything before is the source. Thus, the goal of this task is to use the source text to generate a response that matches the target (see Table 7). Since dialogue responses are challenging to evaluate, we report a wide variety of metrics for this task.

ROUGE-L and METEOR ROUGE-L (Lin, 2004; Lin and Och, 2004) is a common text evaluation metric which naturally takes into account sentence level structure by identifying the longest overlapping word sequence between two sentences. METEOR (Banerjee and Lavie, 2005) is a word-level precision and recall scoring method that encompasses different ways to represent a word, including stems and synonyms.

BERTScore and MoverScore Various methods were developed to leverage contextual embeddings

	Source text (on-going conversation)
	[...]
A:	What do you mean by BC Housing Starts?
U:	I'm required to research all of the housing starts for BC on a quarterly basis[...]
U:	Housing starts are the number of new residential construction projects that have begun during any particular month
A:	[...] I would have monthly data regarding new building permits being issued.
	Retrieval target (StatCan table)
	Table 34-10-0066 (Building permits, by type of structure and type of work)

Table 6: Source and targets of the retrieval task, based on Table 1. Given the on-going conversation, the goal is to retrieve a StatCan table.

from BERT (Devlin et al., 2019) to evaluate similarity between two sentences. BERTScore (Zhang et al., 2019) computes the cosine similarity at the token level, whereas MoverScore (Zhao et al., 2019) computes the earth mover distance (Rubner et al., 2000) at the word or sentence level, thus capturing the cost of transforming the distribution of the generated responses into the distribution of the original responses.

Title accuracy In addition to the general metrics for text generation, we also explored this task-specific metric. We define it as the proportion of generated messages that contain the title of a table shared in the reference messages. Consequently, this metric only includes turns where a table is shared by an agent. To compute this, we (i) find the product ID in the reference message, (ii) look up the title, (iii) check if that title appears exactly in the generated and reference text.

5 Models

To help understand the performance of finetuned models on our tasks, this section presents an overview of the methods for the English splits, whereas the implementation details are covered in Appendix A.4. Similar architectures were used for French (described in Appendix A.5).

5.1 Retrieval

BM25 We use Robertson and Zaragoza (2009)'s algorithm to retrieve the metadata of a table (passage) similar to a given query by weighting the *idf*-scaled term frequency of query words with respect to the passages.

	Source text (on-going conversation)
U:	Hi, I'm looking to obtain quarterly data in regards to GDP grow (Canada), BC Housing STarts, Canada Oil Price/BBL
A:	Hello, my name is Kelly C. Give me one moment as I search [...]
A:	For GDP growth rates, please consult [...]
U:	I'm required to research all of the housing starts for BC on a quarterly basis [...]
	Generation target (next response by agent)
A:	I would have monthly data regarding new building permits being issued. [...]

Table 7: Source and targets of the response generation task, based on Table 1. Given the on-going conversation, the goal is to generate the agent's response.

DPR Proposed by Karpukhin et al. (2020), Dense Passage Retrieval (DPR) is a pair of transformer models that separately encode a query and a passage, and the dot product of the resulting vectors will have a higher score if the passage is relevant to the query. We finetune this model to retrieve the metadata of a table (passage) given the on-going conversation (query).

TAPAS and TAPAS-NQ Herzig et al. (2020) introduced a model that learned to encode flattened tables cells in a self-supervised manner during pretraining. We finetuned it to retrieve the truncated content of a table given an on-going conversation. Subsequently, Herzig et al. (2021) finetuned TAPAS to perform open-domain table retrieval on 12K questions-answer-table triplets extracted from NQ; we further finetune this variant in the same way and report the results as TAPAS-NQ.

Exploring table representation In the simplest scenario, only the title is given to BM25 and DPR. Moreover, we evaluate variants that encode the basic information, member items, footnotes, or a combination of them. For TAPAS and TAPAS-NQ, we also finetuned a variant that retrieves the title, dimensions and member items, since the original TAPAS could attend titles and column names.

5.2 Response generation

T5 We finetuned the large variant of T5 (Raffel et al., 2020) (named *No aug.* in Table 10) to autoregressively decode the target (agent reply) after first encoding the source (on-going conversation).

Augmenting T5 with top-k title(s) For every partial conversation, we use DPR (basic+member) to retrieve the top-k tables (where $k \in \{1, 5\}$), and append their titles to the partial conversation. This

Metadata	R@1	R@10	R@20
Basic	14.7	45.0	55.0
Basic + member	15.7	46.2	56.3
Basic + footnotes	13.9	44.4	54.2
Member	10.7	35.0	46.3
Title	13.9	43.8	53.4

Table 8: Retrieval results of DPR for the English test split with varying table representations. Overview of metadata in Section 3.3.

Model	R@1	R@10	R@20
BM25	0.3	2.3	3.8
DPR	14.3	45.1	54.2
TAPAS	6.1	22.1	31.5
TAPAS-NQ	7.4	30.0	39.3

Table 9: Retrieval results for the English test split when encoding title and member items. DPR and TAPAS were run 3 times and averaged.

allows T5 to decide between using one of the suggested titles and generating something else (e.g., clarification question). This is similar to the agents' behavior, as they tend to return a title with the URL when sharing a relevant table. Furthermore, supervising T5 to ignore or return a title is equivalent to an implicit binary classification.

6 Results and Discussions

Based on our baselines and data, we report the results and analyze the challenges that our dataset and tasks pose for existing models. For the English splits, the main retrieval results are reported in Table 9 and Table 8, and main generation results are in Table 10. Full results can be found in Appendix A, respectively in Table 16 and Table 33, and relevant statistical tests in Appendix A.7.

Impact of table representation In Table 9, we observe that the metadata representation affects the retrieval recall. Although DPR can achieves respectable results when it only retrieves the title, including basic information (defined in Section 3.3) yields slight improvements, and further adding member items results in a significant difference from only using title ($p = 0.014$). However, only using member item result in drastic decrease in recall ($p = 0.00086$), indicating the importance of the title. Moreover, footnotes do not yield any improvement, which may be because they often exceed the maximum context span (see Table 20). Thus, concisely but meaningfully representing metadata will be crucial to achieve a good recall on the retrieval task.

Metrics	No aug.	Top-1 Title	Top-5 Titles
METEOR	23.35	24.07	24.41
ROUGE-L	30.65	30.76	30.88
MoverScore	59.82	60.23	60.31
BERTScore	86.04	86.11	86.17
Title Acc.	6.96	7.99	10.82

Table 10: Response generation results for the English test split.

Transfer to table retrieval task Our experiments allow us to analyze the effectiveness of open-domain QA fine-tuning (NQ) and tabular pretraining when transferring to our table retrieval task. We observe in Table 9 that DPR outperforms TAPAS and TAPAS-NQ by respectively 23.0% and 15.1% in test recall@10. Moreover, TAPAS-NQ achieves a better performance when it only retrieves the title and member items instead of the full table ($p = 0.016$), likely due to repetitions and truncation due to context size limits. Although both DPR and TAPAS-NQ were trained on NQ, the latter was trained on a small subset (12K vs 320K) that contains tables. Our experiments indicate that TAPAS transfers poorly from one task (NQ-Tables) to another (StatCan).

Response generation We compare the performance of fine-tuned T5-large models with and without DPR-augmented table titles. In Table 10, we notice that retrieval-augmented models show modest improvements on the 4 non-task specific metrics. However, the top-5 augmented model achieves an absolute improvement of 3.86% in title accuracy, indicating that the information provided by DPR does help T5 in generating the desired title. It is nevertheless surprising that T5 without augmentation achieves a score of 6.96%, suggesting that the T5 model is capable of storing the titles seen at training time, and, to a limited extent, is able to recall and return them at test time. Finally, we point out that the title accuracy is still 5.91% lower than top-1 recall of the DPR retriever (Table 8), indicating that T5 fails to learn when to return a table (despite the agent retrieving a table in 23.4% of all turns). In the case of top-5 titles, T5 struggles to decide which table title to return.

Qualitative analysis of generated responses We examine various conversations to understand what type of responses are generated by T5. We find that it can generate simple speech acts like greetings, but can struggle with context-specific speech acts such as clarification questions. Moreover, it can

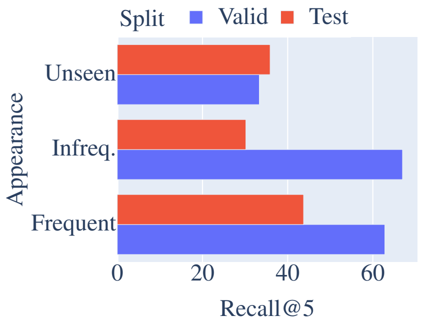

Figure 3: Results for DPR B+M for tables appearing in the training set frequently (10+ times), infrequently (1-10 times), and unseen at train time.

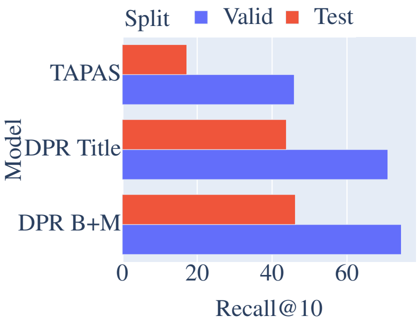

Figure 4: Validation and test recall for a selected set of retrieval models. We observe a significant drop in performance. *B+M* denotes Basic + member.

reliably reply with the title of a common table, struggles for uncommon ones, and is sometimes capable of generating unseen titles with the help of DPR. The full analysis is in Appendix A.6.

Temporal drifts As explained in Section 3.4, we use a temporal split to test the model's ability to generalize to future conversations. We observe a significant drop in recall (13%-28.3%) in Figure 4 when we compare the validation and test set performance, even when the models are trained with varying metadata representations. Similarly, T5 achieves low scores on the test split for the response generation task (Table 10). This large gap suggests that trained models struggle to generalize to future conversations. First, we found that this is likely caused by the number of new tables that appear in the test split (145) compared to validation (41), as shown in Table 3. Moreover, the subjects of the conversations have significantly changed: users started to care more about businesses, health and IT, and less about demography, income and pensions. This is likely motivated by real-world events affecting the users, which are more difficult to implicitly capture from simulated environments, but desirable in order to understand a model's robustness in temporal shift and for real world applications. In the Appendix, Figure 8 displays the differences between the training and test splits for all subjects.

Generalizing to unseen tables As shown in Figure 3, DPR performs well for tables appearing frequently in the validation split, but poorly in the test split, which could be caused by temporal drift. As expected, tables that were not seen during training resulted in poor recall@5 in either splits. Moreover, the difference in recall between valid and test for infrequent tables could be caused by many potential reasons (learning bias, temporal overfitting, spurious correlation with hidden factors). Thus, future models should aim to close the gap between unseen and frequent tables and within the temporal spectrum of infrequent tables.

French results In both tasks, we see a drop across all metrics for all models, likely due to the smaller dataset size. Some observations remain valid: temporal drift, poor BM25 performance, and augmentations benefit mT5 for certain metrics. However, others differ: adding member items hurts test results and mT5 performs poorly on *title accuracy*. Modeling details and results can be found in the Appendix A.5.

7 Conclusion

In this paper, we introduce the StatCan Dialogue Dataset, a novel corpus consisting of 20K+ English and French conversations between online visitors of statcan.gc.ca and operators of Statistics Canada. Based on this dataset, we propose two tasks centered on helping users find specific data tables: the table retrieval task and the response generation task. For the table retrieval task, we experiment with various DPR and TAPAS variants, finding that DPR strongly outperforms its TAPAS counterpart, as well as the BM25 baseline. For the response generation task, we investigate fine-tuned T5-large models and explore variants where the input is augmented with table titles from DPR. We find that retrieval-augmented T5 models more frequently return the correct tables, although its title accuracy is still lower than the corresponding recall of the DPR retriever. This result suggests that the generation models struggle to decide when to return a table. We also find that retrieval and generation have difficulty generalizing to future conversations, as our temporal test split revealed a big performance gap between the validation and test set. All in all, we believe that our tasks pose significant challenges to currently available models and encourage the research community to further explore this dataset and build conversational models that help users of Statistics Canada.

Limitations

Tasks and models limitations The tables in the retrieval task are sourced from statcan.gc.ca, which means that the content is primarily about Canadian demographics[2] and are professionally edited by StatCan employees. Moreover, the generation task is specifically designed to model responses with high fidelity based on retrieved tables, so this task should not be directly used in an unintended or non-research setting (e.g., deploying a virtual assistant) as they pose risks of hallucination that could negatively impact stakeholders. Furthermore, those limitations can be reflected in the models we trained, so we will share those limitations in the model cards (Mitchell et al., 2019) on release.

Environment impact We acknowledge the models in Section 5 used hardware with significant energy consumption. We purposefully chose models of reasonable sizes that can be reproduced on one GPU. Additionally, our hardware is powered by renewable energy.

Artifacts and computational experiments We trained models using libraries based on their intended use and we will release the relevant artifacts following the original licenses. The computational details of the experiments are described in Appendix A.4.

Ethics Statement

Privacy and data access As discussed in Section 1, significant efforts were made to remove Personally Identifiable Information (PII). However, we do not rule out the possibility that certain details could have been missed in that process. Thus, any user that wishes to use the data will need to authenticate and accept the terms of use through an institutional data repository; the terms will require the user to report any instance of PII leak, which will be removed with a dataset update. Additionally, we request any derivative or modifications to be published in the same data repository with the original terms of use and licenses preserved or extended.

Risk of toxicity in online discourse StatCan agents are trained to work with online users in a professional manner. Moreover, since the users access statcan.gc.ca anonymously and virtually, it is more likely to observe toxic online disinhibition (Lapidot-Lefler and Barak, 2012), which could translate to toxicity in users' utterances. Thus, we request dataset users to report any instance of toxicity in conversations, which will be reviewed in the same manner as PII leaks.

Acknowledgement

We thank our collaborators at Statistics Canada for providing us the dataset, guiding us through the technical aspects of the tables, and sharing valuable feedback on the project. We thank Sivan Milton for the helpful discussions on dialogue acts and analysis.

A Appendices

A.1 Complete User Intents

To provide insight into what kind of help is offered by StatCan's live chat, we qualitatively analyze the conversations and highlight examples of the main user intents below.

Finding a table The main intent of the chat functionality is to help users find specific data tables. For example, one user was looking for the population numbers in certain regions of Montreal for 2012-2016. This intent is the focus of our work.

Obtaining meta-information of table Instead of finding data tables some users are interested in meta information of a specific table. For example, one visitor wanted to know when the next Census is released. Another user was interested in understanding the definition of Workforce Availability (WFA) and Labour Market Availability (LMA).

Manipulating a data table Some users would like to obtain the data tables in a different format or representation. For example, one user was looking at a specific data table and asked if they can see annual instead of monthly values.

Help with user interface Some users are looking for help with the user interface. For example, one user wanted to download a specific data table but they were unable to find the download link.

Out of domain requests We find many conversations that are outside of the scope of StatCan's live chat. For example, some user asked what documentation needs to be provided to ship a specific product to a foreign country.

The first intent is covered in Table 1, and subsequent intents are in Table 18. While we believe all intents are interesting directions for dialogue research, we focus on the table retrieval intent because (i) there are many conversations available for them and (ii) there is a clear measure of task success i.e., whether the correct table is retrieved. Throughout the rest of this paper, we work with conversations where the agent returns a table URL.

A.2 Supplementary Table Description

A.2.1 Formatting and size

Full tables are stored in a *long* format, where each column corresponds to a dimension, except the last one which corresponds to the value. The number of rows corresponds to the Cartesian product of the dimensions' members. This means that for n_i members across d dimensions, we have a total of $\prod_{i=0}^{d} n_i$ rows in the full table. When a table has many member items, the full table can become extremely large. Moreover, tables shown on the statcan.gc.ca are usually a pivoted and filtered view of the full table, which means certain members will become columns, others will become rows, and many are simply omitted.

A.2.2 Detailed Specifications

This section provides supplementary details for Section 3.3.

Product ID (PID) Unique 8 to 10-digit identifier given to each published data table. Although other types of tables might be shared by the agent, the PID will always be given for the official data tables; as a result, any table that does not have a PID in the URL is not considered for this task. The first two digits (1-2) represent the code of the subject associated with the table (this can be found in the basic information), then 3-4 represent the product type, which in our case are tables and are common coded as "10". Digits 4-8 is a unique identifier representing that table for the given subject. Digits 9-10 indicate the view of the table and will commonly be "01", which represents the default view; they are needed when constructing the URL but they are otherwise optional, and are omitted in the released dataset.

Member items Labels for individual tables, and can either be represented as a column or a row index through a pivot operation. Each table will have member items different from other tables.

Dimensions Non-overlapping sets of member items; each member item must belong to a dimension. For a table with d dimensions, each data value is associated with a single d-tuple in the d-fold Cartesian product of the dimensions, but not every tuple in the product will have an associated data value (if it was not recorded or if the tuple is invalid).

Basic information Metadatum consisting of the title, the date range, the frequency, the dimensions, the subject category, and the survey[3] from which the data was sourced.

Footnotes Unstructured comments often included with a table if supplementary details need to be given; usually, those notes are associated with a specific member item that requires more explanations.

Full table For all tables with a PID, the full tables (as a CSV file), their complete metadata, and their basic information are made available as part of the data release and can be used in our proposed tasks. A sample table can be found in Section 3.3.

---

[3] The list of surveys and link to detailed information can be found at https://www.statcan.gc.ca/en/survey/list

A.2.3 Table updates and archives

Tables on Statcan will sometimes be updated regularly, whereas in other times they may only be released once. When they stop being updated and the information becomes outdated, they will be marked as archived. In some cases, a new version of an archive table may be created with substantial changes (such as new columns). As shown in Table 14, tables are released without a predetermined schedule, but has been on average increasing since 2000, with major peaks in 2017, which was caused by many health-related tables, and 2021, which was caused by the release of many labour, science, and income tables, as shown in Figure 6. Moreover, Figure 5 shows that a majority of tables released between 2019 and 2021 are still up-to-date (current), whereas most of the tables before then have been archived.

A.3 Supplementary Statistics

A.3.1 Frequently requested tables

The most frequent tables are summarized in Table 21. Whereas 2 of them are sourced from the consumer price index survey (commonly used to track inflation), the 4 other tables cover more general and broad subjects like income, demography, business performance and crime. Each of those 4 tables are sourced from different surveys. One table is updated monthly, another semi-annually, and the rest are updated annually. The oldest table was updated in 2019, which is when the conversations started being recorded.

A.3.2 Table Frequency Statistics

In tables 3 and 12, we can calculate that a table is returned on average 5.68 times (with standard deviation of 12.86) in English conversations and 4.25 times (standard deviation of 9.73) in French conversations. Thus, the most requested tables are disproportionately represented compared to less popular tables, and there's a very high variance in the number of time a table is used. In fact, there are 294 tables that appear only once in either splits (i.e., 28.9%).

A.3.3 Fine-grained Conversation Statistics

In Table 13, we observe that the number of messages and turns will vary significantly around the mean, with over 68% conversations lasting between 2 and 7 turns. In extreme cases, a conversation can last up to 28 turns. Moreover, we also notice that, although most messages will have around 32 tokens, the longest message can have up to 1374 tokens; in those scenarios, we will see agents write a large body of text, and sometimes also copy and paste large amount of text (for example, from a database of templates) when responding to the user. Although those are usually sent in multiple consecutive messages within a turn, they may decide to send everything all at once.

A.4 Implementation Details

This section provides the details for implementing the models in Section 5.

Implementing transformer models All models based on the transformer architecture (Vaswani et al., 2017) were implemented using HuggingFace's library (Wolf et al., 2020).

BM25 To facilitate reproducibility, we implemented the model in Gensim (Rehurek and Sojka, 2010).

DPR and TAPAS-NQ We used the base variant of DPR and the large variant of TAPAS-NQ. We use the DPR checkpoints that were trained on 320K questions from Natural Questions (Kwiatkowski et al., 2019) (NQ). During training, the networks were optimized with AdamW (Loshchilov and Hutter, 2017) at a learning rate of 10^{-5} and zero weight decay. Based on the original work, the networks were trained for 30 epochs, with a batch size of 64 queries, positive passages, and hard negative passages (the latter are retrieved with BM25). Negative in-batch sampling was used to increase negative examples. To ensure reproducibility, the networks were trained on a single 32GB GPU and used gradient checkpointing (Chen et al., 2016) to reduce memory usage. The conversation lengths was 512 tokens, and the metadata token lengths were 128 for title, 256 for basic information (defined in Section 3.3), and 512 for the rest.

T5 We used an Adafactor optimizer (Shazeer and Stern, 2018) with a learning rate of 0.001. We used batch sizes of 16 with 8 steps of gradient accumulation and gradient checkpointing to reproduce the batch size of 128 samples in the original implementation. The models were trained on a single 32GB GPU for 10 epochs. The source and target lengths were respectively 512 and 256 tokens, where the source was truncated from the right to ensure that the latest messages remained after truncation. We used a beam size of 4 and length penalty of 0.6 following the original implementation.

Training time For the English split, each variant of DPR can be trained in 68 minutes on a A100 GPU. Each large variant of TAPAS-NQ takes 15h to train on a V100 GPU. Each variant of T5 can be trained in 16h on a V100 GPU. All DPR results can be reproduced in 8h, TAPAS in 90h, and T5 in 96h, and proportionally less time would be needed for the French split.

A.5 Modeling the French subsets

Basic statistics The number of messages by conversation varies between 2 and 59 with a median of 11 for the English split (see Figure 7 for the distribution). Based on Table 12, there's on average 3.9 turns but 12.3 messages. On average, there are over 30 tokens for each message (using the T5 tokenizer).

Language splitting In order to determine the language of each conversation, we used two popular language identification libraries: *langid.py* (Lui and Baldwin, 2011) and a fasttext network fine-tuned for language detection (Joulin et al., 2017). After apply the models on every conversation, we only retain the conversations with matching language labels (both English or both French).

Training and evaluation The training procedure and evaluation on the French subsets follow exactly the tasks specified in Section 4.

Modeling response generation Instead of T5, we used the multilingual T5 model by Xue et al. (2021) as it naturally handles text in French.

Modeling retrieval We used a variant of DPR derived from CamemBERT (Martin et al., 2020) and trained on three French Q&A datasets (Keraron et al., 2020; d'Hoffschmidt et al., 2020; Kabbadj, 2021) by Etalab Lab-IA (2021).

Retrieval results In Table 17, we observe that, unlike the English split, adding member items to the basic information or to the title improves validation results but not test results, which likely indicates overfitting. However, we notice a high variance between the runs, which makes it difficult to determine whether member items is helpful. Both overfitting and high variance are likely caused by the smaller size of the training set. Moreover, BM25 perform extremely poorly on any metadata view, which can also be linked to the dataset size.

Generation results In Table 33, we notice a significant decrease across all metrics, with the title accuracy being consistently 0%. This is likely because the French split is significantly smaller, yet remains as complex as the English split, which becomes challenging for mT5 to model. In the case of title accuracy, we found 55 instances in the French test split where the title is in the target text (i.e., returned by an agent). However, in 54 cases, the augmented mT5 returned a generic reply (e.g., “Veuillez patienter pendant que j'effectue une recherche.") instead of the expected title, which indicates that mT5 is incapable of determining when it is relevant to return a title and can't generate non-templated responses.

A.6 Responses generated by T5

In this section, we select a few conversations from the validation set and examine the messages generated by T5 and T5 augmented with DPR-retrieved titles (T5+D).

Common and uncommon responses In Table 23, we notice that both T5 and T5+D are capable of generating common speech acts like “Thank you” and “Please wait...”, but struggles when faced with an unfamiliar situation (having to ask for clarification for a user that has been accidentally disconnected).

Common table In Table 24, among the retrieved tables (R_i) titles, the first one was partially correct. Both T5 and T5+D extended the title and also output the desired ID, matching the expected agent's response, which is one of the most popular table in the training set (see Table 21).

Multiple tables, date selection In Table 28, we notice that T5 only returns one of the two tables that the agent returned. On the other hand, the correct tables were retrieved by DPR, but T5+D failed to select the ones with the correct dates (it selected June 2019 instead of December 2019) but the select were otherwise relevant.

Verbosity of explanations T5+D additionally provided a paragraph of explanation while linking to relevant resources, both on the StatCan website (non-tabular) and external resources. This is because T5+D memorized this information during training, and simply replaced the tables with the updated dates (Table 27).

Uncommon tables In the conversations shown in Tables 25, 26, 29, the retrieved table appears 10 times in the training set, which is significantly less common than the table retrieved in Table 24. For Table 25, the table returned by the agent was not retrieved by DPR, leading to T5+D returning the first title retrieved. However, in Table 26, the correct title was retrieved by DPR (title #4), yet T5+D failed to use that correct title in the generated message. As for Table 29, the agent gave a hint by stating “As a standard product, we have tables about employment by industry”, which was correctly acknowledged by DPR as the second retrieved title perfectly matches the PID of the table in the agent’s response. However, T5+D fails again at selecting the correct title, instead opting to return a generic response (“Please hold while I find the information”), and T5 hallucinates a PID that is different from the title it generated (both of which are wrong).

Tables unseen during training Among the tables that do not appear in the training set (see Table 11 for more information), there are seven that appear 3 or more times in the validation or test sets (Table 32). In Table 30, we see a conversation where DPR retrieves the correct title, which is correctly returned by T5+D, whereas T5 fails to return it. On the other hand, when DPR also correctly retrieves the title in Table 31, T5+D fails to return it, as it was likely mislead by the agent saying “Unfortunately,...”.

A.7 Statistics Tests

To back the claims in Section 6, we performed multiple single-tailed Welch t-tests, using the mean and corrected standard deviation from 16. The null hypotheses are that means of experiments A are different from the means of experiments B, across 3 runs. Unless otherwise specified, we use R@1 on the test split.

1. Claim: Adding basic information and member items to title results in a significant difference for DPR. With A being the model using only title, and B using basic + member, our p-value is 0.014.

2. Claim: For DPR, using member item result in drastic decrease. With A being the model using only member and B using title + member, our p-value is 0.00086.

3. Claim: TAPAS-NQ performs better with title and member items compared to the full table. With A being the model using the full table, and B using title + member, our p-value is 0.016.

4. Claim: In Figure 4, the validation recall@10 are higher than the test split for TAPAS, DPR Title and DPR Basic + member. With A being the validation score and B the test scores, the p-values are respectively $0.00197, 2.18 \times 10^{-5}, 0.00014$.

B Dataset Card

This section presents a dataset card that follows the format proposed by Lhoest et al. (2021), which was inspired by Mitchell et al. (2019) and Gebru et al. (2021).

Summary The StatCan Dialogue Dataset consists of over 20K+ conversations between agents working at Statistics Canada (StatCan) and users who are visiting StatCan's website and need support via the official live chat system.

Tasks A subset of 19K conversation turns is used to build two tasks:

1. Automatic retrieval of relevant tables based on a on-going conversation. For each partial conversation, the task is to return the ID of the most likely table returned by an agent. This is evaluated using the recall@k metric.
2. Automatic generation of appropriate agent responses at each turn. For each partial conversation, the task is to return the most likely response by an agent, including link to a relevant table. This is evaluated using four metrics described in Section 4.2.

Leaderboard The leaderboard and submission instructions can be found on the project webpage. Each submission will be accompanied with a tag indicating if:

- It was self-reported;
- The submissions were externally evaluated;
- The inference was reproduced following provided instructions;
- The complete training process was independently reproduced.

Languages The conversations were held in Canadian English (en-CA) and Canadian French (fr-CA).

B.1 Dataset Structure

B.1.1 Data Instances

Conversation A full example of a conversation can be found in Table 19. Instances for each user intent can be found in Table 18, and two conversations with annotated dialogue acts can be found in Table 22. For our case study in A.6, we show partial conversations in Tables 24, 25, 26, 27, 28, 29, 30, 31.

Tables The complete metadata of a table can be found in Table 20, which can be access at doi.org/10.25318/3210035401-eng. Table 21 shows the basic information for the most popular tables.

B.1.2 Data Fields

Full dataset A CSV file with the following fields is provided:

- `conversation`: The partial conversation (before a table is returned) in JSON format.
- `conversation_index`: A unique index that serves at identifying the conversation outside of this task.
- `conversation_processed`: The conversation converted into a readable text format, with extra information (such as timestamp) removed, the URLs replaced with a special tag, and separation tags (`</s>`) added.

Retrieval task CSV files with the following fields is provided for each split:

- `conversation`
- `conversation_index`
- `conversation_processed`
- `target_pid`: The product ID of the table that is returned by the agent
- `language`: The language reported by the live chat system, which may not always be accurate due to mislabeling.
- `ft_detected_lang`: The language predicted by fastText.
- `ft_detected_lang`: The score output by fastText.
- `lid_detected_lang`: The language predicted by langid.py.
- `lid_detected_prob`: The score output by langid.py.

Metadata The metadata that was used during retrieval is provided as a CSV file with the following fields (one for each of the 5907 tables):

- `pid`: The product ID of the table
- `title`: The title of the table

- `basic_info`: The basic information in the textual format
- `member_info`: The member items enumerated as text
- `footnote_info`: The footnotes enumerated as text
- `full_info`: The basic information, member items and footnotes all in a single entry
- `x_and_y`: An combination of two items above, for example `x=title` and `y=footnotes`.
- `*_fr`: All of the above are also available in French, indicated by the suffix `_fr`.

Generation task CSV files with the following fields is provided for each split:

- `source`: Equivalent to `conversation`.
- `source_processed`: Equivalent to `conversation_processed`.
- `target`: The message written by the agent following the conversation.
- `target_processed`: The message written by the agent following the conversation, with URLs replaced with a special tag.
- `conversation_index`

An augmented variant of each CSV file for the conversation task is provided with all of the above as well as the following fields:

- `source_augmented`: The same content as `conversation`, appended with the title of the top-5 tables retrieved by best DPR variant trained on the basic information.
- `target_augmented_1`: The same content as `source_augmented`, but using only the first table instead of top-5.

Conversation JSON formatting A conversation follows the following JSON format:

```
[
  ...
 {’timestamp’: ’13.03.2019 17:03:22’,
  ’actor’: ’user’,
  ’actor_name’: ’<NAME>’,
  ’text’: "I’ll take a look at that",
  ’urls’: []},
 {’timestamp’: ’13.03.2019 17:04:12’,
  ’actor’: ’operator’,
  ’actor_name’: ’Kelly C’,
  ’text’: ’Building permits...’,
  ’urls’: [’https:...’]},
  ...
]
```

B.1.3 Data Split

The retrieval splits has the following number of samples:

- Train: 3782 (en); 869 (fr)
- Validation: 799 (en); 201 (fr)
- Test: 870 (en); 141 (fr)

They correspond to the number of queries in Table 3 and Table 12 because each query results in a table being retrieved, which can happen more than once in a conversation. In such cases, the partial conversations will be truncated at different turns in the conversation.

The generation splits have the following number of samples:

- Train: 21582 (en); 3977 (fr)
- Validation: 4464 (en); 861 (fr)
- Test: 4850 (en); 884 (fr)

There are fewer samples than the number of messages in Table 3 and Table 12 because the goal of the task is only to predict the messages that will be written by the agent. Just like the retrieval task, the partial conversations will be truncated at different turns in the conversation.

B.2 Dataset Creation

B.2.1 Curation Rationale

Section 1 extensively motivates the curation of the dataset. To summarize, we enumerate the major points:

- Data from real users: We wanted a dataset that captures the linguistic challenges that exist in the real world
- Task-oriented dialogue: We wanted tasks with the specific goal of helping live chat users in their search of statistics.
- Real-world applications: Our model can be directly applied other statistics offices that want to set up a chat system, and our dataset will be useful for any organization that has (1) a chat system, and (2) a database of tables.

- Multilingual dialogue: We wanted to build models that can handle languages beyond English, which is why we also offer French versions of our tasks.

B.2.2 Source Data

Conversations The data was retrieved from the live chat system on statcan.gc.ca, which was anonymized by the development team at StatCan. The conversations happened between March 2019 and March 2021.

Tables The tables are publicly available and were downloaded following the instructions in the Web Data Service user guide: statcan.gc.ca/en/developers/wds/user-guide. The tables were released by Statistics Canada between 2000 and 2021. The data are either collected directly by Statistics Canada (e.g., through a census or a survey) or were compiled from existing sources (such as private sector organizations and government agencies) into official statistics. Existing sources include:

- Administrative data: Collected by government or the private sector as part of ongoing operations, and include records of birth and death, taxes, border control, and satellite data.
- Microdata Linkage: Existing information is linked to create new data. The existing information may not always be available publicly (for privacy purposes), thus linkage could add new information that was previously unavailable, while protecting the confidentiality of the public.
- Open data: Machine-readable and freely available data sourced from various channels (e.g., OpenStreetMap).
- Web scraping: Data from the internet that were scraped by Statistics Canada (this excludes personal information and "any information that will not be used to produce statistical output").

B.2.3 Annotations

The dataset does not contain any additional annotations beyond the ones collected through the live chat system and included in the table metadata.

B.2.4 Personal and Sensitive Information

Personal and sensitive information were removed programmatically from the conversations, and officially published tables only contain aggregated information that preserve the confidentiality of the participants. Although the removal process is highly advanced, there is a non-zero chance that some information can be used to reconstruct the profile of a user. For this reason, the access to the data will require researchers to sign-up and agree to the terms of use, and any derivative must be shared on the same platform and include the same terms.

B.3 Considerations for Using the Data

B.3.1 Social Impact of Dataset

The purpose of this dataset is develop and evaluate models that can assist knowledge workers in finding relevant tables from a data source. By providing a specialized retrieval system capable of returning more relevant results compared to general purpose, the productivity of the knowledge workers can be increased. For public agencies and statistics offices, this would benefit many live chat users interested in statistics related to a certain community.

B.3.2 Discussion of Biases

As discussed in Section 7, there are always risks of toxicity in online discourses, which means that the live users may exhibit negative biases in their messages. However, the StatCan agents are tasked to communicate with online users in a professional manner. Thus, researchers should not use this dataset to build models that generate messages written by live users, and any model trained on the dataset should not be used in scenarios where biases can negatively impact stakeholders.

B.3.3 Other Known Limitations

Section 7 describes other known limitations.

B.4 Additional Information

B.4.1 Dataset Curators

The dataset was curated by the authors of this paper based on the original data collected and processed by StatCan developers and agents.

B.4.2 Licensing Information

The conversations use a custom license, which needs to be accepted by researchers interested in accessing the conversation. The tables are released under the the Statistics Canada Open Licence: statcan.gc.ca/en/reference/licence.

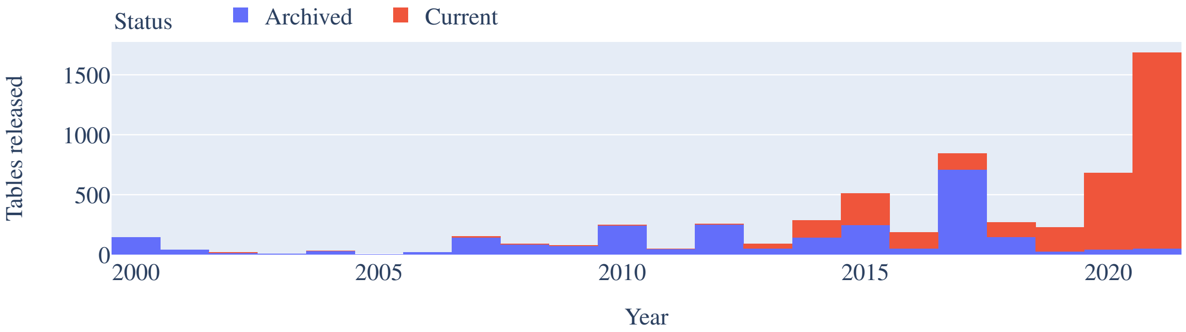

Figure 5: The release year of all tables available on statcan.gc.ca

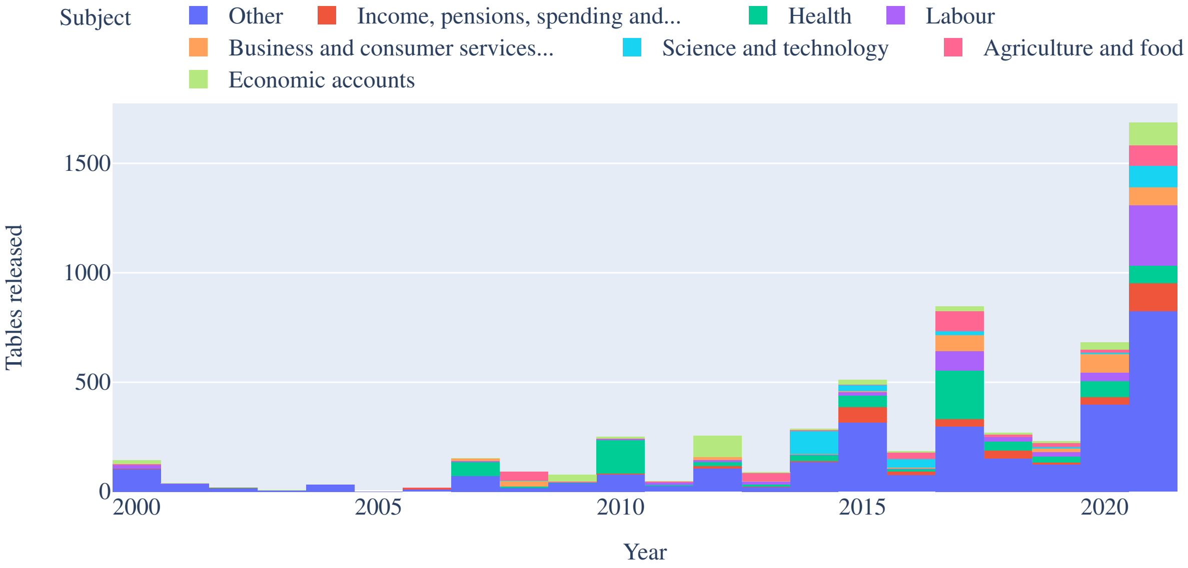

Figure 6: The release year of all tables by subject. Only the top 8 subjects are shown for readability.

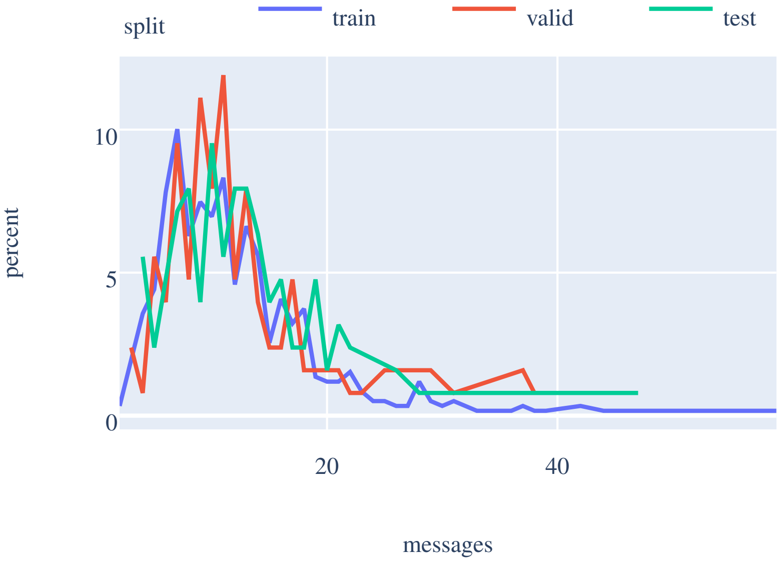

Figure 7: Histogram of messages by conversation in the French task splits. English split in Figure 1.

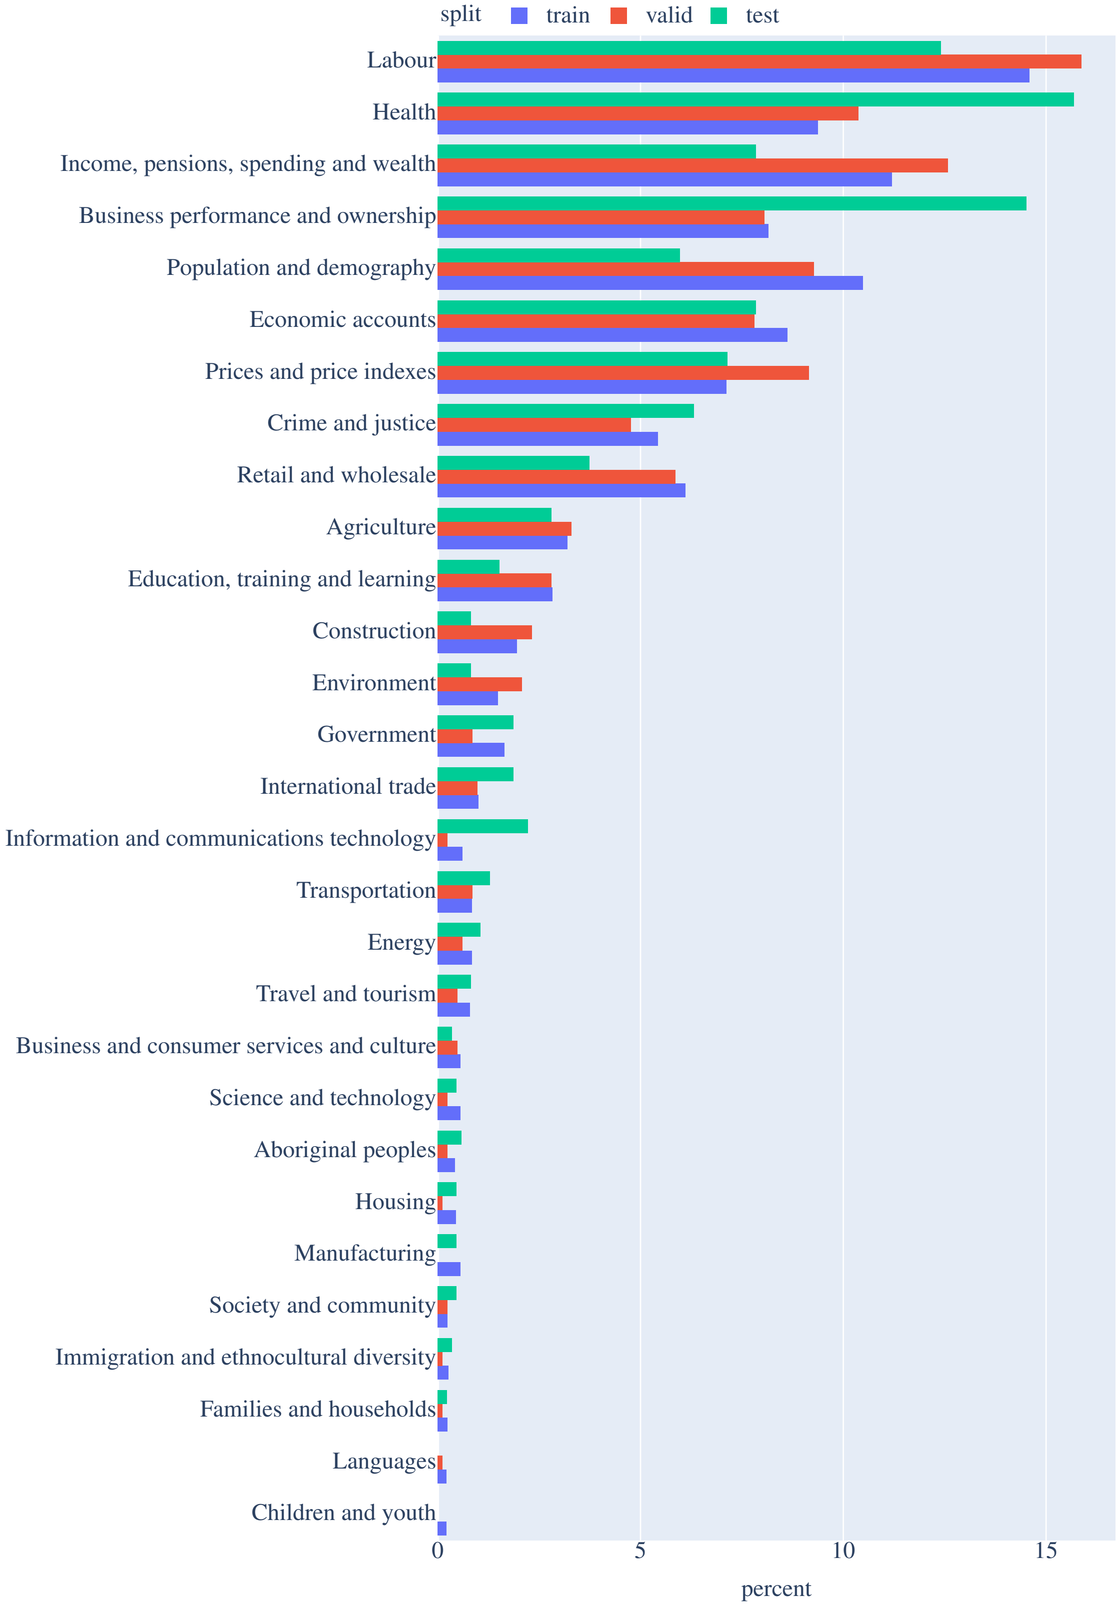

Figure 8: Distribution of subject categories for tables in the retrieval task, colored by the split.

	Train	Valid	Test	Overall

	Obtaining meta-information of table
U:	Hi I have a question on the date of new census
A:	Hello my name is Graham, how may I help you?
U:	Hi Graham
U:	I am currently looking at : Census of Canada and National Household Survey
U:	I see that the last census were made in 2011 and 2016
U:	should I expect a new census in the coming month in 2020 ?
A:	no - the next Census is going to be taking place in May 2021
A:	it's every 5 years
U:	Ok perfect thank you
A:	you're welcome! have a good day
	Help with user interface
U:	Hello Graham - is there way I can see total annual values instead of monthly?
U:	for - https://www150.statcan.gc.ca/t1/tbl1/en/cv!recreate.action?...
A:	please hold - I will see if a table like this with an annual frequency is available
U:	wonderful thank you
A:	unfortunately no, the only active table on construction investment is the monthly one I sent you - there is an inactive quarterly table Investment in Building Construction (https://www150.statcan.gc.ca/n1/en/surveys/5014)
A:	it is also possible to download the monthly data in .CSV form, add together the months in a spreadsheet to get annual totals
A:	or if you'd prefer, you can make a custom request to our analysts (a fee may apply).Please send us your request, clearly indicating the variables, geographic areas, time frame and data frequency (i.e., annually, monthly or quarterly) needed at infostats@canada.ca (mailto:infostats@canada.ca) and refer to Case number: 986005 so we can access the transcript of this live chat. Your request must include your name, address, postal code, and phone number (please do not share your personal information on the live chat.)An agent will get in touch with you to provide an estimate and proceed with the payment, if applicable.You may also submit your request by telephone at 1-800-263-1136.
U:	thats fine! thank you very much :)
U:	very helpful
U:	:)!
U:	have a good day!
A:	glad I could help! you too
	Help with user interface
U:	Hello, Do you know where I can download the dataset for General Social Survey Cycle 32?
A:	Please wait while I try to find this information for you.
U:	Thank you
U:	(I'm referring to this one: https://www23.statcan.gc.ca/imdb/p2SV.pl?...)
A:	General Social Survey: Caregiving and Care Receiving, Public Use Microdata File (https://www150.statcan.gc.ca/...)
U:	I'm sorry, but im having trouble finding the download link for cycle 32 (2018)
A:	you have to click on 'More information' and that will bring you to the order form
U:	ohhhh, I see
U:	thank you for letting me know
U:	thank you for your help!
A:	you're welcome - happy to help!
	Out of domain requests
U:	I'm wondering how to obtain a copy of an autopsy that's been done for a family member. Doctor office says they don't get the autopsy report.
A:	Statistics Canada does not issue certificates for birth, death or marriage. Civil registration is a provincial jurisdiction. Therefore, you must contact the government ministry, registry or vital statistics office of the province or territory in which the birth, death or marriage occurred. To obtain the contact information for your provincial or territorial government, please call Service Canada at 1-800-O-Canada (1-800-622-6232) or visit the following page: Vital Statistics contacts (https://www.statcan.gc.ca/eng/health...) .
A:	also: Coroner's report (https://spvm.qc.ca/en/...)

Table 18: Examples of user intents described in Section A.1.

U: Hi, I'm looking to obtain quarterly data in regards to GDP grow (Canada), BC Housing STarts, Canada Oil Price/BBL
A: Hello, my name is Kelly C. Give me one moment as I search

U: thanks!
A: For GDP growth rates, please consult the following link: Gross domestic product (GDP) at basic prices, by industry, monthly, growth rates
A: I'll continue searching for the rest. One moment
A: What do you mean by BC Housing Starts?

U: I'm required to research all of the housing starts for BC on a quarterly basis
A: Define "starts".

U: unit basis
U: Housing starts are the number of new residential construction projects that have begun during any particular month
A: Perfect. Give me one moment.
A: I'm still searching. Sorry about the wait.

U: no worries
A: I would have monthly data regarding new building permits being issued.

U: I'll take a look at that
A: Building permits, by type of structure and type of work (https://www150.statcan.gc.ca/t1/...)
A: Do play with the variables to get what you are looking for.

U: thank you
A: To view/ manipulate the variables available in a data table: • Click on "Add/Remove data" • Select at least one variable in each tab and click on "Apply" in order to view your customized table To download the data: • Click on "Download" • Select one of the three output formats then click on the hyperlink and save the table The following video may also be helpful to you: How to use the data tables (https://www.statcan.gc.ca/eng/sc/video/howto) .
A: I'll have a look for oil prices. One moment.

U: Do you also have data to Canada'as oil Price/BBL ("WTI")?
U: okay thanks!
A: Are you looking for the retail prices of oil?
A: If so, I found some data for smaller geographies.
A: Monthly average retail prices for gasoline and fuel oil, by geography (https://www150.statcan.gc.ca/t1/...)

U: yes
A: Would those geographies be enough?
A: Or are you looking for Canada only?

U: hmm
U: I would need something that pertains more to all of canada
A: What about this? Monthly average retail prices for food and other selected products (https://www150.statcan.gc.ca/t1/...)
A: Is there anything else I can do for you?

U: I thinks that's all
U: I
U: i'll try and use this thanks!
A: No problem. Have a good one!

Table 19: Full Example (Sample #42) taken from the conversations dataset. URLs were updated to link to default view (rather than filtered). See Table 1 for truncated conversation.

Title: Production and value of maple products

Date range: 1924-01-01 to 2020-01-01
Dimensions: Geography, Maple products
Subject: Agriculture
Survey: Maple Products
Frequency: Annual

Geography:
ID: 1, Parent: None, Name: Canada
ID: 2, Parent: 1, Name: Nova Scotia
ID: 3, Parent: 1, Name: New Brunswick
ID: 4, Parent: 1, Name: Quebec
ID: 5, Parent: 1, Name: Ontario
Maple products:
ID: 9, Parent: None, Name: Maple products expressed as syrup, total
ID: 10, Parent: None, Name: Gross value of maple products
ID: 1, Parent: None, Name: Production of maple sugar
ID: 2, Parent: None, Name: Value of maple sugar
ID: 3, Parent: None, Name: Production of maple syrup
ID: 4, Parent: None, Name: Value of maple syrup
ID: 5, Parent: None, Name: Production of maple taffy
ID: 6, Parent: None, Name: Value of maple taffy
ID: 7, Parent: None, Name: Production of maple butter
ID: 8, Parent: None, Name: Value of maple butter

ID: 0, Note: Conversion factors: 1 gallon of syrup equals 10.0 pounds of maple sugar. One gallon of syrup weighs 13.24760 pounds. One gallon of syrup equals 10.4 pounds of taffy. Maple taffy is reported by Quebec and Nova Scotia only and commenced reporting in 1965 and 1983 respectively. The conversion of maple taffy to syrup varies with the density of syrup that year.
ID: 0, Note: Commercial production and value figures exclude inventory.
ID: 2, Note: Estimates produced by Nova Scotia horticulture industry specialists.
ID: 3, Note: Beginning in 1986, survey data for New Brunswick and Ontario are weighted using the number of taps made on maple trees in the spring of the year of the most recently completed census of agriculture.
ID: 4, Note: Estimates produced by l'Institut de la statistique du Québec, Groupe AGÉCO and Fédération des producteurs acéricoles du Québec.
ID: 5, Note: Beginning in 1986, survey data for New Brunswick and Ontario are weighted using the number of taps made on maple trees in the spring of the year of the most recently completed census of agriculture.
ID: 9, Note: "These products are represented by North American Product Classification System (NAPCS) Canada 2017 category 115136

Maple syrup and other maple products. Data collected for maple butter, maple taffy and maple sugar are converted into a maple syrup equivalent and are included in this category."
ID: 10, Note: "These products are represented by North American Product Classification System (NAPCS) Canada 2017 category 115136 – Maple syrup and other maple products. Data collected for maple butter, maple taffy and maple sugar are converted into a maple syrup equivalent and are included in this category."
ID: 0, Note: "These products are represented by North American Product Classification System (NAPCS) Canada 2017 category 115136 – Maple syrup and other maple products. Data collected for maple butter, maple taffy and maple sugar are converted into a maple syrup equivalent and are included in this category."

Table 20: Full metadata of table in Section 3.3. Single lines were added to delimit the scope: Title, basic information, item names, and footnotes. The double line was added to delimit the truncation limit of the DPR and TAPAS model (512 tokens). The basic information is presented in Table 5.

Abstract

Automatic generation of questions from text has gained increasing attention due to its useful applications. We propose a novel question generation method that combines the benefits of rule-based and neural sequence-to-sequence (Seq2Seq) models. The proposed method can automatically generate multiple questions from an input sentence covering different views of the sentence as in rule-based methods, while more complicated "rules" can be learned via the Seq2Seq model. The method utilizes semantic role labeling to convert training examples into their semantic representations, and then trains a Seq2Seq model over the semantic representations. Our extensive experiments on three real-world data sets show that the proposed method significantly improves the state-of-the-art neural question generation approaches.

1 Introduction

Question Generation (QG) from text has gained increasing interest due to its usefulness in various applications such as educational reading comprehension assessment (Chen et al., 2018; Kumar et al., 2018), data augmentation for training question-answering systems (Sultan et al., 2020), and response generation in conversational systems (Gu et al., 2021). We have been working on QG for the purpose of automatically creating the knowledge base (KB) for a conversational QA system of an industry partner[1]. The knowledge base consists of QA pairs extracted from a domain-specific document (such as car manuals). Previously, the creation of their KB was done manually, which is very labor-intensive. To automate this KB generation process, we have tried both rule-based and neural sequence-to-sequence (Seq2Seq) QG methods.

The rule-based methods create rules based on linguistic features that capture the relationships among components of a sentence and can generate multiple questions from an input sentence to cover different aspects of the sentence. However, designing such rules is a very *labour-intensive* task as well. Also, these rules may not capture the *complexity* of ways a human asks questions (Yuan et al., 2019). As we will show in Section 4, the rule-based method does not lead to good results compared to neural Seq2Seq models.

While the Seq2Seq methods achieve better results, such methods are highly data-driven. For domains with limited training data (such as car manuals), relations that map the input text to questions cannot be well captured. In addition, Seq2Seq models often generate a single question from an input text. However, multiple questions can be asked about a piece of text from different aspects. One way to generate multiple questions with Seq2Seq models from an input text is to mark the input text with different *answer spans* or keywords to show the focus for QG so that multiple questions may be generated from the same text, one for each answer span/keyword. However, in our application, such answer spans or keywords are not available as marking answer spans or keywords when creating training data requires intensive labor work. Our partner prefers an answer-unaware QG system that can automatically generate multiple factual questions without indicating answer spans or keywords in either training or inference time. Another technique for generating multiple questions is to use diverse beam search (Vijayakumar et al., 2018) However, the beam search methods require the user to specify the number of questions returned, which is hard to specify as the ideal number of generated questions varies among different input texts.

To address these issues, we propose a novel approach to question generation, which uses semantic role labeling (commonly used in rule-based systems) that can label an input sentence in different ways corresponding to multiple semantic views of

an input sentence, and then trains a Seq2Seq model with SRL-labeled sequences for question generation. Our method does not need keyword/answer span labels in the training data nor specifications of the number of multiple answers to be generated. The use of SRL also increases the number of training examples, which may help alleviate the problem of the limited labeled data problem.

We evaluate the proposed method on three real-world data sets and compared the proposed method with several state-of-the-arts QG methods including the ones that generate multiple questions. The extensive experiments on these data sets show that proposed framework is significantly better than the state-of-the-art Seq2Seq models and rule-based methods, especially in terms of coverage and overall scores considering both precision and recall.

2 Related Work

The question generation approaches broadly fall into two categories: rule-based approaches and neural Seq2Seq learning approaches. Rule-based approaches mainly relay on hand-crafted templates/rules built upon linguistic features (Chali and Hasan, 2015; Flor and Riordan, 2018; Khullar et al., 2018; Lindberg et al., 2013). These methods use rigid heuristic rules to transform a source sentence into one or more questions. However, rules have limited power in expressing the complicated mapping function that the human uses for question generation. Designing a comprehensive set of rules is a very labour-intensive task.

Recently, neural Seq2Seq models have been successfully applied to question generation due to its capability to extract effective features and model complicated functions. Early Seq2Seq-based QG models are based on RNN structures. Examples include an LSTM-based Seq2Seq model with the global attention mechanism (Du et al., 2017) and LSTM-based model with the maxout pointer and gated self-attention network (MP-GSN) (Zhao et al., 2018). More recent Seq2Seq models are based on Transformer which relies entirely on self-attention to compute representations of its input and output without using sequence-aligned RNNs. State-of-the-art Transformer-based models that have been pre-trained for QG include T5 (Raffel et al., 2020), BART (Lewis et al., 2020), ProphetNet (Qi et al., 2020), UNILM (Dong et al., 2019), UNILMv2 (Bao et al., 2020), and Ernie-Gen (Xiao et al., 2020), to list some examples. While the Seq2Seq methods achieve better results than rule-based methods (Du et al., 2017), they are highly data-driven. In addition, Seq2Seq models often generate a single question given an input text, which does not cover multiple views of a sentence.

To solve this single-question-generation problem, different strategies have been proposed. One strategy is to use diverse beam search (Vijayakumar et al., 2018; Zhang and Zhu, 2021) or sampling techniques (such as top-p nucleus sampling used in (Sultan et al., 2020)). While these methods showed promising results, the user has to specify the bin/sample size and the number of questions to be generated (whose ideal number may depend on the input sequence). Another strategy for generating diverse questions is to mark or extract keywords in the input text and generate questions by conditioning on keywords or keyword positions (e.g., (Pan et al., 2020; Shen et al., 2020; Subramanian et al., 2018; Sun et al., 2018; Song et al., 2018; Zhang and Zhu, 2021)). However, extracting keywords (either automatically or manually) to build keyword-labeled training data often needs domain knowledge, a pre-defined keyword list, or documents beyond the training data. The QG method we propose solves these problems by learning Seq2Seq models with semantic role labeled QAs. It can generate multiple and diverse questions without specifying the number of questions to be generated or requiring keyword-labeled training data.

A recent method that also uses SRL and Seq2Seq models is a 2-step method in (Pyatkin et al., 2021). It tackles role question generation that, given a predicate mention and a passage, generates a set of questions asking about all possible semantic roles of the predicate. It first generates prototype questions for all the roles based on the ontology in PropBank (Palmer et al., 2005). It then trains a BART model to generate all questions (including ones that cannot be answered by the input text) given these prototype questions contextualized over the input text. Both the problem definition and the methodology are very different from ours. Our method does not need to generate prototype questions and we generate only the information-seeking questions that can be answered by the input text.

3 Proposed Methodology

Given a set of answer (i.e., sentence) and question pairs, our goal is to train a model to generate from an unseen sentence one or more questions that can be answered by the sentence. [2]

3.1 Overview of the Method

Our method contains a *Semantic Role Labeler (SRLer)*, a Seq2Seq model, and two semantic mappers (namely, *Question2SRL* and *SRL2Question*). First, *SRLer* extracts semantic representations (i.e., SRL labels) from answers in the training set. Then *Question2SRL* maps questions in the training set to their corresponding semantic representations. Next, a Seq2Seq model is trained using these semantic representations to convert an SRL representation of an answer to that of a question. In the inference stage, *Semantic Role Labeler* extracts semantic representations ($\widehat{a}_{sem}$) of an answer $\widehat{a}$. Then, $\widehat{a}_{sem}$ is converted to an SRL representation of a question ($\widehat{q}_{sem}$) by the learned Seq2Seq model. Finally, *SRL2Question* converts $\widehat{q}_{sem}$ into a natural language question $\widehat{q}$.

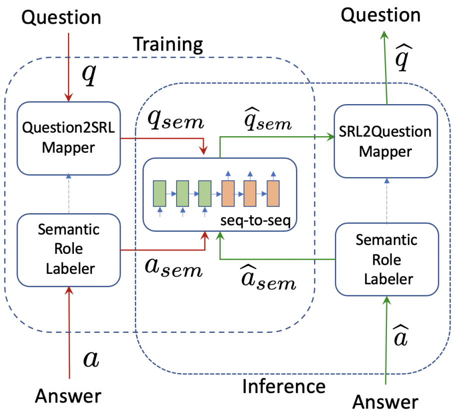

Figure 1: Overview of Proposed Framework

3.2 Semantic Role Labeler

A Semantic Role Labeler (SRLer) is used in both training and inference. In the training phase, an SRLer is used to convert each answer a in the training set into its semantic representation (denoted as a_{sem}) that contains semantic role labels (SRL).

An SRLer recognizes the predicate-argument structure of a sentence and assigns labels (i.e., semantic roles, such as agent, goal or result) to words or phrases in a sentence. We use *SRL BERT* (Shi and Lin, 2019) provided in AllenNLP (Gardner et al., 2017) to produce the semantic labels for the input text, which is the state-of-the-art model for SRL extraction[3]. This method generates a predicate-argument structure for a sentence based on a BERT-based approach. In this model, each sentence is represented by one or more propositions, consisting of a predicate (usually a verb) and its semantic arguments. For example, the semantic representation of sentence *"ABS is activated during braking under certain road or stopping conditions"* is "[ARG1] *is activated* [ARGM-TMP]", where [ARG1] (representing patient) and [ARGM-TMP] (representing time) are semantic role labels for *ABS* and *during braking under certain road or stopping conditions*, respectively.

Table 1 provides more examples of semantic representations for answers. Note that if a sentence contains more than one verb, more than one semantic representation may be generated. For example, S3 and S4 in Table 1 are from the same sentence.

3.3 The Question2SRL Mapper

The *Question2SRL* mapper converts a question q in the training data into its semantic representation q_{sem}. Instead of applying an SRLer directly on q, *Question2SRL* uses the semantic role labels in the semantic representation a_{sem} of q's corresponding answer a to label the phrases or words in q. We design two approaches for *Question2SRL*, namely, *Hard-Question2SRL* and *Soft-Question2SRL*:

Hard-Question2SRL: In this approach, for each semantic role label l that occurs in an answer's SRL representation, if its corresponding phrase or word occurs in the question, the phrase or word in the question is replaced with label l. The reason why we did not use semantic role labeling to directly label the question is that we would like to keep the question words (e.g., what, where, when, etc.) in the semantic representation of the question, and also that semantic role labeling may generate labels for a question which do not occur in its answer. The lower part of Table 1 provides the semantic representations of the questions corresponding to the answer SRL representations in the upper part of the table. Note that Q3 and Q4 are two different representations of the same question, resulting from two different SRL representations of the same answer (S3 and S4). Thus, one original training example

---

[2] We work on sentence-level QG instead of paragraph-level QG because the paragraphs in our application domain (car manuals) are often short and contain a single sentence. Also, an answer sentence in our car manuals dataset does not contain answer words labels, which is different from most paragraph-level QG systems where answer words/phrases are marked in an input paragraph. Sentence-level QG can be extended to paragraph-level QG via sentence segmentation after coreference resolution.

[3] We also used the *Clear Parser SRL* (Choi and Palmer, 2011) in our experiments. *SRL BERT* leads to better results. In this paper we report the results from *SRL BERT*.

Table 1: Semantic representation of answers and questions (ARG0: agent , ARG1: patient, ARG2: attribute, ARGM-NEG: negation, ARGM-PRP: purpose)

Semantic representation for sample input sentences (answers):
S1. [ARG1: the fuel filler funnel] is [ARG2: under the luggage compartment floor covering] .
S2. [ARG0: this vehicle] has a capless refueling system and does [ARGM-NEG: not] have [ARG1: a fuel cap] .
S3. distribute [ARG1: the trailer load] [ARGM-PRP: so 10 - 15 % of the total trailer weight is on the tongue] .
S4. distribute the trailer load so [ARG1: 10 - 15 % of the total trailer weight] is [ARG2: on the tongue] .

Semantic representation for the questions corresponding to the above sentence representations in the training data:
Q1: where is [ARG1: the fuel filler funnel] ?
Q2: does [ARG0: this vehicle] have [ARG1: a fuel cap] ?
Q3: how much of [ARG1: the trailer load] should be on the tongue ?
Q4: how much of the trailer load should be [ARG2: on the tongue] ?

can be converted to one or more SRL-labeled examples for training a Seq2Seq model, resulting in an increase in the size of training data.

***Soft-Question2SRL**:* The words/phrases labeled with a semantic role in an answer may not occur exactly in the question, but their synonyms or similar expressions may. In this case, *Hard-Question2SRL* may not find the exact match in the question. To address this issue, we design *Soft-Question2SRL* that considers the semantic similarity between the words/phrases corresponding to a semantic role label in a_{sem} and potential words/phrases in a question to find the best match. Algorithm 1 outlines the procedure. Given a set of SRLs (L) generated for answer a by *Semantic Role Labeler*, and question q, we first generate all possible n-grams (nG) from q, then compare the phrases/words corresponding to each label $l \in L$, denoted by $words(l)$, with each n-gram $ng \in nG$. The n-gram with maximum similarity with $words(l)$ is selected to be replaced by l as long as the similarity is greater than or equal to a threshold α. We calculate the similarity between n-grams and semantic role label words based on cosine similarity between their corresponding *Sentence-BERT* embeddings (Reimers and Gurevych, 2019).

Table 2 shows how the algorithm works using an example. The first box of the table illustrates the answer a, and its respective question q. Each subsequent box shows a semantic role label $l \in L$ in a_{sem}, the best n-gram ng matching with $words(l)$, and their respective similarity score. The final box shows the semantic representation of question q_{sem} after replacing n-grams with SRLs in previous steps. Note that we replace the n-gram with an SRL label if the score is higher than or equal to a threshold (i.e., α).

Algorithm 1: *Soft-Question2SRL*

```
Input  : $L$  // a set of SRLs generated for $a$
         $q$  // question
Output : $q_{sem}$  // semantic rep. of $q$
$nG \leftarrow$ Generate all n-grams from $q$
for each $l \in L$ do
    $score \leftarrow 0$
    for each $ng \in nG$ do
        $sim \leftarrow$ Cosine($words(l)$, $ng$)
        if $score < sim$ then
            $score \leftarrow sim$
            $l_{best} \leftarrow l$
    if $score \geq \alpha$ then
        $q_{sem} \leftarrow$ replace $ng$ in $q$ with $l_{best}$
```

3.4 Sequence-to-Sequence Learning

Given a set of $\langle a_{sem}, q_{sem} \rangle$ pairs (where a_{sem} and q_{sem} are an SRL-labeled answer and an SRL-labeled question, respectively), we train a Seq2Seq model to convert a_{sem} to q_{sem}. Any Seq2Seq model can be used for this purpose. In our experiment, we use the state-of-the-art models T5 (Raffel et al., 2020) and BART (Lewis et al., 2020) to evaluate our method.

We feed the Seq2Seq model with a_{sem} as the input sequence, where some of words/phrases in the original answer a are replaced by SRLs. While SRLs provide the Seq2Seq model with useful information, this replacement may reduce the information to which model is exposed. As another strategy, we add the actual answer a as a context to the input sequence. That is, the input to the Seq2Seq model is $\langle answer$: a_{sem} $context$: $a\rangle$, where $answer$: and $context$: are tokens prepended to a_{sem} and a, respectively. Alternatively, we can add the SRL labels of the actual answer a and their corresponding

Table 2: An example of *Soft-Question2SRL* mapper converting a question into its semantic representation. Each row shows the best score and corresponding n-gram in the question ($\alpha = 0.85$).

Semantic representation (a_{sem}) for sample answer sentence a and its corresponding question q: a_{sem} = [ARGM-TMP: in january 2009] , [ARG0: the green power partnership -lrb- gpp , sponsored by the epa -rrb-] [V: listed] [ARG1: northwestern] [ARG2: as one of the top 10 universities in the country in purchasing energy from renewable sources] . q = in 2009 , who named northwestern as one of the top 10 universities in the country in purchasing renewable energy ?
l = [ARGM-TMP], $words(l)$ = "in january 2009" *Best matching ng* = "in 2009", $Similarity\ score = 0.91 > \alpha \Rightarrow$ **Replace** ng **with** l **in** q_{sem}
l = [ARG0], $words(l)$ = "the green power partnership -lrb- gpp , sponsored by the epa -rrb- *Best matching ng* = "in purchasing renewable energy ?", $Similarity\ score = 0.46 < \alpha$
l = [V], $words(l)$ = " listed" *Best matching ng* ← "in", $Similarity\ score = 0.42 < \alpha$
l = [ARG1], $words(l)$ = "northwestern" *Best matching ng* = "northwestern", $Similarity\ score = 1.00 > \alpha \Rightarrow$ **Replace** ng **with** l **in** q_{sem}
l = [ARG2], $words(l)$ = "as one of the top 10 universities in the country in purchasing energy from renewable sources" *Best matching ng* = "as one of the top 10 universities in the country in purchasing renewable energy", $Similarity\ score = 0.98 > \alpha \Rightarrow$ **Replace** ng **with** l **in** q_{sem}
q_{sem} = ARGM-TMP , who named ARG1 ARG2 ?

words separated by a special token <*sep*> to the input sequence. The input to the Seq2Seq model is $\langle answer\colon a_{sem}$ <*sep*> *label words* <*sep*>$\rangle$.

Table 3 shows a training example with three variations of the input. We will compare the three input versions of the Seq2Seq model in the experiment.

3.5 The SRL2Question Mapper

In the inference phase, the SRLer is first used to convert an input sentence (i.e., answer $\widehat{a}$) into its semantic representation ($\widehat{a}_{sem}$). Then, the trained Seq2Seq model is used to convert $\widehat{a}_{sem}$ into a semantic representation of a question ($\widehat{q}_{sem}$). After that, the *SRL2Question* mapper transforms all the semantic role labels in the generated semantic representation $\widehat{q}_{sem}$ into words or phrases. In particular, for each semantic role label l in the semantic representation $\widehat{q}_{sem}$ generated by the Seq2Seq model, the *SRL2Question* mapper looks for label l in all the semantic representations $\widehat{a}_{sem}$ of the input sequence $\widehat{a}$, and uses the phrase or word in $\widehat{a}$ that corresponds to l to replace l in $\widehat{q}_{sem}$. Table 4 shows examples of generated semantic representations and converted questions, together with their input sentences, semantic representations of the input sentences, and ground truth questions.

4 Empirical Evaluation

We investigate (1) whether using SRL with Seq2Seq models improves the QG performance of Seq2Seq without SRL, and (2) how our method compares with the state-of-the-art QG methods.

4.1 Datasets

We evaluate our method on 3 datasets[4]. The first one contains QAs created by human annotators from two car manuals of Ford and GM, denoted as Car Manuals. The second dataset is SQuAD (Rajpurkar et al., 2016), containing QAs created by Amazon Mechanical Turk crowd-workers from Wikipedia articles. We use the processed sentence-level SQuAD dataset (Du et al., 2017), where the answer in a QA pair is a single sentence. The third dataset is NewsQA (Trischler et al., 2016), a machine comprehension dataset of human-generated QA pairs from CNN news articles. We created a sentence-level NewsQA dataset. The sentences were extracted from corresponding paragraphs based on their answer span. All the datasets contain training, testing and development sets. Their statistics are given in Table 5. In these datasets, multiple QA pairs may have the same answer sentence but different questions. For example, two QA pairs in SQuAD share "alfred north whitehead was born in ramsgate, kent, england, in 1861" as the answer, but their questions (i.e., "in what year was whitehead born?" and "where was alfred north whitehead born?") are different and cover different aspects of the answer sentence.

4.2 Automatic Evaluation Metrics

For automatic evaluation, we use the $precision$, $recall$ and F scores proposed in (Schlichtkrull and Cheng, 2020)[5] for measuring the quality and diversity of generated questions. Given a test example

---

[4] The code and data sets are available at `https://github.com/Naeiji/QGwSRL`

[5] These scores are called u, v and F scores in (Schlichtkrull and Cheng, 2020).

Table 3: A training example for Seq2Seq model with 3 different strategies for input (i.e., answer) representations.

input	*answer*: [ARG1] was named [ARG2], [ARGM-PRD].
input+C	*answer*: [ARG1] was named [ARG2], [ARGM-PRD]. *context*: denver linebacker von miller was named super bowl mvp, recording five solo tackles, 2 1/2 sacks, and two forced fumbles.
input+L	*answer*: [ARG1] was named [ARG2], [ARGM-PRD]. <*sep*> [ARG1] denver linebacker von miller <*sep*> [ARG2] super bowl mvp <*sep*> [ARGM-PRD] recording five solo tackles , 2 1/2 sacks , and two forced fumbles <*sep*>
output	who won the [ARG2] ?

Table 4: Examples of sentence $\widehat{a}$, its semantic representation $\widehat{a}_{sem}$, the outcome $\widehat{q}_{sem}$ generated by Seq2Seq, the question $\widehat{q}$ converted from $\widehat{q}_{sem}$, and ground-truth question Q_t from the Car Manuals dataset.

$\widehat{a}$:	before placing a child in the child restraint , make sure it is securely held in place .
$\widehat{a}_{sem}$:	before placing [ARG1] [ARG2] , make sure it is securely held in place .
$\widehat{q}_{sem}$:	what should i do before placing [ARG1] [ARG2] ?
$\widehat{q}$:	what should i do before placing a child in the child restraint ?
Q_t:	what should i do before placing a child in the child restraint ?
$\widehat{a}$:	adjust the temperature setting using the + and - temperature buttons on the right-hand side of the climate controls .
$\widehat{a}_{sem1}$:	adjust the [ARG1] setting using the + and - temperature buttons on the right-hand side of the climate controls .
$\widehat{a}_{sem2}$:	adjust the temperature setting using [ARG1] [ARGM-LOC] .
$\widehat{q}_{sem1}$:	how do i adjust the [ARG1] setting ?
$\widehat{q}_{sem2}$:	how do i adjust the temperature [ARGM-LOC] ?
$\widehat{q}_1$:	how do i adjust the temperature setting ?
$\widehat{q}_2$:	how do i adjust the temperature on the right-hand side of the climate controls ?
Q_t:	how do i adjust the temperature on the passenger 's side ?

Table 5: Statistics of Three Datasets

Dataset	training set	test set	development set
Car Manuals	9,184 QAs	1,869 QAs	1,403 QAs
SQuAD	70,484 QAs	11,877 QAs	10,570 QAs
NewsQA	91,536 QAs	5,067 QAs	5,136 QAs

consisting of input text a and a set of ground-truth questions T, the $precision$ and $recall$ of a set of questions G generated from a by a QG method are defined as:

$$precision(G,T,s) = \frac{1}{|G|}\sum_{g\in G}\max_{t\in T} s(g,t)$$

$$recall(G,T,s) = \frac{1}{|T|}\sum_{t\in T}\max_{g\in G} s(g,t)$$

where s is a scoring function that measures the similarity between two questions. We use the similarity function used in BLEU-n (n-gram text overlap), ROUGE-L (longest common subsequence text overlap) and METEOR (which takes into account word re-ordering, stemming, synonyms, and paraphrase matching) to compute s. *F-score* is defined as the harmonic mean of precision and recall.

4.3 Comparison of Seq2Seq+SRL with Seq2Seq methods

To investigate whether the use of SRL with Seq2Seq models improves the QG performance of Seq2Seq models trained with original sentences, we conducted experiments with two state-of-the-art transformer-based Seq2Seq models: (1) **BART** (Lewis et al., 2020) and (2) **T5** (Raffel et al., 2020).

We fine-tune the Huggingface pretrained models (Wolf et al., 2019) of BART-base and T5-small with 139 and 60 million parameters respectively. We use the smallest available model sizes of BART and T5 to avoid GPU memory error. Four V100-SXM2 32GB GPUs are used for fine-tuning. For baselines, T5 and BART are fine-tuned using the original sentence-based QA pairs in each training set to generate a question given an answer.

For our method, we use a pre-trained SRL BERT model (Shi and Lin, 2019) provided in AllenNLP (Gardner et al., 2017) as the Semantic Role Labeler to convert answer sentences to their SRL representations. We then fine-tune T5 or BART to learn a model that maps an SRL representation of an input sentence to that of the question, which is then mapped to a natural language question.

To determine the values of hyperparameters in the Seq2Seq model (T5 and BARR) in either baseline or our model, we conduct random search (Bergstra and Bengio, 2012) due to its efficiency. To do so, we randomly select 10 combinations of learning rates (LR) and epoch numbers (EP) as follows: "LR = 5×10^{-6}, EP = 2"; "LR = 10^{-5}, EP = 8"; "LR = 5×10^{-5}, EP = 5"; "LR = 5×10^{-5}, EP = 10"; "LR = 10^{-4}, EP = 10"; "LR = 10^{-4}, EP = 4"; "LR = 5×10^{-4}, EP = 3"; "LR = 5×10^{-4}, EP = 7"; "LR = 10^{-4}, EP = 4"; and "LR = 10^{-4} EP = 10". The best model for each dataset and each method is chosen based on the final loss of the development set. We combine an actual batch size of 16 with 2 gradient accumulation steps per minibatch to artificially create a batch size of 32. The maximum sequence length is set to 512 for both input and output. For decoding method, we use beam search with a beam size of 10.

4.3.1 Results of Automatic Evaluation

Table 6 shows the automatic evaluation results on Car Manuals with BART and T5 as the baseline. **Hard** is our method using *Hard-Question2SRL* for *Question2SRL*. **Soft** is our method with *Soft-Question2SRL* with 80% as the soft-matching threshold (α). **Soft+C** and **Soft+L** are our methods with *Soft-Question2SRL* plus using the original question or SRL labels and their corresponding words as the context, respectively.

Table 6: Automatic evaluation results on **Car Manuals** with **BART** and **T5** as Baselines (P, R and F mean Precision, Recall and F-score in %). Hard and Soft+ methods are variations of our method with BART or T5 as the Seq2Seq model.

	BLEU-4			ROUGE-L			METEOR		
QG Method	F	P	R	F	P	R	F	P	R
BART	57.2	63.7	51.9	71.7	75.9	68.0	57.6	63.7	52.6
Hard	70.9	68.3	73.6	76.4	75.7	77.1	58.7	57.5	59.9
Soft	82.6	76.3	90.1	90.6	87.9	93.5	58.8	55.7	62.2
Soft+C	88.3	**85.4**	91.4	94.3	**94.0**	94.6	63.0	**62.1**	63.9
Soft+L	**89.0**	85.1	**93.2**	**94.8**	93.7	**95.9**	**63.6**	61.8	**65.5**
T5	45.0	50.3	40.7	62.4	66.0	59.2	46.3	50.0	43.1
Hard	63.9	58.8	70.0	71.5	69.1	74.0	52.3	49.3	55.7
Soft	77.0	71.5	83.5	85.9	82.7	89.4	53.6	50.4	57.1
Soft+C	**85.9**	**84.1**	**87.8**	**91.9**	**91.5**	**92.4**	**59.9**	**59.3**	**60.5**
Soft+L	84.7	82.8	86.6	91.0	90.1	92.0	58.8	57.6	60.0
Rule Based	17.4	13.9	23.2	36.2	31.6	42.5	22.0	18.5	27.1

As shown in Table 6, using SRL representations to train a QG model with either BART or T5 significantly improves the baseline performance on Car Manuals. This is due to generalization of sentences into SRL representations, allowing general semantic patterns to be modeled and used in QG. The use of SRLs also increases the number of training examples due to the fact that the SRLer can convert a sentence into multiple SRL-labeled sentences. All the variations of our method significantly increase the recall and F-scores in all types of measures (BLEU, ROUGE and METEOR) and they also increase precision in almost all of the cases. The recall increase is due to the fact that the SRLer can convert a sentence into multiple SRL-labeled sentences, leading to questions asking about different aspects of the sentence.

Comparing the hard and soft versions of our method, Soft-Question2SRL is better than Hard-Question2SRL in all cases, indicating that allowing different but similar expressions in the corresponding question and answer when labelling the question with SRLs is important and beneficial. We also see that the use of the original source sentence or SRL labels as a context in the input is beneficial. This is probably because the error propagation from semantic role labeling has less impact when (part of) the original sentence are given as a context.

Table 7: Automatic evaluation results on **SQuAD** with **BART** and **T5** as baselines (P, R and F mean Precision, Recall and F-score). Hard and Soft+ methods are different variations of our method with BART and T5 as the Seq2Seq models.

	BLEU-4			ROUGE-L			METEOR		
QG Method	F	P	R	F	P	R	F	P	R
BART	15.2	**21.4**	11.7	42.9	**48.0**	38.8	20.6	**22.6**	18.9
Hard	17.8	17.9	17.6	45.0	44.0	46.2	21.4	20.3	22.6
Soft	19.6	18.5	**20.9**	46.6	44.3	49.1	22.4	21.0	24.0
Soft+C	19.7	20.5	19.0	47.4	47.0	47.9	22.9	21.8	24.1
Soft+L	**20.0**	20.2	19.9	**48.1**	46.9	**49.3**	**23.3**	21.8	**25.0**
T5-single	15.0	19.9	12.0	41	46.3	36.7	19.5	**23.2**	16.7
Hard	16.6	16.1	17.1	43.4	42.2	44.5	20.3	19.6	21.1
Soft	18.0	16.6	**19.8**	44.8	43.0	46.8	21.5	20.9	22.2
Soft+C	19.0	19.6	18.4	45.7	45.7	45.8	22.1	22.2	22.0
Soft+L	**19.9**	**20.4**	19.4	**48.0**	**47.1**	**48.9**	**23.2**	21.8	**24.8**

Tables 7 shows the automatic evaluation results on the SQuAD dataset with BART and T5 as the baseline. Again, we observe that all variations of our method significantly outperform the baseline on recall and F-score. On this data set, the BART baseline shows the best precision. However, the lower precision of our method is due to the incompleteness of the ground truth questions in SQuAD. That is, many of the questions our method generates are good questions, but they do not match the ground truth questions in the data set[6].

Table 11 in Appendix B shows the generated questions for 3 testing examples from our method (Soft+L) with T5 and T5 without SRL. As shown, our method generates more questions covering different aspects of an input sentence, while T5 without SRL generates only one question. In all the 3 examples, there is only one ground-truth question. When precision is computed, the extra questions we generated have a low precision due to poor match with the ground truth even though they are good questions. This explains why our methods have lower precision scores than the baselines.

The results on this dataset also show that soft matching is better than hard matching, and the use of context is better with T5, but has no obvious

---

[6] Such a problem is also mentioned by others such as in (Sultan et al., 2020)

advantage for BART. We show the impacts of soft-matching threshold α in Appendix E. In practice, α can be tuned using the development set.

Similar results are observed on the NewsQA dataset, as shown in Table 12 in Appendix C.

4.3.2 Human Evaluation

We randomly selected 50 input sentences from the SQuAD dataset and asked 5 English speakers to rate the quality of generated questions from each method in terms of *recall*, *clarity*, *Q&A relatedness* and *grammar*. All the criteria are rated based on a 5-point scale. A precision score for each question is computed by averaging the scores for clarity, Q&A relatedness and grammar. An overall score (F score) for each test input sentence is computed as the harmonic mean of precision and recall scores. Detailed information on the questionnaire we provided to the human evaluators is provided in Appendix 4.3.2.

Table 8 shows the average scores among the human evaluators. The results show that our methods (Soft+L with BART and T5+Soft with T5) are significantly better than their corresponding baseline in recall and F-measure, and they are also better than the baselines in precision.

4.4 Comparison with other SOTA methods

We compare our method with additional SOTA baselines, most of which can generate multiple questions from an input sentence:

- **BART-multi** and **T5-multi**. BART or T5 model fine-tuned to generate multiple sequences given an input sequence by using <*sep*> tokens to separate the ground-truth questions in the output part of each training example.
- **BART-divbeam** and **T5-divbeam**. BART or T5 model that uses decoding-based diverse beam search (Vijayakumar et al., 2016) to generate multiple questions. We use beam size of 6 with 3 diverse groups and diversity penalty of 0.4 all same as in (Zhang and Zhu, 2021). We select 3 best questions for the evaluation[7].
- **ProphetNet-single** and **ProphetNet-multi**. ProphetNet (Qi et al., 2020) is another Transformer-based SOTA model. In ProphetNet-single, ProphetNet is fine-tuned to generate a single question. In ProphetNet-multi, it is fine-tuned to generate multiple sequences from an input sequence by using <*sep*> tokens to separate the ground-truth questions.
- **MP-GSN** (Zhao et al., 2018) An LSTM-based Seq2Seq QG model. We use the sentence-level MP-GSN with the default setting in the implementation of MP-GSN in (Lee, 2019).
- **Rule-based method** with 75 rules based on semantic role labels to convert a sentence into questions.[8]

The hyper-parameters for all the Seq2Seq methods are determined through random search (described in Section 4.3).

Table 9 shows the results of these SOTA methods on SQuAD compared to our method (Soft+L) with BART or T5 as the Seq2Seq model. As shown, our methods outperform all the baselines in F-score and recall. It is also the best in precision in all underlying metrics except for precision using METEOR where ProphetNet-single is the best and our methods are the second best.

Compared to Seq2Seq-multi, our methods outperform them significantly in all metrics, indicating using SRL to generate multiple questions is much more effective than using the <*sep*> tokens in the output parts of the training sequences.

Our methods also outperform the diverse-beam-search-based methods for generating multiple questions, indicating different SRL representations of a sentence can more effectively lead to generation of diverse questions that cover different aspects of the input sentence.

Compared to the rule-based method, our method outperforms it significantly on all measures with big margins. This indicates that SRL-based Seq2Seq model better captures the relations between SRL representations of questions and those of answers than rules, which complicated "rules" can be learned by Seq2Seq models.

5 Performance with Different Data Sizes

Among the 3 datasets, Car Manuals is the smallest, and the improvements of our method on this dataset over the baselines are the largest. To further investigate whether our method makes better improvement when the data set is small, we conducted an experiment with one quarter of the SQuAD dataset.

---

[7] We select top-3 questions because the average number of questions generated by our method per input sentence is 3 (see Table 10 for more details), to make the comparison fair. In general, the more questions are generated, the lower the precision but better the recall.

[8] An example rule is "Replace [ARG1] with *what* if it appears at the beginning of the sentence".

Table 8: Human evaluation results on 50 test sentences from SQuAD. Precision is the average of Clarity, Relatedness and Grammar scores. F-measure is the harmonic mean of precision and recall scores

QG System	F-measure Score (1-5) ± stdev	Precision Score (1-5)	Recall Score (1-5)	Clarity Score (1-5)	Relatedness Score (1-5)	Grammar Score (1-5)
BART	3.64 ± 0.33	4.73	3.06	4.70	4.56	**4.94**
Soft+L (with BART)	**4.32 ± 0.28**	**4.77**	**4.16**	**4.75**	**4.61**	4.93
T5	3.63 ± 0.37	4.71	3.08	4.66	**4.63**	4.85
Soft+L (with T5)	**4.40 ± 0.29**	**4.73**	**4.25**	**4.72**	4.48	**4.90**

Table 9: Comparison with SOTA models on **SQuAD**

	BLEU-4			ROUGE-L			METEOR		
QG Method	F	P	R	F	P	R	F	P	R
BART-multi	15.2	18.4	12.9	41.8	44.5	39.3	20.0	21.2	18.8
T5-multi	14.9	16.5	13.6	40.5	42.2	39.0	19.3	20.9	17.9
BART-divbeam	17.5	19.2	16.1	46.7	46.9	46.5	22.6	21.7	23.5
T5-divbeam	17.6	19.2	16.3	46.3	46.4	46.1	22.4	21.8	23.1
ProphetNet-single	16.2	20.3	13.5	43.0	46.4	40.2	21.2	**22.7**	19.8
ProphetNet-multi	14.5	17.7	12.3	39.6	43.7	36.2	19.8	21.3	18.5
MP-GSN	12.1	17.0	9.5	39.5	43.9	35.8	17.7	19.1	16.5
Rule Based	9.1	8.0	10.4	25.1	23.0	27.5	15.0	14.5	15.4
Soft+L (Ours with BART)	**20.0**	20.2	**19.9**	**48.1**	46.9	**49.3**	**23.3**	21.8	**25.0**
Soft+L (Ours with T5)	19.9	**20.4**	19.4	48.0	**47.1**	48.9	23.2	21.8	24.8

Figure 3 in Appendix F illustrates the relative improvement of our method over the T5 baseline in F-measure, precision and recall. The relative improvement is computed as: $\frac{score_{our}-score_{t5}}{score_{t5}}$. The blue bars in the figure represent the improvement on the one-quarter subset of SQuAD and yellow ones represent that on the whole SQuAD dataset. Clearly, the improvements of our method over the T5 baseline are larger on the smaller dataset than on the whole SQuAD dataset. This indicates that our SRL-based Seq2Seq method can better handle smaller datasets than its Seq2Seq baselines due to the increase in training examples when we label the QAs with SRLs.

6 Conclusions

We proposed a novel QG method that learns a Seq2Seq model to convert an SRL representation of an input sentence into an SRL representation of a question, which is then converted to a natural language question. Similar to rule-based methods, our SRL-based Seq2Seq methods can generate multiple questions from an input sentence, significantly improving the recall and overall performance of Seq2Seq QG. It is also much better than rule-based methods because better and more complicated "rules" can be learned via the Seq2Seq model. Our evaluation on three real-world datasets shows that the proposed method significantly outperforms both rule-based, original Seq2Seq methods and several other SOTA models, especially in recall and overall performance. As future work, we will extend this method to paragraph-based question generation.

Limitations

A limitation of our method is that its performance depends on the SRL performance. If the input sentences are not well-formed, semantic role labeling may not produce correct labels. Also, we found that some of the questions generated by our method for the same input sentence may be similar or same in meaning with some minor differences in the use of words. This may not be a problem if the application allows similar questions to be generated (e.g., for reading compression). But in the application where duplicated questions are not allowed or not desired, a post-processing step to remove questions with the same meaning is needed.

Acknowledgements

We would like to thank iNAGO Corporation for providing the Car Manuals dataset used in this research and for their collaboration on the research topic. This work is supported by an NSERC Alliance grant from the Natural Sciences and Engineering Research Council (NSERC) of Canada.

A Average Number of Questions Generated by our Methods

Table 10: Average numbers of generated questions per source sentence by our method with BART and T5

QG Method	Avg. # of questions
BART+Soft	3.3
BART+Soft+C	2.8
BART+Soft+L	3.0
T5+Soft	3.3
T5+Soft+C	2.7
T5+Soft+L	3.0

Table 10 provides the average number of questions generated by different versions of our methods on the SQuAD dataset.

B Examples of Generated Questions from SQuAD

Table 11 shows 3 examples of an input sentence $\widehat{a}$, its ground-truth question (q_g) and the generated questions ($\widehat{q_i}$) from our method (Soft+C) with T5 compared to the question (g_t) generated from the T5 baseline without the use of SRLs. As shown, our method generates more questions covering different aspects of the input sentence, while T5 without SRL generates only one question. In all these 3 examples, there is only one ground-truth question in the data set. When precision is computed, the extra

Table 11: Three Examples showing the input sentence $\widehat{a}$, its ground-truth question q_g, the question generated by T5 (q_t), and the questions $\widehat{q_i}$ generated by our Soft+L method with T5 and alpha=80% on the SQuAD dataset

$\widehat{a}$:	there are two categories of repetitive dna in genome : tandem repeats and interspersed repeats .
q_g:	what are two types of repetitive dna found in genomes ?
q_t:	what are the two categories of repetitive dna in genome ?
$\widehat{q}_1$:	what are the two categories of repetitive dna in the genome ?
$\widehat{q}_2$:	how many categories of repetitive dna are there in the genome ?
$\widehat{a}$:	before the solar/wind revolution , portugal had generated electricity from hydropower plants on its rivers for decades .
q_g:	through what renewable resource had portugal generated electricity before the solar/wind revolution ?
q_t:	before the solar/wind revolution, portugal had generated electricity from what ?
$\widehat{q}_1$:	what had portugal generated electricity from before the solar/wind revolution ?
$\widehat{q}_2$:	how long had portugal generated electricity from hydropower plants on its rivers ?
$\widehat{a}$:	the term parinirvana is also encountered in buddhism , and this generally refers to the complete nirvana attained by the arahant at the moment of death , when the physical body expires .
q_g:	what term is used for the complete nirvana attained by the arahant at death ?
q_t:	what is the term parinirvana used in buddhism ?
$\widehat{q}_1$:	what term is also encountered in buddhism ?
$\widehat{q}_2$:	when is the complete nirvana attained by the arahant ?
$\widehat{q}_3$:	who attained the complete nirvana at the moment of death ?
$\widehat{q}_4$:	what does the term parinirvana refer to at the moment of death ?
$\widehat{q}_5$:	what term is used in buddhism to describe the complete nirvana attained by the arahant at the moment of death ?

questions we generated have a low precision due to poor match with the ground truth even though they are good questions. This explains why our methods sometimes have lower precision scores than the baseline method in automatic evaluation. This unfairness is due to the incompleteness of ground truth questions in the SQuAD dataset.

C Results on NewsQA Dataset

Table 12: Automatic evaluation results on **NewsQA** with **BART** and **T5** as Baselines (P, R and F mean Precision, Recall and F-score). Hard and Soft+ methods are different variations of our method with BART and T5 as the Seq2Seq models.

	BLEU-4			ROUGE-L			METEOR

Table 12 shows the results of different variations of our method on the NewsQA dataset, compared with BART and T5 baselines.

D Questionnaire for Human Evaluation

We ask the human evaluators to rate the quality of generated questions from each method in terms of *recall*, *clarity*, *Q&A relatedness* and *grammar* on a scale of 1-5 using the following criteria.

For **Recall**, the ratings are:

- 1= Bad: the generated questions do not cover any fact in the answer;
- 2= Unacceptable: the generated questions cover only a small portion of the facts in the answer;
- 3= Borderline: the generated questions cover around 50% of the facts in the answer;
- 4= Acceptable: the generated questions cover most of the facts in the answer; and
- 5= Good: the generated questions cover all the facts in the answer.

For **Clarity**, the ratings are:

- 1= Bad: the question is completely unclear in meaning or makes no sense;
- 2= Unacceptable: the question is mostly unclear;
- 3= Borderline: the question is between unacceptable and acceptable;
- 4= Acceptable: the question is clear and understandable, but the use of words can be improved; and
- 5= Good: the question has no problem. It is clear, simple and uses the right words.

For **Q&A Relatedness**, the ratings are:

- 1= Bad: the question is completely unrelated to the answer sentence it is generated from;
- 2= Unacceptable: the question is somewhat related to the answer sentence, but it cannot be answered by the answer sentence;
- 3= Borderline: the question can be partially answered by the answer sentence, but far from completely;
- 4= Acceptable: the question can be mostly answered by the answer sentence, although maybe not completely; and
- 5= Good: the question can be very well answered by the answer sentence.

For **Grammar**, the ratings are:

- 1= Bad: the grammar of the question is completely wrong;

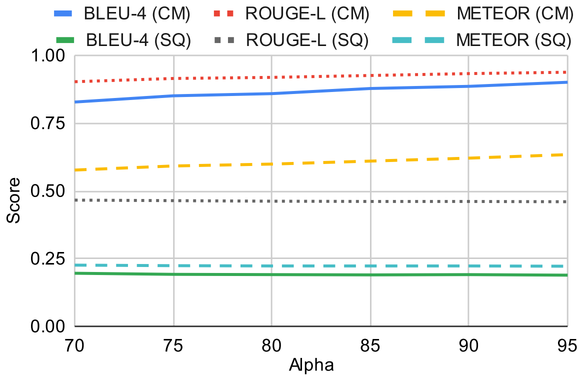

Figure 2: BLEU-4, ROUGE-L and METEOR F-scores of T5 on SQuAD (SQ) and Car Manuals (AM) using different alphas values.

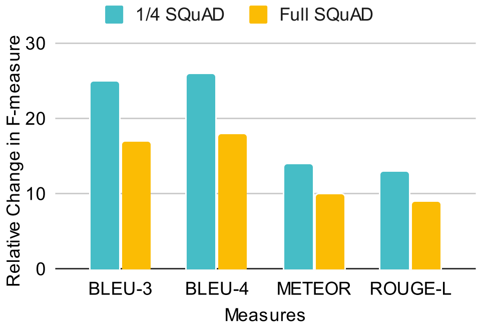
- 2= Unacceptable: the question has major grammatical problems;
- 3= Borderline: the question has a grammatical error, which is between major and minor;
- 4= Acceptable: the question has only a minor grammatical problem; and
- 5= Good: the question is completely grammatically correct.

E Sensitivity Analysis

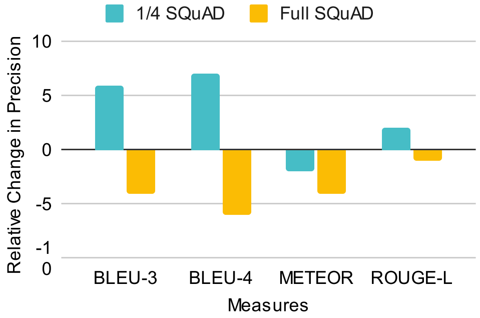
To see how the soft-matching threshold α affects the results, we experiment with different α values ranging from 70 to 95 and use the resulting datasets to fine-tune T5. In this experiment, we use the best configurations of the T5 model on the Car Manuals and SQuAD datasets. Six α values of 70, 75, 80, 85, 90, and 95 are selected for this purpose. Figure 2 shows how the F-score of BLEU-4, ROUGE-L and METEOR changes with α on SQuAD (SQ) and Car Manuals (CM). As can been seen, on SQuAD all the lines are quite flat, indicating α values do not have much impact on the performance. This is likely due to the best-matching n-gram in a ground-truth question either matches with the word/phrase replaced by an SRL in the answer very well or very poorly, leading to insensitivity to the threshold value between 70 and 95. Similar results are observed on the Car Manuals dataset although the scores are increasing with the α on this dataset, but slowly.

F Performance vs Different Data Sizes

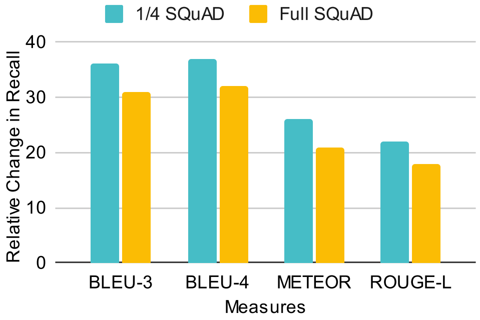
To further investigate whether our method makes better improvement over the baselines when the data set is small, we conducted an experiment with one quarter of the SQuAD dataset. Figure 3 illustrates the relative improvement of our method over the T5 baseline in F-measure, Precision and Recall. The relative improvement is computed as: $\frac{score_{our}-score_{t5}}{score_{t5}}$.



(a) F-measure



(b) Precision



(c) Recall

Figure 3: Comparison of relative change (percent) between the first quarter of SQuAD and whole SQuAD dataset using T5+C versus T5 with alpha=85%.

The blue bars in the figure represent the improvement on the one-quarter subset of SQuAD and yellow ones represent that on the whole SQuAD dataset. Clearly, the improvements of our method over the T5 baseline are larger on the smaller dataset than on the whole SQuAD dataset. This indicates that our SRL-based Seq2Seq method can better handle smaller datasets than its Seq2Seq baselines due to the increase in training examples when we label the QAs with SRLs.

StyLEx: Explaining Style Using Human Lexical Annotations

Abstract

Large pre-trained language models have achieved impressive results on various style classification tasks, but they often learn spurious domain-specific words to make predictions (Hayati et al., 2021). While human explanation highlights stylistic tokens as important features for this task, we observe that model explanations often do not align with them. To tackle this issue, we introduce **StyLEx**, a model that learns from human annotated explanations of stylistic features and jointly learns to perform the task and predict these features as model explanations. Our experiments show that StyLEx can provide human-like stylistic lexical explanations without sacrificing the performance of sentence-level style prediction on both in-domain and out-of-domain datasets. Explanations from StyLEx show significant improvements in explanation metrics (sufficiency, plausibility) and when evaluated with human annotations. They are also more understandable by human judges compared to the widely-used saliency-based explanation baseline.[1]

1 Introduction

People use style as a strategic choice for their personal or social goals in communications, making style analysis a long-studied field in NLP (Hovy, 1987; Kabbara and Cheung, 2016; Kang and Hovy, 2021). While large language models have obtained state-of-the-art results on many NLP tasks, they have been shown to overfit to spurious correlations in data across several datasets (Sen et al., 2021; Schlangen, 2021; Bras et al., 2020). Hayati et al. (2021) found a phenomenon in style classification tasks where the model's word-level explanation do not align with human's stylistic cues (stylistic cues are words that signify the style of a text). For instance, words such as "performances" and "wrench" in Figure 1 are marked as important cues for sentiment by a saliency method. However, they are different from words that humans perceive as essential features for predicting the style ("top," "notch").

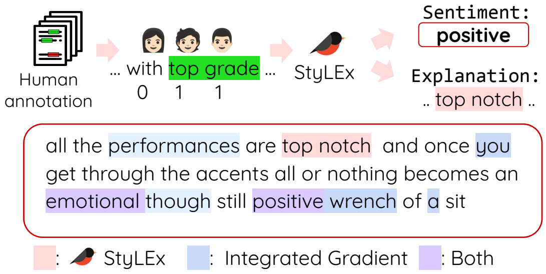

Figure 1: StyLEx classifies the input sentence's style and provides lexical explanation. Compared to explanations computed by the integrated gradient method (Mudrakarta et al., 2018), StyLEx can find more accurate stylistic words. Green highlight refers to human's annotated positive word, pink for StyLEx, blue for baseline, and purple for both StyLEx and the baseline.

Prior research in style have developed stylistic lexicon dictionary to identify the style of a text, such as sentiment or emotion, and in-turn incorporated them for style classification tasks (Mohammad and Turney, 2010; Hutto and Gilbert, 2014; Tausczik and Pennebaker, 2010). While lexicon-based matching methods (Taboada et al., 2011; Eisenstein, 2017) provide interpretability for the task, they lack coverage and do not incorporate the context for prediction. On the other hand, current large scale models like BERT (Devlin et al., 2019) are effective at style classification. However, their explanations often reveal that the model do not rely on the stylistic words to make the prediction. In this work, we hypothesize that leveraging stylistic lexica along with the effectiveness of a large scale model like BERT can not only predict style but also provide meaningful explanations that align with human style explanations.

Towards this, we introduce **StyLEx**, a style classification model that jointly learns to align human-annotated stylistic cues as explanations and then

predict the style of the overall sentence based on the cues (Figure 1). StyLEx uses a semi-supervised approach to expand the stylistic words from a handful number of human-annotated stylistics words. First, we train StyLEx using existing small human stylistic word annotation from Hayati et al. (2021). Then, we obtain predicted stylistic words on the larger benchmarking style datasets and retrain StyLEx on this expanded data to predict both the sentence's style label and the stylistic lexical explanation.

In this study, we show that for both in-domain and out-of-domain data, StyLEx not only shows competitive classification performance with BERT-based model, but also generate stylistic lexical explanations that have higher alignment with human explanations. In terms of explanation quality, StyLEx surpasses the baseline method across multiple explanation metrics. For the sufficiency metric, we improve upon the baseline by 14.12% on the average. For plausibility, StyLEx's lexical explanations correlate highly with human lexical annotation ground truth with an average Pearson's r correlation score of 44% compared to the baseline's correlation score of 3.9%. Finally, we found that 72.5% of StyLEx's explanations are more preferred by human judges compared to the baseline.

2 StyLEx: Style Classification with Human Lexical Annotations

2.1 StyLEx Model Architecture

StyLEx is a joint model for word-level and sentence-level style prediction. Unlike a multi-task learning approach where tasks are independent of each other, StyLEx exploits these stylistic word scores obtained from human annotation and then helps predict the sentence's styles. As displayed in Figure 2 (left), StyLEx involves three modules: a transformer-based (Vaswani et al., 2017; Devlin et al., 2019) encoder, a word-level style predictor and a sentence-level style predictor. This work is based on BERT although the encoder can be applied to any transformer architecture.

Given an input of token sequence $\mathbf{x} = \{x_1, ..., x_n\}$ and its corresponding set of stylistic word scores $\{s_1, ..., s_n\}$, we encode $\mathbf{x}$ using a pretrained transformer model. We extract the final layer output as $\mathbf{h} = \{\mathbf{h}_1, ..., \mathbf{h}_n\}$ and feed $\mathbf{h}$ to the word-level style prediction layer which is a neural classifier that outputs stylistic word logits for each word l_{word_i} computed as follows:

$$l_{word_i} = \mathbf{W}_{word}\mathbf{h}_i + \mathbf{b}_{word}$$

where $i \in \{1, .., n\}$, $\mathbf{W}_{word}$ is a matrix with the size $H \times d_{l_{word}}$, and $\mathbf{b}_{word} \in \mathbb{R}^{d_{l_{word}}}$ is the bias term. H is the size of the default hidden layer in BERT which is 768 and $d_{l_{word}}$ denotes the number of classes of each style (e.g., positive or negative word in a sentiment classification task).

For the sentence-level style classification, we first take both the encoded representation $\mathbf{h}$ and stylistic word logits l_{word}. We then apply max pooling on the aggregation of $\mathbf{h} \oplus l_{word}$ along the sequence, resulting in vector $\mathbf{v} \in \mathbb{R}^{H+d_{l_{word}}}$ consisting of important logits. Finally, we input $\mathbf{v}$ into the sentence-level style classifier defined as follows:

$$l_{sentence} = \texttt{softmax}(\mathbf{W}_{sentence}\mathbf{v} + \mathbf{b}_{sentence})$$
$$P_{sentence} = \arg\max\,(l_{sentence})$$

where $l_{sentence} \in \mathbb{R}^2$ denotes sentence-level style logits, $\mathbf{W}_{sentence}$ is a matrix with the size $(H + d_{l_{word}}) \times 2$, and $P_{sentence}$ is the index of the predicted sentence-level style.

During training, StyLEx's objective is to maximize the probability of the sentence's style and stylistic word scores. The loss for both sentence-level style predictor and word-level style predictor is computed using binary cross entropy loss function. To jointly train the model, we optimize the following loss:

$$\mathcal{L} = \mathcal{L}_{style} + \alpha \times \mathcal{L}_{word}$$

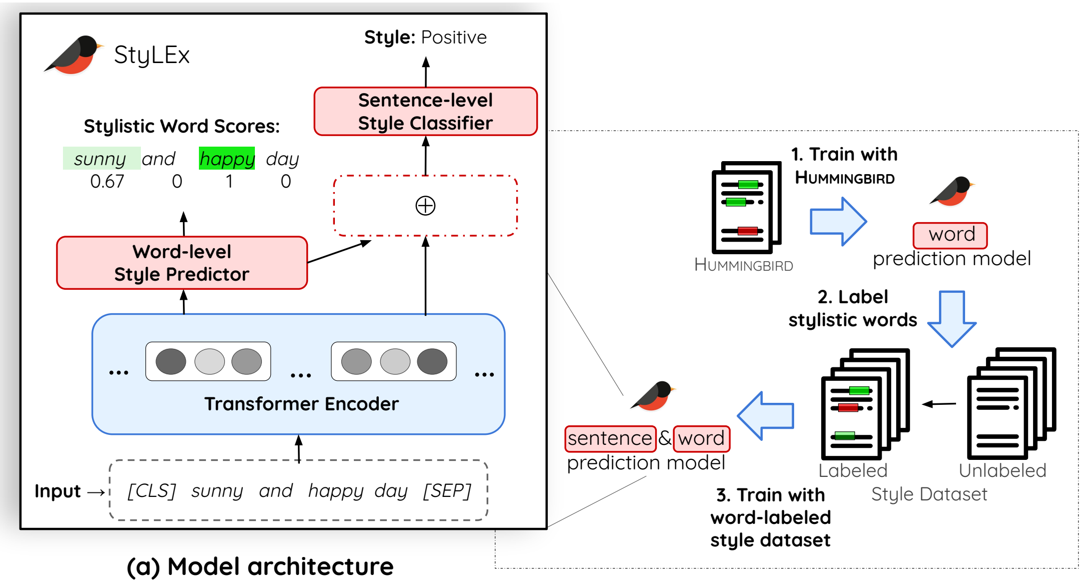
where α is a regularization hyperparameter.

2.2 StyLEx Model Training

To train StyLEx, we need a dataset of stylistic sentences along with their corresponding stylistic words (§2.2.1). We use the HUMMINGBIRD dataset (Hayati et al., 2021) that contains 500 sentences with word-level style annotation for obtaining the stylistic lexical explanation. Due to HUMMINGBIRD's small size, we first train StyLEx on HUMMINGBIRD and then predict pseudo stylistic words on larger benchmark style datasets (> 6.8k sentences in the training sets) for training the final StyLEx model for both sentence classification and lexical explanation.

2.2.1 Datasets

Following Hayati et al. (2021), we explore the same set of eight styles used in the dataset: politeness, sentiment, offensiveness and five emotions (anger, disgust, fear, joy, and sadness) for style classification tasks. We use three sets of publicly available style datasets for our experiments as follows.



(a) Model architecture

(b) Model training

Figure 2: **(a) StyLEx model architecture** (left). Our model has two new modules: a word-level style predictor and a sentence-level style classifier. An aggregator appends the word-level style logit for each word to the hidden layer representations of each word and takes the max pooling of this aggregation. **(b) Model training** (right). Human labels come from HUMMINGBIRD (Hayati et al., 2021) for stylistic word scores and from ORIGINAL datasets from sentence-level style classification. (1) We train a stylistic word-level prediction model on HUMMINGBIRD dataset in order to (2) obtain *pseudo-stylistic words* of sentences in the ORIGINAL datasets. (3) Then we train another stylistic word and sentence prediction model on this ORIGINAL sentences, now labeled with stylistic words.

HUMMINGBIRD is a multi-style dataset annotated with human perception scores on its important stylistic lexicons (Hayati et al., 2021). HUMMINGBIRD contains 500 sentences based on eight style datasets: politeness, sentiment, offensiveness, and five emotions (anger, disgust, fear, joy, and sadness). Three different crowd workers annotate each word in a sentence with 1 if they perceive the word as stylistic and 0 if not. The human perception score for a word is the average score of these annotators' labels. This perception score is what we call as stylistic word score and it is within the range [-1, 1]. We use HUMMINGBIRD for training StyLEx's word-level style predictor.

ORIGINAL datasets are used by Hayati et al. (2021) to curate HUMMINGBIRD.[2] Since some style labels in ORIGINAL may contain continuous numbers rather than binary labels, we follow the same setting of Hayati et al. (2021) which only uses binary labels: polite or impolite, positive or negative, offensive or not offensive, anger or not anger, and so on. The politeness dataset comes from StackExchange and Wikipedia requests (Danescu et al., 2013) (9.8k training instances). The sentiment dataset is a collection of movie review texts (Socher et al., 2013) (117k training instances). The offensiveness dataset is from Twitter (Davidson et al., 2017) (20k training instances). The emotions dataset (Mohammad et al., 2018) is collected from tweets (6.8k training instances). For all these ORIGINAL datasets, we use the default train/dev/split as explained in their papers.

Out-of-Domain (OOD) datasets are used to evaluate StyLEx's performance on different domains. For each style, we use data from different sources or topics, but their style labels are in HUMMINGBIRD and ORIGINAL datasets. For politeness, we use the polite and impolite sentences from the Enron email corpus (Klimt and Yang, 2004; Madaan et al., 2020). For sentiment, we test StyLEx on 5-core reviews from Amazon review dataset (Ni et al., 2019) for each product categories, except for movie reviews. We exclude movie reviews because it would be similar to the domain of the ORIGINAL's sentiment dataset. We convert ratings of 4-5 to positive labels and ratings of 1-2 as negative labels. For offensiveness, we use OffensEval (Zampieri et al., 2019) dataset for offensiveness. For five emotions, we collect Reddit comments

---

[2] We will refer to these individual datasets as "ORIGINAL"

Style	ORIGINAL (%)		OOD (%)	
	BERT	**StyLEx**	**BERT**	**StyLEx**
Politeness	67.96	65.84	71.45	74.18
Sentiment	96.52	96.59	86.70	86.99
Offensiveness	97.75	97.81	88.62	89.00
Anger	89.04	89.01	77.49	77.51
Disgust	86.50	86.90	74.06	74.63
Fear	95.66	95.63	78.42	78.48
Joy	88.02	88.12	75.20	74.26
Sadness	88.38	88.41	78.37	78.71

Table 1: For the sentence-level style classification task, StyLEx does not sacrifice the task performance (F1-scores) of the **BERT** model across all of the style tasks across both **ORIGINAL** and **OOD** settings.

from GoEmotions corpus (Demszky et al., 2020).[3]

2.2.2 Training

The whole pipeline of StyLEx model training is in Figure 2 (right). First, we train a stylistic word score prediction model with the same StyLEx architecture in Figure 2 (left). We do this since the sentences in the benchmarking style datasets do not have human annotations of stylistic word scores. We then use a semi-supervised learning approach called, pseudo-labeling (Lee et al., 2013; Rizve et al., 2020), to label the stylistic words. Now the sentences in ORIGINAL contain stylistic word scores which are output by the stylistic word predictor. Finally, we use both HUMMINGBIRD and ORIGINAL for training another model of StyLEx which predicts sentence-level binary style labels (polite and impolite, positive and negative etc.,) and provides lexical explanation scores within the range of [0, 1].[4]

3 Evaluation on Style Classification

3.1 Baseline

To assess StyLEx's classification performance, we compare it with a fine-tuned BERT-based classifier as a baseline. The training data for the baseline is also a combination of HUMMINGBIRD and ORIGINAL. For explanation evaluation, we compare StyLEx's explanation with the commonly-used explanation method called integrated gradients (Mudrakarta et al., 2018; Sundararajan et al., 2017), implemented in Captum[5]. Integrated gradient, which can be viewed as an approximate method of estimating Shapley values, is defined as follows. For the input sequence of words x and a neural network function F, an attribution score (the explanation) for each word is defined as the gradient between the input x and baseline x' of the function F where x' is a zero scalar.

3.2 Results

In our experiment, we have eight StyLEx models for each style: politeness, sentiment, offensiveness, and five emotions. For each style, we run StyLEx on the ORIGINAL test sets and OOD datasets for five times with different seeds and report the average of F1-scores in Table 1. For ORIGINAL datasets, StyLEx achieves higher F1 scores compared to the fine-tuned BERT model on sentiment, offensiveness, disgust, joy, and sadness. Overall, we observe that StyLEx does not sacrifice task performance of the state-of-the-art classifiers while predicting stylistic word scores. When tested on the OOD test sets, StyLEx achieves higher F1 score against the fine-tuned BERT model for all styles. Politeness has the greatest improvement from 71.48% to 74.18% since we observe that the ORIGINAL dataset of politeness contains many spurious content words. When we use bigger language models such as RoBERTa (Liu et al., 2019), XLNet (Yang et al., 2019), and T5 (Raffel et al., 2020) for StyLEx, StyLEx still has better results than the baseline for five styles: sentiment, offensiveness, anger, and disgust.

From example sentences from the test sets in Table 2, we can see how StyLEx helps task performance. ORIG-1 and ORIG-2 sentences show how StyLEx can capture stylistic words and correct the sentence's style label to *disgust*. For example, "insult" and "injury" in ORIG-1 are initially labeled by the integrated gradient method as unimportant for identifying *disgust*, but StyLEx identifies the words as stylistic cues. Similarly, for the word "downfall" in ORIG-2, StyLEx finds it as offensive, but the baseline does not. StyLEx also has a higher stylistic word score for indicating "stogie" as an offensive word.

As we look at the politeness classification results, we find that most of the incorrect cases are when StyLEx mislabels subtle *impolite* sentences as *polite*. As we observe in Table 2 ORIG-3, StyLEx finds the word "please" as a polite cue, but the ground truth label of the sentence is *impolite*. We

---

[3] More details on the datasets are in Appendix A.1.

[4] Other implementation details are in Appendix A.2.

[5] `https://captum.ai`

ID	Model	Sentence with Predicted Stylistic Word Scores	Sentence Style
Incorrect Baseline Prediction → Correct StyLEx Prediction			
ORIG-1	StyLEx	... because i'm gonna ' add insult to injury	Disgust ✓
	Baseline	... because i'm gonna ' add insult to injury	Not Disgust ✗
ORIG-2	StyLEx	... yet you say i'm a stogie you're your own downfall	Offensive ✓
	Baseline	... yet you say i'm a stogie you're your own downfall	Not Offensive ✗
Correct Baseline Prediction → Incorrect StyLEx Prediction			
ORIG-3	StyLEx	please put them all back are you on dsl	Polite ✗
	Baseline	please put them all back are you on dsl	Impolite ✓
ORIG-4	StyLEx	... can't just be mean and do horrid things busy without paying the price	Not Fear ✗
	Baseline	... can't just be mean and do horrid things busy without paying the price	Fear ✓

Table 2: Error analysis on prediction-flipped sentences. Baseline refers to sentence-level style prediction result by fine-tuned BERT model and highlights are stylistic words found by the integrated gradient method. Green highlights on the words mean that the model predicts high positive word-level stylistic scores; red for the opposite label (e.g., *impolite* or *negative*). Sentence Style is a model's sentence-level style prediction ✓ marks correct prediction and ✗ denotes incorrect prediction.

then inspect its continuous score from the original politeness dataset by Danescu et al. (2013). It turns out that its politeness score is -0.38 in the range of [-2, 2] as -2 being the most impolite sentence. This shows that this sentence score is closer to neutral than impolite. This finding also reflects how HUMMINGBIRD dataset has been collected: as mentioned in Hayati et al. (2021), words from the offensive dataset (mostly swear words) are often labeled as impolite by human annotators. Thus, it may bias the annotators' view that sentences with impolite labels are not as bad as offensive sentences, making them not mark offensive sentences as *impolite*. Therefore, for such subtle impolite sentences, human annotators in HUMMINGBIRD may not label the sentence and words as impolite.

In contrast, StyLEx misclassifies *anger* sentences as *not anger* and *fear* as *not fear*. As we look at ORIG-4 in Table 2, StyLEx weakly finds *fear* cues ("horrid", "things") but they do not help in boosting the model to predict the sentence as *fear*. We conjecture that this is because there are very few training samples labeled with *fear* and *fear* has quite low word-level inter-annotator agreement as reported in Hayati et al. (2021).

4 Style Explanation Evaluation

We investigate StyLEx's explanations if they are sufficient, plausible, and understandable following previous works (DeYoung et al., 2020; Jacovi and Goldberg, 2020; Wiegreffe and Marasovic, 2021; Rajagopal et al., 2021). Jacovi and Goldberg (2020) define that a faithful interpretation represents a model's reasoning process. To evaluate whether StyLEx's explanations are faithful, we run a sufficiency test that evaluates whether the model explanations alone are highly relevant for predicting the label (Jacovi et al., 2018). Meanwhile, we measure plausibility to examine whether the explanation is agreeable to humans (DeYoung et al., 2020). Finally, understandability measures if a user is able to understand model explanations (Rajagopal et al., 2021). For investigating sufficiency and plausibility, we run automatic metrics. To assess understandability, we ask human judges to choose the explanation that can be better understood by a non-expert between StyLEx and the integrated gradients (IG) method.

4.1 Sufficiency

Following Jain et al. (2020); Rajagopal et al. (2021)'s sufficiency test, we fine-tune a BERT model on the top-k words as explanation instead of the whole sentence. We limit an explanation to contain 30% words of the average sentence length for each of the style datasets. These words are ranked based on their importance score by the baseline integrated gradient method and StyLEx for all the positive stylistic words (polite words, positive words, offensive words, angry words).

In Table 3, we can see that explanations from StyLEx show much higher predictive performance

Style	ORIGINAL		OOD	
	IG	StyLEx	IG	StyLEx
Politeness	43.92	**63.08**	52.89	**8.19**
Sentiment	87.18	**89.39**	64.93	**77.52**
Offensiveness	84.87	**91.26**	82.93	**84.75**
Anger	68.36	**86.90**	53.76	**73.99**
Disgust	82.54	**85.91**	71.36	**75.76**
Fear	87.82	**96.10**	35.85	**65.26**
Joy	45.54	**83.16**	55.49	**72.71**
Sadness	70.49	**87.94**	47.83	**70.95**

Table 3: The results for sufficiency test on the **ORIGINAL** and **OOD** data show the F1 scores on top-k words. IG stands for integrated gradient.

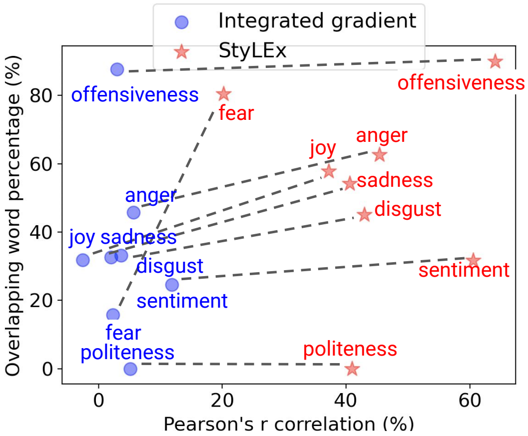


Figure 3: Plausibility experiment result. There are two points for each style in this plot. A blue circle point is for the baseline IG method and a red star point for StyLEx. X-axis is Pearson's r correlation score for each style. Y-axis is the percentage of stylistic sentences with style words appearing in the existing style lexicon dictionary.

compared to explanations extracted by the integrated gradient method for all styles in both datasets, ORIGINAL and OOD. This result suggests that human-like stylistic words are much more strongly predictive of a sentence's style compared to the gradient-based explanation methods that often rely on content words as an explanation. This indicates that StyLEx's explanations are relatively more faithful compared to the integrated gradients based method.

4.2 Plausibility

We use two approaches to measure the agreement between StyLEx's lexical explanations and stylistic words perceived by humans to assess the plausibility of StyLEx's explanations. In the first approach, we compare StyLEx's stylistic words on the HUMMINGBIRD test set and compare it with the ground truth human perception scores in HUMMINGBIRD. Second, we compare StyLEx's top-k stylistic words with existing expert-curated stylistic lexicon dictionaries. The domain of the existing expert-curated stylistic lexicon dictionaries could be different from the domain of the datasets in our study which range from social media texts to Wikipedia. However, it is still useful to compare how much StyLEx and the baseline agree human experts on identifying stylistic words.

Figure 3 shows a scatterplot of StyLEx vs. the integrated gradient. X-axis represents the Pearson's r correlation score on the HUMMINGBIRD test set. Y-axis is the percentage of overlapping words between the important words found by StyLEx and the baseline compared with the human-curated style lexicon dictionary. We calculate the overlapping word percentage as follows. We compute how many of the top 30% of the stylistic words in the ORIGINAL datasets found by StyLEx or baseline appear in human-curated dictionaries for the emotion/sentiment/offensive lexicons.

In Figure 3, the higher the Pearson's correlation score is (to the right), the better the explanation words produced by the model (StyLEx or baseline) are aligned with human perception ground truth from HUMMINGBIRD. The dashed lines show how much StyLEx's generated stylistic words align more with human annotations for stylistic words from both HUMMINGBIRD and human-curated stylistic lexicon dictionaries.

(1) Correlation with human perception. We investigate how similar StyLEx's explanations are with human perceptions. To do so, we compute the Pearson's correlation r between stylistic word scores predicted by StyLEx and annotated by humans from HUMMINGBIRD annotations for each word by concatenating all the predicted stylistic word scores. Our correlation score is different from Hayati et al. (2021) because we split the Hummingbird dataset into a training set and test set even though we use the same human perception scores and the integrated gradient method. The correlation score we reported in Figure 3 is from the HUMMINGBIRD test set.

In Figure 3 (vertical trend), we can see that StyLEx explanations correlate more with ground truth human perception for all styles, as red stars are stretched to the right. Sentiment and offen-

Style	🐦 🤖 **Both**	🐦 **StyLEx**	🤖 **Integrated gradient**
Positive	good, fun, love	associate, develop, instruct	deserve, endure, football
Negative	bad, horror, silly	mess, chaos, disappoint	maternal, banger, yell
Offensive	bitch, bitches, pussy	blind, racist, panties	fairy, amateur, fisting
Anger	angry, anger, awful	frowning, scare, lose	belt, campaigning, destroying*
Disgust	awful, terrible, angry	dismal, frowning, animosity	congress, finally, sentence*
Fear	fear, anxiety, nervous	horrid, war, threaten	rejects, mum, beating
Joy	happy, love, good	faith, sing, succeed	deal, independence, football
Sadness	depression, sadness, lost	bad, offended, leave	funeral, bloody, case*

Table 4: Three important words found by StyLEx (🐦) and the integrated gradient method (🤖) that appear in the stylistic lexicon dictionary.* = words only appear one time in the test data.

siveness are styles that have the highest correlation scores (60.53% and 64.09%) while fear is the lowest (20.17%)). Explanations from integrated gradient correlate very loosely with human perception ground truth with sentiment as the highest (11.89%) and joy negatively correlates with human perceptions (-2.55%).

(2) Comparison with stylistic lexicon dictionaries. We then investigate how similar the stylistic words found by StyLEx are to the stylistic words curated by humans in the existing lexicon dictionary. We use sentiment emotion lexicons from Mohammad and Turney (2010) and offensive lexicons from von Ahn's research group (2021).[6] Using the same set up of sufficiency test, we select top-30% stylistic words from each sentence in ORIGINAL datasets with the positive style label. Then we check if at least one of these words appear in the existing lexicon dictionary and compute its average across all training samples.

In Figure 3 (horizontal trend), we see that StyLEx consistently has higher percentage of word occurrences in the lexicon dictionary compared to the integrated gradient method where fear has the highest percentage difference (15.78% → 80.43%) and offensiveness has the lowest percentage change (87.67% → 89.99%). Averaging across all styles, we find that 56.70% of the stylistic sentences with StyLEx stylistic words appear in the existing style lexicon dictionary while integrated gradient only identifies 37.01% of those words.

The score is higher for offensiveness than for sentiment or emotion. We observe that people use more offensive words in social media, which is the source for dataset collection. We also examine the lower occurrence for emotions. From our analysis, we found that the emotion lexicon dictionary contains several colloquially rare words "aberration" or "meritorious", leading to a very low overlap with the datasets that we used for the analysis.

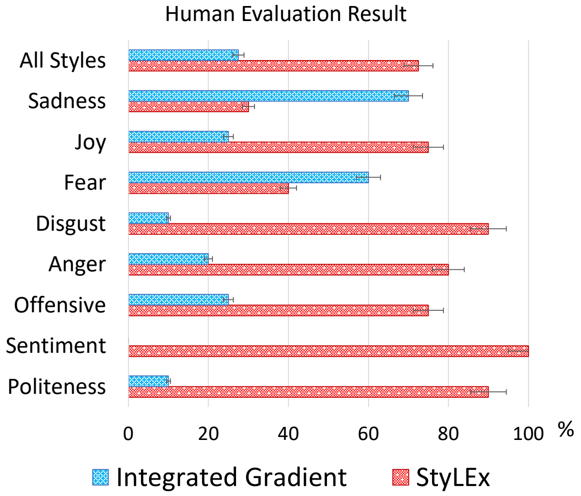

Figure 4: Human evaluation results. X-axis is the percentage of explanations preferred by human judges.

We also take a closer look at how many and the nature of important words are captured by StyLEx and/or the integrated gradient method as shown in Table 4. These word scores are obtained by averaging their scores and then we sort them based on these average scores. In general, we find that StyLEx can find more diverse stylistic words as defined in the existing lexicon dictionary for all styles except for positive sentiment. Some emotion words found by the integrated gradients only appear rarely in the data (mostly only once).

4.3 Understandability

To investigate the quality of StyLEx's explanation, we ask human judges to evaluate StyLEx's expla-

---

[6] We couldn't find a publicly available politeness lexicon dictionary.

nations compared to baseline explanations. *Understandability* asks whether human judges understand our explanation better than the explanation computed using integrated gradients. For this study, we randomly select 20 stylistic sentences for each of the eight styles, resulting in total 160 sentences. These 20 sentences are constructed by 10 sentences from ORIGINAL test set and 10 sentences from OOD test set. We normalize the stylistic word scores for sentence length across all sentences.

A human judge is shown two versions of the same sentence with different anonymized highlights, as shown in Figure 1. We then ask three different human judges to select (through Amazon Mechanical Turk) the explanation that was more understandable. Each worker annotated 20 sentences of the same style. The order of explanations is randomized to remove bias. We say that an explanation by a method is preferred by human judges when the majority choose that method. If the majority chooses a method for all the 20 sentences, the X-axis score will be 100%. Results in Figure 4 show that across all styles (160 pairs of explanations), StyLEx gives an overall gain of 27.5%.

5 Related Work

Styles in NLP Research on style in NLP has addressed various tasks including style classification (Danescu et al., 2013; Socher et al., 2013), style transfer (Rao and Tetreault, 2018; Li et al., 2018), style and content disentanglement (John et al., 2018; Zhu et al., 2021), and multiple style analysis (Hayati et al., 2021; Kang and Hovy, 2021). This work focuses on understanding stylistic variation in style classification. Style classification models often produce spurious features (Sen et al., 2021; Schlangen, 2021; Bras et al., 2020), motivating us to leverage stylistic variation from human perspectives to distinguish between stylistic words and content words. Past work have used stylistic lexica for classification (Taboada et al., 2011; Eisenstein, 2017), but in this work, we fine-tune the language model to generate these lexica and use them to help style prediction. Our work is most closely related to Hayati et al. (2021), but they do not develop any new models to use the human perception scores as explanations. Moreover, while linguistics styles can cover an author's writing style or figurative language, we limit our study to high-level style as used in Kang and Hovy (2021); Hayati et al. (2021).

Explainable NLP Heat maps generated from attention values from the models (Bahdanau et al., 2014) are widely used as an interpretability tool, but these attention maps are often unfaithful and unreliable (Jain and Wallace, 2019; Wiegreffe and Pinter, 2019; Zhong et al., 2019; Pruthi et al., 2020). Saliency maps computed via gradients offer an alternative (Sundararajan et al., 2017; Smilkov et al., 2017; Mudrakarta et al., 2018). Annotating explanations as *rationales* (part of input) (Lei et al., 2016) through expert annotations (Zaidan and Eisner, 2008) is widely used to model explanations in NLP when external annotations are available. Another class of inherently interpretable models aims to optimize model explanations without any external annotations (Card et al., 2019; Croce et al., 2019; Rajagopal et al., 2021). Our work is similar in spirit to the rationale approaches (Lei et al., 2016) but focuses on understanding style attributes in text and computationally modeling them based on human annotation of the important words.

6 Conclusion

We proposed StyLEx, a style classification model for learning stylistic variations through lexical explanation. With only 500 sentences with word-level style annotation, we find improvement in both classification and explanation. Compared to the commonly-used integrated gradient method, StyLEx's explanations are more accurate for model prediction, more consistent with human-found stylistic words from existing datasets and lexicon dictionaries, and better understandable by human judges, without sacrificing task performance on both in-domain and out-of-domain datasets.

Future Work Our approach opens up future work on human-centered lexical explanation for correcting the spurious behavior of NLP models and for better explaining linguistic styles. We plan to investigate collecting more human lexical annotations to more accurately model stylistic variation, especially with larger pretrained language models. Broader usage of StyLEx in providing stylistic cues will be applicable to lexical style and content disentanglement (Cheng et al., 2020; John et al., 2019), counterfactual data augmentation for style-related tasks (Sen et al., 2021), and stylistic paraphrasing (Pavlick and Nenkova, 2015).

Limitations Our work has some limitations, mostly stemming from the size and nature of the human-annotated data. The training data (500 sentences) from HUMMINGBIRD is quite small to train deep learning models. However, our work shows that with just 500 sentences we could achieve a huge improvement in interpretability as well as a slight improvement in OOD performance, using semi-supervised training. Moreover, there is sparsity of stylistic words in the sentences. We also found that some stylistic words have various scores of human perception; capturing such subtle stylistic words is difficult. An interesting future work would be to handle these problems of sparsity and subtlety. We also notice that HUMMINGBIRD is annotated by people residing in the United States. Thus, their perception of styles may not reflect the perception of those with different cultural backgrounds. Nevertheless, StyLEx can be applied to any dataset training with similar human lexical annotations, and not limited to HUMMINGBIRD.

Ethical Considerations When collecting the explanation evaluation from human judges, we inform them that the content may contain offensive languages that could be upsetting.

Acknowledgments

We would like to thank Karin de Langis for her valuable feedback during the early version of writing and the anonymous reviewers for their thoughtful comments.

A Appendix

A.1 Sampling OOD Data and Data Statistics

- Politeness: We randomly sample 500 polite sentences and 500 impolite sentences from the Enron email corpus (Klimt and Yang, 2004; Madaan et al., 2020) since the size of entire corpus (>600k) is too large for inference.

- Sentiment: We test StyLEx on 5-core reviews from Amazon review dataset (Ni et al., 2019). For each category, we sample 100 positive sentences and 100 negative sentences from review categories, except for movie reviews which would be similar to the domain of the ORIGINAL dataset. We convert ratings of 4-5 to positive labels and ratings of 1-2 as negative labels.

- Offensiveness: We use OffensEval (Zampieri et al., 2019) dataset for offensiveness. We select all offensive tweets (3,002 instances) and all non-offensive tweets (2,991 instances) since OffensEval dataset is already nearly balanced.

- Emotions: For five emotions, we collect samples from GoEmotions corpus (Demszky et al., 2020) that contains Reddit comments labeled with 27 emotions, but we only select the five relevant emotions. For each emotion, we use all data for the positive emotion (e.g., joy) and undersample the negative emotion (e.g., not joy) data to equal the number of positive emotion samples.

The three dataset statistics are summarized in Table 6.

A.2 StyLEx Implementation Details

Throughout the experiment, we set $d_{l_{word}} = 2$ for politeness (polite, impolite) and sentiment (positive, negative) which have two style classes and $d_{l_{word}} = 1$ for the other styles. At the loss calculation step, we set the regularization hyperparameter α to 0.05 which gives the best style and perception prediction found searching the range [0.01, 100]. For the pseudo-labeling approach, we use the same architecture and hyperparameters with StyLEx model. We first train StyLEx with HUMMINGBIRD training set only to predict stylistic word scores for 50 epochs. Then we select the model with the best F1 score as a stylistic word score prediction to provide stylistic word scores for tokens in ORIGINAL training set. Then, we use both human-annotated perception score from HUMMINGBIRD and predicted stylistic word scores from ORIGINAL to train the sentence-level style prediction as in Figure 2. For the sentence-level model, we train the model for 5 epochs. For both stylistic word prediction and sentence-level style classification, we use BERT-base-uncased pretrained model. We set 0.1 dropout rate, 512 maximum sequence length, AdamW optimizer of learning rate $2e^{-5}$. For other hyper-parameters, we follow the default setting from HuggingFace's transformer library (Wolf et al., 2020).

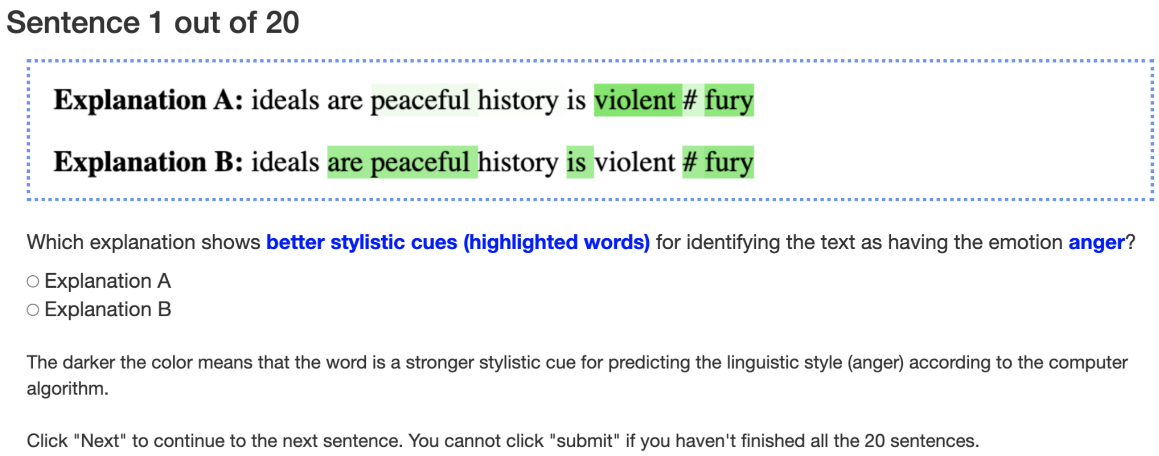
Our interface for human evaluation is shown as in Figure 5. Table 7 shows results for other pretrained language models. We report word-level style predictor performance tested on HUMMINGBIRD test data in the form of Pearson's r correlation scores as follows in Table 5.

Style	**Word-level Pearson's r**
Politeness	0.41
Sentiment	0.61
Offensiveness	0.37
Anger	0.45
Disgust	0.43
Fear	0.20
Joy	0.37
Sadness	0.41

Table 5: Pearson's r scores from training the word-level predicion model and testing it on HUMMINGBIRD.

	HUMMINGBIRD		ORIGINAL			OOD
Styles↓	Train	Test	Train	Dev	Test	Test
Politeness	256 (38%)	64 (28%)	9,855 (55%)	530 (56%)	567 (57%)	1,000 (50%)
Sentiment	312 (30%)	79 (37%)	117,219 (55%)	825 (51%)	1,749 (50%)	5,200 (50%)
Offensiveness	400 (34%)	100 (32%)	20,680 (82%)	1,173 (82%)	1,159 (81%)	5,993 (50%)
Anger	400 (35%)	100 (34%)	6,838 (37%)	886 (36%)	3,259 (34%)	16,168 (50%)
Disgust	400 (43%)	100 (38%)	6,838 (38%)	886 (36%)	3,259 (34%)	10,602 (50%)
Fear	400 (17%)	100 (13%)	6,838 (18%)	886 (14%)	3,259 (15%)	6,394 (50%)
Joy	400 (24%)	100 (19%)	6,838 (36%)	886 (45%)	3,259 (44%)	15,966 (50%)
Sadness	400 (29%)	100 (17%)	6,838 (29%)	886 (30%)	3,259 (29%)	13,516 (50%)

Table 6: Dataset statistics in our experiments. Note that these datasets are preprocessed from existing datasets. For HUMMINGBIRD (Hayati et al., 2021) and ORIGINAL datasets, the train, dev, and test sets have the same size for all emotions. We do not report the training size of Out-of-Domain (OOD) datasets since we are not using them for training. The label distributions for positive labels are in the parentheses.



Sentence 1 out of 20

Explanation A: ideals are peaceful history is violent # fury

Explanation B: ideals are peaceful history is violent # fury

Which explanation shows **better stylistic cues (highlighted words)** for identifying the text as having the emotion **anger**?

○ Explanation A
○ Explanation B

The darker the color means that the word is a stronger stylistic cue for predicting the linguistic style (anger) according to the computer algorithm.

Click "Next" to continue to the next sentence. You cannot click "submit" if you haven't finished all the 20 sentences.

Comparing Intrinsic Gender Bias Evaluation Measures without using Human Annotated Examples

Abstract

Numerous types of social biases have been identified in pre-trained language models (PLMs), and various intrinsic bias evaluation measures have been proposed for quantifying those social biases. Prior works have relied on human annotated examples to compare existing intrinsic bias evaluation measures. However, this approach is not easily adaptable to different languages nor amenable to large scale evaluations due to the costs and difficulties when recruiting human annotators. To overcome this limitation, we propose a method to compare intrinsic gender bias evaluation measures without relying on human-annotated examples. Specifically, we create multiple *bias-controlled* versions of PLMs using varying amounts of male vs. female gendered sentences, mined automatically from an unannotated corpus using gender-related word lists. Next, each bias-controlled PLM is evaluated using an intrinsic bias evaluation measure, and the rank correlation between the computed bias scores and the gender proportions used to fine-tune the PLMs is computed. Experiments on multiple corpora and PLMs repeatedly show that the correlations reported by our proposed method that does not require human annotated examples are comparable to those computed using human annotated examples in prior work.

1 Introduction

Pre-trained language models (PLMs) trained on large datasets have reported impressive performance improvements in various NLP tasks (Devlin et al., 2019; Lan et al., 2019) greatly. However, these PLMs also demonstrate significantly worrying levels of social biases (Bolukbasi et al., 2016; Kurita et al., 2019). To address this issue, numerous intrinsic bias evaluation measures for PLMs have been proposed (Nangia et al., 2020; Dhamala et al., 2021; Nadeem et al., 2021; Kaneko and Bollegala, 2022; Zhou et al., 2022), which are also used for comparing debiasing methods for PLMs (Webster et al., 2020; Kaneko and Bollegala, 2021a; Schick et al., 2021).

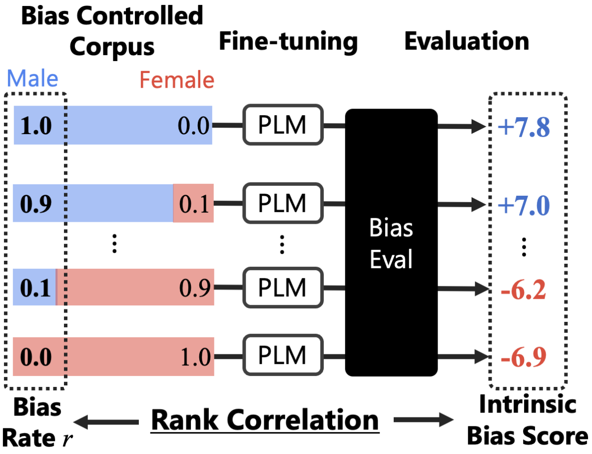

Figure 1: Overview of our proposed method. We first create *bias-controlled* PLMs by fine-tuning a PLM on male and female gendered sentences that are automatically mined from unannotated corpora. Next, we measure the rank correlation between the scores reported by an intrinsic bias evaluation measure and the male/female bias rates (r) used to fine-tune the PLMs.

Existing bias evaluation methods use different criteria such as pseudo likelihood (Kaneko and Bollegala, 2022), cosine similarity (Caliskan et al., 2017; May et al., 2019), inner-product (Ethayarajh et al., 2019) etc. Moreover, current bias evaluation methods require manually-annotated datasets containing stereotypical and antistereotypical examples that express different types of social biases (Nangia et al., 2020; Nadeem et al., 2021). Therefore, we consider that it is important to compare the differences in existing bias evaluation measures proposed for PLMs (Orgad and Belinkov, 2022; Dev et al., 2021; Kaneko et al., 2022a) to understand their relative strengths and weaknesses.

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2857–2863
May 2-6, 2023

To objectively compare the existing bias evaluation measures, Kaneko and Bollegala (2022) calculated the rank correlation between the number of human annotators who labelled an example to be stereotypically biased towards a protected attribute in Crowds-Pairs (CP), and the bias score for that example returned by an intrinsic bias evaluation measure (Nangia et al., 2020; Nadeem et al., 2021). However, due to the costs and difficulties in recruiting human annotators, this approach cannot be easily adapted to different languages, accommodate large-scale evaluations, or compare evaluation metrics that do not use human-annotated data.

We propose a method to compare intrinsic bias evaluation measures without using human annotated examples. Figure 1 outlines the intuition behind our proposed method. First, we train *bias-controlled* versions of PLMs obtained via fine-tuning a PLM on male and female gendered sentences, automatically mined from an unannotated corpus using a gender-related word list. We define *rate of bias* (r) as the ratio between male and female gendered sentences in a training sample used to fine-tune a PLM. A PLM fine-tuned mostly on male sentences is likely to generate sentences containing mostly male words, while a PLM fine-tuned on female sentences is likely to generate sentences containing mostly female words (Kaneko and Bollegala, 2022; Kaneko et al., 2022c). Therefore, an accurate intrinsic bias evaluation measure is expected to return a score indicating a bias towards the male gender for a male bias-controlled PLM, while it is expected to return a score indicating a bias towards the female gender for a female bias-controlled PLM. We then compute the rank correlation between (a) the rate of biases in the bias-controlled PLMs, and (b) the bias scores returned by an intrinsic evaluation measure for the corresponding PLMs, as a measure of accuracy of the bias evaluation measure.

Our experiments with multiple corpora and PLMs show that the correlations reported by our proposed method, which does not require human annotated examples, are comparable to those computed using human annotated examples in previous studies. Furthermore, by examining the output probabilities of the PLM, we verify that the proposed method, which fine-tunes bias-controlled PLMs with varying amounts of male vs. female sentences, is indeed able to control biases associated with male and female gender directions.

2 Bias-controlled Fine-Tuning

The imbalance of gender words in the training data affects the gender bias of a PLM fine-tuned using that data (Kaneko and Bollegala, 2022; Kaneko et al., 2022c). Using this fact, we propose a method to learn *bias-controlled* versions of PLMs that express different levels of known gender biases. Let us first assume that we are given a list of female gender related words $\mathcal{V}_f$ (e.g. *she, woman, female*), and a separate list of male gender related words $\mathcal{V}_m$ (e.g. *he, man, male*). Next, we select sentences that contain either at least one of female or male words from an unannotated set of sentences $\mathcal{D}$. Sentences that contain both male and female words are excluded here. Let us denote the set of sentences extracted for a female or a male word w by $\Phi(w)$. Moreover, let $\mathcal{D}_f = \bigcup_{w \in \mathcal{V}_f} \Phi(w)$ and $\mathcal{D}_m = \bigcup_{w \in \mathcal{V}_m} \Phi(w)$ be the sets of sentences containing respectively female and male words. We appropriately downsample $\mathcal{D}_f$ and $\mathcal{D}_m$ to have equal numbers of sentences N (i.e. $|\mathcal{D}_f| = |\mathcal{D}_m| = N$).

Next, we create training datasets $\mathcal{D}_r$ by varying the rate of bias, r ($\in [0, 1]$), by randomly sampling a subset $\mathcal{S}_r(\mathcal{D}_m)$ of Nr sentences from $\mathcal{D}_f$ and a subset $\mathcal{S}_{1-r}(\mathcal{D}_f)$ of $N(1-r)$ sentences from $\mathcal{D}_m$ such that $\mathcal{D}_r = \mathcal{S}_r(\mathcal{D}_m) \cup \mathcal{S}_{1-r}(\mathcal{D}_f)$. When $r = 0$, $\mathcal{D}_r$ consists of only female sentences (i.e. $\mathcal{D}_r \subseteq \mathcal{D}_f$), and when $r = 1$, it consists of only male sentences (i.e. $\mathcal{D}_r \subseteq \mathcal{D}_m$). To obtain multiple bias-controlled PLMs at different levels of gender biases, we fine-tune a given PLM on different datasets, D_r, sampled with different values of r. We use a given intrinsic bias evaluation measure to separately evaluate each bias-controlled PLM. Finally, we measure the agreement between the bias scores reported by the intrinsic bias evaluation measure under consideration and the corresponding rates of biases of those PLMs using Pearson's rank correlation coefficient.

3 Experiments

3.1 Settings

In our experiments, we used the female words *she, woman, female, her, wife, mother, girl, sister, daughter, girlfriend* as $\mathcal{V}_f$, and male words *he, man, male, him, his, husband, father, boy, brother, son, boyfriend* as $\mathcal{V}_m$. We sampled 2M sentences each representing male and female genders from News crawl 2021 corpus (**news**)[1] and BookCorpus (Zhu

Measure	BERT			ALBERT		
	news	book	HA	news	book	HA
TBS	0.14	0.09	-	0.25	0.14	-
SSS	0.22	0.22	0.45	0.31	0.22	0.53
CPS	0.30	0.27	0.57	0.37	0.22	0.48
AUL	0.37	0.32	0.68	0.55	0.36	0.56
AULA	0.42	0.34	0.71	0.60	0.42	0.57

Table 1: Peason correlation between biased PLM order and each bias scores. News and book represent the corpus used for biasing, respectively. HA is AUC value of method using human annotation (Kaneko and Bollegala, 2021a).

et al., 2015) (**books**) for training bias-controlled PLMs and a separate 100K sentences as development data. We used BERT[2] (Devlin et al., 2019) and ALBERT[3] (Lan et al., 2019) as the PLMs. We fine-tune PLMs with masked language model learning. We use publicly available Transformer library[4] to fine-tuning PLMs, and all hyperparameters are set to their default values. We trained 11 bias-controlled PLMs for r in $\{0.0, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0\}$ on four Tesla V100 GPUs.

3.2 Intrinsic Bias Evaluation Measures

We compare five previously proposed intrinsic gender bias evaluation measures in this paper: Template-Based Score (**TBS**; Kurita et al., 2019), StereoSet Score (**SSS**; Nadeem et al., 2021), CrowS-Pairs Score (**CPS**; Nangia et al., 2020), All Unmasked Likelihood (**AUL**; Kaneko and Bollegala, 2022), and AUL with Attention weights (**AULA**; Kaneko and Bollegala, 2022). Further details of these measures are given in the Appendix.

Note that TBS uses templates for evaluation and cannot be used with human-annotated stereotypical/anti-stereotypical sentences. On the other hand, SSS, CPS, AUL, and AULA all require human-annotated sentences that express social biases.

3.3 Comparing Intrinsic Gender Bias Evaluation Measures

We compare the proposed method and Kaneko and Bollegala (2022)'s method using CP dataset, which has human annotations, and show the effectiveness of the proposed method. In addition, we will use several PLMs and corpora to analyze the trends of the proposed method. Table 1 shows the correlation results of the proposed method for TBS, SSS, CPS, AUL, and AULA when fine-tuning BERT and ALBERT on news or book corpora, respectively. HA is the AUC value of the Kaneko and Bollegala (2022)'s method using human annotations. Since TBS uses templates, it cannot be evaluated using HA.

For BERT, the proposed method induces the same order among measures (i.e. AULA $>$ AUL $>$ CPS $>$ SSS) as done by HA in both news and book. For ALBERT, only the rankings of SSS and CPS differ between the proposed method and HA. These results show that the proposed method and the existing method that use human annotations rank the intrinsic gender bias evaluation measures in almost the same order.[5] It can be seen that the values of the correlation coefficients vary depending on the PLM and corpus. For example, ALBERT has a maximum correlation of 0.60, while BERT has a maximum correlation of only 0.42.

A major limitation of human annotation-based evaluation is that it cannot be used to compare TBS that does not human annotated examples against other intrinsic bias evaluation measures. However, our proposed method does *not* have this limitation and can be used to compare TBS against other bias evaluation measures. As it can be seen from Table 1, TBS consistently reports the lowest correlations, indicating that it is not an accurate intrinsic gender bias evaluation measure. This finding agrees with Kaneko et al. (2022a), who highlighted the inadequacy of templates as a method for evaluating social biases.

3.4 Bias-controlled PLMs

To verify that the proposed method can indeed control the bias of a PLM, we investigate the variation of the output probabilities of the PLMs fine-tuned with different r. Specifically, we investigate the output probabilities of masked *he* and *she* in the input text "*[MASK] is a/an [Occupation].*" for the bias-controlled PLMs. For *[Occupation]*, we use gender- and stereotype-neutral occupational words[6] (e.g. *writer*, *musician*) from the word list created by Bolukbasi et al. (2016). When r in-

[3] `https://huggingface.co/albert-base-v2`

[4] `https://github.com/huggingface/transformers/tree/v4.22.2`

[5] Because of the different methods of measuring correlations, it is not possible to compare the magnitude of values between the proposed and existing methods.

[6] `https://github.com/tolga-b/debiaswe`

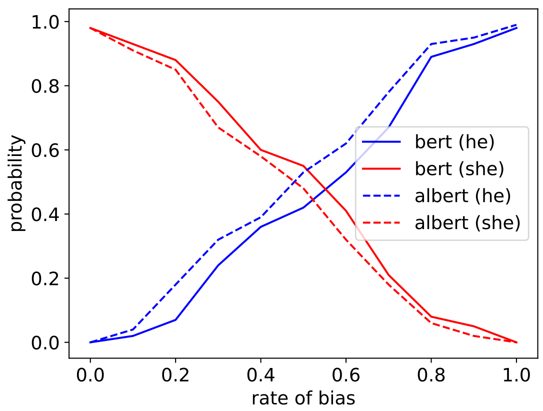

Figure 2: Average output probabilities for "*[MASK] is a/an [Occupation]*" produced by the bias-controlled BERT and ALBERT PLMs fine-tuned with different r on the news dataset.

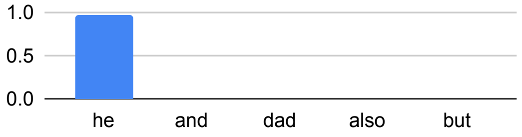
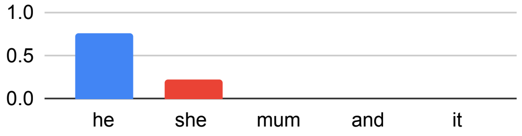
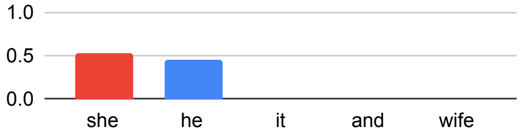


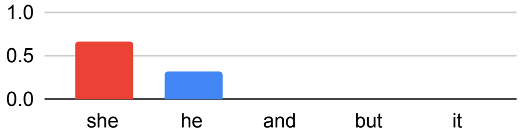
(a) $r = 1.0$



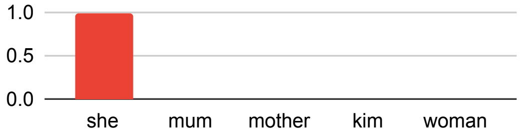
(b) $r = 0.7$



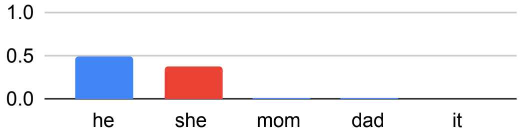
(c) $r = 0.5$



(d) $r = 0.3$



(e) $r = 0.0$



(f) original (without fine-tuning)

Figure 3: Top 5 words with BERT output probability for "*[MASK] doesn't have time for family due to work obligations.*". Blue and red represent masculine and feminine words, respectively.

creases, a PLM will be fine-tuned with increasing amounts of male sentences. Therefore, if the average probability of *he* increases with r, it would imply that the PLMs are correctly bias-controlled by the proposed method.

Figure 2 shows that the average output probabilities of *he* and *she* when r is incremented in step size of 0.1. When $r = 1$ the PLM predicts *he* with fairly high probability and when $r = 0$ the PLM predicts *she* with fairly high probability. Furthermore, when $r = 0.5$, the probability of *he* and *she* is almost 0.5. Original BERT (without fine-tuning) returns 0.48 and 0.28, respectively for *he* and *she*, while the corresponding probabilities returned by ALBERT are respectively 0.64 and 0.22. Both the original BERT and ALBERT predict relatively larger output probabilities for *he*, indicating that they are male-biased, without performing any bias-control. From these results, it can be seen that the output probabilities of *he* and *she* fluctuate according to r, and the proposed method can control the bias of the PLM. On the other hand, when r is less than 0.2 or greater than 0.8, the output probabilities of *she* and *he* are greater than the proportion in the data set, respectively. Therefore, finer increments of r may make it difficult to control bias more finely when r is small or large.

To illustrate how bias-controlled PLMs produced by the proposed method for different rates of biases (r) predict the probabilities of gender pronouns, we consider the masked sentence "*[MASK] doesn't have time for the family due to work obligations.*" selected from the CP dataset. Here, *He* and *She* are unmodified tokens. Figure 3 shows the probabilities of the tokens predicted for the [MASK] by the different bias-controlled PLMs. We see that the original BERT model predicts both *he* and *she* with approximately equal probabilities. However, when r is gradually increased from 0 to 1, we see that the probability of *he* increases, while that of *she* decreases, demonstrating that the proposed method correctly learns bias-controlled PLMs.

4 Conclusion

We proposed a method to compare intrinsic gender bias evaluation measures using an unannotated corpus and gender-related word lists. Experiments show that the correlations computed by the proposed method for existing bias evaluation measures agrees with the prior evaluations conducted using human annotations.

5 Limitations

In this paper, we limited our investigation to English PLMs. However, as reported in a lot of previous work, social biases are language independent and omnipresent in PLMs trained for many languages (Kaneko et al., 2022c; Lewis and Lupyan, 2020; Liang et al., 2020; Zhao et al., 2020). We plan to extend this study to cover non-English PLMs in the future.

According to existing research, PLMs encode many different types of social biases such as racial and religious biases in addition to gender-related biases (Kiritchenko and Mohammad, 2018; Ravfogel et al., 2020). On the other hand, in this paper, we focused on only gender bias. Extending the proposed method to handle other types of social biases beyond gender bias is beyond the scope of the current short paper and is deferred to future work.

Furthermore, discriminatory bias is learned in word embeddings as well as PLMs (Bolukbasi et al., 2016; Brunet et al., 2019; Kaneko and Bollegala, 2019, 2020, 2021b; Kaneko et al., 2022b). Therefore, it may be possible to make it applicable to word embeddings as well.

6 Ethical Considerations

Our goal in this paper was to compare the previously proposed and widely-used intrinsic bias evaluation measures of gender bias in pre-trained PLMs. Although we used a broad range of existing datasets that are annotated for social biases, we did not annotate nor release new datasets as part of this research. Moreover, we fine-tune a large number of bias-controlled PLMs for evaluation purposes that demonstrates varying levels of gender biases. However, these PLMs are not supposed to be used in downstream tasks other than for evaluation purposes.

Even with the highly correlated bias evaluation measure in our proposed method, the bias of the PLM may not be sufficiently evaluated. Therefore, we consider that it important to select intrinsic gender bias evaluation measures carefully and not purely based on correlation coefficients computed by the proposed method alone.

There are various discussions on how to define social bias in PLMs (Blodgett et al., 2021). Since the proposed method can use any method as the bias-controlled fine-tuning of the PLMs, the bias-controlled fine-tuning can be selected according to the definition of social bias.

A Intrinsic Bias Evaluation Measures

TBS Kurita et al. (2019) proposed template-based bias evaluation measure. The log-odds of the likelihood of a template sentence masked with a gender word (e.g. *"[MASK] is a programmer"*) and the likelihood of a gender word masked with an occupation word (e.g. *"[MASK] is a [MASK]"*) are calculated for male and female words, respectively. TBA then calculates the difference between them as the bias score.

SSS SSS (Nadeem et al., 2021) uses stereotypical and anti-stereotypical sentence pairs (e.g. *"She is a nurse"* and *"He is a nurse"*) to evaluate bias in PLMs. Calculate the likelihood of masked modified tokens (e.g. *She, He*) given unmasked unmodified tokens (e.g. *is, a, nurse*) for each stereotypical and anti-stereotypical sentence. The bias score is calculated by dividing the number of sentences for which the total likelihood is higher for stereotypical sentences compared to anti-stereotypical sentences by the total number of data.

CPS CPS (Nangia et al., 2020) also uses stereotypical and anti-stereotypical sentence pairs. On the other hand, calculate the likelihood of masked unmodified tokens given unmasked modified tokens for each stereotypical and anti-stereotypical sentence. The bias score is calculated by dividing the number of sentences for which the total likelihood is higher for stereotypical sentences compared to anti-stereotypical sentences by the total number of data. As with SSS, the bias score is calculated using the sum of the likelihoods of the stereotyped and anti-stereotyped sentences.

AUL and AULA AUL and AULA (Kaneko and Bollegala, 2022) also uses stereotypical and anti-stereotypical sentence pairs, but they calculate the likelihood of unmasked unmodified tokens and modified tokens for each stereotypical and anti-stereotypical sentence. As with SSS and CPS, the bias score is calculated using the sum of the likelihoods of the stereotyped and anti-stereotyped sentences. AULA calculates the likelihood of the entire sentence by weighting and averaging with the attention weights to prioritize the likelihood of important words.

Faithfulness-Aware Decoding Strategies for Abstractive Summarization

Abstract

Despite significant progress in understanding and improving faithfulness in abstractive summarization, the question of how decoding strategies affect faithfulness is less studied. We present a systematic study of the effect of generation techniques such as beam search and nucleus sampling on faithfulness in abstractive summarization. We find a consistent trend where beam search with large beam sizes produces the most faithful summaries while nucleus sampling generates the least faithful ones. We propose two faithfulness-aware generation methods to further improve faithfulness over current generation techniques: (1) ranking candidates generated by beam search using automatic faithfulness metrics and (2) incorporating lookahead heuristics that produce a faithfulness score on the future summary. We show that both generation methods significantly improve faithfulness across two datasets as evaluated by four automatic faithfulness metrics and human evaluation. To reduce computational cost, we demonstrate a simple distillation approach that allows the model to generate faithful summaries with just greedy decoding.[1]

1 Introduction

Recent developments in large pre-trained language models have achieved remarkable performance on abstractive summarization (Lewis et al., 2020; Zhang et al., 2020a). However, such models often suffer from the problem of hallucinations, where the generated summary contains facts or entities not present in the original document. Prior research has analyzed and defined potential error types and typology (Maynez et al., 2020; Pagnoni et al., 2021; van der Poel et al., 2022), and developed methods to improve faithfulness, including post-processing models (Chen et al., 2021b; Dong et al., 2020; Liu and Liu, 2021; Ladhak et al., 2022) and faithfulness-aware training (Goyal and Durrett, 2021; Nan et al., 2021; Cao and Wang, 2021; Wan and Bansal, 2022; Zhang et al., 2022; Xiao and Carenini, 2022).

One aspect that is less understood on faithfulness of abstractive summarization is the effect of decoding strategies, which determine how the model generates the output strings. Our primary objective is to understand whether different types of exploration of the search space, such as traversing and maintaining multiple possible output hypotheses with beam search or encouraging diversity with nucleus sampling (Holtzman et al., 2020), have an impact on faithfulness. To this end, we first conduct a thorough analysis comparing the faithfulness of popular decoding strategies, including greedy decoding, beam search, and nucleus sampling for two popular summarization datasets XSum (Narayan et al., 2018) and CNN/DM (Hermann et al., 2015). Evaluating the generated summaries using four faithfulness metrics, including BertScore (Zhang et al., 2020b), FactCC (Kryscinski et al., 2020), DAE (Goyal and Durrett, 2021), and QuestEval (Scialom et al., 2021), and human evaluation, we find a consistent trend that beam search provides the most faithful summaries with its large exploration of the search space, and the randomness introduced by sampling hurts faithfulness.

To further improve faithfulness beyond the common decoding strategies, we propose two faithfulness-aware decoding methods. First, similar to Falke et al. (2019), we make use of the multiple candidates generated by beam search and propose a simple re-ranker, which selects the best summary according to a faithfulness metric. Instead of using a specific metric, we rank and select the summaries with a composite metric, a weighted combination of popular faithfulness metrics. Next, inspired by Lu et al. (2022), we propose a faithful-

(a) Ranker (b) Lookahead

Figure 1: Illustration of our proposed decoding methods. 1a shows our ranker that re-ranks the candidates produced by beam search according to faithfulness metrics. The first summary achieves a high score and would be used as the final summary for beam search, but it is not faithful. Our ranker ensures that the more faithful summary is ranked higher. 1b shows the lookahead heuristics that provide a faithfulness score given the full future summary. The model assigns a higher score to the word "World" than "British". However, by looking ahead we know that the completed summary following the most likely token will result in an unfaithful summary. Hence, the lookahead heuristics will ensure selecting the token "British" so that the resulting summary will be faithful.

ness heuristic that looks into the future to generate a full summary starting with the current tokens of any partially generated summary so as to provide a faithfulness score of the future summary during generation. The added heuristic ensures that the selected tokens will lead to a more faithful path in the search space. Compared to the baseline decoding strategies we analyzed, the two proposed methods significantly improve faithfulness as evaluated by four automatic faithfulness metrics and further confirmed by human evaluation.

Finally, to overcome the computational and runtime overhead of our proposed decoding methods, we explore distillation to transfer the knowledge of generating faithful summaries from a teacher model to a student model. Specifically, we use the faithfulness-aware decoding strategies as the teacher model to generate reference summaries. Then, we train student models, which have not been fine-tuned on the original task, to imitate the more faithful generation techniques using an additional cross-entropy loss between the generated summaries by the student and teacher models. Results indicate that the student model is able to generate summaries of similar faithfulness to that of the full teacher model while reducing the decoding time (seconds per example) up to $1/6$ of what the teacher model takes. This process can be performed iteratively by using the student model as the teacher for the next iteration (See Figure 2). With each iteration, the new student model is able to generate more faithful summaries, and outperform the original teacher model with just two iterations.

To summarize, our contributions are:

1. An analysis of the effect of popular decoding strategies, including greedy, beam, and nucleus sampling, on the faithfulness of abstractive summarization.
2. Two faithfulness-aware generation methods, ranking and lookahead, that improve faithfulness over existing decoding strategies.
3. A simple distillation approach that allows a student model to generate faithful summaries with just greedy decoding.

2 Faithfulness Behavior of Popular Decoding Strategies

We first describe our experiment investigating the effect of popular decoding strategies on faithfulness. We wish to primarily investigate whether better exploration of the search space, such as the candidate expansion with beam search, can improve faithfulness, and how randomness introduced through sampling impacts faithfulness. These investigations in turn motivate our more advanced, faithfulness-aware decoding strategies in Section 3.

Decoding Strategies (Greedy, Beam, and Nucleus Sampling). For generation, we assume the common left-to-right, auto-regressive setting where the model generates a summary y with n tokens given the input document x:

$$P(y|x) = \prod_{t=1}^{n} p(y_t|y_{1:t-1}, x)$$

The summary tokens are selected with probability according to the decoding strategies. We explore three common decoding strategies: greedy, beam search, and nucleus sampling (Holtzman et al., 2020). **Greedy search** selects the next token by the most probable token $y_t = \arg\max_y p(y|y_{1:t-1}, x)$. **Beam search** extends greedy search by keeping top-k hypothesis at each time step, where k is the number of beams. Another approach to decoding is to use sampling, where we consider **nucleus sampling**. Holtzman et al. (2020) surprisingly find that methods that optimize probability, such as beam search, may lead to text degeneration, and thus propose nucleus sampling, a method that randomly selects from top tokens whose cumulative probability satisfies the threshold p. A small p means less randomness and becomes greedy search, while a large p allows for a more diverse output.

3 Faithfulness-Aware Decoding Strategies

We hypothesize (and later test and confirm whether it is true in Section 6.1 and Appendix E) that current decoding methods, such as beam search which explores a large space, may not explore the paths that focus on faithfulness directly and effectively. Hence, we propose two faithfulness-aware methods that can be applied on top of the base decoding strategies to modify how the space is explored from two different perspectives: (1) Ranking makes use of the large exploration of beam search and picks the explored path that is most faithful; (2) Lookahead directly guides the search process by adding faithfulness heuristics when selecting the next token starting from the initial decoding process.

3.1 Ranking with Faithfulness Metrics

Since beam search already explores many different suitable candidates during the decoding process, we hypothesize that more faithful summaries exist in the list of possible candidates, even if the model score is not directly optimized towards faithfulness (we show that this is true later in Section 6.1). Thus, we propose to rerank the generated candidates from beam search according to faithfulness metrics.

The process is illustrated in Figure 1a. Assuming a beam search with beam size k, we have k summaries generated by the decoding method. We compute a faithfulness metric (details of the metrics are presented in Section 5.2) over all summaries and select the summary that achieves the highest faithfulness score. In the example, the more faithful summary that was originally ranked low according to model score is now ranked as the top summary according to faithfulness.

Re-ranking candidates for abstractive summarization have been studied primarily from the informativeness perspective (Ravaut et al., 2022a,b), and our focus is on improving faithfulness. Our idea is most similar to Falke et al. (2019), where the authors use NLI models to re-rank. However, the results indicate that the NLI performance does not translate to improvement in faithfulness; their best-ranking model actually increases the number of unfaithful summaries at the top summary after re-ranking by 3%. The authors attribute it to domain shift and NLI models relying on simple heuristics like lexical matching. We thus explore using faithfulness metrics directly for ranking.

Composite Metric. While it is possible to use one of the faithfulness metrics to rank the candidates, it often leads to over-fitting for one particular metric (each metric can have its own domain biases and idiosyncrasies) and hurts the overall faithfulness scores evaluated by other metrics. We instead tune a composite metric that aggregates the vote of several popular metrics (See Section 5.4). We use linear regression to provide weights for each metric and tune on human judgments of faithfulness. We refer the readers to Appendix D and Appendix E for details and ablations for the composite metric.

3.2 Lookahead

Lu et al. (2022) use lookahead to provide a future constraint satisfaction estimate and show its effectiveness in several constrained generation tasks (commonsense generation, constrained machine translation, table-to-text generation, and constrained question generation). We extend this idea to improve faithfulness of abstractive summarization. Instead of relying on explicit constraints that are available for the constrained generation tasks, we use reference-free faithfulness metrics on the full future summaries as an estimate. Unlike reranking which is constrained by the search space explored by beam search, lookahead allows for exploration of a much larger number of candidates.

Figure 1b shows an example of the lookahead. When selecting the next token, the usual decoding scheme would select the word "World" that has the highest probability. However, if we were to follow this path, the resulting summary would introduce hallucinations. Instead, we would like to guide the

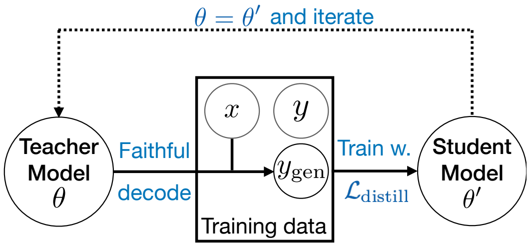

Figure 2: Illustration of the iterative distillation process. We train a student model θ' with summaries generated by the teacher model θ, which uses faithfulness-aware decoding methods. The resultant student model θ' that is trained on more faithful summaries can in turn be used as θ to generate the training data for the next iteration.

model to select the less probable token "British," which will yield a faithful summary sentence.

Formally, each summary token is selected by:

$$f(y_t) = \log P(y_{1:t} \mid x) + w \cdot \max_{L_{y \leq t}} h(y_{1:t+l}, x)$$

where $\log P(y_{1:t} \mid x)$ is the model score, $h(\cdot)$ is a reference-free faithfulness evaluation function that assigns a score to the summary, w is the weight, and l is the number of tokens to look into the future.

Here, $L_{y \leq t}$ is a set of possible generated summaries that start with the summary tokens $y_{1:t}$. The number of summaries for L varies given the decoding strategies we use to generate future summaries. Greedy search and sampling produce a single expansion, and beam search produces k number of summaries depending on the beam size. Although the lookahead length l can be specified, we instead generate the full summary, as current faithfulness metrics expect full summaries as input and do not work well on partial summaries (see Appendix E).

3.3 Combining Ranking and Lookahead

We can combine the two methods to further improve faithfulness. We first use the BEAM+LOOKAHEAD to generate faithful beam candidates and then select the best candidates with ranking. We refer to this method as BEAM+LOOKAHEAD+RANKING.

4 Efficient Decoding via Distillation

One drawback of the proposed decoding methods is the heavy computational cost during decoding. We thus explore using distillation to transfer the knowledge of faithfulness-aware decoding to a student model that can generate summaries of similar faithfulness with just greedy decoding. We note here that our distillation aims at improving the decoding time rather than downsizing the model. Similar to Kim and Rush (2016), we assume that we have a teacher model and a student model. In our setting, the teacher model does not necessarily need to be a different model, but it needs to decode with more faithfulness-aware methods. Typical distillation methods use the teacher's probability distribution (Kim and Rush, 2016) as the target for the student model to imitate. In our case, however, that distribution is the same for all methods – the difference lies in how the probability is used to generate the next tokens. Thus, we propose a new decoding distillation loss. We use the teacher model to generate summaries y_{gen} as additional reference summaries, and interpolate between the cross-entropy loss using the original reference summaries and the cross-entropy loss where we consider y_{gen} as reference summaries. Formally, the training loss is:

$$\mathcal{L}_{\text{distill}} = \mathcal{L}_{\text{XE}}(y', y) + \lambda \mathcal{L}_{\text{XE}}(y', y_{\text{gen}})$$

where $\mathcal{L}_{\text{XE}}$ is the cross entropy, y' is the generated summary by the student model, and λ is a hyperparameter for the weight of the cross-entropy loss on the generated summaries.

Iterative Distillation. While we use the student model with just greedy decoding to improve decoding speed, the student model can also benefit from using our proposed faithfulness-aware decoding methods. Thus, the student models can also serve as a new teacher model to distill more faithfulness knowledge to a new student model. The distillation process thus becomes iterative, illustrated in Figure 2. We use the trained student model as a new teacher model, where we decode with our proposed faithfulness methods to create additional reference summaries y_{gen} for the next iteration.

5 Experiments

5.1 Datasets and Models

We perform experiments on two popular datasets for abstractive summarization, XSum (Narayan et al., 2018) and CNN/DM (Hermann et al., 2015). More details on the datasets are described in Appendix A.1. We use the released checkpoint of BART-large (406M) for the two datasets.[2] The

---

[2] We use the checkpoint BART-LARGE-XSUM (`https://huggingface.co/facebook/bart-large-xsum`)

same experiment is done with PEGASUS (Zhang et al., 2020a), which is presented in Appendix B.

5.2 Evaluation Metrics

We use the F1 measure of ROUGE-L (Lin, 2004, RL), i.e., the overlap of the longest common subsequence between a generated summary and reference summary, and the F1 measure of BERTScore (Zhang et al., 2020b, BS) to evaluate summary quality. In addition, we use BS-Fact, i.e., the BERTScore precision of a summary with respect to its source document rather than the reference summary, FactCC (Kryscinski et al., 2020), DAE (Goyal and Durrett, 2021), and QuestEval (Scialom et al., 2021) for faithfulness evaluation. Details of the metrics are presented in section A.

5.3 Human Evaluation Setup

We use Amazon Mechanical Turk (AMT) to ask human annotators to judge the faithfulness and informativeness of the summaries generated with different decoding.

Faithfulness. We ask workers to judge the faithfulness of a summary sentence using a 3-star rating (1=major factual error, 2=minor factual error, 3=no factual error. Three judgments per summary are then aggregated using majority voting. We randomly select 200 examples from both datasets and use the summaries generated using greedy, sampling, beam search, as well as the ranking and lookahead strategies applied to beam search. We report the percentage of summaries that are fully factual (i.e. the percentage of summaries rated as 3-star) as the faithfulness score, and also report the distribution of summaries rated as 1, 2, and 3 stars. Details on qualification, payment and other aspects of the evaluation can be found in Appendix A.4.

Informativeness. We also evaluate the generated summaries in terms of informativeness. We consider summary to be informative if its content is important and relevant, but it does not necessarily need to be long. We use best-worst-scaling (BWS) for evaluating the informativeness of the generated summaries, as this method is "a less labor-intensive alternative to paired comparisons that has been shown to produce more reliable results than rating scales" (Kiritchenko and Mohammad, 2017). Accordingly, for each dataset, we select 200 random articles with the corresponding summaries from five systems in random order. We ask three annotators to select the most informative ("best") and the least informative ("worst") among the five. A rating per system is computed as the percentage of times it is chosen as best minus the percentage of times it is selected as worst. A value of 100 means that the system has been unanimously picked as "best", whereas a value of -100 means that the system has been unanimously picked as "worst". Additional details, as well as the screenshot of the annotation interface, are in Appendix A.4.

5.4 Decoding Setting Details

We describe the settings of the basic decoding methods, our faithfulness-aware decoding methods and distillation. More details are in Appendix A.3.

Basic Decoding Method. We compare the summaries generated using greedy search, beam search ($k = 10$), and nucleus sampling ($p = 0.9$). Additional experiments with various beam sizes and top-p values can be found in Appendix B.

Ranking and Composite Metric. We use beam search ($k = 10$) and rank the candidates using the composite metric introduced in Section 3.1. To train the composite metric, we explore combining FactCC, BS-Fact, DAE, and QuestEval. We use FACTCOLLECT (Ribeiro et al., 2022), a large collection of four faithfulness annotations to train a linear regression on the human-labeled faithfulness judgments. More details of the composite metric and its robustness to another domain can be seen in Appendix D.

Lookahead. We use BS-Fact as the faithfulness metric for the lookahead as it correlates highly with human judgment (Pagnoni et al., 2021) and is quick to compute without the need for additional pre-processing. We use greedy search to generate future summaries and apply it to both greedy and beam searches.

Distillation. We use the checkpoint of our two proposed faithfulness-aware decoding methods as the teacher model, and train the student model from BART-LARGE.[3] We follow the original fine-tuning hyperparameters provided by the authors (Lewis et al., 2020) and use $\lambda = 1$ for the weight of the additional cross-entropy loss.

---

and BART-LARGE-CNN (`https://huggingface.co/facebook/bart-large-cnn`).

			XSum			
Greedy	36.16	92.03	89.28	**23.53**	65.35	36.51
Nucleus	31.15	91.26	88.62	21.04	76.20	34.98
Beam	**37.11**	**92.12**	**89.45**	22.97	**63.49**	**37.05**

Table 1: Baseline results of popular decoding methods measured by summarization quality metrics (Rouge-L (RL) and BertScore (BS)) and faithfulness metrics. We observe a general trend where beam search performs the best and nucleus sampling performs the worst in terms of faithfulness. Full result with different beam sizes and top-p probability for nucleus sampling is in Table 7.

6 Results

6.1 Baseline Decoding Results

We show the analysis of common decoding strategies in Table 1. Both datasets show a similar trend. Beam search performs the best in terms of faithfulness except for FactCC on the XSum dataset. Compared to greedy decoding, which is beam search with $k = 1$, the candidate expansion with a larger beam size provides better exploration for faithfulness. Nucleus sampling degrades faithfulness compared with greedy search, showing that the introduced randomness is not helpful for faithfulness. This aligns with observations from Narayan et al. (2022) and Chen et al. (2021a), which show that nucleus sampling produces less relevant text for data-to-text generation.

The results are surprisingly mixed for both datasets in terms of summary quality, i.e., RL and BS scores. Comparing beam search with greedy decoding, we see improvement of both scores on XSum but not for CNN/DM. Nucleus sampling, on the other hand, is also worse than greedy search on this aspect, suggesting that randomness may not be suited for the task of abstractive summarization.

Search Space for Beam Search. Inspired by Xu et al. (2022) who hinted at the potential of better faithfulness with a large exploration of the search space, we use beam search to explore whether larger beam sizes (and hence larger exploration) derive more faithful summaries. To this end, we use all summaries generated by beam search and select the beam that would result in the highest possible score for each metric. We show the maximum score (Max) for the four faithfulness metrics and the faithfulness score of selecting the top beam (Top) given different beam sizes in Figure 3. We see a clear trend that increasing the beam size improves all faithfulness scores. This confirms our hypothesis that larger exploration of the search space can provide additional faithfulness gain, and thus showing the potential of our proposed decoding strategies, especially our reranking strategy, to output more faithful summaries. The faithfulness scores of TOP only increase marginally compared to the increase for Max, showing the importance of having better faithfulness guidance, such as our proposed faithfulness lookahead heuristics.

6.2 Faithfulness-Aware Decoding Results

We now show the impact of faithfulness-aware methods compared with the traditional decoding methods, which is shown in Table 2. We first observe that applying ranking on top of beam search improves faithfulness significantly over beam search, as measured by all faithfulness metrics. Specifically, QuestEval reaches 62.57 (2.5 points improvement) and 40.10 (3.1 points improvement) on CNN/DM and XSum respectively. DAE error rate reduces from 63.49 to 51.48 and 3.30 to 1.92, which is a relative improvement of

	Rouge-L	BERTScore	BS-Fact	FactCC	DAE ↓	QuestEval
			CNN/DM			
Greedy	**30.93**	**88.39**	93.15	69.61	8.15	59.13
Beam	29.99	88.03	94.20	84.23	3.30	60.03

Beam+Lookahead+Ranking	34.71	91.90	**90.78**	38.86	**41.04**	**41.94**

Table 2: Results for our proposed decoding strategies. Compared to the baseline methods (greedy and beam search), both ranking and lookahead improve faithfulness. The combination of both methods further increases faithfulness.

18.92% (12.01 points) and 41.8% percent (1.38 points) on XSum and CNN/DM, respectively.

We observe similar improvement for lookahead as well, where applying the lookahead improves the faithfulness over the base decoding strategy over all faithfulness metrics. Nevertheless, the base decoding strategy is still the dominating factor, as Beam+Lookahead generates more faithful summaries than greedy+lookahead for all faithfulness metrics. Greedy+Lookahead outperforms Beam on the XSum dataset, showing that better guidance with future faithfulness heuristics can improve faithfulness without large exploration. Finally, the combination of lookahead and ranking can further improve faithfulness as evaluated by FactCC, DAE, and QuestEval.

In terms of ROUGE score, applying faithful decoding methods decreases RL. This tradeoff between faithfulness and ROUGE has been observed in many prior works (Chen et al., 2021b; Kryscinski et al., 2020; Wan and Bansal, 2022). One reason for this phenomenon is that more than 70% of the reference summaries contain hallucinations (Maynez et al., 2020), so the more faithful summaries that do not contain such hallucinations will have lower ROUGE scores. To investigate this problem, we perform a human evaluation study, where we find that the summaries generated by Beam+Lookahead are considered to be most informative. More details are in Appendix A.4.

6.3 Human Evaluation Results

Faithfulness. The observation on automatic faithfulness metrics aligns with the result of human evaluation in Table 3. For XSum, among the baseline decoding methods, we see that sampling performs the worst. Interestingly, greedy is more faithful than beam search, but the difference is only 1.5 points. Our proposed decoding strategies generate summaries that are judged more faithful compared to that of the baseline decoding strategies. Specifically, Beam+Lookahead reaches 56.5, even outperforming Beam+Ranking by 5 points. We also observe that our proposed methods are able to significantly reduce the percentage of summaries that are considered to contain major factual errors; Compared to beam search, ranking reduces the percentage from 44.5 to 36.5, and lookahead further reduces the percentage by 3 points. For CNN/DM, we see the striking result that the summaries generated by our proposed methods achieve the highest faithfulness, and among the two systems, there are no major errors for Beam+Lookahead.

Informativeness. The result is shown in Table 4. The output of the Beam+Lookahead is clearly seen as the most informative among the five methods. This result suggests that Rouge-L and BERTScore may not be good indicators for informativeness, as Beam+Lookahead achieves the lowest scores for the two automatic metrics on both datasets.

6.4 Abstractiveness

Models can "trivially" become more faithful by becoming more extractive (Dreyer et al., 2023), and thus it is important to understand where the gain in faithfulness stems from. We experiment on XSum, as methods can achieve larger improve-

	XSum			CNN/DM		
	1	2	3	1	2	3
Greedy	43.0	12.0	45.0	4.0	3.5	92.5
Sampling	55.0	13.0	32.0	8.0	10.5	81.5
Beam	44.5	12.0	43.5	0.0	2.0	98.0
Beam+Ranking	36.5	14.0	49.5	0.5	1.0	**98.5**
Beam+Lookahead	31.5	12.0	**56.5**	0.0	1.5	**98.5**

Table 3: Human evaluation results on faithfulness with the 3-star rating system (1=major factual error, 2=minor factual error, 3=no factual error). Our proposed faithfulness-aware methods are judged as the most faithful (the percentage of summaries rated as 3), confirming our observation with automatic faithfulness metrics.

ment in faithfulness and thus potentially more gain through extensiveness. We experiment with the 200 examples used for human evaluation and calculate Mint (Dreyer et al., 2023) for abstractiveness and plot this score against the human-labeled faithfulness, similar to Ladhak et al. (2022). The result is shown in Figure 4. Similar to the observation of Dreyer et al. (2023), more faithful models tend to be more extractive; however, the gain in faithfulness is considerably larger than the decrease in abstractiveness. For example, comparing Beam+Lookahead with beam search, the relative increase in faithfulness (29.89%) is quadruple the decrease (7.27%) in abstractiveness. Similar experiments on CNN/DM are in Appendix F.

Lookahead with Faithfulness and Abstractiveness. We further show that our lookahead method can easily allow additional heuristics, such as balancing both faithfulness and abstractiveness. Specifically, we replace $h(\cdot)$ with combination of BS-Fact and Mint:

$$h(y, x) = \alpha \text{BS-Fact}(y, x) + (1 - \alpha)\textsc{mint}(y, x)$$

We use $\alpha = 0.75$ and the same hyper-parameters as Beam+Lookahead. We refer to this model as Beam+Lookahead+Abstr and show the point in Figure 4. Compared to Beam+Lookahead, this model can increase abstractiveness at a small cost in faithfulness, demonstrating the flexibility of our lookahead method to incorporate various characteristics for summarization.

6.5 Distillation

We present the distillation result in Table 5. While the student models are not able to outperform the teacher models, they approach the performance of the teacher models. The student models are also able to generate more faithful summaries compared to the greedy search baseline, which is only trained using the cross-entropy loss $\mathcal{L}_{\text{XE}}(y', y)$.

	XSum	CNN/DM
Greedy	3.0	− 8.2
Sampling	−20.5	−23.8
Beam	1.8	8.5
Beam+Ranking	1.0	− 2.8
Beam+Lookahead	**17.7**	**31.0**

Table 4: Human evaluation results on informativeness with best-worst-scaling (100=unanimous best, −100=unanimous worst).

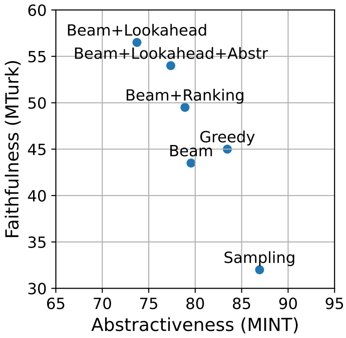

Figure 4: Faithfulness and abstractiveness tradeoff results on 200 XSum examples used for human annotation. Beam+Lookahead+Abstr is the model that is trained with additional abstractiveness heuristics (See Section 6.4 for more details).

The main benefit of the student model comes from the improved decoding speed. The ranking time reduces from 0.77 seconds per example to 0.47, which is a 40% improvement. The largest gain can be seen for lookahead, where the decoding speed reduces from 3 seconds per example to 0.49, only 1/6 of the time it was originally taking.

For example, the student model distilled from Beam+Ranking improves DAE by 6.6 points and QuestEval by a point compared to the greedy search baseline and only differs from the teacher model by 2.5 points for DAE and 0.5 points for QuestEval. When using a more faithful teacher model, i.e. Beam+Lookahead, the student model is able to generate more faithful summaries, as evaluated by BS-Fact, DAE, and QuestEval.

Iterative Distillation. Next, we show the result of distilling Beam+Ranking iteratively on XSum in Table 6. We see that with each iteration, the model is able to improve faithfulness further. When compared to the original teacher model, Beam+Ranking, the student model is able to out-

	RL	BS	BS-Fact	FC	DAE ↓	QE	Speed

Iter. 3	35.09	91.73	90.48	22.77	50.66	38.86
Iter. 4	34.32	91.54	90.81	24.49	47.83	39.64
Iter. 5	33.60	91.34	**91.11**	**25.52**	**45.85**	**40.39**

Table 6: Iterative distillation results using BEAM+RANKING as the teacher decoding method. With two iterations, the student model is able to outperform the original teacher model in terms of faithfulness, and further iterations continuously improve faithfulness.

perform all faithfulness metrics with two iterations. We stress that here all models only use greedy decoding, thus showing the potential of combining decoding with training for more faithful models.

7 Related Work

Many of the related works of our proposed decoding methods have been discussed in Section 3; here we cover other related areas.

Decoding methods. A decoding method for text generation explores an approximate search method to select the best tokens to form a hypothesis. Several works have critically analyzed different decoding strategies for natural language generation, including beam search (Meister et al., 2020a; Stahlberg and Byrne, 2019; Xu et al., 2022; Holtzman et al., 2020), best-first-search (Meister et al., 2020b), and lattice (Xu et al., 2022). While these works investigated the effectiveness of decoding methods on generated outputs from the perspective of diversity and repetitiveness, to our best knowledge, none of the works have explicitly analyzed their performance on faithfulness.

Distillation. Distillation aims at compressing the knowledge from a larger model into a smaller one. A conventional approach uses soft targets, i.e. learning the logits of a teacher model rather than final predictions (Buciluundefined et al., 2006; Hinton et al., 2015; Kim and Rush, 2016). While this method has shown to be very effective, it is less applicable to our case where the underlying distribution for the next probable tokens does not necessarily change (for ranking, we do not modify the model scores at all) and thus not useful to learn soft labels. Different from compressing model size, our approach focuses on reducing the computational cost during decoding. Our method is most similar to pseudo-labeling (Shleifer and Rush, 2020), where we use generated summaries as "hard" labels. We do not replace reference summaries with our generated ones. Instead, we use interpolation (Kim and Rush, 2016) to account for both faithfulness and quality.

8 Conclusion

In this paper, we show a thorough analysis of the effect of decoding strategies on faithfulness for abstractive summarization. We present an analysis of popular decoding strategies, as well as our two newly proposed faithfulness-aware decoding strategies, ranking and lookahead, that can further improve faithfulness upon the base decoding methods. Finally, we show a simple (and optionally iterative) distillation trick where the training of a student model incorporates the summaries generated with more faithfulness-aware methods, and the student model generates summaries of similar faithfulness with minimal decoding time.

Future experiments could extend similar analysis of faithfulness and factuality beyond summarization and develop a combination of heuristics that also encompasses other aspects and styles.

9 Limitations

While the decoding strategies with lookahead show improvement in faithfulness, they require a heavy computational overhead, especially when they are coupled with beam search for the base decoding strategy and for generating the future summary. We provide one solution with our distillation to improve decoding speed. Many of the computations, including the generated future summaries and the faithfulness scores on them, during this online process, are also later disregarded, similar to how any candidates are pruned during beam search. We believe an interesting direction might be to store the already generated future summaries so that the decoding may directly use the future summary if it is considered a good summary candidate.

10 Ethical Impact

While our work aims to reduce potential malicious or unintended harmful effects, our methods rely on the use of faithfulness metrics. The inherent problems and biases when using such metrics have been under-studied. Our decoding strategies can also be applied to be used for other metrics, even those that could be optimized for malicious intents. Another aspect to consider is the environmental impact of our proposed methods, as they require large computations. We hope that our distillation can mitigate this problem and future work can work towards more environmentally friendly approaches while improving faithfulness for safer use of large models.

A Experiments Details.

A.1 Datasets

We evaluate on XSum and CNN/DM. We use the dataset processed and provided by DATASETS (Lhoest et al., 2021).[4] Both datasets contain English news articles and the corresponding summaries. XSum contains 204045, 11332, and 11334 examples for training, validation, and test set, respectively, and CNN/DM contains 287113, 13368, and 11490 for the splits.

A.2 Metrics

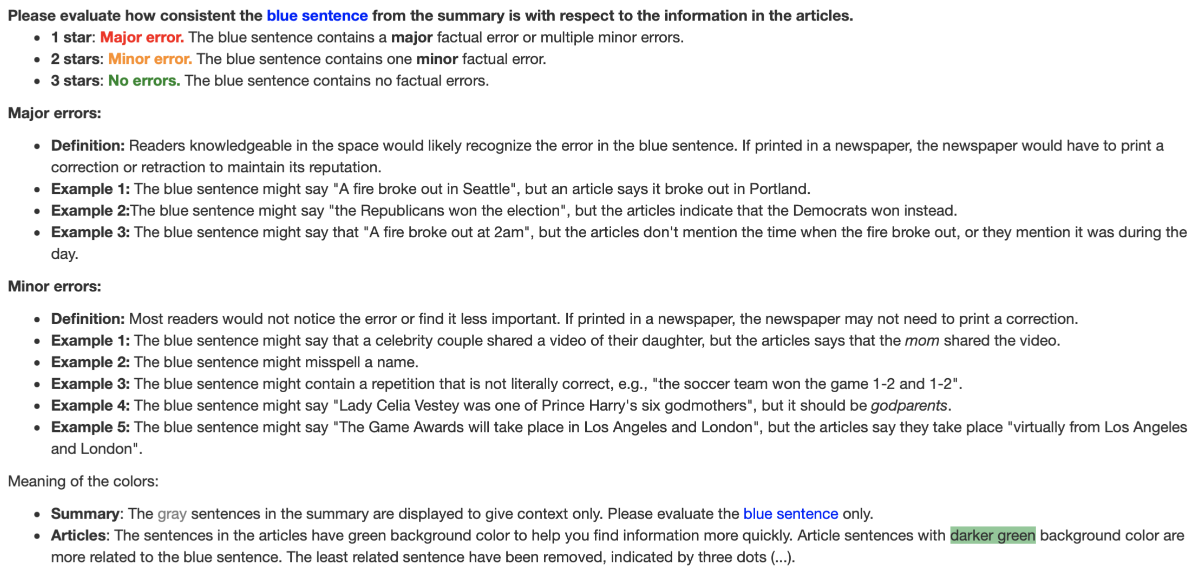
We use the official code and follow the instructions to set up and run all the metrics we used. We use the ROUGE package from `https://github.com/google-research/google-research/tree/master/rouge`. We report all scores of our models from single runs. For BS and BS-Fact, we use the default model for English (ROBERTA-LARGE). For DAE, we use the sentence error, which considers the sentence to contain an error if one of its arcs is predicted to be not factual.

A.3 Decoding Details

Basic Decoding Method Details. We use the official generation code provided by TRANSFORMERS

---

[4] The link to the processed data is found in `https://huggingface.co/datasets/xsum` and `https://huggingface.co/datasets/cnn_dailymail`.



Please evaluate how consistent the blue sentence from the summary is with respect to the information in the articles.

- **1 star**: **Major error.** The blue sentence contains a **major** factual error or multiple minor errors.
- **2 stars**: **Minor error.** The blue sentence contains one **minor** factual error.
- **3 stars**: **No errors.** The blue sentence contains no factual errors.

Major errors:

- **Definition:** Readers knowledgeable in the space would likely recognize the error in the blue sentence. If printed in a newspaper, the newspaper would have to print a correction or retraction to maintain its reputation.
- **Example 1:** The blue sentence might say "A fire broke out in Seattle", but an article says it broke out in Portland.
- **Example 2:**The blue sentence might say "the Republicans won the election", but the articles indicate that the Democrats won instead.
- **Example 3:** The blue sentence might say that "A fire broke out at 2am", but the articles don't mention the time when the fire broke out, or they mention it was during the day.

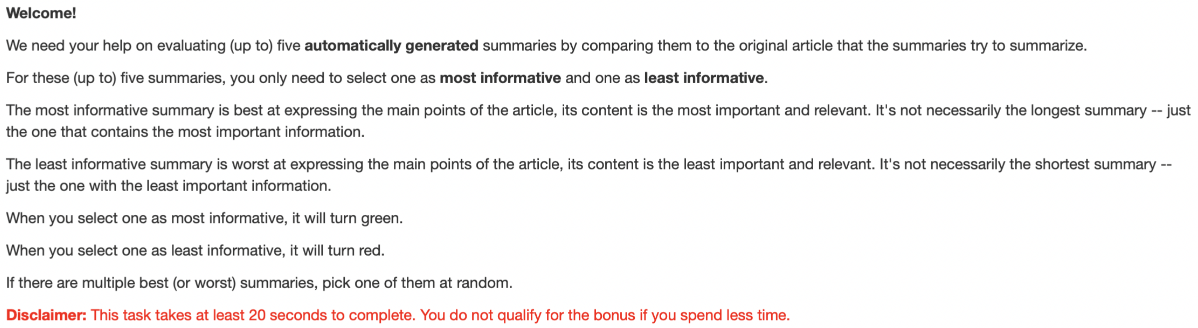
Minor errors:

- **Definition:** Most readers would not notice the error or find it less important. If printed in a newspaper, the newspaper may not need to print a correction.
- **Example 1:** The blue sentence might say that a celebrity couple shared a video of their daughter, but the articles says that the *mom* shared the video.
- **Example 2:** The blue sentence might misspell a name.
- **Example 3:** The blue sentence might contain a repetition that is not literally correct, e.g., "the soccer team won the game 1-2 and 1-2".
- **Example 4:** The blue sentence might say "Lady Celia Vestey was one of Prince Harry's six godmothers", but it should be *godparents*.
- **Example 5:** The blue sentence might say "The Game Awards will take place in Los Angeles and London", but the articles say they take place "virtually from Los Angeles and London".

Meaning of the colors:

- **Summary**: The gray sentences in the summary are displayed to give context only. Please evaluate the blue sentence only.
- **Articles**: The sentences in the articles have green background color to help you find information more quickly. Article sentences with darker green background color are more related to the blue sentence. The least related sentence have been removed, indicated by three dots (...).

Figure 5: Annotation instructions to annotate factual consistency on Mechanical Turk.



Welcome!

We need your help on evaluating (up to) five **automatically generated** summaries by comparing them to the original article that the summaries try to summarize.

For these (up to) five summaries, you only need to select one as **most informative** and one as **least informative**.

The most informative summary is best at expressing the main points of the article, its content is the most important and relevant. It's not necessarily the longest summary -- just the one that contains the most important information.

The least informative summary is worst at expressing the main points of the article, its content is the least important and relevant. It's not necessarily the shortest summary -- just the one with the least important information.

When you select one as most informative, it will turn green.

When you select one as least informative, it will turn red.

If there are multiple best (or worst) summaries, pick one of them at random.

Disclaimer: This task takes at least 20 seconds to complete. You do not qualify for the bonus if you spend less time.

Figure 6: Annotation instructions to annotate informativeness on Mechanical Turk.

(Wolf et al., 2020). We use a single NVIDIA V100 GPU to generate the summaries. Greedy and sampling experiments take around 2 hours and beam search variants take 4 hours.

Ranking. We do not need to do additional computation as we already have the outputs of beam search and the metric scores.

Lookahead. To reduce computational overhead, we only calculate and incorporate the lookahead heuristics for the top 5 tokens according to the model score at each time step. Experiments using beam search or sampling to generate a future summary can be found in Appendix C. We show additional ablations on the length of the future summaries and how the exploration changes with the heuristics in Appendix E. For tuning the w, the weight for the heuristics, we search over the interval from 5 to 55 with a step of 5, and evaluate the generated summaries on the development set. We use the average of all metric scores, including RL and BS so that we do not over-optimize for faithfulness. We find 25 to be optimal for CNN/DM and 55 for XSum. The time to run for XSum is 33 hours, and that for CNN/DM is around 70 hours.

Distillation Details. We use the example code from TRANSFORMERS to train summarization models. We follow the authors' hyper-parameters to train BART-Large models. We use 8 V100 GPUs and the training time is around 5 hours. To generate the summaries for the training data, The BS-Fact Ranker takes around 3 hours to generate the summaries when parallelized across the 8 GPUs. Lookahead takes 10 hours to generate the training data split across 8 GPUs.

A.4 Human Evaluation Details

Human Evaluation on Faithfulness. The screenshot of the annotation can be seen in Figure 5. We required annotators to pass a custom

Table 8: Full results of beam search and nucleus sampling for fine-tuned PEGASUS-LARGE models. We observe a similar observation as Table 7, showing that the faithfulness trend holds for different models.

qualification test consisting of three summaries with factual errors. To pass the test, the annotators had to correctly describe the factual errors in words. Workers also needed to have previously completed 100 or more tasks with an acceptance rate of 95% or higher. We recruited workers from countries whose main language is English. To prevent any one worker from dominating the results, we set a maximum of 100 HITs per worker per dataset. The payment for judging each summary was $0.22 plus a bonus of $0.03. Annotators who spent more than 10 seconds per HIT and maintained high accuracy on HITs with known answers obtained the bonus. Annotators spent a median amount of 57.5 seconds per HIT, which amounts to a pay of $15.65 per hour. Krippendorff alpha (Krippendorff, 1980) for the CNN/DM factuality annotation is 0.63, and Krippendorff alpha for the XSum annotation is 0.57.

Human Evaluation on Informativeness. The screenshot of the annotation can be seen in Figure 6. To achieve good quality, we set up a qualification task of three documents with their associated summaries. A selected pool of workers who had passed previous factuality qualification tests was allowed to take this current qualification test. The workers who passed the current qualification test were allowed to participate in this evaluation. In addition, we added the same three documents with known answers to the evaluation and observed that workers had 100% accuracy on them. We set the same maximum of 100 HITs per worker per dataset as in the factuality evaluation. The pay was $0.40 plus $0.10 bonus per HIT. Annotators spent a median time of 112 seconds per HIT, amounting to a pay of $16.07 per hour. For inter-annotator agreement, Krippendorff alpha (Krippendorff, 1980) for the CNN/DM annotation is 0.22, and Krippendorff alpha for the XSum annotation is 0.32.

B Full Analysis

Table 7 shows the full result. We see the general trend where increasing beam size improves faithfulness and increasing p for sampling is not helpful for faithfulness.

We similarly run the experiment on PEGASUS, a 568M model specifically trained for the task of abstractive summarization, with its respective checkpoints.[5] The result is presented in Table 8.

C Lookahead Methods

We show the result of combining different decoding strategies for the base decoding strategy as well

as for lookahead in Table 9 shows the result. We experiment with greedy and beam search as the base decoding strategies. For greedy, we experiment with all three decoding strategies for lookahead. For beam search, we are unable to run it with sampling or beam search due to the large computational cost. Interestingly, using beam for lookahead does not provide additional gains. We suspect that this is because exploring the future with more beams cannot guarantee that the base decoding strategy is able to explore them, as it is limited to selecting only the top tokens.

D Composite Metric

As described in Section 3.1, we train the composite metric on FACTCOLLECT and tune it on FRANK (Pagnoni et al., 2021). We use the test set of Pagnoni et al. (2021) for evaluation and the rest for tuning the composite metric. The resulting weights for the metrics are 0.29, -0.29, 1.97, and 0.94 for the FactCC, DAE, BS-Fact, and QuestEval, respectively, and the intercept is -1.91. We additionally compute partial correlations on FRANK, shown in Table 10. We see that the composite is able to further increase the correlations in all settings except for XSum's Spearman correlation. Ablations on the effect of ranking with a single metric in Appendix E.

	RL	BS	BS-Fact	FactCC	DAE ↓	QuestEval
Greedy	26.36	**89.09**	88.93	89.57	75.34	38.39

BEAM+RANKING	**27.60**	87.62	**89.64**	**91.11**	**47.01**	**41.91**

Table 11: Results for ranking on the WikiHow dataset.

Since FACTCOLLECT only contains annotations on XSum and CNN/DM, we analyze whether the composite metric is robust for another dataset and domain. We use WikiHow (Koupaee and Wang, 2018) and decode using PEGASUS[6] with greedy and beam decoding. The result of applying ranking to the beam output can be seen in Table 11. We see consistent gains in all faithfulness metrics when we apply ranking, showing its robustness of improving faithfulness in another domain.

E Ablations

We present several ablation studies for our proposed faithfulness-aware decoding methods. More ablation studies exploring how lookahead explores the search space can be found in Appendix E.

Lookahead Length. We first present the result of using the lookahead heuristics but with $l = 0$. This means that at each time step, we do not use future heuristics but directly evaluate the

---

[6] We use the checkpoint PEGASUS-WIKIHOW (`https://huggingface.co/google/pegasus-wikihow`).

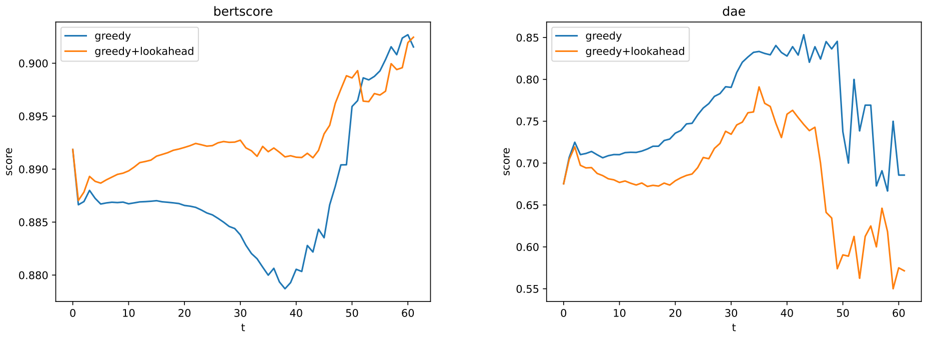

Figure 7: Faithfulness score of the lookahead summaries at each time step. Adding lookahead as the heuristics improves the search space to generate more faithful summaries.

	RL	BS	BS-Fact	FactCC	DAE ↓	QuestEval
			CNN/DM			
Greedy	**30.93**	**88.39**	93.15	69.61	8.15	59.13
$l = 0$	30.71	88.34	93.13	70.41	8.19	58.65
$l =$ full	30.75	88.35	**93.90**	**71.54**	**5.70**	**60.13**
			XSum			
Greedy	36.16	92.03	89.28	23.53	65.35	36.51
$l = 0$	35.73	92.00	89.39	23.43	64.06	36.55
$l =$ full	**36.25**	**92.11**	**89.71**	**24.21**	**60.46**	**37.17**

Table 12: Lookahead ablation with different lengths. $l = 0$ provides the faithfulness heuristic score only on the partially generated summaries while $l =$ full is our lookahead model that evaluates on the full future summary. The faithfulness score calculated on the partial summaries does not provide an effective estimate that improves the faithfulness of the generated summary.

Table 13: Ranking results with different faithfulness metrics. Top is the best summary from beam search, and each subsequent rows represent the ranker using the corresponding faithfulness metric. We abbreviate FactCC as FC, QuestEval as QE, and Composite as Comp.

faithfulness of the already generated partial summaries as the additional score. The result using GREEDY+LOOKAHEAD is shown in Table 12. Compared to greedy decoding, adding the faithfulness score of the current partial summary shows mixed results; the heuristic can only slightly improve BS-Fact, DAE, and QuestEval for XSum. However, we only see substantial gain when the future is taken into account (i.e. $l =$ full). This shows the necessity of using the full summary to achieve the full potential of current faithfulness metrics.

Ranking with Faithfulness Metrics. Next, we present the result for ranking with each respective faithfulness metric. The result is shown in Table 13. Generally, optimizing for one metric will lead to improvement in other faithfulness metrics. While optimizing each of the faithfulness metrics will undoubtedly perform the best when we use that metric for evaluation, the composite metric is able to achieve a similarly good score for **all** faithfulness metric that we are considering.

Evaluating the Search Space. We hypothesize that by incorporating lookahead, we can improve the search space even when a few tokens are generated. To better understand this, we greedily decode the full summary at each time step given the prefix similar to how lookahead works. We then use BS-Fact and DAE to score all generated summaries and analyze the faithfulness score at each time step. Here, we focus on XSum and compare greedy and GREEDY+LOOKAHEAD. The plots of faithfulness scores using the current prefix to generate the full summaries are shown in Figure 7, where we see the benefit of having the lookahead heuristics. For BS-Fact, we see a large gap between the two methods especially when t is between 5 and 50. Though it may be less surprising as this is the faithfulness metric that the lookahead heuristic optimizes on,

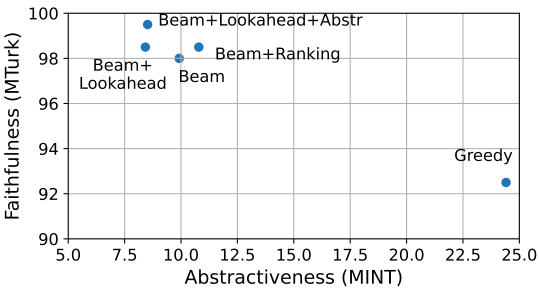

Figure 8: Faithfulness and abstractiveness tradeoff results on the 200 CNN/DM examples used for human annotation. While our proposed methods are less abstractive, the gain in faithfulness is much larger than the decrease in abstractiveness.

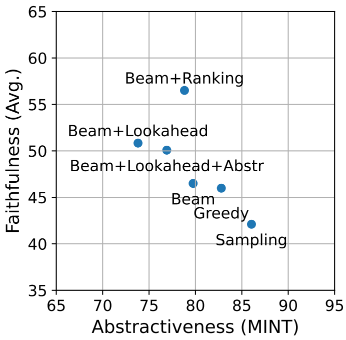

Figure 9: Faithfulness and Abstractiveness tradeoff results on the full examples XSum test set. Faithfulness is calculated by taking the average across all automatic faithfulness metrics.

the heuristic can nevertheless prevent the score to dip, which we see for greedy search between $t = 5$ to $t = 40$. This shows that it is able to lead the model to a more faithful path to prevent straying away from a less faithful path. When we evaluate DAE, we show that optimizing on BS-Fact with lookahead heuristic can consistently improve the score for all lengths.

F Abstractiveness

We first show the same tradeoff result in CNN/DM in Figure 8. BEAM+LOOKAHEAD+ABSTR does achieve a slightly higher MINT score while also improving faithfulness.

We also extend the analysis to the whole test dataset and show the faithfulness score by taking the average of all faithfulness metrics (Avg.). Since DAE is an error rate, we subtract the score from 100 so that a higher score means it is more faithful.

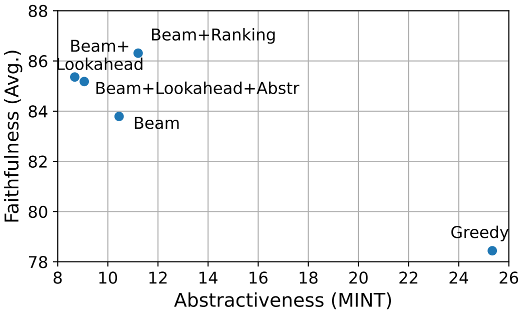

Figure 10: Faithfulness and Abstractiveness tradeoff results on the full examples CNN/DM test set. Faithfulness is calculated by taking the average across all automatic faithfulness metrics.

We do not use the composite metric as the ranking directly optimizes for it.

We can see a similar trend with the average of faithfulness metrics for both datasets in Figure 9 and Figure 10, where the gain in faithfulness outweighs the decrease in abstractiveness. The difference from the result using human faithfulness score is that BEAM+RANKING achieves the highest average score since ranking with composite metric optimizes the faithfulness metrics.

Dynamic Benchmarking of Masked Language Models on Temporal Concept Drift with Multiple Views

Abstract

Temporal concept drift refers to the problem of data changing over time. In NLP, that would entail that *language* (e.g. new expressions, meaning shifts) and *factual knowledge* (e.g. new concepts, updated facts) evolve over time. Focusing on the latter, we benchmark 11 pretrained masked language models (MLMs) on a series of tests designed to evaluate the effect of temporal concept drift, as it is crucial that widely used language models remain up-to-date with the ever-evolving factual updates of the real world. Specifically, we provide a holistic framework that (1) *dynamically* creates temporal test sets of any time granularity (e.g. month, quarter, year) of factual data from Wikidata, (2) constructs fine-grained splits of tests (e.g. updated, new, unchanged facts) to ensure *comprehensive* analysis, and (3) evaluates MLMs in three distinct ways (single-token probing, multi-token generation, MLM scoring). In contrast to prior work, our framework aims to unveil how *robust* an MLM is over time and thus to provide a signal in case it has become *outdated*, by leveraging *multiple views of evaluation*.

1 Introduction

In the real world, what people talk about and how they tend to speak and write changes constantly over time. In Natural Language Processing (NLP), this entails a challenging shift of the textual data distribution that is commonly referred to as *temporal concept drift*. Prior work has identified that pretrained language models (PLMs) tend to become outdated soon after new topics and concepts are emerging (Lazaridou et al., 2021; Dhingra et al., 2022; Agarwal and Nenkova, 2022; Luu et al., 2022), limiting their capability to be robust to newly generated data.

We consider the desiderata of language models' robustness to temporal drift to be twofold. First, LMs should be well adapted to the dynamic use of language, from the *linguistic* perspective. Language changes over time, pronunciations evolve, new words and expressions are borrowed or invented, the meaning of old words drifts, and morphology develops or decays (Blank, 1999; Traugott and Dasher, 2001; Kulkarni et al., 2015). Second, LMs should be aware of the ever-changing reality of the world, from a *factual* perspective. Models' factual knowledge should be up-to-date with new facts and concepts (e.g. Covid-19) to be of use continuously. In this work, we focus on the latter; *the temporal robustness of LMs to facts that change over time*.

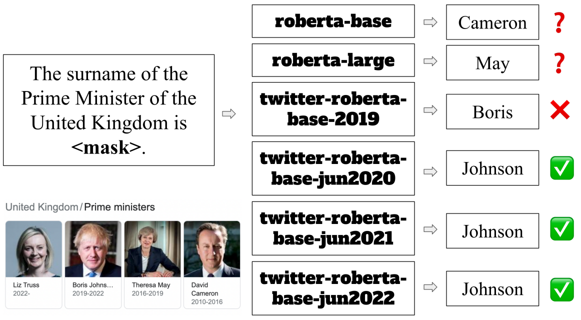

Figure 1: Querying pretrained MLMs on their knowledge about the Prime Minister of the United Kingdom.

In an ideal scenario, we would like to know exactly when the factual knowledge of a model is "expired" so that we could adapt it to the new (or updated) set of facts. In reality, this is a challenging task. A large body of work has focused on the part of (continually) *adapting* an "outdated" model to the new data distribution (Guu et al., 2020; Yogatama et al., 2021; Sun et al., 2020; Biesialska et al., 2020; Jang et al., 2022b; Jin et al., 2022; Chakrabarty et al., 2022). This line of work is parallel to ours, as we focus on the crucial step before adaptation, the evaluation of the model on temporal concept drift: *How can we know if a language model is outdated or not?*

Let us consider the case where we desire a lan-

guage model to be up-to-date with the Prime Minister of the United Kingdom (Figure 1).[1] A plausible way to evaluate this is to use the LAMA-probe paradigm (Petroni et al., 2019) and query the LM as a knowledge base (KB). This would mean that we could form the query as "`The surname of the Prime Minister of the United Kingdom is <mask>.`", give it as an input to a (masked) LM and inspect the output token distribution for the `<mask>` token. Figure 1 shows the top prediction for a series of RoBERTa models.[2] We first observe that the most widely used RoBERTa `base` and `large` models are both outdated in terms of factual knowledge, as they predict the names of PMs that served from 2010 until 2019. Next, while the last three models (2020-2022) answer correctly, the 2019 model answers the (correct) *first name* of the PM (`Boris`), not the *surname* (`Johnson`) which is asked for.

This is a handy illustration of the many *challenges* in evaluating MLMs for temporal robustness in the LMs-as-KBs framework. First, this 2019 model would be considered to have made a mistake (as the prediction is different than the gold label and the metric is accuracy), even though the factual knowledge was correct (the name of the PM of the UK). Second, notice that we designed the query to ask for the surname (instead of the name of the PM), as this results in a single mask. The LAMA-probe and related frameworks do not handle *multi-token* queries for MLMs (e.g., `Boris Johnson`). Finally, we mark with a ? the answers of the first two RoBERTa models, because even though their answers are out-of-date for our current evaluation (October 2022), their answers could have been correct in an evaluation setting in the time of the training data (2019). This illustrates the obscurity of the temporal window in which the model is expected to be correct, if the model is not trained with a temporally-aware design (Lazaridou et al., 2021; Dhingra et al., 2022; Loureiro et al., 2022; Jang et al., 2022a).

In this work, we aim to address such limitations and provide a holistic framework for dynamic benchmarking of masked language models on temporal concept drift, with a focus on facts that change over time. Following the propositions of Kiela et al. (2021) and Søgaard et al. (2021) that advocate for a focus on *dynamic* (i.e., test sets should not become saturated) and *targeted* (i.e., use of multiple, independent test sets for realistic performance estimates) benchmarking respectively, and building on prior work (Jiang et al., 2020b; Dhingra et al., 2022; Jang et al., 2022a), we create a large open-source test set that can be dynamically updated over time, containing temporal fine-grained subsets of examples that can be used to query masked language models and evaluate their factual knowledge over time.

Contributions **(1)** We release DynamicTempLAMA, an improved version of the static TempLAMA (Dhingra et al., 2022) test set consisting of Wikidata relations, that is used to evaluate temporal robustness of MLMs. We provide data and code to dynamically keep DynamicTempLAMA up-to-date over time.[3] **(2)** We propose a novel evaluation framework to first create temporal splits of test sets of any granularity (month, quarter, year) and then to further create fine-grained splits of facts that are *unchanged*, *updated*, *new* or *deleted*, aiming to improve comprehensiveness (§3.1). **(3)** We introduce three distinct evaluation views with multiple metrics (§3.3) to ensure comprehensive results and provide analysis of benchmarking a large set open-source temporal RoBERTa models (§3.2).

2 Related Work

Temporal Concept Drift Evaluation of the robustness of language models on temporal concept drift has seen a rising interest in the recent years. Previous work has focused on methods to continually adapt models over time (Hombaiah et al., 2021; Rosin et al., 2022; Lazaridou et al., 2022). Another area of research is evaluation of temporal robustness which has been explored both in the upstream LM pretraining task (Jiang et al., 2020b; Lazaridou et al., 2021; Dhingra et al., 2022; Jang et al., 2022a; Loureiro et al., 2022) and in downstream tasks such as sentiment analysis (Lukes and Søgaard, 2018; Agarwal and Nenkova, 2022), named entity recognition (Rijhwani and Preotiuc-Pietro, 2020; Onoe et al., 2022), question answering (Mavromatis et al., 2021; Liška et al., 2022), and rumor detection (Mu et al., 2023). It has also been studied for model explanations (Zhao et al., 2022) and for text classification in legal, biomedical (Chalkidis and Søgaard,

---

[1] The time of writing of this paper is September 2022.

[2] Except for the RoBERTa `base` and `large` models, we also show the predictions of models trained with Twitter data until 2019, 2020, 2021, and 2022, respectively (Loureiro et al., 2022).

[3] `https://github.com/amazon-science/temporal-robustness`

2022), and social media (Röttger and Pierrehumbert, 2021) domains.

Luu et al. (2022) explore the setting of temporal misalignment (i.e., training and test data drawn from different periods of time) for both upstream and downstream tasks and find that temporal adaptation should not be seen as a substitute for finding temporally aligned labeled data for fine-tuning.

The closest work to ours is TEMPLAMA (Dhingra et al., 2022). However, we differ across four axes: (i) TEMPLAMA is static, while we provide code to dynamically download facts in a fine-grained fashion from any periods of time (not only yearly), (ii) we evaluate the *same* models over time focusing on the evaluation of robustness over time, we do not explore the best adaptation technique to address the problem, (iii) we do not fine-tune the models to adapt them to the domain/format of the test data, and (iv) we address benchmarking of masked LMs (not auto-regressive) including more evaluation techniques. Finally, similar to our motivation, Jang et al. (2022a) recently explored lifelong adaptation and evaluation of temporal concept drift in LMs and introduced TEMPORALWIKI for continual adaptation and TWIKI-PROBES for evaluation. The major difference is that the authors focus on providing corpora to adapt an LM over time, while in our paper we focus on evaluating temporal robustness of LMs. DYNAMICTEMPLAMA is a holistic evaluation framework, while "TWIKI-PROBES are not natural sentences; they are factual phrases synthetically generated from a naive concatenation of Subject, Relation, and Object".

Language Models as Knowledge Bases The cloze-style LM evaluation framework for factual knowledge, LAMA Petroni et al. (2019), follows the setting depicted in Figure 1. A knowledge base relation is transformed into natural language text with a manually created template and then passed as an input to an LM. The framework is based on treating the output distribution for the `mask` token as the retrieved answers to the query (AlKhamissi et al., 2022). The LAMA probe has since been extensively used to evaluate factual knowledge in LMs (Petroni et al., 2020; Talmor et al., 2020; Kassner et al., 2021; Sung et al., 2021; Dhingra et al., 2022; Fierro and Søgaard, 2022), while other works have been exploring its limitations and ways to improve it (Kassner and Schütze, 2020; Haviv et al., 2021; Elazar et al., 2021; Zhong et al., 2021; Qin and Eisner, 2021). A particular challenge in our experimental setting, is the text compatibility between the model (i.e., its pre-training data) and the format of test examples, named as "language mismatch" by Talmor et al. (2020). Dhingra et al. (2022) opts to fine-tune the model under evaluation with part of the test set to adapt it to the format of the task. We argue that this process suffers from many caveats; it is inefficient and impractical to fine-tune a model whose capabilities are under evaluation, it risks optimization stability and overfitting issues due to the small training dataset, and enforces extra biases and errors, especially in the case of temporal robustness evaluation.

3 Dynamic Benchmarking of Temporal Concept Drift

In this section we describe in detail the steps to (re)create DYNAMICTEMPLAMA, our dynamically updated test set with facts from Wikidata (§3.1). We then present the open-source temporal ROBERTA models (TIMELMS) (Loureiro et al., 2022) that we use for benchmarking (§3.2). Finally, we introduce the evaluation framework under which we investigate how well the TimeLMs perform in terms of temporal robustness (§3.3).

The research question that we try to address with our work is: *How can we measure temporal drift robustness of PLMs with an evaluation framework that is*: *unsupervised* (no labeled downstream data), *efficient* (quality test set of facts—no need to run inference on a large corpus to compute perplexity for every token), *dynamic* (test set easily generated per request—can be used to dynamically evaluate new concepts over time), *general* (option to create test sets of any time granularity), and *comprehensive* (battery of targeted test sets that evaluate different LM capabilities and multiple views of evaluation).

3.1 DYNAMIC-TEMPLAMA

We base our implementation on the TEMPLAMA (Dhingra et al., 2022) code, while we make several changes in terms of accessibility (i.e. option to dynamically update the test set), flexibility (i.e. option to adjust the granularity of the temporal splits) and comprehensiveness (i.e. fine-grained splits and multiple evaluation views). We provide a high-level overview of the process to create DYNAMICTEMPLAMA in Figure 2.

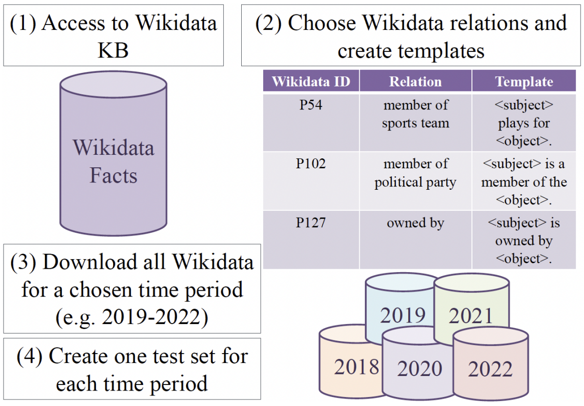
Data Collection We start the process by selecting a set of *relations* collected from the Wikidata KB

WIKIDATA ID	RELATION	TEMPLATE	#FACTS	#EXAMPLES	POSSIBLE SPLIT(S)
P54	member of sports team	`<subject> plays for <object>.`	3772	50558	$\mathcal{D}^{\text{UPDATED}}$
P69	educated at	`<subject> attended <object>.`	232	2420	$\mathcal{D}^{\text{UPDATED}}$, $\mathcal{D}^{\text{UNCHANGED}}$
P6	head of government	`<object> is the head of the government of <subject>.`	578	7815	$\mathcal{D}^{\text{UPDATED}}$
P279	subclass of	`<subject> is a subclass of <object>.`	5	70	$\mathcal{D}^{\text{NEW}}$, $\mathcal{D}^{\text{UPDATED}}$

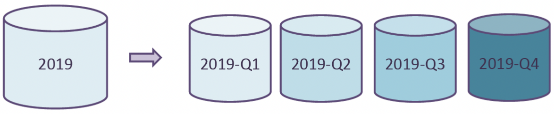
Table 1: Examples of relations and their corresponding templates that we include in DYNAMICTEMPLAMA. #FACTS denote the unique number of facts for each relation, while #EXAMPLES denotes the total number of example we have collected for each relation in the time range between `2019-Q1` and `2022-Q2`. POSSIBLE SPLIT(S) indicate the type of fine-grained split that each relation would potentially belong to.

(Figure 2a).[4] Specifically, we use the 9 relations used in the TEMPLAMA dataset, followed by 7 more that we also decided to collect. We collect all relations from Wikidata in the span of 2019 – 2022. We then manually craft a cloze style query, i.e template, for each relation.Table 1 shows a few examples of relations and templates, along with dataset statistics.[5] We explain the data collection process in detail in Appendix A.1.

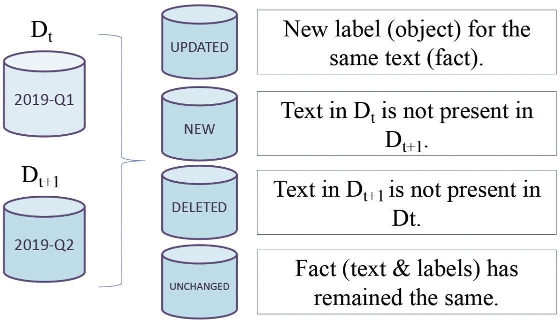
Temporal Splits In this stage, we have a very large collection of facts for which we have temporal information (i.e., that the fact is true) in the time range we investigate (2019 – 2022). In the TEMPLAMA dataset, the facts are divided yearly. However, we would ideally like to benchmark temporal models of any time granularity. Specifically, since we benchmark temporal models that are trained quarterly (§3.2), a yearly split would not be useful to evaluate temporal concept drift of the four models trained on each quarter of a year. Consequently, we divide the large set of collected facts per quarter (Figure 2b), while adding the functionality to our implementation to split the facts in any time granularity (monthly, quarterly, yearly).



(a) Data collection



(b) Temporal Splits



(c) Fine-grained Splits

Figure 2: The process for creating DYNAMICTEMPLAMA. We first collect data from Wikidata (a), we then divide it to quarterly temporal splits (b) and finally we create more targeted fine-grained sets (c).

Fine-grained Splits For a given time range, from timestep t to $t+1$ (e.g. `2019-Q1`→`2019-Q2`), we further create comprehensive test sets that contain examples with *unchanged*, *updated*, *new* or *deleted* facts, denoted by $\mathcal{D}^{\text{UNCHANGED}}_{t+1}$, $\mathcal{D}^{\text{UPDATED}}_{t+1}$, $\mathcal{D}^{\text{NEW}}_{t+1}$ and $\mathcal{D}^{\text{DELETED}}_{t+1}$ respectively (Figure 2c). We create these splits to be able to measure different capabilities of the MLM in terms of robustness to temporal concept drift. The motivation for this stems from limitations of prior work (Dhingra et al., 2022) to shed light into what kind of data each temporal test set contains. For instance, we pose questions like *How many facts were updated from timestep* $t \rightarrow t+1$*? How many facts remained unchanged? What was the change? The object or the subject? Are there new facts in timestep* $t+1$ *that were not present before?* We argue that it is

---

[4] All possible relations from Wikidata can be found here `https://www.wikidata.org/wiki/Wikidata:List_of_properties`.

[5] Details on all relations and templates of DYNAMICTEMPLAMA can be found in Tables 6 & 7 in the Appendix A.1.

essential to distinguish between these sub-tests, so that each split can target specific capabilities of the LM. First, we can use $\mathcal{D}_{t+1}^{\text{UNCHANGED}}$ to evaluate knowledge preservation (i.e. how well a model can preserve knowledge over time). Second, we can use $\mathcal{D}_{t+1}^{\text{UPDATED}}$, $\mathcal{D}_{t+1}^{\text{NEW}}$ and $\mathcal{D}_{t+1}^{\text{DELETED}}$ to measure adaptation (i.e. how well a model adapts to new information/facts). Finally, we can measure overall temporal robustness by evaluating a temporal model from timestep t on $\mathcal{D}_{t+1}^{\text{UPDATED}}$ and $\mathcal{D}_{t+1}^{\text{NEW}}$ in timesteps for $t \in [t+1, t+2, ...)$. We believe that this framework is particularly useful for insightful evaluation of methods that aim to adapt language models over time (Guu et al., 2020; Yogatama et al., 2021; Sun et al., 2020; Biesialska et al., 2020; Jang et al., 2022b; Jin et al., 2022; Chakrabarty et al., 2022).

3.2 Temporal Models

In contrast with prior work that uses private, in-house models for temporal robustness evaluation that are not accessible by the community (Lazaridou et al., 2021; Dhingra et al., 2022), we instead benchmark a series of open-source temporal models. Despite our aim for transparency, energy efficiency (Strubell et al., 2019) and reproducibility, we also believe that the *dynamic* nature of the task at hand requires *accessibility* to past, present and future models, to ensure that the findings of evaluation studies in temporal concept drift are meaningful, trustworthy and serve their purpose in evaluating models in a ever-evolving world. Under this assumption, we believe that studies on temporal robustness should ideally build on each other, so that we can have a holistic view as to how these models truly evolve over time.

To this end, we use the Diachronic Language Models (TIMELMS) (Loureiro et al., 2022) that are publicly available in the `HuggingFace` hub (Wolf et al., 2019).[6] TIMELMS are ROBERTAmodels (Liu et al., 2019) trained *quarterly* on Twitter data. All models are initialised from the original `roberta-base` model checkpoint and are later trained using data from the previous quarters and the new temporal data from the new time period. For instance, the first model (`2019-Q4`) was trained with data sampled from Twitter until December 2019, while the second model (`2020-Q1`) was trained on the concatenation of all the data used to train `2019-Q4` and temporally-aligned data sampled from the first quarter of 2020. There are 11 TIMELMS in total, from `2019-Q4` until `2022-Q2`.

Finally, we would like to draw attention to two specific points. First, all TIMELMS are trained using the same ROBERTA (base) tokenizer and thus have the same vocabulary. This is crucial when evaluating models in a Cloze-style format, like the LAMA-probe, in order to evaluate fair comparison among the models. Second, Loureiro et al. (2022) aim to continue training and releasing TIMELMS every quarter, which is a very important and promising initiative to help with the *dynamic* evaluation of LMs in temporal concept drift in the future.

3.3 Temporal Concept Drift Evaluation

Single-token probing Our first evaluation type is single-token probing, which was introduced in the seminal LAMA-probe work of Petroni et al. (2019). The idea is simple and follows the fill-in-the-blank format. Specifically, we convert each relation using its template to natural language text (see Figure 2(a)) replacing the `<object>` with the mask token (i.e., `<mask>` for ROBERTA). Then, as shown in Figure 1, we give the prompt as an input to the MLM and obtain a probability distribution over the vocabulary for the `<mask>` token. We use the metrics from Petroni et al. (2019), that are `Accuracy`, Mean Reciprocal Rank (`MRR`) and Precision at k (`P@k`).[7] Note that a crucial limitation of this approach is that it considers only facts with single-token objects. This results in trimming down the test sets by 95%, while limiting the actual value of the test (as most facts and concepts contain multiple words).

Multi-token generation We aim to address this limitation and include multi-token objects to our evaluation framework. It is important to note that we are benchmarking *masked* language models instead of autoregressive left-to-right language models like Dhingra et al. (2022). This is crucial because the latter, decoder-based family of models, can be used off-the-shelf to generate multiple tokens. In contrast, MLMs are trained with 15% of their inputs masked and optimized to predict *only the masked tokens*. We therefore use the formulation introduced by Wang and Cho (2019), that is essentially a decoding-based strategy for MLMs based on Gibbs sampling. Specifically, we consider

---

[6] `https://huggingface.co/cardiffnlp`

[7] `P@k`$=1$, if the gold label is in the top-k predictions of the model, therefore `P@1` corresponds to `Accuracy`.

the setting that we do not know a priori the correct number of masks for each label. Instead, we enumerate from a single mask up to M masks, i.e., $m = 1, ..., M$. Following Jiang et al. (2020a), we choose $M = 5$, as all our facts are in the English language. When $m > 1$, we add m consecutive masks to the input and we pass the input to the model m times, when each time we sequentially sample each mask from left to right. At each iteration we replace the mask with the corresponding token prediction of the previous iteration. This way, we can extend the LAMA probe to include multi-token labels in our test set. The setting is entirely different than the single-token approach, as here we have m predictions from the model with an increasing number of tokens, while the correct label can consist of any number of tokens in the range of $1, ..., M$. Another difference here is the evaluation metrics. Because we converted the task to text generation, we borrow generation metrics such as `ROUGE` (Lin, 2004), while also including standard metrics like `F`$_1$`-macro`. Finally, we also include as a metric `BERT-score` (Zhang* et al., 2020) as an additional informative metric from the perspective of contextual semantics. In effect, we evaluate factual knowledge over time of MLMs, where facts include *multiple correct answers* and each answer consists of *multiple tokens*. We consider a prediction correct if the model correctly predicts *any* of the acceptable answers.

MLM scoring Finally, as a third lens of evaluation we use the MLM scoring framework of Salazar et al. (2020). Contrary to the previous approaches, MLM scoring aims to *measure* the probability of the correct answer (i.e., of the masks), instead of *generating* the most probable answer. More specifically, we evaluate MLMs out of the box via their *pseudo-log-likelihood scores* (PLLs), which are computed by masking tokens one by one. PLLs have been widely used to measure the equivalence of perplexity (of autoregressive language models) for MLMs in unlabelled data (Lazaridou et al., 2021). Still, computing PLLs for large corpora is a very costly process in terms of time and resources (Loureiro et al., 2022). Instead, we propose to combine the LAMA and MLM scoring frameworks to create an efficient and targeted evaluation framework for temporal factual knowledge.

3.4 Dataset Analysis

We consider different subsets of the DYNAMICTEMPLAMA test sets for the three different evaluation settings (§3.3). For the multi-token and MLM scoring settings, we keep the full dataset, for single-token we first tokenize the labels and keep only the test examples that have at least one label with a single token. This results in a very aggressive filtering of the dataset. Specifically, each quarterly temporal split consists of 8500 test examples on average for the multi-token setting, but for the single-token this results in only 450 examples, marking a loss of 95% of the data.[8] Additionally, the distribution of the fine-grained splits is of great interest, as it will shape the interpretation of the results and the general challenges of the evaluation framework. $\mathcal{D}^{\text{UPDATED}}$ and $\mathcal{D}^{\text{UNCHANGED}}$ (i.e., the splits of the most interest) constitute around 96% and 0.3%, respectively, of the total examples for the single-token evaluation, and 95% and 1.8% for the multi-token. This is arguably a very skewed distribution, showing the importance of our work in diving the temporal splits into further fine-grained splits. This is essential, because we would have different expectations for a model trained on timestep t while tested on data from both t and $t-1$; for *unchanged* facts it would be desirable to keep equal performance in both sets (i.e., knowledge preservation §4.2), while for updated facts we would like to see improved performance in timestep t (i.e., adaptation §4.3).

4 Results

4.1 Temporal robustness

We first evaluate *temporal robustness* of the 11 TIMELMS, defined as the *overall* performance over time (§3.1). Figure 3 shows the average performance in *all* temporal and fine-grained splits in the time range from `2019-Q4` to `2022-Q2` for two types of evaluation, single-token probing and multi-token generation. For the former evaluation type, (Fig. 3a), all models perform similarly for all metrics. However, when we evaluate multi-token generation the models gradually improve over time. (Fig. 3b). This difference shows the importance of considering *multiple views* and evaluations for the same LM capability (i.e., temporal robustness).

We attribute the similar single-token performance to the fact that these temporal datasets con-

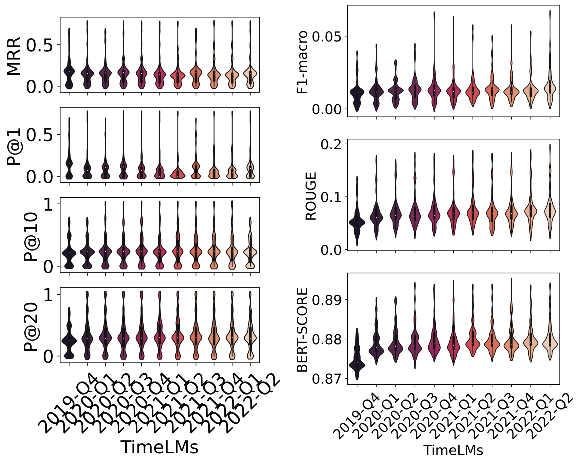
Table 2: MLM scoring (median pseudo-log-likelihood scores) averaged for each temporal split.



(a) Single-token

(b) Multi-token

Figure 3: *Overall* performance over time ($2019 - 2022$) for both single and multi-token evaluation. X-axis corresponds to the TIMELMS and the Y-axis to different metrics depending on the type of the evaluation.

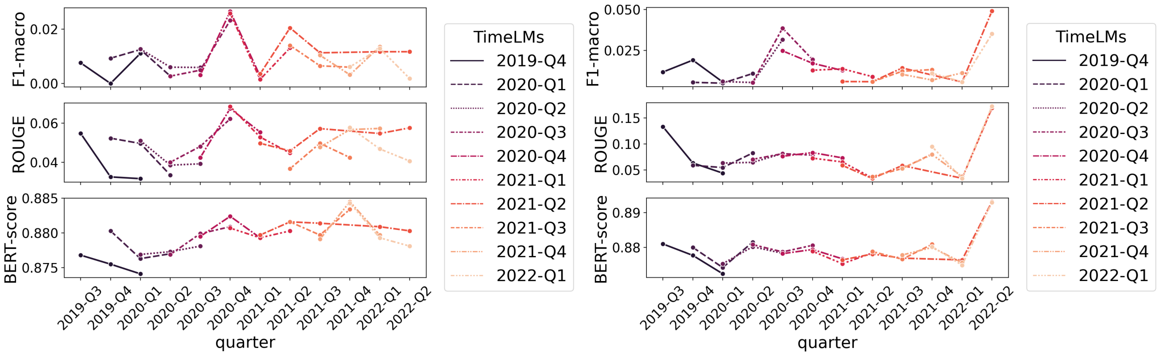
tain almost exclusively *unchanged* facts (§3.4). It is therefore a positive outcome to observe that TIMELMS can preserve acquired knowledge (§4.2). The findings for overall multi-token evaluation corroborate the intuition that more recent models, that are trained with temporal data of the entire range, should perform better than "past" (e.g. `2020`) models that have not seen "future" data (e.g. `2022`) during training. We also provide the overall results with MLM scoring in Table 2. We also observe that the last model performs best across all temporal splits, showing the effectiveness of adaptation with more recent unlabelled data (§3.2). Even though we observe that this pattern holds for most temporal splits (i.e., scores improving for each column ↓), the `2020-Q4` and `2021-Q1` TIMELMS produce worse PLL scores than their previous or later versions. This is more evident in the overall density plot in Figure 5. This finding entails that either the distribution shift in these quarters was a lot stronger than the other temporal periods, or the training of these particular models was not as successful as it would have been expected.

4.2 Knowledge preservation

We use the $\mathcal{D}^{\text{UNCHANGED}}$ split to evaluate the capability of MLMs to preserve knowledge over time. Figure 6 shows that for both single and multi-token evaluation all TIMELMS demonstrate similar performance over time, showing strong knowledge preserving skills. Surprisingly, different metrics show different patterns among the models for a single split. While in general we should not compare the performance of the single model over time (as the test sets are different), the comparision is valid in this case because the splits contain unchanged facts, and hence most temporal test sets are almost identical. All plots are shown in Figure 7 in the Appendix.

4.3 Adaptation to emerging & evolving concepts

Finally, we use the $\mathcal{D}^{\text{NEW}}$ and $\mathcal{D}^{\text{UPDATED}}$ splits for evaluation of emerging and evolving concepts, respectively. Here to ensure fair comparison, we evaluate the TIMELMS for a specific time window; for each model trained on timestep t, we keep the test sets from $t - 1$, t and $t + 1$. We observe in Figure 4 that in these cases the results vary among the models. There is not a very clear pattern as before, so case-by-case examination would be required. Still, a common pattern for the UPDATED split is that the middle set tends to have the highest performance ($\wedge$ shape). This means that models manage to effectively adapt to the updated facts of that timestep (t), but on the next timestep ($t + 1$)



(a) UPDATED split.

(b) NEW split.

Figure 4: Multi-token evaluation for evolving and emerging facts.

EXAMPLE INPUT	GROUND TRUTH LABELS	#TOKENS	#ANSWERS	SPLIT
1 `Alex Morgan plays for _X_.`	`United States women's national soccer team`	7	2	`2021-Q4`
	`Orlando Pride`	2		
2 `Cristiano Ronaldo plays for _X_.`	`Juventus F.C.`	5	1	`2021-Q2`
	`Juventus F.C., Manchester United F.C.`	5, 6	2	`2021-Q3`
	`Manchester United F.C.`	6	1	`2021-Q4`
2 `_X_ is the head of the government of Italy.`	`Giuseppe Conte`	5	1	`2020-Q4`
	`Giuseppe Conte, Mario Draghi`	5, 3	2	`2021-Q1`
	`Mario Draghi`	3	1	`2021-Q2`

Table 3: Qualitative analysis of certain examples in DYNAMICTEMPLAMA.

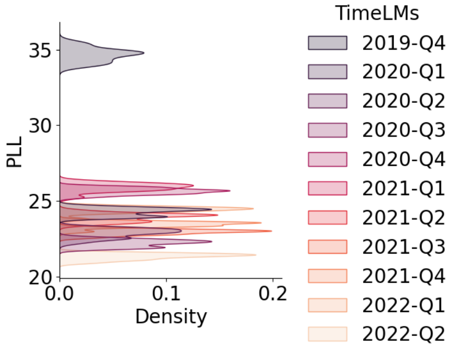


Figure 5: *Overall* PLL distributions for TIMELMS.

they underpeform as they are unaware of the factual changes, thus requiring adaptation. We provide all plots in the Appendix, including the DELETED split, which is more difficult to interpret intuitively (i.e., why are some facts deleted from Wikidata after a certain point?).

5 Qualitative Analysis

Table 3 provides some examples from the DYNAMICTEMPLAMA test set that can help us further interpret our results and inspect existing challenges. We first observe that all examples have multi-token labels (i.e., objects from the `Subject-relation-object` format) and are in effect discarded in the single-token evaluation setup, making the inclusion of multiple views essential for this task.

More specifically, in 1, we observe that one label (`United States women's national soccer team`) has more than $M = 5$ tokens. It is therefore excluded even from the multi-token the test set, leaving MLM scoring to be the only method that could evaluate it. Interestingly, we manually tested the `2021-Q4` temporal model and found that it produces 1.6 and 307.3 average PLL scores for the two options respectively, making the disregarded label a far more confident prediction.

In the second and third example, we observe how the correct answer for the query changes over time, making the granularity of the evaluation (i.e., yearly, quarterly, monthly) an important factor in the correct assessment of the model's temporal factual knowledge. For instance, for the example 3, we can carefully inspect how the predictions of the models change for facts that change over time (Table 4). However, even though PLL scores can follow intuitive temporal patterns (i.e., the PLL value can increase or decrease according to the point in time that the fact has changed), comparison between scores is not always helpful (i.e., word frequency can obscure factual knowledge) leaving

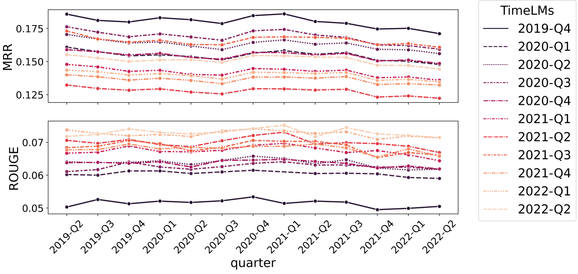

Figure 6: Single and multi-token evaluation for the UNCHANGED split.

TIMELMS	Guiseppe Conte	Mario Draghi
2020-Q4	3.8	33.3
2021-Q1	3.5	22.7
2021-Q2	3.5	25.7
2021-Q3	3.8	23.8

room for improving the LAMA formulation.

6 Conclusion & Future Work

We addressed MLMs' robustness on temporal concept drift and introduced DYNAMICTEMPLAMA: a dataset for dynamic benchmarking of factual knowledge in temporal, fine-grained splits, from `2019-Q4` to `2022-Q2` that contain facts over time. We release our codebase to *dynamically* update the current test set over time and the option to extend it with custom (i) templates, (ii) relations from Wikidata, (iii) any period of time (years) and (iv) granularity of time (month/quarter/year). We include *multiple views of evaluation*, showing that it is essential in order to properly interpret the results of our benchmarking study of 11 temporal ROBERTA models. We consider experimentation with improving MLM decoding and addressing "domain mismatch" as open areas of research for future work. Our code can be found at `https://github.com/amazon-science/temporal-robustness`.

Limitations

Lower bound estimate A very common issue with the LAMA probe evaluation framework (Petroni et al., 2019) is that it constitutes a lower bound estimate for its performance on factual knowledge retrieval. Specifically, if a model performs well, one can infer that it has the tested reasoning skill. However, failure does not entail that the reasoning skill is missing, as it is possible that there is a problem with the lexical-syntactic construction we picked (Talmor et al., 2020). Any given prompt only provides a lower bound estimate of the knowledge contained in an LM (Jiang et al., 2020b).

Domain mismatch Despite the advantages of zero-shot evaluation, performance of a model might be adversely affected by mismatches between the language the pre-trained LM was trained on and the language of the examples in our tasks (Jiang et al., 2020b). It is quite possible that a fact that the LM does know cannot be retrieved due to the prompts not being effective queries for the fact (Jiang et al., 2020b). Prior work proposes to fine-tune the model with a small set of examples taken from the test set (and removed of course) in order to address the incompatibility problem or 'language mismatch' (Talmor et al., 2020; Dhingra et al., 2022). We argue that this process suffers for multiple limitations, such as that it not practical for a fast evaluation of the capabilities of a PLM at hand and it faces optimization stability issues due to the small training dataset, inter alia. The major limitation, however, is that such fine-tuning enforces extra biases and errors, especially in the case of temporal robustness evaluation.

MLM decoding (multi-token labels) In this work we tried to address the problem of *decoding from masked language models*, by incorporating two distinct approaches to the evaluation framework; multi-token generation with MLMs (Wang and Cho, 2019) and MLM scoring (Salazar et al., 2020). Still, we observe that both methods provide results that are hard to interpret (§5), leaving the problems of (i) decoding or generating multiple tokens from MLMs and (ii) evaluation of factual knowledge in LMs as open areas of research.

Manual Templates For LAMA-style probing (Petroni et al., 2019), prior work creates the templates *manually*. This is a limitation both in terms of scale (i.e., generalization to many different kinds of inputs) and consistency (i.e., how do models perform with minimal changes to their inputs?). LMs do not reason in an abstract manner and are context-dependent (Talmor et al., 2020). It is therefore essential to address this problem and include functionalities to incorporate a set of diverse templates for each evaluation setup.

English Twitter MLMs Finally, our dataset, DYNAMICTEMPLAMA, following prior work (Dhingra et al., 2022), collects and evaluates facts from the Wikidata in the *English* language alone, and benchmarks RoBERTa language models trained in English Twitter data. We understand that this is a limitation and further data collection and experimentation in more languages would be strongly encouraged.

Table 5: Total number of examples for each temporal and fine-grained split in DYNAMICTEMPLAMA. We show both the *single-token* and the *multi-token* datasets (up to $M = 5$ tokens). Cell scheme to be read *single* | *multi*. %UNCHANGED and %UPDATED show the percentage of the total examples that are part of the UNCHANGED and UPDATED set respectively. %LOST shows the percentage of examples we lose when we filter out the dataset for the *single-token* evaluation setting.

A Appendix

A.1 Data Collection for DYNAMICTEMPLAMA

Following Dhingra et al. (2022), we identify all facts in the Wikidata snapshot, which have either a start or an end date after 2010 and whose subjects and objects are both entities with Wikipedia pages.1 Among these 482K facts, we identify subject and relation pairs which have multiple objects at different times and select 16 relations with the most such subjects. Then, for these relations we manually write template cloze queries (i.e., templates) and populate them with the 1000 most frequent subjects per relation. For each subject and each relation we gather all the objects with their associated time interval and construct a separate query for each year in that interval. When intervals for the object entities overlap, we add all of them to the list of correct answers. The query and the corresponding year form the input texts and the temporal information t, while the object entity is the target that we want to predict (i.e., gold label). In contrast to Dhingra et al. (2022), we do extra temporal divisions. Specifically, we get each yearly split and divide it further in quarterly splits (§3.1, Figure 2b), following the same algorithm.

A.2 Full Results

We provide the full results with all metrics for the UNCHANGED split in Figure 7, and the UPDATED, NEW and DELETED splits for multi-token generation in Figure 9.

Abstract

Recent research has shown that language models exploit 'artifacts' in benchmarks to solve tasks, rather than truly learning them, leading to inflated model performance. In pursuit of creating *better benchmarks*, we propose VAIDA, a novel benchmark creation paradigm for NLP, that focuses on *guiding crowdworkers*, an under-explored facet of addressing benchmark idiosyncrasies. VAIDA facilitates sample correction by providing real-time visual feedback and recommendations to improve sample quality. Our approach is domain, model, task, and metric agnostic, and constitutes a paradigm shift for robust, validated, and dynamic benchmark creation via human-and-metric-in-the-loop workflows. We evaluate via expert review and a user study with NASA TLX. We find that VAIDA decreases effort, frustration, mental, and temporal demands of crowdworkers and analysts, simultaneously increasing the performance of both user groups with a 45.8% decrease in the level of artifacts in created samples. As a by-product of our user study, we observe that created samples are adversarial across models, leading to decreases of 31.3% (BERT), 22.5% (RoBERTa), 14.98% (GPT-3 fewshot) in performance.[1]

1 Introduction

Researchers invest significant effort to create benchmarks in machine learning, including ImageNet (Deng et al., 2009), SQUAD (Rajpurkar et al., 2016), and SNLI (Bowman et al., 2015), as well as to develop models that solve them. *Can we rely on these benchmarks?* A growing body of recent research (Schwartz et al., 2017; Poliak et al., 2018; Kaushik and Lipton, 2018) is revealing that models exploit spurious bias/artifacts– unintended correlations between input and output (Torralba and Efros, 2011) (e.g. the word 'not' is associated with the label 'contradiction' in Natural Language Inference (NLI) (Gururangan et al., 2018))– instead of the actual underlying features, to solve many popular benchmarks. Models, therefore, fail to generalize, and experience drastic performance drops when testing with out-of-distribution (OOD) data or adversarial examples (Bras et al., 2020; Mishra et al., 2020a; McCoy et al., 2019; Zhang et al., 2019; Larson et al., 2019b; Sakaguchi et al., 2019; Hendrycks and Gimpel, 2016). This begs the question: *Shouldn't ML researchers consequently focus on creating 'better' datasets rather than developing increasingly complex models on bias-laden benchmarks?*

Deletion of samples based on bias baseline reports– hypothesis-only baseline in NLI (Dua et al., 2019))– and mitigation approaches such as AFLite (Sakaguchi et al., 2019) (adversarial filtering which deletes targeted data subsets), (Clark et al., 2019; Kaushik et al., 2019), have the following limitations: (i) data deletion/augmentation and residual learning do not justify the original investment in data creation, and (ii) crowdworkers are not provided adequate feedback to learn what constitutes high-quality data– and so have additional overhead due to the manual effort involved in sample creation/validation. Furthermore, (Parmar et al., 2022a) show that biased samples are created even when crowdworkers are provided with an initial set of annotation instructions. One potential solution to these problems is continuous, *in situ* feedback about artifacts while benchmark data is being created. *To our knowledge, there are no approaches that provide real-time artifact identification, feedback, and reconciliation opportunities to data creators, nor guide them on data quality.*

Contributions: (i) We propose *VAIDA* (Visual Analytics for Interactively Discouraging Artifacts), a novel system for benchmark creation that provides continuous visual feedback to data creators in real-time. VAIDA supports artifact identification

---

Component Name	**DQI Implication**	**VAIDA Usage**	**Artifacts Evaluated**
1. Vocabulary	Ambiguity and diversity of a dataset's language	Does the sample contribute new words?	Sample Length (Wallace et al., 2019), New Words Introduced (Yaghoub-Zadeh-Fard et al., 2020; Larson et al., 2020), Jaccard Index between n-grams (Larson et al., 2019a)
2. Inter-Sample N-gram Frequency and Relation	Word/phrase repetition and similarity between samples	Does the sample contribute new combinations of words and phrases?	N-gram overlap (Wallace et al., 2019; Yaghoub-Zadeh-Fard et al., 2020), Mean-IDF (Stasaski et al., 2020)
3. Inter-Sample STS	Syntactic, semantic, and pragmatic sentence parsing	How similar is the hypothesis to all other premises or hypotheses?	Multi-hop reasoning (Wallace et al., 2019), Similarity and overlap (Yaghoub-Zadeh-Fard et al., 2020), Diversity (Larson et al., 2019a)
4. Intra-Sample Word Similarity	Word overlap and similarity within sample statements	How similar are all words within a sample?	Coreference Resolution, Multi-hop reasoning (Wallace et al., 2019), Word Overlap (Larson et al., 2020)
5. Intra-Sample STS	Phrase/sentence level overlap within a sample	How similar is the hypothesis to the premise?	N-gram repetition and overlap (Yaghoub-Zadeh-Fard et al., 2020)
6. N-gram Frequency per Label	Distribution of samples according to annotation	Is the hypothesis too obvious for the system?	Logic and Calculations (Wallace et al., 2019), Diversity (Larson et al., 2019a), Outliers, Entropy (Stasaski et al., 2020)
7. Inter-Split STS	Optimal similarity between train and test samples	Is the sample too similar to an existing sample?	Entity Distractors, Novel Clues (Wallace et al., 2019), Coverage (Larson et al., 2019a)

Table 1: Language properties considered in DQI that indicate artifact presence, their interpretation in VAIDA, and corresponding methods used in crowdsourcing pipeline evaluation; STS: semantic textual similarity.

and resolution, implicitly educating *crowdworkers* and *analysts* on data quality. (ii) We evaluate VAIDA empirically through expert review and a user study to understand the cognitive workload it imposes. The results indicate that VAIDA decreases mental demand, temporal demand, effort, and frustration of crowdworkers (31.1%) and analysts (14.3%); it increases their performance by 34.6% and 30.8% respectively, and educates crowdworkers on how to create *high-quality* samples. Overall, we see a 45.8% decrease in the presence of artifacts in created samples. (iii) Even though our main goal is to reduce artifacts in samples, we observe that samples created in our user study are adversarial across language models with performance decreases of 31.3% (BERT), 22.5% (RoBERTa), and 14.98% (GPT-3 fewshot).

2 Related Work

This work sits at the intersection of two primary areas: (1) *visual analysis of data quality* (higher presence of artifacts indicates lower quality), and (2) *development of a novel data collection pipeline*.[2]

2.1 Sample Quality and Artifacts

Data Shapley (Ghorbani and Zou, 2019) has been proposed as a metric to quantify the value of each training datum to the predictor performance. However, the metric might not signify bias content, as the value of training datum is quantified based on predictor performance, and biases might favor the predictor. Moreover, this approach is model and task-dependent. VAIDA uses DQI (Data Quality Index), proposed by (Mishra et al., 2020b), to: (i) compute the overall data quality for a benchmark with n data samples, and (ii) compute the impact of a new $(n+1)^{th}$ data sample. Table 1 broadly defines DQI components, along with their interpretation in VAIDA, and juxtaposes them against evaluation methods used in prior works on crowdsourcing pipelines, as discussed in 2.2. (Wang et al., 2020) propose a tool for measuring and mitigating artifacts in image datasets.

2.2 Crowdsourcing Pipelines

Several pipelines have been proposed to handle various aspects of artifact presence in samples.

Adversarial Sample Creation: Pipelines such as Quizbowl (Wallace et al., 2019) and Dynabench (Kiela et al., 2021), highlight portions of text from input samples during crowdsourcing, based on how important they are for model prediction; this prompts users to alter their samples, and produce samples that can fool the model being used for evaluation (Talmor et al., 2022). While these provide more focused feedback compared to adversarial pipelines like ANLI (Nie et al., 2019), which do not provide explicit feedback on text features, adversarial sample creation is contingent on performance against a specific model (Quizbowl for instance is evaluated against IR and RNN models, and may therefore not see significant performance drops against more powerful models). Additionally, such sample creation might introduce new artifacts over time into the dataset and doesn't always correlate with high quality– for instance, a new entity introduced to fool a model in an adversarial sample might be the result of insufficient inductive bias, though reducing the level of spurious bias.

A similar diagnostic approach is followed for

---

[2] Detailed related work is in the Supplemental Material.

unknown unknown identification– i.e., instances for which a model makes a high-confidence prediction that is incorrect. (Attenberg et al., 2015) and (Vandenhof, 2019) propose techniques to identify UUs, in order to discover specific areas of failure in model generalization through crowdsourcing. The detection of these instances is however, model-dependent; VAIDA addresses the occurrence of such instances by comparing sample characteristics between different labels to identify (and resolve) potential artifacts and/or under-represented features in created data.

Promoting Sample Diversity: Approaches focusing on improving sample diversity have been proposed, in order to promote model generalization. (Yaghoub-Zadeh-Fard et al., 2020) use a probabilistic model to generate word recommendations for crowdworker paraphrasing. (Larson et al., 2019a) propose retaining only the top k% of paraphrase samples that are the greatest distance away from the mean sentence embedding representation of all collected data. These 'outlier' samples are then used to seed the next round of paraphrasing. (Larson et al., 2020) iteratively constrain crowdworker writing by using a taboo list of words, that prevents the repetition of over-represented words, which are also a source of spurious bias. Additionally, (Stasaski et al., 2020) assess the new sample's contribution to the diversity of the entire sub-corpus.

Controlled Dataset Creation: Previous work (Roit et al., 2019) in controlled dataset creation trains crowdworkers, and selects a subset of the best-performing crowdworkers for actual corpus creation. Each crowdworker's work is reviewed by another crowdworker, who acts as an analyst (as per our framework) of their samples. However, in real-world dataset creation, such training and selection phases might not be possible. Additionally, the absence of a metric-in-the-loop basis for feedback provided during training can potentially bias (through trainers) the created samples.

As shown in Table 1, DQI encompasses the aspects of artifacts studied by the aforementioned works; it further quantifies the presence of many more inter and intra-sample artifacts,[3] and provides a one-stop solution to address artifact impact on multiple fronts. VAIDA leverages DQI to identify artifacts, and further focuses on educating crowdworkers on exactly 'why' an artifact is undesirable, as well as the impact its presence will have on the overall corpus. It is also easily extensible to incorporate additional metrics such as quality control measures (Ustalov et al., 2021), enabling benchmarking evaluation in a reproducible manner. This is in contrast to the implicit feedback provided by word recommendation and/or highlighting in prior works, based on a static set of metrics– VAIDA facilitates the systematic elimination of artifacts without the unintentional creation of new artifacts, something that has hitherto remained unaddressed.

3 Modules

In this section, we describe VAIDA's important backend processes.

DQI: DQI can be expressed as a quality metric that examines different sources of artifacts in text, by scoring samples along 7 different components. We use DQI in order to demonstrate VAIDA's ability to cover multiple facets of artifact creation, although VAIDA is metric agnostic. VAIDA uses an intuitive traffic signal color coding (high>>moderate>>low) to indicate levels of artifacts (i.e., quality) in samples. Hyperparameters for color mapping with respect to DQI component values depend on (i) the application type, and (ii) characteristics of pre-existing samples present in the corpus at the time of new sample creation.[4] For instance, when recreating SNLI (Bowman et al., 2015) with VAIDA, we tune hyperparameters separating the boundary between red, yellow, and green flags on 0.01% of the SNLI training dataset manually in a supervised manner (Mishra et al., 2020b).

AutoFix: We propose AutoFix as a module to help crowdworkers avoid creating bad samples by recommending changes to a sample to improve its quality. The AutoFix algorithm is explained in Figure 1. Given a premise, hypothesis, and DQI values for the hypothesis, AutoFix sequentially masks each word in the hypothesis and ranks words based on their influence on model output, i.e., their importance. The hypothesis word of highest importance is replaced, to achieve at least moderate quality. DQI hence controls the amount and aspect of changes made by AutoFix. By incrementally changing the sample, users can understand how and why their sample is being modified and how DQI values are affected.

TextFooler: From an analyst's perspective,

---

[3] See Supplemental Material for details on artifacts that DQI identifies.

[4] See Supplemental Material: Evaluation, for details across all DQI components, hyperparameter tuning, and analyses.

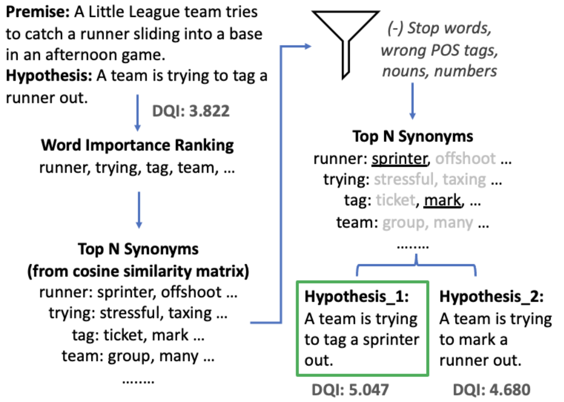

Figure 1: AutoFix Algorithm applied to an SNLI entailment sample, replacing one word per iteration. The DQI of the hypothesis changes from 3.822 to 5.047.

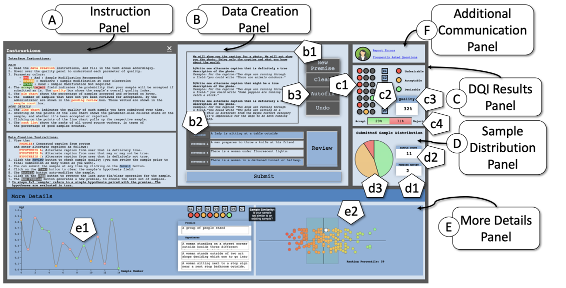

Figure 2: VAIDA's crowdworker interface consists of six linked panels: (A) Instructions, (B) Data creation, (C) DQI results, (D) Sample distribution, (E) More details, and (F) Additional communication.[5]

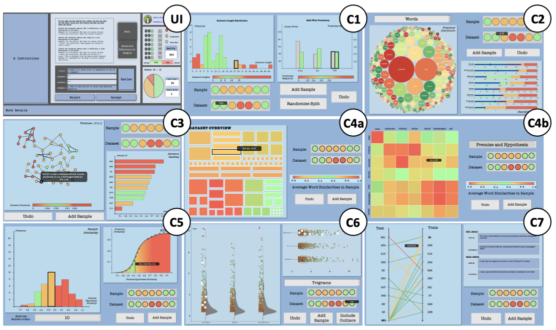

Figure 3: VAIDA provides a collection of interfaces for the analyst supporting detailed analysis and investigation of submitted samples and the overall benchmark.[5]

the quality of a submitted sample might be "too low" because (i) the crowdworker might not employ AutoFix appropriately, or (ii) there is a narrow acceptability range due to the criticality of the application domain, such as in BioNLP (Lee et al., 2020; Parmar et al., 2022b). We therefore implement TextFooler (Jin et al., 2019) to adversarially transform low-quality samples (instead of discarding them), to improve benchmark robustness, and ensure that crowdsourcing effort is not wasted. We initially use AFLite (Bras et al., 2020), to bin samples into *good* (retained samples) and *bad* (filtered samples) splits. Using TextFooler, we adversarially transform bad split data to flip the label; we revert back to the original label and identify sample artifacts using DQI (see Figure 5).

4 Interface Design and Workflow

VAIDA provides customized interfaces for both crowdworkers and analysts, as shown in Figures 2, 3 respectively.[5] We describe VAIDA's workflow via a case study for sample creation (crowdworker) and review (analyst) in Figures 4,5.

The crowdworker interface provides instructions **(A)** to navigate through the panels and how to interpret feedback for created samples. Communication links for FAQs, and error reporting are also provided (F). Crowdworkers can then review the instructions for data creation **(B)**– here, we use the same instructions provided in the original SNLI crowdsourcing interface **(b1)**.

1. Sample Creation: The premise field auto-populates with a caption from the Flickr30 corpus **(b2)**. The crowdworker must create three hypotheses (for the entailment, neutral, contradiction labels) at a time, though they are reviewed individually.

2. DQI Evaluation Feedback: On clicking the review button, DQI feedback is shown in **(C)**, for each component. Each colored circle **(c1)** indicates the level of artifacts present corresponding to each DQI component for the created sample; hovering displays a tooltip that explains and highlights **(c2)** the artifacts in the created sample, pertaining to the category of bias covered by that component. The overall sample quality **(c3)** is calculated, by averaging over the artifact percentiles of all 7 DQI components for the sample. By comparing sample quality with that of pre-existing samples, the probability that the sample will be accepted/rejected is shown **(c4)**. The user can choose to either revise or submit the sample.

3a. Sample Revision: *Manual Revision* or *AutoFix* can be done. We illustrate the improvement of sample quality in this step in Figure 4.

3b. Sample Submission: After review (and potentially iterative DQI evaluations/sample revi-

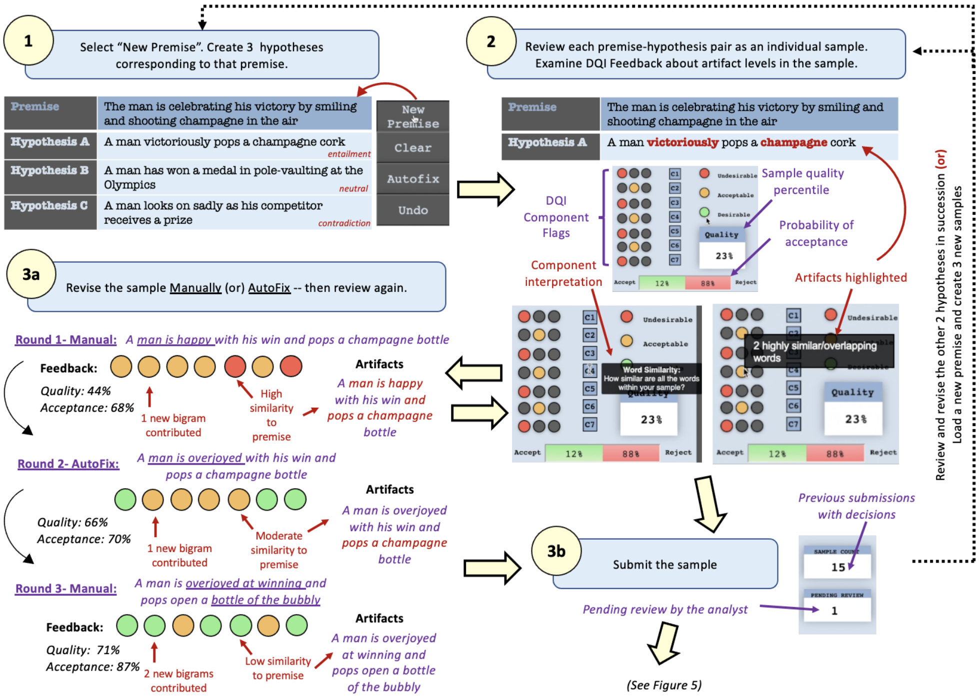
[5] See Supplemental Material: Interface Design for interface intuitions and detailed descriptions, with full-resolution images.



1 Select “New Premise”. Create 3 hypotheses corresponding to that premise.

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man victoriously pops a champagne cork *entailment*
Hypothesis B	A man has won a medal in pole-vaulting at the Olympics *neutral*
Hypothesis C	A man looks on sadly as his competitor receives a prize *contradiction*

2 Review each premise-hypothesis pair as an individual sample. Examine DQI Feedback about artifact levels in the sample.

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man **victoriously** pops a **champagne** cork

3a Revise the sample Manually (or) AutoFix -- then review again.

Round 1- Manual: A man is happy with his win and pops a champagne bottle

Feedback: Quality: 44% Acceptance: 68%

Artifacts: A man is happy with his win and pops a champagne bottle

Round 2- AutoFix: A man is overjoyed with his win and pops a champagne bottle

Quality: 66% Acceptance: 70%

Artifacts: A man is overjoyed with his win and pops a champagne bottle

Round 3- Manual: A man is overjoyed at winning and pops open a bottle of the bubbly

Feedback: Quality: 71% Acceptance: 87%

Artifacts: A man is overjoyed at winning and pops open a bottle of the bubbly

3b Submit the sample

Review and revise the other 2 hypotheses in succession (or) Load a new premise and create 3 new samples

Figure 4: VAIDA workflow for the creation of a single sample by a crowdworker.

sions), the sample can be submitted for benchmark inclusion. On submission, a sample enters a *pending* state **(d1)** until review by the analyst.

While crowdworkers work within a single tightly-coordinated interface to create, submit, and review samples, analysts can navigate between a set of nine screens (Figure 3) to review samples in detail to make ‘accept’, ‘reject’, and ‘modification’ decisions, and to assess overall benchmark quality. Analysts review samples in batches of size 50.[6]

4. Analyst Review: Review can consist of several different operations by the analyst.

(i) Direct Acceptance– The home page **(UI)** for the analyst provides a view similar to the crowdworker interface, and allows the analyst to review the work of a single crowdworker. If the data quality is deemed to be sufficiently high by just viewing the DQI color flags and quality percentile, the analyst can directly accept the sample into the corpus from this screen, as shown in Figure 5.

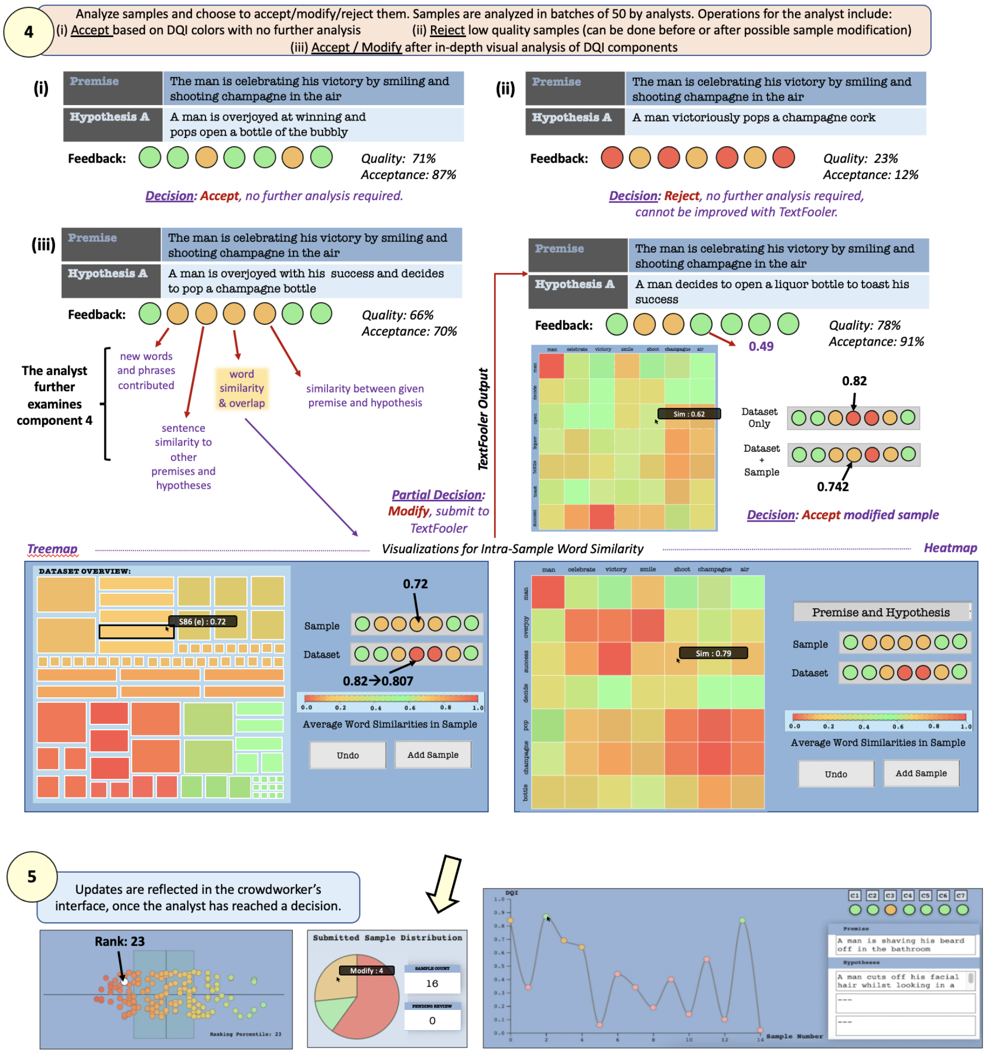
(ii) Visual Analysis and Modification– VAIDA provides several visualizations **(C1-C7)** to support detailed analysis and review of submitted samples, and to assess artifact presence (i.e., quality) in the overall benchmark. Each visualization allows the analyst to simulate how adding one or more submitted samples affects the benchmark’s quality.

For example, in Figure 5, we show the visualizations for analysis of DQI component 4 (C4), which deals with artifacts caused due to word similarity within a sample. For each sample in the corpus, the word similarities between all possible pairs of words are averaged; the samples are then hierarchically displayed as a treemap based on their DQI color mapping and average word similarity. We note that the color scale followed is bilinear, as while artifacts must be eliminated, there still needs to be a sufficient inductive bias for the sample to be solvable. The size of a rectangle indicates the distance of each sample from the average word similarity across all samples. The new sample is highlighted in the treemap with a black outline. In the example shown, we see that the dataset’s C4 value decreases slightly (0.807) when the new sample is added, though the flag color remains red.

Further examination of the new sample can be done, to establish why the sample has low effect on the dataset’s C4; the user clicks on the sample rectangle in the treemap, and is taken to a heat map view. The heatmap shows the similarity values between every word pair (from the premise/hypothesis/both) in a tooltip on hover, with the values mapped to the same color scale used for

---

[6] DQI components 1, 2, 3, 6, and 7, gauge artifact presence relative to pre-existing samples. We observe given at least 50 pre-existing samples, DQI component values change by less than 5% for the overall dataset if another 50 samples are accepted.



4

Analyze samples and choose to accept/modify/reject them. Samples are analyzed in batches of 50 by analysts. Operations for the analyst include:
(i) Accept based on DQI colors with no further analysis (ii) Reject low quality samples (can be done before or after possible sample modification)
(iii) Accept / Modify after in-depth visual analysis of DQI components

(i)

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man is overjoyed at winning and pops open a bottle of the bubbly

Feedback: Quality: 71% Acceptance: 87%

Decision: Accept, no further analysis required.

(ii)

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man victoriously pops a champagne cork

Feedback: Quality: 23% Acceptance: 12%

Decision: Reject, no further analysis required, cannot be improved with TextFooler.

(iii)

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man is overjoyed with his success and decides to pop a champagne bottle

Feedback: Quality: 66% Acceptance: 70%

The analyst further examines component 4

Partial Decision: Modify, submit to TextFooler

Premise	The man is celebrating his victory by smiling and shooting champagne in the air
Hypothesis A	A man decides to open a liquor bottle to toast his success

Feedback: Quality: 78% Acceptance: 91%

Decision: Accept modified sample

5

Updates are reflected in the crowdworker's interface, once the analyst has reached a decision.

Figure 5: VAIDA workflow for the evaluation of a single sample by an analyst, and subsequent analyst feedback provided to the crowdworker.

the treemap . For instance, in Figure 5, the words 'man' and 'champagne are repeated verbatim, and 'overjoyed', 'smiling', 'celebrating', 'pop', and 'shoot' also have similarity of [0.6–1]. This indicates that several words in the sample are too closely related and constitute artifacts.

Each such visualization is therefore individually tailored to represent a specific DQI component of interest, based on the linguistic features examined for artifact creation in that component. We further elaborate on the design intuitions and analysis conducted with all the component visualizations available to the analyst in the supplementary.

Post analysis, if the analyst feels that the submitted sample requires only a minor change (for instance, reshuffling or the addition of a single word) to warrant acceptance, then they can invoke the TextFooler module to transform the sample adversarially, and then accept, thereby ensuring minimal data loss. In the case shown, TextFooler improves the sample's C4 with most of the heatmap varying from 0.3-0.7. Due to this, the analyst decides to accept the updated sample.

5. Analyst Feedback: Once the analyst has reached a decision, the crowdworker sees updates (Figure 5) in (D) to the reviewed sample count (d2) – increases to 16– and the pie chart that indicates the distribution of actions taken by the analyst over all samples submitted by the crowdworker (d3). Additionally, in (E), the line chart (e1), which contains the history of previously submitted samples is updated. The x-axis denotes the sample number and the y-axis denotes the quality percentile (c3), of the corresponding sample. On click, the corresponding sample is loaded, along with its DQI component values and feedback to the crowdworker. The crowdworker can also use the box plot (e2), to view their current rank, and choose to view the sample history of another crowd worker.

5 Evaluation

We evaluate VAIDA's efficacy at providing real-time feedback to educate crowdworkers during benchmark creation using expert review and a user study. We also evaluate model performance (BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), GPT-3 (fewshot) (Brown et al., 2020)) on data created with VAIDA during the user study.

5.1 Expert Review

We present an initial prototype of our tool, to a set of three researchers with expertise in NLP and knowledge of data visualization. For each expert, the two interfaces were demoed in a Pair-Analytics session (Arias-Hernandez et al., 2011). Participants could ask questions and make interaction/navigation decisions to facilitate a natural user experience. All the experts appreciated the easily interpretable traffic-signal color scheme (and further suggested that alternates be provided to account for color blindness) and found the organization of the interfaces—providing separate detailed views within the analyst workflow– a way to prevent cognitive overload (too much information on one screen). A caveat of this would be the inability for an analyst to simultaneously juxtapose different component visualizations. It was also hypothesized that a learning curve of $\sim$50–60 samples would be required for cohesive use of all system modules by both types of users; however, this would be offset by the eventual capability of users to deal with samples of middling quality based on their multi-granular feedback about artifact presence.

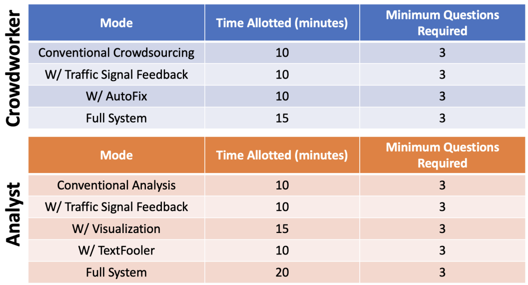
5.2 User Study

Setup: We approach several software developers, testing managers, and undergraduate/graduate students. Based on their domain familiarity (in NLP and visualization, rated from 1:novice-5:expert), we split them into 23 crowdworkers and 8 analysts for constructing NLI samples, given premises. There are 100 high-quality samples in the system at the time each participant participates in each ablation round (Table 2). For both types of users, a preliminary walkthrough of the system configuration, using 2 fixed samples, is conducted for each round of the study (Figure 6). At the end of each round, they are also asked for their comments.[7]

Configuration	Description	User
Conventional Crowdsourcing	No feedback or auto modification tools	C
Conventional Analysis	Manual review without feedback or modification tools	A
Traffic Signal Feedback	Color mapping based on DQI values	C, A
AutoFix	Incremental sample auto-modification functionality	C
TextFooler	Adversarial sample transformation functionality	A
Visualization	Data visualizations for in-depth exploration (also includes traffic signal feedback)	A
Full System	All modules and system functionalities	C,A

Table 2: System configurations used for randomly ordered ablation rounds presented to users functioning as crowdworkers (C) and analysts (A) in the study.

User experience (mental workload) is subjectively evaluated using NASA Task Load Index (Hart, 2006)[7] (NASA TLX); each dimension is scored in a 100-points range, with 5-point steps. Users are also asked to report overall ratings for each system configuration at the end of the study.



Crowdworker

Mode	Time Allotted (minutes)	Minimum Questions Required
Conventional Crowdsourcing	10	3
W/ Traffic Signal Feedback	10	3
W/ AutoFix	10	3
Full System	15	3

Analyst

Mode	Time Allotted (minutes)	Minimum Questions Required
Conventional Analysis	10	3
W/ Traffic Signal Feedback	10	3
W/ Visualization	15	3
W/ TextFooler	10	3
Full System	20	3

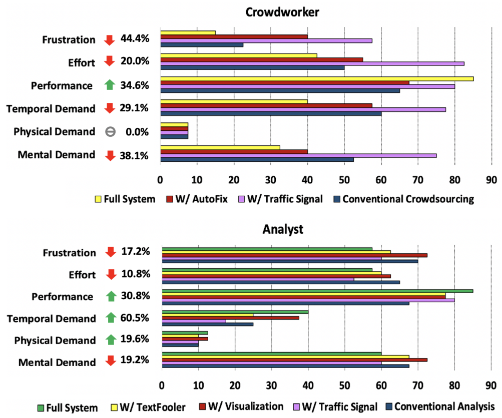
Figure 6: User Study Setup– describes the timeframe and requirements of the user study over ablation rounds.

Analysis: Figure 7 summarizes study results,[8] averaged over all user responses, for different system configurations. The general trend across both crowdworkers and analysts is that there is: (i) significant improvement across all NASA TLX dimensions, (ii) increase in number of samples created/reviewed, and (iii) user ratings for the system, when comparing VAIDA to conventional interfaces. In the case of partial module availability, we find that the effectiveness of traffic signal feedback and visualizations is comparable. The use of AutoFix and TextFooler7 is more prevalent initially, on creation/evaluation of a low or middling quality sample for users as: (i) crowdworkers find constructive

---

[7] See Supplemental Material: User Study for more details. We do aggregated analysis of comments, full quotes of comments are present in the Supplemental Material. We also have IRB approval to conduct this user study.

[8] All results are found to have $p \leq 0.02$



Crowdworker

Mode	Number of Questions Created	System Score (/100)
Conventional Crowdsourcing	3	50
W/ Traffic Signal Feedback	2.75	72.5
W/ AutoFix	3.5	62.5
Full System	5.25	85

Analyst

Mode	Number of Questions Analyzed	System Score (/100)
Conventional Analysis	3	40
W/ Traffic Signal Feedback	5	67.5
W/ Visualization	2.75	72.5
W/ TextFooler	3.75	65
Full System	5.5	82.5

Figure 7: User Study Results– NASA TLX dimension scores, and user scoring of the configurations, averaged across participant responses, for each ablation round. Percentages shown indicate comparison of full system scores with respect to the conventional system.

sample modification more difficult initially, and (ii) analysts are initially unsure of how to deal with middling quality samples.

Learning Curve: At the end of the study, all users are asked the following: *"What do you think high quality means?"* We find that users are able to distinguish certain patterns that promote higher quality, such as keeping sentence length appropriate and uniform across labels (not too long/short), using complex phrasing ('not bad')/gender information/modifiers across labels, decreasing premise-hypothesis word overlap; they also do not display undesirable behavior like tweaking previously submitted samples just to create more. We also find an overall decrease of -45.8% in the level of artifacts of created samples, across all rounds of ablation.

User Education: We also conduct a secondary study where a subset of participants (7 crowdworkers and 2 analysts) agreed to create/ analyze samples, for varying numbers of pre-accepted samples (Figure 8), in only the full system condition. We find that when participants are directly started in situations with $>$ 500 samples in the system, their unfamiliarity with the system initially causes a steepening of the learning curve compared to the cold start condition; this also tapers and saturates more slowly than cold start as the users gain experience. This is attributed to: (a) an increased likelihood of samples of low/middling quality (more artifacts) being created (evinced by performance), and (b) lower impact of an individual sample on overall dataset quality. We also find that users who create $\sim$50 samples report lesser reliance on AutoFix as they get better at creating higher quality samples; those who analyze $\sim$75 samples use TextFooler more efficiently as they understand how to deal with samples of middling quality better in the cold start condition. These numbers increase by $\sim$25% when users start with 500 pre-existing samples.

5.3 Model Performance Results

We evaluate BERT and RoBERTa (trained on the full SNLI dataset), and GPT-3 (in fewshot setting) against the data created during the ablation rounds of the user study.[9] There are 100 high-quality samples(DQI>0.7) from the original SNLI dataset present in the system for the study[10]. This remains constant across all ablation rounds and for all users. 69 samples are created per ablation round during our study, across all users, for a total of 345(69*5) samples that we evaluate with the models. Figure 9 shows the results for samples over each round of ablation. ([10]) In the case of TextFooler, samples are created using the 'full system' condition and then further modified using TextFooler by the analyst. The other sample sets are not modified by the analyst, and are directly accepted after evaluation.

We find that across all models, performance is lower when explicit quality feedback (via the traffic signal scheme) is provided, compared to the regular crowdsourcing condition. The highest drop is seen for BERT (-20.66%), while GPT-3 shows a lesser magnitude of performance decrease (-12.89%). Performance further decreases for all models when AutoFix is implemented, indicating the effectiveness of this module in seeding suggestions for sample improvement; the magnitude of performance loss follows BERT>>RoBERTa>>GPT-3. We can attribute this apparent variation in model robustness i.e., BERT<<RoBERTa<<GPT-3 as proportionate to increase in size of (i) the respective language models, and (ii) the pre-training corpora.

A significant decrease is seen in the full system and TextFooler conditions. Particularly, in the TextFooler round, performance sharply decreases

---

[9] We also create samples for the Story CLOZE dataset in the full system condition; see Supplementary Material

[10] The dataset is included in the Supplemental Material.

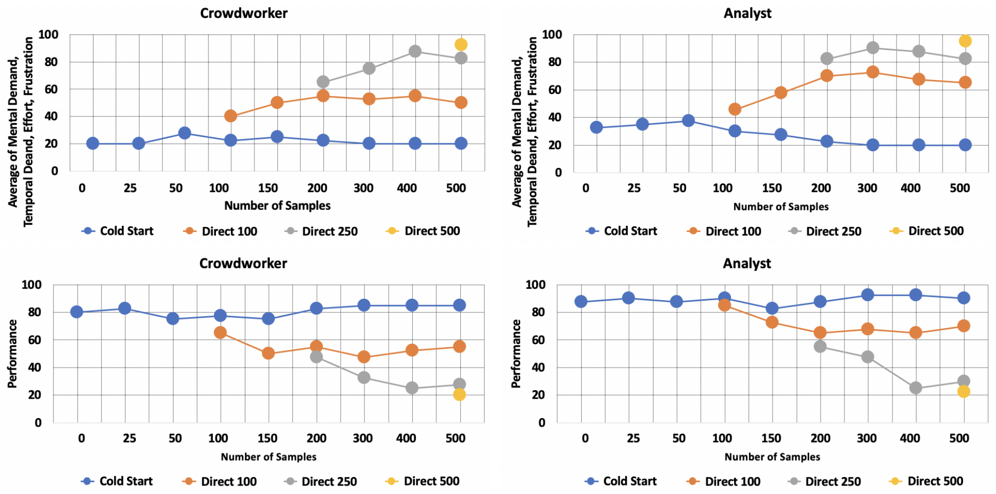


Figure 8: User education curves. Cold start has no pre-existing samples, and direct-n has n pre-existing samples. Mental Demand, Temporal Demand, Frustration, and Effort are averaged, Physical Demand is ignored. Performance is plotted separately as it shows differing behavior from the others.

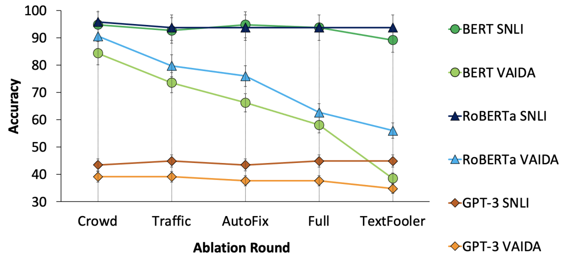

Figure 9: Model performance results for samples created during each ablation round of the user study.

for all models (-31.3% BERT, -22.5% RoBERTa, -14.98% GPT-3). Furthermore, in the TextFooler round, there is a -71.70% decrease in the level of sample artifacts. This indicates that crowdworkers and analysts are able to utilize VAIDA's affordances to create more robust text samples.

6 Discussion and Conclusion

We propose VAIDA, a paradigm to address benchmark artifacts, by integrating human-in-the-loop sensemaking with continuous visual feedback. VAIDA uses several visualization interfaces to analyze quality considerations (based on artifact levels) at multiple granularities. While we do not explicitly address computational quality control or fairness consideration (though some aspects can be targeted by currently integrated metrics), since VAIDA is extensible to the incorporation of customized backend-metrics, we believe our paradigm can support multi-faceted benchmark evaluation.

In our usability evaluation, we see that users report greater satisfaction, and lower difficulty with their work and system experience; this implies possible higher crowdworker retention and engagement. Additionally, in our study, we see that users effectively identify and avoid artifact patterns during sample creation. Based on our study results, we believe that a minimum of 30 annotators would be needed for large-scale data creation to ensure timely feedback (i.e., sample decision provided within 24 hours) to crowdworkers. Based on our secondary study, we believe analysts will exhibit increased performance and maintain satisfaction ratings in full-scale creation, as they will become well-versed in the nuances of bias for the data-creation task they are evaluating, as well as the visualizations being used. This, however, is contingent on restricting the visualization views to display only the 200–300 samples with closest artifact levels to the sample being evaluated.

Overall, samples created with VAIDA are found to not only of higher quality than achieved with conventional crowdsourcing, but are also seen to be adversarial across transformer models. This is also maintained across multiple task types– we additionally create StoryCLOZE (Schwartz et al., 2017) samples with VAIDA[9]. This was done independent of the study described in the paper, with 4 crowdworkers creating samples. However, for this, several interface features had to be changed, so we focus on reporting only NLI results in the main paper. VAIDA hence demonstrates a novel, dynamic approach for building benchmarks and mitigating artifacts, and serves as a starting point for the next generation of benchmarks in machine learning.

Limitations

In future work, we intend to integrate VAIDA with an actual crowdsourcing framework, and run a full-scale data creation study to create a high-quality benchmark. Expanding to such a setup will require additional back-end engineering, to ensure that (i) timely and accurate feedback continues to be provided in real-time to crowdworkers, (ii) analysts are available on hand to process samples in a timely manner. This is out of scope for the current paper (e.g., it would require a significant budget), but we see our current work as a stepping stone in this direction. Additionally, studying the problem and designing the visualizations and real-time feedback mechanisms are essential steps before moving to large-scale evaluation; the novel affordances and designs are a necessary first step, and we believe they will be impactful to the NLP community.

Crowdworker retention and engagement in this full-scale setting also need to be evaluated, in order to better contextualize the learning curve associated with system usage and handling artifact creation, given an increasingly higher number of pre-existing system samples. Comparing this setup directly with the effect of in-depth user training (Roit et al., 2019) on artifact creation and review, prior to crowdsourcing, would also further help analyze and quantify if/how user strategy and performance changes during VAIDA usage.

Design modifications when creating different types of datasets will mainly require the redesigning of sample input fields, corresponding to the application and the type of metric used for artifact evaluation. However, in full-scale dataset creation, the visualization views for the analyst corresponding to different artifact types will have to be restricted to the $\sim$300 samples closest artifact levels, to the given sample being created, in order to facilitate scalable processing for analysts. Additionally, since visualization familiarity is required for the analyst to effectively review samples, the analysts may choose to streamline analysis by only using a subset of the provided visualization types in their version of the system, corresponding to the application domain.

- DQI Evaluation: Artifact Case Study

A.1 Infrastructure Used

In Section 3, we describe VAIDA's flow by high level workflow and back-end processes(DQI, AutoFix, and TextFooler). Further, as discussed in Subsection 3.2 DQI can be used for quantifying artifact presence for the: i) overall benchmark, and ii) impact of new samples. Depending on the task at hand we run our experiments in different hardware settings. The DQI calculations run mostly using CPU, for new samples as well as overall samples. The AutoFix procedure, as explained in Subsection 3.2, gives the user assistance in improving quality on a per submission basis. Therefore that does not require high GPU intensive systems; we have provisions to shift execution to a GPU as well if necessary to speed up the process. For TextFooler the fine tuning of the model is run on "TeslaV100-SXM2-16GB"; CPU cores per node 20; CPU memory per node: 95,142 MB; CPU memory per core: 4,757 MB– this is not a necessity as code has been tested on lower configuration GPUs as well but we have run our experiments in this setting. The attack part of the TextFooler requires more memory and we run that code on "Tesla V100-SXM2-32GB" com-pute Capability: 7.0 core Clock: 1.53GHz, coreCount: 80, device Memory Size: 31.75GiB device Memory Bandwidth: 836.37GiB/s.

A.2 Run-time Estimations

The DQI calculations run on CPU (for real life setting purposes); for the approximate estimate of the time taken, we run experiments for fixed data size of 10K samples. If the DQI calculations are done to calculate the impact of individual new samples it take a couple of seconds. On the other hand, If we take the whole 10k size dataset it takes around 48 hours to complete the process on CPU. This whole process can be run in parallel to reduce the time taken to 16 hours.

The TextFooler part consists of two steps– the fine tuning part and attack part– for generating adversaries. For fine tuning models we use "TeslaV100-SXM2-16GB", and it takes 20-30 minutes to complete the process. For the attack part we use "Tesla V100-SXM2-32GB", which takes 2-3 hrs for completing 20k data samples. This estimate requires the cosine similarity matrix for word embeddings to be calculated before hand which takes around 1-2 hrs, but this step has to be done only if the word embeddings are modified. This is a rare task so we have kept this separated.

A.3 Hyper Parameters

To look at the estimations of DQI and its variations, we have kept basic hyper-parameters fixed in the experiments. We keep the learning rate to 1e-5, the number of epochs during the experiments are varied from 2-3, the per gpu train batch and eval batch sizes vary from 8-64 samples (the results shown are with respect to a batch size of 8), adam epsilon is set to 1e-8, weight decay is set to 0, maximum gradient normalisation is set to 1, and maximum sequence length is set to 128. For TextFooler the the semantic similarity is fixed to 0.5 uniformly for all the experiments shown in this paper.

Additionally, the variations and range in the DQI parameters are dataset specific, i.e., hyperparameters depend on the application task. (Mishra et al., 2020b) design DQI as a generic metric to evaluate diverse benchmarks. However, the definitions of what constitutes high and low quality will vary depending on the application. For example, BiomedicaNLP might have lower tolerance levels for spurious bias than General NLP. Another case is in water quality– cited as an inspiration for DQI by (Mishra et al., 2020b)– where the quality of water needed for irrigation is different than that of drinking or medicine. We can therefore say that the hyper-parameters in the form of boundaries separating high and low quality data (i.e., inductive and spurious bias) are dependent on applications.

A.4 Related Work

A.4.1 Sample Quality and Artifacts

Data Shapley (Ghorbani and Zou, 2019) has been proposed as a metric to quantify the value of each training datum to the predictor performance. However, the metric might not signify bias content, as the value of training datum is quantified based on predictor performance, and biases might favor the predictor. Moreover, this approach is model and task-dependent. VAIDA uses DQI (Data Quality Index), proposed by (Mishra et al., 2020b), to: (i) compute the overall data quality for a benchmark with n data samples, and (ii) compute the impact of a new $(n+1)^{th}$ data sample. (Wang et al., 2020) concurrently propose a tool for measuring and mitigating artifacts in image datasets.

Data Shapley (Ghorbani and Zou, 2019) has been proposed as a metric to quantify the value of each training datum to the predictor performance. However, this approach is model and task dependent. More importantly, the metric might not signify bias content, as the value of training datum is quantified based on predictor performance, and biases might favor the predictor. VAIDA uses DQI (data quality index), proposed by (Mishra et al., 2020b), to: (i) compute the overall data quality for a benchmark with n data samples, and (ii) compute the impact of a new $(n+1)^{th}$ data sample. The quality of individual features (aspects) of samples are evaluated based on decreasing presence of artifacts and increasing generalization capability. In a concurrent work (Wang et al., 2020), a tool for measuring and mitigating bias in image datasets has also been proposed. DQI estimates artifact presence by calculating seven component values corresponding to a set of language properties;, along with their interpretation in VAIDA.

A.4.2 Crowdsourcing Pipelines

Adversarial Sample Creation: Pipelines such as Quizbowl(Wallace et al., 2019) and Dynabench(Kiela et al., 2021), highlight portions of text from input samples during crowdsourcing, based on how important they are for model prediction; this prompts users to alter their samples, and produce samples that can fool the model being used for evaluation. While these provide more focused feedback compared to adversarial pipelines like ANLI (Nie et al., 2019), which do not provide explicit feedback on text features, adversarial sample creation is contingent on performance against a specific model (Quizbowl for instance is evaluated against IR and RNN models, and may therefore not see significant performance drops against more powerful models). Additionally, such sample creation might introduce new artifacts over time into the dataset and doesn't always correlate with high quality– for instance, a new entity introduced to fool a model in an adversarial sample might be the result of insufficient inductive bias, though reducing the level of spurious bias.

A similar diagnostic approach is followed for unknown unknown identification– i.e., instances for which a model makes a high confidence prediction that is incorrect. (Attenberg et al., 2015) and (Vandenhof, 2019) propose techniques to identify UUs, in order to discover specific areas of failure in model generalization through crowdsourcing. The detection of these instances is however, model-dependent; VAIDA addresses the occurrence of such instances by comparing sample characteristics between different labels to identify (and resolve) potential artifacts and/or under-represented features in created data.

Promoting Sample Diversity: Approaches focusing on improving sample diversity have been proposed, in order to promote model generalization. (Yaghoub-Zadeh-Fard et al., 2020) use a probablistic model to generate word recommendations for crowdworker paraphrasing. (Larson et al., 2019a) propose retaining only the top k% of paraphrase samples that are the greatest distance away from the mean sentence embedding representation of all collected data. These 'outlier' samples are then used to seed the next round of paraphrasing. (Larson et al., 2020) iteratively constrain crowdworker writing by using a taboo list of words, that prevents the repetition of over-represented words, which are also a source of spurious bias. Additionally, (Stasaski et al., 2020) assess the new sample's contribution to the diversity of the entire sub-corpus.

DQI encompasses the aspects of artifacts studied by the aforementioned works; it further quantifies the presence of many more inter and intra-sample artifacts, and provides a one stop solution to address artifact impact on multiple fronts. VAIDA leverages DQI to identify artifacts, and further focuses on educating crowdworkers on exactly 'why' an artifact is undesirable, as well as the impact its presence will have on the overall corpus. This is in contrast to the implicit feedback provided by word recommendation and/or highlighting in prior works– VAIDA facilitates the elimination of artifacts without the unintentional creation of new artifacts, something that has hitherto remained unaddressed.

A.4.3 Task Selection and Controlled Dataset Creation

In this work, we demonstrate VAIDA for a natural language inference task (though it is task-independent), and mimic the SNLI dataset creation and validation processes. Elicited annotation has been found to lead to social bias in SNLI using probablistic mutual information (PMI) (Rudinger et al., 2017). Visual feedback is provided based on DQI (which takes PMI into account) to explicitly correct this bias, and discourage the creation of such samples. Also, human annotation of machine-generated sentences/sentences pulled from existing texts instead of elicitation has been suggested to reduce such bias (Zhang et al., 2017). However, machine-generated text might look artificial, and work has shown that text generation has its own set of quality issues (Mathur et al., 2020). While we use AutoFix and TextFooler as modules to automatically transform samples, they are designed to be used in parallel with human sample creation. Their results can also be further modified by humans prior to submission. We see less reliance on these tools over the course of our user study, as discussed in Subsection 6.2. Additionally, previous work (Roit et al., 2019) in controlled dataset creation trains crowdworkers, and selects a subset of the best-performing crowdworkers for actual corpus creation. Each crowdworker's work is reviewed by another crowdworker, who acts as an analyst (as per our framework) of their samples. However, in real-world dataset creation, such training and selection phases might not be possible. Additionally, the absence of a metric-in-the-loop basis for feedback provided during training can potentially bias (through trainers) the created samples.

A.5 DQI Components

DQI shows the (i) the overall data quality and (ii) the impact of new data created on the overall quality. In this paper, higher quality implies lower artifact presence and higher generalization capability. DQI clubs artifacts into seven broad aspects of text, which cover the space of various possible interactions between samples in an NLP dataset. Please refer to (Mishra et al., 2020b) and (Mishra et al., 2022) for a full explanation of parameters.

A.6 Interface Design Intuitions

Careful Selection of Visualizations Prior to the design of test cases and a user interface, data visualizations highlighting the effects of sample addition are built. Considering the complexity of the formulas for the components of empirical DQI, we carefully select visualizations to help illustrate and analyze the effect to which individual text properties are affected.

A.6.1 Vocabulary

Which Characteristics of Data are Visualized? The contribution of samples to the size of the vocabulary is tracked using a dual axis bar chart. This displays the vocabulary size, along with the vocabulary magnitude, across the train, dev, and test splits for the dataset. By randomizing data splits, the distribution of vocabulary across dataset samples can clearly be identified. We use a dual axis chart as juxtaposition of the vocabulary magnitude against raw counts of words better reflects the evenness of the vocabulary distribution; it is not useful to have only a few samples contributing new words as other samples automatically become easy for the model to solve.

To further clarify the contribution of individual samples to vocabulary, the distribution of sentence lengths is plotted as a histogram. Each sample contributes two sentences, i.e., the premise and hypothesis statements. Figure 10 illustrates this. The histogram provides analysts with a frame of reference to identify gaps or outliers in the distribution, essential for determining which sentences are undesirable for the corpus due to extremely high (low inductive bias) or extremely low (high artifact–spurious bias) vocabulary contribution.

A.6.2 Inter-sample N-gram Frequency and Relation

Which Characteristics of Data are Visualized? There are different granularities of samples that are used to calculate the values of this component, namely: words, POS tags, sentences, bigrams, and trigrams. The granularities' respective frequency distributions and standard deviations are utilized for this calculation.

Bubble Chart for visualizing the frequency distribution: A bubble chart is used to visualize the frequency distribution of the respective granularity. This design choice is made in order to clearly view the contribution made by a new sample when added to the existing dataset in terms of different granularities. The bubbles are colored according to the bounds set for frequencies by the hyperparameters, and sized based on the frequency of the elements they represent. Additionally, some insight into variance can be obtained from this chart, by observing the variation in bubble size.

Bullet Chart for impact of new sample: The impact of sample addition on standard deviation can be viewed using the bullet chart. The bullet chart is useful to visually track performance against a target (in this case ideal standard deviation), displaying results in a single column; it looks like a thermometer and is therefore easy to follow. The red-yellow-green color bands for each granularity represent the standard deviation bounds of that granularity. The vertical black line represents the ideal value of the standard deviation of that granularity. The two horizontal bars represent the value of standard deviation before and after the new sample's addition. Figure 12 illustrates the visualization.

A.6.3 Inter-sample STS

Which Characteristics of Data are Visualized? The main units used in this DQI component are the similarity values between sentences across the dataset. This refers to either premise or hypothesis statements, relative to all other premise/hypothesis statements. In order to understand the similarity relations of sentences, a force layout and horizontal bar chart are used. This is illustrated in Figure 14.

Force Layout for Similar Sentence Pairs In the force layout, those sentence pairs with a similarity value that meets the minimum threshold are connected. Each node represents a sentence. The thickness of the connecting line depends on how close the similarity value is to the threshold. Similarity values are used to create this network, as the aim of this component is to drill down into whether a sample has sufficient inductive bias (i.e., is closely

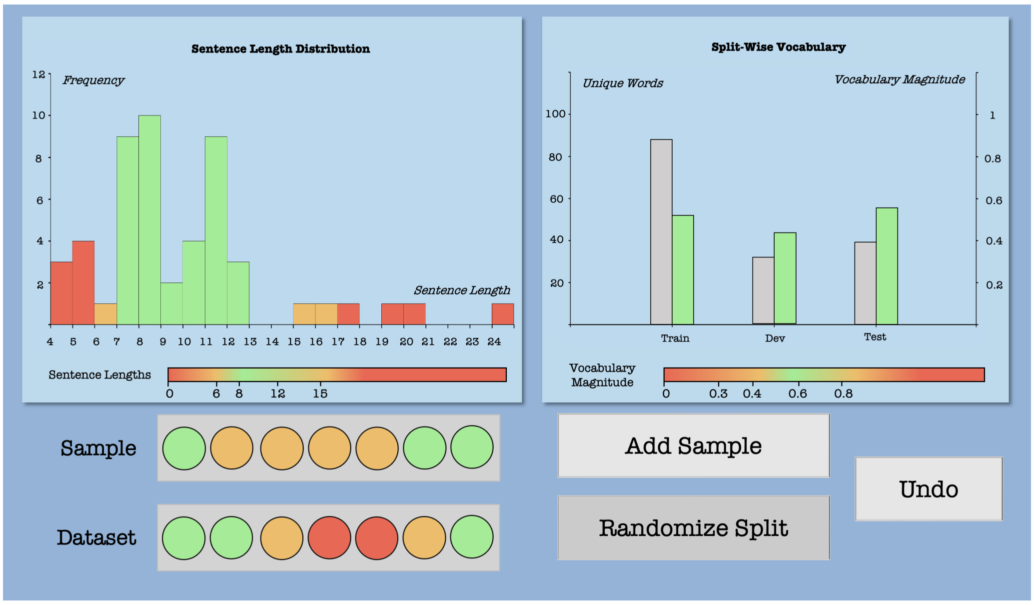

Figure 10: DQI_{c1} Visualization Prior to New Sample Addition

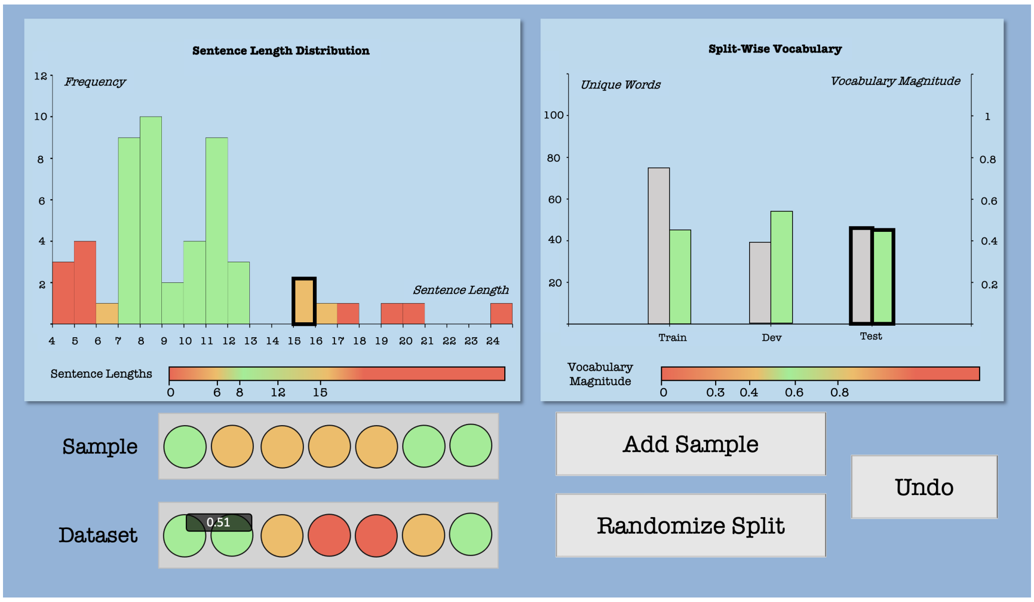

Figure 11: DQI_{c1} Visualization On New Sample Addition

linked to a sufficient extent to exiting samples), and also if a sample is too similar (spurious bias) to existing samples.

Horizontal Bar Chart for Most Similar Sentences In the horizontal bar chart, the sentences that are most similar to the given sentence are ordered in terms of their similarity value. The bar colors are centered around the threshold. This helps identify the most important subset to juxtapose the given sample against;the analyst can use this subset to for instance, decide if a moderate quality sample requires a small or big change in order to reacch acceptable quality..

A.6.4 Intra-sample Word Similarity

Which Characteristics of Data are Visualized? In this section, A sample's word similarity is viewed in terms of premise-only, hypothesis-only, and both. The relationship between non-adjacent words in the sample's sentences is analyzed specifically.

Overview Chart for Average Word Similarities and Heatmap for Single Sample The overview chart that is used is a tree map, which uses the average value of all word similarities per sample- i.e., concatenated premise and hypothesis- to color and group its components. This is illustrated in Figure

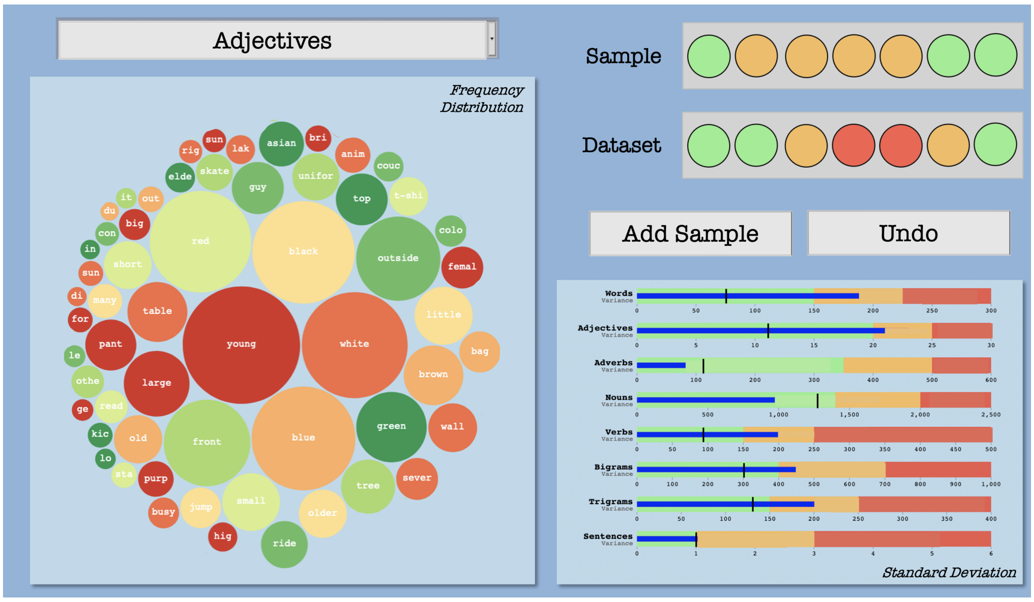

Figure 12: DQI_{c2} Visualization Prior to New Sample Addition

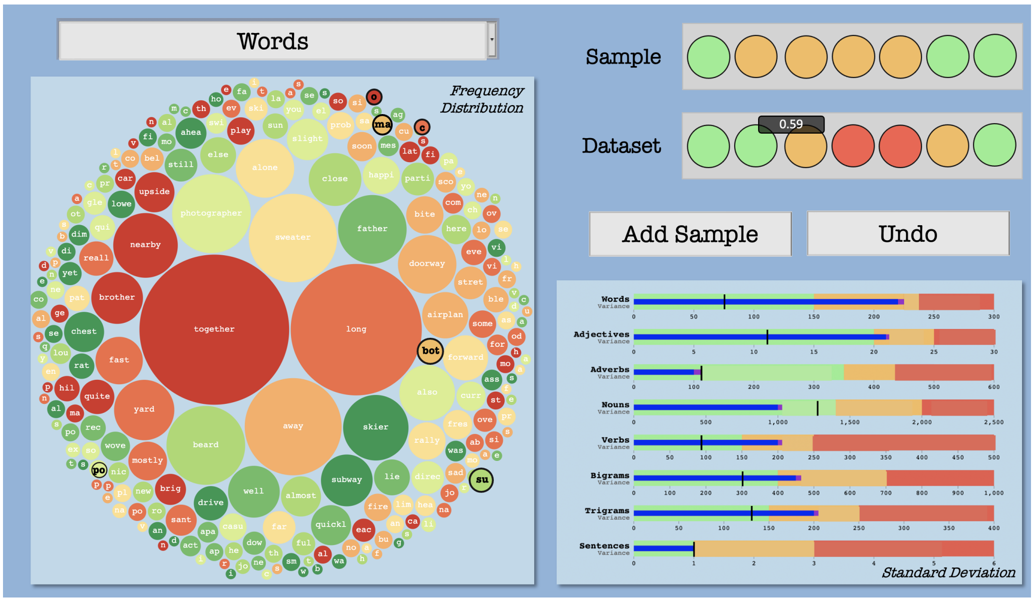

Figure 13: DQI_{c2} Visualization On New Sample Addition

16. Treemaps capture relative sizes of data categories, allowing for quick perception of the items that are large contributors to each category. This makes them ideal to analyze the inter-relationships between different word pairs across sample, in a concise manner.

The treemap also makes it easy to drill down into the specifics of a particular sample even further. This detailed view is provided in the form of a heatmap. All the words in a single sample, are plotted against each other, as shown in Figure 18. The heatmap provides a mechanism for word-level drill down of sample similarity. Like with the previous component, this helps provide the analyst with a frame of reference as to whether a moderate quality sample can be sent to TextFooler or not.

A.6.5 Intra-sample STS

Which Characteristics of Data are Visualized? Premise-Hypothesis similarity is analyzed on the basis of length variation, meeting a minimum threshold, and similarity distribution across the dataset. The first is addressed already in the vocabulary property by viewing the sentence length distribution. The other two are visualized using a histogram and kernel density estimation curve, as shown in Figure 19.

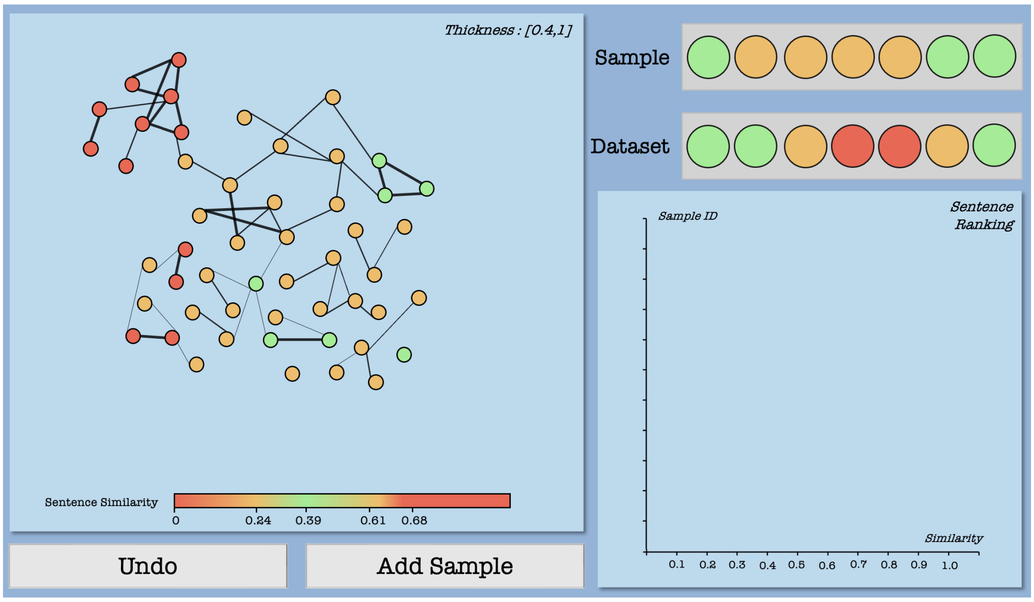

Figure 14: DQI_{c3} Visualization Prior to New Sample Addition

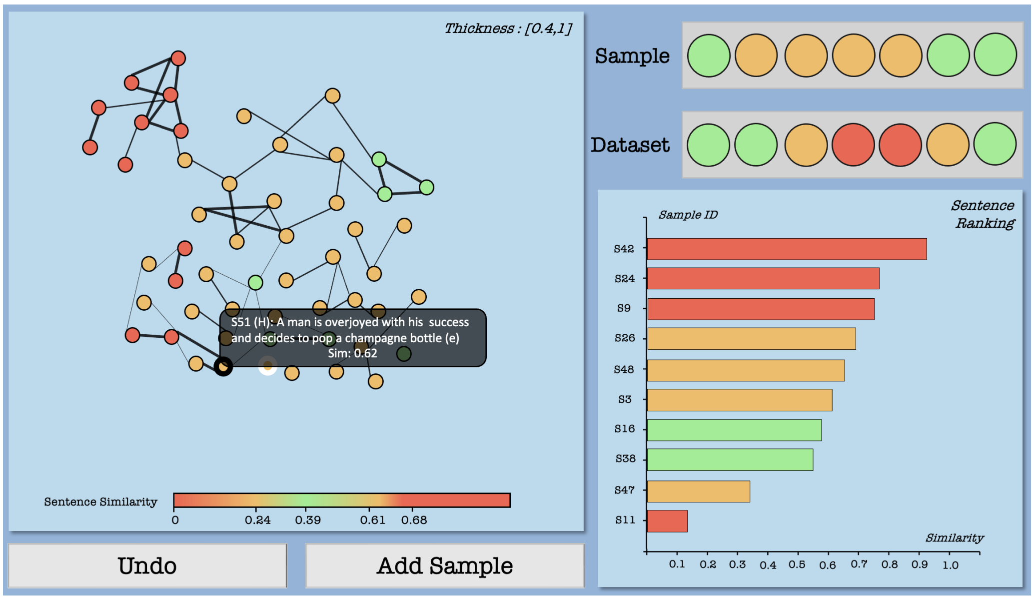

S51 (H): A man is overjoyed with his success and decides to pop a champagne bottle (e)
Sim: 0.62

Figure 15: DQI_{c3} Visualization On New Sample Addition

Histogram and Kernel Density Curve for Sample Distribution The histogram represents the distribution of the samples, and is colored by centering around the threshold as the ideal value. The number of bins can be changed, and therefore multilevel analysis can be conducted. This helps identify the proportion of samples that are of non-optimal range.

The kernel density curve is used to check for the overall skew of the distribution. KDE helps visualize the distribution sans user defied bins; this is colored to reflect the bi-linear color scale, and indicates the probability with which a sample will be correctly solved by a model given its similarity. This helps contextualize the level of artifacts relating to word overlap and sentence similarity in the sample.

A.6.6 N-Gram Frequency per Label

Which Characteristics of Data are Visualized? This component drills down on the second component, to view the patterns seen in granularities per label. There are two small multiples charts, divided based on label, used in this view- a violin plot and a box plot.

Violin plot and Kernel Density Curve for Skew of Distribution: The violin plots are structured to display both jittered points, according to their

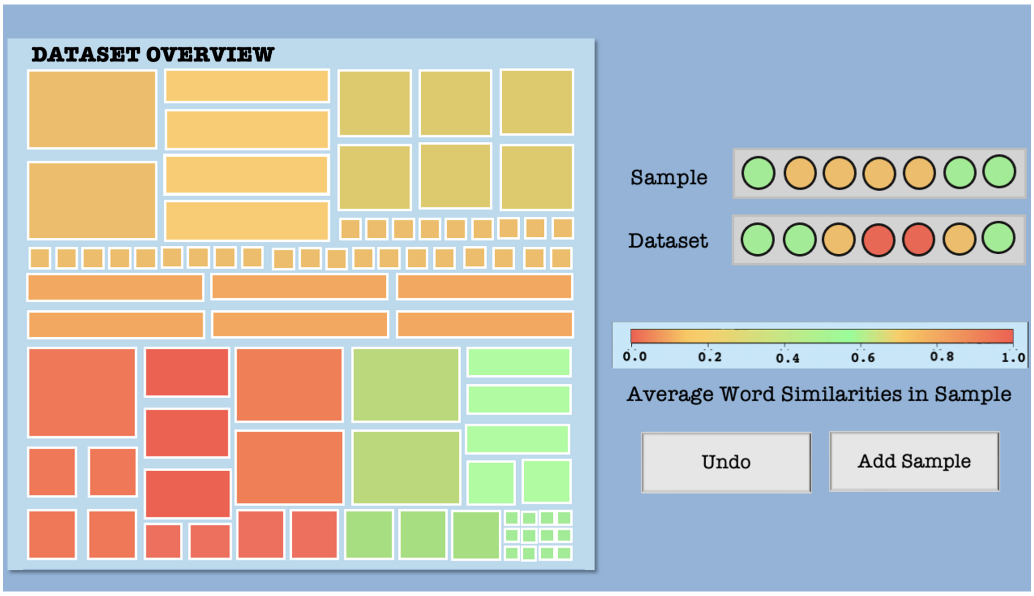

Figure 16: DQI_{c4} Visualization Prior to New Sample Addition

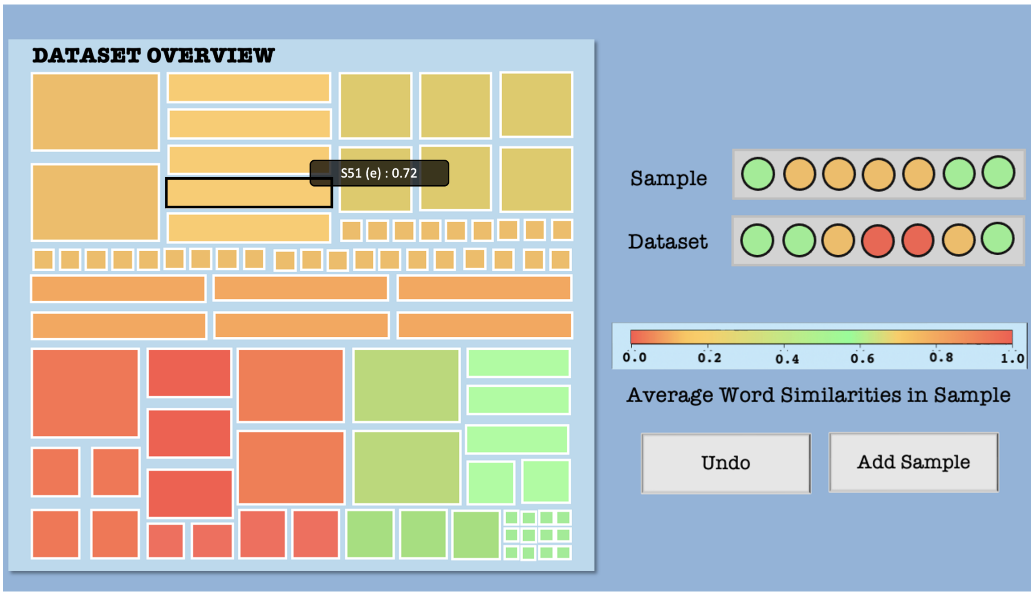

Figure 17: DQI_{c4} Visualization On New Sample Addition: Dataset View

frequency distribution, as well as a kernel density curve to judge the skew of the distribution. The points each represent an element of the granularity.

Box Plots for More Information The box plots are used to garner more information about the distribution, in terms of its min, max, median, mean, and inter quartile range. These help further characterize the distribution, as well as provide a quantitative definition of the skew seen using density curves. Jittered points representing elements are present in this plot as well.

A.6.7 Inter-split STS

Which Characteristics of Data are Visualized? Train-Test similarity must be kept minimal to prevent data leakage. This component's main feature is finding the train split sample that is most similar to a given test split sample.

Parallel Coordinate Graph for Train-Test Similarity: A subset of test and train samples, all found to have close similarity within their respective splits, and significant similarity across the splits are plotted as a one step parallel coordinate graph, with test samples along one axis, and train samples along the other. This subset is seeded

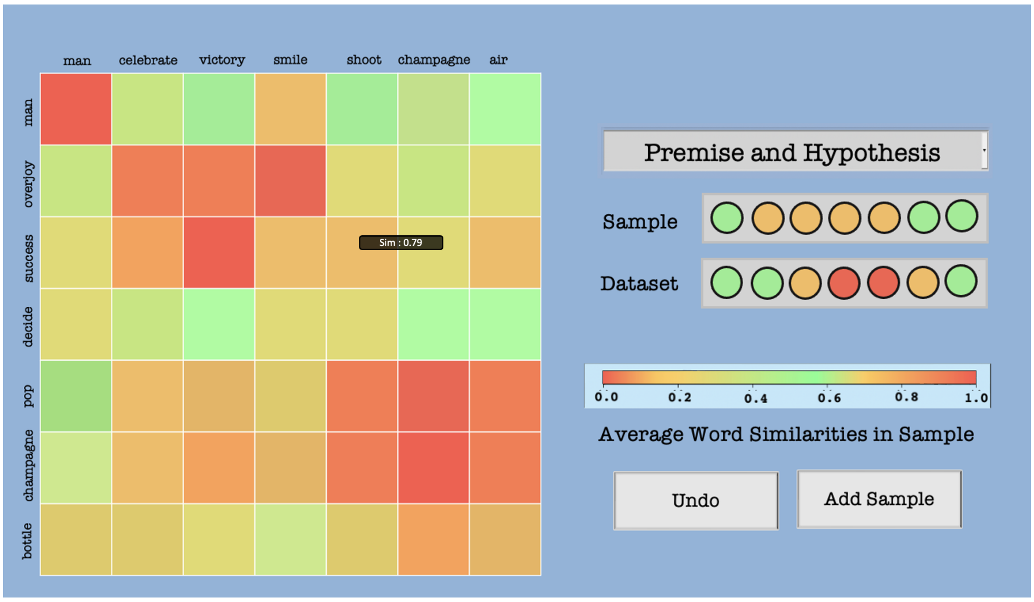

Figure 18: DQI_{c4} Visualization On New Sample Addition: Sample View

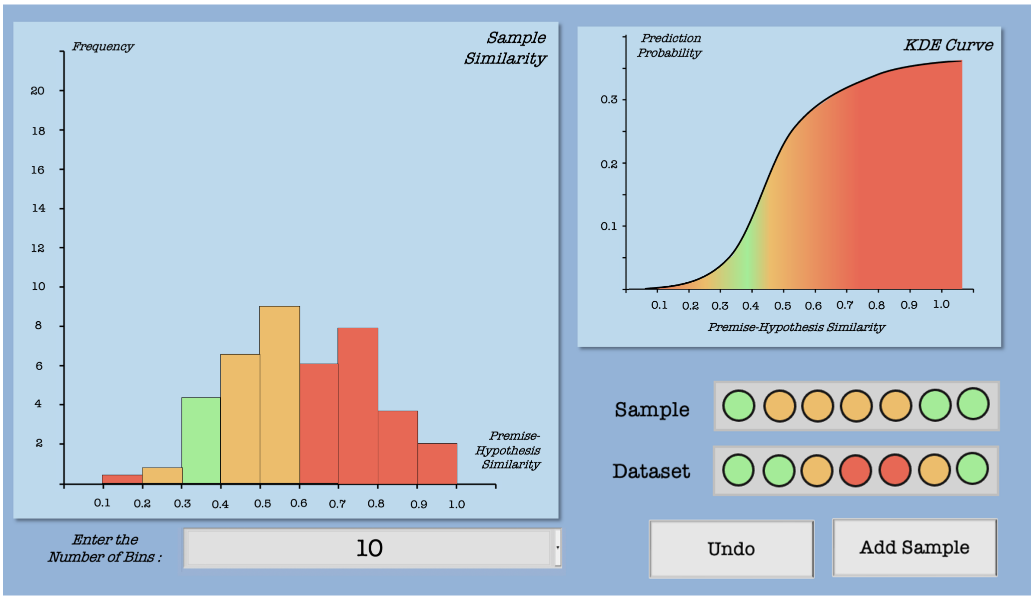

Enter the Number of Bins : 10

Figure 19: DQI_{c5} Visualization Prior to New Sample Addition

with those samples closest in similarity to the new sample to be introduced, based on the third component's visualization. The links connecting points on the two axes are drawn between the most similar matches across the split, as shown in Figure 24.

A.7 AutoFix and TextFooler Examples

See Tables 4, 5.

A.8 User Study

AutoFix Suggestions: See Tables 6, 5.

NASA TLX: The NASA Task Load Index (NASA-TLX) is a subjective, multidimensional assessment tool that rates perceived workload in order to assess a task, system, or team's effectiveness or other aspects of performance (Hart, 2006).

NASA-TLX divides the total workload into six subjective subscales that are represented on a single page. There is a description for each of these subscales that the subject should read before rating. They rate each subscale within a 100-point range, with 5-point steps, as shown in Figure 28. Providing descriptions for each measurement can be found to help participants answer accurately (Schuff et al., 2011). The descriptions are as follows:

- **Mental Demand:** How much mental and perceptual activity was required? Was the

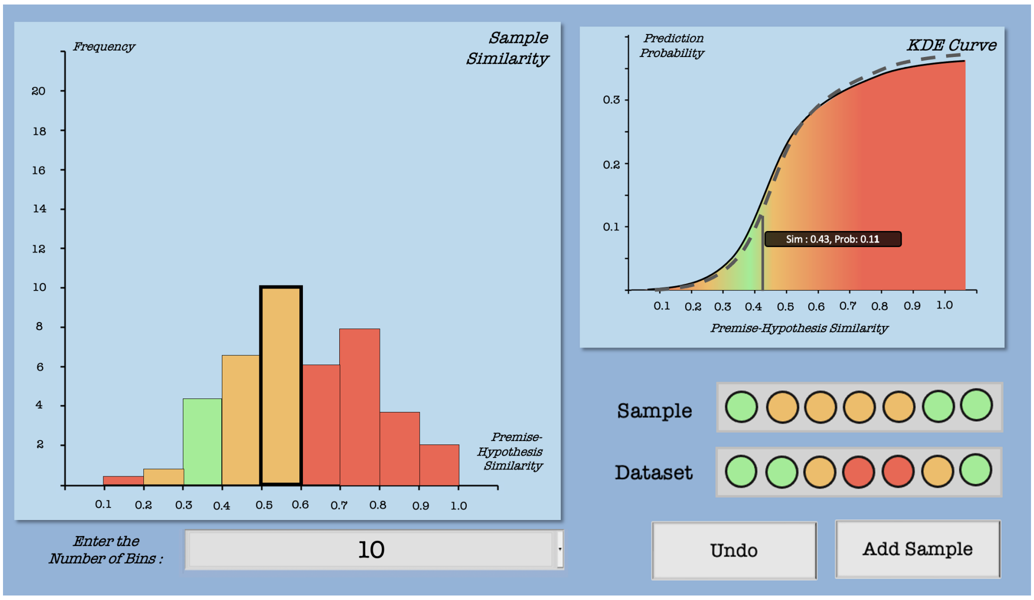

Figure 20: DQI_{c5} Visualization On New Sample Addition

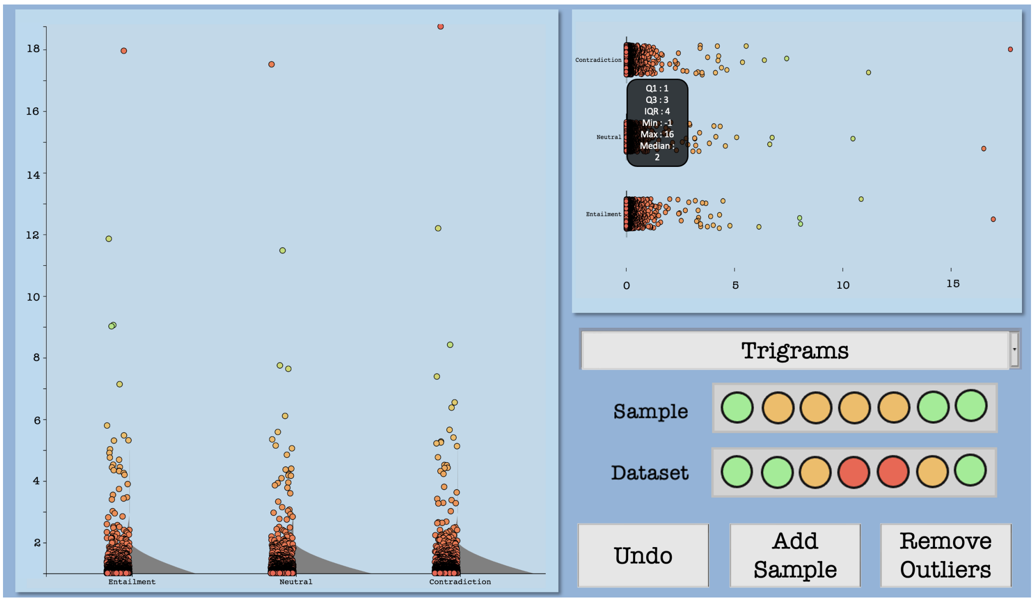

Figure 21: DQI_{c6} Visualization Prior to New Sample Addition

task easy or demanding, simple or complex?

- **Physical Demand:** How much physical activity was required? Was the task easy or demanding, slack or strenuous?
- **Temporal Demand:** How much time pressure did you feel due to the pace at which the tasks or task elements occurred? Was the pace slow or rapid?
- **Performance:** How successful were you in performing the task? How satisfied were you with your performance?
- **Effort:** How hard did you have to work (mentally and physically) to accomplish your level of performance?
- **Frustration:** How irritated, stressed, and annoyed versus content, relaxed, and complacent did you feel during the task?

We record participant demographics– age, gender, and occupation. We also ask participants to rate their familiarity with Visualization and NLP, on a scale of 1 (novice) to 5 (expert). Demographic information is shown in Figure 29. Participants are asked to fill this form at the end of each round of the user study. We also record the number of questions participants successfully create, as well as a

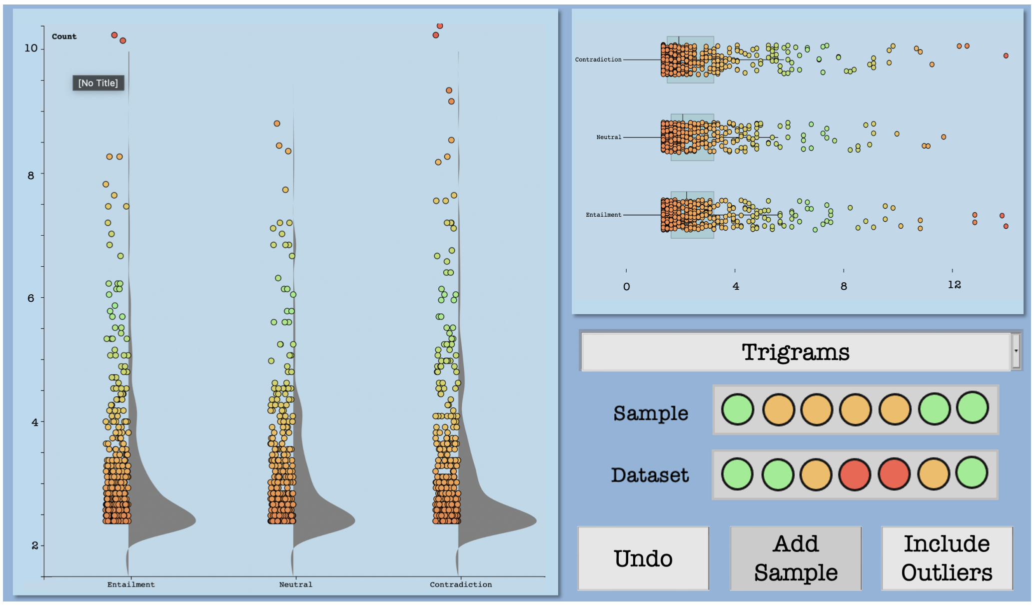

Figure 22: DQI_{c6} Visualization after removing outliers Prior to New Sample Addition

record of how often participants use each module in the full system round. At the end of the user study, participants are asked what their impression of data quality is, and their free response is recorded.

Subscale Wise Results: Individual results of the averaged subscales in Figure 8 are shown in Figures 30,31. Physical demand does not change significantly across user study rounds.

A.9 Expert and User Comments

Experts *(P)*: We present an initial prototype of our tool, to a set of three researchers with expertise in NLP and knowledge of data visualization, in order to judge the interface design. For each expert, the crowdworker interface and then analyst interfaces were demoed. Participants (P) could ask questions and make interaction/navigation decisions to facilitate a natural user experience. All the experts appreciated the easily interpretable traffic-signal color scheme and found the organization of the interfaces—providing separate detailed views within the analyst workflow– a way to prevent cognitive overload (too much information on one screen); P_2 said the latter *"… enhances readability for understanding the data at different granularities."*. P_1 suggested the inclusion of *"… a provenance module within the analyst views to show historical sample edits and overall data quality changes over time to understand how data quality evolves as the benchmark size increases… this would help with the bubble plot and tree map which will get more cluttered and complex as data size increases"*. Additionally P_3 remarked that *"The frequency of samples of middling quality should increase as benchmark size increases, but the initial exposure that analysts will have with higher or lower quality samples should lessen the learning curve as they are familiar enough with interface subtleties by the time they begin to encounter more challenging cases."*

Crowdworkers *(C)*: When presented with traffic signal feedback, crowdworkers report that the time and effort required to create high quality samples increases–*"You need to keep redoing the sample since when you see it's all red, you know it's probably not going to be accepted"*(C_3); however, they are more confident about their performance and sample quality *"...when there's green, I know I've done it right, and it cuts down on my having to create a lot of samples to get paid"* (C_{15}). We find that AutoFix usage [7] causes an unexpected increase in mental and temporal demand, as well as frustration; we attribute this to observed user behavior– *"I'm not sure how much I trust this recommendation without seeing the colors"*(C_{12}), and *"I'd prefer to change a couple of things since I can't see the feedback anymore*(C_{21}). The drastic improvement over all aspects (highest for frustration) in the case of using the full system is in line with this observation–*"This is so easy, I can create samples really fast, and I have a better chance of getting more accepted."*(C_8) and *"Now that I get the feedback along with the recommendation, I can see*

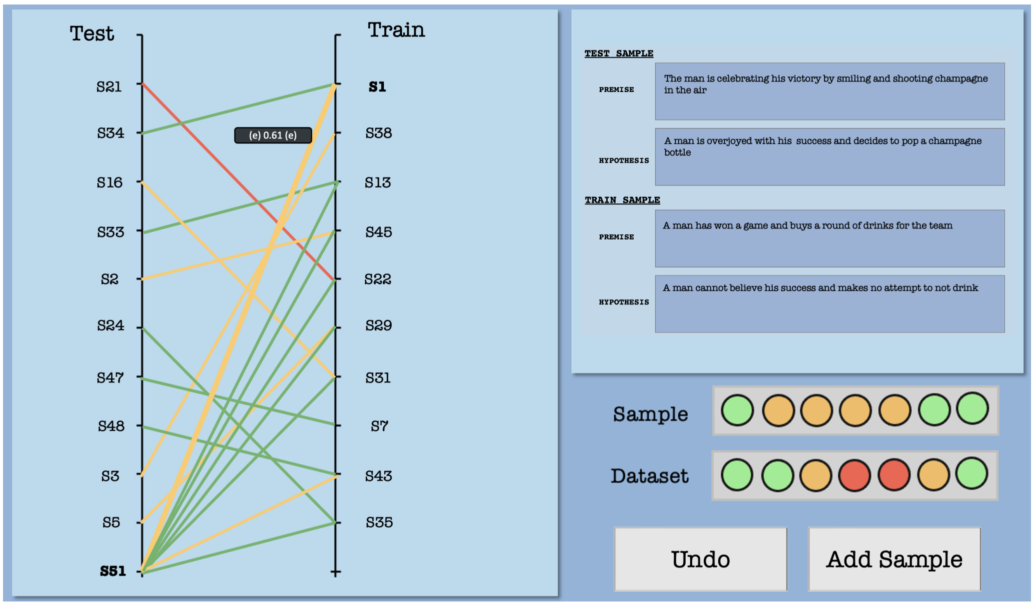
the quality improvement. So using the recommendation is now definitely faster."(C_{12}). The number of questions created per round as well as system scores also follows this trend, across all types of crowdworkers.

Summary: Traffic signal feedback initially increases time (+25%) and effort (+60%) required to create high quality samples, as users have to correct them. However they are more confident (performance– +27%) of sample quality. AutoFix usage causes an unexpected increase in effort (+5%) and frustration (+88.8%), as users do not fully trust recommendations without visual feedback. The drastic improvement over all aspects (frustration– -44.4%, mental demand– -38.1%, temporal demand– -29.1%, effort– -20%, average decrease in difficulty– -31.1%, performance– +34.6%) in the case of using the full system is in line with this observation. The number of questions created per round (traffic signal– -8.3%, AutoFix– +25%, full system– +83.3%) as well as system scores (traffic signal– +27.3%, AutoFix– +13.6%, full system– +54.5%) also follows this trend, across all types of crowdworkers.

Analysts *(A)*: In the case of direct quality feedback, i.e., traffic signals, analysts report an in-



TEST SAMPLE

HYPOTHESIS: A man is overjoyed with his success and decides to pop a champagne bottle

TRAIN SAMPLE

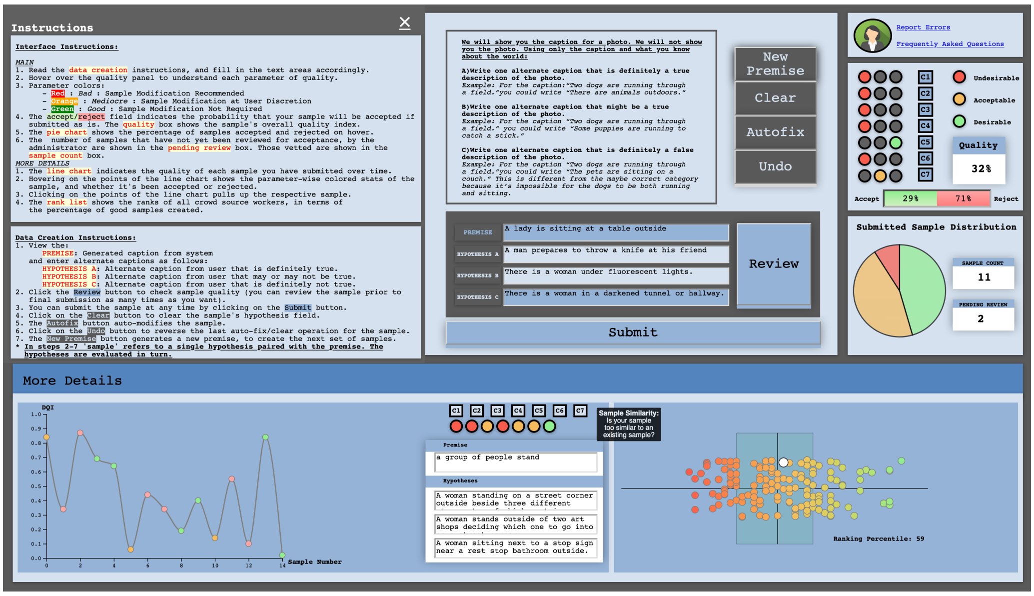
PREMISE: A man has won a game and buys a round of drinks for the team

HYPOTHESIS: A man cannot believe his success and makes no attempt to not drink

Figure 25: DQI_{c7} Visualization On New Sample Addition

creased performance and find the task easier–*"... it's easier to directly choose based on quality... and it takes care of typos too, the typo samples are marked down so the work goes pretty fast"*(A_3). When analysts are shown the visualization interfaces, they are explicitly taught to differentiate the traffic signal colors in the visualizations as being indicative of how the sample affects the overall dataset quality, i.e., the colors in different component views represent individual terms of the components calculated over the whole dataset (analysts can toggle between the states of original dataset and new sample addition). We find that users initially find this more difficult to do– *"It takes a little time to figure out how to go through the views. I learned that in the samples I looked at, components three and seven seemed to be linked. So I'd look at those first the next time I used the system"* (A_6) and *"... it takes me some time to figure out how to read the interfaces effectively, but it does make me more secure in judging sample quality at multiple granularities and that would help if I was doing this for a particular application"*(A_1). Analysts averaged behavior on TextFooler models the conventional approach quite closely, as analysts are seen to have a tendency to either– *"... deciding to reject or repair is difficult when you don't have the sample or dataset feedback... and what if the repaired sample still isn't good enough?"*(A_4), or– *" I like having this option to repair... I don't need to waste time on analyzing something that isn't outright an accept or reject, I can send it to be repaired and come back to it later"*(A_8). When shown the full system, analysts also report improvement in all aspects, particularly mental demand and performance–*"I can be sure of not having to redo things since it's likely that I will be able to get a low hypothesis baseline using this system"*(A_2, A_1). The visualization usage also improves– *"... I went to component three right off the bat this time, I knew that I could look at the linked components..."* (A_6). Altogether, sample evaluation by analysts increases, following this trend, and analysts are more assured of their performance.

Summary: Analysts find the task easier (effort– -19.3%, performance– +26.9%) with traffic signal feedback, as quality is clearly marked. When analysts are shown the visualization interfaces, they are explicitly taught to differentiate how the traffic signal colors in the visualizations indicate a sample's effect on the overall dataset quality. Analysts can toggle between the states of original dataset and new sample addition. We find that analysts initially find toggling more difficult to do (mental demand– +15.4%, temporal demand– +36.4%, frustration– 3.5%), though they agree that it improves their judgement of quality (performance– +15.9%). Analysts' average behavior on TextFooler models the conventional approach quite closely, as analysts are seen to have a tendency to send all samples that are unclear to TextFooler immediately. With the full system, analysts also report improvement in all aspects (average decrease in difficulty– -14.3%), particularly mental demand (-19.2%) and performance



Interface Instructions:

MAIN
1. Read the data creation instructions, and fill in the text areas accordingly.
2. Hover over the quality panel to understand each parameter of quality.
3. Parameter colors:
   - Red : *Bad* : Sample Modification Recommended
   - Orange : *Mediocre* : Sample Modification at User Discretion
   - Green : *Good* : Sample Modification Not Required
4. The accept/reject field indicates the probability that your sample will be accepted if submitted as is. The quality box shows the sample's overall quality index.
5. The pie chart shows the percentage of samples accepted and rejected on hover.
6. The number of samples that have not yet been reviewed for acceptance, by the administrator are shown in the pending review box. Those vetted are shown in the sample count box.

MORE DETAILS
1. The line chart indicates the quality of each sample you have submitted over time.
2. Hovering on the points of the line chart shows the parameter-wise colored stats of the sample, and whether it's been accepted or rejected.
3. Clicking on the points of the line chart pulls up the respective sample.
4. The rank list shows the ranks of all crowd source workers, in terms of the percentage of good samples created.

Data Creation Instructions:
1. View the:
   PREMISE: Generated caption from system
   and enter alternate captions as follows:
   HYPOTHESIS A: Alternate caption from user that is definitely true.
   HYPOTHESIS B: Alternate caption from user that may or may not be true.
   HYPOTHESIS C: Alternate caption from user that is definitely not true.
2. Click the Review button to check sample quality (you can review the sample prior to final submission as many times as you want).
3. You can submit the sample at any time by clicking on the Submit button.
4. Click on the Clear button to clear the sample's hypothesis field.
5. The Autofix button auto-modifies the sample.
6. Click on the Undo button to reverse the last auto-fix/clear operation for the sample.
7. The New Premise button generates a new premise, to create the next set of samples.

* **In steps 2-7 'sample' refers to a single hypothesis paired with the premise. The hypotheses are evaluated in turn.**

We will show you the caption for a photo. We will not show you the photo. Using only the caption and what you know about the world:

A)Write one alternate caption that is definitely a true description of the photo.
Example: For the caption:"Two dogs are running through a field."you could write "There are animals outdoors."

B)Write one alternate caption that might be a true description of the photo.
Example: For the caption "Two dogs are running through a field." you could write "Some puppies are running to catch a stick."

C)Write one alternate caption that is definitely a false description of the photo.
Example: For the caption "Two dogs are running through a field."you could write "The pets are sitting on a couch." This is different from the maybe correct category because it's impossible for the dogs to be both running and sitting.

PREMISE: A lady is sitting at a table outside
HYPOTHESIS A: A man prepares to throw a knife at his friend
HYPOTHESIS B: There is a woman under fluorescent lights.
HYPOTHESIS C: There is a woman in a darkened tunnel or hallway.

Abstract

A characteristic feature of human semantic cognition is its ability to not only store and retrieve the properties of concepts observed through experience, but to also facilitate the inheritance of properties (*can breathe*) from superordinate concepts (ANIMAL) to their subordinates (DOG)—i.e. demonstrate *property inheritance*. In this paper, we present COMPS, a collection of English minimal pair sentences that jointly tests pre-trained language models (PLMs) on their ability to attribute properties to concepts and their ability to demonstrate property inheritance behavior. Analyses of 22 different PLMs on COMPS reveal that they can easily distinguish between concepts on the basis of a property when they are trivially different, but find it relatively difficult when concepts are related on the basis of nuanced knowledge representations. Furthermore, we find that PLMs can show behaviors suggesting successful property inheritance in simple contexts, but fail in the presence of distracting information, which decreases the performance of many models sometimes even below chance. This lack of robustness in demonstrating simple reasoning raises important questions about PLMs' capacity to make correct inferences even when they appear to possess the prerequisite knowledge.

1 Introduction

The ability to learn, update and deploy one's knowledge about concepts (ROBIN, CHAIR) and their properties (*can fly*, *can be sat on*), observed during everyday experience is fundamental to human semantic cognition (Murphy, 2002; Rogers and McClelland, 2004; Rips et al., 2012). Knowledge of a concept's properties, combined with the ability to infer the `IsA` relation (Sloman, 1998; Murphy, 2003) leads to an important behavior known as *property inheritance* (Quillian, 1967; Smith and Estes, 1978; Murphy, 2002), where subordinates of a concept inherit its properties. For instance, one is likely to infer that an entity called *luna* can meow, has a tail, is a mammal, etc., even if *all* they know is that it is a cat. The close connection between a word's meaning and its conceptual representation makes these abilities crucial to language understanding (Murphy, 2002; Lake and Murphy, 2021), making it critical for computational models of language processing to also exhibit behavior consistent with these capacities. Indeed, modern pre-trained language models (PLMs; Devlin et al., 2019; Brown et al., 2020, etc.) have made impressive empirical strides in eliciting general knowledge about real world concepts and entities (Petroni et al., 2019; Weir et al., 2020, *i.a.*), as well as in demonstrating isomorphism with real world abstractions like direction and color (Abdou et al., 2021; Patel and Pavlick, 2022), often times without even having been explicitly trained to do so. At the same time, their ability to robustly demonstrate such capacities has recently been called to question, owing to failures due to reporting bias (Gordon and Van Durme, 2013; Shwartz and Choi, 2020), lack of consistency (Elazar et al., 2021; Ravichander et al., 2020), and sensitivity to lexical cues (Kassner and Schütze, 2020; Misra et al., 2020; Pandia and Ettinger, 2021).

In this work, we cast further light on PLMs' ability to robustly demonstrate knowledge about concepts and their properties. To this end, we introduce Conceptual Minimal Pair Sentences (COMPS), a collection of English minimal pair sentences, where each pair attributes a property (*can fly*) to two noun concepts: one which actually possesses the property (ROBIN), and one which does not (PENGUIN). Following standard practice in the minimal pairs evaluation paradigm (Warstadt et al., 2020, etc.), we test whether PLMs prefer sentence stimuli expressing correct property knowledge over those expressing incorrect ones. COMPS can be decomposed into three subsets, each containing stimuli that progressively isolate deeper understanding of the task of attributing properties to concepts,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2928–2949
May 2-6, 2023

by adding controls for more superficial heuristics. Our first subset—COMPS-BASE—measures the extent to which PLMs attribute properties to the right concepts, while varying the similarity of the positive (ROBIN) and the negative concepts (PENGUIN [high] vs. TABLE [low]). This controls for the possibility that models are relying on coarse-grained concept distinctions. For instance, in this setup a model should prefer (1a) over both versions of (1b).

(1) a. A **robin** can fly.
    b. *A (**penguin/table**) can fly.

Next, drawing on the phenomenon of property inheritance, the COMPS-WUGS set introduces a novel concept, WUG, expressed as the subordinate of the positive and negative concepts from a subset of the COMPS-BASE set, and tests the extent to which PLMs successfully attribute it the given property when it is associated with the positive concept. This increases the complexity of the reasoning task, as well as the distance between the associated concept (ROBIN) and property (*can fly*). These manipulations help to control for memorization of the literal phrases being tested, forcing models to judge properties for a novel concept that inherits the property from a known concept. In this task, given that a model successfully prefers (1a) over (1b), it should also prefer (2a) over (2b):

(2) a. A wug is a **robin**. Therefore, a wug can fly.
    b. *A wug is a **penguin**. Therefore, a wug can fly.

The final subset—COMPS-WUGS-DIST, combines the aforementioned controls by using negative concepts as distracting content and inserting them into the COMPS-WUGS stimuli. Specifically, we transform the stimuli of COMPS-WUGS by creating two subordinates for every minimal pair; one for the positive concept (ROBIN, subordinate: WUG) and the other for the negative concept (PENGUIN, subordinate: DAX), which acts as a distractor. This way, we control for the possibility that models may be relying on simple word associations between content words—of which there are only two in the prior tests—by introducing additional, irrelevant but contentful words into the context. Here, we consider models to be correct if they prefer (3a) over (3b), given that they prefer (1a) over (1b):

(3) a. A **wug** is a robin. A **dax** is a penguin. Therefore, a **wug** can fly.
    b. *A **wug** is a robin. A **dax** is a penguin. Therefore, a **dax** can fly.

Together, the three sets of stimuli tease apart more superficial predictive behaviors, such as contextual word associations, from more robust reasoning behaviors based on understanding of concept properties. While we can expect superficial predictive strategies to be brittle in the face of shallow perturbations and irrelevant distractions, robust property knowledge and reasoning behaviors should not.

We use COMPS to analyze robust property knowledge and its inheritance in 22 different PLMs, ranging from small masked language models to billion-parameter autoregressive language models. In our experiments with COMPS-BASE, we find PLMs to demonstrate strong performance in attributing properties to the correct concepts in our minimal pairs. However, we observe this strong performance largely when the concepts in the minimal pairs are trivially different (e.g., LION and TEA for the property *is a mammal*). When the concept pairs are similar (on the basis of different knowledge representations), we find models' performance to degrade substantially, by as much as 25 points. We observe a similar trend in our analyses on COMPS-WUGS—models first appear to show desirable behavior, potentially indicating proficiency in the more complex property inheritance reasoning. However, their overall performance declines drastically when investigated in the presence of distractors (i.e., on COMPS-WUGS-DIST). This failure is particularly pronounced in larger autoregressive PLMs, whose performance in fact drops below chance in cases where distracting information is proximal to the queried property, indicating the presence of a proximity effect. Together, our findings highlight brittleness of PLMs with conceptual knowledge and reasoning, as evidenced by failures in the face of simple controls. We make our code and data available at: `https://github.com/kanishkamisra/comps`.

2 Conceptual Minimal Pair Sentences (COMPS)

2.1 Connections to prior work

Prior work in exploring property knowledge in PLMs has adopted two different paradigms: one which uses probing classifiers to test if the applicability of a property can be decoded from the representations of LMs (Forbes et al., 2019; Da and Kasai, 2019; Derby et al., 2021); and the other which uses cloze-testing, in which LMs are tasked to fill in the blank in prompts that describe specific properties/factual knowledge about the world (Petroni et al., 2019; Weir et al., 2020). We argue that both approaches—though insightful—have key limitations for evaluating property knowledge, and that minimal pair testing overcomes these limitations to a beneficial extent.

Apart from ongoing debates surrounding the validity of probing classifiers (see Hewitt and Liang, 2019; Ravichander et al., 2021; Belinkov, 2022), the probing setup does not allow the testing of property knowledge in a precise manner. Specifically, several properties are often perfectly correlated in datasets such as the one we use here (see §2.2). For example, the property of being an animal and being able to breathe and grow, etc., are all perfectly correlated with one another. Even if the model's true knowledge of these properties is highly variable, probing its representations for them would yield the exact same result, leading to conclusions that overestimate the model's capacity for some properties, while underestimating for others. Evaluation using minimal pair sentences overcomes this limitation by allowing us to explicitly represent the properties of interest in language form, thereby allowing precise testing of property knowledge.

Similarly, standard cloze-testing of PLMs (Petroni et al., 2019; Weir et al., 2020; Jiang et al., 2021) also faces multiple limitations. First, it does not allow for testing of multi-word expressions, as by definition, it involves prediction of a single word/token. Second, it does not yield faithful conclusions about one-to-many or many-to-many relations: e.g. the cloze prompts "Ravens can ___." and "___ can fly." do not have a single correct answer. This makes our conclusions about models' knowledge contingent on choice of one correct completion over the other. The minimal pair evaluation paradigm overcomes these issues by generalizing the cloze-testing method to multi-word expressions—by focusing on entire sentences—and at the same time, pairing every prompt with a negative instance. This allows for a straightforward way to assess correctness: the choice between multiple correct completions is transformed into one between correct and incorrect, at the cost of having several different instances (pairs) for testing knowledge of the same property. Additionally, the minimal pairs paradigm allows us also to shed light on how the nature of negative samples affects model behavior, which has been missing in approaches using probing and cloze-testing. The usage of minimal pairs is a well-established practice in the literature, having been widely used in works that analyze syntactic knowledge of LMs (Marvin and Linzen, 2018; Futrell et al., 2019; Warstadt et al., 2020). We complement this growing literature by introducing minimal-pair testing to the study of conceptual knowledge in PLMs.

Our property inheritance analyses closely relate to the 'Leap-of-Thought' (LoT) framework of Talmor et al. (2020). In particular, LoT holds the taxonomic relations between concepts *implicit* and tests whether models can abstract over them to make property inferences—e.g., testing the extent to which models assign *Whales have bellybuttons* the 'True' label, given that *Mammals have bellybuttons* (with the implicit knowledge here being *Whales are mammals*). With COMPS-WUGS (and COMPS-WUGS-DIST), we instead explicitly provide the relevant taxonomic knowledge in the context and target whether PLMs can behave consistently with knowledge they have already demonstrated (in the base case, COMPS-BASE) and attribute the property in question to the correct subordinate concept. This also relates to recent work that measures consistency of PLMs' word prediction capacities in eliciting factual knowledge (Elazar et al., 2021; Ravichander et al., 2020).

2.2 Ground-truth Property Knowledge data

For our ground-truth property knowledge resource, we use a subset of the CSLB property norms collected by Devereux et al. (2014), which was further extended by Misra et al. (2022). The original dataset was constructed by asking 123 human participants to generate properties for 638 everyday concepts. Contemporary work has used this dataset by taking as positive instances all concepts for which a property was generated, while taking the rest as negative instances (Lucy and Gauthier, 2017; Da and Kasai, 2019, etc.) for each property. While this dataset has been popularly used in related literature, Misra et al. (2022) recently discovered striking gaps in coverage among the properties included in the dataset.[1] For example, the property *can breathe* was only generated for 6 out of 152 animal concepts, despite being applicable for all of them—as a result, contemporary work can be expected to have wrongfully penalized models that attributed this property to animals that could

---

[1] See also Sommerauer and Fokkens (2018) and Sommerauer (2022), who also discuss this limitation.

indeed breathe, and similarly for other properties. To remedy this issue, Misra et al. (2022) manually extended CSLB's coverage for 521 concepts and 3,645 properties. We refer to this extended CSLB dataset as XCSLB, and we use it as our source for ground-truth property knowledge.

2.3 Choosing negative samples

We rely on a diverse set of knowledge representation sources to construct negative samples for COMPS. Each source has a unique representational structure which gives rise to different pairwise similarity metrics, on the basis of which we pick out negative samples for each property:

Taxonomy We consider a hierarchical organization of our concepts, by taking a subset of WordNet (Miller, 1995) consisting of our 521 concepts. We use the `wup` similarity (Wu and Palmer, 1994) as our choice of taxonomic similarity.
