Property Norms We use the XCSLB dataset and organize it as a matrix whose rows indicate concepts and columns indicate properties that are either present (indicated as 1) or absent (indicated as 0) for each concept. As our similarity measure, we consider the jaccard similarity between the row vectors of concepts. This reflects the overlap in properties between concepts, and is prevalent in studies utilizing conceptual similarity in cognitive science (Tversky, 1977; Sloman, 1993, etc.).

Co-occurrence We use the co-occurrence between concept words as an unstructured knowledge representation. For quantifying similarity, we use the cosine similarity of the GloVe vectors (Pennington et al., 2014) of our concept words.

Sampling Strategy Each property (p_i) in our dataset splits the set of concepts into two: a set of concepts that possess the property (Q_{p_i}), and a set of concepts that do not ($\neg Q_{p_i}$). We sample $\min(|Q_{p_i}|, 10)$—i.e., at most 10—concepts from Q_{p_i} and take them to be our positive set. Then for each concept in the positive set, we sample from $\neg Q_{p_i}$ the concept that is most similar (depending on the source) to the positive concept and take it as a negative concept for the property. We additionally include a negative concept that is randomly sampled from $\neg Q_{p_i}$, leaving out the concepts sampled on the basis of the three previously described knowledge sources. Examples of the four types of negative samples for the concept ZEBRA and the property *has striped patterns* are shown in Table 1.

Knowledge Rep.	Negative Concept	Similarity
Taxonomy	HORSE	0.88
Property Norms	DEER	0.63
Co-occurrence	GIRAFFE	0.75
Random	BAT	-

Table 1: Negatively sampled concepts selected on the basis of various knowledge representational mechanisms, where the property is *has striped patterns*, and the positive concept is ZEBRA.

2.4 Minimal Pair Construction

Following our negative sample generation process, we end up with total of 49,280 pairs of positive and negative concepts that span across 3,645 properties (14 pairs per property, on average). Every property is associated with a property phrase—a verb phrase which expresses the property in English, as provided in XCSLB. Using these materials, we construct our three datasets of minimal pair sentence stimuli, examples of which are shown in Figure 1.

COMPS-BASE The COMPS-BASE dataset contains minimal pair sentences that follow the template: "`[DET] [CONCEPT] [property-phrase]`." where `[DET]` is an optional determiner, and `[CONCEPT]` is the noun concept. Applying this template to our generated pairs results in 49,280 instances. See Figure 1a for an example.

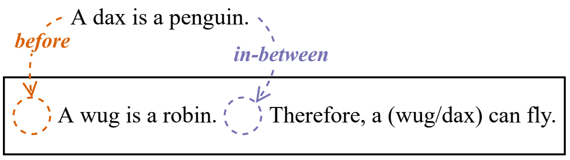
COMPS-WUGS We test property inheritance in PLMs using only the animal kingdom subset of COMPS-BASE (152 concepts, 944 properties, and 13,888 pairs), keeping the same negative samples. We convert the original minimal pair sentences in COMPS-BASE, in which the positive concept is an animal, into pairs of two-sentence stimuli by first introducing a new concept (WUG) to be the subordinate of the concepts in the original minimal pair. We then express its property inheritance in a separate sentence. Our two sentence stimuli follow the template: "A wug is a `[CONCEPT]`. Therefore, a wug `[property-phrase]`." Although we use *wug* as our running example for the subordinate concept, we use four different nonsense words {*wug*, *dax*, *blicket*, *fep*} equal numbers of times, to avoid making spurious conclusions based on a single nonsense word.[2] Introducing an intervening novel concept allows us to robustly control for simple word-level associations between concepts and properties that models might have picked up during

---

[2] As we describe in §4, we also tried a different set of nonce words, to address concerns about possible impacts of using nonce words from existing literature (e.g., *wug*).

Property: *can fly*
Positive: ROBIN
Negative: PENGUIN
Subordinate: WUG
COMPS-BASE: A (**robin/penguin**) can fly.
COMPS-WUGS: A wug is a (**robin/penguin**). Therefore, a wug can fly.

(a) Instances of COMPS-BASE and COMPS-WUGS.



(b) Distraction scheme for stimuli in COMPS-WUGS-DIST, where the distractor is inserted either **before** or **in between** each COMPS-WUGS stimulus.

Figure 1: Examples of materials used in our experiments. In this example, ROBIN is the positive concept.

training. Figure 1a shows an example.

COMPS-WUGS-DIST To add distracting information, we follow Pandia and Ettinger (2021) and convert the COMPS-WUGS stimuli by associating a different subordinate concept (DAX) with the negative concept (`[NEG-CONCEPT]`), and inserting it **before** or **in-between** the sentence containing the positive concept and its subordinate, separately. This results in two subsets (**before** and **in-between**) of three-sentence minimal pair stimuli, which differ in the subordinate to which the property is attributed. We use the following template to create our stimuli: "A **wug** is a `[CONCEPT]`. A **dax** is a `[NEG-CONCEPT]`. Therefore, a (**wug/dax**) `[property-phrase]`." That is, we have stimuli that resemble COMPS-WUGS but instead deal with a pair of competing subordinate concepts in context.[3] See Figure 1b for an example.

3 Methodology

3.1 Models Investigated

We investigate property knowledge and property inheritance capacities of 22 different PLMs, belonging to six different families. We evaluate four widely used masked language modeling (MLM) families: (1) ALBERT (Lan et al., 2020), (2) BERT (Devlin et al., 2019), (3) ELECTRA (Clark et al., 2020), and (4) RoBERTa (Liu et al., 2019); as well as two auto-regressive language modeling families: (1) GPT2 (Radford et al., 2019), and (2) the GPT-Neo (Black et al., 2021) and GPT-J models (Wang and Komatsuzaki, 2021) from EleutherAI. We also use distilled versions of BERT-base, RoBERTa-base, and GPT2, trained using the method described by Sanh et al. (2019). We list each model's parameters, vocabulary size, and training corpora in Table 3 (Appendix A).

3.2 Measuring Performance

To evaluate models on COMPS, we compare their log-probabilities for the property phrase—conditioned on contexts (to the left) containing the positive and negative noun concepts. That is, we hold the property phrase constant, and compare across minimally differing conditions to evaluate the probability with which a property is attributed to each concept. For example, we score stimuli in COMPS-BASE, e.g., "*A dog can bark.*" as:

$$\log p(\text{can bark.} \mid \text{A dog}),$$

its corresponding stimulus in COMPS-WUGS, "*A wug is a dog. Therefore, a wug can bark.*" as:

$$\log p(\text{can bark.} \mid \text{A wug is a dog. Therefore, a wug}),$$

and similarly—assuming CAT as the negative concept—the corresponding stimuli in our COMPS-WUGS-DIST subset, "*A wug is a dog. A dax is a cat. Therefore, a wug can bark.*" as:[4]

$$\log p(\text{can bark.} \mid \text{A wug is a dog. A dax is a cat. Therefore, a wug}).$$

This approach to eliciting conditional LM judgments is equivalent to the "scoring by premise" method (Holtzman et al., 2021), which has been shown to result in stable comparisons across items. Additionally, this also takes into account the potential noise due to frequency effects or tokenization differences (Misra et al., 2021). Estimating these conditional log-probabilities using auto-regressive PLMs can be directly computed in a left-to-right manner. For MLMs, we use their conditional pseudo-loglikelihoods (Salazar et al., 2020) as a proxy for conditional log-probabilities.

Based on this simple method of eliciting relative acceptability measures from PLMs, we evaluate

---

[3] We again choose from our list of four nonsense words (*wug*, *dax*, *blicket*, and *fep*), which amounts to 12 unique ordered pairs, after accounting for counterbalancing.

[4] Here we show an example where the distractor is added **in-between** the context specifying the positive concept, and the queried property knowledge.

a model's accuracy on all COMPS stimuli as the percentage of times its log-probability for a property is greater when conditioned on the context that attributes the property to the positive—as opposed to the negative—concept. Since all cases are forced-choice tasks between two instances, chance performance is set to 50%. Table 4 (Appendix B) shows examples of all COMPS stimuli and GPT-J's conditional log-probabilities for them.

4 Experiments and Analyses

4.1 Base property knowledge of PLMs and their sensitivity to similarity effects

We begin by evaluating the 22 PLMs on COMPS-BASE. Here we focus on the extent to which models robustly associate properties to the correct concepts across stimuli with varying kinds of similarity between the positive and negative concepts. We report accuracies of the 22 PLMs on COMPS-BASE across the four different negative sampling schemes that we specified in §2.3. We additionally report a more stringent accuracy measure that we refer to as 'Overall accuracy,' which is calculated for every property and its positive concept, as the percentage of times a model correctly attributes the property to the positive concept in **all four types of negative sampling schemes**. Chance performance for only the 'Overall' case is then 6.25% ($0.5^4 \times 100$). Figure 2 shows these results.

From Figure 2, we see that models strongly distinguish between positive and negative concepts in cases where they are dramatically different—i.e., where negative concepts were sampled randomly (e.g., BEAR [positive] vs BOTTLE [negative] for the property *can breathe*). However performance drops substantially when there are subtler differences between the two concepts—e.g, the concepts WALRUS (positive) and SHARK (negative) for the property *is a mammal*. For instance, the best performing model in any similarity-based negative sampling scheme (GPT-J, 76%, 'Co-oc') only slightly outperforms the worst model in the random negative sampling scheme (Neo-125M, 71%). The performance of PLMs is not substantially different across the three similarity-based negative sampling schemes, suggesting that the dynamics of model sensitivity in attributing properties to concepts are largely harmonized across various types of similarities. As a result of models' insensitivity in presence of similar negative concepts, the overall accuracies are very modest in value, with the overall accuracy of the best performing model (GPT-J) being only 53%. This overall performance is, however, significantly above chance (6.25%). We discuss additional findings, such as performance by property type and model size, in Appendix C, since they are incidental to the main conclusions of this analysis.

4.2 Property inheritance in PLMs

Having established the base property knowledge of PLMs, we now investigate the extent to which they can show behavior that is consistent with reasoning required to handle property inheritance. We first investigate their performance on COMPS-WUGS, created using the subset of COMPS-BASE containing only animal concepts (see §2.4 for stimulus construction). Table 2 shows average accuracies obtained by PLMs on our property inheritance stimuli, and compares them to average accuracies on COMPS-BASE—aggregating across all negative sampling schemes. Recall that the stimuli in COMPS-WUGS present a more challenging property attribution task than in COMPS-BASE, by

COMPS subset	Size	Acc.
BASE	49.3K	$68.4_{1.7}$
BASE (*animal kingdom only*)	13.8K	$67.1_{2.0}$
WUGS	13.8K	$68.9_{2.3}$
WUGS-DIST (**before**)	13.8K	$59.2_{3.9}$
WUGS-DIST (**in-between**)	13.8K	$47.2_{4.5}$

Table 2: Average accuracy (and standard error of the mean) of PLMs ($N = 22$) on each of our COMPS subsets. Chance performance is 50% throughout.

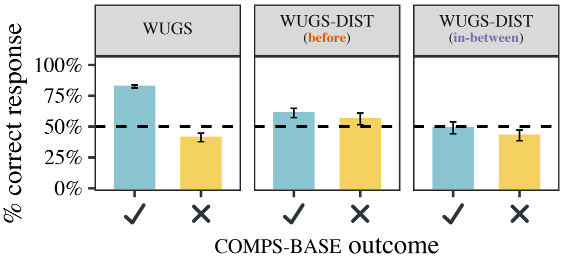

Figure 3: Distribution of model performance on COMPS-WUGS and COMPS-WUGS-DIST (both subsets) across possible outcomes (correct = ✓, incorrect = ✗) of the models on corresponding minimal pairs in COMPS-BASE. Error bars indicate 95% CI, while dashed line indicates chance performance (50%).

not only controlling for coarse-grained similarity effects, but also introducing an intervening novel concept that is expected to inherit the properties of the positive concept. By measuring attribution of properties more indirectly, these stimuli increase the complexity of the reasoning and control for memorization of the literal phrase initially tested with COMPS-BASE.

Table 2 shows the average accuracy of the PLMs on each subset of COMPS. Despite the increase in complexity, we see that PLMs actually show slightly stronger performance on COMPS-WUGS (68.9%) than on COMPS-BASE (67.1%). This means that there are instances in which models prefer the property in the positive context over the negative context (4a > 4b), but show the opposite behavior in COMPS-BASE (4d > 4c).

(4) a. A wug is a **robin**. Therefore, a wug can fly.
b. A wug is a **penguin**. Therefore, a wug can fly.
c. A **robin** can fly.
d. A **penguin** can fly.

This pattern of performance could lead to spurious conclusions that models are successfully executing property inheritance, when in fact they show a lack of the pre-requisite property knowledge based on their failure on COMPS-BASE. We will discuss these inconsistencies in more detail below. Overall, however, the relatively strong performance on COMPS-WUGS suggests that models are largely unaffected when we control for simple memorization of tested phrases—e.g., *robin can fly*—by linking known concepts to properties through an intervening subordinate concept (*wug*). This suggests that models are not relying on simple memorization, but does not control for the possibility of simple association between content words (*robin* and *fly*)—for this we turn to COMPS-WUGS-DIST.

The COMPS-WUGS-DIST test assesses whether models retain strong property attribution performance when content words in the context are not all relevant for the property prediction. The stimuli thus include irrelevant distractor concepts and their subordinates—which, in a robust model, should not affect attribution of the property to the correct concept (see §2.4 for stimulus construction).

From Table 2, the average accuracies of PLMs on both subsets of COMPS-WUGS-DIST (**before** and **in-between**) indicate that overall, models now show clear degradation in property inheritance performance as a result of the distracting information. Specifically, the PLMs' performance drops by 9.7 points on instances when the distracting information is added **before** the relevant context and queried property, and by 21.7 points on instances where it is added **in-between** the two, relative to the undistracted property inheritance stimuli (COMPS-WUGS). Notably, the latter drop in performance brings models level with chance accuracy (we fail to reject the null hypothesis that avg. accuracy of models is 50%; $p = .62$, Wilcoxon signed rank exact text), highlighting a pronounced lack of robustness in PLMs' capacity to attribute properties to the correct concepts in their input context.

Accounting for spurious performance The COMPS-WUGS results above raise the concern that models are often showing spurious performance: accurately demonstrating property inheritance behavior without actually possessing the right property knowledge. To shed more light on this potential issue, we plot the distribution of model accuracies on our property inheritance stimuli (COMPS-WUGS and COMPS-WUGS-DIST) divided based on their outcomes on the corresponding stimuli in COMPS-BASE. Figure 3 shows these distributions. In COMPS-WUGS and both subsets of COMPS-WUGS-DIST, models show this spurious correct behavior on 41.3%, 55.6%, and 42.8% of instances in which they produce incorrect judgments on the corresponding COMPS-BASE stimuli (yellow bars

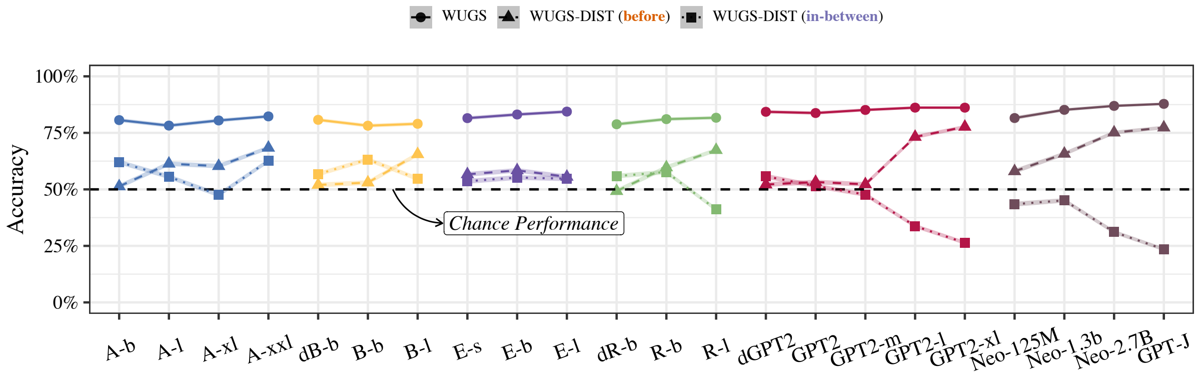

Figure 4: Accuracies of individual models (grouped by family, in increasing order based on number of parameters) on COMPS-WUGS and COMPS-WUGS-DIST. Black dashed line indicates chance performance (50%). Refer to Table 3 for unabbreviated model names. Error bands indicate 95% Bootstrap CIs.

in Figure 3). This non-trivial proportion of cases with spurious performance further reinforces the idea that PLMs' successful predictions on these tests are likely relying on heuristics rather than robust inferences about property knowledge. We can remove the effects of these spurious instances by filtering to items in which models give the correct answer on COMPS-BASE (**blue** bars in Figure 3)—though we see that the overall conclusions remain the same after this filtering.

On the pronounced effect of proximity in autoregressive PLMs Our previous discussion summarized the aggregate property inheritance behavior of the 22 PLMs we considered—we now zoom in for a model-wise analysis. Figure 4 shows models' relative accuracies on COMPS-WUGS and COMPS-WUGS-DIST, filtering to items with correct COMPS-BASE performance, as in the blue bars of Figure 3. Consistent with our overall findings, we observe distracting content to substantially degrade model performance across the board.[5] A particularly noteworthy pattern is that the degradation in autoregressive PLM families—GPT2 and EleutherAI—shows a stark sensitivity to *proximity effects*. While these classes of model seem to suffer less when distracting content is added **before** the context containing the positive concept (thus placing the distraction farther from the queried property), they show substantially worse performance when the opposite is the case (i.e., when distraction is added **in-between**, and is therefore closer to the queried property). This degradation due to proximity of the distracting content becomes **catastrophically worse as models grow larger in the number of pre-trained parameters**—in fact bringing their performance down to as much as 26.2 points **below chance** (in GPT-J, which has 6B parameters). While MLMs also show similar levels of degraded performance in presence of distraction, they do not seem to show any systematic sensitivity to proximity effects, likely due to their bidirectional nature.

Results on GPT-3 In addition to our main experiments, we also evaluate GPT-3 (Brown et al., 2020) models on a small subset of COMPS stimuli (denoted as miniCOMPS). Results from this analysis (shown in Appendix C.1) are largely aligned with our main conclusions, with all GPT-3 models—including the largest one (175B parameters)—performing worse than chance on the **in-between** subset of miniCOMPS-WUGS-DIST, while performing substantially better on miniCOMPS-WUGS and miniCOMPS-WUGS-DIST (**before**). Together with our main results, this indicates that scaling alone may be insufficient to elicit robust inferences about concepts and their properties.

Choice of nonce words Nonce words constitute an important design decision for our stimuli—we followed precedents in language acquisition research (Berko, 1958; Gopnik and Sobel, 2000, *i.a.*) and used previously existing nonce words (such as *wug* and *blicket*) to represent novel concepts in context. While these are expected to be novel for humans, they may appear in pre-training corpora on which PLMs are usually trained.[6] This raises a potential concern that PLMs could already be biased toward certain properties for these words (e.g., *wug* is commonly depicted as a bird), and

---

[5] See also Pandia and Ettinger (2021) for a similar degradation of performance on cloze-tasks involving factual retrieval.

[6] e.g., *wug* appears in wikipedia: `https://en.wikipedia.org/wiki/Jean_Berko_Gleason` (accessed on Jan 23)

may struggle to associate them with different properties.[7] To explore this empirically, we conducted experiments with alternative nonce words (generated synthetically, similar to Kim et al. (2022); see Appendix C.2). Figure 7 (Appendix C.2) shows results on COMPS-WUGS and COMPS-WUGS-DIST with randomly sampled nonce words. We see that the new results are comparable to those in Figure 4, with models showing the same preference on both stimulus versions 80% of the time on average. This suggests that the choice of nonce words is not producing any noteworthy bias.

Framing of novel taxonomic information Another relevant stimulus design decision is the phrasing for introducing novel concepts in context. While we used *"A wug is a* `[CONCEPT]`*"* for our main experiments, we additionally tested with an alternate framing: *"A wug is a type of* `[CONCEPT]`*."* From Figure 9 (Appendix C.3), we again see that the overall patterns of results are comparable to the original results, with models showing the same preference across both versions of the stimuli on COMPS-WUGS and COMPS-WUGS-DIST 90% of the time, on average.

5 General Discussion and Conclusion

The overall goal of COMPS is to shed light on the extent to which PLMs can robustly (1) attribute to real world concepts (e.g., HORSE, WHALE) their correct properties (e.g., *is a mammal*); and (2) demonstrate behavior consistent with *property inheritance*: a reasoning process in which concepts are endowed with the properties of their superordinates (Smith and Estes, 1978; Sloman, 1998; Murphy, 2002). Testing PLMs for these abilities allows us to ask key questions about how they encode and transfer knowledge. To target these capabilities more precisely, and mitigate potential inflation of performance by superficial heuristics such as coarse-grained similarity and word association, we propose incrementally increasing levels of controls in constructing our minimal pair stimuli, progressively making the task of attributing properties to concepts more challenging.

Findings from our initial experiment on COMPS-BASE established that the basic capacity of models to attribute properties to everyday concepts is largely coarse grained. PLMs were more successful in making correct property attributions when the candidate concepts were radically different, and struggled when the concepts shared semantic relations or had high co-occurrence. On testing for 'property inheritance' behavior (via COMPS-WUGS), PLMs initially appeared to demonstrate reasonable success, but they also showed spurious behavior in achieving correct performance on a non-trivial number of instances for which they did not succeed in the prerequisite base condition. Furthermore, this performance declined substantially in the presence of distracting information (COMPS-WUGS-DIST), providing further evidence that what property knowledge and reasoning we appear to see in these PLMs is more reliant on superficial heuristics than on ideal reasoning behavior. Of particular note is our finding of *catastrophic distraction* in large autoregressive PLMs, whose sensitivity to proximity effects brings their overall performance well under chance, especially when scaled up to billions of parameters.

Contemporary work has highlighted the promise of PLMs on high-level tasks requiring—among other things—access to proper relational knowledge between concepts (see Petroni et al., 2019; Safavi and Koutra, 2021; Piantadosi and Hill, 2022). By drawing on the concept of property inheritance, our experiments target reasoning ability based on perhaps the most well-established of relations—the taxonomic or the `IsA` relation (Murphy, 2003). Recent work has also alluded to the proficiency of PLMs in capturing taxonomic information about everyday objects and entities (Weir et al., 2020; Chen et al., 2021, though see Ravichander et al. (2020)). Findings from our controlled experiments suggest that PLMs' approximation of the consequences of the taxonomic relation is at best noisy, in light of clear failures especially in presence of similarity-governed competition. We conclude from our analyses that instead of robustly extracting relational information and reasoning about properties of concepts, it is likely that the PLMs tested here are optimized to prefer superficial cues in making word predictions, leading to mistakes and inaccuracies in presence of irrelevant and distracting information. Since robust natural language understanding will be critically reliant on understanding of property knowledge and implications of property transfer, we hope that these findings will motivate adoption of rigorous assessment methods as well as work toward more robust property knowledge and reasoning in PLMs.

---

[7] We thank Reviewers 1 and 3, Najoung Kim and Kyle Mahowald for raising this concern.

Limitations

Zero-shot setup Using a zero-shot setup to test PLMs for human-like capacities such as property inheritance (as we have done in this work) has recently come under scrutiny. In particular, Lampinen (2022) argues that such a setup could be problematic because PLMs are trained to imitate the language produced by countless individuals with different beliefs, cultures, and behaviors. As a result, PLMs are likely to be handicapped in assigning sufficient probability mass to the desired family of continuations, given minimal prompts without any particular task-specific context. Instead, Lampinen (2022) suggests the need for PLMs

> "[...] to be guided into an experiment-appropriate behavioral context, analogously to the way cognitive researchers place humans in an experimental context, and orient them toward the task with instructions and examples."

This criticism is valid, and it is possible that models could overcome their lack of robustness to distraction effects by observing examples of our stimuli in context, though this has largely been shown in PLMs that are significantly larger than the ones we have tested in this work (Brown et al., 2020; Chowdhery et al., 2022; Wei et al., 2022a).[8] Indeed, recent work has demonstrated these larger PLMs to achieve strong performance on other types of reasoning—such as those required for solving math problems, reversing sequences, etc.—by priming models to produce additional textual content that represents intermediate reasoning steps and explanations (Nye et al., 2021; Wei et al., 2022b; Lampinen et al., 2022), in a few-shot setting.[9] At the same time, a few-shot version of COMPS stimuli could expose models to the possibility of leveraging heuristics that are naturally absent in the zero-shot setup, and therefore such a setup would critically require the design of additional controls, which we leave for future work.

Ideal reasoning behavior Another limitation of our work is that it takes ideal and robust property inheritance behavior as the monolithic gold-standard for human cognition, something that recent work has cautioned against (Pavlick and Kwiatkowski, 2019; Dasgupta et al., 2022; Webson et al., 2023). Although we relied on a database of concept-property pairs that were largely generated by human participants, whether or not humans will be robust to the types of distraction that were observed in PLMs is an open question and requires further investigation. However, notably we are not making direct comparisons between models and humans here—we argue that our primary contribution of controlled stimuli that tease apart shallow processing from robust conceptual reasoning in PLMs bears substantial merit that is independent from any comparisons between humans and computational systems. Furthermore, we emphasize that we are setting a reasonable—and to a certain extent, human-independent—desideratum in this work, which is that models should robustly capture ground-truth knowledge about everyday concepts and their properties and reflect this knowledge in their inferences about newly introduced concepts.

Behavioral evaluation This work tests and analyses PLMs on property knowledge and property inheritance only from a behavioral perspective, which at its core is a correlational endeavor. Potential future work could complement our results by providing evidence from representational analyses, or by devising causal interventions, similar to those recently explored in the realm of syntactic agreement (Finlayson et al., 2021), or in testing of negation and hypernymy in NLI models (Geiger et al., 2020), among others. Importantly, this would require the development of new methods that shed light on how new information—such as the ones we use in COMPS-WUGS and COMPS-WUGS-DIST—is integrated into the model (see Misra et al. (2022) for an example of such an analysis for novel properties).

Targeted language Finally, COMPS only consists of sentences in English, thereby biasing our results only for PLMs trained in that language.

A Model Metadata

Table 3 shows the different models used in our experiments, along with their abbreviation, tokenization scheme, total parameters, vocabulary size, number of tokens encountered during training, and corpora on which they are pre-trained. All models were accessed using `minicons` (Misra, 2022),[10] a python library that serves as a wrapper around Huggingface's `transformers` (Wolf et al., 2020), and provides a unified mechanism for eliciting log-probabilities in batch-wise manner for any autoregressive or masked LM that is accessible through the huggingface hub, or is trained using the transformers library. Experiments were performed using an NVIDIA V100 GPU (32 GB RAM) and took about 6 hours to run, discounting the time it took to download the models from the Huggingface Hub.[11]

B Preview of COMPS stimuli

We show examples of stimuli from our COMPS-BASE, COMPS-WUGS, and COMPS-WUGS-DIST datasets in Listing 1 and Listing 2, respectively. Stimuli with distraction—i.e., in COMPS-WUGS-DIST—are similar to that in Listing 1, but with the `distraction_type` value set to either '`before`' or '`in-between`'.

```
{
    "id": 12706,
    "property": "can fly",
    "acceptable_concept": "owl",
    "unacceptable_concept": "squirrel",
    "prefix_acceptable": "an owl",
    "property_phrase": "can fly.",
    "prefix_unacceptable": "a squirrel",
    "condition": "co-occurrence",
    "similarity": 0.62
}
```

Listing 1: An instance of COMPS-BASE. "`condition`" represents the negative sampling scheme, and "`similarity`" represents the similarity between the acceptable concept and the unacceptable concept on the basis of the condition (either Taxonomic, Property Norm, Co-occurence, or Random).

```
{
    "item": 8343,
    "comps_id": 28798,
    "property": "has hooves",
    "acceptable_concept": "horse",
    "unacceptable_concept": "dog",
    "prefix_acceptable": "A dax is a
    ↪  horse. Therefore, a dax",
    "prefix_unacceptable": "A dax is a
    ↪  dog. Therefore, a dax",
    "property_phrase": "has hooves.",
    "negative_sample_type":
    ↪  "co-occurrence",
    "similarity": 0.62,
    "distraction_type": "undistracted"
}
```

Listing 2: An instance of COMPS-WUGS. "`condition`" and "`similarity`" are the same as in Listing 1. "`distraction_type`" denotes the type of distraction used (undistracted, before, in-between).

Table 4 shows examples from each subset of COMPS, and the conditional log-probability scores as computed by GPT-J (Wang and Komatsuzaki, 2021), the largest LM tested on the full set of stimuli.

C Additional findings and analyses

C.1 Testing GPT-3/3.5

Recent work in scaling PLMs to hundred billion parameters has led to models such as GPT-3 (Brown et al., 2020), which are significantly larger than the largest model tested in the results discussed above (i.e., GPT-J, with 6B parameters). Testing them on the entire set of COMPS stimuli (49K + 3 × 13.8K pairs of sentences) is prohibitively expensive since they are only accessible through paid APIs. Nonetheless, we sampled a small set of COMPS stimuli—which we term as miniCOMPS—in order to get a glimpse of how well substantially larger PLMs elicit property knowledge and demonstrate reasoning behavior compatible with property inheritance. Specifically, we created miniCOMPS by sampling 1200 minimal pairs from each of our original COMPS subsets (matched in terms of real world concepts and properties across the subsets), such that all pairs of nonce words in the resulting miniCOMPS-WUGS-DIST end up being sampled equal number of times (100 times each).

*As estimated by Warstadt et al. (2020).

COMPS subset	Stimulus	Score
BASE	A **horse** has hooves.	-3.829
	A **dog** has hooves.	-4.963
WUGS	A fep is a **horse**. Therefore, a fep has hooves.	-2.153
	A fep is a **dog**. Therefore, a fep has hooves.	-3.392
WUGS-DIST (**before**)	A wug is a dog. A fep is a horse. Therefore, a **fep** has hooves.	-2.919
	A wug is a dog. A fep is a horse. Therefore, a **wug** has hooves.	-2.895
WUGS-DIST (**in-between**)	A fep is a horse. A wug is a dog. Therefore, a **fep** has hooves.	-3.616
	A fep is a horse. A wug is a dog. Therefore, a **wug** has hooves.	-3.092

Table 4: An example of matched stimuli across different COMPS subsets, as well as conditional log-probabilities elicited by GPT-J. Here, the property of interest is *has hooves*, the positive concept is HORSE, and the negative concept is DOG. The negative concept in this case was sampled using the co-occurrence knowledge representation method (see §2.3). Emboldened words indicate items that are different in the minimal pair. Refer to §3.2 for discussion on how 'Score' is computed.

Models As test subjects, we chose four GPT-3 models (Brown et al., 2020): `ada`, `babbage`, `curie`, `davinci`, with the last one being the largest (at 175B parameters), and an additional fifth `davinci`-based model called `text-davinci-001`, which fine-tunes `davinci` on human-written demonstrations. We also test the recently proposed GPT-3.5 models, `text-davinci-002` and `text-davinci-003`, which improve over `davinci` by additionally fine-tuning it on code *and* human-

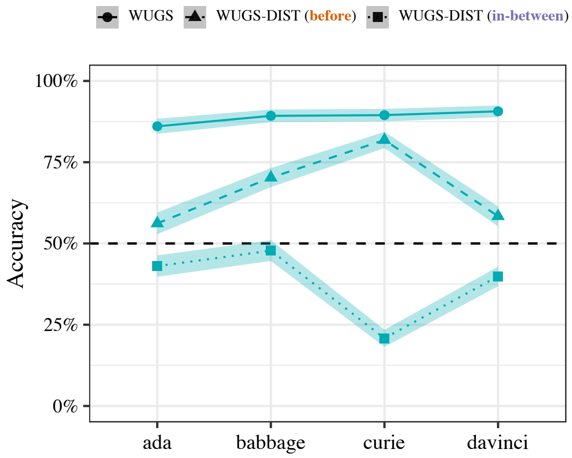

Figure 5: Accuracies of GPT-3 models (arranged in increasing order of the number of trained parameters) on miniCOMPS-WUGS and miniCOMPS-WUGS-DIST. Black dashed line indicates chance performance (50%). Error bands indicate 95% Bootstrap CIs.

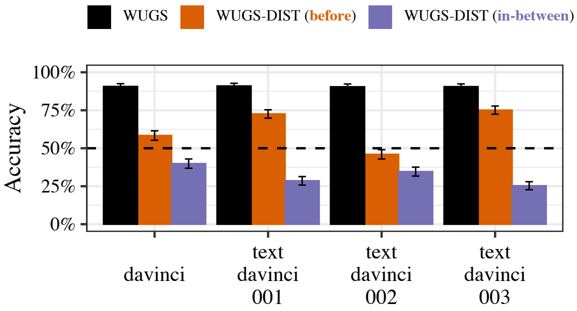

Figure 6: Accuracies of `davinci` models (GPT-3 and GPT-3.5) on miniCOMPS-WUGS and miniCOMPS-WUGS-DIST. Black dashed line indicates chance performance (50%). Error bars indicate 95% Bootstrap CIs. `davinci` and `text-davinci-001` are GPT-3 (Brown et al., 2020) models, while `text-davinci-002` and `text-davinci-003` are GPT-3.5 models.

written demonstrations (Ouyang et al., 2022).[12] All these models are autoregressive in nature, so we use the same scoring and evaluation method as described in §3.2. Since the four original GPT-3 models (`ada`, `babbage`, `curie`, `davinci`) are trained using the same LM objective on the same corpora, we analyze them separately from `text-davinci-001`, `text-davinci-002`, and `text-davinci-003`, which we only compare to `davinci`. We do this to remain consistent with the way we displayed results in §4—ordering models based on their number of trained parameters—and also because models in the `text-davinci-XXX` series use the same underlying `davinci` model augmented with additional training mechanisms (e.g., reinforcement learning and fine-tuning on human-feedback) and data (e.g., code) instead of increasing its size, to our knowledge.

Results Figure 5 shows the performance of the four GPT-3 models on miniCOMPS-WUGS and miniCOMPS-WUGS-DIST, while Figure 6 compares GPT-3 `davinci` to its code and human-feedback adapted counterparts. From Figure 5, we see robustness issues to persist even for GPT-3 models, similar to our main results. Models perform remarkably well in the absence of distraction (i.e., on miniCOMPS-WUGS), but struggle in its presence, especially when it is closer to the queried property. In particular, performance on miniCOMPS-WUGS-DIST (**before**) increases with an increase in parameters until the largest model (`davinci`), where the performance drops closer to chance. On miniCOMPS-WUGS-DIST (**in-between**), all models perform catastrophically worse than chance. This noteworthy pattern of proximity-based degradation in performance mimics the results shown in Figure 4, though we do not see a systematic decline in performance with an increase in parameters as observed in the GPT2 and EleutherAI models—with the 175B parameter model (`davinci`) demonstrating an increase in performance over the relatively smaller `curie` model.

While the above results demonstrate that simply scaling autoregressive PLMs is unlikely to overcome the lack of robustness against distracting content, we now test whether augmenting these large PLMs by additionally training on code (GPT-3.5 models) and aligning them with human-provided demonstrations (`text-davinci-001` and both GPT-3.5 models) could lead to any improvements. For instance, training on code could provide training signals to PLMs that encourage entity tracking, which could potentially enable them, in our case, to resolve which subordinate concept (e.g., *wug* vs. *dax*) the target property is more likely to be associated with. Similarly, aligning with human-written demonstrations could potentially improve their truthfulness, which in our case, could lead to them to prefer correct property assignments. However, from Figure 6, we see no noteworthy improvements demonstrated by these augmented models. All augmented models achieved similar ac-

---

[12] These models are also known as InstructGPT, as discussed in `https://platform.openai.com/docs/model-index-for-researchers`.

curacies on COMPS-WUGS as the `davinci` model (within 90.5% and 91%), suggesting that their augmentations preserved the general associations between the lexical items that denote everyday concepts and properties. On stimuli containing distraction (i.e., both subsets of COMPS-WUGS-DIST), either the models performed systematically worse as compared to `davinci` (with `text-davinci-002` showing below-chance performance on both subsets), or they showed mixed results, where an improvement on COMPS-WUGS-DIST (**before**) was accompanied by a decline on COMPS-WUGS-DIST (**in-between**).

Together, these results suggest that neither an increase in scale nor additional training methods such as alignment with human instructions/feedback or training on code prevents models from being distracted in associating properties to novel subordinate concepts introduced in the input context. In fact, the catastrophic effects of proximity-based distraction persists even for the most recent state of the art GPT-3/3.5 models.

C.2 Results with alternate nonce words

Here we report results on COMPS-WUGS and COMPS-WUGS-DIST using an alternate set of nonce words, which we constructed by sampling (with replacement) from 26 lower-case ASCII alphabet characters. Specifically, we constructed novel character sequences—each assigned as a replacement for our original four nonce words—of lengths ranging from 4-8 by sampling in an alternate fashion from consonants (odd positions) and vowels (even positions).[13] A replication of Figure 4 using the stimuli with these newly sampled nonce words is shown in Figure 7. On comparing figures 4 and 7, we observe largely similar patterns of results on stimuli containing nonce words constructed using randomly sampled characters. That is, models generally performed well on COMPS-WUGS, while they struggled on COMPS-WUGS-DIST. There were some exceptions: (1) GPT-Neo 1.3B and 2.7B showed improvements (relative to the original stimuli) in cases where distraction is added closer to the queried property (i.e., **in-between**), though they still hover around chance performance, and additionally the performance of GPT-J, like in the original results is still substantially below chance; and (2) there were non-trivial improvements demonstrated by ALBERT models (large and xl) on the **before** subset of COMPS-WUGS-DIST, and BERT-large on the **in-between** subset of COMPS-WUGS-DIST.

Stimuli	**Avg. Agreement**
COMPS-WUGS	$93.1_{0.8}$
COMPS-WUGS-DIST (**before**)	$73.9_{4.6}$
COMPS-WUGS-DIST (**in-between**)	$73.0_{4.6}$
Overall	$80.0_{2.9}$

Table 5: Average agreement (× 100) in PLMs' preference on stimuli containing original and synthetically constructed nonce words.

To precisely quantify the difference between the two sets of results, we measured the agreement between the predictions of the PLMs for both sets of stimuli, taken as the proportion of minimal pairs in which the models' relative preference agree.

Figure 8 shows individual model agreement on COMPS-WUGS and COMPS-WUGS-DIST, while Table 5 shows agreement percentages averaged across all models. From these results we observe models to show greater robustness to the variability introduced by the choice of nonce words in stimuli with one novel concept (COMPS-WUGS) than in stimuli with multiple novel concepts (COMPS-WUGS-DIST). Despite this discrepancy, there is generally a high average agreement (80%) between a given model's set of decisions on stimuli with original and alternative nonce words.

C.3 Results with alternate templates

Here we report results on an alternate phrasing of our stimuli, where instead of using the original template for introducing novel concepts in context (*a wug is a* `[CONCEPT]`), we use: *A wug is a type of* `[CONCEPT]`, where *wug* indicates the novel concept. In all cases, we simply alter the template, keeping everything else constant, including the choice of nonce words.

Figure 9 shows accuracies of the models on stimuli with this alternate phrasing, while Figure 10 and Table 6 show individual and averaged overall agreement between models' preference on original and the alternatively-phrased stimuli, respectively. The agreement percentages between models' preferences are quite high (average agreement being 90%)—in fact even greater than the agreement observed as a result of altering the nonce words (Table 5), further cementing the robustness of our

---

[13] the resulting set of words is: {*ruhisin, kifosa, rosibif, lepuvu*}, still amounting to 12 unique ordered pairs in the COMPS-WUGS-DIST stimuli.

results.

C.4 How does performance on COMPS-BASE vary by property type?

Devereux et al. (2014) have categorized the properties that we use in our experiments to lie in 5 different categories: (1) **Taxonomic**, e.g., *is a mammal*, *is a vehicle*, etc.; (2) **Functional**, e.g., *can keep the body warm*, *is used to hit nails*, etc.; (3) **Encyclopedic**, e.g., *uses electricity*, *is warm blooded*, etc.; (4) **Visual Perceptual**, e.g., *has webbed feet*, *has thick fur*, etc.; and (5) **Other Perceptual**, e.g., *makes grunting sounds* and *is sharp*, etc. We report results of the 22 PLMs on the COMPS-BASE stimuli across the five different property types, in Figure 11.

From Figure 11, we observe that PLMs are substantially stronger in eliciting taxonomic properties of concepts as compared to other types, with highest overall accuracy being 70%, as compared to 48% on encyclopedic properties, 50% on visual perceptual properties, 57% on functional properties, and 43% on non-visual perceptual properties. Recall that chance accuracy for the 'Overall' scenario is just 6.25%, so these scores are fairly high. This corroborates evidence from previous work in analyzing property knowledge of distributional semantic models as well as LM representations to lack perceptual knowledge (Lucy and Gauthier, 2017; Da and Kasai, 2019; Rubinstein et al., 2015; Weir et al., 2020), likely due to reporting bias (Gordon and Van Durme, 2013; Shwartz and Choi, 2020).

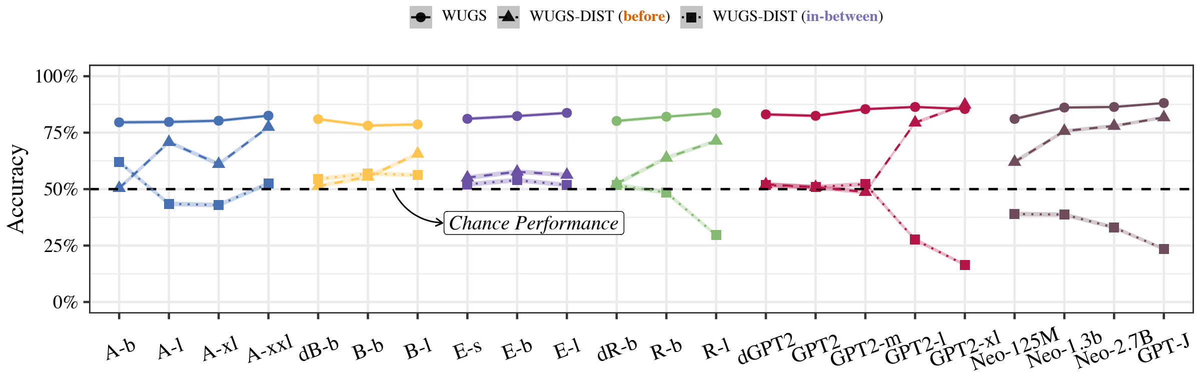

Figure 9: Accuracies of individual models (grouped by family, in increasing order based on number of parameters) on COMPS-WUGS and COMPS-WUGS-DIST with **alternate framing of novel taxonomic information**. Black dashed line indicates chance performance (50%). Refer to Table 3 for unabbreviated model names.

Figure 10: Proportion of cases (in COMPS-WUGS and both subsets of COMPS-WUGS-DIST) **where each listed model's preference on the original stimuli matches that in stimuli with alternate framing of novel taxonomic information**, measured as the 'Agreement'. An agreement of 1.0 suggests that a given model's preferences are perfectly matched across both sets of stimuli.

However, different to most of these works, the gap between performance on perceptual properties and non-perceptual properties is small. We conjecture that this could be primarily due to the extension of the CSLB by Misra et al. (2022), which lead to an increase in coverage of property knowledge for several properties. For instance, the property *has teeth* was mentioned only for 45 out of 67 potential concepts, having been left out for concepts such as CALF,[14] BUFFALO, KANGAROO, etc. So it could be the case that previous research has underestimated the extent to which property knowledge is encoded by PLMs and other distributional semantic models of language.

C.5 Does performance on COMPS-BASE depend on scale?

We plot the accuracies of PLMs on COMPS-BASE per model family (in order to control for differences in training corpora and tokenization) in Figure 12. In all families except BERT, we see that accuracy increases with the model size, following standard scaling laws. We notice that distilBERT-base (Sanh et al., 2019) is able to outperform even BERT-large on stimuli with 'Random' negative samples, suggesting that pruning BERT might sometimes unintentionally improve the model's ability to associate properties and concepts. We do however caution against interpreting these results as robust conclusion for scaling laws on COMPS-BASE. Such an endeavor would require comparing performance of models across multiple checkpoints with varying number of parameters, paired with rigorous statistical inference (Sellam et al., 2021; Zhang et al., 2021).

Abstract

We introduce our probabilistic robustness rewarded data optimization (PRoDO) approach as a framework to enhance the model's generalization power by selecting training data that optimizes our probabilistic robustness metrics. We use proximal policy optimization (PPO) reinforcement learning to approximately solve the computationally intractable training subset selection problem. The PPO's reward is defined as our $(\alpha, \epsilon, \gamma)$-Robustness that measures performance consistency over multiple domains by simulating unknown test sets in real-world scenarios using a leaving-one-out strategy. We demonstrate that our PRoDO effectively filters data that lead to significantly higher prediction accuracy and robustness on unknown-domain test sets. Our experiments achieve up to +17.2% increase of accuracy (+25.5% relatively) in sentiment analysis, and -28.05 decrease of perplexity (-32.1% relatively) in language modeling. In addition, our probabilistic $(\alpha, \epsilon, \gamma)$-Robustness definition serves as an evaluation metric with higher levels of agreement with human annotations than typical performance-based metrics.

1 Introduction

Modern machine learning works with massive amounts of data on a range of tasks like language modeling, object detection, and data mining. Using large amounts of training set to build machine learning systems requires extensive computational resources and creates problems like domain shifts and input noise. These unfiltered training data harm model learning robustness (Frénay and Verleysen, 2013) that leads to prediction errors and serious consequences like self driving car fatality and medical misdiagnosis (Tian et al., 2018).

One problem causing this model instability is that the model learning is opt for the system's quality, which is typically evaluated by measuring how close this system's output of a test set is from its human label using metrics such as accuracy, error rate, perplexity, human evaluation score, and so on. However, such a system performance metric highly depends on the test set's choice and is thus unreliable. For instance, if our training set is drawn from the news domain, then the performance on a test set from the news domain (in-domain test set) is usually much higher than that from the Twitter domain (out-of-domain test set). As a result, in NLP, while some systems produce human parity results like the use of a pre-trained Transformer (Hendrycks et al., 2020) on in-domain test sets, these systems are easily corrupted by out-of-domain (OOD) samples from the real world.

Existing studies on data selection and robust learning demonstrate a need for test domain knowledge during training. Some data selection work (Moore and Lewis, 2010; Kirchhoff and Bilmes, 2014; van der Wees et al., 2017; Fan et al., 2017; Qu et al., 2019; Liu et al., 2019; Kang et al., 2020) chooses critical in-domain data for domain adaptation, and other work defends against adversarial attacks but offers little help for out-of-domain robustness (Taori et al., 2020) under natural distributional shifts (Wang et al., 2021) that occurs more frequently than extreme adversarial cases. This out-of-domain robustness is often measured by testing on a specific domain and a single task like sentiment classification (Müller et al., 2019; Hendrycks et al., 2020). The problem with these existing approaches is that the target domain knowledge is often unknown, as is the case for most real-world applications that do not know the domain of test data they will receive before launch.

To address these challenges, our goal is to select training data to achieve high accuracy on OOD test set, without requiring any target domain insight during data selection or model training process. We distinguish the out-of-domain and *unknown-domain test sets* by assigning the out-of-domain as the test domain known during the training, and the

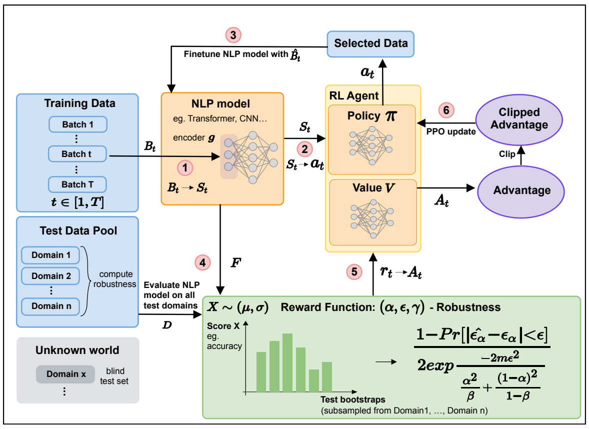

Figure 1: Probabilistic Robustness Rewarded Data Optimization (PRoDO) Framework.

unknown-domain as the test domain along with its information that are not known during the training. Practical applications often apply the latter case where we do not have any target domain knowledge, a condition we call "unknown-domain" robustness. To move our understanding forward, there is an urgent need to revisit out-of-domain robustness in "unknown worlds" to bridge the gap between laboratory observations and real-life results.

In our approach to the measurement of robustness on unknown domains, we define robustness as the consistency of the behavior of a machine learning system. The more a machine learning system's behavior deviates from the typical, the less robust the system is defined to be. Notice that this definition does not necessarily give a notion of whether system performance is good or bad. For example, in terms of sentiment analysis, this definition refers to consistency in prediction accuracy for a trained classifier.

To measure a system's performance consistency, we combine test sets for evaluation from various domains, like news, biomedical, and Twitter; randomly sample their subsets, and take each subset as this system's input and obtain an output. Then, we measure the performance of each output. If these output performances are close to each other, we say they are consistent. To quantify this consistency, we define our robustness metric as a notion of a probabilistic definition on the distribution of performance across different test domains, called $(\alpha, \epsilon, \gamma)$**-Robustness**, where the higher the probability of the consistent prediction performance, the more robust the system.

Our objective is to measure the probability of upper bounding the prediction accuracy gap between any test subset and its average. More specifically, we call an NLP system $(\alpha, \epsilon, \gamma)$-robust, if for every subset uniform-randomly drawn from a distribution, its prediction error, a combination of the target domain error and the source domain error weighted by the parameter α, is centered around the mean error, which is bounded through a parameter ϵ with a probability depending on γ, an indicator of how robust a system is, see definition in Figure 1 (in green) and details in Section 2.2.

In our approach, we *do not need any target-domain data* since we "simulate" unknown target-domain test sets using the *leave-one-out* error stability (Mukherjee et al., 2006). We assume that the non-left-out test sets are the simulated target domain while the left-out test is the real target domain for evaluation. For example, given biomecial as our unknown target domain to evaluate, we take the training data as the source-domain set and sample different subsets from a combination of other test domain data (e.g., news, TED talks, etc.) to simulate our target-domain test sets. The hyperparameter α is the target-domain error weight and offers flexibility to balance the trade-offs between source- and target-domain errors.

The $(\alpha, \epsilon, \gamma)$-Robustness takes a new direction away from adversarial robustness to a general consistency of a model's quality as meta-evaluation methods that measure the consistency of user-defined quality metrics. Thus, *any standard performance evaluation metrics, such as accuracy, can be used within the definition of our robustness.*

After defining our robustness metric as our data optimization goal, we ask, *how should we select a subset of data that can maximize the robustness?* We assert that in general, the subset selection problem is computationally intractable. We conjecture that this condition holds true for every objective function, including our notion of probabilistic robustness, and is the reason why we use Proximal Policy Optimization (PPO) (Schulman et al., 2017) deep reinforcement learning to optimize the training set, which has the advantages of low variance, monotonic policy improvement, and sampling efficiency (Schulman et al., 2015; Uc-Cetina et al., 2021) compared to A2C (Konda and Tsitsiklis, 2000) and policy gradient (Sutton et al., 1998). Our Probabilistic Robustness rewarded Data Optimization (PRoDO) framework equipartitions the training data into mini-batches and simultaneously learns a policy network to select data iteratively and a value network to estimate future returns using our $(\alpha, \epsilon, \gamma)$-Robustness as the reward functions illustrated in Figure 1 .

Our empirical results on sentiment analysis and language modeling show that the use of our robustness definition consistently and significantly enhances a model's out-of-domain performance. The main contributions of this work include:

1. Probabilistic Robustness definition of $(\alpha, \epsilon, \gamma)$-Robustness;
2. The creation of PPO Deep Reinforcement Learning framework for data selection;
3. The improvement of NLP model accuracy and out-of-domain generalization on showcase applications of sentiment analysis and language modeling.

The rest of the paper is as follows: In Section 2.1, we describe our PRoDO framework. In Section 2.2, we introduce the $(\alpha, \epsilon, \gamma)$-Robustness. Section 3 introduces experimental details including baselines, NLP tasks and ablation study. In Section 4, we discuss the previous literature on robustness in machine learning. Section 5 concludes the paper.

2 Method

Our goal is to enable our task model $\mathcal{F}$ (any Deep Learning-based NLP model, such as Transformer, etc.,) to achieve consistent while superior performance on any unknown test domain $\mathcal{D}_x$ whose distribution is different from the source training set $\mathcal{X}$, by learning an effective subset of $\mathcal{X}$ that can maximize the robustness of model $\mathcal{F}$.

The entire process details are depicted in Figure 1. Our method consists of reinforcement learning (RL), data selection, and training NLP models using the selected data. Specifically, we use reinforcement learning to train a data selection policy, and we use the data selection policy to select a subset of training data to fine-tune NLP models. Following Yu et al. (2022a), we pre-train the task model $\mathcal{F}$ on the full training data set $\mathcal{X} = \{x_i\}_{i=1}^{N}$, where x_i is a sentence, N is training set size. Then, the training set $\mathcal{X}$ is shuffled and randomly partitioned into T disjoint data batches such that $\mathcal{X} = \{\mathcal{B}_t\}_{t=1}^{T} = \{\mathcal{B}_1, \mathcal{B}_2, ..., \mathcal{B}_T\}$, with $\mathcal{B}_t = \{x_{(t-1)N|T+1}, x_{(t-1)N|T+2}, ..., x_{tN|T}\}$, where $N|T$ is the integer division of N by T, and $T \leq t$. For each batch, we select a subset of data $\hat{\mathcal{B}}_t = \{(x_i)_{i=1}^{o} | x_i \in \mathcal{B}_t\}$ with size o according to the data selection policy trained by reinforcement learning, and use it to fine-tune the model $\mathcal{F}$. In general, $\mathcal{F}$ and its encoder g are updated on $\hat{\mathcal{B}}_t$ for T times in an epoch, and each update is based on the previous checkpoint. Besides training set, we use a test data pool $\mathcal{D}$ containing n test domains $\mathcal{D} = \{\mathcal{D}_1, \mathcal{D}_2, \ldots, \mathcal{D}_n\}$ to simulate the real world scenario and compute the robustness score with it.

In the following sections, we will first introduce how our PRoDO framework learns to select data (Section 2.1) and then our reward function based on the probabilistic robustness definition (Section 2.2).

2.1 PRoDO framework

We now present the details of our Probabilistic Robustness Rewarded Data Optimization (PRoDO) framework.

2.1.1 RL training

The goal of our reinforcement learning agent is to learn an optimal data selection policy π to maximize the expected return $\mathcal{R}_t = \sum_{j=0}^{T-t} \gamma^j r_{t+j}$ from each state s_t, where the scalar reward r_t measures how good the action a_t taken by the policy is at the time step t and $\gamma \in [0, 1]$ is the discount factor. Specifically, each time step can be split into six steps as in Figure 1. Firstly, the encoder (e.g. an embedding layer in LSTM, or an encoder in transformer) inside the NLP model transforms the batch of raw data $\mathcal{B}_t$ into a batch of (document) embeddings, denoted as s_t. Secondly, the agent takes action a_t based on state s_t. The agent takes the state s_t as input and outputs a probability distribution for s_t, so that each sentence is associated with a probability, representing how likely it is going to be selected. The selected subset, denoted as $\hat{\mathcal{B}}_t$, is then obtained by Bernoulli sampling each sentence in the state s_t. The result of Bernoulli sampling is represented as an action vector a_t, where each value in it is either 0 or 1 representing each sentence in the batch not being or being selected. Thirdly, as soon as we obtain $\hat{\mathcal{B}}_t$, the NLP model $\mathcal{F}$ as well as encoder g are fine-tuned by the selected subset $\hat{\mathcal{B}}_t$. Then, the scalar reward $r_t = \mathcal{R}(\mathcal{D}, \mathcal{F})$ is calculated by our reward functions $\mathcal{R}$ (defined in Section 2.2) based on all available test domains D and current NLP model $\mathcal{F}$. Next, the advantage A_t over action a_t is computed by the difference of reward r_t and the output of value function $V(s_t)$. Finally, we update the policy function following the gradient with regard to the objective in PPO (details in next section 2.1.2) using the advantage A_t.

2.1.2 PPO

In the conventional policy based (Sutton et al., 1998) or actor-critic (policy-value) (Mnih et al., 2016) based reinforcement learning, the precision of the value function often corrupts the policy optimization process for two reasons. First, some collected states might introduce noise to the prediction of $V(s_t)$, and thus lead to an inaccurate estimate of advantage A_t following with an inaccurate update of policy gradient. Secondly, a trajectory of interaction (consider a large dataset with a large interaction horizon $\mathcal{T}$) might take long time, while one collection of data can only be used to update the policy once, thus leading to severe sample inefficiency.

Trust Region Policy Optimization (TRPO) (Schulman et al., 2015) and Proximal Policy Optimization (PPO)(Schulman et al., 2017) are proposed to solve the aforementioned problems by introducing importance sampling and advantage clipping. We adopt PPO as our framework since it is much simpler to implement than TRPO. PPO has the following properties, which are very desirable to achieve our goals: low variance, monotonic policy improvement and sampling efficiency (Grondman et al., 2012; Schulman et al., 2017). Our framework consists of policy and value networks jointly and dynamically learned together with the task model using the advantage error computed from the reward function, as shown in Algorithm 1. PPO uses $A(s_t, a_t)$, the advantage of action a_t in state s_t to scale the policy gradient. Specifically, the advantage of action (Mnih et al., 2016) a_t in state s_t is defined as

$$A(s_t, a_t) = \mathcal{Q}(s_t, a_t) - \mathcal{V}(s_t) \approx \sum_{j=0}^{T-t} \gamma^j r_{t+j} - \mathcal{V}(s_t), \tag{1}$$

where $\gamma \in (0, 1]$ is the discounting factor set as 0.99. $\mathcal{V}$ is the value function implemented as a value network.

Let $\mathbf{r}_t(\theta)$ denote the probability ratio $\mathbf{r}_t(\theta) = \frac{\pi_\theta(a_t|s_t)}{\pi_{\theta old}(a_t|s_t)}$, the objective of PPO is defined in Schulman et al. (2017) as

$$A_{t_{clipped}} = clip(\mathbf{r}_t(\theta), 1 - \epsilon, 1 + \epsilon) A_t \tag{2}$$

$$\mathcal{J}(\theta) = \mathbb{E}_t \left[\min(\mathbf{r}_t(\theta) A_t, A_{t_{clipped}}) \right], \tag{3}$$

where ϵ is a hyperparameter, and we set it as 0.2. The objective function clips the range of change of policy gradient into $[1 - \epsilon, 1 + \epsilon]$, which forces the new policy to not deviate too much from the old policy. This clipping design of PPO ensures monotonic improvement and thus it has the advantages of sample efficiency and ease of tuning compared to other policy-based algorithms.

Algorithm 1 PRoDO Training Algorithm

Input: Epoch L, learning rate α, discount factor γ, training set $\mathcal{X}$, pre-trained task model $\mathcal{F}$(including encoder g), reward function $\mathcal{R}$ (discussed in section 3.2)

Output: selected data, fine-tuned $\mathcal{F}$, policy π_θ, data value estimator $\mathcal{V}_{\theta_v}$

```
Initialize data selection policy $\pi_\theta$ and value estimator $\mathcal{V}_{\theta_v}$
for episode $l = 1$ to $L$ do
    Shuffle (uniformly at random) all training samples;
    Equipartition $\mathcal{X}$ into $T$ (disjoint) sets with same size $n|T$: $\mathcal{X} = \{\mathcal{B}_t\}_{t=1}^T = \{\mathcal{B}_1, \mathcal{B}_2, ..., \mathcal{B}_T\}$;
    Initialize an empty list: episode history $\Upsilon$
    for all $\mathcal{B}_t \in \mathcal{X}$ (uniform transition probability) do
        $s_t = g_t(\mathcal{B}_t)$;
        Obtain batch action $a_t$ by sampling based on $\pi_\theta(s_t)$;
        $\hat{\mathcal{B}}_t = \{(x_i)_{i=1}^o | a_i = 1\}$, where $o$ is selected sample size;
        Update task model $\mathcal{F}(g_t)$ by fine-tuning on $\hat{\mathcal{B}}_t$;
        $r_t = \mathcal{R}(\hat{\mathcal{B}}_t, \mathcal{F})$;
        Store $(s_t, a_t, r_t)$ to episode history $\Upsilon$;
    end for
    for all $(s_t, a_t, r_t) \in \Upsilon$ do
        Obtain $A(s_t, a_t)$ for each batch;
        Update policy weights $\theta$ and value estimator weights $\theta_v$;
    end for
    Clear episode history $\Upsilon$;
end for
return $\mathcal{F}$,$\pi_\theta$ and $\mathcal{V}_{\theta_v}$
```

The objective of value network is:

$$\nabla_{\theta_v} \mathcal{V}(\theta_v) = \mathbb{E}_{\pi_\theta} \nabla_{\theta_\mathcal{V}} (r_t - \mathcal{V}(s_t; \theta_v))^2 \tag{4}$$

The parameters of value function θ_v is updated by:

$$\theta_{v(t+1)} = \theta_{vt} + \alpha \nabla_{\theta_{vt}} (r_t - \mathcal{V}(s_t; \theta_{vt}))^2 \tag{5}$$

2.2 Reward function: $(\alpha, \epsilon, \gamma)$-Robustness

The reward function in Section 2.1 is the robustness of the NLP model $\mathcal{F}$.

In the real world, the out-of-domain data are often much less than the in-domain data. Formally, consider a pool of m samples where βm samples are drawn from *target* domain D_t and $(1 - \beta)m$ samples are drawn from *source* domain D_s where $\beta \in [0, 1)$, β is often small in many scenarios. Thus, the minimization of empirical target error $\hat{\epsilon}_t$ becomes hard with the constraint of limited target data. To solve this, we instead try to minimize a convex combination of empirical source and target error:

$$\hat{\epsilon}_\alpha = \alpha \hat{\epsilon}_t + (1 - \alpha) \hat{\epsilon}_s \tag{6}$$

where $\alpha \in [0, 1]$. We also denote ϵ_α as the weighted combination of the true source and target errors measured with respect to source domain D_s and target domain D_t, as shown in Figure 2.

According to the learning theory of Ben-David et al. (2010), the probability that the difference between the weighted empirical error $\hat{\epsilon}_\alpha$ and the weighted true error ϵ_α of an NLP system exceeds a given threshold has an upper bound as shown in Equation 7. Since we are more interested in bounding the difference between the weighted empirical error $\hat{\epsilon}_\alpha$ and the weighted true error ϵ_α to some threshold, so as to consider the system as "robust", we can transform the inequality to derive a lower bound of the probability as shown in Equation 9:

$$Pr[|\hat{\epsilon}_\alpha - \epsilon_\alpha| \geq \epsilon] \leq 2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}} \tag{7}$$

$$\Leftrightarrow 1 - Pr[|\hat{\epsilon}_\alpha - \epsilon_\alpha| \geq \epsilon] \geq 1 - 2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}} \tag{8}$$

$$\Leftrightarrow Pr[|\hat{\epsilon}_\alpha - \epsilon_\alpha| < \epsilon] \geq 1 - 2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}} \tag{9}$$

The right hand side of Equation 9 is the lower bound of the probability that the difference of the empirical error and the true error of an NLP system is smaller than some threshold ϵ. We can introduce the robustness factor γ ($\gamma \in [0, 1]$) to the right hand side to control how tightly we would like to bound the probability of error difference:

$$Pr[|\hat{\epsilon}_\alpha - \epsilon_\alpha| < \epsilon] \geq 1 - 2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}} \cdot \gamma \tag{10}$$

$$\Leftrightarrow \gamma \geq \frac{1 - Pr[|\hat{\epsilon}_\alpha - \epsilon_\alpha| < \epsilon]}{2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}}} \tag{11}$$

In consequence, we give the formal definition of $(\alpha, \epsilon, \gamma)$-robustness as:

Definition *We call an NLP system* $(\alpha, \epsilon, \gamma)$*-robust, if for any source domain* D_s *and target domain* D_t*, the difference between the empirical error* $\hat{\epsilon}_\alpha$ *and the true error* ϵ_α *is bounded through a threshold parameter* ϵ *with a probability of* $1 - 2e^{\frac{-2m\epsilon^2}{\frac{\alpha^2}{\beta}+\frac{(1-\alpha)^2}{1-\beta}}} \cdot \gamma$*, where* $\alpha \in [0, 1]$ *is the weight of target domain error and* $\beta \in [0, 1)$ *is the ratio of target data within all data.*

Based on this definition, we can interpret $\gamma \in [0, 1]$ **as the inverse indicator of robustness** for an NLP system. For example, a larger γ indicates a lower probability that the difference between empirical error $\hat{\epsilon}_\alpha$ and true error ϵ_α is within our expected threshold, so that the empirical error is probably with large variance, and thus the large γ indicates a less robust system.

2.2.1 Compute robustness by bootstrapping

We estimate robustness metrics using the *leave-one-out* error stability (Mukherjee et al., 2006) by excluding a left-out test set from all available datasets where we measure robustness. More precisely, for a given model, we randomly select one leaving-one-out test set and then combine all other tests to compute the robustness of the left-out datasets. Specifically, we consider the test domain as the target domain (an unknown domain that will not be used in training) and use all other test domains as available resources to compute mean and variance.

In practice, it often occurs that only limited test domains are available. Thus, the test scores of test domains are discrete values and hard to form a distribution. To solve this problem, we seek to a modified bootstrap algorithm to construct a pool of subsamples from the combined test set, as proposed by Yu et al. (2022b). For each subsample, instead of random sampling from the complete test pool, we randomly sample from the elements not present in the current subsample to minimize the intersection between each.

3 Experiments

3.1 Baselines

We compare our measure with four baselines. The first baseline denoted as **All** is the normal NLP model trained on all training samples. **Minmax** is derived from classic min-max objective in robust optimization. **Diff** (Zhang et al., 2022) and **Ratio** (Niu et al., 2020) are recently introduced robustness metrics defined by input perturbations.

Min-max robustness The notion of robustness can be originated from robust optimization (Ben-Tal and Nemirovski, 1998; Bertsimas and Sim, 2004) in which the optimization goal is to find a solution h satisfying

$$\min_h [\max_{\delta_1, \ldots \delta_n \in \Delta} \sum_{i=1}^{n} l(h, x_i + \delta_i)] \tag{12}$$

where x_i are the observed training samples, δ_i are deviations or perturbations from the observed samples, $l(\dot{;})$ is the loss function, and Δ are all possible

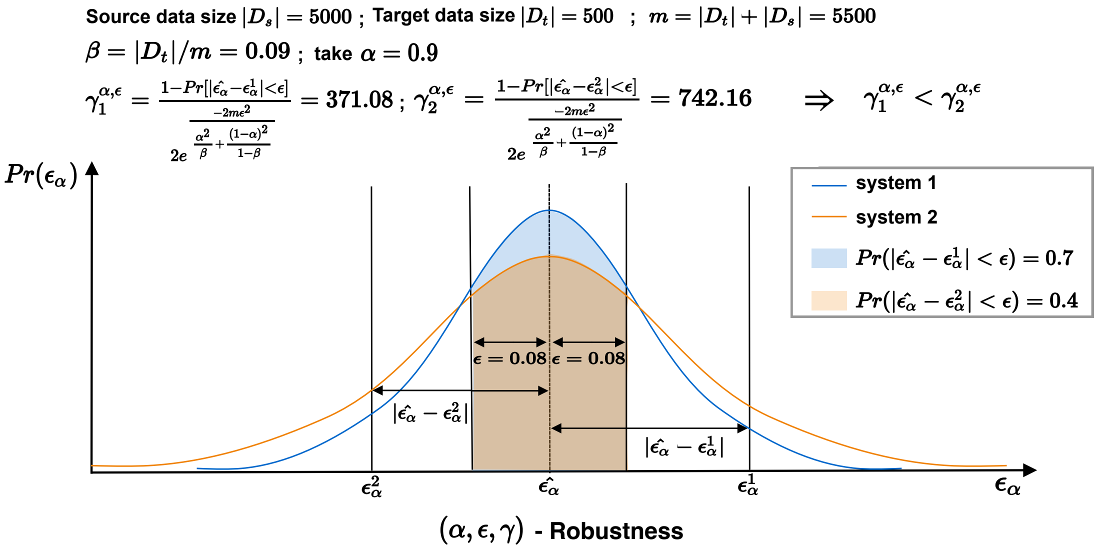

Figure 2: Illustrations of $(\alpha, \epsilon, \gamma)$-Robustness for two NLP systems. Orange curve and blue curve are the probability density function (PDF) of the test scores (X) of two NLP systems. The inference of robustness comparison is shown in top.

perturbations. Robust algorithms satisfying this definition are expected to minimize the empirical error under the worst possible perturbation. Since min-max objective targets the "worst possible perturbation", we consider the most challenging test set that will degrade the NLP performance most as "the worst possible perturbation" and use the evaluation score of such test set as a quantitative measure to denote model robustness under the min-max objective.

3.2 Improvements on NLP tasks

We experiment on a typical classification task of sentiment analysis and a generation task of language modeling.

3.2.1 Sentiment Analysis

In the task of sentiment analysis, we train a CNN classifier (Kim, 2014) using Amazon product review dataset (Blitzer et al., 2007). Specifically, we use the combined set of DVD, kitchen and books domains as source data. To compute robustness metrics, we use the full pre-processed Amazon product review dataset, which contains other domains such as grocery, tools, beauty and computer. We treat the test accuracy on the bootstrapped subsamples as a distribution and compute the $(\alpha, \epsilon, \gamma)$-Robustness by setting ϵ as 0.001 and α as 0.9. From Table 1, the classifiers optimized with $(\alpha, \epsilon, \gamma)$-Robustness outperforms all baselines. Specifically, the Min-max robustness achieves the second highest average accuracy score on test domains.

3.2.2 Language Modeling

Our baseline is a Transformer language model (Vaswani et al., 2017) with default hyper-parameters. We experiment with two moderate size datasets WikiText-2 (Merity et al., 2016) and Penn Treebank. As for evaluation, we report perplexity scores on four translation datasets from different domains, IWSLT'17 (TED talk) (Cettolo et al., 2012), Biomedical'21 (medical) (Yeganova et al., 2021), MTNT'18 (Reddit) (Michel and Neubig, 2018) and WMT'15 (news). The baseline models are trained using the fairseq toolkit (Ott et al., 2019) and stop training until the validation perplexity score does not improve for 5 epochs. The evaluation results are shown in Table 2. The perplexity (PPL) on all test domains have been improved. Specifically, test perplexity of MTNT'18 has an improvement of 28.05 (32.1% relative improvement) compared to the best baseline (Niu et al., 2020).

3.3 Ablation study

3.3.1 Comparison with human evaluation

We give a case study to compare the robustness of four language models trained on four different domains from the OPUS dataset (Tiedemann, 2012) using proposed robustness metrics. We combine MTNT'18, BIO'21, WMT'15 and IWSLT'17 test sets as a test pool, then subsample 50% of the test pool for 30 times. Next, we collect PPL scores on each subsampled bootstrap, and compute the mean and variance for the PPL score distribution. Fig-

ure 3 shows the normalized γ values against each corresponding epsilon value for the four language models. We can observe the γ values for the model trained by medical are much smaller than the values for other models, and the γ values for office are the highest. This shows that the model trained by medical is the most robust among all models, while the model trained by office is the least robust.

office	medical	medical	medical	YES
office	books	books	books	YES
books	medical	medical	medical	YES

Table 3: Robustness Metrics pair-wise comparison on each two models.

To evaluate how our robustness measures match human judgments, we compare the rank given by Figure 3 with the rank given by perplexity score and the rank given by human annotators, as shown in Table 4. Each human annotator is assigned with two language models selected at random. The human annotators do not know any details about the model or the training data used for each model. She/He can only use these models to get two generated sentences for the same input prompt. This step can be repeated as many times as possible until the human annotator decides which model is more *consistent* in its generations. The decision is based on consistency of generation quality but rather the quality itself. The results of pair-wise comparison between two language models are shown in Table 3. Our $(\alpha, \epsilon, \gamma)$-robustness perfectly aligns with decisions made by human annotators, while the rank based on perplexity score fails to match human evaluation results.

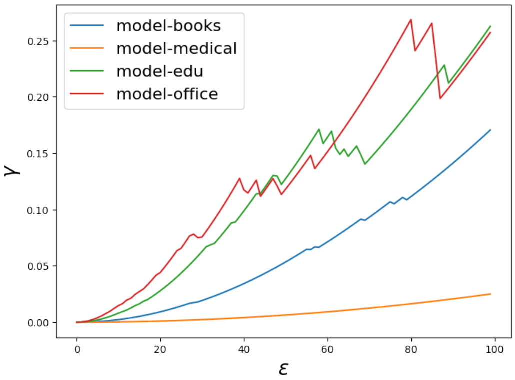

Figure 3: $(\alpha, \epsilon, \gamma)$-Robustness plot on four language models. "model-books" denotes the language model trained by the books domain from the OPUS dataset (Tiedemann, 2012)

3.3.2 Domain distance

Many data selection work use target domain knowledge to select best in-domain data samples that are close to target domain (Aharoni and Goldberg, 2020; Liu et al., 2019; Ma et al., 2019). Our method does not use target domain knowledge, thus, we question whether our selected data resembles target domain under such zero-knowledge setting. We follow Aharoni and Goldberg (2020) using DistilBert (Sanh et al., 2019) to embed all domain data, Penn Treebank data and our $(\alpha, \epsilon, \gamma)$-Robustness

Model	CE	PPL	rank$_{CE}$	rank$_{PPL}$	rankγ	rank$_{Human}$
edu	11.34	2474.16	1	1	3	3
books	12.03	4039.17	2	2	2	2
office	12.06	4181.39	3	3	4	4
medical	13.41	9426.04	4	4	1	1

Table 4: $(\alpha, \epsilon, \gamma)$-Robustness 100% agrees with human ranking, while perplexity (PPL) and cross entropy (CE) 25% agree with human. "office" means the model is trained on the office domain.

	BIO	MTNT	WMT	IWSLT
All	89.95	92.94	93.35	92.99

Table 5: Cosine similarity [%] between (row,column) data set. With zero-knowledge of four target domains, our method selects subsets of training data that are more close to the target domain.

selected PTB data into sentence embeddings and compute pairwise cosine similarity between the centroid of each domain. The result is shown in Table 5. With zero-knowledge of four target domains, our method selects subsets of training data that are more close to the target domain. Furthermore, we find the larger domain distance between the source domain and the target domain, the larger improvement will be, by computing the pearson correlation coefficient (0.83) between the domain distance and the relative improvement normalized by test set size.

4 Related Work

In previous years, a crucial direction of work on robustness of NLP models lies on the vulnerability of NLP models to input perturbations, such as crafted noises (Song et al., 2020; Boucher et al., 2022; Li et al., 2020; Schwinn et al., 2021). For instance, Cheng et al. (2018) proposes an adversarial stability training objective to enable neural machine translation models robust to input perturbations. Niu et al. (2020) evaluates robustness to input perturbations for neural machine translation. Compared to them, our approach handles new test inputs with distribution shifts from any unknown domains.

Some literature propose evaluation metrics for robustness from the perspectives of statistics or input perturbations (Weng et al., 2018; Niu et al., 2020; Mangal et al., 2019; Couellan, 2021). However, they either focus on the worst-case scenario of adversarial inputs or sampling single instances without considering the full distribution of the system performance.

5 Conclusion

We introduce probabilistic robustness rewarded proximal policy data optimization (PRoDO) framework to improve NLP model's generalization by selecting training data. Our framework is rewarded by the $(\alpha, \epsilon, \gamma)$-Robustness to measure an NLP model's performance consistency over multiple domains. Our experiments show the effectiveness of probabilistic robustness measure to enhance learning generalization and prediction accuracy. Our work also demonstrates a successful step towards general robustness evaluation and data selection without target domain insight.

6 Limitations

Time efficiency is one limitation of this work. For one thing, like other data selection work with reinforcement learning (RL), introducing RL requires convergence of the policy network and the value network, which takes quite a long time empirically. Referring to our time comparison results, our methods are roughly ten times slower than training with all source data directly. For another, our robustness measure requires the tuning process for hyperparameters α and ϵ, which also takes additional time.

Abstract

Masked language modeling (MLM) plays a key role in pretraining large language models. But the MLM objective is often dominated by high-frequency words that are sub-optimal for learning factual knowledge. In this work, we propose an approach for influencing MLM pretraining in a way that can improve language model performance on a variety of knowledge-intensive tasks. We force the language model to prioritize informative words in a fully unsupervised way. Experiments demonstrate that the proposed approach can significantly improve the performance of pretrained language models on tasks such as factual recall, question answering, sentiment analysis, and natural language inference in a closed-book setting.

1 Introduction

Pretrained language models (PLMs) such as BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), BART (Lewis et al., 2020), T5 (Raffel et al., 2020) use a Masked Language Modeling (MLM) objective during pretraining. However, a traditional MLM objective may not be optimal for knowledge-intensive tasks (Peters et al., 2019). It has been shown that language models can benefit from incorporating knowledge within the training objective in the form of entity embeddings (Peters et al., 2019; Zhang et al., 2019), knowledge retriever (Guu et al., 2020), knowledge embedding (Wang et al., 2021; Sun et al., 2020) or augmented pretraining corpora created from Knowledge Graphs (Agarwal et al., 2021). Despite their effectiveness, these approaches rely on existing knowledge bases and entity embeddings to incorporate knowledge within the training objective. These resources are expensive to construct and may not be available for all languages and domains (Huang et al., 2022).

In this work, we propose a pretraining approach that can achieve better performance on knowledge-intensive tasks without using any existing knowledge base. We combine two key strategies to influence MLM objective. Firstly, the tokens with higher informative relevance should be masked more frequently (Sadeq et al., 2022). Secondly, mistakes on informative tokens should be penalized more severely. The informative relevance of the tokens can be computed efficiently with a one-pass computation on the pretraining corpora. Experiments demonstrate that the proposed training strategy can help the language model achieve better performance on the factual knowledge recall benchmark LAMA (Petroni et al., 2019), extractive question answering (QA) benchmark SQuAD (Rajpurkar et al., 2016, 2018), prompt based sentiment analysis and natural language inference (NLI) tasks in AutoPrompt (Shin et al., 2020).

The key contribution of this work is proposing a completely unsupervised stand-alone MLM pretraining objective for language models that can significantly improve performance on knowledge-intensive tasks. Unlike prior works in the area, our method does not require existing knowledge bases to incorporate knowledge during pretraining. We make the code publicly available. [1]

2 Related Work

PLMs as knowledge bases It has been shown that large-scale PLMs such as BERT can be used as a knowledge base (Petroni et al., 2019, 2020). Prior works have focused on factual knowledge with regards to generative PLMs (Liu et al., 2021), multilingual setting (Jiang et al., 2020a), entities and query types (Heinzerling and Inui, 2021), fact checking (Lee et al., 2020).

Designing better prompts Jiang et al. (2020b) propose mining-based and paraphrasing-based methods for automatically generating prompts for improved factual recall performance. A similar

approach is explored by Zhong et al. (2021); Haviv et al. (2021); Qin and Eisner (2021). Shin et al. (2020) propose an approach for automatically creating MLM prompts for a diverse range of tasks such as sentiment analysis, natural language inference, relation extraction, etc.

Knowledge integration during pretraining Peters et al. (2019) use entity embeddings from existing knowledge bases and incorporate an entity linking loss jointly with an MLM loss to improve the factual recall performance of BERT. Similarly, Zhang et al. (2019); Wang et al. (2021); Févry et al. (2020); Sun et al. (2020); Liu et al. (2020) use entity representations or knowledge representation from existing knowledge bases to incorporate knowledge into the PLM. Guu et al. (2020) jointly pretrain a knowledge retriever along with a language modeling objective for knowledge integration. Agarwal et al. (2021) synthesize a text corpus from existing knowledge bases and use that during pretraining. Sun et al. (2019) use entity-level and phrase-level knowledge masking during training.

Knowledge modification after pretraining De Cao et al. (2021); Zhu et al. (2020) use constraint optimization for editing existing world knowledge within PLMs with minimal impact on the rest of the factual knowledge. Similarly, Verga et al. (2021) develop a fact injection language model architecture that allows easy integration of existing knowledge bases into PLMs without additional pretraining.

3 Methodology

We use MLM objective for pretraining, similar to prior works (Devlin et al., 2019; Liu et al., 2019; Lewis et al., 2020; Raffel et al., 2020). Given a sequence of tokens Z, a subset of tokens $X \subset Z$ is randomly sampled for replacement ($|X|/|Z| \approx 0.15$ in Devlin et al. (2019)). For the replacement candidates in X, 80% of the time the replacement is done with a special token `[MASK]`, 10% of tokens are replaced with a random token, and the other 10% of candidates are left unchanged (Devlin et al., 2019; Liu et al., 2019; Joshi et al., 2020). The task of the model during pretraining is to predict the original tokens from the modified input sequence. For a set of replaced tokens $X(x_1, x_2, ..., x_N)$ and their corresponding output tokens $Y(y_1, y_2, ..., y_N)$, the loss $\mathcal{L}_{MLM}$ is computed as follows:

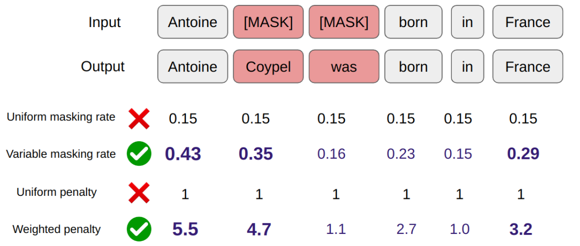

Figure 1: Simplified illustration of variable masking rate and weighted penalty

$$\mathcal{L}_{MLM} = -\sum_{i=1}^{N} \log \frac{e^{x_{i,y_i}}}{\sum_{v \in V} e^{x_{i,v}}} \tag{1}$$

Here, $x_{i,j}$ is the logit produced for output candidate j given input x_i and V is the vocabulary set. In traditional MLM loss computation, a uniform penalty is applied for all tokens within the vocabulary. In our work, we try to influence the MLM objective during pretraining to incorporate more factual knowledge. We differ from traditional MLM pretraining in two ways: **(a)** Instead of masking all tokens with equal probability, we allow some tokens to be masked more frequently if they have higher informative relevance, **(b)** We use weighted cross entropy loss to penalize mistakes on some tokens more severely if they have higher informative relevance. Simple illustrations of these two concepts are shown in Figure 1. We compute the loss as follows:

$$\mathcal{L}_{MLM} = -\sum_{i=1}^{N} w_{y_i} \log \frac{e^{x_{i,y_i}}}{\sum_{v \in V} e^{x_{i,v}}} \tag{2}$$

w_{y_i} is a penalty weight specific to a particular output token y_i. The magnitude of the weight is chosen based on the informative relevance of the tokens. A demonstration of this weighting is shown in Figure 1. Each token in the language model vocabulary has a unique masking rate and penalty weight associated with it. These values can be computed with a one-pass computation before pretraining.

In this context, the informative relevance of tokens represents how important a particular token is with regard to the factual knowledge. Tokens that are more important for factual knowledge (e.g. named entities) are expected to have a higher informative relevance. We use Pointwise Mutual Information (PMI (Fano, 1961)) to compute informative relevance in an unsupervised manner. We hypothesize that words that have high PMI with their

Figure 2: Informative relevance of tokens in a particular document, by computing row-wise summation of the PMI matrix of all token pairs

neighboring words tend to have higher informative relevance. Firstly, we compute word co-occurrence statistics for the pretraining corpus within a skip-gram window. Secondly, PMI between all word pairs within the vocabulary is computed. Thirdly, we consider the pairwise PMI between all words within a particular document in the form of a matrix (as shown in Figure 2), so that the row-wise sum in that matrix reflects the token-specific informative relevance within that document. Then informative relevance for a token is averaged across the corpus. Finally, the computed values are normalized and converted to token-specific masking rates and token-specific penalty weights. Those masking rates are used to create masked inputs and the penalty weights are then incorporated during MLM loss computation, as shown in Equation 2.

4 Experiments

4.1 Pretraining Setup

We use the Wikipedia corpus available in Hugging Face (Lhoest et al., 2021) for pretraining, using a wordpiece tokenizer with a vocabulary size of 100k. The vocabulary size is chosen to ensure the inclusion of most entities. Word co-occurrence statistics are computed using a skip-gram window size of 10. The size of the matrix that holds the PMI between words is $100k \times 100k$. The one-pass computation involving informative relevance of tokens takes around two hours and requires 11 GB of memory. The masking rate for individual tokens varies between 15%-50%, depending on their informative relevance. The average masking rate for all tokens is 19%. The penalty weights for tokens are normalized within the range $[1, 5]$. Training is done with Hugging Face Transformers (Wolf et al., 2020) on an AWS p3.8xlarge machine with 4 Nvidia V100 GPUs. Our model architecture is similar to BERT-base (Devlin et al., 2019) with 12 layers and a hidden dimension of 768. The overall batch size is 128 with a learning rate of 5e-5 and an AdamW optimizer (Loshchilov and Hutter, 2019). Training is done for 10 epochs with a maximum document length of 128. Unlike BERT (Devlin et al., 2019), we do not use the next sentence prediction objective during pretraining. Additionally, the increased masking rate and penalty weight only apply to whole-word tokens. For the subword tokens, we use the minimum masking rate of 15% and penalty weight of 1.

4.2 Evaluation Benchmarks

We use LAMA knowledge probes (Petroni et al., 2019) for evaluating the factual recall performance of the model. LAMA has around 70k samples across 46 factual relations. To evaluate the performance on extractive QA, we use SQuAD v1 and v2 (Rajpurkar et al., 2016, 2018). For zero-shot performance evaluation on closed-book QA, we use the SQuAD portion from LAMA (Petroni et al., 2019). For closed-book sentiment analysis and NLI, we use SST2 and NLI probes from AutoPrompt (Shin et al., 2020). We also report the performance of the models on GLUE (Wang et al., 2018).

4.3 Baselines

We train four models using the same corpus, tokenizer and hyper-parameter setting mentioned in Section 4.1: **(a)** BERT_{uu}: Similar to Devlin et al. (2019), it uses a uniform masking rate and uniform penalty across tokens. This is our baseline. **(b)** BERT_{uw}: uses a uniform masking rate and weighted penalty. **(c)** BERT_{vu} (Sadeq et al., 2022): uses a variable masking rate across tokens and uniform penalty. **(d)** BERT_{vw}: This is our proposed approach that combines both a variable masking rate and weighted penalty across different tokens.

4.4 Results and Discussion

Factual Recall and Zero-shot QA The model using the proposed pretraining approach (BERT_{vw}) significantly outperforms the baseline (BERT_{uu}) on factual recall tasks in LAMA (shown in Table 1). The relative improvement of Mean Reciprocal Rank (MRR) over the baseline is 17.5%, 6%, and 8.1% for ConceptNet, GoogleRE, and TREx respectively. The SQuAD portion of the LAMA benchmark is a set of zero-shot QA samples adapted in a closed-book template. In this task,

Model	LAMA (Petroni et al., 2019)				AutoPrompt (Shin et al., 2020)		
	ConceptNet	GoogleRE	SQuAD	TREx	SST2	NLI (3 way)	NLI (2 way)
BERT_{uu}	0.114	0.281	0.156	0.578	0.651	0.397	0.620
BERT_{uw}	0.120	0.289	0.169	0.592	0.655	0.439	0.676
BERT_{vu}	0.129	0.292	0.175	0.616	0.700	0.457	0.697
BERT_{vw}	**0.134**	**0.298**	**0.187**	**0.625**	**0.704**	**0.481**	**0.711**

Table 1: Factual Recall performance on LAMA, Sentiment Analysis and Natural Language Inference on AutoPrompt. The metrics used for LAMA and AutoPrompt are Mean Reciprocal Rank (MRR) and Accuracy respectively.

Model	SQuAD		GLUE (Wang et al., 2018)								
	v1 (2016)	v2 (2018)	CoLA	SST2	MNLI	QNLI	QQP	STSB	RTE	WNLI	MRPC
BERT_{uu}	69.96	83.22	**31.06**	88.30	79.42	87.72	89.77	85.41	**66.43**	42.25	87.78
BERT_{uw}	71.17	84.17	28.55	89.11	79.82	87.15	89.59	85.70	58.84	49.30	87.93
BERT_{vu}	71.17	85.07	29.11	89.79	80.02	88.21	**90.10**	85.60	61.37	54.93	88.29
BERT_{vw}	**72.61**	**85.28**	28.93	**89.91**	**80.25**	**88.49**	89.82	**85.82**	59.93	**56.34**	**88.32**

Table 2: Performance on SQuAD and GLUE development set. For SQuAD, we report the F1 score. We report the Matthews correlation for CoLA, Pearson correlation for STSB, and accuracy for other GLUE tasks. The fine-tuning parameters for SQuAD and GLUE can be found in Appendix B.

we achieve 19.9% relative improvement over the baseline.

Case studies on factual recall are shown in Table 3. There are two key observations in these case studies. Firstly, the proposed model (BERT_{vw}) is more likely to rank the ground truth label higher during knowledge probes. This helps the model achieve better overall MRR. Secondly, the proposed model is more likely to produce specific words given a particular context when the baseline is only producing generic words. For example, when we use the prompt 'During Super Bowl 50 the `[MASK]` gaming company debuted their ad for the first time', the top three candidates from the baseline model are comparatively common words such as 'computer', 'electronic', and 'American'. But the proposed model is able to produce more specific words associated with three gaming companies ('Nintendo, 'Walt', and 'Atari'), including the correct answer 'Nintendo'. Similar observation can be made with the probe 'The organization that runs the satellite that measured dust that landed on the Amazon is `[MASK]`', where the proposed model makes specific predictions with the given context, such as 'NASA', 'Brazil' and 'Amazon'. But the baseline can only produce generic words like 'unknown', 'the', and 'unclear'.

Closed-book Sentiment Analysis and NLI We use AutoPrompt (Shin et al., 2020) to evaluate the closed-book sentiment analysis and NLI performance of the system. AutoPrompt provides a way to convert certain NLP tasks into a template-based probing format. The advantage of this type of prompting is that it allows us to exploit the factual knowledge within language models without the limitations of fine-tuning (Wallat et al., 2020). The prompt contains the input, a placeholder for the answers, and a span of trigger words (prompt templates shown in Appendix C). The trigger words are tuned using the training dataset and then subsequently used during evaluation. The proposed system achieves 8.1%, 21.1%, and 14.7% relative improvement in accuracy over the baseline in sentiment analysis, 3-way NLI, and 2-way NLI respectively (Table 1).

Fine-tuning vs Prompt-tuning Our proposed model achieves better performance compared to the baseline when fine-tuned on the extractive QA benchmark SQuAD (Rajpurkar et al., 2016, 2018) and text classification benchmark GLUE (Wang et al., 2018). It outperforms the baseline on both SQuAD v1 and v2 tasks and seven out of nine GLUE tasks (shown in Table 2). However, the relative performance improvement with fine-tuning is not as significant as factual recall, zero-shot QA, or prompt-tuning scenarios. The reason behind this may be explained by the findings of Wallat et al. (2020). The main strength of our approach is the ability to store more factual knowledge during pretraining. However, Wallat et al. (2020) have

Table 3: Case Study from factual recall samples from LAMA (Petroni et al., 2019)

shown that the factual knowledge learned during pretraining may be lost during fine-tuning, limiting the advantage of our proposed system. On the other hand, relational probing, zero-shot QA, and prompt-tuning-based NLP tasks can exploit the additional knowledge of our model more effectively, leading to much better performance.

Ablation Study We investigate how much performance improvement is due to the variable masking rate as opposed to the weighted penalty during MLM pretraining. This can be found by comparing BERT$_{\text{uw}}$ with BERT$_{\text{vu}}$ (Table 1 and 2). In most cases, we find that a variable masking rate performs slightly better than a weighted penalty.

5 Conclusion

In this work, we propose a pretraining strategy that can be effective in storing factual knowledge within language models. The additional knowledge helps the model outperform previous approaches on a variety of knowledge-intensive NLP tasks, such as factual recall, zero-shot QA, closed-book sentiment analysis, and natural language inference. Our model also achieves better performance when fine-tuned on SQuAD and GLUE tasks. In the future, we aim to extend our work for text-to-text pretrained models such as T5 (Raffel et al., 2020).

Acknowledgements

This work was performed during the first author's internship at Intuit. We thank anonymous reviewers for providing their valuable feedback on this work.

Limitations

One limitation of the proposed system is that it under-performs compared to the baseline in some fine-tuning tasks, such as CoLA (Table 2). The proposed training objective reduces the importance of stopwords in the pretraining objective. This may have a negative impact on performance in tasks where the syntax is important. More investigation is needed to understand and mitigate this issue.

Ethics Statement

A potential concern for the proposed system is that this training strategy may amplify the existing toxic behavior or bias of the language model if the related keywords get prioritized in the training objective. Reducing the toxic or biased behaviors of the proposed model can be an interesting research direction for future work.

Learning to Ignore Adversarial Attacks

Abstract

Despite the strong performance of current NLP models, they can be brittle against adversarial attacks. To enable effective learning against adversarial inputs, we introduce the use of rationale models that can explicitly learn to ignore attack tokens. We find that the rationale models can successfully ignore over 90% of attack tokens. This approach leads to consistent and sizable improvements (∼10%) over baseline models in robustness on three datasets for both BERT and RoBERTa, and also reliably outperforms data augmentation with adversarial examples alone. In many cases, we find that our method is able to close the gap between model performance on a clean test set and an attacked test set and hence reduce the effect of adversarial attacks.

1 Introduction

Adversarial robustness is an important issue in NLP, asking how to proof models against confounding tokens designed to maliciously manipulate model outputs. As such models become more powerful and ubiquitous, research continues to discover surprising vulnerabilities (Wallace et al., 2019), demanding improved robustness methods.

A common defense method to combat adversarial attacks is adversarial training. Given knowledge of attack strategies, it constructs synthetic adversarial examples to augment clean examples during training (Zhang et al., 2020). Intuitively, the model will *implicitly* learn to ignore attacking tokens and become robust to that type of attack. In practice, however, this goal can be challenging through data augmentation alone.

In this study, we propose a simple yet effective adversarial training schema for additive attacks: *explicitly* training the model to ignore adversarial tokens. We do this by augmenting the underlying model with a rationale extractor (Lei et al., 2016) to serve as an input filter, and then training this extractor to ignore attacking tokens as an additional joint objective to overall label accuracy (Fig. 1).

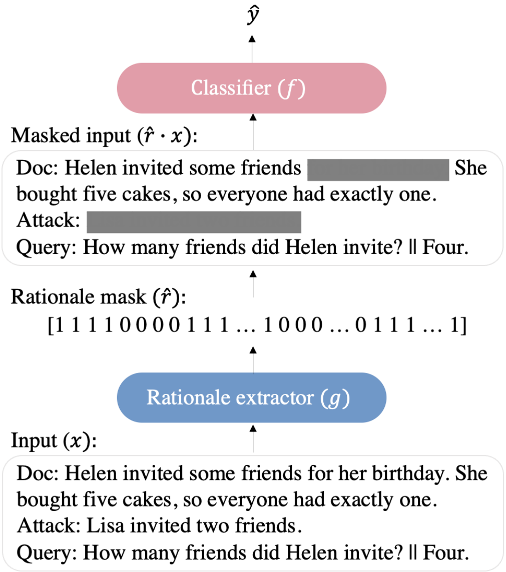

Figure 1: Example illustration of an ideal rationale model that is robust to added attack tokens. The rationale extractor filters out the confounding sentence (*"Lisa invited two friends"*) added by the adversary, and extracts the supporting spans (*"Helen invited some friends"* and *"She bought five cakes, so everyone had exactly one"*) to help the model deduce the correct answer (*"Four"*).

In addition to training the extractor to distinguish the attacking/non-attacking token dichotomy, we also explore the utility of human-provided explanations in this regard. In doing so, we ask: does learning from human rationales help the model avoid attending to attacking tokens?

Fine-tuning BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) on multiple datasets, we demonstrate that the additive attack proposed by Jia and Liang (2017) does reduce model accuracy, and that data augmentation with adversarial examples provides limited benefit in defending these models from this attack in most cases.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 2970–2984
May 2-6, 2023 ©2023 Association for Computational Linguistics

Our main results are that rationale-style models learn to ignore these attacks more effectively than only with data augmentation, leading to an improvement of ∼10% in accuracy on attacked examples compared to baseline models and an advantage of 2.4% over data augmentation alone, mostly recovering clean test performance. While human explanations may potentially improve the interpretability of these models, they are of limited use in improving this defense even further.

In summary, we offer three main contributions:

- We show that explicitly training an extractive rationale layer to ignore attack tokens is more effective than implicitly training a model via data augmentation with adversarial examples.
- We assess whether human-annotated rationales augment this defense, showing that they have only a limited benefit.
- We conduct an in-depth error analysis of differences between models, explaining some of the patterns we observe in our main results.

Our code is available at `https://github.com/ChicagoHAI/rationalization-robustness`.

2 Related Work

We build on prior work on adversarial robustness and learning from explanations.

Adversarial robustness. Adversarial attacks against NLP models seek to maliciously manipulate model output by perturbing model input. Zhang et al. (2020) present a survey of both attacks and defenses. Example attacks include character-level manipulations (Gao et al., 2018; Li et al., 2019), input removal (Li et al., 2017; Feng et al., 2018), synonym substitutions (Ren et al., 2019), and language model-based slot filling (Li et al., 2020; Garg and Ramakrishnan, 2020; Li et al., 2021). A distinction in attack types is whether the attack requires access to the model (Ebrahimi et al., 2018; Yoo and Qi, 2021; Wallace et al., 2019) or not (Alzantot et al., 2018; Jin et al., 2020). TextAttack (Morris et al., 2020) is a framework and collection of attack implementations. Our work focuses on the ADDSENT attack proposed by Jia and Liang (2017) in reading comprehension.

As interest in adversarial attacks has increased, so has interest in developing models robust to these attacks. A popular defense method is adversarial training via data augmentation, first proposed by Szegedy et al. (2014) and employed by Jia and Liang (2017) to bring their model *almost* back to clean test performance. A recent example in this vein is Zhou et al. (2020), which proposes Dirichlet Neighborhood Ensemble as a means for generating dynamic adversarial examples during training. Another popular approach is knowledge distillation (Papernot et al., 2016), which trains an intermediate model to smooth between the training data and the final model. Our work explores a new direction that explicitly learns to ignore attacks.

Learning from explanations. Recent work has sought to collect datasets of human-annotated explanations, often in the form of binary *rationales*, in addition to class labels (DeYoung et al., 2019; Wiegreffe and Marasović, 2021), and to use these explanations as additional training signals to improve model performance and robustness, sometimes also known as *feature-level feedback* (Hase and Bansal, 2021; Beckh et al., 2021).

An early work is Zaidan et al. (2007), which uses human rationales as constraints on an SVM. More recently, Ross et al. (2017) uses human rationales to penalize neural net input gradients showing benefits for out-of-domain generalization, while Erion et al. (2021) use a similar method based on "expected gradients" to produce improvements in in-domain test performance in certain cases. Katakkar et al. (2021) evaluate feature feedback for two attention-style models, finding, again, gains in out-of-domain performance, while Han and Tsvetkov (2021) use influence functions (Koh and Liang, 2017) to achieve a similar outcome. Where our study differs from most previous work is in using feature feedback for adversarial rather than out-of-domain robustness. A concurrent work by Chen et al. (2022) uses rationalization to improve robustness. The proposed method is similar to our work, but we explore supervision with attack tokens and achieve stronger robustness to additive attacks.

3 Adversarial Attacks and Datasets

In this paper, we focus on model robustness against the ADDSENT additive attack proposed by Jia and Liang (2017). The attack is designed for reading comprehension: consider each instance as a tuple of document, query, and label (d, q, y), where y indicates whether the query is supported by the document. The attack manipulates the content of the query to form an attack sentence (A) and adds A to the document to confuse the model. Specifically, ADDSENT proceeds as follows:

Query q:
FC Bayern Munich was founded in 2000.
Mutated Query $\hat{q}$:
DYNAMO Leverkusen Cologne was founded in 1998.
Modified Document d'
…has won 9 of the last 13 titles. DYNAMO Leverkusen Cologne was founded in 1998. They have traditional local rivalries with…

Figure 2: An example of the AddSent attack.

1. We modify the query q by converting all named entities and numbers to their nearest neighbor in the GloVe embedding space (Pennington et al., 2014). We flip all adjectives and nouns to their antonyms using WordNet (Miller, 1995) and yield a mutated query $\hat{q}$. If we fail to mutate the query due to not being able to find matching named entities or antonyms of adjectives and nouns, we skip the example.
2. We convert the mutated query $\hat{q}$ into an adversarial attack A using CoreNLP (Manning et al., 2014) constituency parsing, under a set of about 50 rules enumerated by Jia and Liang (2017). This step converts it into a factual statement that resembles but is not semantically related to the original query q.
3. The adversarial attack A is inserted at a random location within the original document and leads to a new tuple (d', q, y).[1]

The key idea behind the AddSent attack is that the mutations alter the semantics of the query by mutating the named entities and numbers, so that the attack contains words or phrases that are likely confusing to the model without changing the true semantics of the input. An example of the AddSent attack is given above.

The original approach includes an additional step of using crowdsourced workers to filter ungrammatical sentences. We do not have access to this manual validation process in all datasets. Occasionally, AddSent generates ungrammatical attacks but it nevertheless proves empirically effective in reducing the performance of our models.

Datasets. To evaluate our hypotheses on learning to ignore adversarial attacks, we train and evaluate models on the Multi-Sentence Reading Comprehension (MultiRC; Khashabi et al., 2018) and Fact Extraction and VERification (FEVER; Thorne et al., 2018) datasets. Both are reading comprehension datasets, compatible with the AddSent attack. For MultiRC, the query consists of a question and potential answer about the document, labeled as true or false, while for FEVER it is a factual claim about the document labeled as "supported" or "unsupported". Both datasets include *human rationales*, indicating which tokens are pertinent to assessing the query. Table 1 summarizes their basic statistics.

Dataset	Text length	Rationale length	Total size
MultiRC	336.0	52.0	32,088
FEVER	335.9	47.0	110,187
SQuAD	119.8	——	87,599

Table 1: Basic statistics of MultiRC, FEVER, and SQuAD.

In modeling these two datasets, we follow standard practice in appending the query to the end of the document with [SEP] tokens. We use train/validation/test splits prepared by the ERASER dataset collection (DeYoung et al., 2019). Because we are interested in relative differences between training regimes rather than absolute performance, we subsample the FEVER training set to 25% so that it is comparable to MultiRC for the sake of training efficiency.

Directly applying the synthetic AddSent attack to MultiRC and FEVER leads to occasionally ungrammatical adversarial examples due to incorrectly applied conversion heuristic or errors in constituency parsing. To alleviate this concern, we further evaluate on SQuAD (Rajpurkar et al., 2016), for which Jia and Liang provide an AddSent-attacked *evaluation* set that is re-written and approved by human workers. However, this dataset does not have human rationales. We again use the train/validation/test splits provided by Jia and Liang in our experiments.

4 Modeling

Our study assesses whether adding an explicit rationale extractor to a model and training it to ignore attack tokens results in a more effective defense than simply adding attacked examples to the training set. This comparison results in several combinations of model architectures and training regimes.

We denote each training instance as $(\boldsymbol{x}, \boldsymbol{r}, y)$: a text sequence $\boldsymbol{x}$ consisting of the concatenated document and query, a ground-truth binary rationale sequence $\boldsymbol{r}$, and a binary label y.

---

[1] We experimented with variants of inserting only at the beginning or the end. The results are qualitatively similar, so we only report random in this paper.

Augmented with attack data (Adv.)	None
	Non-attack (ADV. + ATK. SUP.)
	Human (ADV. + HUMAN SUP.)

Table 3: Summaries of rationale model setups.

Baseline models and training. We use BERT (Devlin et al., 2018) and RoBERTa (Liu et al., 2019) as basis models. In the baseline training condition we fine-tune these models as normal, evaluating them on both the original test set and a version of the test set where each item has been corrupted with the ADDSENT attack described above. We denote this condition as "NO ADV."

In the baseline adversarial training via data augmentation condition (denoted ADV.), we add ADDSENT-attacked versions of each training example to the training set on a one-to-one basis, allowing the model to train for the presence of such attacks. This represents a fairly standard baseline defense in the literature (Zhang et al., 2020).

Following prior adversarial robustness literature (Jia et al., 2019), we also consider a stronger baseline by augmenting the training set with K perturbed examples for each training example. For our main experiments, we use $K = 10$. This setting (denoted ADV.-10X) measures whether the baseline method implicitly adapts to the ADDSENT attack when abundant signal is provided.

Rationale model. To lend the baseline model an extractor capable of filtering out confounding tokens, we use the rationale model proposed by Lei et al. (2016). It comprises a rationale extractor g and a label predictor f (Fig. 1). The rationale extractor generates a binary predicted rationale $\hat{\boldsymbol{r}}$, which is applied as a mask over the input to the predictor via masking function m, producing a predicted label:

$$\begin{aligned} g(\mathbf{x}) &\rightarrow \hat{\boldsymbol{r}} \\ f(m(\mathbf{x}, \hat{\boldsymbol{r}})) &\rightarrow \hat{y} \end{aligned} \tag{1}$$

The two components are trained together to optimize predicted label accuracy as well as loss associated with the predicted rationale. In an unsupervised scenario, this loss punishes the norm of the predicted rationale, encouraging sparsity on the (heuristic) assumption that a sparse rationale is more interpretable. In this study, we rather consider the supervised scenario, where we punish $\hat{\boldsymbol{r}}$'s error with respect to a ground-truth rationale $\boldsymbol{r}$. However, we find empirically that the rationale sparsity objective is useful in combination with the rationale supervision objective, leading to the following joint objective function using cross-entropy loss $\mathcal{L}_{CE}$ with hyperparameter weights λ_1 and λ_2:

$$\mathcal{L}_{CE}(\hat{y}, y) + \lambda_1 \mathcal{L}_{CE}(\hat{\boldsymbol{r}}, \boldsymbol{r}) + \lambda_2 ||\hat{\boldsymbol{r}}||. \tag{2}$$

Adversarial training with rationale supervision. To introduce rationale supervision, we augment the training set with attacked examples on a one-to-one basis with original examples, similar to adversarial training. Moreover, we can change the ground-truth rationale to reflect the desired behavior for the model. We consider two options for this new ground-truth $\boldsymbol{r}$: (1) a binary indicator of whether a token is adversarial or not (ADV. + ATK. SUP.), and (2) the human-annotated rationale (ADV. + HUMAN SUP.), which also filters adversarial tokens. Table 2 contains an example illustrating the distinction between ADV. + ATK. SUP. and ADV. + HUMAN SUP.

Table 3 summarizes all the combinations of setups that we use in our study. For each of these setups, we test one rationale model using independent BERT modules for g and f, and one using independent RoBERTa modules for both. We present additional implementation details in Appendix A.

Taken together, these conditions address our three research questions: (1) Is adversarial training via rationale supervision more effective than via attacked examples? (2) Does training the model to emulate human explanation make it intrinsically more robust to attacks? (3) Do human explanations improve upon adversarial training with non-attack tokens as rationale supervision?

5 Experimental Setup and Results

We start by describing our experimental setup and evaluation metrics. We then investigate model performance with different training regimes and conduct an in-depth error analysis.

5.1 Experimental Setup

Our study compares whether rationale-style models are better at learning to explicitly ignore adversarial tokens than standard models via adversarial training. As we describe above, we train three variants of the standard classification model (NO ADV., ADV., ADV.-10X), and three variants of the rationale model (ADV. + ATK. SUP., HUMAN SUP., ADV. + HUMAN SUP.).

Exploring these 6 architecture/training combinations for three datasets (MULTIRC, FEVER, and SQUAD) and two underlying models (BERT and RoBERTa), we report results from all trained models in Table 4. We report relevant metrics on both the clean test set and the attacked test set for each model. For MULTIRC and FEVER, the metric we use is accuracy. Since SQUAD is a span extraction task, we report the Span F1 score instead. Performance on the attacked test set is our key measure of robustness.

Additionally, for the rationale models, we report the mean percentage of attack and non-attack tokens included in each predicted rationale, two metrics that help explain our accuracy results. The mean percentage of attack tokens included in the predicted rationale indicates the effectiveness of ignoring attack tokens: the lower the better.

5.2 Main Results

We focus our analysis on three questions:

1. Does adversarial rationale supervision on augmented data improve robustness over adversarial data augmentation alone?
2. Does human rationale supervision improve adversarial robustness over a standard model?
3. Does the addition of human rationales to adversarial training further improve robustness?

Table 4 summarizes the main results of the paper, showing the accuracy of each combination of architecture, training regime, underlying model and dataset. Looking at the attacked versus clean test set performance for the standard model, we see that **the ADDSENT attack is effective**, reducing accuracy on MULTIRC (∼6%), FEVER (∼10%), and SQUAD (∼12-24%).

Adversarial rationale supervision (ADV. + ATK. SUP.). Rationale models provide an interface for explicitly supervising the model to ignore attack tokens. Our *key* question is whether they can be used to improve the effectiveness of adversarial training. We first discuss the effect of data augmentation and then show that rationale models are indeed more effective at ignoring attack tokens.

Data augmentation with adversarial examples works, mostly. In almost all cases, data augmentation does result in improved performance on the attacked test set, improving +5.9% (FEVER) and +17.6% (SQUAD) for BERT, as well as +6.4% (MULTIRC), +9.7% (FEVER), and +9.4% (SQUAD) for RoBERTa. The exception is BERT on MULTIRC, where it causes a decrease of -1.0%. However, in only one case out of six does data augmentation with adversarial examples bring the model back to clean test performance (RoBERTa on MULTIRC, +0.3%).

Surprisingly, BERT on MULTIRC is the only scenario where the ADV.-10X augmentation significantly improves attack accuracy (4.3% improvement over ADV.). In all the other cases, adding more adversarial examples does not improve robustness and even leads to a 3.5% drop in SQUAD for RoBERTa. This result demonstrates that BERT and RoBERTa may not learn from adversarial examples alone.

Adversarial rationale supervision improves on adversarial training baselines in all cases. We see an improvement of +4.6% for BERT on MULTIRC, +2.9% for BERT on FEVER, +2.7% for BERT on SQUAD, +2.2% for RoBERTa on MULTIRC, +0.7% for RoBERTa on FEVER, and +1.0% for RoBERTa on SQUAD (2.4% on average). For the one case where adversarial data augmentation recovered clean test performance (RoBERTa on MULTIRC), adversarial rationale supervision actu-

Table 4: Model performance on clean and attacked test sets for MultiRC, FEVER, and SQuAD. Attacked$_\text{S}$ are synthetic attacks produced by AddSent, and Attacked$_\text{H}$ are attacks generated by human workers. We vary the level of augmentation for the standard classification models (No Adv., Adv., Adv.-10x). For rationale models, we control for the presence of adversarial training data and the type of rationale supervision: Adv. + Atk. Sup. treats non-attack tokens as rationale, and Human Sup. does not use adversarial training. Rationale models outperform the baseline classifiers across all attacked datasets.

Model	Training	MultiRC		FEVER		SQuAD	
		Attack %	Non-A %	Attack %	Non-A %	Attack %	Non-A %
BERT	Adv. + Atk. Sup.	1.4	98.4	0.2	96.7	27.8	99.7
	Human Sup.	87.5	8.2	66.7	17.8	- - -	- - -
	Adv. + Human Sup.	9.5	14.4	0.5	24.4	- - -	- - -
RoBERTa	Adv. + Atk. Sup.	6.0	96.7	0.9	95.8	16.1	99.0
	Human Sup.	92.4	12.6	60.0	12.2	- - -	- - -
	Adv. + Human Sup.	32.1	15.6	0.1	23.0	- - -	- - -

Table 5: Percentage of attack and non-attack (Non-A) tokens *included* in the predicted rationales. Lower is better for attack tokens. Arguably, a lower percentage of non-attack tokens is also better as it improves interpretability.

ally improves clean test performance by +2.5%.

The effectiveness of Adv. + Atk. Sup. is even more salient if we compare with No Adv. on attacked test: 3.6%, 8.8%, and 20.3% for BERT on MultiRC, FEVER, and SQuAD, 8.6%, 10.4%, and 10.4% for RoBERTa on MultiRC, FEVER, and SQuAD (10.4% on average).

The above findings remain true even when we compare our methods against the theoretically stronger baseline of Adv.-10x, where the training dataset is augmented with 10 perturbed examples for every training example. Our models trained with adversarial rationale supervision outperforms Adv.-10x across all datasets and models, and our best model outperforms the Adv.-10x baseline by 3.3% on average. This result highlights both the efficiency and the effectiveness of our method: with adversarial rationale supervision, BERT and RoBERTa achieve greater defense against the AddSent attack using 10% of the adversarial examples.

Interestingly, the adversarially-supervised rationale model demonstrates a strong ability to generalize knowledge learned from synthetic attacks to tune out human-rewritten attacks (+20.3% on SQuAD; recall we do not have human-rewritten attacks during training), indicating the potential of our method in a real-world scenario.

Table 5 explains this success. The adversarially-supervised rationale model includes 6% or fewer attacking tokens on MultiRC and FEVER, indicating that it did largely succeed in learning to occlude these tokens for the predictor. Additionally, both BERT and RoBERTa rationale models are able to tune out most human-generated attack tokens, ignoring over 70% of attack tokens while keeping 99% of the original text for both models.

Effect of human rationale supervision alone (Human Sup.). We find mixed evidence for whether human rationale supervision alone improves adversarial robustness. For BERT on MULTIRC and RoBERTa on FEVER, human rationale outperforms the standard classification model, but the opposite occurs for the other two model/dataset combinations.

Table 5 contextualizes this mixed result: the rationale model supervised solely on human rationales includes 60.0% to 92.4% of attack tokens in its rationale (compared to between 8.2% and 17.8% of non-attack tokens), indicating that it is largely fooled by the ADDSENT attack into exposing the predictor to attack tokens.

This result may be explained by the fact that human rationales for these datasets identify the part of the document that pertains particularly to the query, while the ADDSENT attack crafts adversarial content with a semantic resemblance to that same query. Hence, it is understandable that human rationale training would not improve robustness.

Human and adversarial rationale supervision (ADV. + HUMAN SUP.). Although human rationales alone may not reliably improve model robustness, a final question is whether human rationales can serve as a useful addition to adversarial training. Does training the model to both ignore adversarial tokens and emulate human explanations further improve robustness against the ADDSENT attack?

In two out of four cases, the performance of ADV. + HUMAN SUP. is equal to that of ADV. + ATK. SUP. Only for BERT on MULTIRC does ADV. + HUMAN SUP. result in an improvement, being the only configuration that brings performance back to that of clean test for that model, and dataset. For RoBERTa on MULTIRC, it actually weakens attacked test performance.

While these results are mixed, Table 5 shows that the model does at least achieve this result at a much lower included percentage of non-attack tokens ($\sim$20% vs. >95%), a concession toward model interpretability.

Overall, our results suggest that human rationales have limited effect in defending against adversarial attacks, but can be important in developing sparse (and potentially interpretable) models.

5.3 Error Analysis

To better understand the behavior of the models, we examine mistakes from BERT compared to explicitly training a rationale extractor on MULTIRC. We start with a qualitative analysis of example errors, and then discuss general trends, especially on why human rationales only provide limited benefits over ADV. + ATK. SUP. More in-depth analyses can be found in the appendix for space reasons, including a Venn diagram of model mistakes.

Qualitative analysis. We look at example errors of ADV. to investigate attacks that are confusing even after adversarial augmentation. Table 6 shows example outputs of the rationale models based on either non-attack tokens or human rationales.

Example 1 shows a case where models with explicit rationale extractors ignore attacks more effectively than ADV. In the attack sentence, "*tete didn't stay in*" is highly similar to the query, so a model likely predicts True if it uses the attack information. In comparison, both rationale models ignore the attack in label prediction, which enables them to make correct predictions.

Example 2 demonstrates that ADV. + HUMAN SUP. makes mistakes when it fails to include crucial information in rationales while avoiding attack tokens. ADV. + HUMAN SUP. predicts the wrong label because it misses information for the number of friends in its rationale. ADV. + ATK. SUP. gets this example correct because it can both ignore the attack and include the necessary information.

Finally, Example 3 shows an example where ADV. + HUMAN SUP. is better than ADV. + ATK. SUP. when generating rationales to ignore noises. ADV. + HUMAN SUP. includes attacks in rationale, but it is still able to predict the label because the attack is not confusing given the selected rationale. The generated rationale helps ADV. + HUMAN SUP. to avoid unnecessary information that may confuse the model. For example, the sentence with "picts" could confuse the model to predict True. On the other hand, ADV. + ATK. SUP. gets this example wrong, despite occluding all attack tokens.

More generally, we find that ADV. + HUMAN SUP. *tends to have high false negative rates*. When ADV. + HUMAN SUP. fails to extract good rationales, it tends to predict False due to missing information from the rationale. In contrast, ADV. + ATK. SUP. rarely occludes necessary information, so it does not suffer from the same issue.

ADV. + ATK. SUP. *is better than* ADV. + HUMAN SUP. *when human rationales are denser and passage length is longer (see Table 9 in the appendix).* We observe that denser human rationales usually comprise evidence from different parts of the passage. Since ADV. + ATK. SUP. predicts almost all non-attack tokens as rationale, they have

Table 6: Example outputs from Adv. + Atk. Sup. and Adv. + Human Sup. with BERT in MultiRC. Attack tokens are marked in red. True human rationales are marked in yellow, and predicted rationales are marked in blue. We only show tokens where generated rationales disagree with each other or with the human rationale/attack.

higher human rationale recall (98.6%) than Adv. + Human Sup. (57.6%). Thus, Adv. + Atk. Sup. generates higher quality rationales when human rationales are dense. Similarly, long passages prove difficult for Adv. + Human Sup.

In summary, these analyses highlight the challenges of learning from human rationales: it requires precise occlusion of irrelevant tokens while keeping valuable tokens, and must account for variance in human rationale and input lengths. These challenges partly explain the limited benefit of Adv. + Human Sup. over Adv. + Atk. Sup.

6 Concluding Discussion

In this study, we find that adding an explicit extractor layer helps a model learn to ignore additive adversarial attacks produced by the AddSent attack more effectively than conventional adversarial training via data augmentation.

This is an exciting result because it defeats an attack which is otherwise stubbornly effective against even copious adversarial data augmentation. It is a novel use for this type of explicit token relevance representation, which is more typically applied for model interpretability (Lei et al., 2016).

This makes it related to defenses like Cohen et al. (2019) which allow the model to reject inputs as out-of-distribution and abstain from prediction, but it differs in rejecting only part of the input, making a prediction from the remainder as usual.

Generality. As Carlini et al. (2019) note, it is easy to overstate claims in evaluating adversarial defenses. Hence, we note that our results pertain only to the ADDSENT attack, and perform favorably against a baseline defense in adversarial training via data augmentation. Since most adversarial training approaches assume the ability to *generate* a large number of synthetic attack examples, it is reasonable to further assume that we have access to the positions of the attacks. However, such knowledge about attacks may not be available in general. Nevertheless, the success of the rationale model architecture in learning to occlude adversarial tokens does hold promise for a more general defense based on a wider range of possible attacks and possible defenses by the extractor layer.

Utility of human rationales. We explore the possibility that human-provided explanations may make the model more robust against adversarial attacks. We mostly find that they do not, with the notable exception of BERT on MULTIRC, the only case in which the augmentation brings the model back to clean test accuracy. While it does provide an advantage of sparsity over supervision with non-attack tokens, this advantage alone may not justify the cost of collecting human explanations for robustness. Further understanding of human rationales and novel learning strategies are required for improving model robustness.

Future directions. A generalization of our approach might convert the "extractor" layer into a more general "defender" layer capable of issuing a wider range of corrections in response to a wider range of attacks. It could, for example, learn to defend against attacks based on input removal (e.g. Feng et al. (2018)) by training to recognize gaps in the input and fill them via generative closure. This defender could be coupled with a self-supervision style approach (e.g., Hendrycks et al. (2019)) involving an "attacker" capable of levying various types of attack against the model. We leave such a generalization for future work.

Limitations

Our work focuses on improving model robustness by explicitly ignoring adversarial attacks. In this work, we only explore a known type of adversarial attack (ADDSENT), and the performance of our method against unknown attacks is yet to be validated. Since our method uses rationalization as the underlying mechanism for ignoring tokens, it would take non-trivial work to make our method compatible with attacks in the form of token removal and flipping. Finally, we limit our experiments to the domain of QA, where the ADDSENT attack is naturally applicable.

Ethics Statement

Our work contributes to the line of research that focuses on improving the adversarial robustness of language models. We also explore novel ways to integrate human explanations into the training paradigm. We believe robustness to adversarial attacks is essential to the deployment of trustworthy models in the wild, and we hope this work brings current research a step closer to this objective. To avoid ethical concerns related to over-claiming results, we emphasize in both our concluding discussion and the limitations section that our work builds on the assumption that we know the type of attack and only experiments with ADDSENT. Furthermore, our approach tends to increase the computational cost compared to adversarial training both during training and inference. One should consider the tradeoff between robustness and computation.

Acknowledgements

We would like to thank members of the Chicago Human+AI Lab for feedback on early versions of this work, and Howard Chen for fruitful discussions on additive adversarial attacks and sharing findings of his concurrent work. We further thank all anonymous reviewers for their insightful suggestions and comments. This work was supported in part by an NSF grant, IIS-2126602, and gifts from Google and Amazon.

A Design choices and implementation details

We use the HuggingFace (Wolf et al., 2020) distributions of BERT and RoBERTa, and Pytorch Lightning (Falcon, 2019) for model training. Models are trained for a minimum of 3 epochs with early stopping based on a patience of 5 validation intervals, evaluated every 0.2 epochs.

In practice, we find it useful to pretrain the predictor layer f of the rationale model on full input before jointly training it with the extractor g. We observe that this trick stabilizes training and helps prevent mode collapse. In producing the predicted rationale, we automatically assign a 1 (indicating relevance) to every token in the query, so that they are always fully visible to the predictor and the effect of the extractor is in adjudicating which tokens of the document are used or ignored.

Traditionally, this style of rationale model produces binary predicted rationales via either reinforcement learning (Williams, 1992) or categorical reparameterization such as Gumbel Softmax (Jang et al., 2016). One argument for this approach is that binary rationales are more interpretable, leaving less ambiguity about the precise role of a given token in the model's output. Another argument is that transformer-based models like BERT don't have a native interpretation for partially-masked input, whereas fully-masked input can represent in-distribution modifications such as the [MASK] token substitution used in masked-LM pretraining.

However, we find that relaxing this binary constraint leads to better outcomes for adversarial training. Thus, our model produces predicted rationale $\hat{\boldsymbol{r}}$ by passing predicted rationale logits $\boldsymbol{\phi}$ through a sigmoid function. The masking function m we use is simply to multiplicatively weight $\boldsymbol{x}$ by predicted rationale $\hat{\boldsymbol{r}}$ during training (we discretize $\boldsymbol{r}$ during testing),

$$m(\boldsymbol{x}, \hat{\boldsymbol{r}}) = \hat{\boldsymbol{r}} \cdot \boldsymbol{x} \tag{3}$$

From a theoretical perspective, jointly optimizing the rationale extractor g and label predictor f should allow the model to predict rationale $\hat{\boldsymbol{r}}$ that is more adapted to the predictor. Separately optimizing both components implies that the rationale extractor does not get penalized for poor label prediction performance, and often leads to predicted rationale that is closer to human rationale $\boldsymbol{r}$. In our experiments, we include both training setups as a hyperparameter.

B Hyperparameters

For our experiments, we fine-tune both the rationale extractor g and predictor f for the rationale models from a pretrained language model. We fine-tune BERT components from a pre-trained *bert-base-uncased* model, and RoBERTa from a pre-trained *roberta-large* model. We use an Adam optimizer with with $\beta_1 = 0.9$ and $\beta_2 = 0.999$ for all experiments.

We find gradient accumulation helps with training stability of BERT and RoBERTa, and we report gradient accumulation as a hyperparameter for both models. Table 7 describes a list of hyperparameters we use for both BERT and RoBERTa. We do a grid search over all combinations of hyperparameters listed in table 7, and we report results of the model that achieves the highest performance on the original dev set.

C Computation Details

We ran our experiments on a mix of RTX 3090, A30 and A40 GPUs. All experiments combined take less than 300 GPU hours.

The rationale model has about two times the parameters of its base model. The BERT-based rationale model has 220 million parameters and RoBERTa-based rationale model has 708 million parameters. Both models can be trained on a GPU with 24GB of memory. Training the rationale model typically takes double the training time compared to the standard model. On a RTX 3090 GPU, training a BERT Rationale model for SQuAD takes

Parameter	BERT Rationale	RoBERTa Rationale
Batch Size	8	8
Learning Rate	2e-5	5e-6
Gradient Accumulation	10 batches	8 batches
Masking Strategy m	m_{zero}, m_{mask}	m_{zero}, m_{mask}
Prediction Supervision Loss Weight	1.0	1.0
Rationale Supervision Loss Weight λ_1	1.0	1.0
Sparsity Loss Weight λ_2	0.0, 0.1, 0.2, 0.3	0.0, 0.1, 0.2, 0.3
Jointly Optimized	True, False	True, False

Table 7: Hyperparameters used in parameter search and training.

about 4 hours, while training the standard BERT model takes 2.5 hours.

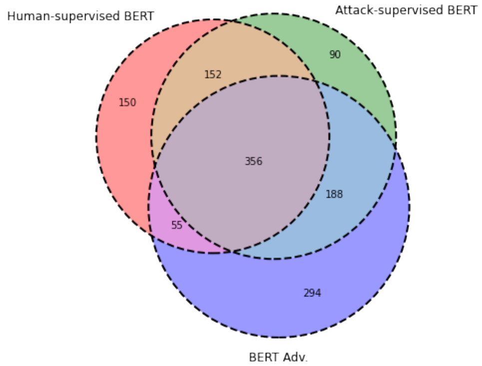

Figure 3: Venn diagram for errors by BERT (ADV.), human-supervised BERT, and attack-supervised BERT.

D Statistical Significance

Due to limited computational resources and a large number of experiment conditions, our experiments are not repeated across multiple random seeds. To verify the statistical significance of improvements of the top-performing rationale models against the strongest baselines, we report Wilcoxon signed-rank test results in Table 8. Note that we do not report SQUAD results due to the incompatibility of the statistical test with the metric (Span-F1). We find that for 3 out of 4 model-dataset pairs, the observed improvements of the rationale models over the baselines are highly significant.

E More Error Analysis

Easy examples have high jaccard similarity between human rationale and QUERY+ANSWER. All three models excel at these examples. High similarity should help models to find human rationale or generate rationales that mimic human rationale easily, but we also observe that the generated rationales do not necessarily provide the greatest alignment with human rationale for examples BERT rationale models get correct. For instance, rationale F1 is 53.9 for examples that human-supervised BERT gets correct and BERT gets wrong, which is smaller than rationale F1 (56.2) for examples both models get wrong. Notice that attack and human rationale are similar due to the attack generation technique, but this does not affect model performance because training with augmentation allows the rationale models to ignore attack tokens (attack recall = 89.3 and 97.4 for BERT rationale models). Likewise, we think BERT (ADV.) also benefits from the high similarity to identify important text areas and learns to ignore attacks from training augmentation.

BERT rationale models handle denser human rationale slightly better than BERT (ADV.). We define sparsity of $\mathbf{X}$ as the number of tokens in $\mathbf{X}$ divided by the total number of tokens in the input, so larger sparsity correspond to dense rationales. Counter-intuitively, all three models are bad at examples with the most dense human rationale. This can be accounted for by the fact that these are also examples where QUERY+ANSWER and human rationale have the least jaccard similarity: human rationale sparsity and the jaccard similarity has a Pearson's coefficient of 0.25 ($p < 0.001$). Thus, examples with denser human rationale are likely to contain confusing information for models. We find BERT rationale models can resist this confusion better than BERT (ADV.). For instance, human rationale sparsity = 0.167 when human-supervised BERT is correct bu BERT is wrong, and it is 0.165 when BERT is correct but BERT rationale is wrong.

Model	Dataset	Baseline Variant (Acc)	Rationale Variant (Acc)	p-value
BERT	MULTIRC	ADV.-10X (65.9%)	ADV. + HUMAN SUP. (69.4%)	1.0×10^{-4}
BERT	FEVER	ADV. (84.8%)	ADV. + ATK. SUP. (87.7%)	8.1×10^{-13}
RoBERTa	MULTIRC	ADV. (84.8%)	ADV. + ATK. SUP. (85.1%)	9.4×10^{-4}
RoBERTa	FEVER	ADV.-10X (93.4%)	ADV. + ATK. SUP. (93.2%)	0.18

Table 8: Wilcoxon signed-rank test for statistical significance of improvements of the top-performing rationale models over the strongest baselines across models and datasets.

	Input Length	Human Rationale Length
human-supervised BERT correct, attack-supervised BERT wrong	357.097	360.278
attack-supervised BERT correct, human-supervised BERT wrong	81.191	79.098

Table 9: Input and human rationale length of mistakes by attack-supervised BERT and human-supervised BERT.

F More Results on SQUAD

In Table 10, we report the F1 scores of BERT Classification and BERT Rationale models on four different evaluation sets: the original SQUAD development set dev, the synthetic attack set ADDSENTS, the human re-written and filtered attack set ADDSENTH and the human-generated, model-free attack baseline ADDONESENTH.

Similar to §5.2, we find the performances on the clean set (SQUAD dev) to be approximately equal across models and training schemes. We observe a slight drop (-0.4%) on dev accuracy when adding adversarial training to the BERT classification, which points to compromised learning on the original SQUAD task after adding adversarial examples. Without adversarial training, we observe roughly 38%, 24%, 15% performance decreases for ADDSENTS, ADDSENTH, ADDONESENTH, respectively. All three attacks lead to much more significant performance drops than the ADDSENT attack on MULTIRC and FEVER, which yields an approximate 6% performance drop. This observation is likely due to the differences in how the tasks are formulated across datasets: it is plausible that an additive attack such as ADDSENT is more effective on a span-extraction style QA task (SQUAD) than on answer classification style QA tasks (MULTIRC and FEVER).

Surprisingly, the synthetic attack ADDSENTS is more effective than human generated ADDSENTH prior to adversarial training. Since the ADDSENT attack works by mutating the query and adding a fake answer, the synthetic attack often appears syntactically similar to the query. On the other hand, human generated attacks in ADDSENTH often fits more naturally in the document and grammatically correct, but does not mirror the structure of the query. For a model that solves the QA task by simply looking for the best match of the query inside a document while skipping complex reasoning, it's conceivable that ADDSENTS leads to the greatest performance drop.

Since ADDSENTH and ADDONESENTH are attack examples re-written and filtered by humans, we use them as a proxy for understanding the model behavior in a real-world setting. We find the BERT Rationale model with attack rationale supervision significantly outperforms the BERT Classification baseline trained with adversarial augmentation (+2.7% on ADDSENTH, +2.2% on ADDONESENTH). Similar to findings in §5.2, we observe attack rationale supervision (ADV. + ATK. SUP.) as a more effective adversarial training method than adversarial data augmentation (ADV.). It is worth noting that the despite training on the synthetic attacks, the rationale model demonstrates strong ability to generalize knowledge learned from synthetic attacks to tune out human-rewritten attacks, which explains the strong performance on ADDSENTH and ADDONESENTH.

An apparent anomaly in Table 10 is the strong performance of BERT Classification on ADDSENTS (93.3%), which is even greater than the performance on the clean development set

Architecture	Training	dev	ADDSENTS	ADDSENTH	ADDONESENTH
Bert Classification	NO ADV.	86.4	48.7	62.8	71.2
	ADV.	86.0	93.3	80.4	81.9
	ADV.-10X	82.2	**95.9**	78.0	79.7
Bert Rationale	NO ADV.	**86.6**	47.7	62.0	70.4
	ADV. + ATK. SUP.	86.5	88.3	**83.1**	**84.1**

Table 10: F1 scores of BERT Rationale and Classification models on the SQUAD task.

(86.0%). During the ADDSENT attack, the answer is mutated into an incorrect, but similar phrase (e.g. Dallas Cowboys → Michigan Vikings). The presence of a mutated answer in the passage likely gives the model additional information on what the correct answer looks like, while the rationale model avoids utilizing this information to a much higher degree (88.3%) due to attack rationale supervision. This "mutated answer" signal is akin to spurious correlations in datasets, and our method helps the BERT rationale model ignore such spurious correlations a lot more effectively than the baseline BERT model.

Overall, these analyses shine light on the benefits of including rationale supervision in adversarial training. Our method achieves greater adversarial robustness in a close-to-real-world setting (ADDSENTH and ADDONESENTH) by generalizing from synthetic attacks.

Should You Mask 15% in Masked Language Modeling?

Abstract

Masked language models (MLMs) conventionally mask 15% of tokens due to the belief that more masking would leave insufficient context to learn good representations; this masking rate has been widely used, regardless of model sizes or masking strategies. In this work, we revisit this important choice of MLM pre-training. We first establish that 15% is not universally optimal, and larger models should adopt a higher masking rate. Specifically, we find that masking 40% outperforms 15% for BERT-large size models on GLUE and SQuAD. Interestingly, an extremely high masking rate of 80% can still preserve 95% fine-tuning performance and most of the accuracy in linguistic probing, challenging the conventional wisdom about the role of the masking rate. We then examine the interplay between masking rates and masking strategies and find that uniform masking requires a higher masking rate compared to sophisticated masking strategies such as span or PMI masking. Finally, we argue that increasing the masking rate has two distinct effects: it leads to more corruption, which makes the prediction task harder; it also enables more predictions, which benefits optimization. Using this framework, we revisit BERT's 80-10-10 corruption strategy. Together, our results contribute to a better understanding of MLM pre-training.[1]

1 Introduction

Pre-trained language models have transformed the landscape of natural language processing (Devlin et al., 2019; Liu et al., 2019; Raffel et al., 2020; Brown et al., 2020, *inter alia*). They are trained on vast quantities of text data and acquire rich and versatile language representations. Compared to autoregressive models, which always predict the next token in a sequence, masked language models (MLMs) like BERT (Devlin et al., 2019) predict a masked subset of input tokens based on the remaining context and are more effective on downstream tasks due to their bidirectional nature.

BERT chooses a 15% masking rate, based on the reasoning that models cannot learn good representations when too much text is masked, and the training is inefficient when too little is masked. Surprisingly, this important choice has been underexplored since 15% masking is used ubiquitously by BERT's successors (Liu et al., 2019; Joshi et al., 2020; Lan et al., 2020; He et al., 2021; Levine et al., 2021; Izsak et al., 2021), regardless of model sizes, masking strategies and optimization recipes.[2]

In this work, we aim to understand the impact of masking rates. We hypothesize that the optimal masking rate is not universally 15%, but should depend on other factors. First, we consider the impact of model sizes and establish that indeed larger models should adopt higher masking rates (§3). Specifically, we find that under an efficient pre-training recipe (Izsak et al., 2021), 40% outperforms 15% for BERT-large size models when fine-tuning on GLUE and SQuAD.

Interestingly, we observe that large models can still learn good representations even for very high masking rates: if we mask as much as 80% of input tokens and pre-trained models have a perplexity of more than 1000, the learned representations can still preserve more than 95% of fine-tuning performance on downstream tasks, compared to the default 15% masking (Table 1), and show considerable performance in linguistic probing (§4). This challenges common intuitions about masking rates and what models learn in MLM pre-training.

We then focus on the strategy of which tokens to mask as an additional factor to the optimal masking rate of MLMs (§5). We find that different masking rates should be used with different masking strategies, and the default uniform masking bene-

Table 1: Masked examples, validation perplexity (calculated in the same way as Devlin et al., 2019) of different masking rates on the one billion word benchmark (Chelba et al., 2013), and downstream task development performance (SQuAD: F1; accuracy for others). All the pre-trained models have a BERT-large architecture and are trained with the efficient pre-training recipe (§2.2). Full results are provided in Table 7.

fits more from higher masking rates than more sophisticated masking strategies such as span (Joshi et al., 2020; Raffel et al., 2020) and PMI masking (Levine et al., 2021); when all methods are considered at their optimal masking rate, uniform masking achieves competitive performance.

Finally, we propose to dissect the masking rate into two factors (§6): the *corruption rate*—how much of the context is corrupted (masked)—and the *prediction rate*—how much of the tokens the model predicts on. In MLMs, both are set to the masking rate. However, these two factors have opposing effects: higher prediction rates generate more training signals and benefit the optimization, while higher corruption rates make the prediction task more challenging by providing less context. To study the two factors independently, we design ablation experiments to disentangle corruption and prediction rates. Thus, we can verify that models benefit from higher prediction rates and suffer from more corruption. Using this framework, we also discuss BERT's practice of predicting on original or random tokens (the 80-10-10 rule), and we find that models usually perform worse under this corruption strategy (§7).

Together, our results demonstrate the overlooked impact of the masking rate in MLM pre-training and our analysis disentangles its opposing effects of corruption and prediction. We conclude by discussing the relation to work in other models and modalities (§8) and by highlighting several new avenues for efficient MLM in the future (§9).

2 Background

2.1 Masked Language Modeling

We focus on the widely popular masked language modeling (Devlin et al., 2019), a form of denoising-autoencoding, where a model is trained to restore a corrupted input sequence. Specifically, masked language models make independent predictions on the subset of masked tokens:

$$L(\mathcal{C}) = \mathop{\mathbb{E}}_{x \in \mathcal{C}} \mathop{\mathbb{E}}_{\substack{\mathcal{M} \subset x \\ |\mathcal{M}| = m|x|}} \left[\sum_{x_i \in \mathcal{M}} \log p(x_i | \tilde{x}) \right], \quad (1)$$

where one masks m (masking rate, typically 15%) percentage of tokens from the original sentence x and predicts on the masked token set $\mathcal{M}$ given the corrupted context $\tilde{x}$ (the masked version of x).

Different masking strategies have been proposed to sample $\mathcal{M}$: Devlin et al. (2019) randomly choose from the input tokens with a uniform distribution; Joshi et al. (2020) sample contiguous spans of text; Levine et al. (2021) sample words and spans with high pointwise mutual information (PMI). These advanced sampling strategies are adopted to prevent models from exploiting shallow local cues from uniform masking.

MLMs can encode bidirectional context while autoregressive language models can only "look at the past", and thus MLMs are shown to be more effective at learning contextualized representations for downstream use (Devlin et al., 2019). On the other hand, MLMs suffer a significant computational cost because it only learns from 15% of the tokens per sequence, whereas autoregressive LMs predict every token in a sequence. In this work, we focus on MLMs and study the effects of different masking rates on downstream performance.

2.2 Experiment Setup

We build most of our experiments on a recent efficient pre-training recipe—the 24hBERT recipe from Izsak et al. (2021)—by using which models can match BERT-base performance 6× faster (tested on 8×Titan-V). This efficient pre-training recipe allows us to run a large amount of experiments in an academic setup. Izsak et al. (2021)

---

[3] For our SQuAD v1.1 experiments, we continue training the models with 512-token sequences for 2,300 steps and report F1. See Appendix A for more details.

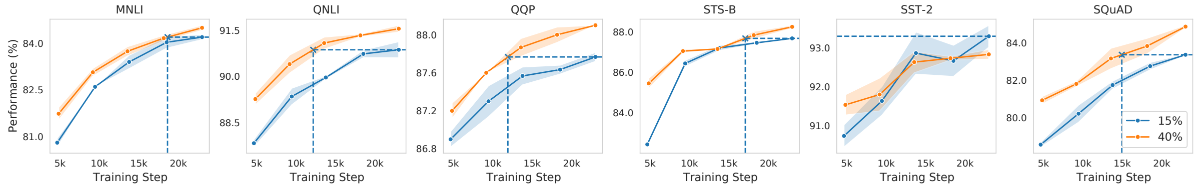

Figure 1: Downstream task development performance of `large` models trained with the efficient pre-training recipe, under masking rates of 15% and 40%. We highlight by the blue dotted line how long the 40% model takes to achieve the same performance as the 15% baseline; On QNLI and QQP, the 40% model achieved the same performance with almost half the training time.

make the pre-training faster by using a BERT-large architecture, a larger learning rate (2e-3), a larger batch size (4,096), a shorter sequence length (128)[4], and fewer training steps. We deviate from the 24hBERT with a few simple changes:

1. We adopt RoBERTa's BPE tokenizer (Sennrich et al., 2016; Liu et al., 2019) rather than BERT's tokenizer for it performs better in our preliminary experiments (see Appendix C).
2. Instead of adopting BERT's 80-10-10 token corruption strategy, we simply replace all the masked tokens with `[MASK]` by default. We find that the 80-10-10 corruption strategy does not perform better for most downstream tasks, as discussed in §7.

Following 24hBERT, we also do not perform next sentence prediction during pre-training, which was shown to hurt performance (Liu et al., 2019). We show hyperparameters for the efficient pre-training recipe and a comparison to other recipes (Devlin et al., 2019; Liu et al., 2019) in Appendix A. For models of different sizes, masking rates, and masking strategies, we follow the same recipe as our preliminary experiments show that it still performs the best.

We use fine-tuning downstream task performance as the measurement of how good the MLMs are, since fine-tuning is the predominant way to use pre-trained MLMs in downstream use. As evident from Table 1, pre-training metrics like perplexity do not correlate well with the downstream performance. We describe our downstream fine-tuning setting and hyperparameters in Appendix A.

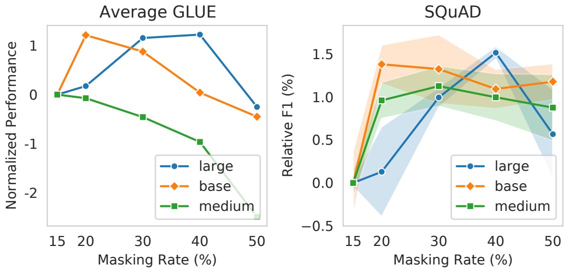

Figure 2: Impact of masking rates on different model sizes (`large`>`base`>`medium`).[5] We see that larger models favor larger optimal masking rates.

3 Larger Models Can Benefit From Higher Masking Rates

Devlin et al. (2019) choose the mysterious masking rate of 15%, for the belief that masking more leads to insufficient context to decode the tokens, and masking fewer makes the training inefficient, and this masking rate has been viewed as a constant across different model sizes. In this section, we train models of size `large` (354M parameters), `base` (124M parameters), and `medium` (51M parameters) for masking rates varying from 15% to 50%. The model configurations are listed in Appendix E.

Optimal masking depends on model sizes. The impact of masking rate across the model sizes is summarized by Figure 2, with detailed results given in Appendix E. We see that larger models possess higher optimal masking rates: on average, under the efficient pre-training recipe, `large` models take 40% as the optimal masking rate; `base` models take 20% and `medium` models take 15%. This shows that larger MLM models favor higher masking rates. We hypothesize that the additional capacity allows the large MLM to "handle" the more challenging task of predicting many tokens given less context.

Large models learn faster with 40% masking. We now compare the best performing masking rate 40% to the conventional 15% in more detail for our

---

[4] Izsak et al. (2021) only evaluate on GLUE tasks instead of SQuAD because of the short sequence length. We further train the model with 512 tokens for SQuAD in Table 1.

[5] For each task and each model size, *normalized performance* is calculated by $\frac{x - x_{15\%}}{\sigma}$ where $x_{15\%}$ is the performance of 15% masking rate and σ is the standard deviation across all masking rates. *Relative F1* is the F1 score subtracted by the 15% model F1.

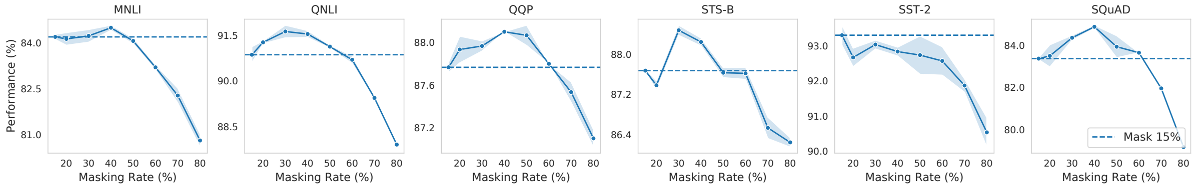

Figure 3: Impact of masking rates on `large` models with the efficient pre-training recipe. We see that on most tasks, higher masking rates outperform 15%. 40% is the optimal masking rate overall.

`large` model. First, we plot how the downstream task performance changes with different training steps in Figure 1. For most tasks, we see that 40% masking outperforms 15% consistently during the course of training, such that on QNLI and QQP, the 40% model can achieve the same performance as the 15% baseline with only half the training time. We also report the test results in Table 2, where again masking 40% outperforms 15% with our efficient pre-training recipe. However, the optimal masking rate can be task-dependent, as SST-2 performs better with 15% masking at the end of training. We acknowledge that the optimal masking rate may also depend on the training recipe. Since the efficient pre-training recipe uses a relatively small number of training steps, we explore training for over 4× more steps, as well as training with a more expensive recipe from RoBERTa (Liu et al., 2019), and we find in Appendix D that using a 40% masking rate still performs well, achieving similar performance to the 15% masking rate. The experiments in the remaining sections of this paper are all based on large models.

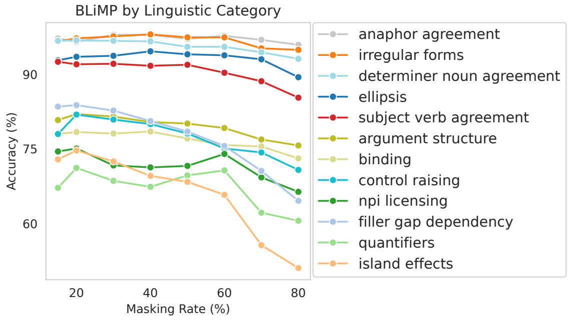

Figure 4: Evaluating our models on the BLiMP benchmark (Warstadt et al., 2020) using pseudo log-likelihood scoring (Salazar et al., 2020).

4 MLMs in High-Masking Regimes

The success of masking 40% over 15% motivates us to explore what happens at even larger masking rates. Therefore, we pre-train additional `large` models with masking rates of up to 80%. We consider the question of what representations an MLM can learn with such limited input as the last masked sentence in Table 1, which is hard to decipher even for a human. While He et al. (2022) recently pioneered such high masking rates in the vision domain, and they reason that images are natural signals with heavy redundancy, while language is highly semantic and information-dense. To our knowledge, nobody has examined such high masking rates in masked language modeling before.

MLMs learn with extreme masking. We first confirm in Table 1 that the validation perplexity when pre-training with an 80% masking rate is extremely high (>1,000), which suggests that the MLM is unable to reconstruct corrupted inputs with independent token predictions. Therefore our setting differs from vision, where good reproductions are possible with high masking rates (He et al., 2022). Nevertheless, we find that MLMs can surprisingly still learn good representations: Figure 3 shows the performance of the models fine-tuned on a range of tasks, and we observe that pre-training with an 80% masking rate can retain 95% of fine-tuning performance, which is substantially better than fine-tuning from a random initialization, which is reported in Appendix B.

We hypothesize that MLMs at such high masking rates may be understood as a powerful skip-gram model (Mikolov et al., 2013), e.g., masking 80% of a 128 token sequence still learns skip-grams of length up to 26. Furthermore, when compared to the simple word2vec model, our Transformer models have access to positional information for each context token and prediction.

Analysis of linguistic probing. Besides downstream performance, we study the models' linguistic abilities by evaluating them on the BLiMP benchmark (Warstadt et al., 2020). We employ zero-shot pseudo log-likelihood scoring (Salazar et al., 2020), where a score is computed by masking each token individually, which is a greater distri-

	MNLI-m/mm	QNLI	QQP	RTE	SST-2	MRPC	CoLA	STS-B	SQuAD
Masking 15%	84.2/83.4	90.9	70.8	73.5	**92.8**	88.8	**51.8**	87.3	88.0
★ Masking 40%	**84.7/84.0**	**91.3**	**70.9**	**75.5**	92.6	**89.8**	50.7	**87.6**	**89.8**

Table 2: The test results on the GLUE benchmark with `large` models, the efficient pre-training recipe (Izsak et al., 2021), and with 15% or 40% masking rates. For RTE, MRPC, and STS-B we fine-tune from the MNLI model following convention set by Phang et al. (2018). For SQuAD v1.1, we take the same setting as Table 1.

butional shift from higher masking rates. We show our results in Figure 4. We find that most linguistic phenomena are acquired evenly across masking rates from 15% to 60%, but they are still captured well by an MLM trained with 80% masking—which on average preserves 90% of the probing accuracy of the 15% model baseline. However, some categories such as filler gap dependencies and island effects show clear trends that performance deteriorates with higher masking rates—although it remains unclear to what extent such linguistic knowledge is required by downstream tasks in GLUE (Sinha et al., 2021). Overall, our results suggest that useful linguistic knowledge can be learned from a "patchy" training signal.

5 Masking Rates vs. Masking Strategies

Devlin et al. (2019); Liu et al. (2019) use uniform sampling for selecting which tokens to mask. Subsequent work showed that adopting more sophisticated masking strategies—such as span masking or PMI masking—can outperform uniform masking on a range of downstream tasks (Joshi et al., 2020; Levine et al., 2021). The argument for adopting advanced masking is that uniform masking enables models to exploit shallow local cues (Levine et al., 2021). An example is given by "`[MASK]` Kong": the model can easily predict "Hong" without using more context. However, all the previous studies used a constant 15% masking rate regardless of masking strategies, which raises the question of whether the conclusions still hold with a higher masking rate.

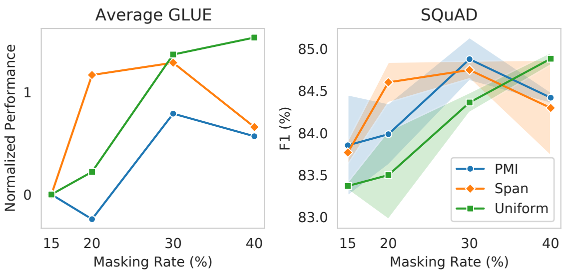

Figure 5: Performance of different masking strategies trained with different masking rates (efficient pre-training recipe, `large` models).

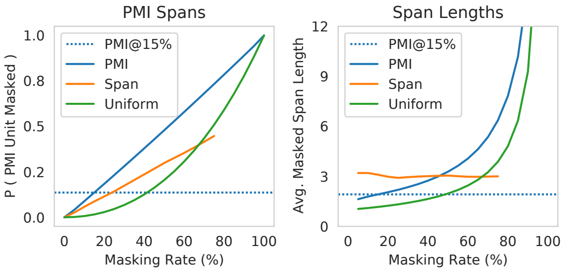

Figure 6: Higher masking rates increase the probability that an entire PMI span is masked (left) under different masking strategies. Uniform masking with a 40% rate masks as many PMI spans as regular PMI masking at 15%. Masks form longer spans for higher masking rates in uniform sampling, while the average length is fixed at 3 for T5-style span masking (which cannot be enforced for very high masking rates).

We experiment with multiple masking strategies as an additional factor for the optimal masking rate in `large` models. Figure 5 shows the results of uniform masking, T5-style span masking (Raffel et al., 2020)[6], and PMI masking (Levine et al., 2021) under masking rates from 15% to 40%. We see that (1) for all masking strategies, the optimal masking rates are higher than 15%; (2) the optimal masking rates for span masking and PMI masking are lower than that of uniform masking; (3) when all strategies adopt the optimal masking rates, the uniform masking achieves similar and even better results compared to the advanced strategies. We also remark that, when masking with 15%, simply increasing the masking rate can be a more effective way to increase performance on SQuAD than switching from uniform masking to another more advanced strategy. More fine-grained results with these masking strategies are included in Appendix E.

Interestingly, higher masking rates naturally increase the chance of masking neighbouring co-

---

[6] Span maskings in Raffel et al. (2020) and Joshi et al. (2020) differ in sampling procedures and we follow Raffel et al. (2020) for implementation simplicity.

m_{corr}	m_{pred}	**MNLI**	**QNLI**	**QQP**	**STS-B**	**SST-2**

10%	40%	86.3↑	92.3↑	88.3↑	88.9↑	93.2↑
5%	40%	86.9↑	92.2↑	88.5↑	88.6↑	93.9↑

Table 3: Corruption vs. prediction. We take 40% masking as the baseline model (standard deviation reported), disentangle m_{corr} and m_{pred}, and manipulate each independently. The trend is clear: more prediction helps and more corruption hurts.

occuring tokens, similar to the effect of the advanced masking strategies. We consider the masked tokens over one epoch of training, and count the number of PMI n-grams (e.g., "Hong Kong") that were completely covered by different masking strategies. Figure 6 shows that raising the masking rate from 15% to 40% results in an 8-fold increase in the chance of masking a PMI n-gram under uniform masking and gives a value comparable to PMI masking at 15% masking rate. Similarly, higher masking rates also make the masked tokens form longer spans. However, at a given masking rate, uniform masking remains an easier task than span masking or PMI masking—it appears reasonable for uniform masking to admit a higher optimal masking rate for a given model capacity.

6 Understanding Masking As Corruption and Prediction

In this section, we analyze how masking rates affect the pre-training process of MLMs, through two distinct perspectives: task difficulty and optimization. We identify that the masking rate m determines two import aspects of the pre-training problem: the *corruption* rate m_{corr} and the *prediction* rate m_{pred}. m_{corr} is the proportion of tokens that are erased from the input sequence—typically by substituting `[MASK]`. m_{pred} is the proportion of tokens that the models predict, and each of those tokens contributes to the cross-entropy loss.

In Eq. (1), m_{corr} controls how much content is corrupted in $\tilde{x}$ compared to the original sentence x, and m_{pred} controls the number of predictions in the set $\mathcal{M}$. Usually, both the corruption and the prediction rates are tied to the masking rate, i.e., $m_{\text{corr}} = m_{\text{pred}} = m$, but they may impact representation quality differently.

m_{corr} controls task difficulty. Masked language modeling attempts to learn a conditional probability distribution over the vocabulary given the corrupted context $p(\cdot \mid \tilde{x})$ during pre-training. If a larger proportion of the input is corrupted, a token prediction is conditioned on fewer context tokens, making predictions harder and more uncertain.

m_{pred} affects optimization. Predicting more means the model learns from more training signals, so higher prediction rates boost the model performance. From another perspective, each prediction at each masked token leads to a loss gradient, which is averaged to optimize the weights of the model. Averaging across more predictions has a similar effect to increasing the batch size, which is proved to be beneficial for pre-training (Liu et al., 2019).

Experiments. In masked language modeling, both m_{corr} and m_{pred} are determined by the overall masking rate. To study how m_{corr} and m_{pred} affect the downstream performance independently, we design a simple ablation experiment to disentangle them:

1. If $m_{\text{pred}} < m_{\text{corr}}$, we mask m_{corr} of tokens and only make predictions on m_{pred} of the tokens. This can be implemented without additional cost. For example, with $m_{\text{corr}} = 40\%$ and $m_{\text{pred}} = 20\%$, we mask 40% and only predict on 20% tokens.

2. If $m_{\text{pred}} > m_{\text{corr}}$, we duplicate each sequence $\lceil \frac{m_{\text{pred}}}{m_{\text{corr}}} \rceil$ times and mask disjoint sets of m_{corr} of the tokens in different sequences. For example, with $m_{\text{corr}} = 20\%$ and $m_{\text{pred}} = 40\%$, for each sentence, we do twice 20% masking on different tokens and predict on all the masked tokens—this leads to a 20% corruption but a 40% prediction on each sequence. Note that this ablation takes $\lceil \frac{m_{\text{pred}}}{m_{\text{corr}}} \rceil$ times longer because we do multiple passes on every sequence, and is not efficient in practice.

Table 3 shows the ablation results with disentangled m_{corr} and m_{pred}. We see that (1) fixing the m_{corr} as 40%, lowering the m_{pred} from 40% to 20% results in a consistent drop on downstream tasks, showing that more predictions lead to better performance; (2) fixing the m_{pred} as 40%, lowering the m_{corr} leads to consistently better performance, suggesting that lower corruption rates make the pre-training task easier to learn and are better for pre-training. Though we see that the performance gain by lowering m_{corr} from 10% to 5% is much smaller than that by lowering m_{corr} from 40% to 20%, suggesting a diminishing marginal

	MNLI	QNLI	QQP	STS-B	SST-2
40% mask	$84.5_{0.1}$	$91.6_{0.1}$	$88.1_{0.0}$	$88.2_{0.1}$	$92.8_{0.1}$
+5% same	84.2↓	91.0↓	87.8↓	88.0↓	93.3↑
w/ 5% rand	84.5	91.3↓	87.9↓	87.7↓	92.6↓
w/ 80-10-10	84.3↓	91.2↓	87.9↓	87.8↓	93.0↑

Table 4: Impact of substituting masks with random/same tokens. "+5% same": do extra 5% same token predictions. "w/ 5% rand": use mask for 35% mask tokens and random tokens for 5% . "w/ 80-10-10": for the 40% masked tokens, 10% are same token predictions and 10% are random token corruptions.

return of reducing the corruption rate. (3) comparing $m_{\text{corr}} = 20\%, m_{\text{pred}} = 20\%$ and $m_{\text{corr}} = 40\%, m_{\text{pred}} = 40\%$, we see that the gain brought by more predictions transcends the drawback of more corruption, leading to better performance.

The ablation shows that when we tune the masking rate, we are tuning the corruption rate and the prediction rate together, which have antagonistic effects. The final outcome is decided by which rate weighs more—the model benefits from higher masking rates if the hindrance brought by high corruption is surpassed by the advantage from predicting more. Many factors may affect the balance between the two—for example, model sizes and masking strategies as we discussed in §3 and §5.

7 Revisiting BERT's Corruption Strategy

Devlin et al. (2019) suggest that it is beneficial to replace 10% of `[MASK]` tokens with the original token (*same token predictions*) and 10% with random tokens (*random token corruptions*). Since then, this 80-10-10 rule has been widely adopted in almost all the MLM pre-training work (Liu et al., 2019; Joshi et al., 2020; He et al., 2021). The motivation is that masking tokens create a mismatch between pre-training and downstream fine-tuning, and using original or random tokens as an alternative to `[MASK]` may mitigate the gap. With our corruption and prediction framework, we revisit the two kinds of mask replacements in the 80-10-10 rules and empirically verify whether they are beneficial to downstream performance.

Same token predictions. The loss from same token predictions is very small and should be regarded as an auxiliary regularization. Thus, same token predictions should neither count towards the corruption nor to the prediction—they do not corrupt the input and contribute little to learning.

Random token corruptions. Replacing with random tokens contribute to corruption and prediction rate, as the input is corrupted and the prediction task is non-trivial. In fact, we find that the loss is slightly higher on random tokens compared to `[MASK]`, as (1) the model needs to decide for all tokens whether the information at the input is from a corruption or not, and (2) predictions need to be invariant to large changes in the input embeddings.

Ablation experiments. We adopt the $m = 40\%$ model using only `[MASK]` replacements as the baseline, on top of which we add three models:

1. "+5% same": we mask 40% of tokens but predict on 45% of tokens. Adding same token predictions does not change m_{corr} or m_{pred}.
2. "w/ 5% random": we mask 35% of tokens and randomly replace another 5% of tokens, predicting on 40% in total.
3. "80-10-10": the original BERT recipe. Due to same token predictions, $m_{\text{corr}} = m_{\text{pred}} = 36\%$.

As shown in Table 4, we observe that same token predictions and random token corruptions deteriorate performance on most downstream tasks. The 80-10-10 rule performs worse than simply using all `[MASK]`—with the exception of SST-2, where same token predictions are beneficial. Overall, our results suggest that in the fine-tuning paradigm, the model can adapt to full, uncorrupted sentences, regardless of the use of alternative corruption strategies in pre-training. Therefore, we suggest to use only `[MASK]` for MLM pre-training. We also present an analysis based on information flow (Voita et al., 2019) in Appendix G.

8 Related Work

Masking rates and masking strategies. There exist a few works on studying the impact of masking rates, among which Liao et al. (2020) show that dynamically sampling the masking rate from 0% to 100% for each sequence can improve MLM's downstream performance as well as the ability as a generation model. On the other hand, masking strategies are heavily explored for both pre-training (Joshi et al., 2020; Raffel et al., 2020; Levine et al., 2021) and intermediate pre-training (Ye et al., 2021) without considering the effect of masking rates.

"Unrealistic" MLM training. A recent line of work shows that linguistically implausible MLM objectives can achieve competitive or non-trivial downstream performance, e.g., training with shuffled word order (Sinha et al., 2021), with randomly generated sequences (Krishna et al., 2021), or predicting only the first character of masked tokens (Yamaguchi et al., 2021; Alajrami and Aletras, 2022). These studies echo our findings that even an “unrealistical” high masking rate can still lead to good downstream results.

Masking in other language models. Besides MLMs, there are other pre-training schemes, namely autoregressive language models (Radford et al., 2018; Brown et al., 2020) and sequence-to-sequence (seq2seq) language models (Raffel et al., 2020; Lewis et al., 2020). Similar to MLMs, seq2seq models corrupt text with a masking rate, but they predict with an autoregressive decoder and are fine-tuned in different ways; Song et al. (2019) also point out that masking rates control whether seq2seq models are closer to encoder-only MLMs (masking less) or decoder-only autoregressive LMs (masking more). Thus, we expect the masking rate studies in seq2seq models to draw a different conclusion from ours (Raffel et al., 2020; Tay et al., 2022b). Besides, Tay et al. (2022a) show that pre-training metrics are not correlated with downstream performance, echoing our findings that perplexity does not correlate with fine-tuning results.

ELECTRA (Clark et al., 2020) uses a smaller MLM to fill in 15% of the blanks and trains a model to distinguish whether a token was generated by the MLM or not. Despite the complicated training procedure, the main motivation of ELECTRA is to improve the training efficiency by predicting on 100% of tokens. Interestingly, we find that the corruption rate in ELECTRA becomes very low towards the end of training—the average corruption rate is roughly only 7%, but the replacements are “hard” negatives generated by the smaller MLM. We leave the study of its connection to corruption and prediction rates as future work.

Masking in other modalities. Recently, a number of works extend MLM training to images and videos and demonstrate strong pre-training results (He et al., 2022; Zhou et al., 2022; Feichtenhofer et al., 2022; Tong et al., 2022) . They adopt extremely high masking rates (e.g., 75% on images and 90% on videos) compared to their language counterparts, with the argument that images and videos are highly information redundant. Baevski et al. (2020) propose a similar style masked model in speech and adopt a masking rate of around 50%.

9 Conclusion & Discussion

In this work, we conduct a comprehensive study on the masking rates of MLMs. We discover that 15% is not universally optimal, and larger models should adopt a higher masking rate. We also find that masking strategies should be considered together with masking rates, and uniform masking needs a higher masking rate than more sophisticated masking strategies. We gain a better understanding of masking rates by disentangling them as corruption rates and prediction rates and analyze the 80-10-10 corruption strategy that are widely used in BERT models. Based on our findings, we discuss the implications of high masking rates and future directions of efficient MLM pre-training:

Implications on higher masking rates. A direct takeaway from our findings is that larger models may adopt higher masking rates for better sample efficiency. Figure 1 shows that a large model with 40% masking can achieve comparable results to a 15% baseline on several tasks with half the training time. Larger models also exhibit faster convergence for a given computational budget: Li et al. (2020) suggest it is more efficient to train larger models for fewer steps, as opposed to training smaller models for longer. This can be combined with higher masking rates for better sample efficiency.

Separating masked and unmasked tokens. The training efficiency can potentially benefit from encoding masked and unmasked tokens separately, where masked tokens use a much lighter-weight module. If a high masking rate is taken, this can significantly reduce the training cost due to the shorter input to the encoder. A similar approach has been explored by masked autoencoders in vision (He et al., 2022), where 75% of the input patches are masked and removed from the input of the heavy encoder to achieve a $4.1\times$ speedup. Recently, Liao et al. (2022) have applied these architectural improvements to natural language pre-training, and together with a high masking rate can accelerate MLM by a third of the pre-training budget.

Disentangling corruption and prediction. Models perform better when trained with lower corruption rates and higher prediction rates. However, in standard MLMs, those two factors are always tied to the masking rate. Methods which can encode a sequence once and then efficiently predict many small sets of masks, for example by manipulating the attention, could substantially accelerate masked language modeling pre-training.

Limitations

(1) Our analysis of masking rates applies to a specific type of pre-training method, masked language modeling. We are also interested in studying masking rates in other pre-trained methods, e.g., seq2seq models and ELECTRA, and leave it for future work. (2) While we have shown how the optimal masking rate depends on model size and masking strategy, there may be additional factors, such as the vocabulary size, pre-training corpus or language family. In particular, our experiments focus on English, but languages with different structural and morphological features may have lower or even higher optimal masking rates, or rely more on advanced masking strategies. (3) We consider a well-established yet relatively small set of downstream tasks, which do not benchmark domain-specific knowledge or more advanced reasoning skills. (4) Due to the expensive nature of our pre-training experiments, we were not able to train multiple pre-trained models over multiple seeds. (5) Finally, our findings point out several promising directions but the paper primarily aims to study and understandthe impact of masking rates with respect to different factors. We leave exploring better architectures and methods for efficient pre-training to future work.

Ethical Considerations

Large language models can exhibit various kinds of stereotypes, as they capture societal biases encoded in the training data. These associations are not detected by standard GLUE or SQuAD evaluation. We do not expect that simple modifications of masking rates can make progress towards solving these problems. Language model pre-training is also computationally expensive, which comes at a significant environmental cost. Furthermore, it makes re-production and follow-up research difficult within an academic context. We reduce the computational requirements by following and promoting an efficient pre-training recipe and our findings point to future research for efficient MLM.

A Experiment Setup

A.1 Pre-training

We implement our pre-training work based on `fairseq` (Ott et al., 2019). To further speed up pre-training, we integrate the `DeepSpeed` (Rasley et al., 2020) Transformer kernel for speedup.

We keep the other setting the same as the 24hBERT (Izsak et al., 2021), except that we use the RoBERTa tokenizer (Liu et al., 2019) and we do not adopt the 80-10-10 rule. We train our model on the English Wikipedia and BookCorpus (Zhu et al., 2015). We want to emphasize that using pre-layernorm (Shoeybi et al., 2019) is essential for the high learning rate in Izsak et al. (2021) to work. The hyperparameters for the efficient pre-training recipe are shown in Table 5. We train with 8 Nvidia GTX 2080 GPUs and use gradient accumulation to achieve the large batch sizes.

Hyperparameter	Efficient pre-training recipe
Peak learning rate	2e-3
Warmup proportion	6%
Batch size	4,096
Training steps	23,000
Sequence length	128
Architecture	`large`

Table 5: Our pre-training hyperparameter settings.

A.2 Downstream Task Evaluation

We fine-tune our model on the GLUE benchmark (Wang et al., 2019), including SST-2 (Socher et al., 2013), CoLA (Warstadt et al., 2019), MNLI (Williams et al., 2018), QNLI (Rajpurkar et al., 2016), RTE (Dagan et al., 2005; Bar Haim et al., 2006; Giampiccolo et al., 2007; Bentivogli et al., 2009), MRPC (Dolan and Brockett, 2005), QQP[7] and STS-B (Cer et al., 2017), and the SQuAD v1.1 (Rajpurkar et al., 2016) dataset. For each dataset we run three random seeds and average the results. We apply grid search for the GLUE datasets, as shown in Table 6. For SQuAD, we use a learning rate of 1e-4, a batch size of 16, and train for 2 epochs. For both GLUE and SQuAD we use a linear scheduling for learning rates.

For all the results in the paper, we report accuracy for MNLI, QNLI, RTE, SST-2; we report F1 score for QQP, MRPC, and SQuAD; we report Matthew's correlation for CoLA and Spearman's correlation for STS-B.

Hyperparameter	MNLI, QNLI, QQP
Peak learning rate	{5e-5, 8e-5}
Batch size	32
Max epochs	{3, 5}
	RTE, SST-2, MRPC, CoLA, STS-B
Peak learning rate	{1e-5, 3e-5, 5e-5, 8e-5}
Batch size	{16, 32}
Max epochs	{3, 5, 10}

Table 6: Grid search hyperparameters for GLUE tasks.

For the SQuAD results in Table 1 and Table 2, we further train the models for 2300 steps (10% of the training) with a sequence length of 512, a learning rate of 5e-4, and a warmup rate of 10%. For other tables and figures, we present the SQuAD results without further pre-training, and the absolute numbers are lower because of the short pre-training sequence length. For some of the figures in the paper, we only show the results of MNLI, QNLI, QQP, STS-B, SST-2, and SQuAD due to limited space. Those tasks are selected because they have larger training set and the results are more reliable. We always show the development results in all our figures and tables except Table 2, where we report the test numbers for GLUE tasks.

B Different Masking Rates: Full Results

Table 7 shows the performance of 15%, 40% and 80% masked models on all GLUE tasks and SQuAD. We can see that 80% masking largely preserves the downstream performance and 40% outperforms 15% on most tasks.

C Tokenizer Comparison

Table 9 shows the performance of different tokenizers on downstream tasks. We see that on most tasks RoBERTa tokenizer is better than BERT tokenizer.

	MNLI-m/mm	QNLI	QQP	RTE
WordPieces	84.3/**84.9**	90.8	**88.2**	64.8
BPE	**84.5**/84.8	**91.6**	88.1	**67.0**
	SST-2	**MRPC**	**CoLA**	**STS-B**
WordPieces	92.5	75.5	56.6	**88.7**
BPE	**92.8**	**76.9**	**61.0**	88.2

Table 9: Comparison between BERT's uncased WordPieces tokenizer and RoBERTa's BPE tokenizer. Both models are `large` and trained with the efficient pre-training recipe with a 40% masking rate.

---

[7] `https://www.quora.com/q/quoradata/`

	MNLI-m/mm	QNLI	QQP	RTE	SST-2	MRPC	CoLA	STS-B	SQuAD
Masking 15%	84.2/84.6	90.9	87.8	**67.3**	**93.3**	**77.0**	59.2	87.7	88.0
Masking 40%	**84.5/84.8**	**91.6**	**88.1**	67.0	92.8	76.9	**61.0**	**88.2**	**89.8**
Masking 80%	80.8/81.0	87.9	87.1	58.6	90.5	72.1	38.7	86.3	86.2
Random initialization†	61.5/61.2	60.9	70.7	49.6	80.0	45.4	11.9	17.5	10.8

Table 7: The development results on the GLUE benchmark with `large` models, the efficient pre-training recipe, and with 15%, 40%, or 80% masking rates. The SQuAD development results are attained with the same continuous training as in Table 1. Compared to the random initialization model, 80% masking rates clearly learn good representations for downstream tasks, despite having a very high perplexity. †: The random initialization models are trained with the same fine-tuning hyperparameters as pre-trained models, thus they could be undertrained.

	MNLI-m/mm	QNLI	QQP	RTE	SST-2	MRPC	CoLA	STS-B	SQuAD
Train longer with the efficient pre-training recipe									
Masking 15%	87.47/87.02	92.95	88.40	69.93	94.07	82.50	61.00	88.89	87.29
Masking 40%	86.63/86.83	93.13	88.40	68.87	94.67	79.50	61.23	89.60	87.16
Recipe from RoBERTa									
Masking 15%	87.40/87.23	93.04	88.43	67.53	94.13	80.80	59.80	90.05	90.72
Masking 40%	87.30/87.03	92.90	88.83	67.63	94.10	63.90	56.07	87.94	91.23

Table 8: Development results of 15% vs 40% masking with larger pre-training budget. We use the recipe from Table 3 in Liu et al. (2019), and the efficient pre-training recipe with more training steps. See Table 10 for hyperparameters.

D Longer Training

Hyperparameter	Train longer	RoBERTa
Peak learning rate	2e-3	7e-4
Warmup proportion	6%	6%
Batch size	4,096	2,048
Training steps	125,000	125,000
Sequence length	128	512

Table 10: Comparison between our longer pre-training recipes and a recipe from RoBERTa (Liu et al., 2019).

To see that how the different masking rates perform with longer training, we modify the efficient pre-training recipe for longer steps. We also experiment with a recipe used in the RoBERTa paper (Liu et al., 2019). Since the final RoBERTa models use more training data, we refer to the recipe used in RoBERTa's ablation in its Table 3. Table 10 shows the hyperparameters for the longer training, as well as a comparison to the RoBERTa's recipe. The major difference is that we train with much larger learning rate and only a sequence length of 128.

We train the models with 15% and 40% masking rates longer and evaluate them on downstream tasks. Figure 7 shows the results. We see that on most of the tasks, the trend that 40% is better than 15% still holds, though the 40% has a larger advantage when the training steps are limited.

We also train the model using a recipe from RoBERTa and present the results in Table 8. We see that (1) on most tasks 40% achieves comparable results compared to 15%; (2) our "train longer" results, which uses shorter sequences and larger learning rates, are comparable to the RoBERTa recipe results though with much shorter time.

E Results of Different Model Sizes and Masking Strategies

We show the configurations of different model sizes in Table 11. Figure 8 and Figure 9 show the results of the `base` model and the `medium` model, which serve as complementary materials for Figure 2.

Figure 10 shows the performance of uniform masking, T5-style span masking, and PMI masking on downstream tasks. This serves as a complementary material for Figure 5.

	`medium`	`base`	`large`
#Layers	8	12	24
#Attention heads	8	12	16
Hidden size	512	768	1024

Table 11: Configurations of different model sizes.

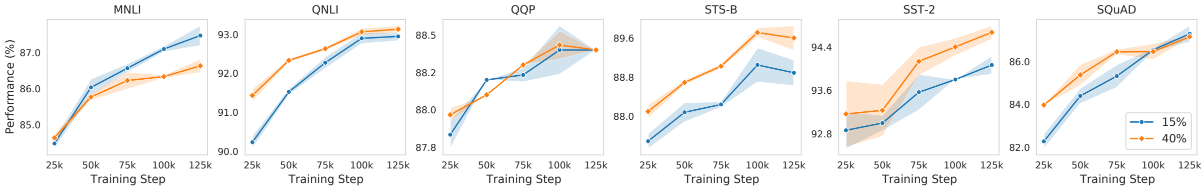

Figure 7: 15% vs 40% masking rates with `large` models and the efficient pre-training recipe but trained longer.

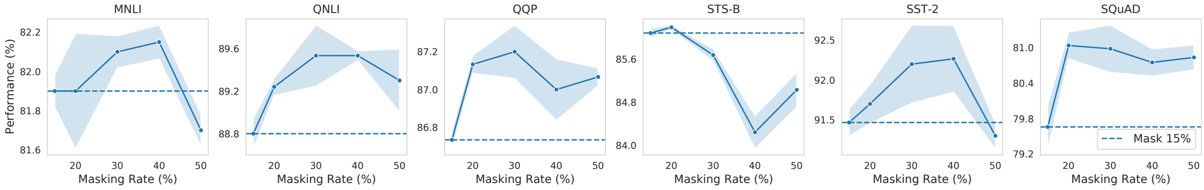

Figure 8: Results on selected downstream tasks with the `base` (124M parameter) model.

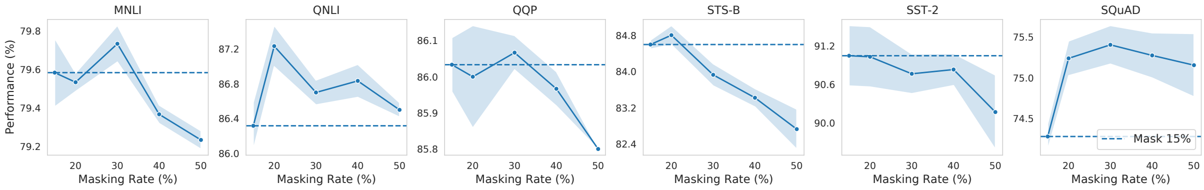

Figure 9: Results on selected downstream tasks with the `medium` (51M parameter) model.

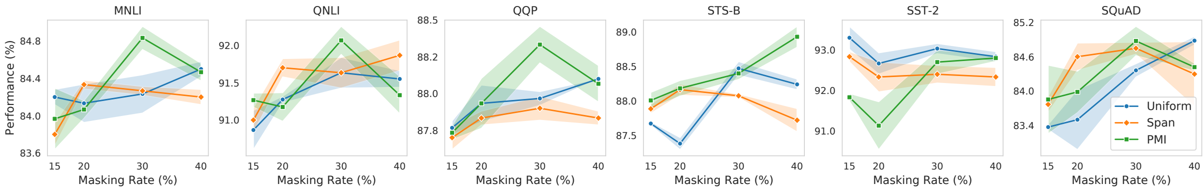

Figure 10: Comparison of different masking strategies on selected tasks. Models are trained with the efficient pre-training recipe, the `large` configuration, and several masking rates.

F Results on French MLM

To validate our conclusions in a new setting, we conduct experiments on MLM on a corpus in French. Similar to Izsak et al. (2021), we pre-train on 2020 French Wikipedia and fine-tuned on French XNLI. We report accuracy averaged over 4 seeds, and make the observation that 40% is better than 15%.

	XNLI-fr	
	valid	test
Masking 15%	78.3	77.3
Masking 40%	78.9	77.5

Table 12: We pre-train on 2020 French Wikipedia and fine-tuned on French XNLI. We report accuracy averaged over 4 seeds.

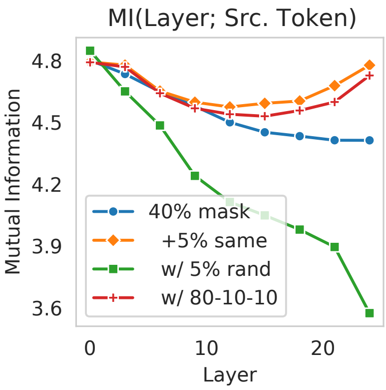

Figure 11: Mutual information between an input token and its intermediate representations for four different corruption strategies. See Table 4 for details on models.

G Information Flow Analysis

To visualize the effect of these corruption strategies (the 80-10-10 rule), we follow Voita et al. (2019)'s analysis of measuring mutual information between an input token and its intermediate representations. Figure 11 shows that each model initially loses some information about the source token while acquiring information from the surrounding context. Using same token predictions during pre-training leads to a "reconstruction" stage in the last few layers, as observed by Voita et al. (2019), whereby information about the source token is restored from the context. However, this second stage is not present when same token predictions tokens are ablated: the `[MASK]`-only baseline propagates contextual features only—and no reconstruction occurs. This is more pronounced with random token corruption, where source information (that was less reliable during pre-training) is lost at a greater rate. One consequence is that information about the input tokens can be more easily extracted when pre-training with same token predictions. However, the reconstruction of the source tokens does not appear to be as important in the fine-tuning setting, as shown in our experiments in Table 4.

How do Words Contribute to Sentence Semantics? Revisiting Sentence Embeddings with a Perturbation Method

Abstract

Understanding sentence semantics requires an interpretation of the main information from a concrete context. To investigate how individual word contributes to sentence semantics, we propose a perturbation method for unsupervised semantic analysis. We next re-examine SOTA sentence embedding models' ability to capture the main semantics of a sentence by developing a new evaluation metric to adapt sentence compression datasets for automatic evaluation. Results on three datasets show that unsupervised discourse relation recognition can serve as a general inference task that can more effectively aggregate information to essential contents than several SOTA unsupervised sentence embedding models. [1]

1 Introduction

Humans are usually able to understand sentence meaning based on a complex cognitive process — composition of words (Löbner, 2013). As main carriers of information, words generally have different levels of contribution to the final sentence semantics. For example, underlined words in *"The city of <u>Austin</u> <u>is</u> <u>considering</u> <u>extending</u> downtown parking <u>meter</u> <u>hours</u> to the weekends and later during the week"* convey the most important information of this sentence. Therefore, determining the primary semantics (or main meaning) of a sentence and estimating how sentence semantics distributes to individual words play critical roles in understanding sentence compositionality.

Recently, with the help of large pretrained Transformers, sentence representation learning has achieved great success in downstream NLP tasks (Qiu et al., 2020). However, most work either heavily relies on human annotation such as Natural Language Inference (NLI) data (Williams et al., 2018; Bowman et al., 2015) to do fine-tuning (Conneau et al., 2017a; Reimers and Gurevych, 2019) or adopt unsupervised contrastive learning to learn sentence embeddings (Gao et al., 2021; Chuang et al., 2022). They neglect one critical property of an effective sentence embedding model that essential contents should contribute to sentence semantics more than non-essential contents when encoding a sentence.

We observe that primary semantics can be acquired by learning to predict discourse relations because sentence primary semantics usually needs to support the logical relations at the discourse level. It is motivated by the distinction between asserted and projected content in semantic theory (Potts, 2003; Tonhauser et al., 2013; Venhuizen et al., 2018). Asserted content is intended to be presented for discussion and information exchange, whereas projected content represents background information that is not under discussion. Thus, asserted content should carry more weight in sentence representations than projected content, because it is at issue in the context by the speaker's intention.

Based on this observation, we apply 36 explicit discourse connectives to four big corpora and extract 9.8M sentence pairs. Acquired sentence pairs are then used to train a universal sentence encoder. Next, by perturbing the trained model, we directly estimate the contributions (importance) from individual words to the final sentence semantics. Our assumption is that the importance of a word in a sentence is proportional to how much the new sentence representation drifts from the original sentence representation if we mask that word. Figure 1 shows the overview of our approach.

To overcome the lack of evaluation data and quantitatively evaluate a sentence encoder's sensitivity to key information of a sentence, we design a new evaluation metric — important information gain, which measures model's ability to concentrate on the important words instead of randomly se-

Figure 1: Overview of our approach.

lected words. Experiments on three datasets show that our model outperforms previous unsupervised and supervised sentence embedding models. Our analysis also demonstrates our model is less biased than the model trained with human-annotated data.

In this paper, we investigate how words, as main carriers of information, contribute to the final sentence semantics with different levels of significance. Our main contributions are summarized as follows: 1) We propose a perturbation method to estimate the contributions from individual words to sentence semantics to understand sentence compositionality. 2) We design a new automatic metric, Important Information Gain, to overcome the lack of evaluation. We find discourse relation recognizer can more effectively aggregate information to essential contents than several SOTA unsupervised sentence embedding models.

2 Related Work

DisSent (Nie et al., 2019) also uses discourse prediction to train sentence embeddings, but their goal is to achieve SOTA fine-tuning results on SentEval tasks (Conneau and Kiela, 2018) and the PDTB task instead of investigating primary semantics. Our work is closely related to sentence compression (Filippova et al., 2015; Kamigaito and Okumura, 2020) and extractive text summarization (Xu and Durrett, 2019; Mendes et al., 2019) that mainly focus on extracting the salient text spans in an end-to-end manner. In contrast, we aim to estimate the semantic saliency distribution to better understand sentence compositionality. Perturbation methods have been also used in data augmentation (Das and Sarkar, 2019), robustness analysis (Niu et al., 2020; Prabhakaran et al., 2019), and textual adversarial attack (Li et al., 2021; Feng et al., 2018). We are the first to use the perturbation method to estimate sentence semantics distribution.

3 Discourse Relation Recognition as a General Inference Task

3.1 Data Collection

To have a broad coverage on different types of texts, we consider four large-scale corpora. **News Articles**. We use English Gigaword 5th edition (Napoles et al., 2012), which contains 10M news articles. **Wikipedia**. We use the Wikipedia dump of 5/20/2021 which consists of 54M web pages. **Novel Books**. BookCorpus (Zhu et al., 2015) contains 11,038 novel books of 16 different genres. **Blogs**. We use the Blog Authorship Corpus (Schler et al., 2006) which consists of 680K blog posts. We applied the Stanford CoreNLP tools[2] to obtain sentence boundaries.

We next select 36 explicit connectives (corresponding to 9 discourse relations)[3] from the PDTB annotation manual (Prasad et al., 2008) and summarize them into extraction patterns. After applying them to four corpora, we extract 9.8M sentence pairs in total. Statistics of acquired sentence pairs are summarized in Table 1.

3.2 Model Architecture

Inspired by Reimers and Gurevych (2019), our model first uses an encoder to get two sentence representations and then compares them to predict the discourse relations. Specifically, we apply a pretrained BERT$_{\text{Base}}$ (Devlin et al., 2019) model to the two sentences and select the model outputs at the `[CLS]` tokens as the corresponding sentence representations u and v. Next, by feeding u, v and $|u - v|$ into a 9-class softmax layer, i.e.,

---

[2] https://stanfordnlp.github.io/CoreNLP/.

[3] We only consider connectives that are less ambiguous in relations. See Appendix for the full list of connectives.

	CT	RS	CJ	EQ	GN	IN	CA	PR	DJ
Pairs	8M	430K	800K	29K	12K	285K	188K	26K	26K

Table 1: Statistics of sentence pairs extracted from four text corpora. 9 discourse relations are Contrast (CT), Result (RS), Conjunction (CJ), Equivalence (EQ), Generalization (GN), Instantiation (IN), Chosen Alternative (CA), Precedence (PR), and Disjunctive (DJ).

$p = \mathrm{softmax}(W_t[u, v, |u - v|])$, our model predicts what is the discourse relation (e.g., Contrast, Result, Equivalence, etc.) between them.

4 Estimating Sentence Semantics Distribution via Perturbation

To estimate the semantic distribution of the input sentence $S = \{w_i\}_{i=1}^{N}$, we mask each word w_i individually to construct a new sentence and apply the sentence embedding model (Section 3.2) to calculate the new representation. Next, we calculate the cosine distance between the new and the original representation. The distance can quantitatively tell us how much the new sentence (after masking one word) semantically drift from the original sentence, which indicates the contribution of that word to the sentence semantics.[4] Finally, we normalize the distances by their summation so that the importance scores of all words sum to 1.

5 Evaluation

5.1 Evaluation Metric

Ideally, if we know the gold standard importance distribution in sentence semantics, we can directly compare a model's prediction with the gold standard. However, it is infeasible for humans to annotate/assign a continuous importance score to each word in a sentence. To address the lack of evaluation data, we adopt two sentence compression datasets and one summarization dataset for evaluation. The main idea is that the compressed sentence, as a shorter version of the original sentence, specifies the most important words in the original sentence. Therefore, we can score a model by its ability of concentrating on important words.

Furthermore, we propose a new evaluation metric — **Importance Information Gain** — to score how much a predicted distribution is superior to a uniform distribution (all words are equally important). Specifically, given a sentence $S = \{w_i\}_{i=1}^{N}$ consisting of $|S| = N$ words, suppose the compressed sentence by human is $S' = \{w_j\}_{j \in 1\sim N}$, where S' is a subset of S. Let $[v_1, v_2, \cdots, v_N]$ be the importance scores over words (normalized such that $\sum_{i=1}^{N} v_i = 1$). We calculate the information gain g to be the average importance score on importance words $\frac{\sum_{i\in S'} v_i}{|S'|}$ over the score that every word is equally important $\frac{1}{|S|}$: $g = \frac{\sum_{i\in S'} v_i}{|S'|} - \frac{1}{|S|}$.

We next normalize g for each test sentence instance by the upper bound g^*, where g^* is defined as the information gain of a model that can perfectly distinguish important words from non-important words (concentrate all information on only important words): $g^* = \frac{1}{|S'|} - \frac{1}{|S|}$. Then, the final Importance Information Gain = $g/g^* \in [0, 1]$.

To validate whether the proposed metric is able to measure the quality of a semantic distribution, we randomly sample 100 pairs from baseline models' predictions in Table 2 and analyze our metric's consistency with human preferences. Specifically, each sampled pair consists of predictions (semantic distributions) of two separate baseline models on the same sentence. Three expert annotators are asked to judge which one better characterizes the importance/contribution of each word to the sentence meaning. We next compare our metric's preferences with the gold human preferences[5]. Our metric agreed on 87/100 with human gold labels, achieving a substantial (Cohen, 1968) kappa agreement score of 0.74.

5.2 Evaluation Datasets

For evaluation, we experiment on three datasets. Google sentence compression dataset (GGL) (Filippova and Altun, 2013) contains 10K test sentence compression pairs and BNC written dataset (Clarke and Lapata, 2008) contains 1.5K test compression pairs. Additionally, we go through the Gigaword summarization dataset (GGW) and compare the first sentence with the title sentence in the news article. We select (first sentence, title) pairs as our testing data if words[6] in the title sentence is a subset of words in the first sentence. We collect the first 10K sentence pairs as our test data.

---

[4] If the target masked word is tokenized into multiple subword pieces by the tokenizer, we mask each subword piece in turn and calculate the summation score as the word importance.

[5] Gold labels are generated based on majority voting. The average Cohen's kappa inter-agreement between three annotators is 0.67.

[6] We use lemma matching in practice.

5.3 Baseline Systems

Rule-Based Model. We use a rule-based primary semantics extraction system (Zhang et al., 2020), which first parses the input sentence into a dependency parsing tree and extracts the sentence skeleton.[7] Words in the sentence skeleton are considered equally important.

GloVe Embedding. We calculate the sentence embeddings by averaging GloVe embeddings (Pennington et al., 2014) among all words except w_i.

Original BERT. We apply the original BERT-base model[8] that uses next sentence prediction as the training objective.

BERT-CT (Carlsson et al., 2021) introduces an unsupervised learning method called Contrastive Tension (CT) that only requires raw sentences and achieves SOTA performance on Semantic Textual Similarity (STS) tasks. CT tries to maximize the dot product between sentence representations for identical sentences and minimize the dot product for differing sentences. BERT-CT-STSb and BERT-CT-NLI[9] are two supervised CT models fine-tuned on STSb and NLI, respectively.

SimCSE (Gao et al., 2021) is a contrastive sentence embedding framework that achieves SOTA performance on sentence similarity tasks. The unsupervised model (SimCSE-unsup) takes an input sentence and predicts itself in a contrastive objective with dropout as the data augmentation method. The supervised model (SimCSE-sup) incorporates sentence pairs from the NLI data (Williams et al., 2018; Bowman et al., 2015) into a contrastive learning framework, by using *entailment* pairs as positives and *contradiction* pairs as negatives.

DiffCSE (Chuang et al., 2022) augments SimCSE contrastive learning with the edited sentences sampled from a masked language model.

SBERT (Reimers and Gurevych, 2019). Sentence-BERT (SBERT) uses siamese and triplet network structures to derive sentence embeddings. SBERT-NLI is the original model introduced by Reimers and Gurevych (2019) that is fine-tuned on NLI. Moreover, we also consider four more recent SBERT models that are fine-tuned with more sentence pair data.[10] Specifically, SBERT-MSMarco is fine-tuned on the MSMarco Passage Ranking Dataset containing 500K (query, relevant passage) pairs from Bing search. SBERT-Paraphrase is fine-tuned on NLI and 11 paraphrase datasets. SBERT-MultiQA is fine-tuned on 214M (question, answer) pairs from 17 QA datasets. MPNet-All is fine-tuned on all available sentence pair tasks including 32 tasks with 1,170M sentence pairs.

	Models	GGL	BNC	GGW	Avg.
	Supervised				
1	BERT-CT-STSb	7.4	19.3	8.3	11.7
2	BERT-CT-NLI	7.5	10.0	6.5	8.0
3	SimCSE-sup	15.8	25.1	10.2	17.0
4	SBERT-NLI	14.3	23.2	14.2	17.2
5	SBERT-Paraphrase	23.7	15.4	31.8	23.6
6	SBERT-MultiQA	33.0	28.6	35.6	32.4
7	SBERT-MSMarco	31.7	28.3	32.7	30.9
8	MPNet-All	**52.6**	**33.3**	**58.2**	**48.0**
	Unsupervised				
9	Parsing Tree	18.7	19.8	7.2	15.2

11	Original BERT	2.0	0.3	0.8	1.0
12	BERT-CT	12.0	16.3	12.4	13.5
13	SimCSE-unsup	13.9	14.9	10.1	13.0
14	DiffCSE	21.6	**28.7**	20.8	23.7
15	Our Model-disc.	**36.9**	27.2	**36.6**	**33.6**

Table 2: Importance Information Gain (%) on three evaluation datasets. We group models based on whether it requires human-labeled data in training or not.

Table 2 shows the results of all models. We group models based on whether they use human-labeled data or not. Line 15 is our model trained on 9.8M sentence pairs that are extracted by discourse connectives. Our unsupervised discourse recognition model achieves the highest overall information gain among all unsupervised approaches, which is even higher than several supervised models that are trained using millions of human-annotated data (Lines 3-7). Surprisingly, even SimCSE and DiffCSE report better performance than MPNet-All on STS tasks, they are much worse than MPNet-All on capturing sentence primary semantics.

5.4 Visualization and Analysis

While previous studies (Conneau et al., 2017b) empirically show that fine-tuning towards NLI data yields good sentence embedding models, we visualize and compare the model trained on the NLI data with the model trained on discourse pairs. We find the NLI data model sometimes is biased to specific numbers, time expressions, etc (Figure 2). It may be mainly due to the bias introduced during the NLI data construction process when human annotators sometimes just replace the numbers or time

expressions to produce a contradictory sentence. In contrast, the discourse relation recognizer is less sensitive to those specific expressions. Appendix II contains more examples.

6 Conclusion

In this paper, we have introduced a perturbation method for estimating sentence semantic distribution and designed a new metric to achieve automatic evaluation. We find discourse relation recognition can serve as a general inference task to train an unsupervised sentence embedding model that estimates such distribution meaningfully than several SOTA sentence embedding models.

7 Limitations

To benefit from large-scale training data, we train the discourse relation recognizer on data that are automatically generated by matching explicit connectives. Even we only select explicit connectives that have one dominant discourse relation, some of them may still reflect a different relation in some contexts. For example, connective *in other words* indicates a "Equivalence" relation most of the time, but sometimes it can also indicate a "Generalization" relation. In this regard, our method shares the same limitations as the broad class of weakly supervised methods where training data are automatically generated. Considering discourse parser is not the main focus of this paper, we leave how to generate cleaner discourse relation data and train a better discourse relation recognizer for future work.

Appendix I

Experiment details. We generally follow the hyper-parameter setting of previous work to train our model. In experiments, we train our model using cross-entropy loss and Adam (Kingma and Ba, 2015) optimizer with initial learning rate 5e-5, dropout rate 0.5, and batch size 256 for 5 training epochs. The training of the discourse relation recognizer was run on one machine with 8 NVIDIA P40 GPUs, taking about 6 hours per epoch and three epochs in total. We simply use the standard hyper-parameters to train our model without any hyper-parameter search.

Abstract

Deep neural models for named entity recognition (NER) have shown impressive results in overcoming label scarcity and generalizing to unseen entities by leveraging distant supervision and auxiliary information such as explanations. However, the costs of acquiring such additional information are generally prohibitive. In this paper, we present a novel two-stage framework (AUTOTRIGGER) to improve NER performance by automatically generating and leveraging "*entity triggers*" which are human-readable cues in the text that help guide the model to make better decisions. Our framework leverages post-hoc explanation to generate rationales and strengthens a model's prior knowledge using an embedding interpolation technique. This approach allows models to exploit triggers to infer entity boundaries and types instead of solely memorizing the entity words themselves. Through experiments on three well-studied NER datasets, AUTOTRIGGER shows strong label-efficiency, is capable of generalizing to unseen entities, and outperforms the RoBERTa-CRF baseline by nearly 0.5 F1 points on average.

1 Introduction

Named Entity Recognition (NER) serves as a key building block in information extraction systems. Recent advances in deep neural models for NER have yielded state-of-the-art performance when sufficient human annotations are available (Lample et al., 2016; Liu et al., 2018; Peters et al., 2017; Ma and Hovy, 2016). However, such success cannot easily transfer to practitioners developing NER systems in specific domains (*e.g.*, biomedical papers, financial reports, legal documents), where domain-expert annotations are expensive and slow to obtain. Moreover, NER systems face challenges in real-world applications where novel entities, unseen in training data, are often encountered (Lin et al., 2021). Recent attempts addressing label scarcity and improving generalization to unseen entities have explored various types of human-curated resources as auxiliary supervision, such as entity dictionaries (Peng et al., 2019; Shang et al., 2018; Yang et al., 2018; Liu et al., 2019a), labeling rules (Safranchik et al., 2020; Jiang et al., 2020), prompts (Ding et al., 2021; Cui et al., 2021), demonstrations (Lee et al., 2022), retrieved context (Wang et al., 2021), and labeling explanations (Hancock et al., 2018; Wang et al., 2020; Ye et al., 2020; Lin et al., 2020; Lee et al., 2020a). In particular, human-provided labeling explanations as auxiliary supervision signals are cost-effective compared to collecting label-only annotations for larger number of instances. For the NER task, Lin et al. (2020) introduced the concept of an *entity trigger*, an effective way to represent explanations for the labeling decisions (See Figure 1 (a) vs. (b)).

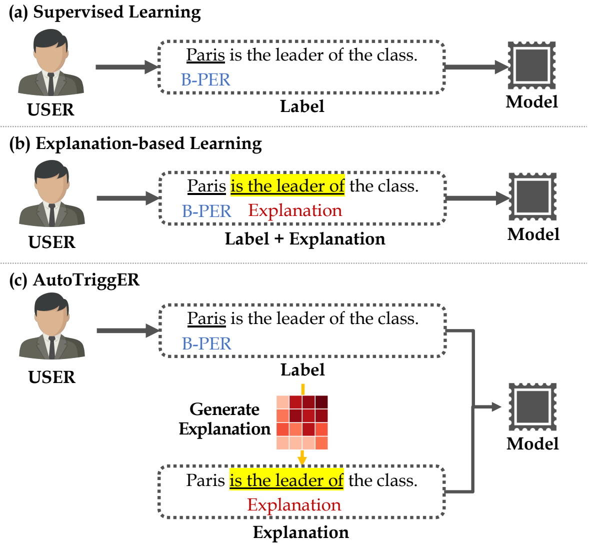

Figure 1: Existing explanation-based learning frameworks mostly rely on humans provided labeling explanations while our framework automatically generates and leverages explanations to NER.

However, prior works have the following limita-

tions: (1) *Expense of collecting rationales*: Prior works primarily use a limited number of *crowd-soured* explanations (e.g., *entity trigger*) for improving data (label) efficiency of model training. While such human-curated auxiliary supervision is of high quality, the crowd-sourcing procedure can be very expensive and time-consuming. This largely limits the scale and domains of the collected rationales; (2) *Unseen entity generalization*: The biggest advantage of leveraging such explanations for NER is a generalization ability towards unseen entities. Reinforcing this prior knowledge in the model rather than memorizing the entity words themselves can make the model robust against unseen entities during training. However, prior works do not evaluate such generalization ability.

To address these limitations, we propose a two-stage NER framework, named AUTOTRIGGER , which improves label efficiency and model robustness without human efforts (see Figure 1 (c)). First, it *automatically* generates entity triggers as explainable features to reduce human effort on collecting rationales. It then strengthens the prior knowledge in the model by interpolating model embeddings of entity-masked sentence which force the model to rely more on triggers and trigger-masked sentence which force the model to rely more on the entity.

The *first* stage of our framework (Sec. 3.1) aims to *automatically extract entity triggers* using a post-hoc explanation. We propose to exploit the syntactic features of a sentence for assigning importance scores to a group of input tokens such that we can extract entity triggers as auxiliary supervision. Specifically, we form a collection of trigger candidates for an entity in a sentence using the phrases extracted from its *constituency parsing tree* (Joshi et al., 2018). Then we score each trigger candidate based on its ability to predict the target entity, while varying the surrounding context to ensure trigger robustness.

The *second* stage (Sec. 3.2) focuses on how to use triggers, which are useful contextual clues, in making the prediction. We propose *Trigger Interpolation Network* (TIN), a novel architecture that effectively uses trigger-labeled NER data to train a model. Here, we employ two separate masking passes when learning our model's embeddings: one masking the entity words (forcing the model to rely more on the triggers) and one masking the triggers (forcing the model to rely more on the entity words). We then interpolate the embeddings of both entity-masked and trigger-masked sentences to learn a mixed sentence representation, which is provided as input to a standard sequence labeling task. In this manner, the TIN can effectively learn to focus on useful contextual clues to infer entity boundaries and types with contextualized embeddings from pre-trained language models such as BERT (Devlin et al., 2019) while it may not miss the entities whose type can be determined by itself. (e.g., inputs that contain only the entities).

Extensive experimental results on several domains show that AUTOTRIGGER framework consistently outperforms baseline methods by 0.5 F1 points on average in fully supervised setting. Our work shows strong performance especially in label scarcity setting and unseen entity generalization. In the label scarcity setting ranging from 50 to 200 number of train instances, assuming a task that needs annotation from scratch, our model gains more than 3-4 F1 score on average. Also, for the filtered test set where the entities did not appear in the train and development sets, assuming a real-world applications in which entities can be out of the distribution of the train data, our model gains more than 2-3 F1 score on average.

2 Problem Formulation

Named Entity Recognition. We let $\mathbf{x} = [x^{(1)}, x^{(2)}, \ldots x^{(n)}]$ denote the sentence consisting of a sequence of n words and $\mathbf{y} = [y^{(1)}, y^{(2)}, \ldots y^{(n)}]$ denote the NER-tag sequence. The task is to predict the entity tag $y^{(i)} \in \mathcal{Y}$ for each word $x^{(i)}$, where $\mathcal{Y}$ is a pre-defined set of tags such as $\{$B-PER, I-PER, $\ldots$, O$\}$. We let $\mathcal{D}_L$ denote the labeled dataset consisting of the set of instances $\{(\mathbf{x_i}, \mathbf{y_i})\}$, where $\mathbf{x_i}$ is the i-th input sentence and $\mathbf{y_i}$ is its output tag sequence. Here, we use BIOES scheme (Chiu and Nichols, 2016).

Entity Trigger Extending from extractive rationales for text classification (DeYoung et al., 2020; Jain et al., 2020), an *entity trigger* is a form of extractive explanatory annotation for NER, defined as *a group of words that help explain the recognition process of an entity mentioned in the sentence* (Lin et al., 2020). For example, in Figure 2, "*had ... dinner at*" and "*where the food*" are two distinct triggers associated with the RESTAURANT entity "*Sunnongdan*". Formally, given a labeled NER instance $(\mathbf{x}, \mathbf{y})$, we use T to denote the set of entity triggers for this instance. Each trigger $t_i \in T$ is

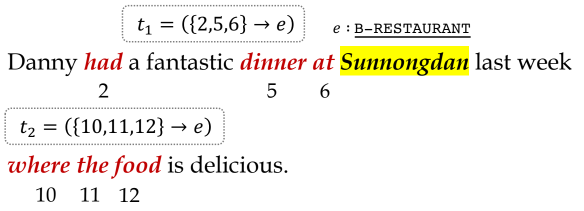

Figure 2: **Example of entity trigger.** Entity trigger t_i is a cue phrase toward the entity e in the sentence, which is represented by a set of corresponding word indices. Both entity triggers (t_1,t_2) are associated to the same entity e ("*Sunnongdan*") typed as restaurant.

associated with an entity e and a set of word indices $\{w_i\}$. That is, $t = (\{w_1, w_2, \dots\} \to e)$ represents an entity trigger. For example, in Figure 2, $t_1 = \{2, 5, 6\}$ is an entity trigger identified for entity "*Sunnongdan*" in the sentence. A *trigger-labeled NER dataset*, $\mathcal{D}_T = \{(\mathbf{x_i}, \mathbf{y_i}, T(\mathbf{x_i}, \mathbf{y_i}))\}$, consists of examples in a labeled NER dataset $\mathcal{D}_L$ with their associated entity triggers.

Problem Definition We focus on the problem of how to *automatically* extract entity triggers to create a trigger-labeled dataset $\mathcal{D}_T$ from $\mathcal{D}_L$ without manual effort and to cost-effectively train a NER model using $\mathcal{D}_T$. Here, we aim to achieve better performance and robustness over existing NER models using the same amount of training instances. Moreover, to check the quality of the automatically extracted triggers, we compare with the model using human-labeled triggers.

3 Approach

AUTOTRIGGER is a two-stage architecture that begins with an *automatic trigger extraction* stage followed by a *trigger interpolation network* (`TIN`). It automatically extracts and scores the importance of entity trigger phrases in the first stage (Sec. 3.1) and uses them in the later stage to train the NER model (Sec. 3.2).

3.1 Automatic Trigger Extraction

Automatic trigger extraction is the first stage of our AUTOTRIGGER framework. Different from prior works on extracting rationales and explanations for sentence classification (Ribeiro et al., 2016; Li et al., 2016b), we look to extract triggers for explaining the detection (occurrence) of an entity in the sentence. In our study, we extend the *sampling and occlusion* (`SOC`) algorithm (Jin et al., 2020), a feature attribution algorithm for post-hoc model explanation, to extract entity triggers. Here, we exploit a token classifier to model the score function of the target entity in the sentence and limit the search space to a set of phrases from the constituent parse tree. Specifically, given a labeled NER corpus $(\mathbf{x_i}, \mathbf{y_i}) \in \mathcal{D}_L$, we consider four main steps for entity trigger extraction: 1) generating a set of candidate phrases $\mathcal{P}$, 2) constructing entity token classifier $\mathcal{M}_t$, 3) trigger phrase scoring, and 4) trigger phase selection.

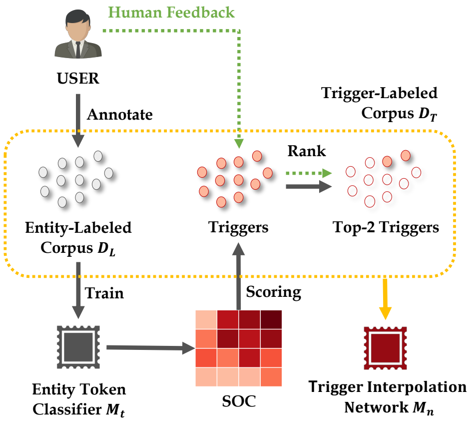

Figure 3: **Overview of the proposed AUTOTRIGGER.** It trains an entity-token classifier $\mathcal{M}_t$ with entity-labeled corpus $\mathcal{D}_L$ and uses the sampling-and-occlusion (SOC) algorithm to extract triggers. There is a provision for leveraging human feedback in the framework for refining automatically generated triggers. Trigger Interpolation Network (TIN) learns the NER model from the trigger-labeled corpus.

Candidate Generation Given a labeled sentence $(\mathbf{x_i}, \mathbf{y_i})$, we obtain its constituency parse tree and consider the set of phrase nodes $\mathcal{P}$ from the tree as trigger candidates (see Figure. 4 for an illustration with examples). `SOC` aims to compute context-independent phrase-level importance for sequence classification tasks such as sentiment analysis and relation extraction (Jin et al., 2020). It uses agglomerative clustering (Singh et al., 2019) to effectively compute the phrase-level importance without evaluating all the possible phrases in the sentence. Here, we provide pre-defined hierarchy for limiting the search space to a set of phrases from the constituent parse tree. Specifically, given a sentence instance $\mathbf{x_i} \in \mathcal{D}_L$ and a target entity mentioned in this sentence $e \in \mathbf{x_i}$, we generate a set of phrase candidate $\mathcal{P} = \{\mathbf{p_i}\}$, where $\mathbf{p_i} = (w_s, w_e)$. Here (w_s, w_e) denote the start and end index of the phrase span $\mathbf{p_i}$. To generate $\mathcal{P}$, we parse the input sentence $\mathbf{x_i}$ using an off-the-shelf constituency parser [1] and

---

[1] https://stanfordnlp.github.io/CoreNLP/parse.html

collect phrase nodes in the parse tree as the set of candidate phrases $\mathcal{P}$. To avoid including target entity as an entity trigger, we discard phrases that contain the target entity, i.e., $\{\mathbf{p_j} | e \in \mathbf{p_j}\}$.

Entity Token Classifier Construction In order to apply SOC to the sequence labeling task, we propose a way to derive the importance score of the phrase $\mathbf{p}$ specific to the input sentence x and target entity e. To achieve this, we use a token classification model $\mathcal{M}_t$ to generate prediction scores in the label space (e.g., probability for target class of a token). Given an input sentence $\mathbf{x_i} = [x_i^{(1)}, x_i^{(2)}, \dots x_i^{(n)}]$, $\mathcal{M}_t$ classifies each token $x_i^{(j)}$ to the named entity tag $y_i^{(j)} \in \mathcal{Y}$ where $\mathcal{Y}$ is a predefined set of named entity tags such as B-PER, I-PER and O. We learn $\mathcal{M}_t$ with labeled corpus $\mathcal{D}_L$ to fit a probability distribution $\mathbb{P}(\mathbf{y}|\mathbf{x})$. Then, we can derive the prediction score function s towards the target entity e which is computed as the average conditional probability over tokens of the target entity $x^{(j)} \in e$ as follows:

$$s(\mathbf{x}, e) = \frac{1}{|e|} \sum_{x^{(j)} \in e} \mathbb{P}(\mathbf{y^{(j)}} | x^{(j)}). \tag{1}$$

Phrase Scoring. Once we have the set of candidate phrases $\mathcal{P}$ for the given input instance (x_i, y_i), we aim to measure the score of each of the candidate phrase $\mathbf{p}$ w.r.t the target entity e. We use the score function s of the $\mathcal{M}_t$ to measure the importance score of each phrase $\mathbf{p}$. Here, we have two steps: (1) *input occlusion*, (2) *context sampling*.

Input occlusion (Li et al., 2016b) computes the importance of $\mathbf{p}$ specific to the entity e in the input $\mathbf{x}$ by measuring the prediction difference caused by replacing the phrase $\mathbf{p}$ with padding tokens $0_\mathbf{p}$. We use $s\left(\mathbf{x_{-p}}, e; \mathbf{0_p}\right)$ to denote the model prediction score after replacing the masked-out context $\mathbf{x_{-p}}$ with padding tokens $0_\mathbf{p}$:

$$\phi(\mathbf{p}, \mathbf{x}, e) = s(\mathbf{x}, e) - s\left(\mathbf{x_{-p}}, e; \mathbf{0_p}\right). \tag{2}$$

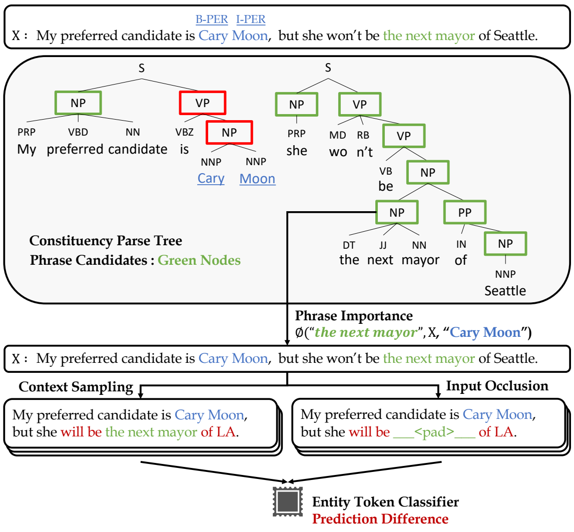

Figure 4: **Overview of the Sampling and Occlusion (SOC)**. It creates a set of phrase candidates with phrase nodes of the constituency parse tree, and then computes the phrase importance by average prediction difference between context sampled sentences and its phrase-masked sentences. Note that the entity mention "*Cary Moon*" is not included as candidate.

However, the importance score $\phi(\mathbf{p}, \mathbf{x}, e)$ from equation 2 has a challenge that it is difficult to model the direct impact of $\mathbf{p}$ towards e since the score is dependent on the context words around $\mathbf{p}$. For example, in Figure. 4, $\mathbf{p}$ ("*the next mayor*") is replaced by pad tokens to compute its importance towards the entity e ("*Cary Moon*"). However, the importance score of $\mathbf{p}$ is dependent on context words around $\mathbf{p}$ ("*won't be ... of Seattle*"). To compute the context independent importance score, SOC proposes *context sampling* that samples the context words around the phrase p and computes the average prediction differences over the samples. Specifically, it samples the context words $\hat{x}_\delta$ from a language model $p(\hat{x}_\delta | x_{-\delta})$ that is trained on $\mathcal{D}_L$, and obtains a set of context word replacements $\mathcal{S}$. Here, we use 20 replacements. For each replacement $\hat{x}_\delta \in \mathcal{S}$, we measure the prediction difference caused by replacing the phrase $\mathbf{p}$ with padding tokens. We take the average of these prediction differences to be the context-independent score $\phi(\mathbf{p}, \mathbf{x}, e)$ of the phrase $\mathbf{p}$, as expressed in equation 3:

$$\frac{1}{|\mathcal{S}|} \sum_{\hat{\mathbf{x}}_\delta \in \mathcal{S}} \left[s\left(\mathbf{x}_{-\delta}, e; \hat{\mathbf{x}}_\delta\right) - s\left(\mathbf{x}_{-\{\delta, \mathbf{p}\}}, e; \hat{\mathbf{x}}_\delta; \mathbf{0_p}\right) \right] \tag{3}$$

In Figure. 4, context words "*won't be*" and "*of Seattle*" around the phrase "*the next mayor*" are replaced into "*will be*" and "*of LA*" which are sampled from the language model. Then, the classifier computes the prediction difference between the sampled sentences with and without the phrase.

Phrase Selection The importance score $\phi(\mathbf{p}, \mathbf{x}, e)$ for phrase $\mathbf{p}$ is the degree to which $\mathbf{p}$ determines the correct entity type of target entity e. After obtaining $\phi(\mathbf{p}, \mathbf{x}, e)$ for all phrase candidates $\mathcal{P} = \{\mathbf{p_i}\}$, we pick the top k candidate phrases with the highest importance score as the entity triggers, where k is a hyperparameter. Specifically,

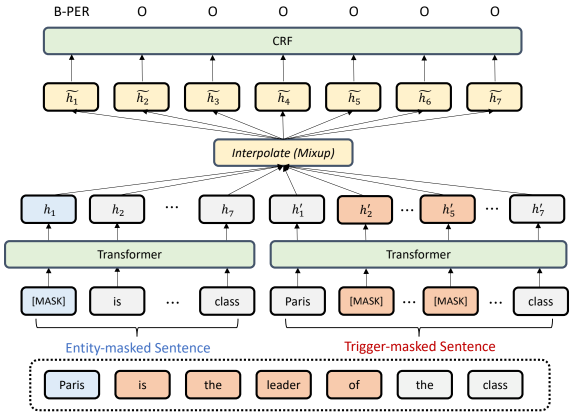

Figure 5: **Overview of the Trigger Interpolation Network (`TIN`).** Given an input sentence we create an Entity-masked sentence and a Trigger-masked Sentence. Then we interpolate token level representations h_i and h'_i to create new hidden state representation, $\tilde{h}_i$. Interpolated hidden representations are fed to a CRF.

for each input instance $(\mathbf{x_i}, \mathbf{y_i}) \in \mathcal{D}_L$, we pick the top k candidate phrases as entity triggers $T(\mathbf{x_i}, \mathbf{y_i})$ per each entity $e \in \mathbf{x_i}$ to create a form $(\mathbf{x_i}, \mathbf{y_i}, T(\mathbf{x_i}, \mathbf{y_i})) \in \mathcal{D}_T$. Here, we search for the best k out of [1, 2, 3, 5, 7, 10] (See Figure 12).

3.2 Trigger Interpolation Network (TIN)

The second stage of AUTOTRIGGER is the trigger interpolation network (`TIN`), which we define as a neural network that learns from a trigger-labeled dataset $\mathcal{D}_T$ consisting of a set of instances of the form $\{(\mathbf{x}, \mathbf{y}, T(\mathbf{x}, \mathbf{y}))\}$. The main idea behind the model is to combine two representations obtained from the sentence with target entity tokens and automatically extracted entity triggers. In one representation, the entity tokens are masked and we hypothesize that it forces the model to infer the entity boundaries and types by leveraging the contextual clues. However, some of the entity tokens itself may already have enough information to infer the entity type without any contextual clues. Thus, in another representation, the entity tokens become the predominant source of information for classifying the entity as we mask out the triggers.

TIN encodes the input sequence $\mathbf{x}$ with a transformer encoder $\mathbf{F}(.;\theta)$ and feeds the hidden representations $\mathbf{h}$ to a CRF tagger. Our proposal is to create two different representations of a token in a sequence and interpolate (mixup) them. By doing this, we expect the model to predict less confidently on interpolations of hidden representations, which eventually make model be robust to both entity-perturbed and trigger-perturbed sentences.

As shown in Figure 5, we first create entity-masked sentence $\mathbf{x}_{-e}$ and trigger-masked sentence $\mathbf{x}_{-t}$ for a given input instance $\{(\mathbf{x}, \mathbf{y}, T(\mathbf{x}, \mathbf{y}))\}$, and then compute the interpolations in the output space of transformer encoder $\mathbf{F}(.;\theta)$ as follows:

$$\begin{aligned} \mathbf{h} &= \mathbf{F}(\mathbf{x}_{-e};\theta), \mathbf{h}' = \mathbf{F}(\mathbf{x}_{-t};\theta) \\ \tilde{\mathbf{h}} &= \lambda\mathbf{h} + (1-\lambda)\mathbf{h}'. \end{aligned} \tag{4}$$

Here, the transformer encoder $\mathbf{F}(.;\theta)$ for both $\mathbf{x}_{-e}$ and $\mathbf{x}_{-t}$ is sharing the weights. Then we use interpolated hidden representations $\tilde{\mathbf{h}}$ as the input to the final CRF tagger.

When inferring tags on unlabeled sentences without entity triggers, we expect the trained $\mathbf{F}(.;\theta)$ to generate representation from the input $\mathbf{x} \in \mathcal{D}_u$, which can generalize well to unseen entities given the seen contextual clues, and seen entities given new surrounding context. We then use it as an input to the final CRF tagger to get tag predictions.

Computational Cost. The computation overhead of training `TIN` is caused by forwarding input two times into the transformers to get two different representations, which is 1.5X larger than vanilla models (e.g. `BERT+TIN+CRF` vs. `BERT+CRF`). However, the overhead of inference is same as vanilla models since the inference steps are same.

4 Experimental Setup

In this section we describe datasets along with the baseline methods and experiment settings.

4.1 Datasets

We consider three NER datasets as target tasks. We consider two datasets for a bio-medical domain: **BC5CDR** (Li et al., 2016a), **JNLPBA** (Collier and Kim, 2004) and one dataset for a general domain: **CoNLL03** (Tjong Kim Sang, 2002). For BC5CDR and CoNLL03, we also have crowd-sourced entity trigger dataset $\mathcal{D}_{HT}$ (Lin et al., 2020) to compare the quality of our automatically extracted triggers with. They randomly sample 20% of the data from each of the train sets and ask crowd-workers to select triggers for entities in those train sets. Details on datasets are discussed in Appendix A.3.

4.2 Compared Methods

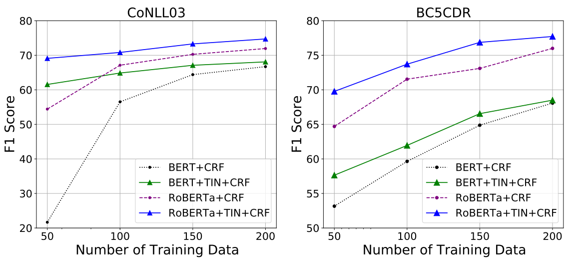
To show the effectiveness of entity triggers, we compare baseline models that learn from entity-labeled dataset $\mathcal{D}_L$ and trigger-labeled dataset $\mathcal{D}_T$ respectively. Here, we compare models under three different embedders: GloVE (Pennington et al., 2014), BERT (Devlin et al., 2019), and RoBERTa (Liu et al., 2019b). We don't include few-shot learning and semi-supervised learning due to following reasons: (1) Few-shot learning (Yang and Katiyar, 2020) is a N-way k-shot task that needs N classes, each with k training examples. This setup is restrictive because it requires a special sampling strategy since the number of training examples for the class must be fixed. (2) Semi-supervised learning (Peng et al., 2019; Shang et al., 2018; Yang et al., 2018; Liu et al., 2019a) uses additional supervisions and in-domain unlabeled data to augment train data by weakly labeling, which is different from our setup that only uses limited in-domain labeled data.

Baselines without triggers We apply the following standard models on $\mathcal{D}_L$: (1) **BLSTM+CRF** first adopts bidirectional LSTM to encode word embeddings into the representations. Then, it feeds the representations into a linear layer to get label scores, and put the scores into a CRF tagger to predict the optimal path of entity tags; (2) **CRF** considers word embeddings directly as the representations and conducts the same process of (1).

Methods with Triggers We apply the following models on $\mathcal{D}_T$: (1) **BLSTM+TMN+CRF** (Lin et al., 2020) adopts the structured self-attention layer (Lin et al., 2017) above the bidirectional LSTM to encode the sentence and entity trigger into vector representation respectively. It then learns trigger representations that can be generalized to unseen sentences to tag the named entity; (2) **TMN+CRF** adopts the structured self-attention layer directly above the embeddings, and conducts the same process of (1); (3) **TIN+CRF** is the *trigger interpolation network* with CRF layer.

5 Results and Analysis

Here we look into a series of analysis questions as follows: (1) Can `TIN` with automatically extracted triggers improve the performance of existing transformer-based models? (2) Can `TIN` with automatically extracted triggers generalize well on the unseen entities? (3) Are automatically extracted triggers work better than human-provided triggers? (4) Can we improve the performance by asking human to refine automatically extracted triggers? We present experiment settings and details in Appendix A.1- A.2.



(a) CoNLL03 (b) BC5CDR

Figure 6: Performance Comparison (F1-score) on CoNLL03 and BC5CDR by small numbers of train data instances (50, 100, 150, 200).

5.1 Performance Comparison

Here, we test all models by varying the amount of training data from 20% to 100% to show the impact of train data size. In Table 1, we report the performance of the baseline approaches and our model variants on three different datasets. Here are findings: (1) `BLSTM` harms the performance of transformer-based models while it works well with GloVE embeddings; (2) Models that receive both entities and triggers as input generally outperform the *entity-only* baselines (See `CRF` vs. `TIN+CRF`, `TMN+CRF`); (3) `TIN` outperforms `TMN`, which shows that `TIN` is doing better leveraging entity triggers for NER, and `RoBERTa+TIN+CRF` outperforms all the baselines regardless of the amount of data that is used to train it; (4) Comparing `BERT+TIN+CRF` to `BERT+CRF`, we observe a performance drop in CoNLL03. We further investigate this phenomenon and find a large drop in F1 score (from 0.82 to 0.79) for the MISC class from the `BERT+TIN+CRF` (See Table 3), which shows that triggers may provide a precision decreasing signal for the MISC type.

Performance in extreme label scarcity settings We hypothesize that our models will have larger performance gains in extreme label scarcity settings, because of their ability to leverage additional information from triggers which enables them to reap more benefits from given training data. To investigate this we observe the performance of our models and baselines starting with only 50-200 sentences to train them. Figure 6 shows the performance under the extreme label scarcity setting. Here, `TIN+CRF` achieves large performance gain in extremely low-resource setting. Specifically, we observe over 50% relative gain compared to the baseline for 50 training sentences.

Unseen entity generalization We hypothesize that our framework can generalize well to unseen

Table 3: Classification Report (F1-score) of `BERT+CRF` and `BERT+TIN+CRF` on CoNLL03.

entities not presented in the training data, attribute to prior knowledge of contextual clues. To evaluate the generalizability of the model, we create a filtered test set which contains instances with only entities that do not appear in the train data. Table 6 shows the performance of model variants on the filtered test set by different amount of training data. Here, `TIN+CRF` shows its effectiveness on predicting unseen entities, and much more when we compare under the small amount of training data.

5.2 Human-in-the-loop Trigger Extraction

We aim to study whether human participation in trigger creation could be helpful. First, we compare the performance of model variants trained with automatically extracted triggers (`auto`) and human-provided triggers (`human`), and check its label efficiency. Then, we conduct a small-scale experiment of trigger refinement by human annotators.

Human-curated vs. Auto Triggers. We use $\mathcal{D}_{HT}$ as the source of human triggers and use the same dataset to extract auto triggers with `SOC` algorithm (see Appendix Table 6). We then sample 25%, 50%, and 75% of the instances from both to construct 5%, 10%, 15% percent of our experimentation dataset (since $\mathcal{D}_{HT}$ is a 20% random sample from $\mathcal{D}_L$). One big difference between `human` and `auto` is whether the triggers are contiguous token spans or not. For example, humans are asked to annotate a group of word tokens that represent *"general"* phrase like *"had dinner at"* from the sentence *"We had a fantastic dinner at Sunnongdan."*, while a set of phrase candidates $\mathcal{P}$ from the constituency parse tree can only contain the contiguous token spans. Figure. 7 shows examples of `human` and `auto`. These examples are from CoNLL03, and `auto` are extracted from the entity token classifier which is trained on 20% of the train data. Tab. 4 shows that `auto` are comparable or even stronger than `human` even though created with no human labeling. The success of auto triggers might be that their impact on the entity labeling is directly at the model level, while human triggers, even if they are meaningful on the surface level, might have less impact in determining the entity label as they do not mimic what the model thinks. We manually inspect the `auto` and `human` and found that `auto` are consecutive while `human` are usually non-consecutive. Even though there could be many reasons for the sub-optimal performance of human selected triggers available in the dataset (Lin et al., 2020), we do not rule out the possibility of leveraging human expertise to help. Further case examples are presented in Appendix A.4.

Table 4: Performance comparison (F1-score) of `TMN` and `TIN` with `human` and `auto` triggers.

Efficiency of Human-curated vs. Auto Triggers. We conduct a study to measure how trigger extraction by human affects labeling efficiency. First, we found that labeling triggers along with the entities is 1.5 times slower than labeling the entities only. Given this observation, we compare the performance between TIN models with `human` and `auto` by holding annotation time constant. We present the study in Figure. 8. Each marker on the x-axis of the plots indicate a certain annotation time, which is represented by approximate time. First, we could find that if we ask human to get triggers from scratch, it may not work better (See `RoBERTa+CRF` vs. `RoBERTa+TIN+CRF+human`). However, if we use auto triggers, we could achieve better performance and label efficiency (See `RoBERTa+TIN+CRF+auto`).

Human-in-the-loop Trigger Refinement. In previous study, we could find that asking human to annotate triggers from the scratch is not efficient. Here, we further think about asking human to refine auto triggers to reflect human decisions in a less labor intensive way. For all our previous experiments, we use the top two auto triggers, which limits our capacity to make the best use of them. In this experiment, given a training set with labeled entities, we extract five auto triggers (Sec. 3.1), show them to a human in a minimal interface, and ask for relevance judgments (relevant/non-relevant). We judge relevance of the automatically extracted triggers for entities in 50 - 200 sentences. Figure. 9 shows that we get an additional performance boost with more than 50 training sentences, when human-refined auto triggers are used. It shows promise for blending human expertise with auto triggers.

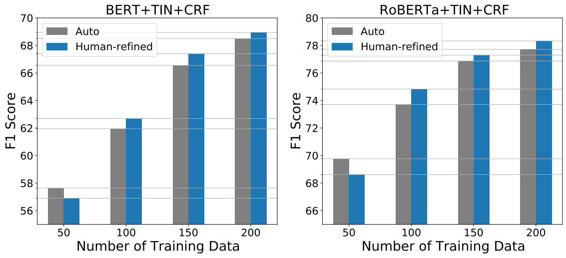

Figure 9: Performance Comparison (F1-score) on BC5CDR by different numbers of train data (50, 100, 150, 200) with auto and human-refined auto triggers.

6 Conclusion

In this paper, we proposed a novel two-stage framework to generate and leverage explanations for named entity recognition. It automatically extracts essentially human-readable clues in the text, which is called entity triggers, by sampling and occlusion algorithm and leverages these triggers with trigger interpolation network. The model effective learns the prior knowledge to infer the entity boundaries and types by leveraging the contextual clues. We showed that our framework, named AUTOTRIGGER, successfully generates entity triggers and effectively leverages them to improve the overall performance, especially in the label scarcity setting for technical domains where domain-expert annotations are very limited due to the high cost. Moreover, it shows better generalizability on unseen entities that do not appear in training data. We believe that this work opens up future works that can be extended to semi-supervised learning or distant supervised learning which can effectively use automatically extracted triggers to weakly label the unlabeled corpus.

Limitations

AUTOTRIGGER could reduce human efforts on collecting rationales for NER to improve the label efficiency and unseen entity generalizability of the model. However, it has a limitation that the time cost of extracting entity triggers is pretty expensive (i.e., (1) train entity token classifier; (2) run constituency parsing to retrieve trigger candidates; and (3) run post-hoc explanation to assign importance score to each candidate). This limitation raises open questions about whether reducing total training time cost or human effort is more efficient and important.

A Appendix

A.1 Experiment Settings

We implement all the baselines using PyTorch (Paszke et al., 2019) and HuggingFace (Wolf et al., 2020). We set the batch size and learning rate to 10 and 0.01 for GloVE embedder models (i.e., `GloVE+BLSTM+CRF`, `GloVE+TMN+CRF`) while we set 30 and 2e-5 for all other transformer embedder models (See Table 5). Note that for experiments in extreme low resource setting (Sec. 5.1), we set the batch size to 4 for training the models due to the extremely limited training data.

Trigger Matching Network For transformer-based `TMN` (i.e., `BERT+BLSTM+TMN+CRF`, `BERT+TMN+CRF`, etc.) we re-implement since the original repository does not support transformer embedders.

Trigger Interpolation Network For our `TIN`, we set the interpolation λ to 0.5.

Automatic Trigger Extraction For automatic trigger extraction stage, we build the entity token classifier with cased BERT-base encoder for `BERT+TIN+CRF` and RoBERTa-large for `RoBERTa+TIN+CRF`. The entity token classifier consists of the transformer encoder to encode each word token followed by a token-level linear layer that classifies each token to an entity tag. We use a batch size of 16 and learning rate of 1e-4 for training. For experiments under extreme low resource setting, we set batch size to 4 similar to the `TIN` models. To run context sampling in the SOC algorithm, we use a LSTM language model which is pre-trained on the training data.

A.2 Evaluation Metrics

We evaluate our framework by recall (R), precision (P), and F1-score (F1), though only report F1 in these experiments. Recall (R) is the number of correctly recognized named entities divided by the total number of named entities in the corpus, and precision (P) is the number of correctly recognized named entities divided by the total number of named entities recognized by the framework. A recognized entity is correct if both its boundary and its entity type are exact matches to the annotations in the test data. F1-score is the harmonic mean of precision and recall.

Embedder	GloVE	Transformer	
		BERT	RoBERTa
batch size	10	30	30
learning rate	0.01	2e-5	2e-5
epochs	10	10	10
LSTM hidden dimension	200	-	-

Table 5: Experimental setting details.

A.3 Data Statistics

BC5CDR (Li et al., 2016a) is a bio-medical domain NER dataset from BioCreative V Chemical and Disease Mention Recognition task. It has 1,500 articles containing 15,935 CHEMICAL and 12,852 DISEASE mentions. **JNLPBA** (Collier and Kim, 2004) is a bio-medical domain NER dataset for the Joint Workshop on NLP in Biomedicine and its Application Shared task. It is widely used for evaluating multiclass biomedical entity taggers and it has 14.6K sentences containing PROTEIN, DNA, RNA, CELL LINE and CELL TYPE. **CoNLL03** (Tjong Kim Sang, 2002) is a general domain NER dataset that has 22K sentences containing four types of general named entities: LOCATION, PERSON, ORGANIZATION, and MISCELLANEOUS entities that do not belong in any of the three categories.

A.4 Performance Analysis

Trigger Candidate Variants. In Sec 3.1, we first constructed a set of phrase candidates $\mathcal{P}$ for which the importance score is computed. To show the efficacy of constituency parsing for constructing trigger candidates, we conduct an ablation study on different variants of it. For the construction, we compare three variants: (1) `RS` is random selection. It randomly chooses n contiguous tokens to be grouped as a phrase for k times. Consequently, $\mathcal{P}$ is composed of k random spans. (2) `DP` is dependency parsing. Here, to generate $\mathcal{P}$, we first parse the input sentence using dependency parsing. Then, we traverse from the position of entity mention in the input sentence using depth-first-traversal and get a list of tokens visited for each hop up to 2-hops. Finally, for each hop, we convert the list of tokens to a list of phrases by merging the tokens that are contiguous into a single phrase. (3) `CP` is constituency parsing, which is our current method (see Sec. 3.1). We expect each variant to provide different syntactic signals to our framework. Figure 10 shows the model's performance with triggers that have been selected from different sets of phrase candidates. As we can see, constituency parsing

(a) BERT+TIN+CRF (b) RoBERTa+TIN+CRF

Figure 11: Performance comparison (F1-score) of entity+trigger baselines on 20% training dataset of BC5CDR with different interpolation weight λ.

yields consistently better performance by providing better quality of syntactic signals than others.

Sensitivity Analysis of interpolation hyperparameter (λ). In Sec 3.2, we linearly interpolated two different sources of knowledge by weight λ 0.5. To show how the weight λ affects the performance, we conduct an ablation study on different λ distribution. As we can see from Figure. 11, the framework achieves the highest performance when λ is set to 0.5. It supports that the model achieves the best when we interpolate the entity and trigger knowledge in equal.

Effect of number of triggers In Sec. 3.1, we pick the top k candidate phrases with the highest importance score as the entity triggers after obtaining the importance score for all phrase candidates. For our main experiment, we use top 2 candidate phrases (see Table 1). To show how the number of triggers affects the performance, we conduct an ablation study on model performance by different k. As we can see from Figure. 12, the framework achieves the highest performance when we use top 2 phrase candidates as triggers.

A.5 Related Works

NER with Additional Supervision Previous and recent research has shown that encoding syntactic information into NER models compensate for the lack of labeled data (Tian et al., 2020). The improvement is consistent across word embedding based encoding (e.g. biLSTM) as well as unsupervised language model based encoding (e.g. BioBERT (Lee et al., 2020b)) of the given text. Typically, the external information that is encoded include POS labels, syntactic constituents, and dependency relations (Nie et al., 2020; Tian et al., 2020). The general mechanism to include linguistic information into NER model is to represent them using word vectors and then concatenate those representations with the original text representation. This approach fails to identify the importance of different types of syntactic information. Recently, Tian et al. (2020) and Nie et al. (2020) both showed that key-value memory network (KVMN) (Miller et al., 2016) are effective in capturing importance of linguistic information arising from different sources. KVMN has been shown to be effective in leveraging extra information, such as knowledge base entities, to improve question answering tasks. Before applying KVMN, contextual information about a token is encoded as the key and syntactic information are encoded as values. Finally, weights over the values are computed using the keys to obtain a representation of the values and concatenate it with the context features. Our approach uses token level features extracted by an explanation generation model, but later train to be able to pick-up those explanations directly from the text at inference time.

Limited Training Data for NER. The simplest way to approach the problem of limited data for NER is to use dictionary based weak supervision. An entity dictionary is used to retrieves unlabeled sentences from a corpus and weakly label them to create additional noisy data. This approach suffers from low recall as the training data covers a limited number of entities. The models tend to

bias towards the surface form of the entities it has observed in the dictionary. There has also been approaches to retrieve sentences from a large corpus that are similar to sentences in the low-resource corpus to enrich it. These self-training approaches have been shown to be effective both in extremely limited data (Foley et al., 2018; Sarwar et al., 2018) as well as limited data scenario (Du et al., 2020). Even though these data enhancement approaches explore a corpus to find related data cases, they do not exploit the explanation-based signals that is available within the limited data.

Learning from Explanations. Recent works on Explainable AI are primarily focused on debugging the black box models by probing internal representations (Adi et al., 2017; Conneau et al., 2018), testing model behavior using challenge sets (McCoy et al., 2019; Gardner et al., 2020; Ribeiro et al., 2020), or analyzing an impact of input examples by input perturbations or influence function looking at input examples (Ribeiro et al., 2016; Koh and Liang, 2017). However, for an explanation of the model to be effective, it must provide not only the reasons for the model's prediction but also suggestions for corresponding actions in order to achieve an objective. Efforts to cope with this issue by incorporating human explanations into the model are called Explanation-based learning (DeJong and Mooney, 2004). These works are aiming to exploit generalized explanations for drawing inferences from unlabeled data while maintaining model transparency. Most prior works on explanation-based learning are mainly focused on facilitating logical rules as an explanation. They use such rules to create weak supervision (Ratner et al., 2017) and regularize posterior (Hu et al., 2016, 2017). Another form of explanations can be specific words in the sentence which aligns to our work. Notable work in this line asks annotators to highlight important words, then learn a generative model over parameters given these rationales (Zaidan and Eisner, 2008).

Incorporating Task-Specific Concept Knowledge into Script Learning

Chenkai Sun, Tie Xu, ChengXiang Zhai, Heng ji

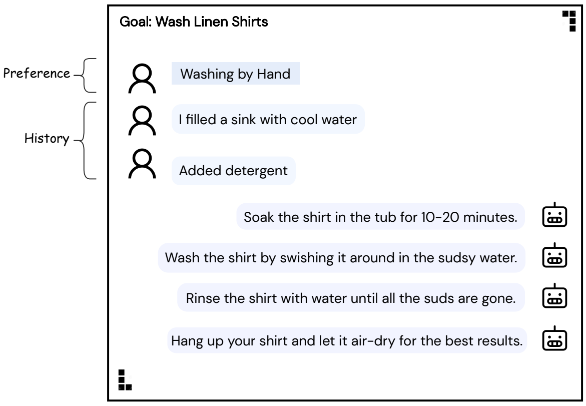
Abstract

In this paper, we present TETRIS, a new task of Goal-Oriented Script Completion. Unlike previous work, it considers a more realistic and general setting, where the input includes not only the goal but also additional user context, including preferences and history. To address this problem, we propose a novel approach, which uses two techniques to improve performance: (1) concept prompting, and (2) script-oriented contrastive learning that addresses step repetition and hallucination problems. On our WikiHow-based dataset, we find that both methods improve performance.

1 Introduction

A Goal-Oriented Script refers to a sequence of events that describe some stereotypical activities for achieving a specified goal (Feigenbaum et al., 1981; Lyu et al., 2021). It is important to study how to automatically construct instructional scripts because it enables many high-impact applications such as robot action planning (Conti et al., 2020; Mohanan and Salgoankar, 2018), causal reasoning (Guo et al., 2020), and task-oriented dialogue generation (Chen et al., 2017). While previous work has shown that neural models are capable of constructing the entire script given a goal (Lyu et al., 2021; Sakaguchi et al., 2021), their proposed tasks are highly restrictive and based on overly simplified assumptions about the application because it ignored both the usage context (e.g., what is a preferred way of solving the problem, and what steps have been executed already) and the variable personal preferences that a user may have (e.g., a goal might need be achieved in different ways). Take "Make Eggless Cupcakes" as an example, the user might want to make it with different equipment (e.g., by using a rice cooker instead of an oven) or styles (e.g., to have some banana flavor), or the user has already completed some steps but would like to seek information on what to proceed next; a machine learning model trained on goal-to-script tasks as done in the existing work cannot adaptively provide solutions under such situations.



Washing by Hand
I filled a sink with cool water
Added detergent
Soak the shirt in the tub for 10-20 minutes.
Wash the shirt by swishing it around in the sudsy water.
Rinse the shirt with water until all the suds are gone.
Hang up your shirt and let it air-dry for the best results.

Figure 1: An example illustrating the task. The input consists of a specified goal (e.g., wash line shirts), an optional preference (e.g., washing by hand), and a history of steps. The model is asked to generate the remaining steps to achieve the goal.

We address the limitations of the previous task formulation and propose TETRIS, a more general task of goal-oriented script learning that allows flexible usage scenarios, and therefore it accommodates more realistic needs in downstream applications. More specifically, as shown in Figure 1, the task considers both user preference and history as input in addition to the goal. From a probabilistic perspective, instead of modeling the problem with $p(\text{Script}|\mathcal{G})$, we model it as

$$p(\text{Completion of Script}|\mathcal{H},\mathcal{P},\mathcal{G}) = \prod_i p(\text{Script}_i|\text{Script}_{<i},\mathcal{P},\mathcal{G})$$

where i indicates each step index in the script, $\mathcal{P}$ denotes user preference, $\mathcal{H}$ indicates History, and $\mathcal{G}$ abbreviates Goal.

To solve the new problem, we can use a com-

monly used baseline method, i.e., using a seq2seq model (Lewis et al., 2019; Raffel et al., 2019), but a direct application of such a model would not be optimal because the model's understanding of the context of the goal is inevitably shallow and thus unlikely be able to fully exploit the extra context information we have in the problem setup. To address this limitation, we propose to enrich the representation with additional task-specific concepts so as to enable the model to understand the context more deeply and leverage relevant knowledge about those concepts encoded in the training data the model has been exposed to. To obtain task-specific knowledge needed for solving script learning, we introduce TASK CONCEPT DICTIONARY (TCD), a novel Key-Value Knowledge Base (KB) that consists of task phrases as the key and the associated concepts involved in the solution process for each task as the value. The concepts contain not only items needed for the task but also concerned attributes (e.g., "thickness") and intermediate products during the process (e.g., "dough" appears during Making Rice Noodles). In our work, as a proof of concept, we automatically construct the knowledge base from WikiHow[1], one of the most used and actively updated How-to websites.

Once we construct a TCD, it can be potentially used for solving the problem of script completion in many ways. In this paper, we focus on exploring how to leverage it to acquire task-specific relevant concepts for enriching the task representation used in a baseline model for script completion. Specifically, inspired by how humans use mind-map to construct solutions, we introduce a novel "concept prompting" framework that first acquires relevant concepts from TCD and then connects them with the input as a prompt for the language generator to complete the script (Figure 2). We further introduce two complementary ways of concept acquisition. The first method retrieves concepts of close neighbors from TCD. The second method involves a generative model pretrained on TCD that is capable of generating associated concepts for a given goal, which can generalize beyond similar cases. Discovering that the model often repeats historical steps and hallucinates actions and entities, we also developed a script-oriented contrastive learning approach to address these issues by constructing corresponding negative samples.

We perform experiments on a dataset constructed from WikiHow and find that our method gives a consistent improvement on both automatic and human evaluations in comparison to the baseline, demonstrating the benefit of TCD for script completion. Moreover, we find that concept acquisition quality has a large impact on this task.

To summarize, we make the following contributions:

- We introduce TETRIS, the task of Goal-Oriented Script Completion that asks a model to complete the task based on a goal, and optionally preference and history. The task poses interesting new challenges and enables new applications.
- We propose TASK CONCEPT DICTIONARY, a novel task-specific knowledge base that encodes knowledge about the associations between goals and concepts and a method composed of (1) extraction and integration of the relevant concepts from TCD, and (2) script learning-oriented contrastive learning objective to enhance the correctness of model-produced scripts.
- We experiment with the proposed methods on the WikiHow dataset and show that our methods outperform the state-of-the-art baseline models consistently, demonstrating the need for task-specific knowledge and the benefit of TCD for improving the performance of script completion.

2 Task Formulation

We define a Goal-Oriented Script to include three types of elements, **Goal**, **Preference**, and **Step**. A **Goal** represents the task desired to be completed. An optional **Preference** defines in what ways the goal should be completed. A **Step** is one procedural event toward solving the task, conditioned on a preference. In this work, given a goal $\mathcal{G}$, a preference $\mathcal{P}$, and a history of steps $\mathcal{H}$ already done, we aim to generate the remaining steps that accomplish the goal in natural language. An example is shown in Figure 1. For convenience, we use $\mathcal{G}_p$ to denote the goal conditioned on $\mathcal{P}$, and $\mathcal{I}$ to denote the entire input (consisting of $\mathcal{G}$, $\mathcal{P}$, and $\mathcal{H}$).

3 Task Concept Dictionary

As in virtually all NLP applications, a main technical challenge in solving the problem of script

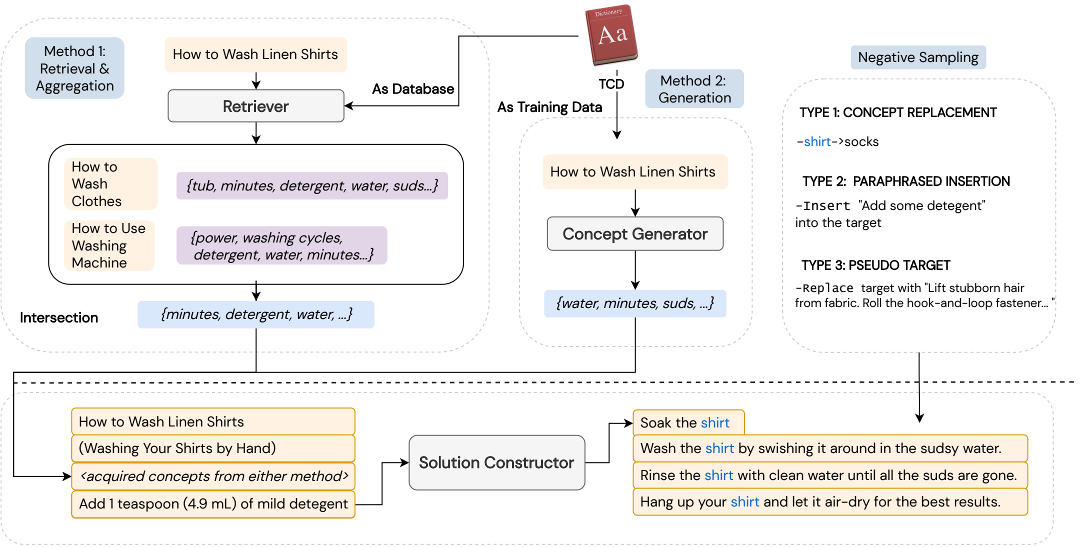

Figure 2: Our goal-oriented script completion framework. The top part shows the methods for automatically acquiring relevant concepts from the Task Concept Dictionary and negative sampling strategies. The bottom part shows the solution constructor, which uses the acquired concepts as an informative prompt to complete the script.

completion is how to acquire the relevant knowledge and leverage the knowledge to generate the remaining steps in a script. In our case, a critical question is: What kind of knowledge representation is likely helpful for solving the script completion problem? In our work, we make a hypothesis that creating task-concept association would help the model generalize better on script completion and propose Task Concept Dictionary (TCD). In TCD, each task key $\mathcal{G}$ from the collection of the keys $\mathcal{D}^{\mathcal{G}}$ (e.g., "How to Modify the Navigation System of an Acura") is mapped to a set of relevant concepts $\mathcal{D}^{\mathcal{G}}_{C}$ during its solution process. Each $c \in \mathcal{D}^{\mathcal{G}}_{C}$ can be associated with $\mathcal{D}^{\mathcal{G}}$ in four types of roles of a concept in that task: as preparation material needed for achieving the task (like ingredients for recipe), as attributes/aspects that need to be considered, as intermediate entities generated during the process, and others. In this work, we made a primal construction of TCD (TCD.v0) as a proof of concept, that is, the association types are not considered between $\mathcal{G}$ and $\mathcal{D}^{\mathcal{G}}_{C}$.

The design of TCD is motivated by the observation that humans can often form solutions through brainstorming and mind-mapping with knowledge about the tasks and relevant concepts involved in the solution process. Analogously, TCD is meant to encode such task-specific knowledge about associations between goals and concepts so as to assist downstream script learning applications. As will be shown in our experiment results, TCD is indeed beneficial for improving performance for script completion by supplying useful relevant concepts to a baseline model.

In general, TCD can be constructed by using any instructional content on the Web. In our experiments, to construct TCD.v0, we first collect all articles from WikiHow. We chose to use WikiHow as the seed corpus for its richness in user preference data. Each article consists of a goal, a list of preferences, and solution steps under each preference. Let $\mathcal{G}^{p_j}_{i}$ be the goal from an article i conditioned on the j-th preference, we then proceed to augment the set $\mathcal{D}^{\mathcal{G}}$ with a key $\mathcal{G}^{p_j}_{i}$, and augment $\mathcal{D}^{\mathcal{G}^{p_j}_{i}}_{C}$ with noun phrases (by using Spacy[2] tagger for extraction) in the solution steps under preference j. We create an association between goals and concepts if they co-occur in the same article. We show the statistics of TCD in Appendix A.1.

4 Method

In this section, we discuss our design of the method for TETRIS. The framework contains two parts, concept acquisition from TCD and solution construction. The first part uses TCD as an aid to acquire concepts relevant to the current input. Specifically, we introduce two different methods (Figure 2), one based on retrieval of closely related tasks and aggregation on the associated concepts, while the other involves training a concept generator on TCD. As shown in Section 5, both of

---

[2] `https://spacy.io/`

them have a positive impact on performance, yet they also introduce different benefits. The concepts fetched from TCD using either method form a concept prompt, which is combined with the input $\mathcal{I}$ (consisting of goal, preference, and history) as an augmented input $\mathcal{I}^*$. $\mathcal{I}^*$ is then fed into an encoder-decoder language model $\mathcal{M}_{\text{EncDec}}$ to complete the script. Below we describe the two methods for the generation of relevant concepts using TCD.

4.1 Concept Retrieval & Aggregation

The intuition of the retrieval method comes from observing how human refers to their past knowledge or the web for similar instructional sources (even though they might not address the need exactly) to achieve the current goal. For instance, if someone has experience in baking cheesecake and chocolate cake, it would be a breeze for them to make a strawberry cake by adapting the knowledge from their past experience. Building on the intuition, we propose to use retrieval as an interpretable way to retrieve similar tasks from the set of keys $\mathcal{D}^G$ in TCD and use their associated concepts to aid the downstream script completion task.

Retrieval. First we encode $\mathcal{G}_p$ (i.e., the preference-conditioned goal in $\mathcal{I}$) into a dense vector $\mathbf{e}_{\text{g}}$ with an encoder model. We similarly encode $\mathcal{D}^G$ into $\{\mathbf{e}_j\}_{j=1}^{|\mathcal{D}^G|}$. A cosine similarity score s_{gj} is computed between $\mathbf{e}_{\text{g}}$ and each $\mathbf{e}_{\text{j}}$. The top-K related tasks $\mathcal{N}^K$ are then retrieved based on the scores. We further obtain a set of concepts $\mathcal{C}_i$ for i-th task $\mathcal{N}^K$. In our experiment, we use SBERT (Reimers and Gurevych, 2019) (pretrained for semantic search) as the encoder. We use FAISS (Johnson et al., 2019), an efficient similarity search library, to perform top-k search.

Aggregation. The retrieved neighborhood of concepts, however, may sometimes introduce contextual noise (e.g., the grape and chocolate-related concepts are not useful in strawberry cake baking). To tackle this issue, we additionally perform operations on the retrieved concepts using the set intersection. The concept set for an input $\mathcal{I}$ is computed as $\mathcal{C}^s = \bigcap_{i=1}^{i=K} \mathcal{C}_i$. We finally map the set $\mathcal{C}^s$ into a list $\mathcal{C}$, neglecting ordering information.

4.2 Concept Generation

While the retrieval method allows an explicit concept acquisition process, it is limited by the width of TCD. For example, if one would like to complete a task from a domain that is not covered well by TCD, the retrieved neighbors can introduce more noise than help. To address this limitation of the retrieval method and enhance generalization, we propose to use language modeling as an alternative way of acquiring concepts. Specifically, inspired by the work (Bosselut et al., 2019), in which a concept is generated given an edge type, we propose to directly generate a set of concepts relevant to a given task and preference. We directly train the model on TCD, where the model is asked to generate the set $\mathcal{D}_C^t$ given each key t. In the inference stage, by feeding $\mathcal{G}_p$ into the trained concept generator, we can then obtain a list of concepts $\mathcal{C}$.

Table 1: Statistics summarizing the WikiHow-based dataset for TETRIS, where F&E indicates Food and Entertainment, F&B indicates Finance and Business, and C&V indicates Cars and Other Vehicles

4.3 Solution Constructor

In this step we aim to encode both of the information from $\mathcal{C}$ (using either of the above methods) and $\mathcal{I}$ to generate the remaining steps that accomplish the goal specified in $\mathcal{I}$. The TCD has enabled us to enrich the representation by augmenting $\mathcal{I}$ with $\mathcal{C}$ and such an augmented representation can then be fed into any baseline script completion method to enable the baseline method to have (indirect) access to the knowledge encoded in TCD, thus improving accuracy of script completion.

Input Formation. An encoder-decoder model $\mathcal{M}_g$ is used for generation. In our experiment, we choose BART (Lewis et al., 2019) as the base model for its impressive performance on other NLP tasks (Liu et al., 2021; Lewis et al., 2020). Clearly, the framework accommodates any other models as well. Given the list of concepts $\mathcal{C}$ generated from either Section 4.1 or 4.2, we form the input $\mathcal{I}_f$ to the encoder as “<s>Goal (Preference) ### $\mathcal{C}$ ### </s>Step$_1$</s>Step$_2$...Step$_{|\mathcal{H}|}$</s>”, where <s> is a special token to represent the start of the sentence and </s> is for separation.

Model Generation. The input is fed through the standard tokenization, embedding mapping, and transformer to produce encoder hidden states. In

Table 2: Automatic metrics for evaluating language generation performance on the test set of Vehicles (top), Finance (middle), and Food (bottom). Our main models **CRA-2** and **CG** outperform the baseline consistently, demonstrating the effectiveness of our mechanism. We also include the performance of **CRA-1** and **CRA-3** to show that the performance varies as the number of neighbors changes. Moreover, we show that our contrastive learning objective (**SOCL**) almost always helps the model to have better performance.

the decoder end, the decoder hidden states (from the previous token) additionally attend to encoder hidden states to produce the next token. The model computes generation probability by taking the dot product between the decoder output and the tokens embeddings from the vocabulary.

Lastly, we use negative log-likelihood loss during training for each sample

$$\mathcal{L}_G = -\sum_{i=1}^{|S|} \log P\Big(s_i | s_{<i}, T\Big) \qquad (1)$$

where S denotes the tokens for the remaining steps.

4.4 Script-Oriented Contrastive Learning

To further improve the accuracy of the generated scripts, we design a contrastive learning framework that addresses deficiencies discovered in the model outputs from 4.1 and 4.2.

Negative Sampling In contrastive learning(Hu et al., 2022), hard negative samples are constructed to guide the model to better distinguish between the incorrect samples and the desired outcome. To construct such negatives, we gain insights from the model output, from which we found that the model elicits two typical types of erroneous behavior: (1) repetition of steps from the history and (2) hallucination of non-relevant actions/concepts for a given task (e.g., sago appeared in the process of making kimchi). Based on the observation, we propose the following strategies: (1) CONCEPT REPLACEMENT, where we randomly replace the concepts in the positive sample with concepts from other tasks in TCD under the same category (e.g., Food category in WikiHow), (2) PARAPHRASED INSERTION, where we paraphrase history steps and insert them into target steps, and (3) PSEUDO TARGETS, where we construct pseudo target by sampling steps from the same category and glue them into a sequence.

Contrastive Loss In computing the contrastive loss, we generate negative targets from the strategy above for each positive script target (composition discussed in the Appendix). To allow the model to distinguish between correct and incorrect script completions, we use the model's hidden states to compute a score to compute the correctness score for each sample, which is then used to compute the triplet loss (Schroff et al., 2015). More specifically, for each training sample

$$
\begin{aligned}
\mathcal{L}_{\mathrm{CL}} &= \sum_k \max\left(0, \phi + c_k^- - c^+\right), \\
c^+ &= \sigma\left(\operatorname{AvgPool}\left(\boldsymbol{W}_c \boldsymbol{H}^+ + \boldsymbol{b}_c\right)\right) \\
c_k^- &= \sigma\left(\operatorname{AvgPool}\left(\boldsymbol{W}_c \boldsymbol{H}_k^- + \boldsymbol{b}_c\right)\right)
\end{aligned}
$$

Where $\boldsymbol{H}^+$ and $\boldsymbol{H}_k^-$ indicate the decoder hidden states for the positive and k-th negative sample, σ is the sigmoid function, AvgPool is the average pooling function, $\boldsymbol{W}_c$ and $\boldsymbol{b}_c$ are learnable parameters.

4.5 Training Objective

We jointly optimize the model on cross-entropy loss from generation and triplet loss from contrastive learning

$$\mathcal{L} = \mathcal{L}_G + \beta \mathcal{L}_{CL}$$

where β is hyper-parameter.

5 Experiments

5.1 Dataset

We collect data from Food & Entertaining (abbreviated as Food), Finance & Business (abbreviated as Finance), and Cars & other Vehicles (abbreviated as Vehicles) categories of WikiHow, which have varying data scales and therefore allow comparison of models' generalization ability. Each article from WikiHow contains a goal, (optionally) several preferences for completing the goal, and steps under each direction. The details of the dataset are shown in table 1. More processing details are in Appendix A.1.

5.2 Implementation and Training Detail

Our model is implemented using Pytorch (Paszke et al., 2019) and Huggingface Transformers (Wolf et al., 2020) with BART-base as the base generator. The reproducibility and hyperparameter details can be found in Appendix A.2.

5.3 Compared Methods

We compare our framework and methods with the state-of-the-art text generation baselines **BART** (Lewis et al., 2019) and **GPT2** (Radford et al., 2019), which don't use any of our proposed methods. The solution constructor in our framework also uses BART. We use **CRA**-k to denote top-k neighbors in 4.1 and set k to be 1,2, or 3 in our experiment. We use **CG** to denote the concept generator in 4.2. Since TCD.v0 is also based on WikiHow as source data, we make some modifications to our methods in the experiment so that we can test the scenarios where the new unseen task cannot be exactly found in the knowledge base. For concept generation, we exclude the evaluation set related articles in the dataset from its training data. For **CRA**-k, when we retrieve relevant tasks from TCD for a given goal, we remove its own key from TCD. **SOCL** indicates that script-oriented contrastive learning is used during the training.

5.4 Automatic Evaluation

Evaluation Metrics We use both deep learning and n-gram-based evaluation strategies. The metrics include BERTScore (Zhang et al., 2019), BARTScore (Yuan et al., 2021), BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and ROUGE (Lin, 2004). Note that BARTScore computes the log-likelihood of producing the reference text given the generated text using a BART model pretrained on ParaBank2[3]. BERTScore computes an embedding matching-based score.

Results The test set results are shown in Table 2. We can see that the performance of our method variants (both CRA and CG) is consistently better than the baselines, empirically demonstrating the effectiveness of both concept acquisition methods and that the task-concept representation of the task-specific knowledge is helpful for downstream script learning. Moreover, while CG outperforms CRA-2 on all metrics in Finance, it is less clearly observed in the others, showing that the level of effectiveness also depends on the domain. The fact that CRA-2 is better than CRA-1 most of the time shows that the set operation in Section 4.1 does improve the retrieval quality for certain domains. Meanwhile, CRA-3 consistently performs worse than CRA-2, showing that setting $k = 3$ may have removed too much useful information. With contrastive learning, the model almost always gains enhancement in performance, showing the effectiveness of our sampling strategies; an exception is shown in the Food category for CG, where it shows positive im-

Name	**Correctness ↑**	**Fluency ↑**	**Average Rank ↓**	**Best ↑**	**Worst ↓**
BART	1.72	2.57	3.57	4.13	72.73
CG	2.32	3.06	2.65	9.09	13.22
CRA-2	**2.52**	**3.15**	**2.34**	**14.88**	**9.92**
Gold-Concepts	**3.40**	**3.55**	**1.44**	**71.90**	**4.13**

Table 3: Human evaluation results for the WikiHow dataset on all three categories combined. Scripts completion outputs (from automatic analysis) from each model are presented to human judges, who are asked to rate on Correctness (i.e., at what level does the generated solve the problem) and Fluency of the output. We also report the average rank and percentage of the time that each model output is chosen as best or worst, after asking each judge to rank outputs from different methods for each input

pact only on half of the metrics, and this might be caused by that the CG itself is effective enough and contrastive learning introduces more noise than help. We also show in Appendix that adding SOCL alone is already effective. Lastly, we observe that the Vehicle and Finance categories contain much less training data than Food, yet the performance improvement is more notable, demonstrating the potential of the methods in low-resource settings.

5.5 Human Evaluation

Evaluation Metrics & Process As mentioned in (Zhang, 2022), automatic metrics do not correlate well with human judgments on script learning tasks due to the diversity of potential solutions. As a complement to automatic metrics, we also recruited five volunteers (who are not authors) and conducted the human evaluation. The volunteers were Master/Ph.D. students with enough background knowledge to rate output. We gave each candidate a quiz composed of 20 random samples from the dataset as filtering to see if the annotator can give scores close to the authors'. We made sure that each annotator understands the assigned data samples during evaluation. In our evaluation process, we compared the output generated by BART, CRA-2, and CG with SOCL, and Gold-Concepts (a variant where concepts come groundtruth in TCD). We presented the input and the corresponding generated outputs from each method to human judges and asked them to rate the Correctness and Fluency of the output, both on a scale from 0 to 4. Correctness (or usefulness) was defined as the level of confidence that the generated steps successfully complete the specified goal and preference. We additionally asked the judges to rank the outputs according to their overall preference and their rating on Correctness & Fluency; after this procedure, we reported the average rank and the percentage of the time that each model output is chosen as the best or worst.

Goal	**How to Store Peaches**
Preference	Keeping Peaches in the Fridge
History	Rinse the peaches to clean off any dirt or debris. Dry the peaches with clean paper towels or a clean hand towel.
BART	<eos>
CG	[*peach, paper bag, store peach, container, term storage*] **Store peaches in the fridge** for up to 3 months.
CRA-2	[*peach, freezer, container, half*] **Store the peaches in an airtight container** in the freezer for up to 3 months.
Reference	Place whole, uncut peaches in the fridge on their own or in a plastic bag. ... **Store sliced peaches in an airtight container** for 1-2 days.

Table 4: Example input and output from the Food category. The noun phrases contained in square brackets in CG and CRA-2 indicate the acquired concepts from TCD. <eos> indicates an empty completion (i.e., the history is believed to contain the complete script). With fridge storage-related concepts, our models correctly produce the storing step.

Results. 121 samples are randomly selected from automatic analysis for human evaluation, where 40 come from the Vehicle category, 40 come from Finance, and 41 from Food. We present the human evaluation results in Table 3. The results align with automatic metrics roughly in general. The Gold-Concept variant is usually the best since it has access to ground-truth noun phrases from the reference. CRA-2 often generates more helpful solutions for users. The outputs from BART are worse than others most of the time, confirming the belief that using acquired task knowledge as prompts can help the model to generate better solutions on average. The Fluency level for all methods is rated to be of acceptable quality most of the time, likely due to the strong generalization capability of the pretrained language model.

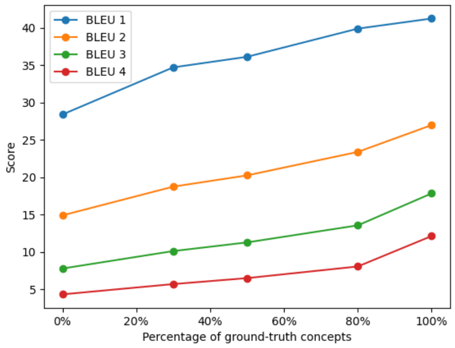

Figure 3: The plot shows that the automatic performance increases as the amount of ground-truth concepts increases, showing that deriving the right task-specific concepts can make the model generate better scripts.

5.6 Impact of Retrieval Quality

One question to be asked is how impactful it is to derive a concept prompt close to the groundtruth (i.e., concepts from TCD by using the current goal as the search key). To answer the question, we randomly draw concepts from the groundtruth at different thresholds and use each of them as a prompt to train a baseline model. From our result shown in Figure 3, we can see that the performance monotonically increases as the number of concepts covering the ground-truth concepts increases, showing the consistent benefit of using the concepts in the right context; this also demonstrates the promising direction of our methods and the significance of developing a concept deriver better at understanding task context.

5.7 Qualitative Analysis

We present an example of generated outputs by different methods in Table 4. Additional examples are available in Appendix A.3. We compare BART, CG, and CRA-2. From the generated output, we can see that BART ends the script immediately, missing the step of storing, likely due to the lack of access to knowledge about storage. On the other hand, with the acquisition from TCD, our methods can reach more contextual knowledge for the current task. Specifically, both methods are able to access storage-related concepts such as term storage, container, and freezer. As a result, the outputs match with the reference more closely. While the alignment with the reference isn't perfect (e.g., peaches are additionally placed in a bag in the reference), to most human judges, the script completion clearly achieves the goal already; this further demonstrates the difficulty of evaluating script completion.

6 Related Work

Script Learning: Scripts (Schank and Abelson, 2013; Feigenbaum et al., 1981; Yang et al., 2021; Zhang et al., 2020b,a) refers to the knowledge of stereotypical event sequences which human is constantly experiencing and repeating every day. One branch of works in script learning focuses on distilling *narrative* scripts from news or stories (Chambers and Jurafsky, 2008; Jans et al., 2012; Lee and Goldwasser, 2019), where the scripts are not goal-oriented. One of the most recent tasks in *narrative* script modeling is Multiple-Choice Narrative Cloze Test (Granroth-Wilding and Clark, 2016), where an event is removed from the chain and the model is asked to predict which event from the choices fills the blank. The other line of work, which is more closely related to our work, centers around *procedural* scripts, where a sequence of events happened often to achieve a goal. Recent work has introduced the task of constructing the entire script given a goal (Lyu et al., 2021) or choosing 1 out of 4 candidates' steps that most likely help achieve a goal (Zhang et al., 2020c). In this work, we propose a more general script learning setup that considers additionally the user preference and history, improving the generalization of models in script learning.

Our method is related to Retrieval-augmented text generation (Li et al., 2022; Zhang et al., 2022; Wu et al., 2021), a paradigm that aims to combine deep learning models with retrieval methods for text generation and has gained significant attention in recent years. For example in (Rubin et al., 2022), the author retrieves similar training examples as prompt to the current input. In our work, we are the first to introduce a framework that retrieves concepts from the concept dictionary as prompts for script learning. Apart from acquiring concepts, we also introduce a way to cancel contextual noise from neighbors by set intersections for better prompt quality. Furthermore, our method is related to contrastive learning (Wang et al., 2022; Hu et al., 2022; An et al., 2022), a line of self-supervised learning methods that improve representation learning by compacting positive samples while contrasting them with negative samples (Cao and Wang, 2021). Previous methods used negative sampling approaches such as replacing the words with synonyms and shuffling target sentences. In our work, we introduced a new script-oriented contrastive learning objective to address script-specific issues and enhance the quality of generated scripts.

7 Conclusion

In this work, we propose TETRIS, the new task of Goal-Oriented Script Completion, which allows a model to produce the remaining steps given a user-specified goal, preference, and history of steps. We also present TASK CONCEPT DICTIONARY (TCD), a knowledge base representing task and concept association, to enable knowledge-based methods for the task. We introduce different methods to acquire concepts as prompts for the downstream text generator. We also introduce a contrastive learning strategy for script learning. The methods present consistently better performance on both automatic and human evaluation, clearly demonstrating the benefit of TCD for improving the performance of script completion. The qualitative analysis further shows that the task-specific knowledge can indeed benefit goal-oriented script learning tasks by feeding relevant knowledge about task completion. Future work could explore how to improve the acquisition quality from TCD and applications of TCD on task-oriented dialog systems.

Limitations

While TCD paired with concept acquisition methods can aid downstream script learning tasks, it doesn't consider the inclusion of actions of each step event, which can potentially benefit the script learning tasks. A possible direction is to extend the design of TCD and the concept prompt to include the semantics of actions and their orders.

Meanwhile, the concepts extracted by our method do not overlap with the ground-truth concepts (i.e., the set of concepts that appear in the reference) very well (e.g., <20% in Jaccard Index). The gap in performance between our methods and the Gold-Concept variant shows that improving the concept derivation quality might be the next step.

Furthermore, because our dataset is constructed from the English version of WikiHow, the benefits of our methods shown in the experiments are only empirically proved to work for English. We plan to further test our methods in multiple languages.

Ethics Statement

The study aims to extend deep learning-based models on the ability to generalize scripts under different user contexts. The script learning models introduced in the work can potentially be helpful for task-oriented dialog systems to suggest solutions to users. The dataset on which we base our experiments is constructed automatically from the publicly available website WikiHow. Since the website is primarily crowdsourced, the models trained on the data might incur subjective bias. During the human evaluation phase of the experiment, all involved human judges participated voluntarily and received decent payment.

A Appendix

A.1 Dataset & TCD

The dataset statistics are shown in Table 1. The raw corpus comes from the 07/20/21 snapshot of WikiHow. We filter out unordered scripts by using both the classification results from (Lyu et al., 2021) and the WikiHow section type. We perform a 6:2:2 split on the articles to create a train, development, and test set. We create a history $\mathcal{H}$ in data samples for TETRIS by randomly splitting a sequence of steps under each preference into two halves. For TCD, we have 206621 keys in total and 10.37 concepts per key on average.

A.2 Implementation Details

We implement the models using the 4.8.2 version of Huggingface Transformer library[5](Wolf et al., 2020). We use the Oct 1, 2021 commit version of the BART-base model (139M parameters) from Huggingface[6]. The contrastive learning variants has 140M parameters. For SBERT in Section 4.1, we use the all-mpnet-base-v2 checkpoint from sentence transformer library [7]. We use Huggingface datasets[8] for automatic evaluation metrics. The BART Score comes from the author's repository[9] and we used the one trained on ParaBank2. The hyperparameters for the experiment (non-contrastive

Method	BERTScore	BARTScore	BLEU 1	BLEU 2	BLEU 3	BLEU 4	METEOR	ROUGE 2
BART	**87.87**	-4.37	16.61	8.31	4.67	2.92	18.92	5.6
BART+SOCL	87.725	**-4.349**	**19.478**	**9.441**	**5.216**	**3.236**	**19.198**	**5.73**

Table 5: On the Finance dataset, our result shows that SOCL alone already brings consistent benefits to the performance.

Table 6: Hyperparameters for non-contrastive learning (CL) models (some are introduced and changed for CL experiment). The ones below the mid-line are generation related. Batch size is changed for contrastive learning.

Name	Value
seed	42
learning rate	3e-5
batch size	16
weight decay	5e-4
RAdam epsilon	1e-8
RAdam betas	(0.9, 0.999)
scheduler	linear
warmup ratio (for scheduler)	0.06
number of epochs	25
metric for early stop	SacreBLEU[4]
patience (for early stop)	15
length penalty	1.2
max length	511
min length	2
beam search size	5

learning) are shown in Table 6 (applied to all models) and the ones not listed in the table are set to be default values from the transformer library. We use RAdam (Liu et al., 2019) as the optimizer. We perform hyperparameter search on batch size from {16, 32}, pretrained language model learning rate from {2e-5, 3e-5, 4e-5}, downstream learning rate for contrastive learning from {1e-3, 5e-4, 1e-4, 3e-5}, negative sample composition from type A “1 sample from each of type 1 2, filling empty case with type 3” and type BCD “2 samples from the type combination (2 3/1 2/1 3), filling empty case with empty string”, and the number of epochs from {8, 15, 25} ({28, 32} for contrastive learning). For contrastive learning experiment negative sampling, we use type A for Vehicles and Food and type B for Finance. We perform our experiments on 40 GB A100 and 32 GB V100 GPU. For contrastive learning, we use batch size of 28 for Vehicles, 32 for Food, and 32 and 28 for CRA and CG respectively in Finance. The downstream learning rates are respectively 1e-3, 1e-3, 5e-4 for CRA-2+SOCL and 3e-5, 1e-4, 1e-3 for CG+SOCL in the datasets of Vehicles, Finance, and Food. We use 0.5 for the margin in the triplet loss function and 0.3 for the β in the training loss. The experiments can take up to 10 hours.

A.3 Additional Model Outputs and Analysis

We present examples in Table 7, 8, and 9, in addition to Section 5.7. From Table 7, we can see that while BART ends the script immediately after finding an agency, our methods are able to provide detail on the interaction with the agency. This shows that training with the acquired concepts as prompts allows the model to gain more task-specific contextual knowledge, which can be potentially shared in the token embeddings of concepts. In Table 8, the user preference in the example contains some ambiguity (i.e., it could mean making just the dough, or the complete process of making the pasta). While BART is missing the further processing on the *dough*, CG and CRA-2 are able to not only include detailed and reasonable steps that process the *dough* but also some information on what to do after the dough is being made, showing the usefulness of incorporating task knowledge. The reason for the improvement could be that the prompts of our method (all including the word *dough*) allow the model to be attentive to the processing of $dough$. In Table 9, the methods without gold concepts all believe the script has ended, which is a reasonable output. Yet they would be low on automatic generation metrics because of not matching reference well (which contains steps not necessarily needed to complete the goal). This shows the difficulty of automatically evaluating script generation since there can be many ways to solve a task and can be different in the amount of detail.

A.4 Discussions

While we show in the experiment that TCD can be used in the script completion task in our work to achieve better performance, it can also naturally be applied to other domains such as task-oriented

Goal	**How to Report Pet Store Neglect**
Preference	Reporting to Local Law Enforcement
History	Document the situation as extensively as possible Check your state's animal welfare law Find out which agency is responsible for enforcing animal laws
BART	Finished
CG	[dog] Report the situation to local law enforcement Follow up with any follow-up questions Finished
CRA-2	[police, report, animal control, authority] Contact local law enforcement agencies if necessary Follow up with any follow-up questions Finished
Gold-Concept	[situation, state, animal welfare law, agency, animal law, documentation, record, report, law enforcement] Gather documentation and record of the report to law enforcement Follow up with your report if necessary Finished
Reference	Gather your documentation and other records File your report with law enforcement Follow up on your report Finished

Table 7: Example output among different methods (Finance and Business)

dialog, event causal identification, and causal inference. Furthermore, since the two different concept acquisition methods in the paper contain different advantages, it would be an interesting task to devise a method that has both benefits of being explicit in the acquisition process and being parametrized.

One natural question to ask is why we represent the KB as concept-based instead of directly using paragraphs to record each goal. While How-to websites contain human-curated solutions, the way of annotation introduces canonicalization problems since different people might have 1. different orders of completing the same task and 2. different levels of detail in the expression; on the other hand, using concepts representation helps alleviate the problem since the core concepts (e.g., "butter", "temperature", "time" in "Baking a Cake") almost always participates regardless of how they are organized in each person's memory. Furthermore, TCD introduces an interesting function of automated self-enrichment. In hierarchically related goals, such as "how to bathe a dog" and "how to bathe a cat", we can use **WordNet Hierarchy** and **Concepts Intersection** to automatically derive new nodes. We leave the experimentation to future work.

Another important problem to be tackled is that, while human evaluation is more reliable than automatic evaluation, it is also much more costly. As mentioned in (Zhang, 2022), automatic metrics do not align with that of humans very well. One promising direction is to create an automatic metric that does not evaluate script generation methods only based on matching with the reference (since many equivalently valid references can exist).

Goal	**How to Make Macaroni Pasta**
Preference	Making Pasta Dough at Home
History	Mix the dry ingredients Create a hole or well in the dry ingredients Add three large eggs Whisk the eggs with a fork Place the dough on a clean counter
BART	Bake the pasta Serve the pasta while it is still warm Finished
CG	[flour, salt, bowl, butter, milk, egg, flour mixture, dough, surface] Roll the dough out into a rectangle Cut the dough into 1/4 inch (0.64 cm) circles Transfer the dough to a plate Repeat the process with the rest of the dough Cook the pasta Place the pasta on a plate to warm up Serve Finished
CRA-2	[dough] Roll the dough into a ball Repeat the process with the rest of the dough Transfer the dough to a baking sheet Bake the pasta Serve or refrigerate Finished
Gold-Concept	[ingredient, hole, egg, fork, dough, counter, surface, bowl] Place the dough on a floured surface Transfer the dough to a serving bowl Serve Finished
Reference	Fold the dough Look for a smooth surface Place the dough in a clean bowl to rest Finished

Table 8: Example output among different methods (Food and Entertaining category).

Goal	**How to Track a Flight in Progress**
Preference	Via Online Websites
History	Gather the information about the flight: Find a flight-tracking website to find out the information about your flight Enter your flight information Watch for plugins that you could need to add to your browsers functionality to run the website Watch a map come up on your screen showing the route the plane has taken, as well as the current location of the plane and the expected route ahead

Abstract

Long video content understanding poses a challenging set of research questions as it involves long-distance, cross-media reasoning and knowledge awareness. In this paper, we present a new benchmark for this problem domain, targeting the task of deep movie/TV question answering (QA) beyond previous work's focus on simple plot summary and short video moment settings. We define several baselines based on direct retrieval of relevant context for long-distance movie QA. Observing that real-world QAs may require higher-order multi-hop inferences, we further propose a novel framework, called the **DeepMaven**, which extracts events, entities, and relations from the rich multimedia content in long videos to preconstruct movie knowledge graphs (movieKGs), and at the time of QA inference, complements general semantics with structured knowledge for more effective information retrieval and knowledge reasoning. We also introduce our recently collected *DeepMovieQA* dataset, including 1,000 long-form QA pairs from 41 hours of videos, to serve as a new and useful resource for future work. Empirical results show the DeepMaven performs competitively for both the new *DeepMovieQA* and the pre-existing MovieQA dataset.[1]

1 Introduction

Our world tells an evolving story of people, objects, and their interactions. This storytelling may exist in various forms, from textual summaries and spoken dialogues, to accompanying images and videos. Because of its dynamically evolving and multi-media nature, long-distance video question answering on movies/TV shows provides a useful setting for studying the computational understanding of interconnected stories and events that aligns closely with real-world application scenarios. Yet, current intelligent systems still struggle with adequately processing the rich multimedia content in long videos and fail to answer many common inquiries that humans are interested in. If we ask a virtual assistant about the relationship between two main characters in a well-known movie/TV show, it likely defaults to some null response such as *"hmm... I don't know this one"*.

The research challenge of long video content understanding and question answering frameworks stems from the need to support information probing on certain specific details over a large multimedia context space. Propagating information across long-distance has been a well-known challenge due to the vanishing gradient and memory loss problem (Hochreiter, 1998). Long videos also can not fit its entire data in-memory typically for end-to-end feature extraction and neural network training. Meanwhile, retrieval-based methodologies, which first find sections in the video relevant to a query through semantic cues from the corresponding dialogues and/or frames, and then return the relevant textual dialogue and/or visual frame context for question answering, tend to narrowly isolate media instances semantically similar to the query inputs. Query inputs are short and succinct in nature, so simply considering data points that match the query semantics will overlook the larger picture behind the selected media instances *i.e.* how they relate to each other as well as to other relevant media components that are initially missed out from retrieval as they involve additional reasoning.

For example, a question about "the hobby interests of *Midge's husband"* in TV show "The Marvelous Mrs. Maisel" would likely be missed by text retrieval if the dialogue mostly uses the name of Midge's husband - *Joel*. A question about "*Midge* and *Joel*'s marriage breakdown" not only needs to identify the point of confrontation between *Midge* and *Joel*, but also other *past*, *concurrent*, or *future* events connected to these two person entities,

May 2-6, 2023

Category	**Question (Q)**	**Natural Language Answer (A)**	**Visual Evidence**
Direct 41% (long-distance)	Who bailed Midge out of jail after she was arrested for public nudity? –“The Marvelous Mrs. Maisel"	Susie Meyerson, the manager of the Gaslight, bailed Midge out.	
Cross-Media 33% (text+visual)	Why does Joel punch someone at Gaslight? –“The Marvelous Mrs. Maisel"	That person insulted Maisel during her act. Joel punches him and asserts that Maisel is good.	
Multi-Scene 11% ($\geq$ 2 scene, tot. min. $>$ 1)	How did Midge and Joel’s marriage fall apart? –“The Marvelous Mrs. Maisel"	Joel has been cheating on Midge, with his secretary Penny. One day, Joel got angry at Midge for giving suggestions that ended in a failed stand-up comedy performance for him. He packed up and left Midge.	
Multi-Hop 11% (higher reasoning through missing links/info)	What does the Mayor oversee on the market? –“Les Miserables"	The mayor oversees which vendors are allowed on the market, what they are allowed to sell, how big their space is and what kind of stands should be added to the market. He charges the vendors his fees and have the police talk to vendors who act up.	Background Knowledge 10% (facts, Wikipedia)	In real history, what ultimately happened to Malcolm X’s friend, singer Sam Cooke? –“One Night in Miami"	He was shot to death by a motel manager for attempting to molest a woman, but his death was controversial and involved conspiracy theories.	

Table 1: Types of data annotated in our new ***DeepMovieQA*** benchmark, along with their statistics. The category pertains to the critical reasoning used in understanding the question, picking up relevant details from textual and/or visual media in the movie/TV show, and deriving to an answer.

Midge and Joel, relevant to their marriage dynamics, such as infidelity, pent-up frustration, and aftermaths. Previous work tends to focus on very high level questions with answers coming only from text summary, such as whether a character is good/bad, or focus on very superficial questions such as what object is behind this person, whereas we want to enable more interesting QAs such as from mimicking MovieClub conversations.

So in this work, we define a new task of deep movie question answering (**DeepMovieQA**), which gauges the content understanding of long movie/TV show videos that align with generic human inquiries. In contrast to previous work, the DeepMovieQA task consists of questions that naturally arise from watching the full length of a movie/TV show asset (as opposed to plot summary or short minute-long clips), and involve a more challenging set of reasoning summarized in Table 1, which make use of many different data modalities: plot summary, textual dialogues, visual frames, and background knowledge. DeepMovieQA additionally involves localizing the time frames that provide evidence for the question answering.

To tackle DeepMovieQA, we propose a novel framework, ***DeepMaven*** , which extracts context from multimedia video asset semantically relevant to the queries and generates a coherent answer conditioned on the retrieved context using a transformer-based backbone, with added benefits of transparency and explainability through this two-stage process. Observing that the new DeepMovieQA task involves more challenging types of reasoning, we further leverage a structured approach to incorporate wider context and better handle multi-hop queries, such as bridging the connection between the mention of *Midge’s husband* in a query and the canonical *Joel* entity.

Our key novel contributions can be summarized as follows: 1) we present a new research task of **DeepMovieQA** in the long-distance multimedia video understanding domain that involves reasoning beyond surface-level understanding of short moments and summaries; 2) we present **DEEPMAVEN**, a novel multimedia approach that leverages complementary information from (local) dialogue passages and visual frames and (wider-context) movieKG subgraph to guide deeper content understanding and question answering, achieving 10+% absolute gain in answer extraction and relative gain in answer generation over single modality baselines; and finally, 3) we contribute a DeepMovieQA dataset that includes 1000 QA annotations, to serve as a new resource for studying and evaluating this challenging but exciting task.

Benchmark/ Dataset	*Total Hrs*	*# Min. per Video Clip*	*# Tokens in Answer*

Table 3: The movies/TV shows in DeepMovieQA.

2 DeepMovieQA Data Collection

Pre-existing video/movie/TV show QA datasets fall into two extremes of either focusing on too narrow and minor scene-specific details such as *an object on the couch* that is irrelevant to the storyline development (Lei et al., 2018), or overly brief and simple details from summaries (Tapaswi et al., 2016) that align poorly with real-world needs such as *the year in which Hook's squad is sent to Belfast*, which is written directly in the short plot summary. In comparison, we aim for QAs closer to the conversations in movie clubs or what we talk about when we step out of the movie theatre i.e. the detailed yet crucial information to main event developments. This means we want question annotations that involve longer context of video clips and answer length, compared to prior work as reported in Table 2.

With this motivation in mind, we collect our dataset, ***DeepMovieQA***, on 4 movies and 5 TV shows listed in Table 3, chosen based on genre diversity. We instruct annotators to come up with QA pairs that arise naturally as they watch the movie/TV shows, through two rounds. In the initial pass, we provide ten annotators movie/TV show assets split into 20 minute video clips for focused attention on detailed plot content. In the second pass, we ask the annotators to re-watch the entire movie/TV show asset, review QAs previously annotated, and come up with interesting QAs that involve piecing information together from several scenes or sources – such as discussion of themes, messages, empathetic reactions[2], and societal background. This two-pass QA labeling process allows annotators to become more familiar with the movie/TV show content and come up with challenging QAs that better align with genuine human audience interests. ***DeepMovieQA*** provides the first long-distance, multi-scene QA benchmark in the multimedia setting, with long-form answers labeled to promote elaborative movie QA model capabilities.

3 Methodology

3.1 Direct Retrieval from Source Data

Given a movie or TV show $V = \{V_f, V_{dial}, V_S\}$, consisting of the video frames, dialogues, and summary, and a question, q, a natural first step is to select relevant context through semantic matching of local features. On the text side, we draw inspirations from previous research (Qu et al., 2020; Mossad et al., 2020) to encode the query, q, and candidate passages V_{dial_i}, truncated from every $n = 5$ utterance exchange (a tweakable hyperparameter), using $BERT$ (Devlin et al., 2019) , which are expressive bidirectional transformers for capturing latent language representations, followed by two separate linear layers, ϕ_q and ϕ_p. Then, we compute the retriever matching score through the cosine similarity of the encoded representations.

$$h_q = \phi_q(ReLU(BERT(q)))$$

$$h_p = \phi_p(ReLU(BERT(V_{dial_i})))$$

$$s_{q,V_{dial_i}} = cos\_sim(h_q, h_p)$$

For visual retrieval, we utilize the powerful multimedia CLiP encoder release (Radford et al., 2021), which consists of a textual encoder component $CLiP_t$ based on GPT (Radford et al., 2019) and a visual encoder component $CLiP_v$ based on ViT

---

[2] Similar to `https://teachwithmovies.org/discussion-questions-for-use-with-any-film-that-is-a-work-of-fiction/`

(Dosovitskiy et al., 2020), pretrained through contrastive learning on 400 million image caption pairs. We compare for semantic proximity between q, and a set of candidate visual frames, V_{f_i} through cosine similarity, similar to text retrieval. But note that as each candidate V_{f_i} is actually a set of visual frames corresponding to the time frame under V_{dial_i}, we take the mean of encoded image representations as the overall feature for V_{f_i}.

$$h_q = CLiP_t(q)$$

$$h_{V_{f_i}} = \frac{1}{|V_{f_i}|} \sum_{j \in 1..|V_{f_i}|} CLiP_v(V_{f_j})$$

$$s_{q,V_{f_i}} = cos\_sim(h_q, h_{V_{f_i}})$$

As dialogue exchanges and visual scenes may contain cues that complement each other in signaling whether a section of the video is relevant to the query, we utilize a linear combination of the textual and visual retrieval scores for multimedia retrieval:

$$s_{q,(V_{f_i},V_{dial_i})} = a * s_{q,V_{dial_i}} + b * s_{q,V_{f_i}}$$

We select the V_{dial_i} and/or V_{f_i} with top k semantic matching score for query q as the relevant context.

3.2 Retrieval from Structured Knowledge

Yet, structured knowledge provides benefits for long-distance and multi-hop information since events and interactions at separate time points (see Table 1 for examples) may then be directly connected through grounded nodes such as character entities.

Multimedia KG Construction To incorporate structured knowledge, we pre-construct *movieKG* using the open-source IE pipeline from (Wen et al., 2021) to extract events/entities/ relations (Lin et al., 2020) from movie summary and dialogue, link entities to background knowledge base (Pan et al., 2015) where applicable, and perform event/entity coreference resolution (Lai et al., 2021). This leads to an initial sparse KG, in which the nodes consist of events ($\mathcal{N}_v$) and entities ($\mathcal{N}_n$) while the edges consist of argument roles and relations (E_r), following a pre-defined ontology which inadequately covers the open-domain in diverse film genres, so we augment ontological-guided IE with Abstract Meaning Representation (AMR) parsing (Fernandez Astudillo et al., 2020; Zhang and Ji, 2021) on the movie dialogue and summaries. For example, let's consider a subgraph extracted from IE containing events such as "<Midge, arrested (by), the police>". IE has the advantage of performing entity/event linking, so the entity nodes have other direct connections in the constructed MovieKG as well, such as "<Midge, located in, Manhattan>" and "<police, (also) arrest, comedian Larry Bruce>". However, other important events may not be captured by the IE ontology due to its more abstract or rarer occurrence in daily life and important news events, such as "<Midge, bailed out by, Gaslight manager Susie Meyerson>" and "<Gaslight manager Susie Meyerson, recognize, Midge's talent>", even though these information triplets can be directly extracted as the noun/verb-form concept nodes from AMR parsing on plot summary and dialogue transcripts. Hence, we add subgraphs from AMR parsing to the movieKG initially constructed from IE where there exists a coreferential event or entity node, such as "Midge".

To further enrich this KG with visual information, we perform event extraction using grounded image situation recognition and localization (Pratt et al., 2020), which extracts the verb in action from the visual frame, as well as the semantic roles of objects detected (agent, item, destination, place, etc). We also perform character mapping for agents that play a role in visual events by finding the closest match from a bank of character profile images[3], using visual features extracted by an iResNet model (Duta et al., 2021) following Meng et al. (2021). Finally, we merge objects and events that occur across textual and visual media based on embedding similarity in a multimedia common semantic space computed from CLiP, introduced in Sec 4.1.

Knowledge Subgraph Retrieval Now, we cannot simply select the neighborhood surrounding seed nodes that best match question q as the relevant subgraph because recurring entities contain many dense connections in the long story-telling domain. So instead, we select relevant subgraph based on context-aware saliency. Given a natural language question, we first represent it as a query graph that has undergone knowledge extraction for closer comparability with the movieKG. For instance, a question about *"the initial encounter between Midge and Larry Bruce"* becomes a graph with two connections: [Midge–the initial encounter, the initial encounter–Larry Bruce]. At the time of probing, we compute contextualized embeddings of node mentions, from BERT

---

[3] These can be manually identified from video frames or automatically collected from `www.imdb.com`.

encoders with awareness of the sentence that they occur in, as the local features for both the query graph and the movieKG, concatenate with wider-context knowledge embeddings from a two-hop neighborhood aggregation of maximally aligning neighbor nodes' local embedding with respect to the query graph nodes. For query graph nodes, we concatenate the sentence-level BERT embedding as their wider context features. We score and rank $KG_{subgraph}$ selection based on the semantic (cosine) similarity of these knowledge embeddings between nodes in the movieKG and query graph.

3.3 Combining Context for Answer Fusion

In this work, we regard extractive QA as the task of selecting the relevant V_{dial_i} and V_{f_i} (as well as summary sentences V_{S_i} and *movieKG*$_{subgraph}$ though these lack labels for evaluation) from a movie/TV show, given question q. We formulate abstractive QA as the task of natural language answer generation, conditioned on these relevant V_{dial_i}, V_{f_i}, *movieKG*$_{subgraph}$, and V_{S_i}, providing complementary context to each other. Though it is tempting to learn an answer generation model that intakes context retrieved from different modalities through a straightforward common semantic space, we note the low-resource setting of our challenging task (in which annotations are expensive and time-consuming to obtain). Thus, we take advantage of pretrained conditional text generation transformers, in particular, BART, which has an encoder to extract context information and a generative decoder for sequential token generation, as a suitable backbone for answer generation (Lewis et al., 2020; Khashabi et al., 2020). Moreover, we aim to match the format of input that robust and high-performing conditional text generators have been pretrained on, which is natural language text. While q, V_{dial_i}, and V_{S_i} directly fit this desirable input format, retrieved V_{f_i} and *movieKG*$_{subgraph}$ should be projected into a textual semantic space for optimal alignment with our pretrained backbone answer generator. Hence, for the retrieved movie$KG_{subgraph}$, we take a stringified representation of its structured connections following (Ribeiro et al., 2020). For the retrieved video frames, we make sure that knowledge elements in these images are included in or concatenated to the stringified movieKG subgraph representation. Although our transformer-based answer fusion mechanism may be relatively simple and straightforward, we observe it can handle QAs such as the ones in Table 6, detailed further in Sec 4. Figure 1 provides a walk-through illustration of our overall framework, which we refer to as the DEEPMAVEN. It is worthy to note that by nature of our information extraction-based QA reasoning, our textual answer generation is inherently supplemented with grounding to the visual context retrieved. This includes bounding box localization of the actions and participants (e.g., event – *'drinking'*, person – *'Midge Maisel'*, etc.) from the video frames.

4 Experiments

4.1 Benchmark and Dataset

DeepMovieQA Corpus This is our newly constructed dataset from 4 TV shows and 4 movies. The QAs may involve deep content beyond plot summary information, background knowledge, and higher-order reasoning across different scenes and events, as well as cross-media inferences. The answers are designed to be conversational friendly in nature and have an average token length of 19. A separate expert annotator manually checked 100 random QA pairs and judged all of them as accurate, informative, and comprehensive. We used a 8:1:1 train/val/test data split due to the corpus size.

Shallow MovieQA Corpus This is a multiple choice QA dataset (Tapaswi et al., 2016) annotated solely from movie plot summaries, with a pre-established 66-13-21% train/val/test data split.

4.2 Experimental Setting

For retrieval (extractive question answering), we include single modality approaches as the natural baselines to our proposed model, **DEEPMAVEN**.

- **Baseline 1: Dialogue Component Only** Here, we simply retrieve the relevant dialogue sections from BERT embedding similarity with respect to the input question, similar to the top performing approach (Mossad et al., 2020) in MovieQA leaderboard.
- **Baseline 2: Visual Component Only** Similarly, here, we use the features from CLiP for semantic matching between the question and visual frames.
- **Baseline 3: Textual & Visual Component w/o Structured Knowledge** We further perform comparison with a simplified version of our DeepMaven framework that focuses on the cross-media dialogue and

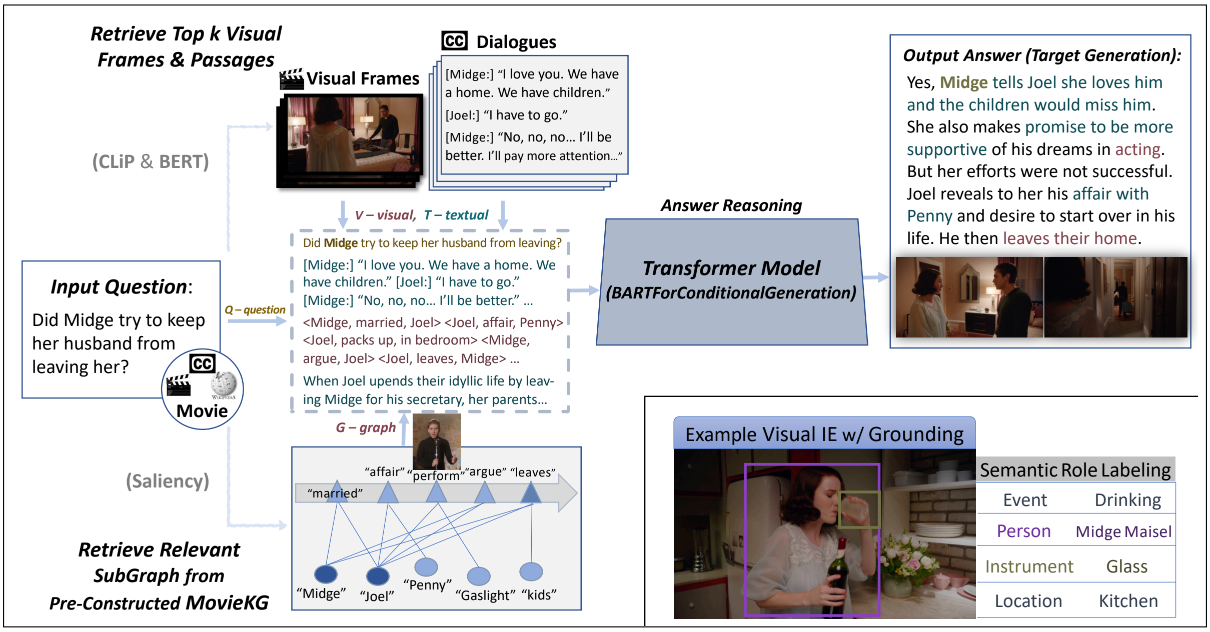

Figure 1: Our DEEPMAVEN model architecture takes as input the question, concatenated with relevant dialogues, visual frames, movie$KG_{subgraph}$, and summary sentences (illustrated by the *dotted box*), for answer stitching through a pretrained conditional text generator backbone. Note: due to low-resource data annotations, we convert the visual frame and $KG_{subgraph}$ into string format to better align with the semantic space of the answer generator.

visual frames without structured knowledge from the movie $\text{KG}_{subgraph}$.

For abstractive question answer generation, we consider the base variant of DEEPMAVEN, which finetunes *BART* (Lewis et al., 2020), using the textual dialogue retrieved from movies/TV shows as input context only. We also include the baseline of *UniVL* (Luo et al., 2020), which has been pretrained on video and language multimodal feature representation and text generation.

4.3 Evaluation Metrics

For long-distance retrieval, we report the hit@K metrics of whether the selected section of the dialogue or visual frames fall under the source time interval from the QA annotation. For natural language answer generation, we compute the ROUGE-L (Lin, 2004) F-scores[4]. However, there might be many variants of words and phrases with different level of granularities that can be used to describe the same answer in the same scenes. Take the question about *"how Midge's parent react to the news that Joel has left Midge"* in "The Mavelous Mrs Maisel" for example. The ground truth answer annotation provides detailed descriptions on how "Midge's dad starts to play the piano frantically and later blames Midge for marrying a weak man against his advice" while "Midge's mother starts crying and whining heavily". We observed that our system generated answers are more general but still correct, outputting "the way the parents are reacting is very upset and blaming each other". A strict measurement of n-gram overlaps from ROUGE would not credit such an answer generation sufficiently. Therefore, we also include a semantic-based BLEURT [5] metric (Sellam et al., 2020). In addition, we conduct a human assessment on the extracted answers as well. For each pair of system extracted answer and ground-truth answer, we ask human assessors to judge whether the system answer is completely correct, partially correct or incorrect.

4.4 Quantitative Results and Analysis

Extractive Question Answer Retrieval As shown in Table 4, retrieval is a non-trivial task in the movie setting, which contains lengthy plot content, and a random approach has a very low hit@K=5 of 0.08. Single modality retrieval baselines perform similarly, with text retrieval using BERT and visual retrieval using CLiP having hit@K=5 of 0.32 and 0.28 respectively, while cross-media retrieval achieves a noticeable boost to hit@K=5 of 0.41, suggesting that textual and visual features offer similar levels of useful signals that complement each other for making sense of

---

[4] `www.pypi.org/project/pycocoevalcap/`

[5] We use the BLEURT-20 scorer model from `https://github.com/google-research/bleurt`.

Approach	*Hit@K=5*
Random	0.08
Textual (BERT)*	0.32
Visual (CLiP)*	0.28
Textual+Visual$^{\triangle}$	0.41
Textual+Visual+KG priming	**0.49**

Table 4: These are the video frame retrieval results, with $*$ as the baselines, $\triangle$ as the simplified DeepMaven without structured knowledge, and **bold** as the full DeepMaven retrieval approach.

question inputs from long movie/TV show content. Finally, movieKG-guided structured information on top of semantic matching from direct source data, using our **DeepMaven** framework, unlocks the best retrieval hit rate (to near 50%).

Abstractive Question Answer Generation Natural language answer generation requires an additional decoder module for outputting tokens. Our **DeepMaven** model achieves a Rouge-L of 61.6% in answer generation on the MovieQA benchmark. Model performance for the new, challenging DeepMovieQA benchmark is reported in Table 5 below.

	Rouge-1	Rouge-L	BLEURT
UniVL	16.8	15.1	22.3
DeepMaven			
- dial. only	13.9	11.1	22.1
- all	**21.6**	**17.4**	**31.7**

Table 5: Answer generation (%) scores on our DeepMovieQA dataset.

4.5 Qualitative Analysis

Table 6 shows answer generation results while Table 7 shows content selection examples, performed by **DeepMaven**. We additionally conduct a human assessment on the DeepMovieQA answer generations from held-out data, rating answers on a likert scale of $0-5$ (with 0 being nonsense and 5 being perfect). Thirteen percent of the generated answers scored ≥ 4, with a Kappa coefficient of 0.42, reflecting moderate inter-annotator agreement.

4.6 Remaining Challenges

	Questions	Answers
MovieQA	Who comes to the officers' rescue? *–World Trade Center*	Two United States marines, Dave Karnes and Jason Thomas. Two United States marines, Dave Karnes and Jason Thomas.
	Where are Stigman and Trench taken after being captured? *–2 Guns*	Mexico To Greco's farm in Mexico
DeepMovieQA	How does Joel leave the apartment after they fell asleep the night before? *–MRSM*	Joel gets out of bed and drives to work. Joel sneaks out Midge's bedroom window the next morning, just like he did when they first dated.
	What were in the boxes in the back of the truck Sajid was driving? *–FMAN*	They were filled with nerve gas. The boxes were filled with canisters of nerve gas that were going to be used to attack New Delhi.

Table 6: Example DeepMaven abstractive QA results, with the generated and grouth truth answers.

In general, we found that DeepMaven retrieval performs worse on QAs that involve commonsense reasoning and reference to objects/entities that may not be easily picked up by our structure-guided cross-media semantic matching system. Some deeper movie QAs may also be more suitable for the conversational question answering setting due to insufficiently detailed question wording and open-ended answer form. Finally, we observed that long-form answer generation with a limited-sized training data is more prone to hallucination. Given questions such as *"What did Susie promise to one of the waiters at the Copacabana Club in return for smuggling her into the club for free?"*, the language model generator backbone tends to fill in some plausible pre-trained knowledge such as *"Susie promises to buy one of the men a drink after every act"* that may not match the actual detailed answer of *"Susie promised him a prime slot for his singing act at the Gaslight Café for 2 weeks. Unfortunately Susie thinks his act is awful but keeps her word even since they had to watch the show from the kitchen"*. Minimizing hallucination in long-form low-resource question answer generation is an important issue that merits future investigation.

5 Related Work

Text QA: QA has been a popular task (Rajpurkar et al., 2016), with significant advances made recently by attention-guided transformers (Qu et al., 2019). Several corpora have been proposed for QA in story comprehension. FriendsQA (Yang and Choi, 2019) bases QA on short dialogue exchanges. MovieQA (Tapaswi et al., 2016) and NarrativeQA (Kocisky et al., 2018) are annotated from plot summaries. (Zhou et al., 2018; Moon et al., 2019; Zhou

	Cue Category	Question	Retrieved Dialogue Passages and	Visual Frames
Impressive Cases	Dialogue Content	What did Kelly threaten Clay with after forcing him into his car? *–WORE*	"Why my family? My wife? My daughter? Why kill my team? Rykov was all in, so I'd like a little bit of what you sold him... Know where we driving? You got a farm out in West Virginia, right? Your daughter should be home from college. Wesleyan. That's a good school. Your wife. Your son too. So I suggest you start talking."		Visual Scenes	Who takes care of Lee after the fight? *–MBTS*	"Settle down, all right? Are we cool? Get off. You'll kill him... Should he go to the hospital? I don't think so. Nothing's broken."	
	Implicit Cross-Media Entity Grounding	What does Midge's mother want to talk about after Midge arrives at her parent's apartment? *–MRSM*	"Thanks for taking the kids last night. Were they okay? - We need to talk about the baby. Why? What's the matter with her? That forehead is not improving. - What? Are you sure?"	
	Implicit Multi-hop Event Reasoning	What does Midge do after Joel falls asleep and before he wakes up again? *–MRSM*	"Good night, Gracie. Hey. Good morning. - Did the alarm go off? - It sure did. Wow. I didn't hear it at all. You never do. - Good morning, Jerry. - Good morning, Mrs. Maisel."	
Erroneous Cases	Failure to Identify Certain Visual Objects	What does Midge suggest in the **taxi** to improve Joel's performance? *–MRSM*	"Maybe you should write a beginning, something that says who you are or something. What do you think? Good evening. What a nice... Good evening, ladies and gentlemen. Thank you for the nice... nice... 'Nice' is a bad, bad word. All that applause for me? What am I, putting out after?..."	
	Mismatch in Level of Detail Between Query and Context	What did Midge do while her friend Imogene is visiting to make sure she's still in shape? *– MRSM*	"She's going on and on about this miracle treatment she had done in Mexico. It involved goat's milk and avocadoes. **Right ankle 8, left ankle 8.** They smear it on your face, wrap a hot towel around your head..."	

Table 7: Impressive and Erroneous Examples of Retrieval Results.

et al., 2020) annotated open-ended conversations with groundings to either Wikipedia pages, or pre-existing structured knowledge graphs such as Freebase (Bollacker et al., 2008) and XLORE (Wang et al., 2013). These benchmarks overlook the full content from the original data, which we address.

Visual QA: The visual question answering (VQA) task (Antol et al., 2015) aims to predict a natural language answer, given a natural language question and image(s) without other textual context. Various datasets have been constructed for this task, such as VQA 2.0 (Goyal et al., 2017), VCR (Zellers et al., 2019), and scientific PlotQA (Methani et al., 2020), in the setting of single images; as well as MSR-VTT-QA (Xu et al., 2016), MovieFIB (Maharaj et al., 2017), and VideoQA (Zhu et al., 2017), in the setting of visual frame sequences. The answers are typically multiple choices or from a predefined vocabulary. Simple baseline methods that only use question understanding (Kazemi and Elqursh, 2017) or sentiment analysis on answer options (Manjunatha et al., 2019) have proven surprisingly well on datasets such as VQA and VQA 2.0 but are unlikely to provide good answers for understanding complex events and person interactions.

Multimedia QA: There are increasing interest nowadays in using information from multiple modalities for answering questions, such as reasoning through text, images, and tables in ManyModalQA (Hannan et al., 2020), MultiModalQA (Talmor et al., 2021), and MuMuQA (Reddy et al., 2022). The (movie/TV) video domain is a further step that involves dynamic events from dialogues and corresponding visual frames. TVQA (Lei et al., 2018) presents a multimedia QA dataset grounded on minute-long video clip snippets from popular TV show, with frame localization added in TVQA+ (Lei et al., 2020a). However, their QAs involve highly scene-specific discussion points, trivial to the deeper contents around the central plotline, e.g. "*Q: What is on the couch behind Joey when he is at the counter? A: A soccer ball*". In contrast, our work highlights deeper knowledge and multi-frame information synthesis.

Other Story-based Video Understanding: Benchmarks such as MovieNet (Huang et al., 2020) and LVU (Wu and Krahenbuhl, 2021) gauge a variety of content classification tasks related to the 'scene/place', 'cinematic style', 'genre', 'produced year', 'popularity', etc. Moreover, Lei et al. (2020b); Huang et al. (2020); Bain et al. (2020) explore retrieval based on sentence-length scene description while Liu et al. (2020) study video-language inference, but these are all less challenging than the natural question answering setting our work focuses on.

6 Conclusions and Future Work

This work is the first to study long-distance movie question answering. Through guidance from multimedia source context and structured knowledge retrieval, our proposed model, DEEPMAVEN, is shown to perform well for extractive question answering, as well as abstractive answer generation for the questions in pre-existing MovieQA benchmarks. But improvements are needed for generating answers to the more challenging questions presented by our new DeepMovieQA benchmark, which serve as a better reflection of real-world application settings with more reasoning involved. We aim to kickstart an extractive movie question answering interface for human users, and through this, naturally acquire genuine movie questions for more effectively expanding DeepMovieQA annotation, and later extend this into interactive conversational AI settings.

7 Limitations

Our work focuses on video question answering that aims to be detailed and engaging. It is not interactive in nature like conversation exchanges. Finally, we bear in mind that automatically generated answers may contain the risk of insensitive phrasing, and mitigating language model bias deserves further exploration and efforts.

Salient Span Masking for Temporal Understanding

Jeremy R. Cole **Aditi Chaudhary** **Bhuwan Dhingra** **Partha Talukdar**

Abstract

Salient Span Masking (SSM) has shown itself to be an effective strategy to improve closed-book question answering performance. SSM extends general masked language model pretraining by creating additional unsupervised training sentences that mask a single entity or date span, thus oversampling factual information. Despite the success of this paradigm, the span types and sampling strategies are relatively arbitrary and not widely studied for other tasks. Thus, we investigate SSM from the perspective of temporal tasks, where learning a good representation of various temporal expressions is important. To that end, we introduce Temporal Span Masking (TSM) intermediate training. First, we find that SSM alone improves the downstream performance on three temporal tasks by an avg. +5.8 points. Further, we are able to achieve additional improvements (avg. +0.29 points) by adding the TSM task. These comprise the new best reported results on the targeted tasks. Our analysis suggests that the effectiveness of SSM stems from the sentences chosen in the training data rather than the mask choice: sentences with entities frequently also contain temporal expressions. Nonetheless, the additional targeted spans of TSM can still improve performance, especially in a zero-shot context.

1 Introduction

Salient Span Masking (SSM), first introduced by Guu et al. (2020) for retrieval-based language modeling, has shown performance gains for closed-book question answering (CBQA) (Roberts et al., 2020; Ye et al., 2020). SSM is a form of intermediate pretraining (Ye et al., 2021), where a pretrained model such as a BERT (Devlin et al., 2019) or T5 (Raffel et al., 2020) is trained further before task-specific finetuning, generally on more specialized data that does not require expensive annotations. Specifically, SSM uses the masked language modeling objective but only masks named entities and dates in sentences from English Wikipedia articles; these "salient" spans likely contain more facts, so the language model must memorize more facts in order to do the task successfully (Petroni et al., 2019). The authors use a named entity recognition model to identify entity spans and a regular expression to identify date spans. While this works well for knowledge intensive downstream tasks, such as entity-centric question answering, it remains unclear whether it is helpful for tasks that are less aligned with the data, such as common sense or temporal reasoning. Moreover, is it possible to select spans that are more related to a downstream task in order to get further performance gains?

In this work, we investigate SSM for tasks that require understanding *temporal* expressions. While SSM does include dates, the tasks we investigate include other complex temporal expressions such as durations and intervals. To that end, we introduce Temporal Span Masking (TSM): an intermediate pretraining strategy for predicting spans that are likely temporal expressions (Figure 1). Similar to SSM, TSM is automatically generated from English Wikipedia articles. We compare models trained on TSM and SSM on three temporal tasks, namely MC-TACO (Zhou et al., 2019), TimeDIAL (Qin et al., 2021) and SituatedQA (Zhang and Choi, 2021), and for one general-purpose question answering (QA) task of Natural Questions (NQ) (Kwiatkowski et al., 2019). We summarize our contributions as follows:

- We propose TSM Intermediate Training, which automatically selects temporal spans for masking.
- The new best reported results on the three temporal tasks: the best average performance is from a mixture of TSM and SSM. This mixture also does slightly better than SSM on Natural Questions.
- Experiments investigating the role of differ-

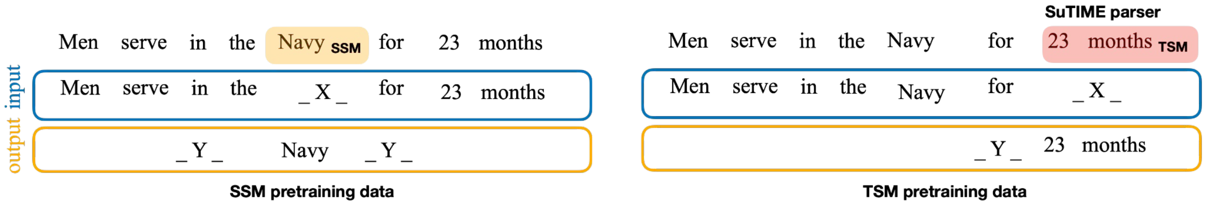

Figure 1: Overview of the TSM and SSM tasks: While SSM (Guu et al., 2020) identifies named entities and dates as salient spans, for TSM we use SUTIME parser that captures other temporal expressions such as durations and intervals. SUTIME is first applied on raw sentences to identify any temporal expressions. Next, training data for TSM is created from those sentences which have at least one temporal expression identified. In SSM, the masked spans comprise of named entity or date spans. Input to each task consists of the sentence with the selected span dropped out where the model is trained to predict the dropped tokens.

ent TSM and SSM span types, showing entity spans alone are helpful, which implies that difficult examples help improve representations of the unmasked spans as well.

2 Methods

Following Roberts et al. (2020), we utilize intermediate training to improve pretrained models' generalization to downstream tasks. All models are initialized from the encoder-decoder T5-1.1-XXL language model (Raffel et al., 2020), which was shown to have the best closed-book QA performance in Roberts et al. (2020).

2.1 Background: Salient Span Masking

Salient Span Masking (SSM) was first introduced by Guu et al. (2020) and is designed to specifically mask named entities and dates or *salient spans*. These salient spans are automatically identified from English Wikipedia using a Named Entity Recognition model to find entities as well as a regular expression to find dates. The authors mask one such span per sentence during training: the model must maximize the probability of the masked entity or date given the corrupted input sentence. Guu et al. (2020) designed the task to improve downstream performance on tasks requiring world knowledge in order to improve their retrieval-augmented model's ability to use retrieved texts. Roberts et al. (2020) then adapted this task for closed book encoder-decoder models.

2.2 Proposed: Temporal Span Masking

Inspired from the success of SSM, TSM is designed to address problems requiring temporal knowledge. To create training examples for TSM, we automatically identify temporal expressions in a large corpus using SUTIME (Chang and Manning, 2012), a rule-based temporal parser, that identifies temporal expressions from raw text. Given an input sentence, SUTIME is built to identify expressions of the following four types: **Time** which indicates a particular point in time such as *next Monday*, **Duration** such as *3 days*, **Set** which indicates periodic set of time that occur with some frequency such as *every 4 years* and **Date** such as *January 1*.

We run SUTIME on all of English Wikipedia[1]. Specifically, we divide the articles into sentences, and apply SUTIME[2] on each sentence. For our TSM training data, we ensure that exactly one temporal span is masked per example. So, if a sentence contains four temporal spans, we create four training examples with exactly one temporal span masked per example. Details of the temporal distribution are in Table 4. Each example is created by masking the tokens belonging to the temporal expression, as shown in Figure 1, corrupting the input sentence by replacing the span with (_X_) and having the model predict the masked tokens. The training objective is to maximize the probability of the target span given the corrupted input sentence, similar to T5's span corruption training objective (Raffel et al., 2020) and the SSM training objective (Roberts et al., 2020).

2.3 Model Variants

All newly reported results are based on T5-1.1-XXL models. Proposed models are named for their intermediate training objective: TSM is trained solely on the masked temporal spans described above; SSM is trained solely on the training objec-

---

[1] We use the 2020 snapshot of English Wikipedia (TFDS datadump *wikipedia20201201en*)

[2] `https://github.com/FraBle/python-sutime`

tive described in Roberts et al. (2020).[3]

We also investigate a version of the SSM pretraining data that only uses the *named entity* spans identified by the NER model; in other words, all of the *date* spans identified by the regular expression are removed, but the task is otherwise the same. We call this objective ENTITIES. Finally, we compare against models that are trained proportional mixtures of both TSM+SSM and TSM+ENTITIES.

For baseline models, we use the same pretrained model (T5-1.1-XXL) with no intermediate training (T5), as well as a T5-1.1-XXL model which has been trained for an additional 100K steps on the prefix LM task (T5-LM; Lester et al. 2021).

2.4 Downstream Temporal Tasks

We evaluate on three downstream temporal tasks for evaluation, finetuning a model on each task separately. Below, we briefly describe the tasks and datasets, with additional training details in Appendix A.

MC-TACO Zhou et al. (2019) release a human-annotated dataset to measure temporal commonsense understanding. It consists of 13k tuples of *(sentence, question, candidate answer)* covering five types of common sense problems such as event frequency, event duration, event ordering, stationarity and event typical time. Given a sentence context, a temporal question about that context, and a possible commonsense answer, the task is to determine whether the provided answer is reasonable for the given context. For instance, for the event of *taking a shower* with four possible answer choices *five minutes, fifteen minutes, fifteen hours*, and *fifteen years*, the first two are plausible and will have the *yes* label while the latter two choices would be *no*. There is no training data released for this task, so we finetune the model on the provided validation set and evaluate on the test set.

TimeDIAL Qin et al. (2021) release a human-annotated multi-turn dialog dataset for measuring temporal commonsense understanding in a dialog setting. The dataset comprises of challenge test set with 1.1k dialog instances derived from the Daily Dialog dataset described in Qin et al. (2021). TimeDIAL dialogs mostly comprise of common sense instances where the answers generally consist of one temporal span. For instance, in the following dialog “I’ll just be a minute’., the span “a minute” may be masked out and the model is required to predict the masked span based on the dialog turns. Given a dialog with a temporal expression masked out, the task is to correctly predict which two of the four provided answers are valid in the given context. We report results without finetuning (styled TimeDIAL-0) as well as results from finetuning the model on the Daily Dialog dataset.

SituatedQA Zhang and Choi (2021) release an open-domain QA dataset derived from existing question answering datasets with additional annotations that resolve temporal and geographic ambiguities. Each example consists of a disambiguated question: for instance, “Which COVID-19 vaccines have been authorized in the US [as of 2020]?” or “What was the first COVID-19 vaccine to be authorized [in the US]?”. For the purpose of this work, we focus on the temporal questions. These consist of 9K additional questions, with a training set of about 4.5K questions. We finetune on the training set and evaluate on the test set.

2.5 Natural Questions

While the focus of our method is improving temporal question answering performance, we also wanted to ensure that our method does not degrade performance on non-temporal question answering tasks. Thus, we also evaluate our model variants on Natural Questions (Kwiatkowski et al., 2019), using the “open” variant popularized by Lee et al. (2019). These examples discard those questions without short answers or that require an evidence document to answer. These consist of about 87K questions for training and an additional 3.6k questions for validation, which we use for evaluation.

3 Results and Discussion

Our main results can be found in Table 1. Results including Natural Questions can be found in Table 2. Note that the Natural Questions results have minor variations from published numbers; we ran these baselines ourselves, and it is possible the training setup differed slightly.

T5 and T5-LM The T5 model sets a relatively high baseline compared to previously reported models. The T5-LM model’s extra non-domain-specific pretraining does not help on any task, suggesting

---

[3] We note that the SSM-spans are derived from the 2018 snapshot of English Wikipedia (same as Guu et al. (2020)) while TSM-spans from the 2020 snapshot.

Entities	29.42	22.82	85.47	66.59	99.91	83.06	97.64	67.93	57.49	52.45
TSM	27.42	21.18	84.89	65.92	99.91	83.88	**99.82**	**77.54**	56.99	54.88
TSM+SSM	29.33	22.76	**86.20**	67.64	**100.0**	83.78	98.19	73.10	58.03	54.5
Entities+TSM	**30.78**	**24.60**	85.32	**68.47**	99.91	84.24	98.91	76.09	**59.09**	**56.39**

Table 1: Aggregate metrics across the three datasets. *Overall* performance is the simple arithmetic average of the harder metric for each approach (EM, EM, 2B); *Overall-0* uses TimeDIAL-0 instead of TimeDIAL. The second section contains our runs of earlier models; the Best Reported uses best known published numbers. The third section represents our models. Note that all models (in the second and third sections) are based on T5-1.1-XXL models. Best Reported results are ALBERT (Lan et al., 2019) from Abramson and Emami (2022) for TimeDIAL, BART results from Zhang and Choi (2021), and DeBERTa (He et al., 2020) results from the leaderboard for MC-TACO. Note that F1 for MC-TACO is based on the precision/recall over answers and EM is based on labeling every answer for a question correctly, while the F1 for SituatedQA is based on the token-level F1 of the answer span.

Model	F1	EM	Overall	Overall-0
SSM	41.57	34.6	52.54	48.33
T5	39.35	32.38	50.31	38.58
T5-LM	37.16	31.14	47.80	35.69
Entities	41.21	34.52	51.75	47.97
TSM	39.24	32.69	50.92	49.33
TSM+SSM	41.80	35.10	52.3	49.65
Entities+TSM	**41.89**	**35.18**	**53.11**	**51.09**

Table 2: Results on Natural Questions – *Overall* and *Overall-0* results include the same metrics from Table 1 with Natural Questions (EM) included. The first section represents our baselines. Note that all models are based on T5-1.1-XXL models.

extra training steps does not in of itself cause improvements on these tasks.

Entities The Entities model, which is trained on only non-temporal entity spans, performs better overall than the TSM task. It only does worse on the TimeDIAL dataset, which is almost entirely focused on conversational, non-knowledge based contexts. It still does substantially better than the base T5 model when no finetuning data is available. This high performance is possibly due to the prevalence of temporal spans in the SSM training data. Running SUTIME on the Entities data reveals that 45% of its training examples contain at least one date, duration, set, or time. This suggests that sentences with named entities in general already carry temporal-salient information useful for downstream temporal tasks. See Appendix B for a full breakdown of the co-occurrences.

SSM The SSM model is the second best overall. It benefits from both its own date spans as well as the frequent presence of temporal spans in the entities data, suggesting difficult example sentences are more important than the type of masked span. It does worse on TimeDIAL-0, however, where the task is to score the best temporal span.

TSM The TSM model improves upon the baseline T5 model but is worse overall than the SSM model. However, it is the best on TimeDIAL-0. This is likely because the DailyDialog training dataset is relatively large, which may overcome the need for intermediate pretraining altogether. Note that TSM achieves a mild performance improvement over the baseline T5 model on Natural Questions, but is notably worse than the other intermediate training methods.

TSM+SSM The TSM+SSM model improves over TSM but is worse than SSM outside of TimeDIAL-0. One possible reason for the regression is that TSM and SSM have overlapping Date span examples, which may make the intermediate task easier and thus less useful. However, it is slightly better than SSM on Natural Questions.

Entities+TSM The Entities+TSM model performs the best overall: with and without the extra training data for TimeDIAL. It has the benefit of

Model	T5	SSM	E+TSM
Duration	88.64	88.28	**89.09**
Set	86.39	**88.22**	87.79
Time	87.74	**88.70**	87.70
Date	65.75	66.63	**66.87**
Entities	42.17	45.76	**46.54**

Table 3: Aggregated performance across types for baselines and the best overall model (ENTITIES+TSM). For TimeDIAL, each answer span is labeled by SUTIME. Duration includes MC-TACO's "Event Duration"; Set includes MC-TACO's "Frequency", Time and Date both include MC-TACO's "Typical Time"; Date also includes SituatedQA; Entities include all of MC-TACO and SituatedQA. Note that the majority of the gains from SSM/TSM seem to be from Entities and Dates. See Appendix B for rationale behind these choices.

TSM spans without containing overlapping spans or losing the world knowledge from entity spans. It also performs slightly better than SSM on Natural Questions.

By Type We analyze model performance by temporal type in Table 3. The main improvement of both SSM and ENTITIES+TSM is in entity and date tasks. Surprisingly, TSM shows a regression on time tasks, and only gets a slight improvement on duration tasks. One possible hypothesis for this is that temporal expressions may be more informative when co-occurring with an entity. Note that these numbers are based on the trained versions of each dataset, excluding Natural Questions. Note that SituatedQA contains further breakdowns based on the scope of the date, but this does not map well to the other datasets.

4 Related Work

Span Masking and Intermediate Training Salient Span Masking (Guu et al., 2020) came out of a series of efforts like SpanBERT (Joshi et al., 2020) to select more difficult examples to improve models memorization of the text.

Most similar to us, Ye et al. (2021) explore a similar paradigm of choosing better spans for a downstream task (e.g., entity linking or relation extraction) where they experiment with both a heuristic masking policy similar to SSM and also a learned masking policy. They similarly find that masking spans that resemble downstream tasks improve performance, however, they also note that learned masking policies suffer from overfitting. Yang et al. (2020) and Zhou et al. (2020) explore intermediate training by designing heuristics to identify sentences containing temporal expressions and then adding additional tasks and losses, rather than using span masking. TSM differs in more closely resembling the pretraining task.

Levine et al. (2021) use pointwise mutual information to jointly mask highly correlated spans to avoid the model relying on local signals but rather learning from the broad context. They find this leads to faster and better pretraining. In the future, it might be interesting to see how PMI-spans can combine with knowledge-oriented span techniques such as SSM, TSM, and whether they can help in the intermediate training paradigm.

Temporal Understanding There has been a surge of interest in probing models' temporal awareness. While we evaluate on a three tasks, it is far from an exhaustive evaluation and we leave further evaluations of our method to future work.

Recently, Thukral et al. (2021) and Vashishtha et al. (2020) construct NLI datasets to test whether pretrained models understand certain types of common sense temporal expressions, such as containment. To probe common sense, we use TimeDIAL (Qin et al., 2021) for its naturalistic dialogues as well as MC-TACO (Zhou et al., 2020), which uses a diverse set of situations and temporal expressions.

For factual questions, open-response temporal questions are closely aligned with our work (e.g., TimeQA; Chen et al. 2021; TempLAMA; Dhingra et al. 2022). All of TempLAMA, TimeQA, and SituatedQA (Zhang and Choi, 2021) rely primarily on the year as the main temporal expression being tested, where facts are scoped to the provided years. To probe temporally scoped facts, we use SituatedQA for its more naturalistic questions.

5 Conclusion

In this work, we investigate SSM as it relates to temporal tasks that require understanding both commonsense and world knowledge questions and propose a new intermediate training method which selects spans generated by a temporal parser. These intermediate training strategies result in the best overall reported results on the selected downstream tasks. However, we find that even the entity spans from SSM are helpful for temporal tasks, likely because entity-containing examples also contain informative temporal knowledge.

Limitations

This analysis investigates only the encoder-decoder model architecture: in particular, encoder-only models such as BERT (Devlin et al., 2019) and decoder-only models such as GPT-2 (Radford et al., 2019) are excluded. Further, large language models, such as PaLM (Chowdhery et al., 2022) or GPT-3 (Brown et al., 2020) are also not investigated. See Appendix B for further discussion.

A Training Details

All models are initialized from the public T5-1.1-XXL checkpoints.[4]

A.1 Intermediate Training

We use 256 Cloud TPU v3 cores for the intermediate training procedure using a batch size of 2048 and the fixed default learning rate of 0.001. Training generally proceeds for one epoch, which is between 100-150K steps depending on the precise task, though we used early stopping for the TSM and TSM+SSM models based on MC-TACO performance, as they seem to overfit.

A.2 Finetuning

We use 64 Cloud TPU v3 cores for finetuning and inference on all tasks. For MC-TACO, Natural Questions, and SituatedQA, we use the same fixed learning rate of 0.001 and train for 10K steps with batch size 128. For TimeDIAL, we attempt to follow their training setup more closely, and use a lower learning rate (0.0001) and train for up to 100K steps, still with batch size 128 and use early stopping on the validation set to inform when to stop. For most of the models that had intermediate training, the early stopping point was for 10K steps. However, for the basic T5 model, it was after 20K steps (improving from (82.97 → 84.51)), implying that it can overcome its lack of intermediate training with additional finetuning data. Note that in the zero-shot variant, no finetuning is done.

B Further Discussion

B.1 Other Experiments

We previously experimented with the T5 Large and T5-XL models, as well the as 1.0 versions of the T5 models that were first described in Raffel et al. (2020). In general, larger models and the 1.1 versions worked better. While we refrain from reporting results due to inconsistent setups, in general the smaller models were notably worse, such that distinguishing between two similar setups (such as TSM and SSM) was difficult on many tasks. While we know of no work testing salient span masking on extremely large models, it is possible it would actually show a larger impact, based on this trend. While left-to-right decoding serves as an awkward fit for the paradigm, if our hypothesis on the reason why SSM works is correct, then it should not prove to be a substantial hurdle. See also below for more discussion on said hypothesis.

Temporal Type	Number of sentences
Date	56,520,912
Duration	8,182,819
Set	1,797,929
Time	2,281,198

Table 4: TSM data statistics: The above table describes the distribution of temporal spans in the English Wikipedia data, which comprises of 121M sentences.

Span Type	Number of sentences
Entity	78,139,341
Date	32,023,769

Table 5: SSM data statistics: The above table describes the distribution of salient spans in the Wikipedia data as processed by (Guu et al., 2020), which comprises of 82M sentences. Each row denotes the number of sentences that contain at least one of the respective span.

TSM Span Type	SSM Span Type	
	Named Entity	Date
Date	29,771,242	-
Duration	5,159,229	3,144,592
Set	1,226,333	844,222
Time	915,084	411,436

Table 6: We apply SUTIME on the SSM training data (Guu et al., 2020) to investigate how many sentences contain temporal information. Each column denotes the number of sentences that contain the SSM identified span (e.g. *named entity* or *date*) and each row denotes the number of those sentences in which SUTIME identified the corresponding temporal span. Number of sentences with at least one *named entity*: 78,139,341 Number of sentences with at least one *date*: 32,023,769 (Table 5)

B.2 Span Distribution vs. Text Distribution

Our hypothesis for SSM's effectiveness is due to it oversampling difficult sentences. This is based on the performance gain for the ENTITIES intermediate training as well as the number of temporal spans that occur in the SSM training data. Table 6 shows the results of SUTIME parser on the SSM training data, and as we can see, significant portion

---

[4] https://github.com/google-research/text-to-text-transfer-transformer

of the SSM data (45%) has temporal spans. Table 6 shows the breakdown of different temporal spans for each SSM salient span type. We leave an exact test of this for future work, but if this is true, then we might expect left-to-right decoding models to also benefit from the sampling procedure of SSM, even though they do not use a masked language modeling paradigm for training.

B.3 Span Types in Table 4

Mapping MC-TACO's span types is somewhat helpful to see the performance breakdown. Note that these are now based on individual answers, while MC-TACO's strict match metric is based on correctly labeling all answers for a given question.

Entities While MC-TACO is a common sense dataset, it frequently relies on reasoning about relatively complicated phenomena. While it is common sense to know that a dynasty does not rule in China for only a few minutes, it is still required to know more about China and dynasties to answer the question correctly. TimeDIAL on the other hand is normally ordinary conversations that are not very entity-centric. SituatedQA is derived from Natural Questions, which is an information seeking dataset that frequently features entities.

Duration MC-TACO's event duration maps well to the Duration type in SUTIME. While there may be some SituatedQA examples that include durations, we do not filter for them.

Set MC-TACO's Frequency type asks question of the "How often" nature while sets frequently have answer types of that nature e.g., "every third sunday", but this is not a perfect mapping.

Date MC-TACO's typical time sometimes includes dates, but it is less likely to be a specific date and more likely to be a generic date like Sunday, rather than a specific knowledge-based date. SituatedQA questions always include dates that decontextualize Natural Questions.

Time MC-TACO's typical time sometimes corresponds with times as well, but they are again less likely to be specific. Unfortunately, Date and Time are not separated in MC-TACO.

Other MC-TACO Types Note that we did not include the "Stationarity" or the "Event Ordering" MC-TACO types in the breakdown, as they do not correspond well to any SUTIME type.

PECO: Examining Single Sentence Label Leakage in Natural Language Inference Datasets through Progressive Evaluation of Cluster Outliers

Michael Saxon, Xinyi Wang, Wenda Xu, William Yang Wang

Department of Computer Science
saxon@ucsb.edu, xinyi_wang@ucsb.edu, wendaxu@ucsb.edu, william@cs.ucsb.edu

Abstract

Building natural language inference (NLI) benchmarks that are both challenging for modern techniques, and free from shortcut biases is difficult. Chief among these biases is *single sentence label leakage*, where annotator-introduced spurious correlations yield datasets where the logical relation between (premise, hypothesis) pairs can be accurately predicted from only a single sentence, something that should in principle be impossible. We demonstrate that despite efforts to reduce this leakage, it persists in modern datasets that have been introduced since its 2018 discovery. To enable future amelioration efforts, introduce a novel model-driven technique, the progressive evaluation of cluster outliers (PECO) which enables both the objective measurement of leakage, and the automated detection of subpopulations in the data which maximally exhibit it.

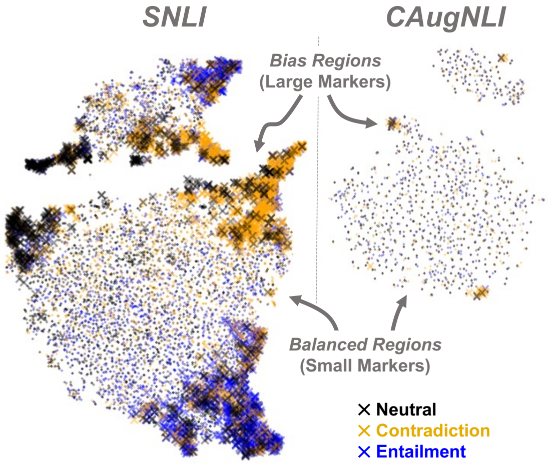

Figure 1: A T-SNE projection of the SNLI and CAugNLI test sets in PECO's model-driven *single sentence condition* (SSC) embedding space, showing **entailment**-, **contradiction**-, and **neutral**-labeled samples. This model was trained on the paired-sentence condition (PSC) where the relation between sentences in a sample are observable. In a leakage-free dataset, a model should be unable to separate subpopulations that disproportionately exhibit one label class in the SSC. Local regions exhibiting an imbalanced label distribution in this subpopulation are considered "biased regions" and plotted with large markers. SNLI exhibits large, continuous regions in the hypothesis only space disproportionately exhibiting the same label, compared to CAugNLI. Accordingly, SNLI exhibits higher single sentence label leakage than CAugNLI (Table 3).

1 Introduction

Natural language inference (NLI) is a fundamentally pairwise task, wherein a logical relation between two statements is predicted. Progress on NLI benchmarks is an important proxy for advancements in natural language reasoning by machines. Models are trained to process the two statements simultaneously, in a *paired sentence condition* (PSC). Unfortunately many modern NLI datasets exhibit **single sentence label leakage**. When this leakage is present, models are able to accurately predict the pairwise relation encoded by the labels in a *single sentence condition* (SSC)—where the model is only shown one of the statements (Poliak et al., 2018). This is a serious problem, rendering NLI datasets' capture of reasoning questionable, and limiting the robustness of models trained on them.

NLI is formalized as predicting a relation $r \in \{\text{neutral, entail, contradict}\}$ from a pair of sentences (premise s_1 and hypothesis s_2). An ideal NLI benchmark without single sentence label leakage will have distribution of r that is conditionally dependent on the **pair** of sentences, but independent from either individual sentence (Wang et al., 2021c). In practice this is difficult to achieve, particularly when constructing usefully large datasets.

Most large-scale NLI datasets are produced by sourcing *seed* sentences from an existing text population to serve as initial premises or hypotheses. Each seed sentence is then assigned one or more relations r, which annotators use to write new *elicited* sentences satisfying each selected relation relative to the seed. Many datasets exclusively build either the hypothesis or premise population from seed sentences, leaving the other exclusively elicited.

Table 1: Information on the NLI datasets we compare in this study. MNLI has "matched" (m) and "unmatched" (u) test sets that we evaluate separately. The ANLI dataset is decomposed into partitions "A1," "A2," and "A3". A Vertical line denotes identical value in cell as above (sub-elements of same dataset).

Systematic, shared biases in the words, sentence structures, or ideas that crowdworkers consider when given a logical relation, coupled with the exclusively elicited nature of one of the sentence populations, then drive relation leakage (Gururangan et al., 2018). For example, a slight preference for words like "not" or "doesn't" when given *contradict* as opposed to *entail* would lead to a bias in the n-gram distribution between the classes in the SSC. Simple heuristics inspired by these findings can produce challenging test sets that hobble models trained on these biased datasets (McCoy et al., 2020), but they require manual guesswork, don't generalize, and may miss higher-level, more nuanced semantic shortcuts and biases.

These "leakage features" encoded in the elicited sentences are visible to NLI models (Zhang et al., 2019), enabling them to "cheat" by attending to them as shortcuts rather than logical correspondences between the two sentences, calling into question the appropriateness of NLI datasets as benchmarks for language understanding (Bowman and Dahl, 2021). In this work we rigorously analyze this problem of single sentence relation leakage in both popular and recent NLI datasets using novel techniques to enable targeted interventions and create higher quality future resources.

Further NLI datasets have been proposed to tackle these problems using machine-in-the-loop adversarial sentence elicitation, (Nie et al., 2020), counterfactual augmentation (Kaushik et al., 2020), and learning dynamic-based debiasing (Wu et al., 2022). These datasets are purported to provide more challenging generalization scenarios for NLI models to better test logical reasoning capabilities. One big question remains—*have these techniques actually eliminated relation leakage biases?*

In this work, we demonstrate the following:

New NLI datasets still exhibit single sentence relation leakage. We compare SSC performance for 10 NLI datasets (including those previously assessed by Poliak et al. (2018)) using a simple transformer baseline, finding that **single sentence relation leakage remains a severe problem**.

NLI models still use the leakage features to cheat. We analyze the datasets using *output decision agreement* and *input token importance* statistics between models trained in the SSC and PSC to demonstrate this.

Automated leakage feature detection is feasible. We introduce a novel model-based metric and dataset analysis tool, the *Progressive Evaluation of Cluster Outliers* (PECO) (Figure 1), for examining the degree of single sentence relation leakage and eliminating it in future datasets.[1]

2 Quantifying NLI Dataset Bias

An ideal NLI benchmark is neither "saturated" nor biased. Saturated benchmarks are datasets for which current approaches already achieve high accuracy. They are "solved" and have limited utility in tracking future progress (Bowman and Dahl, 2021). We refer to as *biased* any NLI benchmarks that exhibit significant single-sentence relation leakage through high achievable SSC accuracy in at least one single sentence condition.

Table 2: For each dataset we analyze, the current state of the art (SOTA) model, base pretrained LM we use for replication, and accuracy for SOTA, our replication (Ours), and majority label-only (Maj.) classification in the standard paired-sentence NLI classification condition (PSC) with selected best-performing hyperparameters.

We analyze 10 datasets containing a total of 14 test or validation sets in terms of *biasedness* and *saturatedness*, across 17 SSC conditions (premise-only (s_1) or hypothesis-only (s_2)). Table 1 provides an overview of this information along with statistics such as train/dev/test set size, and which sentence population is potentially unbalanced.

Each dataset D is composed of (s_1, s_2, r) tuples. We use the standard notation $(X_i, Y_i) \leftarrow D$ to describe the samples, as depending on whether the training condition is standard PSC or SSC, each X_i can be (s_{1i}, s_{2i}), s_{1i}, or s_{2i}. Models trained in condition c are referred to as f_c.

2.1 Saturation and Bias Scoring

We assess accuracy on the test set (or val set when no labeled test set is available) for each dataset in paired- and single-sentence conditions.

Saturation (Accuracy): We report state-of-the-art (SOTA) model performance results in the PSC,

$$\mathrm{A}_{\mathrm{SOTA}}(D) = P(f_{\mathrm{SOTA}}(X_{\mathrm{test}}) = Y_{\mathrm{test}}); \quad X, Y \in D \quad (1)$$

For our model-level and sample-level comparative analysis between the PSC and SSC we train our own transformer-based models using a simple procedure (Sec. 2.4) to assess *replication* accuracy,

$$\mathrm{A}_{\mathrm{PSC}}(D) = P(f_{\mathrm{PSC}}(X_{\mathrm{test}}) = Y_{\mathrm{test}}); \quad X, Y \in D \quad (2)$$

SSC Accuracy: For each elicited population SSC we train a model f_{SSC} according to the procedure described in Sec. 2.4.2, to assess $\mathrm{A}_{\mathrm{SSC}}$:

$$\mathrm{A}_{\mathrm{SSC}}(D) = P(f_{\mathrm{SSC}}(X_{\mathrm{test}}) = Y_{\mathrm{test}}); \quad X, Y \in D \quad (3)$$

Table 2 shows current SOTA models and results for the 10 datasets, as well as our PSC model performance and the relevant training hyperparameters (more detail in Sec. 2.4). Figure 2 shows SSC accuracy against replication (PSC) accuracy for each dataset. Datasets that exhibit higher SSC accuracy have worse single sentence relation leakage, and are thereby questionable in their ability to capture reasoning abilities. Ideally, an **optimal benchmark** for NLI will both have low maximum SSC accuracy and low maximum PSC accuracy (room for future model growth).

These absolute measures of dataset bias and saturation are useful targets for future optimal benchmarks, it is important to understand how these measures interact with each other.

2.2 Relative Dataset Bias Scoring

We assess two relative dataset bias scores.

SSC Improvement over Chance: We subtract the SSC test accuracy from the accuracy achieved by a "guess majority label" strategy following (Poliak et al., 2018):

$$\Delta_{\mathrm{maj}} = P(f_{\mathrm{SSC}}(X_{\mathrm{test}}) = Y_{\mathrm{test}}) - P(Y_{\mathrm{maj}} = Y_{\mathrm{test}}) \quad (4)$$

This metric gives an insight into single sentence relation leakage that compensates for datasets (such as SICK) with an uneven base label distribution.

SSC-PSC Accuracy Recovered: Accuracy achieved by SSC model over PSC:

$$\%\mathrm{R}_{\mathrm{R}} = \frac{P(f_{\mathrm{SSC}}(X_{\mathrm{test}}) = Y_{\mathrm{test}})}{P(f_{\mathrm{PSC}}(X_{\mathrm{test}}) = Y_{\mathrm{test}})} \quad (5)$$

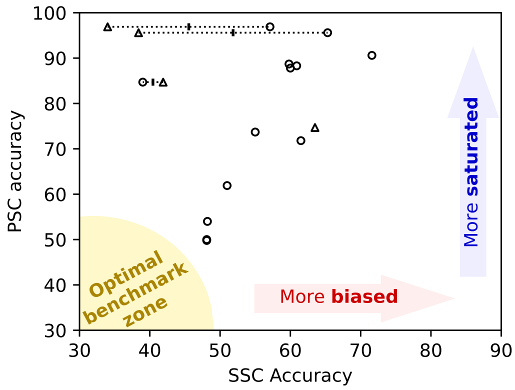

Figure 2: Where the existing NLI datasets fall on the SSC accuracy/PSC accuracy axis. An ideal benchmark isn't saturated (lower SOTA accuracy) and also is unbiased (low SSC accuracy). △ markers represent premise-only SSC results and ∘ markers represent hypothesis-only SSCs. For datasets exhibiting leakage in both conditions, the two points are connected by a dotted line with a | marker for their average SSC accuracy.

Dataset	Cond.	SSC	%R$_{\text{R}}$	Δ_{maj}
SICK	s_2	60.0	68.3	4.0
SNLI	s_2	71.6	79.0	37.8
MNLI-b	s_2	59.8	67.4	24.2
MNLI-u	│	60.9	69.0	24.4
XNLI	s_2	55.0	74.6	21.7

│	s_2	39.0	46.0	5.1
SNLI$_{\text{debiased}}$	s_1	45.3	45.3	2.9
│	s_2	65.3	68.3	29.8
MNLI$_{\text{debiased}}$	s_1	34.0	35.6	-2.2
│	s_2	57.1	58.9	20.9

Table 3: For each NLI dataset and potential leakage-exhibiting single-sentence condition (Cond.) we report *test* accuracy in the single sentence condition (SSC), and three derived metrics from Sec. 2.1. SOTA test accuracy recovery (%R$_{\text{S}}$), replication test recovery (%R$_{\text{R}}$), and biased condition improvement over the chance majority guessing strategy (Δ_{maj}).

This metric captures how similarly the single sentence and normal condition models perform.

2.3 Biased Model Results

Table 3 shows the extent of the single-sentence relation leakage problem across the 17 SSC tests on the 14 splits for the 10 NLI datasets. These results clearly show that *each dataset exhibits significant single-sentence relation leakage* for at least one condition. The comparison columns replication test recovery (%R$_{\text{R}}$), and SSC improvement over the chance majority guessing strategy (Δ_{maj}) are all computed using the single sentence condition accuracy and the standard NLI two-sentence condition SOTA and replication accuracy values in Table 2.

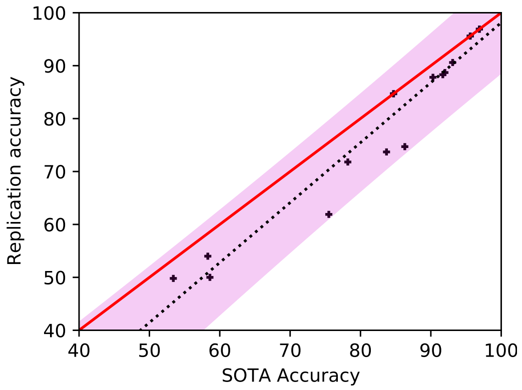

Figure 3: Test set accuracy for SOTA models vs our universal replication procedure models for each dataset in PSC, with a trendline (PCC=0.97) and $y = x$ line.

2.4 Model Training

Our training technique is simple and applied consistently to all datasets. We fine-tune three different language-specific pretrained transformer checkpoints[2] from `HuggingFace` (Wolf et al., 2019) using `Pytorch Lightning`. All models were trained on NVIDIA A-100 GPUs. All models are the HuggingFace `xForSequenceClassification` with `num_classes=3` and no other modifications. All models are trained using the Adam optimizer with cross entropy loss.

We find that this procedure produces broadly near-SOTA performance models, with a maximum relative accuracy difference of 8%, and a 92% Pearson's correlation coefficient (PCC) between SOTA and replication accuracy across the datasets (Figure 3). **Our replications are a reasonable proxy to SOTA for comparative dataset analysis**.

2.4.1 Replication Training Details

Hyperparameters For each dataset in the paired sentence condition (PSC), we select a batch size for maximum GPU utilization. We perform a grid search over lr in {5e–7, 1e–6, 5e–6, 1e–5, 5e–5}.

Single Dataset Fine-tuning We obtain separate fine-tuning checkpoints from the pretrained models for each dataset to enable clean analysis of one dataset at a time. We do not accumulate fine-tuning passes across multiple datasets.

---

2.4.2 Single Sentence Condition Training

To train each dataset's corresponding **SSC** model(s), we use the same setup as the PSC model but follow Poliak et al. (2018)'s formulation of fine-tuning the chosen classification model on only the SSC sentence, *premise only* or *hypothesis only*.

FEVER exhibits bias in the premise distribution, and CAugNLI, $\text{SNLI}_{\text{debiased}}$, and $\text{MNLI}_{\text{debiased}}$ exhibit imbalance in both (Table 1). For the datasets that have imbalanced distributions in both conditions, we separately train bias models for both hypothesis-only and premise-only.

3 Analyzing NLI Dataset Bias

In this section we introduce quantification techniques for more accurately characterizing the extent of these bias problems in the aforementioned NLI datasets, analyze how they interact with the observable bias itself, and develop tools for producing future NLI benchmarks that more closely resemble the ideal benchmark.

3.1 Sample-level Model Behavior

We are particularly interested in understanding the degree to which models trained in the PSC and SSCs "reason" similarly. For this section we use the notations $f(\boldsymbol{X}_{\text{test}})$, $\boldsymbol{Y}_{\text{test}}$ to denote the $(1 \times N)$ column vectors of model output decisions and labels for a test set of N samples, and a simple agreement function $Ag(\boldsymbol{Y}_1,...,\boldsymbol{Y}_n)$ as the ratio of elements that are identical across all $\boldsymbol{Y}_i$ to the vector size N. In other words,

$$Ag(f(\boldsymbol{X}_{\text{test}}),\boldsymbol{Y}_{\text{test}}) = P(Y_{\text{test}} = f(X_{\text{test}})) \tag{6}$$

SSC-PSC Agreement (NBA): The number of samples for which the SSC and PSC models agree over the total number of samples in the set:

$$\text{NBA} = \frac{Ag(f_{\text{SSC}}(\boldsymbol{X}_{\text{test}}), f_{\text{PSC}}(\boldsymbol{X}_{\text{test}}))}{|\boldsymbol{X}_{\text{test}}|} \tag{7}$$

SSC-PSC Recovery (NBR): The number of samples for which the SSC and PSC models agree, *and both classify correctly* over the total number of samples they agree on:

$$\text{NBR} = \frac{Ag(f_{\text{SSC}}(\boldsymbol{X}_{\text{test}}), f_{\text{PSC}}(\boldsymbol{X}_{\text{test}}), \boldsymbol{Y}_{\text{test}})}{Ag(f_{\text{SSC}}(\boldsymbol{X}_{\text{test}}), f_{\text{PSC}}(\boldsymbol{X}_{\text{test}}))} \tag{8}$$

Token Relevance Agreement (TRA): Do SSC and PSC models reason alike? For a sentence X with length n, we compute the gradient of the classification output posterior with respect to each token embedding $emb(w_j)$. We take the 2-norm of the each gradient vector and normalize it over the entire sequence to produce a normalized local explanation vector $m(f(X))$ (Sundararajan et al., 2017):

$$m(f,X) = \left[\frac{|\nabla_{\text{emb}(w_j)}(f(\text{emb}(w_j)))|_2}{\sum_{i=1}^{n}(|\nabla_{\text{emb}(w_i)}(f(\text{emb}(w_i)))|_2)}\right]_{j=1}^{n} \tag{9}$$

To compare "reasoning" similarity between the two models, we compute the samplewise input token relevance agreement can be computed using cosine similarity:

$$\text{TRA}(X_i) = \frac{m(f_{\text{PSC}},X_i) \cdot m(f_{\text{SSC}},X_i)}{||m(f_{\text{PSC}},X_i)||\,||m(f_{\text{SSC}},X_i)||} \tag{10}$$

As the SSC and PSC inputs have different lengths, we pad the SSC importance vector for $m(f_{\text{SSC}}(X_i))$ with zeros either prepended or postpended (depending on if the SSC is hypothesis- or premise-only) to make the two local explanation map vectors of equal length. The dataset-level token relevance agreement is the average of samplewise TRA.

3.2 Cluster-based Bias Evaluation

We are interested in investigating how the biased distributions of the elicited sentences in NLI datasets are captured in the learned representation spaces of models trained on them. In particular, we are interested in answering this question: **is elicited sentence label leakage captured semantically in regions of latent space**?

To answer this we produce dimensionality-reduced *elicited sentence embeddings* for the test set, using the PSC replication models, then fit a high-k k-means clustering to this collection of embeddings. This will allow us to analyze how the local distribution of labels varies over the elicited sentence embedding space. By comparing the KL-divergence of the label distribution within each cluster and the global label distribution, we can compute the **Progressive Evaluation of Cluster Outliers** (PECO) score (Figure 4).

Elicited Sentence Embeddings: To embed the elicited sentences *as they're learned by a model in the PSC*, we feed the elicited sentences s_e through the PSC replication fine-tuned NLI model encoder. We extract the latent codes produced at the output very last fully connected layer of the model before

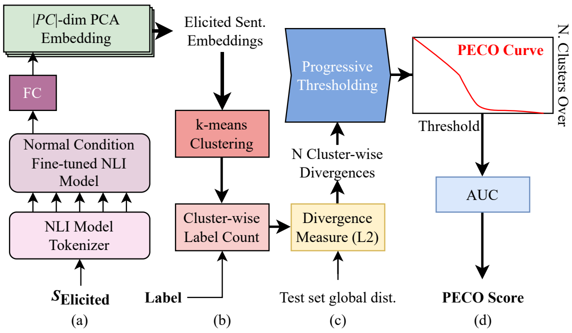

Figure 4: An overview of the approach to computing the PECO score from a collection of elicited population sentences s_{elicited} and their corresponding Labels r. When a fixed threshold is chosen, the Hypothesis embeddings can be dimensionality-reduced using T-SNE to produce plots like Figure 1.

the linear classifier to collect latent codes for every s_e in the test set. We then embed these codes into their 30 principal components to produce the embeddings (Figure 4 (a)).

Clustering: We fit a high-k (in this case, $k = 50$) k-means clustering over the distribution of elicited sentence embeddings to provide a set of local bins for analysis. For each cluster, we count the relation labels its samples contain, to produce a set of 50 cluster-label distributions (Figure 4 (b)).

Computing Cluster Divergences: For each cluster label distribution $p_i = P(Y|\text{cluster} = i)$, we assess the L2 divergence between it and the global label distribution p_{G} to produce divergence scores s_i:

$$s_i = \frac{1}{3}\sum_{j=1}^{3}(P(Y = j) - P(Y = j|\text{cluster} = i))^2 \quad (11)$$

This step is depicted in Figure 4 (c).

Progressive Evaluation: Finally, we compute the PECO score for this collection of cluster divergences as the area under the curve produced by counting the number clusters with divergence s_i over some threshold t for the range of s_i.

$$\text{PECO} = 100\int_{\min(s)}^{\max(s)} \frac{\text{count}_i(s_i > t)}{k}dt \quad (12)$$

Generality of PECO: These same techniques could be applied to a wide variety of potential leakage features on the input to analyze a wide variety of correlation types. For example, input sentence words could be shuffled to test for word order invariance, or word classes could be specifically masked to test for spurious vocabulary correlations.

Dataset	Cond.	NBA	NBR	TRA	PECO

|	s_2	42.2	42.0	58.0	6.8

Table 4: Metrics comparing the behavior of our replication and single-sentence condition models on each dataset using the metrics introduced in Secs. 3.1, 3.2: Normal-Bias Agreement (NBA) and Recovery (NBR), Token Relevance Agreement (TRA) and the Progressive Evaluation of Cluster Outliers (PECO) score.

PECO Parameter Choices: We discuss the impact of PECO parameters (e.g., choice of k-means, number of principal components to reduce to, use of L2 or KL-divergence) in Appendix C.

4 Results

As discussed above, ideal NLI benchmarks are neither *saturated* nor *biased*. Unfortunately, as Table 3 demonstrates, none of the NLI datasets tested thus far satisfy this condition. This is more clearly illustrated in Figure 2. Two questions remain: *to what extent do current models cheat* and *how can we make less biased, less saturated datasets?* Table 4 contains experimental results intended to answer

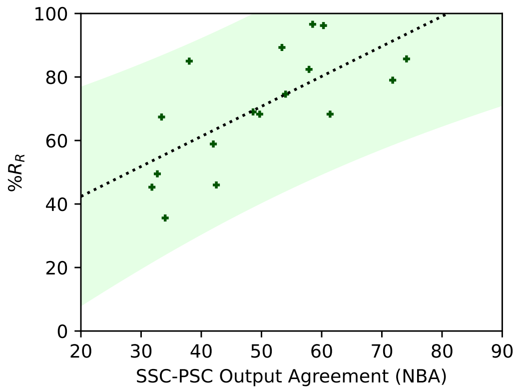

Figure 5: Model-wise output agreement vs Bias accuracy recovery ($\%R_R$). As the replication PSC model and the SSC model agree more often for a given dataset, their performances in the two conditions converge.

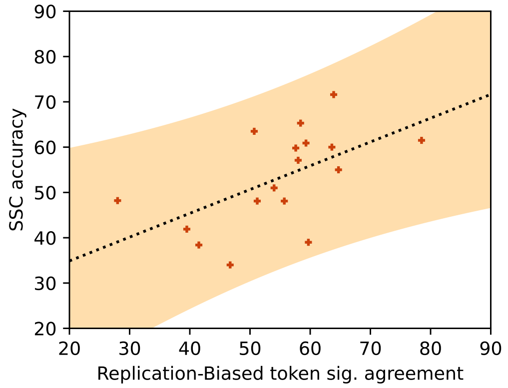

Figure 6: Token releveance agreement (TRA) vs SSC accuracy. When the PSC model and SSC models "reason" more similarly for a dataset, the relation leakage bias exhibited in that dataset tends to be higher.

these two questions. The "agreement metrics" as introduced in Sec. 3.1, SSC-PSC Agreement, SSC-PSC Recovery, and Token Relevance Agreement are provided in Table 4.

4.1 Result-Metric Correlations

We find that SSC-PSC model output agreement (NBA) and recovery rate $\%\mathrm{R}_\mathrm{R}$ are **correlated with a PCC of 0.69** (Figure 5). Datasets where the SSC and PSC models predict more similarly have closer the SSC and PSC performance results are for said datasets. While this result is surprising, ANLI R3 is an interesting outlier (section 5).

We find that TRA and SSC accuracy are also **positively correlated with a PCC of 0.57** (Figure 6). This result demonstrates that for a single dataset, similar reasoning patterns for the single sentence condition and standard sentence pair condition is strongly correlated to single-sentence relation leakage. In other words, **standard condition NLI models trained on biased (high leakage) datasets tend to cheat**. Thus, models indeed rely on annotation artifacts in NLI datasets to achieve high accuracy, and demonstrates that this continues to be a problem in newer NLI datasets, in spite of mitigation attempts. How can we use this knowledge to build better benchmarks?

Figure 7 depicts the relationship between PECO score and bias recovery ($\%\mathrm{R}_\mathrm{R}$). We find the two are **positively correlated with a PCC of 0.64**. This result is fairly intuitive: the more uneven the distribution of labels is in the single-sentence latent spaces (and thus, the higher the area under the PECO curve), the more SSC performance approaches the standard PSC condition performance for a given NLI dataset. This suggests PECO-reducing interventions may be able to target debiasing efforts.

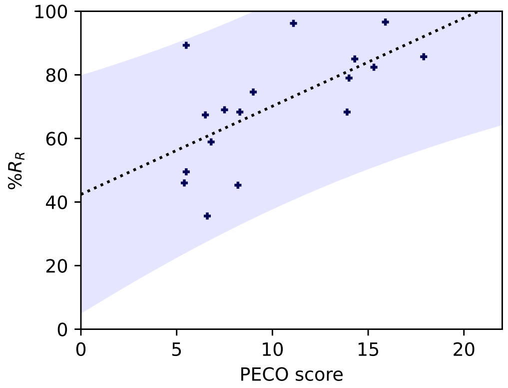

Figure 7: Test-set PECO score vs Bias accuracy recovery ($\%R_R$). This result suggests that interventions that produce lower PECO score datasets tend to yield datasets that exhibit less relation leakage in the SSC.

5 Discussion

Some examples are only correctly classified in the single-sentence condition. A common assumption to discussions of cheating features in machine learning is that they play a role in inflated classification accuracy when present. However, ANLI R3 provides an interesting counterexample. For this dataset, the hypothesis-only model achieves a SSC accuracy of 48.1%, and the PSC model achieves 49.8% (a $\%\mathrm{R}_\mathrm{R}$ of 90%), and SOTA achieves 53%. Despite this score similarity, the samples which the two conditions are able to actually classify correctly vary surprisingly. With an NBR of 58.5%, only ≈ 27% of test samples are correctly classified by both the single and two sentence condition models. This means that around **21% of samples in A3 test are *only* correctly classified by the single-sentence model**.

Perhaps unsurprisingly, ANLI exhibits the lowest TRA out of all datasets tested, indicating that it is somewhat of an outlier in having the SSC and PSC condition models reason differently on it.

XNLI demonstrates the cross-lingual and semantic nature of single-sentence leakage. While previous work has focused on finding words, phrases, patterns, and heuristics in the surface form of the data, our study of XNLI provides an interesting opportunity to investigate the potential for the influence of underlying semantics as a leakage feature. XNLI consists exclusively of 14 language test and val sets, manually translated from MNLI examples. Our XNLI PSC and SSC models are thus trained on MNLI alone, using the multilingual `xlm-roberta` checkpoint.

This produces a natural experiment wherein surface form biases present in the training data are completely eradicated in the test set (as only the 14 non-English languages Table 1 are present), while the underlying meanings encoded by those words remain. In Table 3 we indeed find that XNLI and MNLI exhibit very similar result comparisons. The models on both datasets have a $\Delta_{\text{max}} \approx 20\%$ and $\%R_R \approx 65$. These leakage feature results, being robust to manual translation into 14 different languages, seem to indicate that there is a strong fundamental semantic component to the human biases driving the elicited sentence relation leakage.

Relation leakage remains Unsolved. Elicited sentence relation leakage is a problem for all evaluated NLI datasets, including the new ones intended to fix it. Recent datasets such as XNLI, FEVER, and OCNLI, exhibit high absolute SSC performance over majority ($\Delta_{\text{maj}} > 20$).

Although ANLI and CAugNLI are improvements over the others in terms of Δ_{maj}, with CAugNLI shining particularly in this regard, none eliminate the relation leakage problem entirely, as even CAugNLI still has $\Delta_{\text{maj}} = 8.0$, an 8% performance over chance in the single sentence condition.

$\text{SNLI}_{\text{debiased}}$ and $\text{MNLI}_{\text{debiased}}$, despite their intended purpose, still contain significant amounts of SS label leakage (29.8% and 20.9% over chance). This might be because while their production (Wu et al., 2022) does eliminate bias *originally present in SNLI and MNLI*, it fails to prevent the introduction of *new bias* in the data generation pipeline.

Cluster approaches are promising for future debiasing efforts. Figure 1 shows how the PECO-derived cluster-bias T-SNE plots can be used directly to visualize, analyze, and "debug" biased datasets. In the plot, SNLI clearly has considerably more high-biased clusters taking up a considerable portion of the latent space as compared to CAugNLI, for the bias threshold of 0.2.

An intervention could be performed on identified bias regions in the distribution by having human annotators create new premise sentences from the given hypotheses, thereby forcing the PECO-based bias metrics to reduce. This idea is further backed up by the PCC of 35.8 that we find between PECO and $\%\text{R}_\text{R}$, suggesting that producing datasets of lower PECO score will naturally lead to lower recovered performance in the SSC, and thus less elicited sentence relation leakage.

6 Related Work

Understanding Bias in NLI Huang et al. (2020) demonstrated that counterfactual augmentation alone cannot debias NLI. Multi-task learning can improve model robustness to fitting spurious features (Tu et al., 2020), but because the underlying **benchmarks are biased**, progress on the desired reasoning capability is questionable (Poliak et al., 2018). Geva et al. (2019) strengthen the finding that annotator bias is a key driver of this poor generalization performance, showing that NLI models can struggle to even generalize across disjoint sets of annotators on the same task.

Simple word- and n-gram level approaches have proven surprisingly capable in a-priori characterizations of dataset difficulty (McKenna et al., 2020) and producing difficult test sets (Saxon et al., 2021) in diverse language domains such as SLU. Gardner et al. (2021) show how such purely frequentist approaches can identify word-level spurious correlations with respect to label class which drive in-part the shortcut features for classes of "competency problems" such as NLI.

Mitigating Bias in NLI Belinkov et al. (2019) demonstrate an approach to train NLI models robustly against some of these biases, using Gururangan et al. (2018)'s hard test set. McCoy et al. (2020) utilize simple heuristics like lexical overlap to produce the synthetic debiased HANS NLI dataset to test generalization. This dataset has been used to evaluate techniques including predicate-argument- (Moosavi et al., 2020) and syntactic transformation-based (Min et al., 2020) augmentations. Zhou and Bansal (2020) leverage a bag-of-words approach to debias datasets along lexical features. However, these approaches have yet to improve generalization in comprehensive replication studies has thus far (Bhargava et al., 2021). Meanwhile Varshney et al. (2022) propose a fully unsupervised data collection pipeline for NLI, in order to sidestep the problem of human biases entirely.

Approaches like (Kaushik et al., 2020) and (Wu et al., 2022) are very promising for producing data that reduces bias on a samplewise, but not populationwise level. Using our semantic, model-driven local bias finding strategies, future interventions can lead to the large scale production of debiased NLI datasets and a new generation of higher quality benchmarks for language understanding. Liu et al. (2022) perform such a targeted augmentation approach using the *dataset cartography* sample

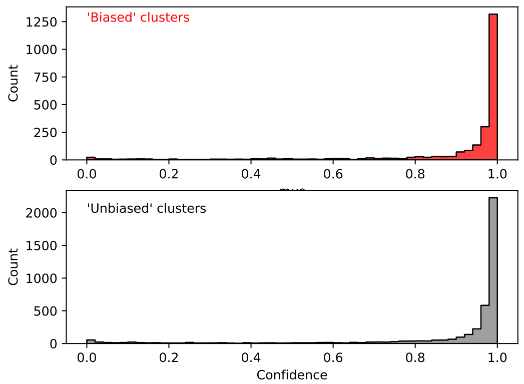

Figure 8: Histograms for the samplewise *confidence* feature from dataset cartography in SNLI, for high- (biased) and low-PECO$_{L2}$ clusters.

characterization scheme from Swayamdipta et al. (2020) to produce WANLI, an NLI dataset that allows for improved performance on the aforementioned challenging test sets.

6.1 PECO vs Dataset Cartography

To determine if PECO-driven dataset augmentation is redundant given the recent release of WANLI, we seek to determine if usable samplewise information for targeting interventions (e.g., presence in a "bias" cluster) is captured during PECO analysis and is redundant to the relevant samplewise characterization produced in dataset cartography.

To do this, we collect the samplewise *confidence* feature (Swayamdipta et al., 2020) during training of the PSC model for each validation set sample in SNLI. We then assign each validation sample to its corresponding PECO cluster (out of the 50) and produce two histograms of the confidence feature, one for **"biased" clusters** (PECO$_{L2}$ > 0.25) and one for the other clusters. Figure 8 shows the results of this experiment. We find that out of the 10k validation set examples, roughly 2 are assigned to an "unbiased" cluster for every 1 assigned to "biased," roughly evenly across all confidence bins.

This result suggests that PECO clusterwise "biasedness" is orthogonal to the samplewise ease of learnability captured by the dataset cartography confidence feature. In other words, we find that **some samples are easy to learn (high confidence) because they are simple, while other samples are easy to learn because the model is using cheating features.** PECO-like analyses will be instrumental in guiding future efforts to eliminate shortcut features in natural language datasets.

7 Conclusion

In the half decade since (Poliak et al., 2018) single sentence relation leakage bias has proven to remain a difficult issue. Efforts to debias NLI have led to datasets that merely exhibit different kinds of bias than those shown before, or less saturated benchmarks that continue to exhibit cheating features. Future work must prioritize reducing observable bias directly using a model-driven approach.

Limitations

Our work is limited primarily by the PECO's reliance on test-set classification. To successfully analyze the train set-only datasets of SNLI$_{\text{debiased}}$ and MNLI$_{\text{debiased}}$, we had to generate our own train/test splits over the data by sampling. Luck in split selection may play a role in the level of observable bias in cases like these. Furthermore, this reliance on observing held-out samples to understand bias in general means that interventions to reduce single sentence label leakage must apply costly multi-fold splitting and analysis, consuming more significant compute resources than would otherwise be needed for other model-driven approaches.

Ethical Considerations

In the short term, progress toward better natural language inference does not appear to lead to significant social risks in its broader impacts. While "underclaiming" progress in natural language processing tasks (e.g. exaggerating the scope or severity of failures of specific models on specific tasks) (Bowman, 2021) may be enabled by this work in the future, our focus on *directly quantifiable and observable single sentence leakage*, use of SOTA-like models (fine-tuned transformers) for analysis, and our side-by-side comparison of our model implementations with SOTA all ensure that our criticisms of current NLI benchmarks are well-founded. All data and tools we utilized were freely distributed for unlimited research use in the academic context.

A Detailed Dataset Info

SICK Sentences Involving Compositional Knowledge (Marelli et al., 2014) was produced by instructing annotators to label existing sourced pairs from 8K ImageFlickr data set (Young et al., 2014) and SemEval 2012 STS MSR-Video Description data set (Agirre et al., 2012). The dataset is in English. Each sentence pair was annotated for relatedness and entailment by means of crowdsourcing techniques.

SNLI The Stanford NLI dataset was produced using (Bowman et al., 2015). The corpus contains content from the Flickr 30k Corpus (Young et al., 2014), VisualGenome corpus (Krishna et al., 2017) and Gururangan et al. (2018). The corpus is in English. The dataset is collected through human-written English sentence pairs.

MNLI The Multi-genre NLI Corpus (Williams et al., 2018) is modeled on the SNLI corpus (Bowman et al., 2015) but it differs in the range of genres of spoken and written English text supporting cross-genre evaluation.

XNLI The Cross-Lingual NLI Corpus (Conneau et al., 2018) consists of manually-translated dev and test samples from MNLI in 14 languages: French, Spanish, German, Greek, Belgian, Russian, Turkish, Arabic, Vietnamese, Thai, Chinese, Hindi, Swahili, and Urdu. It is interesting for analysis because on a high level the semantics of the data follow MNLI. The corpus is made to evaluate the inference in any language when only English data is presented at training time.

FEVER NLI-style FEVER (Nie et al., 2019) is an NLI reformulation of the FEVER claim verification dataset (Thorne et al., 2018). The original dataset was collected by eliciting annotators to write fact sentences that are *supported*, *refuted*, or *unverifiable* relative source passages drawn from Wikipedia. This is converted into an NLI task by treating the elicited sentences as premises and the source passages as NLI pairs with relations *entail*, *contradict*, or *neutral* respectively. This dataset is unique in that the premises were elicited from seed hypotheses, meaning it has a balanced hyp. distribution but potentially biased prem. distribution.

ANLI The adversarial NLI corpus (Nie et al., 2020) is collected through crowdworkers and the purpose of this dataset creation is to make the state-of-art results fail in this dataset. The sentences are selected from the Wekipedia and manually curated HotpotQA training set (Yang et al., 2018). The language is in English. It contains three partitions of increasing complexity and size, which we refer to hereafter as A1, A2, and A3. Detailed data statistics are in Table 1.

OCNLI The Original Chinese NLI corpus was collected following MNLI-procedures but with strategies intended to produce challenging inference pairs (Hu et al., 2020). No translation was employed in producing this data; the source premise sentences and elicited hypotheses are original.

CAugNLI Kaushik et al. (2020) produced counterfactually augmented datasets for NLI and sentiment analysis using human annotators, instructing them to make minimal changes to the sentences beyond those necessary to change the label. It extends the work of Maas et al. (2011) and Bowman et al. (2015). They find that a BiLSTM classifier achieves negligible performance over chance when trained on hypothesis only. However, since their dataset includes elicited modified sentences in both the premise and hypothesis populations, there are opportunities for bias on both.

CAugNLI was produced by having human annotators minimally modify either the premise or hypothesis of 2,500 samples drawn randomly from SNLI so as to produce new samples with similar structure and word distributions but different meanings. These modifications are intended to reduce spurious correlations, in particular by roughly equalizing the distribution of relation labels with respect to word-level and semantic-level patterns in the elicited hypothesis sentences.

SNLI$_{\textbf{debiased}}$ and MNLI$_{\textbf{db}}$ are augmentations of the SNLI and MNLI train sets produced by training GPT-2 (Radford et al., 2019) generators on them, and then generating samples which they check for accuracy using a pretrained RoBERTa NLI classifier, and then reject if they exhibit spurious correlations including samplewise hypothesis-only model classifiability (Wu et al., 2022). To do this they first train static hypothesis-only SNLI and MNLI models, and reject all generated samples that can be successfully classified hypothesis-only by them. However, beyond this test under a static hypothesis-only distribution they do not attempt to assess if their generator models introduce *new leakage features* in the sentence distributions as a result of their accuracy filtering process. To test this we create test splits on the data (as they provide train sets only) which contain no sentence overlap with the train sets through random sampling.

B Training on PSC, Testing on SSC

Here we justify why PECO is computed on single-sentence condition (SSC) examples, using *models trained on the paired-sentence condition* (PSC).

Our core goal is to characterize only the **model-relevant** shortcut features that are present in the SSC data, to enable better model-level understanding and to enable shortcut feature elimination in future datasets. While all SSC accuracy must be driven by SSC-visible shortcuts, it is possible that **some SSC-visible cheating features aren't actually used as shortcuts by PSC classifiers**. Thus, we have to train on PSC and test on SSC, and PECO is an alternative metric of bias that captures this model-level separability of sentences in the SSC notion better than other approaches.

C PECO Parameter Details

The PECO scoring pipeline contains a number of parameters that require motivation, including SSC and PSC model training hyperparameters, number of principal components to reduce to during PCA $|PC|$, and number of k-means clusters k to divide the test set into for analysis (Figure 4). We specify our NN hyperparams that we performed grid search over in subsubsection 2.4.1. However, selecting k and $|PC|$ is not a straightforward simple grid search.

We report PECO scores for all assessed datasets in Table 5, for $k \in 10, 25, 50, 100$ and no PCA projection, $|PC| = 50$, and $|PC| = 100$ PCA conditions. We find that for a given k, the different PCA conditions have limited impact on the final scores. We also find that L2- and KLD-based PECO scores are well-correlated. For smaller test sets (e.g., ANLI and its partitions A1-A3, OCNLI) there is increased sensitivity to variations in k relative to the larger datasets such as SNLI. We selected $k = 30$, $|PC| = 50$ for our main experimental PECO results as it didn't produce the extreme swings in score for small test sets that we observed for higher k.

Table 5: PECO scores for various levels of principal component reduction ($|PC|$), various numbers of k-means clusters, using L2 and KLD distance. These numbers are collected from a separate reproduction to Table 3, which uses different k for different datasets (reflecting their different sizes), and $|PC| = 30$. This table clearly illustrates that e.g., L2 PECO are pretty consistent across different numbers of principal components, for a given number of clusters k. We find that calibrating k based on the number of test-set samples for a given dataset is valuable for producing good characterization of the degree of bias. To improve legibility, we kept PECO_{KLD} in the $[0, 1]$ range.

Weakly-Supervised Questions for Zero-Shot Relation Extraction

Saeed Najafi and **Alona Fyshe**
Department of Computing Science, University of Alberta, Canada
`{snajafi,alona}@ualberta.ca`

Abstract

Zero-Shot Relation Extraction (ZRE) is the task of Relation Extraction where the training and test sets have no shared relation types. This very challenging domain is a good test of a model's ability to generalize. Previous approaches to ZRE reframed relation extraction as Question Answering (QA), allowing for the use of pre-trained QA models. However, this method required manually creating gold question templates for each new relation. Here, we do away with these gold templates and instead learn a model that can generate questions for unseen relations. Our technique can successfully translate relation descriptions into relevant questions, which are then leveraged to generate the correct tail entity. On tail entity extraction, we outperform the previous state-of-the-art by more than 16 F1 points without using gold question templates. On the RE-QA dataset where no previous baseline for relation extraction exists, our proposed algorithm comes within 0.7 F1 points of a system that uses gold question templates. Our model also outperforms the state-of-the-art ZRE baselines on the FewRel and WikiZSL datasets, showing that QA models no longer need template questions to match the performance of models specifically tailored to the ZRE task. Our implementation is available at `https://github.com/fyshelab/QA-ZRE`.

1 Introduction

Building models that capture abstract knowledge rather than just memorizing data is one of the inspirations for zero-shot benchmarks (Alex et al., 2021). In order to test a model's ability to extract higher-level knowledge, these benchmarks measure performance on data unlike what is seen during training. For example, in Zero-shot Relation Extraction (ZRE), a model trained to extract the name of a company's CEO should be able to extract the name of a country's political leader at test time.

In ZRE, the test relations do not appear in the training data, so one cannot apply typical relation classification approaches. One method for ZRE is to reframe the task as a Question-Answering (QA) problem by manually creating question templates for each relation type. Extracting the tail entity is accomplished by finding the answer span for the corresponding question template (Levy et al., 2017). However, this method requires gold question templates ahead of time. Here we ask, is it possible to leverage QA systems without annotating relations with gold question templates?

We treat ZRE as a tail entity generation task for which we consider the dual training of question and answer generators. We create question and answer generators by pre-training the publicly available T5 models (Raffel et al., 2020) on QA corpora, and then fine-tune for ZRE within our proposed learning framework. We investigate four training objectives based on Marginal Maximum Likelihood (MML) optimization, and suggest an off-policy sampling technique to avoid ungrammatical spurious questions in the search space.

Our experiments show that our off-policy sampling technique is critical for creating semantically relevant questions. For ZRE, we show that our weakly-supervised questions produce a model with competitive F1 score of 65.4 compared to the F1 score of 66.1 achieved by using gold question templates. Our contributions can be summarized as the following:

- We propose a new learning objective that combines off-policy sampling and MML optimization.
- We can successfully generate semantically relevant questions for a given relationship signal.
- We report a new state-of-the-art ZRE performance on the RE-QA dataset (Levy et al., 2017) without using gold question templates.
- We outperform SOTA baselines on the FewRel and WikiZSL datasets with a generative approach without using any gold question templates.

2 Problem Formulation

In this work, we train models to extract facts from unstructured text. Facts are represented as triplets (e_1, r, e_2) where e_1 is the head entity, e_2 is the tail entity, and r is the relation keywords. We explore **relation extraction (RE)**, which is the task of predicting r when e_1 and e_2 are known, and **tail entity extraction (TE)**, which is the task of predicting e_2 when e_1 and r are known.

We begin with TE, for which we learn $P(e_2|c, e_1, r)$: the distribution of the tail entity conditioned on an unstructured text context c, head entity, and the relation keywords. We investigate how to transfer models pre-trained on QA corpora to the task of TE by estimating $P(e2|c, e1, r)$. With a gold natural question q^*, which semantically includes the information about both of the head entity e_1 and the relation words r, we can optimize $P(e2|c, q^*)$ to fine-tune any answer generation model on RE datasets[1]. In cases where we do not have gold question templates, we can define a simple baseline using a pseudo question q^{pseudo}, which is the string concatenation of the head entity e_1 and the relation words r. We then can fine-tune a pre-trained QA model on RE datasets by directly optimizing the objective $P(e2|c, q^{pseudo})$.

To transfer the models pre-trained on QA corpora to the task of TE, we can provide a natural question for the given head entity and the relation keywords. However, providing question templates for every relation type is infeasible. We explore the idea of generating questions semantically relevant to the given input context, relation and the head entity. Therefore, we marginalize the joint distribution $P(e_2, q|c, e_1, r)$ with respect to the unobserved questions q to learn the tail entity generator: $P(e_2|c, e_1, r) = \sum_q P(e_2, q|c, e_1, r)$. As illustrated by Figure 1, we factorize $P(e_2, q|c, e_1, r)$ as the following equation where θ_Q and θ_A are respectively the parameters of the question and answer generation modules:

$$P(e_2|c, e_1, r) = \sum_q P(e_2, q|c, e_1, r) = \sum_q P_{\theta_Q}(q|c, e_1, r) \times P_{\theta_A}(e_2|c, q, e_1, r) \quad (1)$$

For example, given a context biography about the person "Donald Trump" and the relation keywords "place of birth," we would use P_{θ_Q} to first generate the question "Where was Donald Trump born?" and then the answer module P_{θ_A} can generate the response "New York."

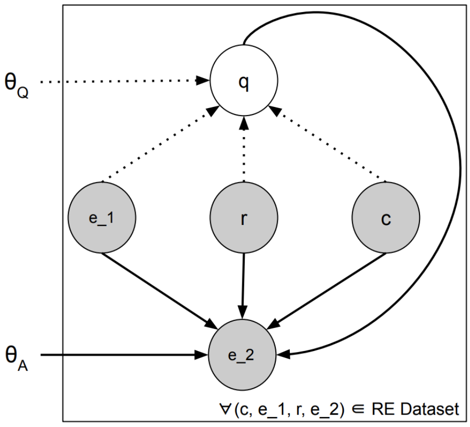

Figure 1: The probabilistic representation of the conditional distribution of the tail entity (e_2) conditioned on the context c, head entity e_1, and the relation keywords r. The question q is not observed. The θ_Q and θ_A are respectively the parameters of the question and answer generation modules.

We then re-purpose this TE model for the task of RE. Whether we train the tail entity generator $P(e_2|c, e_1, r)$ with gold, pseudo, or generated questions, we perform the RE task by scoring every possible relation of the test data and choosing the highest scoring relation:

$$\hat{r} = \arg\max_r P(e_2|c, e_1, r) \quad (2)$$

3 Methods

In this section we discuss the pre-training steps for the question and answer modules and then explore combinations of four training objectives based on maximizing the marginal likelihood of Equation 1. Finally, we introduce off-policy sampling and summarize the search algorithms used during training and test phases.

3.1 Pre-training the Answer Module

The answer generator is based on the publicly available T5 model (Raffel et al., 2020). We fine-tune this T5 model on the following five QA datasets to generate the gold answer in its output given the input passage and the question: 1) SQuAD (Rajpurkar et al., 2018) with unanswerable questions by generating a special unknown token in the output corresponding to these unanswerable questions, 2) NarrativeQA dataset containing abstractive responses for its questions (Kočiský et al., 2018),

---

[1] On an RE dataset, we can fine-tune models for TE and ZRE tasks.

3) RACE dataset as a multiple-choice QA dataset where we generate the question's correct choice as the answer text in the decoder (Lai et al., 2017), 4) BoolQ dataset having Yes/No questions (Clark et al., 2019), and 5) the DropQ dataset to encourage the model to learn discrete reasoning (e.g., addition, counting or sorting, etc.) in paragraphs (Dua et al., 2019). We fine-tune the T5 on the aforementioned QA corpora for four epochs with a batch size of 64. In total, we have fine-tuned this T5 model on 337,768 distinct QA pairs. We use the final model as our pre-trained answer generator which will be the initial checkpoint for learning the distributions $P(e_2|c, q^*)$, $P(e_2|c, q^{pseudo})$, or $P_{\theta_A}(e_2|c, q, e_1, r)$ in our experiments.

3.2 Pre-training the Question Module

We now fine-tune a T5 model using the QA corpora. We learn the distribution $P(q|c, e_1, r, e_2)$, and use the answer in each QA instance as a proxy for the tail entity e_2. To specify the synthetic head entity e_1, we run a named entity tagger[2] over questions in the QA corpus. For questions with multiple extracted entities, one of the entities are randomly selected as the head entity. To specify the relation r from the question, after ignoring punctuation or interrogative words (e.g., what, where, etc.), at most four tokens (excluding the extracted entities) are sampled. We fine-tune the T5 model on this synthetic dataset, giving gold passage as the context c, one of the extracted named entities as e_1, the gold answer tokens as e_2, and the sampled words as the relationship keyword r. We train the model to produce the gold question. We specifically fine-tune the model on the answerable questions from the SQuAD (Rajpurkar et al., 2018), NarrativeQA (Kočiský et al., 2018), and the DropQ datasets (Dua et al., 2019) for 4 epochs. This model will be the initial checkpoint for the question generator $P_{\theta_Q}(q|c, e_1, r)$ in our experiments.

3.3 Training Objectives

Having the pre-trained answer generator, we optimize $\log P(e_2|c, q^*)$, and $\log P(e_2|c, q^{pseudo})$ on RE datasets using the gold q^* and pseudo questions q^{pseudo}, respectively. To generate questions and learn from them, we also directly maximize the Marginal Log-Likelihood (MML) to train both the question and answer modules in Equation 1. With MML training, the objective is approximated with numerical summation using questions sampled from the question module. MML training outperforms the policy gradient methods on weakly-supervised semantic parsing (Guu et al., 2017) as simple policy gradient estimations may have large variances (Roberts and Tedrake, 2009; Guu et al., 2017). With the MML training, we use the following gradient vector to update θ_Q, where $\phi(q)$ approximates the true question posterior $P(q|c, e_1, r, e_2)$:

$$\begin{aligned} \nabla_{\theta_Q} M &= \sum_q \phi(q) \times \nabla_{\theta_Q} \log P_{\theta_Q}(q|c, e_1, r) \\ \phi(q) &= \frac{P_{\theta_Q}(q|c, e_1, r) \times P_{\theta_A}(e_2|c, q, e_1, r)}{Z} \\ Z &= \sum_{q'} P_{\theta_Q}(q'|c, e_1, r) \times P_{\theta_A}(e_2|c, q', e_1, r) \end{aligned} \tag{3}$$

Similarly, we use the following gradient update for θ_A: $\nabla_{\theta_A} M =$

$$\sum_q \phi(q) \quad \times \quad \nabla_{\theta_A} \log P_{\theta_A}(e_2|c, q, e_1, r) \tag{4}$$

As we ultimately want to generate the correct tail entity regardless of the input question in the answer module, we can use the best question from P_{θ_Q} and then optimize the probability of the tail entity for such a decoded question. This idea results in the following G gradient (G: greedy) update for the answer module:

$$\begin{aligned} \nabla_{\theta_A} G &= \nabla_{\theta_A} \log P_{\theta_A}(e_2|c, \hat{q}, e_1, r) \\ \hat{q} &= \arg\max_q P_{\theta_Q}(q|c, e_1, r) \end{aligned} \tag{5}$$

3.4 Off-Policy Search over Pre-trained Question Posterior

We encountered two issues while training the question generator with the previous MML objective. The first issue is that samples become ungrammatical templates as we continue training the question module. We hypothesize that the issue originates from taking direct samples from the question generator $P_{\theta_Q}(q|c, e_1, r)$ while simultaneously updating it during training. These spurious questions can hinder the model from generalizing to a new unseen relation. The program synthesis and semantic parsing research have reported a similar issue (Guu et al., 2017; Misra et al., 2018; Liang et al., 2018; Wang et al., 2019a, 2021).

---

[2] We used the NER tagger from the SpaCy library.

The second issue in taking samples from $P_{\theta_Q}(q|c, e_1, r)$ is that omitting the tail entity in the question generator while using the input context c sometimes results in multiple plausible questions. For example, consider the context "The Facebook brand was replaced by Meta in November 2021." For the ambiguous relationship word "replace", given the head entity "Facebook", we can generate two valid questions: a) "Which brand replaced Facebook?", b) "When was the brand Facebook replaced?".

To resolve the first issue, we apply an off-policy sampling technique (Levine et al., 2020; Pang and He, 2020) and use a fixed separate sampling module to sample questions during training. With this fixed search policy $S(q)$ over questions, we need to optimize the following new objective:

$$\log E_{q\sim S(q)}[\frac{P_{\theta_Q}(q|c, e_1, r)}{S(q)} \times P_{\theta_A}(e_2|c, q, e_1, r)]$$

To resolve the second issue, we feed the tail entity along with the context into the search module; however, we cannot feed the tail entity into the question generator $P_{\theta_Q}(q|c, e_1, r)$ as the correct tail entity is unknown during the test phase. Furthermore, to augment the information of the relationship keyword r, we append the relation description for each r and feed it to the question generator P_{θ_Q} and the sampling module $S(q)$.

We assume that our search module $S(q)$ is a fixed model approximating the question posterior $P(q|c, e_1, r, e_2)$, which can be our pre-trained question generator. Thus, we use two identical copies of our pre-trained question generator. One is fixed and will be used to provide samples for training. The other serves as the initial network for $P_{\theta_Q}(q|c, e_1, r)$, and we update its parameters during the training phase. The search module will also receive the tail entity e_2 as input, whereas the P_{θ_Q} only receives c, e_1, and r. During the test phase, we only generate questions from P_{θ_Q}. Using the off-policy samples, the new MML gradient updates will have the following forms, where $S(q)$ is our pre-trained question module and $\phi(q)$ approximates the true question posterior according to Equation 3:

Training Objective	Q grad.	A grad.
MML-MML	$\nabla_{\theta_Q} M$	$\nabla_{\theta_A} M$
MML-G	$\nabla_{\theta_Q} M$	$\nabla_{\theta_A} G$
OffMML-OffMML	$\nabla_{\theta_Q} O$	$\nabla_{\theta_A} O$
OffMML-G	$\nabla_{\theta_Q} O$	$\nabla_{\theta_A} G$

Table 1: Combinations of the four types of gradient vectors used for training the question (θ_Q) and answer (θ_A) modules. See Equations 3-7. Training objectives are named as (Question-Answer) tuples that refer to the gradient vectors used for the question and answer modules.

$$\nabla_{\theta_Q} O = E_{q\sim S(q)}[\frac{\phi(q)}{S(q)} \times \nabla_{\theta_Q} \log P_{\theta_Q}(q|c, e_1, r)] \tag{6}$$

$$\nabla_{\theta_A} O = E_{q\sim S(q)}[\frac{\phi(q)}{S(q)} \times \nabla_{\theta_A} \log P_{\theta_A}(e_2|c, q, e_1, r)] \tag{7}$$

Table 1 summarizes the four gradient vectors we use for the training phase. With $\nabla_{\theta_Q} G$ gradient update, we always use samples from the question generator (not from $S(q)$) to expose the answer module to errors from P_{θ_Q}.

3.5 Search Algorithms

To generate the tail entity on the test data, regardless of fine-tuning the pre-trained answer module with gold, pseudo, or generated questions, we use greedy decoding to find the top-scoring tokens. To generate questions from $P_{\theta_Q}(q|c, e_1, r)$, we use the top-scoring question found with beam search decoding having the beam size of 8.

During training, to estimate the G gradient vector listed in Table 1, we rely on beam search decoding with the beam size of 8 to find the top scoring question. For MML gradient vectors, we use top-p sampling with the suggested threshold of 0.95 to collect 8 final samples from the question generator $P_{\theta_Q}(q|c, e_1, r)$ or sampling module $S(q)$. In top-p sampling (Holtzman et al., 2019), at each decoding step, we find the smallest set of vocabulary with the cumulative probability above a threshold (e.g., 0.95) and re-scale the distribution among these tokens to perform the sampling. We find this approach has a better exploration compared to beam-search, greedy, or top-k decoding.

Table 2: The example input for the question and search modules. The search module also receives the tail entity in the input.

Module	Input Format
Question	"answer: Isaac Nicola <SEP> place of birth ; most specific known birth location of a person, animal or fictional character context: Isaac Nicola Romero (1916 in Havana, Cuba) was a prominent Cuban guitarist. </s>"
Search	"answer: Isaac Nicola <SEP> place of birth ; most specific known birth location of a person, animal or fictional character Havana context: Isaac Nicola Romero (1916 in Havana, Cuba) was a prominent Cuban guitarist. </s>"

Table 3: The example input for the answer module given gold, pseudo, and the generated questions. The generated question is from the question module trained with the OffMML-G objective.

Question Type	Input Format
Pseudo	"question: Isaac Nicola <SEP> place of birth context: Isaac Nicola Romero (1916 in Havana, Cuba) was a prominent Cuban guitarist. </s>"
Generated	"relation: Isaac Nicola place of birth question: What was the name of the place where Isaac Nicola was born? context: Isaac Nicola Romero (1916 in Havana, Cuba) was a prominent Cuban guitarist. </s>"
Gold	"question: What was Isaac Nicola's city of birth? context: Isaac Nicola Romero (1916 in Havana, Cuba) was a prominent Cuban guitarist. </s>"

4 Experiments Setup

4.1 Datasets

We use three datasets to test our weakly-supervised questions in the ZRE setting. We first use the RE-QA dataset released by Levy et al. (2017) for tail entity (TE) generation using QA models. RE-QA provides ten folds with 84 relation types in the train, 12 on the dev, and 24 on the test splits. There is no overlap among relation types of these splits per fold. Each fold contains 840k sentences in the train, 6k sentences in the dev, and 12k in the test split. Half of the sentences are negative examples with no corresponding e_2 given e_1 and r. The RE-QA dataset provides multiple gold question templates for each relation type.

To compare our system with current SOTA methods for the ZRE, we also consider the FewRel and WikiZSL datasets. The FewRel dataset has 56K sentences over 80 relation types (Han et al., 2018). The WikiZSL dataset has 93483 sentences over 113 relation types (Zhong et al., 2017). Similar to the previous SOTA method ZS-BERT (Chen and Li, 2021), we randomly split the FewRel and WikiZSL datasets into train/dev/test splits where we have 5 and 15 relation types in the dev and test splits, respectively; with no overlap of the types between these splits. We create five train/dev/test folds splitting the datasets with different random seeds.

For all the datasets, if possible, we retrieve the relation description from the wikidata[3] and append it to the relation keyword r in the question generator P_{θ_Q} or the sampling module $S(q)$.

Table 2 lists an example for the input given to our question and search modules. Table 3 also provides an example for the input of the answer module for the gold, pseudo or generated questions.

4.2 Evaluation Metrics

For the TE task, as we generate a single tail entity $e_2^{'}$ for each input sentence, the extracted triple $(e_1, r, e_2^{'})$ matches the ground truth triple (e_1, r, e_2) only if $e_2^{'} = e_2$ (case insensitive). For the negative examples, we generate a special 'NO_ANSWER' output specifying the null tail entity. We then use the official evaluation script[4] to compute the Precision, Recall, and F1-score for the TE task when there are negative examples in the test data. Precision is the true positive count divided by the number of times the system generates a non-null tail entity. Recall is the true positive count divided by the number of positive examples having the tail entity given e_1 and r. For the ZRE performed by the inference objective 2, we compute the macro

---

[4] http://nlp.cs.washington.edu/zeroshot/

Precision, Recall, and F1-score; averaged across relation types only on positive examples.

4.3 Baselines

Few related works have focused on ZRE. The ZS-BERT model (Chen and Li, 2021) maps sentences and relations into a shared semantic space using two BERT encoders and then uses nearest neighbor search to predict the unseen relations. During training, the ZS-BERT minimizes the distance between the attribute vectors of the input sentence and the seen ground-truth relation while maximizing the distance from other incorrect relation representations. The ZS-BERT has outperformed another earlier work that treats the task of ZRE as an entailment task (Obamuyide and Vlachos, 2018).

We also provide the reported ZRE results on the FewRel and WikiZSL datasets from Tran et al. (2022) which introduces discriminative inter-relation and inter-sentence losses along with a comparative network to better separate sentence-relation representation pairs.

We finally consider RelationPrompt (Chia et al., 2022) which is trained to generate the relation triplets for a given sentence using a BART-base sequence-to-sequence model. We also apply its data-generation variant which uses GPT2 to augment the training dataset by generating synthetic (sentence, entity) pairs for the unseen test relations.

4.4 Training Details

For pre-training/fine-tuning T5 on QA and RE datasets, we use the Adafactor optimizer, which requires less memory compared to Adam (Shazeer and Stern, 2018). In addition, we follow the original configuration[5] suggested for fine-tuning the T5 transformers, such as disabling update clipping, no weight decay, and no warm-up starts (Raffel et al., 2020). In all of our experiments, we used the fixed learning rate of 0.0005.

For fine-tuning our models and all the baselines on all the RE datasets, we train them for one epoch using the batch size of 16 on the RE-QA, 4 on the FewRel, and 16 on the WikiZSL datasets, respectively. Every 100 training steps, we evaluate the models on the dev sets, and then we report the performance of the dev set's best model on the test split. For our models, on all the three datasets, we pre-train/fine-tune T5-small with 6 transformer blocks and 512 hidden states. Due to GPU constraints, we use eight samples or a beam size of 8 in the top-p sampling and beam search decoding algorithms, respectively.

5 Results

5.1 Training Objective Comparisons

In our first experiment, we compare the different training objectives listed in Table 1 in the tail entity generation task. To provide a fair comparison between these objectives, we also append the relation description to the relationship word r in the on-policy training objectives MML-MML and MML-G. We compare these four objectives on the ten folds of the RE-QA dataset. We also report the baseline Base-Base that predicts the test data using only the pre-trained question-answer modules without fine-tuning the modules over the RE dataset.

Table 5 summarizes the metrics on the tail entity generation task for these training objectives. OffMML-G, which uses off-policy samples from the pre-trained question module, outperforms the rest of the training methods with the average F1-score of 56.2. Our proposed off-policy sampling technique has improved the performance of the tail entity generator in the model trained with OffMML-G by an average gain of 1.5 F1-score compared to the model trained with the MML-G objective. Furthermore, on the positive examples, the accuracy for generating the correct tail entity is higher when we take the best question from the question module P_{θ_Q} since the OffMML-G outperforms OffMML-OffMML by an average gain of 2.1 Recall points. To assess the grammar in the generated questions, we compute the average perplexity over the test folds using the GPT2-large (Radford et al., 2019) language model. The last column (PP) in Table 5 shows that both the off-policy sampling and the G gradient objective contribute to a lower perplexity compared to the on-policy sampling and the MML gradient objective as the OffMML-G achieves the lowest perplexity of 144. This observation verifies our hypothesis that off-policy sampling helps to avoid ungrammatical spurious questions.

In Table 4, we also provide an example of the generated questions for the following input context: "The Vision of Saint Eustace is a painting by the early Italian Renaissance master Pisanello, now in the National Gallery in London." Given the head entity "The Vision of Saint Eustace," and the

---

[5] `https://discuss.huggingface.co/t/t5-finetuning-tips/684/3`

Table 4: Example generated questions for the relationship type “collection” (“art, museum or bibliographic collection the subject is part of”) given the head entity “The Vision of Saint Eustace.” The semantically correct questions are in blue. The Base-Base model predicts the test data using only the pre-trained question-answer modules. The model name “A-B” denotes questions generated by the question module trained with the objective A while the answer module is trained with the objective B.

Q-A Models	Generated Question
Base-Base	“What collection is part of The Vision of Saint Eustace?”
MML-MML	“What subjects subjects?”
MML-G	“What art collection is The Vision of Saint Eustace?”
OffMML-OffMML	“The Vision of Saint Eustace is part of what collection?”
OffMML-G	“The Vision of Saint Eustace is part of what collection?”
GoldQ	“What is the name of the place where The Vision of Saint Eustace can be found?”

Table 5: The average Precision, Recall and F1-score for the tail entity generation task using our four training objectives on the ten test folds of the RE-QA dataset. The last column (PP) reports the average perplexity of the generated questions over these ten test folds. Best performance bolded, second best underlined.

Q-A Models	P	R	F1	PP
Base-Base	24.4	31.4	27.5	170
MML-MML	57.3	52.3	54.6	10456
MML-G	57.0	52.9	54.7	1309
OffMML-OffMML	**60.7**	52.3	55.9	148
OffMML-G	58.3	**54.4**	**56.2**	**144**

relationship type “collection.” We verify that the proposed off-policy sampling technique is necessary to create semantically and grammatically correct questions as the OffMML-G objective could successfully generate the question “The Vision of Saint Eustace is part of what collection?”

5.2 Baseline Comparisons

We now compare systems trained with the OffMML-G training objective with the two primary baselines of using pseudo or gold questions to fine-tune the answer generator.

Table 6: The average Precision, Recall and F1-score on the 10 test folds of the RE-QA dataset for the tail entity generation task. Highest performance bolded, second highest underlined.

Q-A Models	P	R	F1

Levy et al. (2017)	43.6	36.5	39.6
PseudoQ-Trained	57.9	50.2	53.6
OffMML-G	58.3	54.4	56.2
GoldQ-Trained	**60.1**	**57.9**	**58.9**

Table 7: The average Precision, Recall and F1-score on the ten test folds of the RE-QA dataset for the Zero-shot Relation Extraction (ZRE) task.

Models	P	R	F1
ZS-BERT	34.7	32.2	33.3
PseudoQ-Trained	63.3	60.5	61.8
OffMML-G	66.7	64.2	65.4
GoldQ-Trained	**67.3**	**65.0**	**66.1**

For the tail entity generation task, Table 6 presents the average F1 scores on the ten test folds of the RE-QA dataset, considering both the positive and negative examples. Using the test data’s gold templates, the pre-trained answer generator (GoldQ-Base) achieves an average F1-score of 43.6, and after fine-tuning the answer module, the baseline with gold questions achieves the highest average F1-score of 58.9, outperforming the previous BiDAF method (Levy et al., 2017), which had an average F1-score of 39.6. With the OffMML-G training objective, we boost the performance of the pre-trained answer module from the average F1-score of 27.5 to 56.2. The OffMML-G training objective outperforms the baseline with pseudo questions by an average of 2.6 F1-score.

For the ZRE task, as listed in Table 7, the model trained with OffMML-G objective outperforms the PseudoQ baseline by an average F1 score of 3.6. This superior performance verifies that using semantically relevant questions improves the performance of QA models while fine-tuning them on the RE datasets. Moreover, with our generated questions, OffMML-G achieves the competitive

Table 8: The average Precision, Recall and F1-score for ZRE on five random runs over the FewRel and WikiZSL datasets. There are 15 unseen relations in the test folds. Highest performance bolded, second highest underlined. The † is the reported performance of ZS-BERT (Chen and Li, 2021). The ⋆ is the reported performance of RelationPrompt without using synthetic examples (Chia et al., 2022).

	FewRel			WikiZSL			
Model	P	R	F1	P	R	F1	Avg F1
ZS-BERT†	35.5	38.2	36.8	34.1	34.4	34.3	35.6

OffMML-G	29.4	30.4	29.9	28.2	28.7	28.4	29.2
PseudoQ-Trained (+negs)	62.8	58.4	60.5	62.6	59.5	61.0	60.8
OffMML-G (+negs)	63.7	59.2	**61.3**	**63.6**	60.4	**61.9**	**61.6**

F1 score of 65.4 compared to the F1 score of 66.1 achieved by the system using gold questions.

In our final experiments, we fine-tune the question-answer modules with the OffMML-G objective on the FewRel and WikiZSL datasets which have 15 unseen relations in the test folds. As the FewRel and WikiZSL datasets do not provide any negative examples, we create synthetic negative examples by repeating every train instance once with its ground-truth relation label replaced with another relation class from the train data. This data augmentation approach is simple enough to include with our models as we generate the null tail entity for negative examples. The recent discriminate approaches such as ZS-BERT and the method of Tran et al. (2022) use margin-based or contrastive learning to separate the ground-truth relation class from other negative relation labels. As presented in Table 8, our transferred QA models trained with OffMML-G objective over the mix of positive and negative examples significantly outperforms the ZS-BERT and the recent baseline of Tran et al. (2022) with an average gain of 26.8 F1 points on both the FewRel and WikiZSL datasets. We do not change the architecture of the underlying transformers as apposed to the comparative network of Tran et al. (2022) trained over the BERT encoders.

We finally compare against RelationPrompt (Chia et al., 2022) which directly generates the relation class in the decoder of the BART-base model given the input sentence and the prompt information about the head and tail entities. The OffMML-G (+negs) achieves an average gain of 15.2 F1 points on both the FewRel and WikiZSL datasets (Table 8)[6]. The idea of using synthetic (sentence, entities) pairs generated by a large language model for the test relation classes improves the performance of RelationPrompt (see +supp row in Table 8). Such data augmentation to use synthetic examples can also be helpful for our method to further guide the question generation for the test relation classes.

In Table 9, we provide some example questions generated for the WikiZSL test data using our question module trained with OffMML-G (+negs) objective.

6 Related Works

Weakly-Supervised Semantic Parsing: The objective in Equation 1 follows a similar search-and-learn framework used in the recent works of weakly-supervised program synthesis and semantic parsing (Guu et al., 2017; Misra et al., 2018; Liang et al., 2018; Wang et al., 2019a, 2021). For example, in the task of text-to-SQL generation, a set of possible SQL solutions for a given natural query are generated (searched) and then those solutions are validated with an SQL verifier. The program verifiers in these recent works provide a deterministic score/reward to update the search module. However, in our objective, the feedback for the question module is another stochastic answer generator that needs to be trained along with the search module.

Reading Comprehension for RE: The joint ex-

---

[6] As expected from the model input format, our negative examples do not improve RelationPrompt.

traction of entities and relations has also been reduced as a multi-hop QA task using pre-defined question templates for a few entity and relation types present in the ACE and the CoNLL04 datasets (Li et al., 2019). Another recent work shows that asking diverse question templates could further boost the performance of the QA models for the joint entity-relation extraction (Zhao et al., 2020). Furthermore, QA frameworks have been applied to re-score and verify the extracted relations of a separate relation extractor by forming simple pseudo-questions concatenating the head entity with the relationship words (Cheng et al., 2021).

Several works have done event argument extraction through QA (Liu et al., 2020; Du and Cardie, 2020). Du and Cardie uses predefined question templates for the events. The work of Liu et al. first picks a template query word for the topic of the event and includes it as the prefix for the question, and then translates a descriptive span around the event word into a descriptive question suffix by learning an unsupervised translation model. Although Liu et al. applies their approach only to the task of event extraction on short sentences from the ACE dataset, they manually provide a relevant question prefix for the relation type.

Question Generation: The Question Generation (QG) research aims at generating natural questions given a document such that the answer modules can find the answers to these questions. Recent systems build end-to-end neural sequence-to-sequence models for QG (Du et al., 2017). Moreover, the current research first extracts the key phrases which could be the answer to the question and then feeds it as an extra input signal while training the QG models (Wang et al., 2019b). Multiple QA corpora have been combined to train a single question generator conditioned on multiple answer types (Murakhovs'ka et al., 2021).

Earlier work suggests dual training of the QG and answer-sentence selection tasks, however, they could marginally improve both of the QG and QA tasks (Tang et al., 2017). Closely related to our work, another recent study translates freebase triplets into natural questions to augment the QA corpora (Serban et al., 2016). However, this triplet-to-question translation task does not use any context passages. The rule-based entity extraction and QG have also been explored for open information extraction on financial datasets (Gupta et al., 2021). However, its rules are not comprehensive for generating questions for complex relations.

Apart from training the QG models on supervised data, recent work uses policy gradient reinforcement learning to a) Optimize rewards related to the fluency and answer-ability of the generated questions (Yuan et al., 2017), b) Expose the model to its errors (Song et al., 2017), and c) Include paraphrase probability to properly compare the generated questions with the ground truth ones (Zhang and Bansal, 2019).

Despite the previous studies on QG, we treat questions as latent variables without having access to gold questions given the input context and the relation triplets.

7 Conclusion

This work introduces the OffMML-G training objective to fine-tune the question and answer generators for RE. Our method generates semantically relevant questions for the answer module given the head entity and the relationship keywords. We demonstrated that with these weakly-supervised questions, one could fine-tune QA models on the RE corpora, achieving competitive results in detecting unseen relations. Our future direction would deploy the technique on document-level entity-relation extraction, further exploiting the inference capabilities of QA models.

Limitations

A major limitation in our method is that we need to provide three distributions during training: a) $P(q|c, e_1, r)$ as the question generator, b) $P(e_2|c, e_1, r, q)$ as the answer module, and c) $S(q)$ as our fixed search module over questions. This generative approach (i.e. generating the tail entity) for relation extraction requires more compute resources compared to a direct discriminate approach to learn $P(r|c, e_1, e_2)$, however, such a direct approach cannot be used to transfer QA models into the RE task.

We have used the T5-small models in all our experiments. Further gain can be achieved by switching into T5-large models, however, we leave those large-scale experiments for future work.

Ethics Statement

Many language models show biases in their output due to the data used to train them (Liang et al., 2021). It is possible that these biases could affect the RE results that we present here (e.g., producing poor performance for certain kinds of relations, or for entities with names different from the training data).

Abstract

Identifying the difference between two versions of the same article is useful to update knowledge bases and to understand how articles evolve. Paired texts occur naturally in diverse situations: reporters write similar news stories and maintainers of authoritative websites must keep their information up to date. We propose representing factual changes between paired documents as question-answer pairs, where the answer to the same question differs between two versions. We find that question-answer pairs can flexibly and concisely capture the updated contents. Provided with paired documents, annotators identify questions that are answered by one passage but answered differently or cannot be answered by the other. We release DiffQG which consists of 759 QA pairs and 1153 examples of paired passages with no factual change. These questions are intended to be both unambiguous and information-seeking and involve complex edits, pushing beyond the capabilities of current question generation and factual change detection systems. Our dataset summarizes the changes between two versions of the document as questions and answers, studying automatic update summarization in a novel way.

1 Introduction

Given a pair of statements, how can we identify the difference in their information content? This problem has existed in different forms across NLP research, such as *recognizing textual entailment* (Dagan et al., 2010) and *natural language inference* (Bowman et al., 2015). The initial focus of this type of research was finding the logical implication relations between sentences.

More recently, specialized entailment-like resources and models have been applied to fact verification (Thorne et al., 2018b) with applications to science, education and journalism. This trend has exposed the limited transfer between logical entailment and general factual change detection (Thorne et al., 2018a) as well as the need for interpretable models for this task (Kumar and Talukdar, 2020).

With ~~16~~ 17 NBA Championships, the LA Lakers along with ~~place the second behind~~ the Boston Celtics have won the most in NBA history.

Q: How many NBA championships have the LA Lakers won?
A: ~~16~~ 17

Q: Which team has won the most NBA championships?
A: ~~Boston Celtics~~ LA Lakers along with Boston Celtics

Figure 1: DiffQG consists of paired Wikipedia passages that correspond to factual edits. The goal is to generate a discriminating question given an answer span such that the question is answerable by one of the passages but not the other or yields different answers.

Wikipedia revisions across time provide a large scale and highly available source of sentence pairs, leading to new resources such as WikiAtomicEdits (Faruqui et al., 2018) and VitaminC (Schuster et al., 2021). However, prior work is limited to minimal changes that concern only a single factual addition or change. We introduce DiffQG, a manually annotated dataset spanning changes over multiple years. DiffQG consists of paired passages with complex factual changes including multiple additions and deletions within the same example. Additionally, it provides a way to interpret the prediction in the form of a discriminative question-answer pair that identifies the change.

Question-answer pairs provide a semi-structured summary of a change: more flexible than knowledge graph triples and more useful than free-form text. For instance, question-answer pairs can represent different types of updates: a new prime minister may update an answer, while a new type of

---

[*] Equal Contribution.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3088–3101
May 2-6, 2023

minister would add an entirely new question.

Question generation (QG) is a new NLP task that consists of generating a question that a provided document answers. There are various successful applications of this approach, including augmenting datasets to train question answering systems (Duan et al., 2017; Lewis et al., 2021), capturing implicit information written about text (Pyatkin et al., 2021), and building soft knowledge bases (Chen et al., 2022). Previous work in QG treated the underlying passages as static (Lewis et al., 2021), while real life documents are constantly updated (Dhingra et al., 2022). As the source corpus is updated, new question-answer pairs must be added and existing ones must be updated.

DIFFQG thus addresses two challenges simultaneously: providing an interpretable summarization of factual changes and updating soft knowledge bases consisting of question answer pairs. We hope that this dataset can also help evaluate the quality of QG models in producing natural, semantically correct, unambiguous, and information-seeking questions. The dataset and code for our experiments will be open sourced.[1]

Our contributions are the following:

(a) We introduce DIFFQG, an expert-annotated *evaluation* dataset that consists of questions that summarize the difference between two passages. To the best of our knowledge, no prior dataset exists that covers such long and complicated edits.

(b) We propose a set of metrics that can be used to measure improvements in question generation or factual change detection.

(c) We evaluate a comprehensive set of baselines that surface the shortcomings of current systems.

2 DIFFQG Task

The goal of DIFFQG is to capture how two similar passages differ from each other using question-answer pairs. In particular, given a base passage x_b and a target passage x_t, where x_t and x_b are different versions of the same article, we aim to generate discriminating questions Q_t. For each $q_t \in Q_t$, the information to deduce the corresponding answer span $a_t \in A_t$ must be missing in x_b. To limit the scope of possible questions, each answer span $a_t \in A_t$ must be a substring of x_t. While a_t could also be a substring of x_b, x_b must be missing the required information to deduce a_t is the correct answer. Alternatively, there could be a corresponding answer span a_b, which is the answer resulting from answering q_t with x_b. Note that we consider paraphases of a_t, such as lexicalizing numbers and using alternate entity names, as equivalent answers.

This discriminating question has certain additional requirements: it should be seeking factual information and stand-alone (Choi et al., 2021) (i.e., interpretable when presented by itself without the passage). It is possible that no such discriminating question can be written. The annotators only mark that there is no factual change when they are fairly confident that there is no new information about the answer span in the target passage.

Consider the following example:

- x_b = John Doe won two gold medals at the Olympics in 2012.
- x_t = John Doe won a gold medal at the Olympics in 2012.

Annotators are informed that the goal of the process is to collect *disambiguated* and *information-seeking* queries that can be answered with one passage but not with the other. By *disambiguated* queries, we mean queries that refer to roughly a single answer without any context. For instance, “Who won two gold medals in the 2012 Olympics?” could refer to several different people, and questions of the form “How many medals did he win in the 2012 Olympics?” are not answerable at all without the presence of the John Doe passage.

Information-seeking queries are ones where the questioner would not need to know the answer in advance for the question to make sense. This is related to the original goals of Natural Questions (Kwiatkowski et al., 2019) and corresponds to the *Cranfield*-style questions described by Rodriguez and Boyd-Graber (2021). As an example, “What did Al Capone’s mother do for a living?” seems like an information-seeking query. On the other hand, “Which Italian-American gangster’s mother was a seamstress?” does not: why would the questioner assume that such a person even exists unless they already knew the answer? We describe the annotation process to acquire such discriminating question set in the next section.

3 Data Collection

Collecting such discriminating questions is a nontrivial process. Thus, we introduce a staged annotation process with expert annotators (the authors

---

[1] `https://github.com/google-research/language/tree/master/language/diffqg`

of this paper) and use a question generation model to aid annotation. We describe our process below (visualized in Figure 2).

3.1 Input Passage Pair Selection

First, we extract the Wikipedia pages for entities from the Natural Questions (NQ) training set (Kwiatkowski et al., 2019). In particular, we find the pages for Wikipedia snapshots between the years 2008 and 2020. After sampling a base document, we find the version of that document one year later and use this as the target document. Using the two documents as a corpus, we compute cosine similarity between the TF-IDF vectors over each sentence pair and pick the pair with the highest similarity. Sentence pairs with similarity either greater than 0.8 or less than 0.25 are discarded. In order to retain meaningful changes, we ensure at least one noun or number is edited and up-sample instances where either a named entity or at least five tokens have been edited.

This process thus focuses on edits accumulated over a year and consists of changes ranging from five to twenty tokens, making these semantically richer and more widely applicable than existing factual change detection datasets.

3.2 Seed QA Pair Generation

Each target passage has a very large number of possible answer spans; for convenience, we restrict them to only noun phrases identified using the Berkeley Neural Parser (Kitaev and Klein, 2018). To increase annotation speed, each example starts with a *seed question* that is generated by a question generation model from the target passage and answer span. In particular, we use a T5-XXL model (Raffel et al., 2020) that has been finetuned on the SQuAD dataset (Rajpurkar et al., 2016).

3.3 Annotation Process

DiffQG annotation was done in three phases by six expert volunteers. First, annotators are given the paired passages described above along with the answer span and seed question, which corresponds to one *example candidate*. Then, they label each example candidate with one of the five options:

Accept The seed question follows all requirements for discriminating questions as is.

Context The seed question asks about the appropriate topic but is not answerable outside of the context of the passage. For instance, questions like "What did he win?" or "Where were the Olympics held?" both lack context in order to answer the question successfully.

Edit The example candidate answer has a discriminating question, but the question is different than the seed question. Sometimes, this is because the seed question does not capture the new information contained in the passage; other times, the seed question is simply nonsense.

Reject This example candidate has no valid discriminating question. In other words, these are negative examples. Sometimes, the target passage contains no new information at all; however, it may contain new information about other answer spans but not the one in the example candidate. In our previous John Doe example, there is no new information about "the Olympics", except indirectly.

Skip It is unclear if there is a valid discriminating question for this example candidate. This could be due to awkward or cumbersome answer spans: for instance "two gold medals at the Olympics in 2012." Alternatively, it could seem unclear if there is new information about an answer span due to its indirect relationships with other entities. Finally, it could be difficult to write an information-seeking question even though there is obviously new information: for instance, writing a question with the answer span "John Doe" in the previous example.

Each example candidate is considered by two annotators. Unless both annotators agree to Add, Reject, or Skip, a third annotator decides. In examples where one annotator chose Context or Edit, the third annotator is responsible for writing the correct question according to the guidelines. If one annotator chose Add or Reject and the other skipped, the third annotator can confirm the Add or Reject or also skip if they cannot decide. See Appendix A.2 for the annotation interface.

3.4 Question Writing Guidelines

Note that writing a single, context-free, and information-seeking question that summarizes the difference between the two passages can be challenging. In cases where it seemed impossible, annotators are encouraged to skip the example. For cases where additional Context was needed, annotators are encouraged to add as much context without sacrificing fluency, so that the question can be answered without awareness of the source passage. When an annotator writes a question from scratch

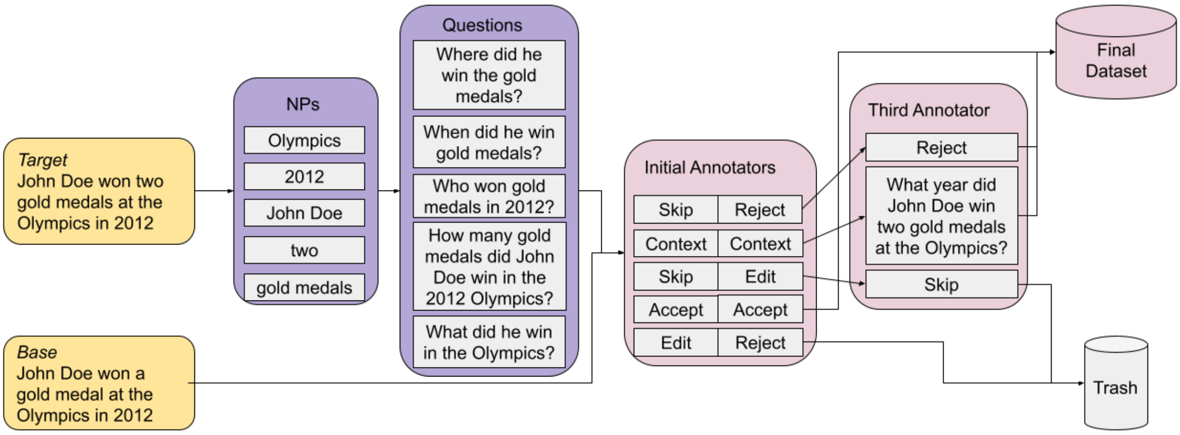

Figure 2: DiffQG annotation process. Noun phrases are extracted from the target passage and a question generation model seeds initial questions. Annotators decide if the generated questions serve as satisfactory discriminating questions (Accept), must be edited (Context, Edit), or contain no new factual information (Reject). After the first phase, a third annotator resolves indecision (Skip), leaving us with a set of questions and negative examples. If the original two annotators disagree or the third annotator cannot resolve indecision, the example is discarded.

in the Edit case, they are encouraged to think of a question that either would have a different answer, be unanswerable, or have a false precondition if posed against the base passage. While conditioning on a single answer span reduces ambiguity, the task is still ambiguous, which is unavoidable when handling large and complex edits.

	Passages	Answers	Avg. Edited tokens
w/ change	391	759	12.9
w/o change	478	1153	14.1
Total	672	1912	13.7

Table 1: Dataset statistics for DiffQG. Edited tokens represents the average tokens added or removed in a given passage pair.

3.5 Data Statistics

Our initial annotation process starts with $8,530$ example candidates drawn from 999 passage pairs. Annotators skipped nearly 75% of the example candidates, leaving $1,912$ examples. Of those, roughly 40%, or 759, had a factual change and thus a discriminating question written about them, leaving 1153 negative examples. Of the spans where a factual change was detected, annotators modified the question in 65%, or 494, of the examples: 45% are labeled as Context and 20% as Edit. Detailed dataset statistics can be found in Table 1.

Note that on all cases where a question was accepted as is or considered a negative example, at least two annotators agreed on that rating. However, human written questions are not verified; both annotators agree that there exists a discriminating question but not necessarily what it is. To address this, we evaluate a small set of fifty questions and found that a second annotator would write an equivalent question around 85% of the time.

4 Motivation

In the previous section, we described DiffQG and its annotation procedure. As mentioned, the purpose of DiffQG is to detect and describe factual changes. In particular, DiffQG is a rough measurement of a model's ability to automatically construct a database of question-answer pairs that encapsulate the changes. There are many possible formats that could be used as an alternative to summarize factual changes, such as paragraphs, knowledge base triples, or individual claims.

While paragraphs can contain nuance, they lack atomicity. It is thus difficult to tell what exactly changed or otherwise compare two changes to each other. This makes them less useful as a database.

On the other hand, knowledge base triples are limiting in the types of factual changes that can be described: regardless of the exact setup, the nodes and relations come from some form of fixed vocabulary that may require discarding interesting changes. For instance, changes related to a set of entities, date ranges, various numbers, or abstract information may all be challenging.

Another alternative method would be a list of claims, similar to Vitamin-C (Schuster et al., 2021). This method is also atomic and more flexible than knowledge base triples. However, question-answer pairs have a few advantages. First, question-answer pairs are semi-structured information, forming a loose key-value pair. Factual edits may change the answer to an existing question or add information corresponding to an entirely new information, requiring a new question. Conversely, claims are more difficult to relate to each other.

Finally, question-answer pairs are interesting because question answering is interesting. Previous work has seen the use of a database of question-answer pairs as a method to improve question answering performance (Lewis et al., 2021). A good method for automatically creating and updating such a database thus seems quite useful. As factual corpora change over time, we envision constructing such a database to require iterative updates.

5 Metrics

DIFFQG can be used to measure performance on three related tasks.

Factual Change Detection Given an example consisting of a base passage, target passage, and answer span, the goal is to determine whether there exists a valid differentiating question. In other words, whether there is new information about this answer span that is present in the target passage when compared to the base passage. To measure this, we report accuracy, precision, recall and F1 score over the existence of a differentiating question in our annotations. Note that always predicting no change achieves 60.3% accuracy but 0% F1, but random guessing corresponds to 44.1% F1.

Discriminating Question Generation Given a target passage and answer span, write a specific, unambiguous and information-seeking query that can be answered with the target passage. To measure this, we compare machine generated questions to those that humans verified, edited, or hand wrote. We use two model-free metrics Rouge-1 and Rouge-L (Lin, 2004) which measure the token-level overlap and longest subsequence overlap of the questions, respectively. We also consider two model-based metrics, BLEURT (Sellam et al., 2020), which is a learned evaluation for text similarity based on BERT (Devlin et al., 2019), and a query similarity model (Reimers and Gurevych, 2019) trained on Quora Question Pairs [2].

Note that we evaluate discriminating question generation despite using a question generation model in our annotation procedure. Note that all of these questions are reviewed by humans and only the very fluent ones are kept. As question generation models vary in which of their productions are very fluent, this set is less trivial than it would initially appear. Nonetheless, we also separate human-written or edited questions and evaluate that set independently.

Full System This is the overall measure of performance on DIFFQG. We reuse the metrics from discriminating question generation, using 0.0 for BLEURT, ROUGE-1, ROUGE-L, and Query Similarity if the factual change detection is incorrect.

6 Methods

As mentioned, DIFFQG can be thought of as a composition of two tasks: factual change detection and discriminating question generation. Our simple baseline systems thus treat this as a pipeline, first predicting whether or not there is a factual change and then generating a discriminating question if there is. We also present baseline models that solve both tasks jointly with a single prediction. Our methods are illustrated in Figure 3.

Note that none of our methods use any part of DIFFQG as training data, as the dataset is only intended to be used for evaluation. Models are instead trained on larger existing datasets for question generation and factual change detection.

6.1 Factual Change Detection

We propose five baselines based on answer equivalence or both question and answer equivalence.

Answer Equivalence Baselines

Our trivial baseline (*Overlapping Answer*) classifies an example as having a factual change if and only if the answer span is not present in the base passage. The span is normalized before looking for token overlap with the passage.

Our simple model-based baseline is similar but uses an Answer Equivalence model (Bulian et al., 2022). It compares the target answer span against all valid base answer spans, finding a factual change if it does not match any of them. The Answer Equivalence model additionally takes as input a candidate question for each answer span.

---

[2] huggingface.co/cross-encoder/quora-roberta-large

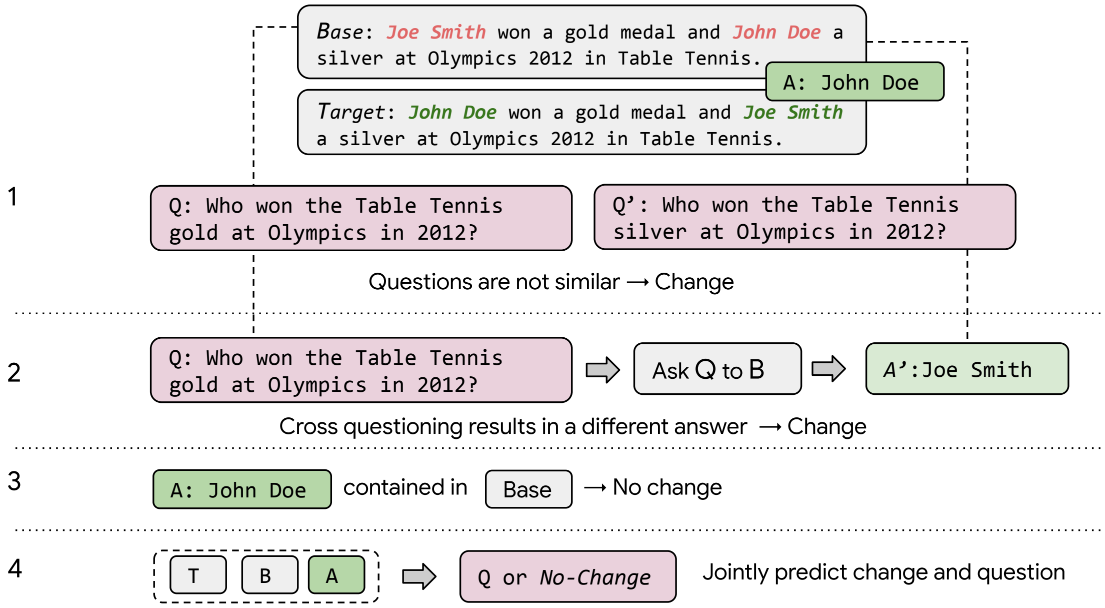

Figure 3: Methods for factual change detection on DiffQG: (1) Question similarity (2) Cross-Questioning. The QA-equivalence method combines (1) and (2), deciding it is a Change only when both the systems find a Change. (3) Overlapping Answers (4) Language model that jointly learns the task of factual change detection and discriminating question generation, decoding the discriminating question or a special token indicating no change.

Question-Answer Equivalence Baselines

The previous methods only consider the answer span, ignoring the context. Here, we consider methods that also use a question generation model on the passages and answer span to determine if there is new information.

For the first method, we find base answer spans equivalent to the target answer span using the *Overlapping Answer* method. Then, we want to see if the questions generated from those answers would also be equivalent in both passages. To do so, we use a T5-XXL (Raffel et al., 2020) model trained on Quora Question Pairs [3] to predict whether the pair of questions is "duplicate" or "not duplicate" . If the question is not a duplicate, then we consider this example to have a factual change. Thus, answer spans present in both passages but with different contexts could now be identified as having a factual change. This will increase the recall of the *Overlapping Answer* method.

The second approach adds a cross questioning filter (*Cross-Q*). Given a candidate question generated from target passage, we attempt to answer the question with the base passage using a reading comprehension model. We train a T5-XXL model on SQuaD v2 (Rajpurkar et al., 2018) question-answering dataset to take the passage and question as input and output the answer. If the model predicts no answer or a different answer from the target span, we classify the example as having a factual change. Finally, the *QA-equivalence* method combines both the query similarity model and cross question model to boost precision. In this case, we consider an example to have a factual change only when both methods determine a factual change.

6.2 Question Generation

Each of our factual change detection baselines is then combined with a question generation model. We use a similar T5-XXL model finetuned on SQuAD as described in Section 3.2. Unsurprisingly, the model we use to seed the questions can do well on the questions that it wrote originally; however, this is an unfair baseline. Thus, we additionally test a version of the model that is sampled and also a retrained version using a different seed. We also test training a similar model trained on Natural Questions (Kwiatkowski et al., 2019).

6.3 Joint systems

Many of the techniques described Section 6.1 are inefficient, requiring multiple runs of various models. For instance, the Query Similarity method requires one model run for each answer span in the base passage per example, which corresponds to quadratic runs for each pair of passages. We

---

[3] https://www.kaggle.com/c/quora-question-pairs

also explore methods that can directly compare the base and target passage without the need for any intermediate steps. These methods instead jointly detect if there is a factual change and generate a discriminating question.

Finetuning on Silver Data

We mine additional pairs of Wikipedia passages using the same process as in Section 3.1. We then identify every possible answer span from the target passage. We create silver training examples for the factual change detection component of the task by labeling each target answer span using our best heuristic method, *QA-equivalence*.

We then convert these labels into a text-to-text task. For each example with a factual change, we use the question generated by the SQuAD model (Section 6.2) as the target. For questions without a factual change, we use "None" as the target. The input to the model is the concatenation of the base and target passages with the target answer span marked by a special token.

The model is a T5-XXL initialized from the same question generation model as the model that produced the original questions.

Finetuning on VITAMINC

The VITAMINC task (Schuster et al., 2021) also has a factual change detection component. We sample negatives from the VITAMINC Revision Flagging dataset, using negative examples with a random noun phrase chosen as the answer span.

For positive examples, we need to identify a specific answer span that contains a factual change as well as the corresponding discriminating question. While there is no direct counterpart of this task in VITAMINC, the Fact Verification task is somewhat similar. The dataset consists of an evidence *e*, a simplified claim *c* supporting *e*, a companion edited sentence *e'* and an edited-claim *c'* refuting *e* and supporting *e'*. An answer span *a* is identified based on the token-level diff between *(c, c')* and a question generated from *c* conditioned on *a* using the question generation model in Section 6.2. Because *c* is a simple sentence, we anecdotally find the generated questions to be of high quality.

The dataset (*e*, *e'*, *a*) is converted to a text-to-text task and used to finetune a T5-XXL model following the same steps as above. Note that a model trained on an equal amount of positives and negatives yielded poor performance on DIFFQG. In our final VITAMINC silver dataset, we used only 10% negatives to achieve a reasonable performance.

Model	Acc	P	R	F1
Random	50.0	39.5	50.0	44.1
Overlapping Ans	82.1	79.1	74.6	76.7
Answer Equivalence	81.1	84.6	64.2	73.0
Query Similarity	77.7	65.4	93.3	76.9
Cross-Q	76.9	65.9	86.8	74.9
QA-equivalence	**83.9**	76.7	85.5	**80.9**
FT on QA-equivalence	<u>82.5</u>	78.4	77.1	<u>77.7</u>
FT on VITAMINC	81.5	79.9	71.4	75.4

Table 2: Metrics for factual change detection. Note that none of these models have change detection training data and are instead verifying with other tasks or heuristics. The random baseline assumes guessing change or No change with equal probability. Acc=Accuracy,P=Precision,R=Recall,F1=F1 Score. **Bold** indicates the best model, second best model is <u>underlined</u>.

7 Results and Discussion

We present results separately for factual change detection, question generation and the full system. We also report results separately for the overall performance and the performance on only the subset of questions that are human written; those sentences labeled as Edit or Context in the annotation phase. Selected examples with model outputs are provided in Appendix A.1 to illustrate the capabilities and typical errors baseline.

7.1 Factual Change Detection

Table 2 compares the performance of various systems on the factual change detection task. We find that QA-equivalence performs better than heuristic baseline methods. In particular, it better handles cases where the answer span text is unchanged, but the surrounding context has changed. For example, in the passage *"On the New Hampshire Executive Council, Laconia is in the 1st District, represented by <ADD: Republican Joe Kenney> <DEL: Democrat Michael J. Cryans>."*, QA-equivalence correctly captures the new information associated with the answer span *"New Hampshire Executive Council"* in the form of the question *"What state council does Joe Kenney represent Laconia in?"* However, the method is prone to detecting spurious changes even when the passages have no semantic edit as illustrated in Appendix A.1.

The joint system finetuned on silver data from QA-equivalence does not seem to improve upon

QA-equivalence. While it seemingly benefits from the additional context, it still struggles with long and complex edits. However, this model only requires a single inference to do both tasks.

The VITAMINC trained model, despite having access to additional data, was also unable to improve on our baseline. VITAMINC style edits are substantially different than DIFFQG edits, generally only consisting of small changes. Thus, the model finetuned on VITAMINC performs poorly on large phrase changes or sentence refactors.

7.2 Question Generation

Model	R-1	R-L	QSim	BLRT
SQuAD-seed	71.7	74.9	66.3	74.1
SQuAD-sampled	59.6	63.2	57.8	65.6
SQuAD-retrained	58.0	61.7	58.9	65.6
NQ	20.4	39.6	22.9	41.5

Table 3: Variation in performance of question generation models on the positive subset of DIFFQG. We report three different versions of the SQuAD model, where the first model is the same as we used to seed the annotations. R-1=ROUGE-1, R-L=ROUGE-L, QSim=Query Similarity model-based accuracy, BLRT=BLEURT.

In Table 3, we compare our question generation baseline models on the subset of the positive examples. In Table 4, we examine the same models on the subset of those that are human written: examples with a change from Table 1.

Model	R-1	R-L	QSim	BLRT
SQuAD-seed	56.5	61.4	48.2	61.3
SQuAD-sampled	50.9	55.2	47.0	58.3
SQuAD-retrained	50.3	54.5	50.4	59.4
NQ	20.4	39.1	20.0	40.2

Table 4: Variation in performance of question generation models on human written questions of DIFFQG. The first model is the same as what we used to seed the questions. R-1=ROUGE-1, R-L=ROUGE-L, QSim=Query Similarity model-based accuracy, BLRT=BLEURT.

The primary goal of this evaluation is to test whether the questions directly produced by the seed model described in Section 3.2 are still useful for evaluating systems on DIFFQG. We find from sampling from that same model and from retraining with the same process (as described in Section 6.2) that performance on the overall set degrades considerably. This suggests that unless someone had access to the same model, these questions that are human-verified but not human written can still be useful for evaluation. Nevertheless, the seed model can be thought of as a rough ceiling on current question generation performance on DIFFQG.

The human written questions (see Table 4) seem to be much more challenging for the question generation models to replicate. Performance degrades substantially: naturally it degrades the most for the seed model that wrote some of the questions in the overall dataset, which it should exactly match.

We note also that a question generation model finetuned on Natural Questions (Kwiatkowski et al., 2019) yields a significantly different question style than SQuaD. This is likely because SQuAD questions are originally generated from passages, while Natural Questions are more free form. In addition the Natural Questions model is found to hallucinate in numerous scenarios. This reflects on the poor performance of the Natural Questions-trained question generation model on DIFFQG.

As a caveat, the possible universe of questions written to summarize a factual change can be very large. While restricting to a single answer span reduces this space, we still find scenarios with multiple valid questions. Thus, there may be some disagreements where the model generates a completely valid question that is simply not the most pertinent one according to our annotators.

7.3 Full System

Full DIFFQG metrics are presented in Table 5 and include the two finetuned systems that are trained on VITAMINC and QA-equivalence, respectively, as well as two pipelined systems with factual change detection models attached to a question generation model. For the pipelined experiments, we use the retrained SQuaD model described in Section 6.2. We evaluate these models on the full DIFFQG as well as human written subset.

Overall, all of the systems are relatively close in performance. QA-equivalence works the best, with the finetuned version and simple heuristic model close behind, indicating substantial room for future innovation. On the human written subset, the performance drops significantly further highlighting the challenge of the human written questions.

Models		Factual Change Detection			Full System					
					All			Human written		
Change	QG	P	R	F1	R-L	Qsim	BLRT	R-L	Qsim	BLRT
Pipelined systems										
Overlapping Answer	SQuAD	79.1	74.6	76.7	71.3	70.8	72.3	40.6	38.1	43.6
QA-equivalence	SQuAD	76.7	85.5	**80.9**	71.4	70.6	**72.7**	46.8	43.7	**50.8**
Joint systems										
FT on QA-equivalence		78.4	77.1	77.7	71.2	70.0	72.3	42.7	36.6	45.9
FT on VitaminC		79.9	71.4	75.4	69.9	68.1	71.1	36.3	32.2	39.9

Table 5: Full system performance of the pipelined and joint systems on DiffQG. Note that the "All" component of the full system metric includes all of DiffQG while the "Human written" portion includes only questions edited by the annotators. The pipelined systems use the retrained SQuaD model for their question generation component. **Bold** represents the best system, second best is underlined. R-L=Rouge-L, Qsim=Query similarity model based accuracy, BLRT=Bleurt, FT=finetuned

8 Related Work

Factual Edits Factual change detection has been of recent interest to the community. For instance, WikiAtomicEdits (Faruqui et al., 2018) rely on Wikipedia revisions to learn to discriminate factual edits. Closest to our work is VitaminC (Schuster et al., 2021) which aims to generate a discriminating claim given a pair of edited sentences. However, both of these datasets primarily rely on smaller edits, frequently consisting of a single entity or number substitution. For instance, VitaminC examples have a median of four token changes and WikiAtomicEdits examples have a median of two token changes. Moreover, these edits are easier to detect using heuristics such as noun or entity overlap. On the other hand, DiffQG examples have a median of thirteen token changes that can involve multiple entity updates. Further, the surrounding contextual information for an entity could be updated even when the entity itself is present in both passages. This makes DiffQG edits harder to summarize and substantially different than previous work; this is also observed in Section 7.1 where using VitaminC training data to solve DiffQG yields poor performance.

Recent work such as Fruit (Iv et al., 2022) and PEER (Schick et al., 2023) also operate on more complicated edits. Fruit generates updated sentences from a base passage given the new evidence in a Wikipedia article. PEER attempts to imitate the editing process using a sequence of planning steps. However, both of these primarily focus on generating the target update, while we focus on succinctly capturing the edited information. Further, the use of question generation as a device for discrimination is novel to the best of our knowledge.

Question Generation Question generation has been successfully applied to various purposes, including augmenting question answering systems (Duan et al., 2017; Lewis et al., 2021), capturing implicit information written about text (Pyatkin et al., 2021), and building soft knowledge bases (Chen et al., 2022). In this work, we apply question generation to the task of discriminating edited sentences. As far as we are aware, there is no prior work on evaluating question generation systems.

9 Conclusion

In this work, we introduce the DiffQG task and dataset to evaluate the ability of NLP systems to summarize changes between two related passages via question generation. We present several heuristic and model baselines as well as a set of metrics to measure performance on the dataset. The DiffQG task requires models to identify changes in factual relationships and ignore other stylistic edits. We find that existing approaches struggle under these conditions. Models trained to perform factual change detection and question generation jointly sometimes fail to understand even simple edits. We hope this work finds value in future research on this important problem.

Limitations

DiffQG is relatively small, consisting of less than a thousand questions and less than two thousand total examples. This makes us unable to provide a training set, limiting claims we can make about the difficulty of the task. Moreover, summarizing complex edits can have a large space of valid solutions. While using questions conditioned on an answer reduces this space, there's still room for ambiguity.

To make annotation easier, we use a question generation model; however, our goal is also to evaluate question generation models, complicating our story. Finally, most of the baselines we evaluate are some form of T5 (Raffel et al., 2020) model. It is possible that other model architectures could have solved this task more effectively.

Abstract

Response generation is one of the critical components in task-oriented dialog systems. Existing studies have shown that large pre-trained language models can be adapted to this task. The typical paradigm of adapting such extremely large language models would be by fine-tuning on the downstream tasks which is not only time-consuming but also involves significant resources and access to fine-tuning data. Prompting (Schick and Schütze, 2020) has been an alternative to fine-tuning in many NLP tasks. In our work, we explore the idea of using prompting for response generation in task-oriented dialog systems. Specifically, we propose an approach that performs *contextual dynamic prompting* where the prompts are learnt from dialog contexts. We aim to distill useful prompting signals from the dialog context. On experiments with MultiWOZ 2.2 dataset (Zang et al., 2020), we show that contextual dynamic prompts improve response generation in terms of *combined score* (Mehri et al., 2019a) by 3 absolute points, and a massive 20 points when dialog states are incorporated. Furthermore, human annotation on these conversations found that agents which incorporate context were preferred over agents with vanilla prefix-tuning.

1 Introduction

With the advent of large language models (LLMs), a vast majority of NLP tasks, including dialog systems, further fine-tune these LMs for their downstream tasks. Although these approaches provide substantial improvements over traditional task-specific models (Ham et al., 2020; Hosseini-Asl et al., 2020; He et al., 2022), it is a time consuming process that also involves significant use of energy/resources in the form of compute. These approaches also require tuning and storing parameters for each downstream task.

A more recent line of work, explores "prompting" LLMs to elicit the necessary knowledge required for the downstream tasks (Shin et al., 2020; Gao et al., 2020; Schick and Schütze, 2020; Petroni et al., 2019; Lee et al., 2021; Zhu et al., 2022). Prompts composed of tokens or short pieces of text (*discrete* prompts) inserted at the end of the input examples. These prompts are typically manually defined based on the specific downstream task. The main motivation behind these approaches stems from the idea that the large corpora that these language models are trained on contain relevant information which is pertinent to the task on hand.

Adapter-tuning was proposed as an alternate approach to fine-tuning. These methods only train task-specific layers that are inserted within pre-trained LMs. Such a lightweight approach that add about 4% task-specific parameters has shown to obtain comparable performances to their fine-tuning counterparts (Rebuffi et al., 2017; Houlsby et al., 2019; Lin et al., 2020a).

Drawing inspiration from prompting, *prefix-tuning* approaches (Li and Liang, 2021) were proposed as another alternative to fine-tuning. These approaches pre-pend a sequence of task-specific *continuous* vectors (aka prefix-) to the input. In contrast to prompting, the prefix consists of free parameters that do not correspond to actual real tokens. Such an approach is more prevalent since it only optimizes the prefix and does not tune parameters of the entire LM.

Most of the existing approaches use static prompts, i.e., the same set of tokens are used as "prompt tokens" regardless of input. However, we believe that taking context into consideration is critical especially in response generation since the current response has to fit not only the domain but also the information being requested in previous turns. For example: In the MultiWOZ dataset, if a customer asks about train bookings, the agent response has to restrict itself to that particular do-

main. To address this problem, we explore the idea of generating input-dependent or *contextual* prompts. We want the prompts to capture and encode different signals for different turns of dialogs depending on the context, hence, we call our approach *dynamic context prompting*. This way, we hope to distill useful signals into the prompts and provide the model with adequate signals to generate a desired system response. In this work, we explore the potential of using dialog context within a prefix tuning approach for the task of response generation in task-oriented dialog systems (TOD). The contributions of this paper are summarized as:

- we propose a context-dependent prefix-tuning method for dialog response generation in TOD systems.
- to illustrate the benefits of such an approach, we conduct experiments on the MultiWOZ dataset. We show that our model significantly outperforms the original task-dependent design of the prefix-tuning method.

2 Related Work

2.1 Dialog Generation

With the prevalence of LLMs, the quest for an answer to "how do we effectively adapt such models for dialog generation?" has been on the forefront of researchers' minds in the dialog community. For task-oriented dialogs, fine-tuning large pre-trained models such as GPT-2 or T5 has made great progress on benchmarks recently (Ham et al., 2020; Hosseini-Asl et al., 2020). Built upon these advances, more recent line of work investigates the effectiveness of using multi-task learning (Su et al., 2021; Lin et al., 2020b; Yang et al., 2021), or pre-training the model on external dialog corpora (Peng et al., 2021; Liu et al., 2021). More recently, prompting has been used to address the sub-task of dialog state tracking (Lee et al., 2021; Zhu et al., 2022). Different from those works, we focus on the task of dialog response generation.

2.2 Prompt-based Learning

As an alternative to the fine-tuning paradigm, prompting involves a sequence of tokens appended to the input text, which can then induce the model to engage in a certain behavior suited to the task. Since the release of GPT-2 (Radford et al., 2018, 2019; Brown et al., 2020), many prompt-related papers have emerged. Most of the leading approaches in prompting use **task-specific prompts**, ranging from discrete prompts (Shin et al., 2020; Gao et al., 2020; Schick and Schütze, 2020; Petroni et al., 2019) to continuous "soft prompts" (Li and Liang, 2021; Lester et al., 2021). These methods have a fixed prompt for each task. However, in dialog systems specifically, the context varies for every turn. In our work, we aim to design prompts which are **context-dependent**.

3 Problem Statement

Response generation is one of the tasks carried out in dialog systems usually in addition to dialog state tracking (DST). Given a dialog context (previous turns between the system and the user) $C = [u_1, s_1, ..., u_{n-1}, s_{n-1}]$ and the current user utterance u_n, the goal of response generation is to generate system response s_n. Note that in the actual task, we generate *delexicalized* system responses, given all the groundtruth previous turns as input, following previous works (Hosseini-Asl et al., 2020; Wen et al., 2015).

Techniques mentioned in (Ham et al., 2020; Hosseini-Asl et al., 2020) rely on fully fine-tuning LLMs to carry out this task. In contrast, our approach builds on the prefix-tuning framework, but incorporates dialog context, C, as an additional signal for the prefix tokens. As a supplement to context C, we added dialog state information D (up to the current turn) to further help response generation.

4 Contextual Dynamic Prompting Framework

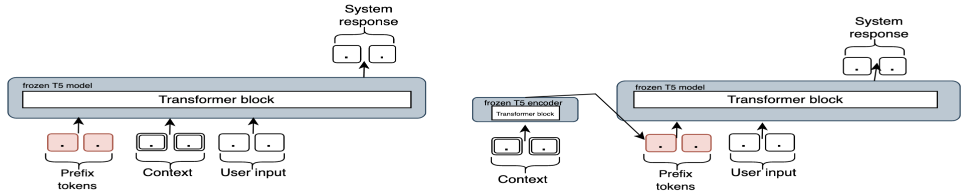
4.1 Prefix-tuning for Response Generation

Our work is built on top of prefix tuning for generation tasks (Li and Liang, 2021), which adds a fixed set of tunable prefix tokens/prompts to the original input x to obtain a new input, [PREFIX; x]. Following the denotation in (Li and Liang, 2021), we use $P_\theta[i,:]$ to denote the i_{th} prefix. $P_\theta[i,:]$ is generated by:

$$P_\theta[:,:] = MLP_\theta(P'), \tag{1}$$

where P' is a fixed smaller matrix as input to a feedforward neural network (MLP_θ). The training objective of prefix-tuning is same as fine-tuning, i.e., the following log-likelihood objective:

$$\max_\theta \log p_\phi(y|x),$$



(a) The original prefix-tuning framework where a set of prefix tokens are added to the input which also consists of dialog context *C* in addition to the current user input u_n

(b) Our changes which now incorporate the dialog context *C* into the prefix by obtaining a representation by passing through a frozen T5 encoder.

Figure 1: The figures above indicate the differences between the vanilla prefix-tuning approach compared to our approach. In both these variants, only the prefix tokens are tuned.

where y is the decoder output and x is the input. θ represents the trainable parameters in the prefix tuning feedforward neural network and ϕ denotes all other parameters that include the frozen parameters of the large language model.

For our task of response generation, we concatenate the prefix with the dialog context and the current user utterance as input [PREFIX; $u_1, s_1, ..., u_{n-1}, s_{n-1}, u_n$]. The target output is the system response s_n as seen in Figure 1 (a).

We adopt T5 (Raffel et al., 2020) as the pre-trained language model. T5 employs an encoder-decoder framework which is prevalent in seq2seq tasks (Sutskever et al., 2014; Cho et al., 2014).

4.2 Contextual Prefix-tuning

In vanilla prefix-tuning, the parameters of the prefix are fixed after training for any particular task to be reused. However, a dialog system involves having multiple turns of conversation between a system and the user. It is imperative in such systems to dynamically incorporate contextual information to carry out a meaningful conversation with the user. We explore how we can distill the dialog context information into the prefix with a prompt encoder.

Different from the original design, we want to encode additional signals into the prefix that differs for each input instances. In other words, we want to generate **contextual prefix** or **contextual dynamic prompts**.

Formally, we modify the equation (1) as follows:

$$P_\theta[:,:] = MLP_\theta(encoder(C)), \qquad (2)$$

where $C = [u_1, s_1, ..., u_{n-1}, s_{n-1}]$ represents the dialog context. We first obtain the representation of the dialog context by feeding C into a T5 encoder which is kept frozen as shown in Figure 1 (b). Subsequently, we use the prompt encoder, i.e., the feedforward neural network, to get the prefix. The generated prefix P_θ is then concatenated with only the current user utterance. Instead of concatenating the whole context as the input to the T5 decoder, we first distill the signal into the prefix tokens. As a consequence of freezing the T5 encoder which generates the context representation, we still have the same number of tunable parameters as the original prefix-tuning framework.

4.3 Input-dependent Prefix-tuning with Dialog State

In most task-oriented dialog systems, we also have access to the dialog state at every turn in addition to dialog context. The dialog state has information such as requested slots and filled slots at every turn. We provide the dialog state D in addition to the context C to obtain contextual dynamic prompts. As a result, we will now modify equation (2) as:

$$P_\theta[:,:] = MLP_\theta(encoder(C; D_{n-1})), \qquad (3)$$

we only provide the most recent dialog state D_{n-1} which is an amalgamation of all previous dialog states $D_{<n-1}$.

5 Experimental Settings

5.1 Dataset and Metrics

We evaluate our proposed framework and model on the MultiWOZ 2.2 dataset (Zang et al., 2020; Budzianowski et al., 2018) which is a large-scale, multi-domain, human-human task-oriented dialog dataset collected via the Wizard-of-Oz framework where one participant plays the role of the system. It consists of seven domains including hotel, restaurant, attraction, train, taxi, hospital, and police, and an additional domain general for acts such as greeting or goodbye. Due to its multi-domain setting, complex ontology, and flexible human expressions, developing dialog systems on MultiWOZ is extremely challenging. The training data contain 8437 dialogs, the dev and test set contain 1000 dialogs each.

We use four evaluation metrics: **BLEU** (Papineni et al., 2002), **Inform**, and **Success** rates, and **combined score**. *Inform* measures whether the

	MultiWOZ 2.2						
	BLEU	Inform	Success	Combined Score	Av. len.	#uniq. words	#uniq. 3-grams
Prefix-Tuning	19.19	54.7	48.0	70.54	13.83	245	1671
Prefix-Tuning (with DS)	19.36	51.8	47.0	68.76	13.08	231	1626
Contextual Dynamic Prompt	19.16	58.1	50.5	73.46	**14.16**	231	1532
Contextual Dynamic Prompt (with DS)	17.94	**77.2**	**68.8**	**90.94**	14.02	**282**	**2390**

Table 1: **Performance Comparison**. All model performance are based on features from all modalities. Contextual Dynamic Prompt (with DS) has the best performance in combined score.

system provides an appropriate entity and *Success* measures whether the system answers all the requested attributes. Specifically, the Inform rate relates to attributes that allow the user to constrain database searches, e.g., restaurant location or price range (the informational slots) and the Success rate focuses on request-able slots, that can be asked by the user, e.g., phone number. Both are calculated on the level of dialogs. The combined score is calculated following (Mehri et al., 2019b) as $BLEU + 0.5 * (Inform + Success)$. We followed a standard script [1] to report different measures.

5.2 Human Evaluation

We chose a 10% subset of the evaluation set (randomly shuffled) conversations with a total of 728 turns across them and provided annotators with the responses generated by each of the methods described in section 4. Annotators were asked to rate each agent on a turn-level and to also pick the agent which carried out the best conversation. If annotators felt more than one agent did well, they could choose multiple agents. The agent numbers, when provided to annotators, were shuffled to avoid bias. Each agent is described as:

- Agent 1: Incorporates only prefix-tuning
- Agent 2: Incorporates prefix-tuning with Dialog State
- Agent 3: Incorporates contextual dynamic prompts
- Agent 4: Incorporates contextual dynamic prompts with Dialog State

When annotating on turn level, from these 728 turns, we saw that the agents tied on 596 occasions, agent 1 had outright win on 12 occasions, agent 2 on 22, agent 3 on 33 occasions, and agent 4 on 65 occasions. This shows that our technique of using contextual dynamic prompts for generating responses is effective (Examples in Appendix B).

Additionally, on the conversation level, we noticed that across 100 conversations, 37 were tied, and agents 3 and 4 were preferred in a total of *53* conversations confirming our hypothesis that incorporating context into prompts leads to better responses. We request readers to refer to Appendix A and B for more details about the annotation task.

6 Results

As shown in Table 1, contextual dynamic prompting with dialog states obtains a combined score of *90.94*, a 20 point jump from our baseline (prefix-tuning). In addition, even though we can't explicitly explain the drop in BLEU, the massive jumps in both success and inform suggest more transparency and coherence for the responses generated by the input-dependent prefix-tuning as these metrics focus on quality of informational and request-able slots in each turn. When comparing our results with the human annotations, we also see that *Agent 4* - which uses contextual dynamic prompting - wins 38 conversations (out of 100). This is majority of wins compared to *Agent 1* winning only 3 conversations, and *Agent 2* winning 7. This further emphasized that adding contextual dynamic prompts leads to better quality of responses. We show some examples from the human annotation task where *Agent 4* was chosen as the winning agent in Tables 2 and 3 below.

7 Conclusion

In our work, we proposed an approach that performs *contextual dynamic prompting* where prompts are learnt from dialog contexts with the goal of distilling useful prompting signals. In our experiments, we showed that contextual dynamic prompts improve response generation in terms of *combined score* (Mehri et al., 2019a) by 3 points, and by 20 points when *dialog states* are incorporated compared to the baseline. Our technique does not expose the models to additional knowledge sources. Human annotation on these conversations

found that agents which incorporate context into prompts were preferred over agents with vanilla prefix-tuning.

Limitations

While our work explores a new technique of contextual dynamic prompts for response generation, we carried out our experiments on a dataset which is in the English language. A potential limitation of this work would be the transfer of our findings on an English dataset to a multi-lingual dataset or a mono-lingual dataset on a language other than English. We plan to address this in our future work and also request the help of the research community in doing so.

Acknowledgements

We would like to thank the anonymous reviewers for their feedback on this work. We also thank the AWS Console/UXP2 Science team at AWS AI Labs for discussions around this work. Lastly, we'd like to thank the human annotators for their efforts.

A Human Evaluation Task

We explored contextual dynamic prompting strategies for the response generation task using the MultiWOZ 2.2 (Budzianowski et al., 2018; Zang et al., 2020) dataset and noticed that the combined score that we obtained was significantly better than the baseline prefix-tuning method of response generation. To understand if the agents which incorporated contextual dynamic prompts did indeed provide a better conversational experience, we designed a small human evaluation task to test our hypothesis.

We picked a random subset of 10% of the conversations from the original MultiWOZ test data to perform this analysis. Once we obtained this random set, we ran our four model variants as described in Section 4 on the conversations to obtain system responses for each of them. We then presented the different agents' responses to the annotator as shown in Table 4 below. In order to avoid potential biases, we shuffled the order of the agents between our annotators i.e., Agent 1 for annotator *a* would not be Agent 1 for annotator *b*. We kept track of which agents corresponded to which of our four methods prior to distribution of data amongst the annotators.

The annotators were given instructions to read every turn of conversation and provide a number between 1 and 4 for the agent which they thought performed the best for that turn. If the annotators found that there was a tie, they could pick more than one agent as [agent_a, agent_b]. In addition to this instruction, annotators were asked to read the entire conversation and pick the agent which performed the best - once again with an option to pick multiple. Table 5 below shows an example annotation style for a single conversation spanning 6 turns. There is an annotation at every turn and a single annotation at the end of the conversation.

We tallied results and re-mapped all agents back to their methods and found that agents 3 and 4 as mentioned in Section 5.2 were preferred at the conversation level in a total of 53 of the 100 conversations while agents 1 and 2 were only preferred 10 conversations in the entire set of 100.

B Examples

In the table below, we provide another examples from the human annotation task where annotators picked agent 4 as the best performing agent for the conversation (we performed the re-mapping to fit the agent numbers in Section 5.2). Table 2 shown in the main paper indicates a scenario where Agent 4 was rightly able to ask the customer about their area of preference for dining, and also considers a booking time change from the user. Table 6 shows an example where agent 4 is able to take into consideration all the different constraints mentioned by the user in terms of slots in the response that it generates. Table 3 shows an example where the agent 4 is able to correctly respond to the user request for number of people to reserve the table for - which none of the other agents captured. All these examples showed that agent 4, which uses contextual dynamic prompts with dialog states was indeed able to provide smoother responses to the customer input compared to the other agents.

C Compute Infrastructure and Experimental settings used

All our experiments were carried out on public AWS p3 GPU instances which are backed by Tesla V100 GPU cores. All four variants of our models required 18-24 hours to reach convergence on these machines. Learning rates were varied based on performance of models on the validation split of our dataset.

Why Can't Discourse Parsing Generalize?
A Thorough Investigation of the Impact of Data Diversity

Yang Janet Liu and **Amir Zeldes**
Department of Linguistics
Georgetown University
`{yl879, amir.zeldes}@georgetown.edu`

Abstract

Recent advances in discourse parsing performance create the impression that, as in other NLP tasks, performance for high-resource languages such as English is finally becoming reliable. In this paper we demonstrate that this is not the case, and thoroughly investigate the impact of data diversity on RST parsing stability. We show that state-of-the-art architectures trained on the standard English newswire benchmark do not generalize well, even within the news domain. Using the two largest RST corpora of English with text from multiple genres, we quantify the impact of genre diversity in training data for achieving generalization to text types unseen during training. Our results show that a heterogeneous training regime is critical for stable and generalizable models, across parser architectures. We also provide error analyses of model outputs and out-of-domain performance. To our knowledge, this study is the first to fully evaluate cross-corpus RST parsing generalizability on complete trees, examine between-genre degradation within an RST corpus, and investigate the impact of genre diversity in training data composition.

1 Introduction

Discourse parsing is the task of identifying and classifying the coherence relations that hold between different parts of a text, such as recognizing that one sentence specifies the cause of events in another, or that a subordinate clause indicates the purpose of a main clause. In hierarchical frameworks, such as the Rhetorical Structure Theory (RST, Mann and Thompson 1988), parsers construct a labeled constituent tree of discourse units as shown in Figure 1. Such trees have numerous applications: retrieving specific relations (e.g. all CONCESSIONS made in any speech by some politician, e.g. unit 26-27 in Figure 1), or hierarchically finding the most central unit in an arbitrary span of text (unit 24 in Figure 1). They can also contribute to downstream tasks such as text generation (Maskharashvili et al., 2021) and summarization (e.g. Louis et al. 2010; Li et al. 2016; Xu et al. 2020; Hewett and Stede 2022) and to qualitative analysis and comparison of texts (Wan et al., 2019).[1]

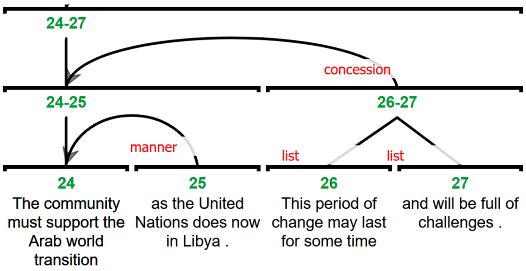

Figure 1: RST Fragment from GUM (Zeldes, 2017).

Recent advances in NLP have resulted in increasingly accurate systems for tasks such as part-of-speech tagging (Heinzerling and Strube, 2019) and dependency parsing (Mrini et al., 2020), which are now commonly applied with confidence to novel data, at least for high-resource languages such as English. At the same time, rising scores on the main standard English RST benchmark, the RST Discourse Treebank (RST-DT, Carlson et al. 2003), with data from the 1989 Wall Street Journal (WSJ), create the impression that discourse parsing too is becoming reliable, and by proxy, applicable to arbitrary text. This has resulted in use of automatic RST parsing to automatically generate large-scale datasets, such as MEGA-DT (Huber and Carenini, 2020) or AMALGUM (Gessler et al., 2020). However, there are some indications that this picture is too optimistic, with some studies revealing problems in RST-DT-based parsing once the target domain changes (Ferracane et al. 2019; Wang et al. 2019; Linscheid et al. 2021; Atwell et al. 2021, 2022; Nishida and Matsumoto 2022; Yu et al. 2022), and qualitative inspection of parser outputs casting doubt on their reliability.

---

[1] This applies to other discourse frameworks too, such as PDTB (Prasad et al., 2019) or SDRT (Asher and Lascarides, 2003), but we limit the scope of this paper to RST parsing.

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3112–3130
May 2-6, 2023 ©2023 Association for Computational Linguistics

A problem in evaluating the stability of RST parsing for English is the scarcity of out-of-domain (OOD) data, as well as potential differences between the annotation schemes of different corpora. Recently, the availability of increasing amounts of non-newswire data, as well as non-WSJ news data, in the English GUM corpus (Zeldes, 2017) has made some detailed comparisons possible, which we explore below. Beyond evaluating OOD degradation, the existence of these large datasets for English RST allows us to test different joint training strategies to increase both the accuracy and generalizability of RST parsing for English.[2]

Our main goals here are: 1) to demonstrate the generalizability limitations of English RST parsing based on RST-DT and quantify them for users; 2) to explore reasons for generalizability issues, with a focus on the genre composition of training sets, pointing the way to the kind of data that robust discourse parsing requires; and 3) to promote multi-genre benchmarks for RST parsing based on our experimental results. Overall we find that diverse training data leads to better generalization on unseen genres regardless of model architecture.

2 Related Work

2.1 English RST Corpora

The RST Discourse Treebank (RST-DT, Carlson et al. 2003) is the standard English RST benchmark, with data from the WSJ section of the Penn Treebank (PTB, Marcus et al. 1993). Another human-annotated English RST corpus is the **G**eorgetown **U**niversity **M**ultilayer (GUM) corpus, which is freely available online and covers 12 written and spoken genres (Zeldes, 2017). GUM is continuously growing, with new data added in each version. For this paper, we used Version 8 of the corpus, which is described in Table 1 next to information about RST-DT (the current version of GUM, V9, was not yet available at submission time, and now contains 213 documents, 203K tokens and 26K EDUs, and the next version 10 is set to add 4 additional new genres).

	RST-DT	**GUM V8**
documents	385	193
train/dev/test	347/–[3]/38	145/24/24
tokens	203,352	180,851
EDUs	21,789	23,107
relation instances	20,163	21,903
relation labels	78 / 17 classes	32 / 15 classes
genres	1[4]	12

Table 1: Overview of the English RST Corpora.

As Table 1 shows, although GUM V8 is smaller than RST-DT in number of tokens and documents, it contains more instances of elementary discourse units (EDUs) and relations, since newswire units from RST-DT are longer on average. EDU segmentation guidelines are identical for the two corpora, and the label set is very similar, with both corpora using the SAME-UNIT pseudo-relation for discontinuous EDUs. GUM's 12 genres make it possible to conduct experiments to investigate parsing generalizability (see Table 12 in Appendix B for their exact size breakdowns). Virtually all work on RST constituent parsing uses only the collapsed coarse relation classes (i.e. 17 labels for RST-DT); we will follow this practice for the evaluation below, but will refer to some issues relating to fine-grained labels in our analysis as well. In addition, we conducted an analysis of **s**atellite-**n**uclearity patterns in the two corpora, confirming that they are quite similar: NS dominates with 77.7% in RST-DT, similar to 74.8% in GUM news; interestingly, proportions in GUM overall are somewhat lower (70.1%).

There are also other corpora annotated in RST dependencies, such as SciDTB (Yang and Li, 2018) and full RST constituent treebanks in other languages (see Zeldes et al. 2021 for an overview); since we focus on hierarchical English RST constituent parsing, we will use the corpora in Table 1 for the experiments below: they differ in content, vocabulary, domains, and more importantly, underlying communicative intents mirroring discourse relations, all of which are the backbone of our experiments to investigate English RST parsing generalizability as a function of training data.

2.2 RST Discourse Parsers

Several approaches have been proposed for RST parsing, primarily distinguished by a BOTTOM-UP vs. TOP-DOWN approach, and the algorithm used (often a neural shift-reduce architecture). Table 2 compares recent high scoring parsers on three metrics: **S**pan (whether subtrees span the right EDUs), **N**uclearity (whether edges point the right way), and **R**elation (whether labels are correct). Following

---

[2] Though we focus on English in this paper, understanding the size and nature of data needed in English will hopefully shed light on what other languages may require.

[3] There is no established dev partition for RST-DT.

[4] Previous work has identified 4 sub-genres in the WSJ data (Webber, 2009), but these are very unevenly distributed, and 29 RST-DT documents were not included in that analysis.

	S	N	R	Neural (Y/N)	Model Architectures	Additional Features / Resources	Pre-trained LM

Liu et al. (2021)$^{\spadesuit}$	**76.5**	65.2	54.2	Y	pointer-network decoder + depth-first span splitting + biaffine classifiers	–	XLM-RoBERTa-base

Table 2: Micro-averaged Parser Scores on RST-DT with Gold Segmentation. * = scores from Morey et al. (2017). $^{\diamondsuit}$ = converted Parseval scores for Yu et al. (2018)'s parser reported by Koto et al. (2021). $^{\spadesuit}$ = 5 run average Original Parseval replication of respective work. $^{\clubsuit}$ = scores from the original paper (not necessarily averaged scores).

Morey et al. (2017), we use the more stringent original Parseval procedure on binary trees.

As Table 2 shows, BOTTOM-UP and TOP-DOWN approaches are currently very close, and all state-of-the-art (SOTA) systems rely on transformer word embeddings as the primary input. To rule out an impact of parser architecture, we test both the BOTTOM-UP from Guz and Carenini (2020), using their best `SpanBERT-NoCoref` setting, and the TOP-DOWN from Liu et al. (2021) as their code is public and both have near-SOTA S and N metrics, which are more robust to differences between label inventories across corpora (relevant hyperparameters and `dev` performance are provided in Appendix C).

2.3 Cross-Genre Variation in RST

Previous work suggests RST trees vary widely across text types,[5] in relation distributions (Taboada and Lavid, 2003; Zeldes, 2018), ways they are signaled (e.g. Eggins and Martin 1997; Liu 2019; Demberg et al. 2019), and variation across languages (Cao et al. 2018; Stede and Neumann 2014; Iruskieta et al. 2013; Redeker et al. 2012; da Cunha et al. 2011; Pisarevskaya et al. 2017).

These differences suggest OOD parsing will be challenging: For example, Taboada and Lavid (2003) showed that in appointment-scheduling conversations, CONCESSION, CONDITION, CAUSE, and RESULT were disproportionately frequent due to the nature of the data, correlating with stages of a conversation (i.e. Opening, Task Performance, Closing): e.g. more RESTATEMENT, EVALUATION, and SUMMARY in the Closing stage. Similarly, Zeldes (2018) showed MOTIVATION often encodes how-to guides influencing one's willingness to act, which almost never occurs in the objective style of news. We therefore expect parsers trained on a single domain to generalize poorly to novel ones.

2.4 Generalizability in RST Parsing

Although some first studies are beginning to appear, generalizability in full RST parsing remains understudied. Three recent papers include some cross-dataset numbers, but not a systematic analysis of full RST constituent parser generalizability. Atwell et al. (2021) examined the subtask of relation classification between PDTB (Prasad et al., 2019) and RST annotated data, and included F1 scores for identifying relations in GUM V5 using the RST-DT training data for relations that appear in both datasets (however, GUM V5's EDU segmentation differed strongly from RST-DT and the parser in the paper was an older non-neural one).

Yu et al. (2022) evaluate a neural parser on RST-DT and report scores on 11/12 genres in GUM V7 (same segmentation as RST-DT, but only 25 relations and less data than V8); however because their focus is not on cross-genre generalization, they do not report micro-averaged scores on the whole GUM corpus, do not evaluate training on GUM or joint training, and do not test held-out genres within GUM. Finally, Atwell et al. (2022) used GUM V6 (with RST-DT's segmentation and 8 genres) to identify relation types between pairs of provided argument spans, similar to PDTB-style shallow discourse parsing in the CoNLL'16 shared task (Xue et al., 2016) and recent DISRPT shared task on relation classification (Zeldes et al., 2021).

This study is therefore the first to fully evaluate cross-genre RST parsing generalizability on complete trees in datasets with the same EDU segmentation. To our knowledge, no previous work has tested an OOD-trained parser on RST-DT, at-

---

[5] We use "text type", "genre", and "domain" interchangeably here to mean different kinds of data, though they are not exactly the same (e.g. see Biber 1988 and Lee 2001).

tempted joint training on both corpora, evaluated between-genre degradation within an RST corpus, or the impact of training data genre composition.

3 Experiments

In this section we conduct four experiments. First, we want to find out how compatible the two English RST corpora are, and how well they generalize to each other's domains (§3.1). Second, we want to test whether we can incorporate training data from GUM in order to exceed SOTA performance on RST-DT, with one of three approaches: joint training, model stacking, and pretraining (§3.2). Third, we would like to know whether generalizability issues are mainly due to differences between corpora (details of annotation guidelines or common practices) or the nature of the texts' genres and domains themselves (§3.3). We test this by leaving out different subsets of GUM genres from training, and quantify OOD degradation for each genre, which also informs users of SOTA parsers of what degradation they can expect on genres 'in the wild'. The final experiment (§3.4) tests whether, given a fixed training set size, having relatively many 'small' genres leads to better OOD stability than having few genres with more material each, when the target is a totally disjoint set of genres. The code, trained and finetuned models, and predicted GUM parses are available at `https://github.com/janetlauyeung/crossGENRE4RST`.

3.1 Cross-Corpus Generalization

In this section we hypothesize that, since GUM contains many genres, models trained on it will degrade less when testing on RST-DT than in the opposite scenario. This is non-trivial, since the corpora are very close in total size, and it is possible that diverse training genres with little data each will prevent effective learning for any genre. We train the two parsers identified in §2.2 from Guz and Carenini (2020) (BOTTOM-UP) and Liu et al. (2021) (TOP-DOWN) on the `train` partition of each dataset, and report scores on the `test` set (since RST-DT has no dev partition, we follow previous work in using 10% of training data stratified by the number of EDUs in each document as a dev set, which remains the same in the training).

A possible limitation of our experiment is annotation differences between the corpora, especially for their relation inventories, which are similar, but not identical. We therefore omit R scores in Tables 3 and 4, though we will return to relations in more detail below. For S and N, however, we expect differences to be small: both corpora use the same segmentation guidelines, and the same guideline of subordinating less prominent satellite units to more prominent nuclei using tests such as deletability and subjective prominence. Although EDU segmentation is not our focus, we can confirm the compatibility of segmentation guidelines by cross-testing the current SOTA EDU segmenter from Gessler et al. (2021). The results show fairly modest degradation training on RST-DT and testing on GUM, from 94.9 to 89.9, while the opposite direction shows a 92.9 to 91 drop (see Table 11 in Appendix A for full numbers). We speculate that segmentation generalizes well due to the syntactic, and hence less sparse and domain-specific nature of the task, which resembles clause boundary detection.

For cross-corpus S and N scores, both parsers show a very significant degradation when training on RST-DT to parse OOD data from GUM, as shown in Tables 3 and 4. For instance, there is a degradation of $\sim$−11 points for S and $\sim$−16 for N using the the BOTTOM-UP architecture. We were also curious whether this applies to GUM's news genre too: indeed, testing only on GUM *news* reduces degradation by about 50% using the BOTTOM-UP parser, but still shows a substantial performance hit, even if the model is trained exclusively on news (albeit from much older, WSJ news data). By contrast, the GUM-trained model actually scores better on RST-DT than on GUM, with minor improvements of +2.8 on S and +0.4 on N using the BOTTOM-UP parser. The same degradation pattern is observed in the TOP-DOWN parser performance: substantial degradation overall, and worse when training on news and testing other genres.[6]

train	test	S	N	R
RST-DT	RST-DT	76.5	65.9	54.8
	GUM	65.3 (-11.2)	49.5 (-16.4)	–
	GUM *news*	71.0 (-5.5)	57.5 (-8.4)	–
GUM	GUM	69.9	57.0	48.5
	RST-DT	72.7 (+2.8)	57.4 (+0.4)	–
	GUM *news*	71.6	58.5	49.5

Table 3: Cross-Corpus Results (5 run average) of the BOTTOM-UP Parser from Guz and Carenini (2020).

---

[6] We further analyzed left vs. right-branching trees during testing. In both corpora, NS outperformed SN: RST-DT in-domain scores are F1=82.6% vs. 73.4% for NS vs. SN; GUM V8 has 81.6% vs. 72.4%, meaning SN transitions are 'easier'.

train	test	S	N	R
RST-DT	RST-DT	76.5	65.2	54.2
	GUM	66.2 (-10.3)	50.8 (-14.4)	–
	GUM *news*	67.9 (-8.6)	55.8 (-9.4)	–
GUM	GUM	68.6	54.9	46.1
	RST-DT	71.1 (+2.5)	55.9 (+1.0)	–
	GUM *news*	73.4	63.3	57.2

Table 4: Cross-Corpus Results (5 run average) of the TOP-DOWN Parser from Liu et al. (2021).

We interpret this result to mean that unlike in EDU segmentation, where results are close in both directions, genre composition of the `train` and `test` data plays a crucial role in the generalizability of RST constituent parsing, regardless of parser architecture. Thus, we opt for the BOTTOM-UP parser for the experiments presented in the rest of the paper as it outperformed the TOP-DOWN parser on both corpora.

To be clear, the results do not suggest that training on GUM is a way of achieving top performance on RST-DT: the GUM model's scores are still almost 4 and 8 points below the RST-DT trained model for S and N. However, it seems that RST-DT news data is less surprising for the GUM model which has already seen some news, and in sum, RST-DT data appears to be a comparatively 'easy' target given the broad genre inventory that the GUM model is trained to tackle.

These results also confirm that training on multiple genres, each with comparatively fewer documents, can lead to good performance with only minor degradation on the very narrow WSJ domain from RST-DT. While we think this result by itself is important and suggests that RST parsing work should devote more attention to multi-genre corpora as benchmarks, it leaves a question open: Can we combine data from both corpora to boost English RST parsing performance on RST-DT?

3.2 Joint Training

If RST parsing generalizes across domains, it may be possible to see gains through joint training. For this we compare three approaches: naive concatenation, model stacking, and pretraining, which we evaluate on the RST-DT benchmark.

For concatenation (CONCAT) we must map relations across corpora. As in previous work, we target coarse relation classes, most of which are identical in both corpora. Exceptions include GUM's PHATIC relation used for dysfluencies and back-channeling (due to conversational data), GUM's PREPARATION, and the mapping between RST-DT's TEMPORAL and COMPARISON classes, which map differently onto GUM's CIRCUMSTANCE and SEQUENCE, or GUM's ANTITHESIS, depending on the precise senses. Although the number of relation instances affected by these mismatches is modest, it is not negligible (13.3%), and we do not expect this approach to outperform in-domain training, and mainly report on it for completeness. Our mapping is given in Appendix D.

For model stacking, we test three variants: 1) FLAIR-LABEL: train an LSTM using FLAIR (Akbik et al., 2019) to predict EDU dependency labels: the LSTM receives text for three-EDU chunks, set apart by separators, and predicts the middle EDU's label in the GUM corpus scheme (using the RST dependency conversion from Li et al. 2014). We then train the parser on RST-DT with predicted GUM labels for each EDU as an additional feature encoded as a dense embedding, requiring no relation mapping. 2) SR-LABEL: train a full shift-reduce parser on GUM, generate predictions for RST-DT in the GUM scheme, and collapse these into dependencies to create the same kind of features; this approach gives the GUM classifier more access to global context than the previous LSTM's EDU triples, but may be more vulnerable to sparseness. 3) SR-GRAPH: because it is possible that incompatibility of RST-DT and GUM labels may cause confusion, we also attempted using the same parser as in the previous approach, but featurizing each EDU's predicted dependency attachment direction, and EDU distance to the parent EDU, instead of the label itself. Finally, we test a simple pretraining approach, in which we finetune the underlying SpanBERT model (Joshi et al., 2020) on full parsing of the GUM corpus, then load the fine-tuned SpanBERT, and train again on RST-DT (SR-FT).

Table 5 shows that SR-FT achieved the best performance compared to the other approaches and is on par with the pure in-domain training on RST-DT for S and R compared to previous work. There is a minor but stable gain on average (65.9→66.2) for N in SR-FT, which was verified by rerunning the experiment, as well as the selected SOTA system from Guz and Carenini (2020), 5 times. The remaining scenarios are virtually equivalent to training on RST-DT alone, suggesting that added features are more distracting than helpful.

This result is somewhat surprising given that scores are not very high, and there should still be

headroom for improvement; however, we suspect some of the missing information responsible for errors may relate to global structure and pragmatic understanding which cannot easily be compensated for by adding more genres with potentially disjoint vocabulary. A further surprising result is that CONCAT is not much worse than the base system, suggesting that most of the score comes from obvious cases (e.g. relative and infinitival clauses) which do not differ substantially across corpora or genres, and were already learned without the added data. Similar results have been found for other NLP tasks where adding a second dataset for joint training creates a 'break-even' effect: the benefit of more data helps about as much as the disparate domains harm within-corpus performance, e.g. for dependency parsing in Hebrew (Zeldes et al., 2022) and English (Zeldes and Schneider, 2023), English coreference resolution (Zhu et al., 2021), and very recent similar results for RST parsing for Chinese (Peng et al., 2022).

3.3 OOD Multi-Genre Degradation

In this section we explore our next question: How badly will a multi-genre trained model degrade on unseen genres, when the annotation scheme remains identical? This question is important for applied, methodological, and ethical reasons. From the practical perspective, while we already know that training only on news leads to severe degradation, we want to inform users of discourse parsing about expected performance on unseen domains if training data is already domain-rich. Methodologically, we want to test the benefit of adding multiple genres and weigh the differences between a few-genre corpus design and a many-genres design, given a fixed total data size capacity for dataset creation. Finally from an ethical perspective, OOD degradation has real life implications for less common types of data, whether they come from underrepresented genres, communicative situations, or speaker demographics (Mengesha et al., 2021). While we cannot fix these problems without more data, we can point them out and increase awareness of skewed data biases at the discourse level.

To explore OOD degradation, we conducted 10 experiments, comparing the normal genre-balanced scenario (GUM `test`) with testing on each genre when it is not in 'train' (ONE-VS-ALL or OVA). For consistency, we test OVA for the 8 roughly equal sized non-growing genres in GUM. Since data for the smaller 4 growing genres may be less reliable and non-comparable, we separately report scores for training on all 8 large genres (ALL-LARGE), tested on each of the four growing genres.

In the last scenario in particular, we would like to see whether small test genres, for which we cannot obtain enough training data, perform better if a training genre exists which may offer a near substitute. For instance, the small *textbook* and *speech* genres have structural organization and formal language similar to *academic* and *news* respectively, and there is some overlap between *speech* vocabulary and *interviews* with politicians. By contrast, *vlog* and *conversation* are highly informal and colloquial, perhaps closest to the *reddit* or *interview* genres, but still likely more challenging. For reproducibility, exact training data compositions are given in Table 17 in Appendix E.

Table 6 shows the results, with the same 4 documents from each held-out genre used to evaluate each OVA model (these are not included in any training set for consistency). The *degradation* column shows that the parser suffers when a genre is removed from training across the board, except for *news* and the Span level of *reddit*; *bio* and *how-to* genres suffer the most: qualitative inspection reveals that this is due to frequent errors on ORGANIZATION and EXPLANATION, which tend to lack explicit cues and require understanding of macrostructure and global topic or pragmatic reasoning to interpret. It is likely that lack of a similar substitute to these genres contributes to the degradation.

By contrast, degradation on *interview* is low (perhaps covered by *conversation* and *news* in training), and the inverse result for *news* suggests that collecting more news data may not be a priority. The minimal degradation for *reddit* is surprising, and is likely due to more instances of explicitly signaled and 'easy' relations such as PURPOSE (e.g. *in order to*) and CONTINGENCY (e.g. *if*), but we note that ordinary scores on *reddit* are low to begin with (second worst after *fiction*, which degrades more). The bottom of the table shows smaller genres suffering, except for a minor gain in *speech* at the Span level. It is unsurprising that *conversation* degrades the most, especially at the R level, since it contains challenging phenomena absent in other genres, such as back-channeling, dysfluencies, and abrupt topic changes. This is mirrored in bad performance on the ORGANIZATION and TOPIC relation classes (see more detailed analysis in §4).

Table 6: Per Genre Scores for GUM `test` vs. the OVA or ALL-LARGE Experiments (3 run average).

3.4 Genre Variety in a Fixed-Size Sample

While §3.3 shows how genres differ in degradation, it falls short of proving that genre diversity promotes generalization when all other things are equal, since train sets for each genre are not identical in size. Our final experiment addresses this: ideally, we want to compare scores on a fixed OOD test set for equal-sized training corpora, divided into fewer or more genres. Although we might expect more genres to be helpful for generalization, this is not trivial or inevitable: If there are not enough recurring examples of infrequent phenomena, because data is so diverse, learning might fail due to sparseness; that is, more genres could be distracting rather than helpful in a meaningful way, which could hurt performance.

Because genres in GUM are small (∼2K EDUs) and we want a critical mass of 5K+ EDUs for reasonable parser performance, our combinatory options are limited to 3+ training genres. The parser can only be trained on complete documents (we cannot select *n* EDUs from each genre – genres must comprise coherent texts), i.e. we must find permutations of the data which total roughly the same number of training instances, but with different genres. Table 7 gives details on the 3 best training cohorts based on these criteria.

ID	**genres**	**docs**	**EDUs**	**ID**	**genres**	**docs**	**EDUs**
C1	*academic*	18	1,970	C3	*academic*	9	1,004

	how-to	15	1,840		*how-to*	8	917
	total	45	5,712		**total**	52	5,712

Table 7: Composition of 3 Fixed-Size Training Cohorts with Different Genre Contents.

As Table 7 shows, the greatest care was taken to ensure that the cohorts sum up to almost exactly as many training instances (∼5,712 EDUs), at the price of somewhat diverse amounts of EDUs and documents per genre. If we cannot control all factors, we prefer to constrain the amount of shift-reduce operations learned, in order to prevent any alternative explanation in which total size effects outweigh genre diversity. Additionally, we assume that EDU count per genre will vary in any multi-genre corpus due to complete document constraints; corpus developers are more likely to target a total fixed size budget. If having too many small genres is harmful, we expect cohort 3 (C3) to perform worst; by contrast, if diversity is helpful, C3 should perform best. In either case, we compare how the S/N/R metrics behave in each training regime.

Table 8 shows 5-run averages on each OOD genre, as well as total micro- and across-genres macro-averaged performance. The 3-genre cohorts, C1 and C2, perform similarly overall, though C2 outperforms C1 on test data (which is held constant for all cohorts). R scores are very close on macro-average, but C1 is particularly bad on *conversation*, where C2 is tied with C3 on R (possibly because both have *interview* data). Conversely, C1 is better on textbooks and travel guides (*voyage*) than C2 (possibly because C1 has *academic*, which predicts textbooks reasonably well, and bios – a descriptive informational genre, something missing from C2).

Overall best performance is obtained by C3, with 6 training genres, but the least data in each. Although C3 loses to C2 in the dialogue-oriented *conversation* and *reddit* genres, degradation is very modest and does not affect all metrics (e.g. C3 has a better N score on *reddit*). C3 also outperforms C1 on *academic* and *voyage*, giving the best performance on both. The average gain for C3 across all

Table 8: Performance of 3 Fixed-Size Train Cohorts with Different Genre Contents (5 run average).

metrics (3-metric average) is around +1%—taking individual scores from each of five runs, and each genre test set as a data-point, this improvement is significant at $p < 0.05$. For individual metrics, we see $\sim$+1.7% on R, +1% on N, and just under +0.3% for S (significant at $p < 0.05$ except for S).

Although all scores are rather low due to the small corpus sizes (about ¼ of GUM), they suggest that more training genres with smaller portions each promotes OOD generalization, though not by a lot. It is an open question whether this gap would increase or decrease with corpus size: on the one hand, more data would allow for more lexical diversity even with few genres. On the other, it is likely that scores in small data are driven by easy to learn cases (e.g. relative clauses as ELABORATION, or PURPOSE infinitives), which stand to gain less from diversity. If more data means models will tackle more sparse phenomena, then genre diversity should matter *more* for OOD material as the training set grows. To an extent, results in §3.1 showing worse generalization from the large but homogeneous RST-DT to GUM seem to support this hypothesis. We interpret the present results to mean that development of more diverse multi-genre data should take priority over building up material in existing genres to promote generalizable parsing.

4 Error Analysis

Due to space, we limit our error analysis to examining dependency conversions of gold vs. predicted trees, which allow us to break down OOD errors by coarse relation class in Table 9 from all test sets in §3.3. We select models with scores closest to average run scores. It is clear that even in the more modest degradation within GUM, over half of relation classes have $< 50\%$ accuracy, with the document ROOT being the hardest to identify—i.e. the Central Discourse Unit (CDU)—followed by RESTATEMENT and EVALUATION, which require reasoning over many EDUs and lack consistent overt signals, as opposed to relations such as ATTRIBUTION (marked by speech verbs), PURPOSE (marked by purpose infinitives or *in order to*), and CONTINGENCY (usually *if*); interrupted clauses (SAME-UNIT) are easier as well. For CDU identification (Iruskieta et al., 2016), which can benefit summarization or long-form QA systems, half of the genres (*academic*, *fiction*, *interview*, *voyage*, *how-to*, *vlog*) score 0%; the highest accuracy is only 50% (*bio*, *news*, *reddit* and *speech*). More alarmingly, in the cross-corpus setting (§3.1), an RST-DT trained model captures only a single GUM CDU correctly (ACC=0.042 vs. 0.375 for a GUM-trained model); scores on RST-DT are much higher: ACC=0.842 for SR-FT trained on RST-DT vs. 0.553 for a GUM-trained model.

Table 10: Max Absolute Error Residuals by Genre.

Errors are also skewed by genre: Table 10 gives the gold label most surprisingly associated with errors per genre, given global error distributions, based on absolute χ^2 residuals. While EVALUATION is problematic in *fiction* and *interview*, EX-

PLANATION and ORGANIZATION are surprisingly hard to predict in 3 genres each: the former is used e.g. in speeches and news for supporting evidence or justifications which are difficult to identify using lexical items, while the latter is used in conversations for phatic responses and back-channeling.

To further investigate genre-specific phenomena, we analyzed OOD parsing errors for *how-to guides*, which had the worst OOD performance in Table 6, using a model *not* trained on this genre from §3.3. Figure 2 shows a confusion matrix produced by converting the automatic parses into the RST dependency representation following Li et al. (2014). We focus on relation instances with correct attachment predictions, although we also discuss cases involving attachment errors as well (Figure 5h in Appendix G). We first observe in Figure 2 that there are five gold CONTINGENCY instances predicted to be CONTEXT: four out of five EDUs begin with a discourse marker (DM), 'once' or 'until', e.g.:

(1) [Don't use a joke] $^{\text{humans: CONTINGENCY}}_{\text{parser: CONTEXT}}$[**until** you're completely comfortable with it.]

According to The Penn Discourse Treebank (PDTB3, Prasad et al. 2019), these prototypically signal spatio-temporal circumstances: 94% of explicit instances with the DM 'once' are annotated as TEMPORAL.ASYNCHRONOUS while less than 5% of the instances (4/85) are annotated as CONTINGENCY.CONDITION. Similarly, 85% of explicit instances with the DM 'until' are annotated as TEMPORAL.ASYNCHRONOUS while 10% are CONTINGENCY.CONDITION. However, Liu (2019) found that these two DMs are frequently associated with CONTIGENCY-CONDITION in *how-to guides* because they are essentially never narrative and always part of an instruction which is uncommon in *news*. This suggests that although DMs are usually considered useful devices to identify certain relations, their usage differs across genres and is sometimes too ambiguous to form a reliable signal. We also observe that there are four gold RESTATEMENT confused with ELABORATION: three of these go back to 'definitional' RESTATEMENTS, which are likely promoted by the genre's descriptive and explanatory properties.

Figure 5h shows cases with attachment errors. One major error concerning global structure is seven gold ORGANIZATION instances being confused with JOINT. Two of the errors are unexpected given that there are strong graphical, structural, and semantic cues (see an example in Figure 3 in Appendix F). The remaining cases are harder to pin down: they are all imperatives, which are atypical for headings outside of *how-to guides*, but normal and frequent in instructional texts (see an example in Figure 4). For complete by-genre confusion matrices (with attachment errors) of the multi-genre degradation experiments, see Appendix G.

	ADVERSATIVE	ATTRIBUTION	CAUSAL	CONTEXT	CONTINGENCY	ELABORATION	EVALUATION	EXPLANATION	JOINT	MODE	ORGANIZATION	PURPOSE	RESTATEMENT	SAME-UNIT

5 Conclusion

The analyses in this paper are meant to inform users of current parsers about what to expect from RST parsing in the wild. Through dozens of experimental runs we have shown a consistent picture: RST parsing has made impressive progress, but OOD degradation is still severe. Our results suggest prioritizing genre diversity in training data is crucial, not only to cover more text types as 'in domain', but also to increase performance on unseen text types. Rather than focusing only on the development of better models to beat the single genre RST-DT benchmark, robust RST parsing would be promoted most by creating more annotated data.

We also hope this paper will motivate researchers to prioritize multi-genre benchmarks and OOD settings for RST parsing, and to explore algorithms, representations and features which better capitalize on joint training and foster generalizability, including using data from other sources and theories of discourse analysis (cf. Braud et al. 2016). We see great challenges for tackling errors which implicate complex pragmatic inference or document level reasoning, but we are also optimistic that as more data becomes available, we will be able to learn more and better representations of discourse structure.

Limitations

One limitation is that the scope of the error analysis presented here is limited, primarily due to space reasons. Although we included full relation confusion matrices (with attachment errors) in Appendix G, the discussion is too limited to describe them in detail, and we encourage interested readers to explore and further compare gold and predicted trees (available in both `.rs3` and `.rsd` formats) on the multi-genre data, which we make available in the repository of this paper.

Another limitation concerns the number of runs of the experiments: some scores were averaged over three rather than five runs. This is due to the fact that SpanBERT-base (Joshi et al., 2020) is fairly large (110M parameters). Training each of our 20 models five times would consume very large amounts of GPU resources, which we feel is hard to justify both financially and environmentally. After completing this study we feel that three-run averaged scores should satisfy the need for reproducibility, though we did use five-run averages for establishing baseline scores and verifying particularly controversial results, such as the improvement on Nuclearity in the fine-tuning condition in §3.2 (i.e. SR-FT). Previous work providing this information reported three-run averaged scores such as Koto et al. (2021) while many papers did not include this information or mention whether the reported scores were averaged over multiple runs.

Ethics Statement

This work contributes to open source progress in RST discourse parsing, an area which has received less attention than some other NLP tasks, and which, at least in English, is currently suffering from a skewed focus towards the 'standard' language of 1990-era Wall Street Journal writing. Previous work has shown that NLP systems retain strong lexical biases mirroring both period and author demographics (Shah et al., 2020), meaning that if language technologies are not pushed to cover diverse data types robustly, they will inevitably perform more poorly on 'non-standard' data, with possible discriminatory effects on underrepresented populations ranging from the political (think opinion mining social media to guide policy) to financial (e.g. higher/lower search hit rates for YouTube videos by small businesses). By promoting higher quality treatments of diverse language samples in this study covering Reddit, YouTube vlogs, and demographically diverse conversations, we hope to help level the playing field across text-types, demographics, and domains.

We recognize that NLP research has a computing cost and carbon footprint, which motivates us to release the trained models in this work (preventing the need to retrain similar models), and to avoid extensive hyperparameter optimization which may not generalize to applications in the wild. Specific model configurations such as hyperparameters and validation performance for the reported `test` results of RST-DT and GUM are detailed in Appendix C.

Finally, we also recognize that NLP tools can be used to do harm. However, we expect that the type of analysis promoted here will do more good than harm by steering tool development away from adhering closely to outdated and narrow-domain data, which this work aims to broaden. Given that discourse parsers already exist, we view the push to reduce topical and authorial bias, as well as the public release of more resources, as net positives.

A Cross-Corpus Segmentation Scores

The scores in Table 11 (3 run average) show fairly modest degradation on cross-corpus EDU segmentation scores in both directions (a little worse for RST-DT→GUM), using DisCoDisCo (Gessler et al., 2021), the winning EDU segmentation system from the 2021 DISRPT shared task (Zeldes et al., 2021).

train	**test**	**P**	**R**	**F1**
RST-DT	RST-DT	95.16	94.64	94.90
RST-DT	GUM V8	90.09	89.69	89.89
GUM V8	GUM V8	92.09	93.73	92.90
GUM V8	RST-DT	92.55	89.57	91.03

Table 11: Cross-Corpus Segmentation Performance.

B Breakdown of the GUM RST Data

The breakdown of genres in GUM V8 is shown in Table 12. Four of the genres in the corpus are still growing, and therefore include less material than other genres at present.

genres	**docs**	**tokens**	**EDUs**	**growing**
academic	18	17,168	1,969	
bio	20	18,209	2,066	
fiction	19	17,508	2,458

C Model Configurations and Training Details

To ensure reproducibility and following the reproducibility criteria and checklist provided by EACL 2023, we provide model configurations and training details relevant to the experimental results presented in this paper.

For the BOTTOM-UP parser, the configurations of `SpanBERT-NoCoref` from Guz and Carenini (2020) was used as our base system, and we followed the hyperparameters and training settings therein across the board except the batch size due to memory limitations and embedding dimensions for organizational features.[7] Specifically, AdamW was used as the optimizer with a learning rate of $1e^{-5}$ for SpanBERT-base (Joshi et al., 2020) and $2e^{-4}$ for model-specific components (Guz and Carenini, 2020). Batch size was set to 1 (as opposed to 5 in the original implementation) and there were 20 epochs for each run. The organizational features used in Guz and Carenini (2020) followed Wang et al. (2017) and were represented as binary features in a learnable 5-dimensional embedding (as opposed to 10 in the original implementation). A vector of zeros of the same shape was used when a given feature is unavailable for the aforementioned organizational features as well as the categorical features experimented in §3.2, which all had an embedding dimension of 10.

For the TOP-DOWN parser, overall we followed the original hyperparameters and training settings therein; however, due to memory limitations, we modified the batch size to 3 from 12. The same `dev` set of respective corpora was used during training as in the training of the BOTTOM-UP parser from Guz and Carenini (2020). Additionally, XLM-RoBERTa-base (Conneau et al., 2020) was used as the language backbone.

All the training sessions were conducted using 1 NVIDIA Tesla T4 GPU on Google Cloud Platform. Table 13 shows the corresponding validation performance on RST-DT `test` and GUM V8 `test` reported in Tables 3 and 5 respectively using the BOTTOM-UP parser. Table 14 presents the corresponding validation performance (averaged over 5 runs) on RST-DT `test` and GUM V8 `test` reported in Table 4.

---

[7] Based on our reproducible results of this model (see Table 2) and comparing them to the reported results in the original paper, we believe that the change of these two configurations do not impact model performance significantly.

	S	N	R	# runs
RST-DT BASELINE	76.0	64.9	55.2	5
GUM `test`	67.0	54.5	45.9	5
RST-DT CONCAT	76.4	65.7	56.0	3
RST-DT FLAIR-LABEL	76.3	65.1	54.9	3
RST-DT SR-LABEL	76.3	64.7	55.2	3
RST-DT SR-GRAPH	76.6	65.5	55.5	3
RS-TDT SR-FT	76.3	64.9	55.4	5

Table 13: Validation Performance on RST-DT `test` and GUM `test` Results in Tables 3 and 5 (i.e. BOTTOM-UP).

	S	N	R	# runs
RST-DT BASELINE	75.3	65.0	55.9	5
GUM `test`	71.3	58.6	50.1	5

Table 14: Validation Performance on RST-DT `test` and GUM `test` Results in Table 4 (i.e. TOP-DOWN).

Note that since RST-DT does not have an established `dev` set, 10% of training data stratified by the number of EDUs in each document is used as the `dev` set following Guz and Carenini (2020) and is held constant across all the RST-DT-related experiments in this work. The list of the document names used in the `dev` set is provided in the code repository.[8] Additionally, since the `test` documents used in all the experiments in §3.3 and §3.4 are OOD data, the corresponding validation performance is not applicable and thus not reported. Information on the average runtime of each epoch for each model is provided in Table 15 below.

RST-DT			
model	**avg. runtime**	**model**	**avg. runtime**
BASELINE	2 hours 53 mins	SR-LABEL	2 hours 53 mins
CONCAT	5 hours 52 mins	SR-GRAPH	2 hours 50 mins

E Data Description for the GUM OOD Multi-Genre Experiments

Table 17 details the number of genres, documents, and EDUs used for training the models in the ten experiments in §3.3. For maximum reliability, testing was always conducted on the held-out genres' standard `dev+test` partitions specified in the official GUM V8 release (which is also provided in the repository of this paper), since the `dev` set for the targeted genres cannot be used for early stopping to simulate real OOD data in the wild.

F An Example OOD Parser Output

Figure 3 provides a comparison of a fragment of parser output versus the corresponding gold annotation to exemplify the distinction between gold ORGANIZATION and predicted JOINT discussed

in Section 4. Additionally, Figure 4 provides a fragment of parser output from one of the OVA models, No How-to, which exemplifies some of the observations and discussions brought up in the error analysis such as the most erroneous relation class ORGANIZATION in how-to guides (EDU 107). Moreover, these figures also demonstrate that although discourse markers (DMs) are cues in many cases, they can lead to errors if they are ambiguous, by distracting the parser from other (non-DM) signals such as the misidentified ELABORATION of EDU 110, where the gold ORGANIZATION is signaled by the colon and the numerical matching of 'Two parts' to the two nucleaus EDUs, 3 and 4 in Figure 3; and the CAUSAL of EDUs 112-116 in Figure 4, where an intensifying 'so' in 112 ('so comfortable') may have misled the parser into a resultative 'so' reading.

G Confusion Matrices

Figures 5a–5h show confusion matrices for all the non-growing genres from their corresponding OVA models, and Figures 5i–5l are for all the growing genres based on the automatic parses from the ALL-LARGE model where the training data contains only the 8 non-growing genres. Note that all the matrices were produced by converting the automatic parses into the RST dependency representation following Li et al. (2014) and do not reflect attachment errors. The conversion code is available at https://github.com/amir-zeldes/rst2dep.

Abstract

Biomedical data and benchmarks are highly valuable yet very limited in low-resource languages other than English, such as Vietnamese. In this paper, we use a state-of-the-art translation model in English-Vietnamese to translate and produce both pretrained and supervised data in the biomedical domains. Thanks to such large-scale translation, we introduce ViPubmedT5, a pretrained Encoder-Decoder Transformer model trained on 20 million translated abstracts from the high-quality public PubMed corpus. ViPubMedT5 demonstrates state-of-the-art results on two different biomedical benchmarks in summarization and acronym disambiguation. Further, we release ViMedNLI - a new NLP task in Vietnamese translated from MedNLI using the recently public En-vi translation model and carefully refined by human experts, with evaluations of existing methods against ViPubmedT5.

1 Introduction

In recent years, pretrained language models (LMs) have played an important and novel role in developing many Natural Language Processing (NLP) systems. Utilizing large pretrained models like BERT (Devlin et al., 2018), XLNET (Yang et al., 2019), ALBERT (Lan et al., 2019), RoBERTa (Liu et al., 2019), GPT-3 (Brown et al., 2020) BART (Lewis et al., 2019), and T5 (Raffel et al., 2019) has become an effective trend in natural language processing. All these large models follow the Transformer architecture proposed by (Vaswani et al., 2017) with the attention mechanism. The architecture has been proven to be very suitable for finetuning downstream tasks leveraging transfer learning with their large pretrained checkpoints. Before the emergence of large Transformer LMs, traditional wording embedding gave each word a fixed global representation. Large pretrained models can derive word vector representation from a trained large corpus. This will give the pretrained model a better knowledge of the generalized representation of a trained language/domain and significantly improve performance on downstream finetune tasks. The success of pretrained models on a generative domain (BERT, RoBERTa, BART, T5, etc.) has created a path in creating more specific-domain language models such as CodeBERT (Feng et al., 2020) and CoTexT (Phan et al., 2021b) for coding languages, TaBERT (Yin et al., 2020) for tabular data, BioBERT (Lee et al., 2019) and PubmedBERT (Tinn et al., 2021) for biomedical languages.

Biomedical literature is getting more popular and widely accessible to the scientific community through large databases such as Pubmed[1], PMC[2], and MIMIC-IV (Johnson et al., 2021). This also leads to many studies, corpora, or projects released to further advance the Biomedical Natural Language Processing field (Lee et al., 2019; Tinn et al., 2021; Phan et al., 2021a; Yuan et al., 2022). These biomedical domain models leverage transfer learning from pretrained models (Devlin et al., 2018; Clark et al., 2020; Raffel et al., 2019; Lewis et al., 2019) to achieve state-of-the-art results on multiple Biomedical NLP tasks like Named Entity Recognition (NER), Relation Extraction (RE), or document classification.

However, few studies have been on leveraging large pretrained models for biomedical NLP in low-resource languages. The main reason is the lack of large biomedical pretraining data and benchmark datasets. Furthermore, collecting biomedical data in low-resource languages can be very expensive due to scientific limitations and inaccessibility.

We attempt to overcome the issue of lacking biomedical text data in low-resource languages by using state-of-the-art translation works. We start

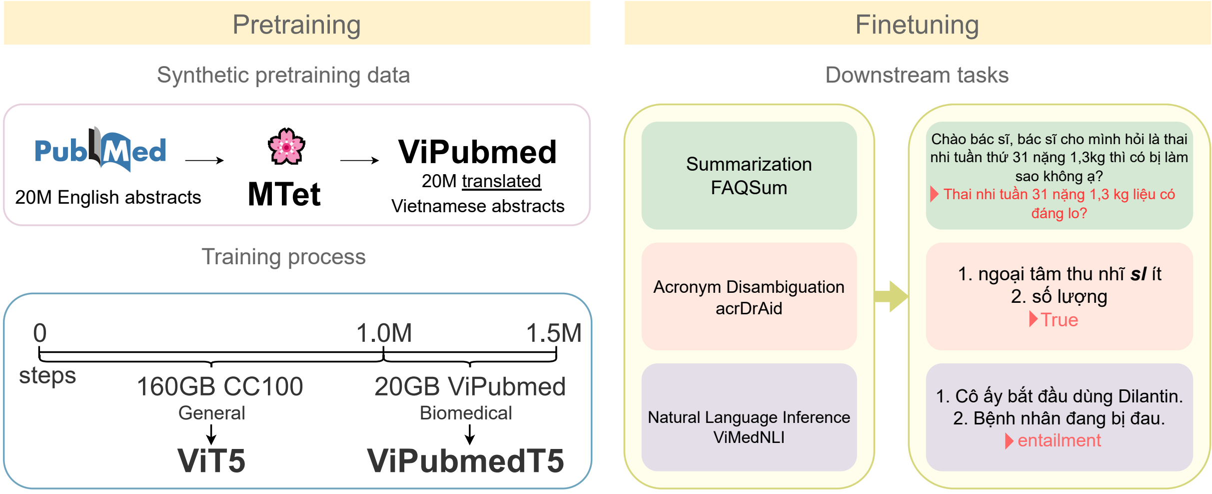

Figure 1: Overview of the pretraining and finetuning of ViPubmedT5

with the Vietnamese language and keep everything reproducible for other low-resource languages in future work.

We introduce ViPubmedT5, a pretrained encoder-decoder transformer model trained on synthetic Vietnamese biomedical text translated with state-of-the-art English-Vietnamese translation work. Meanwhile, we also introduced ViMedNLI, a medical natural language inference task (NLI), translated from the English MedNLI (Romanov and Shivade, 2018) with human refining.

We thoroughly benchmark the performance of our ViPubmedT5 model when pretrained with synthetic translated biomedical data with ViMedNLI and other public Vietnamese Biomedical NLP tasks (Minh et al., 2022). The results show that our model outperforms both general domain (Nguyen and Nguyen, 2020; Phan et al., 2022) and health-specific domain Vietnamese (Minh et al., 2022) pretrained models on biomedical tasks.

In this work, we offer the following contributions:

- A state-of-the-art English-Vietnamese Translation model (with self-training) on medical and general domains.
- A first Encoder-Decoder Transformer model ViPubmedT5 pretrained on large-scale synthetic translated biomedical data.
- A Vietnamese medical natural language inference dataset (ViMedNLI) that translated from MedNLI (Romanov and Shivade, 2018) and refined with biomedical expertise human.
- We publicize our model checkpoints, datasets, and source code for future studies on other low-resource languages.

2 Related Works

The development of parallel text corpora for translation and use for training MT systems has been a rapidly growing field of research. In recent years, low-resource languages have gained more attention from the industry, and academia (Chen et al., 2019b; Shen et al., 2021; Gu et al., 2018; Nasir and Mchechesi, 2022). Previous works include gathering more training data or training large multilingual models (Thu et al., 2016; Fan et al., 2021). Low-Language MT enhances billions of people's daily life in numerous fields. Nonetheless, there are specific domains crucial yet limited such as biomedical and healthcare, in which MT systems have not been able to contribute adequately.

Previous works using MT systems for biomedical tasks includes (Neves et al., 2016; Névéol et al., 2018). Additionally, several biomedical parallel (Deléger et al., 2009) have been utilized just for terminology translation only. Pioneer attempts to train MT systems using a corpus of MEDLINE titles (Wu et al., 2011), and the use of publication titles and abstracts for both ES-EN and FR-EN language pairs (Jimeno-Yepes et al., 2012). However, none of these works targets low-resource languages. A recent effort to train Vietnamese ML systems for biomedical and healthcare is Minh et al. (2022). These, however, do not utilize the capability of MT systems, instead relying on manual crawling. Therefore, this motivation has led us to employ MT systems to contribute high-quality Vietnamese datasets that emerged from the English language. To the best of our knowledge, this is the first work utilizing state-of-the-art machine translation to translate both self-supervised and supervised learning biomedical data for pretrained models in a low-resource language setting.

2.1 Pubmed and English Biomedical NLP Studies

The Pubmed[3] provides access to the MEDLINE database[4] which contains titles, abstracts, and metadata from medical literature since the 1970s. The dataset consists of more than 34 million biomedical abstracts from the literature collected from sources such as life science publications, medical journals, and published online e-books. This dataset is maintained and updated yearly to include more up-to-date biomedical documents.

Pubmed Abstract has been the main dataset for almost any state-of-the-art biomedical domain-specific pretrained models (Lee et al., 2019; Yuan et al., 2022; Tinn et al., 2021; Yasunaga et al., 2022; Alrowili and Shanker, 2021; Phan et al., 2021a). In addition, many well-known Biomedical NLP/NLU benchmark datasets are created based on the unlabeled Pubmed corpus (Doğan et al., 2014; Nye et al., 2018; Herrero-Zazo et al., 2013; Jin et al., 2019). Recently, to help accelerate research in biomedical NLP, Gu et al. (2020) releases BLURB (**B**iomedical **L**anguage **U**nderstanding & **R**easoning **B**enchmark), which consists of multiple pretrained biomedical NLP models and benchmark tasks. It is important to note that all of the top 10 models on the BLURB Leaderboard[5] are pretrained on the Pubmed Abstract dataset.

2.2 English-Vietnamese Translation

Due to its limitation of high-quality parallel data available, English-Vietnamese translation is classified as a low-resource translation language (Liu et al., 2020). One of the first notable parallel datasets and En-Vi neural machine translation is ISWLT'15 (Luong and Manning, 2015) with 133K sentence pairs. A few years later, PhoMT (Doan et al., 2021) and VLSP2020 (Ha et al., 2020) released larger parallel datasets, extracted from publicly available resources for the English-Vietnamese translation.

Recently, VietAI[6] curated the largest 4.2M high-quality training pairs from various domains and achieved state-of-the-art on English-Vietnamese translation (Ngo et al., 2022). The work also focuses on En-Vi translation performance across multiple domains, including biomedical. As a result, the project's NMT outperforms existing En-Vi translation models (Doan et al., 2021; Fan et al., 2020) by more than 2% in the BLEU score.

3 Improvements on Biomedical English-Vietnamese Translation through Self-training

To generate a large-scale synthetic translated Vietnamese biomedical corpus, we first look into improving the existing English-Vietnamese translation system in the biomedical translation domain. Previous work from Ngo et al. (2022) has shown that En-Vi biomedical bitexts are very rare, even for large-scale bitext mining. Therefore, we look into self-training to leverage the available monolingual English biomedical data.

Self-training approach has been experimented with in He et al. (2019) and utilized to improve translation on low-resource MT systems (Chen et al., 2019a). The advantage of this method is that the source side of the monolingual corpus can be domain-specific data for translation. However, the shortcoming is that the generated targets can be low-quality and affect the machine translation performance. Therefore, we start with the English-Vietnamese machine translation model from Ngo et al. (2022), denoted bT_A, which achieves state-of-the-art results on both En-Vi biomedical and general translation domains.

We use bT_A to translate and generate a synthetic parallel biomedical dataset with 1M pairs of English-Vietnamese biomedical abstracts from the Pubmed Corpus. The new 1M En-Vi biomedical pairs are then concatenated with the current high-quality En-Vi translation dataset from MTet (Ngo et al., 2022) and PhoMT (Doan et al., 2021), increasing from 6.2M to 7.2M En-Vi sentence pairs total. To verify the effectiveness of our new self-training data, we re-finetune the bT_A model on this 7.2M bitexts corpus. We report the model performance on the medical test set from MTet and the general test set from PhoMT in Table 1 (the translation performances on other domains like News, Religion, and Law are reported in Appendix A for

Table 1: BLEU Scores Results for En-Vi Translation on MTet Medical and PhoMT General Test Sets

Model	**Finetune Datasets**	**MTet Medical Test Set**	**PhoMT General Test Set**
M2M100	CCMatrix + CCAligned	30.18	35.83
Google Translate	-	38.60	39.86
SOTA	MTet+PhoMT	38.69	45.47
Ours	MTet+PhoMT +1M Self-training Pubmed Abstracts	**45.61**	**46.01**

Notes: The best BLEU scores are in bold. The state-of-the-art (SOTA) model and MTet dataset are from Ngo et al. (2022); PhoMT dataset and Google Translate's result are from Doan et al. (2021). M2M100 model is from Fan et al. (2020).

further reference).

The results show that our model outperforms existing Machine Translation systems in English-Vietnamese translation by applying self-training. We obtain a significant gain of 6.61 BLEU Score (38.69->45.61) on the MTet Medical test set. Our model with self-training also achieves state-of-the-art results on the PhoMT general domain test set by 0.53 BLEU Score (45.47->46.01). This shows that our approach not only improves the English-Vietnamese translation performance in the biomedical context but also generalizes to general translation. We further discuss our self-training model performance on other translation domains in Appendix A.

4 ViPubmed

After developing a new state-of-the-art machine translation system for English-Vietnamese translation in the biomedical domain in Section 3, we apply the system, denoted bT_B, on downstream translation to generate the first large-scale synthetic translated biomedical corpus for Vietnamese.

To ensure that our translated ViPubmed dataset contains up-to-date biomedical research (for example, Covid-19 diseases and Covid-19 vaccines), we use the newest Pubmed22[7] which contains approximately 34 million English biomedical abstracts published. The raw data is compressed in XML format. We then parse these structured XMLs to obtain the abstract text with Pubmed Parser[8] (Achakulvisut et al., 2020).

The machine translation model bT_B is an Encoder-Decoder Transformer based model with 512 token-length for input and output. Therefore, we filter out English Pubmed abstracts with more than 512 tokens. For fair size comparison with the unlabeled dataset of other health-related Vietnamese pretrained models (discussed in Section 7.2), we take a subset of 20M biomedical abstracts (20GB of text) for translation and leave a larger subset for future releases. We then translate the 20M English biomedical abstracts with the bT_B model using 4 TPUv2-8 and 4 TPUv3-8.

5 ViMedNLI

Along with an unlabeled dataset for pretraining, we also introduce a benchmark dataset generated by translation and refined with human experts. We start with a natural language inference (NLI) task as it is less prone to errors in biomedical entity translation compared to named-entity recognition (NER) or relation extraction (RE) tasks. The process of creating the ViMedNLI is shown in Figure 2.

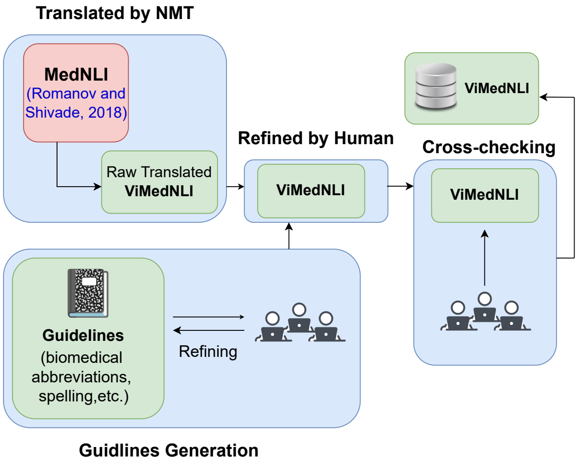

Figure 2: The Process of ViMedNLI Corpus Creation

[8] https://github.com/titipata/pubmed_parser

Table 2: Some Examples of Abbreviations and Spelling Refining

#	MedNLI	Translated by NMT	Refined by human
Abbreviations Refining			
1	Electrocardiograms revealed no QRS changes	Điện tâm đồ cho thấy không có thay đổi về QRS.	Điện tâm đồ cho thấy không có thay đổi về phức độ QRS
2	Patient has no PMH	Bệnh nhân không có PMH	bệnh nhân không có tiền sử bệnh
3	Patient is post op	Bệnh nhân đã hồi phục (*Patient is recovered*)	Bệnh nhân hậu phẫu thuật
Spelling Refining			
4	The infant was born at herm	Đứa bé được sinh ra ở Herm (*The baby was born at Herm*)	Đứa bé được sinh đủ tháng (The baby was born at term)
5	The patient had an sotesophytes	Bệnh nhân có sinh cảm (*The patient has flu*)	Bệnh nhân bị viêm xương khớp (*The patient had osteophytes*)
6	Patient has delerium	Bệnh nhân có hội chứng delerium (*Patient has delerium syndrome*)	Bệnh nhân bị mê sảng (*Patient has delirium*)

#1: Abbreviation in English can be used in both English and Vietnamese.
#2: Abbreviation can only be used in English. In Vietnamese, abbreviation is different.
#3: Abbreviation in English is wrong when translated to Vietnamese.
#4: The word *"term"* is misspelled as *"herm"*.
#5: The word *"osteophytes"* is misspelled as *"sotesophytes"*.
#6: The word *"delirium"* is misspelled as *"delerium"*.

5.1 MedNLI

MedNLI (Romanov and Shivade, 2018) is an NLI dataset annotated by doctors and grounded in the patients' medical history. Given a premise sentence and a hypothesis sentence, the relation of the two sentences (entailment, contradiction, neutral) is labeled by two board-certified radiologists. The source of premise sentences in MedNLI is from MIMIC-III (Johnson et al., 2016), a large open-source clinical database. The dataset has been widely studied and benchmarked by the Biomedical NLP research community[9] (Peng et al., 2019; Phan et al., 2021a; El Boukkouri et al., 2020; Alrowili and Shanker, 2021; Kanakarajan et al., 2019).

5.2 Dataset Challenges

We follow the same procedures discussed in Section 4 to translate the same training, development, and test sets released in Romanov and Shivade (2018). The time and resources to translate the dataset are negligible as there are a total of 14522 samples.

However, upon translating the dataset with NMT, we find out that the English clinical note domain has a distinct sublanguage with unique challenges (abbreviations, inconsistent punctuation, misspellings, etc.). This observation has also been addressed in Friedman et al. (2002) and Meystre et al. (2008). Such differences in clinical language representation challenge the translation output and our quest to release a high-quality medical dataset.

---

[9] https://paperswithcode.com/dataset/mednli

Table 3: Statistics of finetuned datasets

Corpus	Train	Dev	Test	Task	Domain
acrDrAid, pairs	4000	523	1130	Acronym disambiguation	Medical
FAQSum, documents	10621	1326	1330	Abstractive summarization	Healthcare
ViMedNLI, pairs	11232	1395	1422	Inference	Clinical

5.3 Human Refining

The unique challenges of clinical data under translation settings (discussed in Section 5.2) require us to work with humans who not only have expertise in biomedical knowledge but are also sufficient in both English and Vietnamese languages to refine the dataset. Therefore, we collaborate with premedical Vietnamese students who studied at well-known U.S. Universities to refine the ViMedNLI datasets.

The refining process starts with a comprehensive guidelines document with thorough annotation instructions and examples. Then, as clinical notes contain a significant amount of technical abbreviations that the machine translation system can not translate initially (Section 5.2), we work with the medical annotators to create abbreviations and their expansion forms. To make sure the expansion form of these abbreviations generalizes well in real-world settings, we verify the use case of these words through multiple Vietnamese medical websites, blogs, and online dictionaries. Hence, we decided to keep the original English abbreviations, replace them with a Vietnamese expansion form, or replace them with a Vietnamese abbreviation. Some examples of this process are shown in Table 2.

Aside from the English medical abbreviations, there are several grammatical and spelling mistakes the machine translation system does not understand, translating either into Vietnamese meanings or even failing to translate. Human refining is therefore required. The phrase *"The infant was born at herm"*, for example, was translated as "Đứa bé được sinh ra ở Herm". The word *"herm"*, which should be spelled as *"term"*, is misspelled and has no medical meaning. The accurate translation should be "Đứa bé được sinh đủ tháng" (*"The infant was born at term"*). Table 2 shows more examples of spelling refining cases.

Additionally, the machine translation system occasionally produces incorrect Vietnamese meanings when translating words with proper English spelling and grammar. Considering the sentence *"The patient had post-term delivery"* as an example. Despite having the meaning "Bệnh nhân sinh muộn", it was mistranslated as "Bệnh nhân sinh non" (*"The patient had pre-term delivery"*). Another example is "Narrowing of the vessels", which means "Thu hẹp các mạch" rather than "Thu hẹp các" (no meaning).

6 ViPubmedT5

With an unlabeled synthetic translated ViPubmed Corpus (Section 4) and a benchmark ViMedNLI dataset (Section 5), we pretrain and finetune a Transformer-based language model (Vaswani et al., 2017) to verify the effectiveness of our approach in enriching Vietnamese biomedical domain with translation data. We explain our model and the pretraining settings we applied in this section.

6.1 Model Architecture

We adopt the Transformer encoder-decoder model proposed by Vaswani et al. (2017), the ViT5 (Phan et al., 2022) checkpoints, and T5 framework [10] implemented by Raffel et al. (2019). ViT5 is the first monolingual Vietnamese Transformer model; the model achieves state-of-the-art results on multiple Vietnamese general tasks, including generation and classification. The ViT5 publication releases 2 model sizes - base and large. We train ViPubmedT5 using the base setting (220 million parameters) and leave larger models for future work.

6.2 Pretraining

We pretrain our ViPubmedT5 on 20GB of translated biomedical data ViPubmed (Section 4). We leverage the Vietnamese checkpoints in the original ViT5 work (Phan et al., 2022) and continuously pretrain the model on the synthetic biomedical-specific data for another 500k steps. Previous works (Lee et al., 2019; Tinn et al., 2021) have shown that this approach will allow pretrained language models to learn a better representation of

			(+news)	(+cc100)	(+health text mining)	(+translated ViPubmed)
Healthcare	FAQSum	RougeL	41.16	**61.3**	43.85	60.6
Medical	acrDrAid	Mac-F1	82.51	88	86.7	**89.04**
Clinical	ViMedNLI	Acc	77.29	77.85	79.04	**81.65**

Notes: The best scores are in bold, and the second best scores are underlined. PhoBERT & ViHealthBERT scores on FAQSum and acrDrAid are from Minh et al. (2022)

biomedical language context while maintaining the core Vietnamese language representation.

We train ViPubmedT5 using the same spans-masking learning objective as Raffel et al. (2019). During self-supervised training, spans of biomedical text sequences are randomly masked (with sentinel tokens). The target sequence is formed as the concatenation of the same sentinel tokens and the real masked spans/tokens.

7 Experiments

7.1 Benchmark dataset

We finetune and benchmark our pretrained ViPubmedT5 model on two public Vietnamese biomedical-domain datasets acrDrAid & FAQSum, (Minh et al., 2022) and our released ViMedNLI (Section 5). Detailed statistics of the three datasets are shown in Table 3.

- **acrDrAid** (Minh et al., 2022) is a Vietnamese Acronym Disambiguation (AD) dataset that contains radiology reports from Vinmec hospital[11], Vietnam. The task is correctly identifying the expansion of an acronym in a given radiology report context. The dataset is annotated by three expert radiologists. The acrDrAid has 135 acronyms and 424 expansion texts in total.

- **FAQ Summarization** (Minh et al., 2022) is a Vietnamese summarization dataset collected from FAQ sections of multiple *healthcare* trustworthy sites. For each FAQ section, the question text is the input sequence, and the title is a target summary.

- **ViMedNLI** is our released dataset discussed in Section 5.

7.2 Baseline

To verify the effectiveness of our proposed methods, we compare our ViPubmedT5 model with other state-of-the-art Vietnamese pretrained models:

- **PhoBERT** (Nguyen and Nguyen, 2020) is the first public large-scale monolingual language model pretrained for the Vietnamese language. The model follows the original RoBERTa (Liu et al., 2019) architecture. PhoBERT is trained on a 20GB word-level Vietnamese news corpus.

- **ViT5** (Phan et al., 2022) is the most recent state-of-the-art Vietnamese pretrained model for both generation and classification tasks. The model is trained on a general domain CC100-vi corpus.

- **ViHealthBERT** (Minh et al., 2022) is the first domain-specific pretrained language model for Vietnamese healthcare. After initializing weights from PhoBERT, the model is trained on 25M health sentences mined from different sources.

8 Results

The main finetuned results are shown in Table 4. The main takeaway is that training on synthetic translated biomedical data allows ViPubmedT5 to learn a better biomedical context representation. As a result, ViPubmedT5 achieves state-of-the-art in Medical and Clinical contexts while performing slightly worse than ViT5 in healthcare topics.

On the healthcare domain (FAQSum), ViPubmedT5 approximates the current state-of-the-art result (60.6 and 61.3) while outperforming the other models by a large margin (43.85). The slight difference in performance to ViT5 signifies a difference in data distribution in PubMed abstracts (scientific

---

[11] https://vinmec.com/

writing) and FAQSum (dialogues between patients and doctors).

For both medical and clinical datasets, ViPubmedT5 outperforms other existing models. There are also notable improvements from the general domain ViT5 to ViPubmedT5 (88->89.04 in acrDrAid and 77.85->81.65 in ViMedNLI). This indicates that the translated ViPubmed corpus contains biomedical knowledge that low-resource Vietnamese pretrained models can leverage.

Meanwhile, our newly translated ViMedNLI can serve as a robust baseline dataset for Vietnamese BioNLP research. Both health and biomedical domain models (ViHealthBERT & ViPubmedT5) perform better than general domain models (PhoBERT & ViT5) on the ViMedNLI dataset. This shows that our translated and refined ViMedNLI dataset is high-quality and has robust biomedical contexts.

9 Scaling to Other Languages

Our novel way of utilizing a state-of-the-art NMT system to generate synthetic translated medical data for pretrained models is not limited to the Vietnamese language and is scalable to many other low-resource languages. Recent works focus on improving the quality of multiple low-resource NMT systems (NLLB Team et al., 2022; Fan et al., 2020; Bañón et al., 2020). These new state-of-the-art NMTs make the approach discussed in this paper more practical to produce synthetic translated biomedical data, enriching the Biomedical NLP research knowledge in multiple low-resource languages.

10 Conclusion

We utilize the state-of-the-art translation model MTet to scale up the very low-resourced yet highly valuable biomedical data in Vietnamese. Namely, ViPubMedT5, a T5-style Encoder-Decoder Transformer pretrained on a large-scale translated corpus of the biomedical domain that demonstrated state-of-the-art results on both inference and acronym disambiguation in the biomedical domain. We also introduced ViMedNLI, a machine-translated and human-expert refined benchmark in natural language inference to further grow the Vietnamese suite of benchmarks and data in biomedical data.

11 Limitations

Although our pretrained model trained on synthetic translated biomedical data produces state-of-the-art results on downstream tasks for the Vietnamese language, the approach hugely depends on the quality of the NMTs for other low-resource languages. Thanks to recent studies and contributions from the Vietnamese research community (Section 2.2), the English-Vietnamese translation system has proven strong enough for us to conduct the experiments discussed in this work. However, the NMT's actual performance needed before making the translated biomedical data useful for pretrained models is still a question that requires further studies.

A Results for En-Vi Translation with Self-training

We explore a more drastic measure to expand the amount of data in the biomedical domain by self-training. We also explore how a large expansion in the number of biomedical bitexts affects the performance of our model on other domains such as Law, Religion, and News by using the MTet multi-domain test set (Ngo et al., 2022).

Table 5: BLEU Scores Results for En-Vi Translation on MTet Multi-domain Test Set

Model	**MTet Multi-domain Test Set**			
	Medical	News	Religion	Laws
SOTA	38.69	**51.47**	**41.44**	36.43
Ours	**45.61**	51.003	40.68	**39.51**

Notes: The best BLEU scores are in bold. The state-of-the-art (SOTA) model and MTet dataset are from Ngo et al. (2022); Our model trained with self-training approach on an extra 1M En-Vi synthetic biomedical abstracts is discussed in Section 3

The improvement is not evident across all domains when tested on a diverse domain test set (MTet). For example, while there are notable improvements in the Medical and Law domain, the model performs worse in the Religion and News domains. This can be attributed to the context representation of biomedical Pubmed Abstract data. Scientific abstracts tend to be more formal and academic for knowledgeable audiences with more domain expertise. Therefore, training on such data allows the Machine Translation system to perform better not only on the trained domain (Medical) but also on other formally presented domains, such as Law, while at the same time performing slightly worse on other domains (News and Religion).

Syntax-guided Neural Module Distillation to Probe Compositionality in Sentence Embeddings

Rohan Pandey
Language Technologies Institute
Carnegie Mellon University
rspandey@cs.cmu.edu

Abstract

Past work probing compositionality in sentence embedding models faces issues determining the causal impact of implicit syntax representations. Given a sentence, we construct a neural module net based on its syntax parse and train it end-to-end to approximate the sentence's embedding generated by a transformer model. The distillability of a transformer to a Syntactic NeurAl Module Net (SynNaMoN) then captures whether syntax is a strong causal model of its compositional ability. Furthermore, we address questions about the geometry of semantic composition by specifying individual SynNaMoN modules' internal architecture & linearity. We find differences in the distillability of various sentence embedding models that broadly correlate with their performance, but observe that distillability doesn't considerably vary by model size. We also present preliminary evidence that much syntax-guided composition in sentence embedding models is linear, and that non-linearities may serve primarily to handle non-compositional phrases.

1 Introduction

The principle of semantic compositionality suggests that the meaning of a sentence should derive from its subconstituents in a regular, structured fashion (Montague, 1970). In recent years, transformers (Vaswani et al., 2017) have become effective at producing sentential meaning representations useful for downstream tasks such as Natural Language Inference, Image-Text Matching, and Document Classification (Conneau et al., 2017; Radford et al., 2021). However, it has famously been conjectured that "You can't cram the meaning of a whole %&!$# sentence into a single $&!#* vector" (Mooney, 2014). Since recent models do appear to capture sentence meaning effectively, one wonders how they compose arbitrarily many word meanings together such that their relational structure is captured in a single, fixed-dimensional sentence embedding.

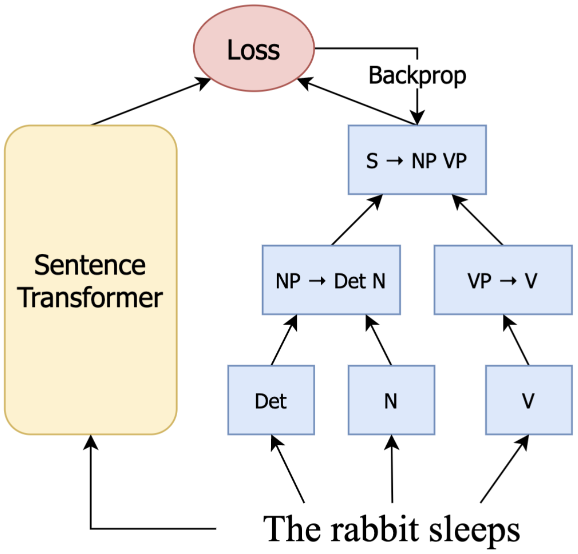

Figure 1: Distilling a transformer to a neural module net structured by the sentence's syntax

Much work has sought to probe these models for syntax representations and their causal relevance to embedding output. Conneau et al. (2018) train linear probes to determine if models encode syntactic features like tree distance and depth (Krasnowska-Kieraś and Wróblewska, 2019; Hewitt and Manning, 2019). One line seeks out direct mappings between neural representations and tree structures (McCoy et al., 2018; Chrupała and Alishahi, 2019; Jawahar et al., 2019; Soulos et al., 2020; Murty et al., 2023). Other work raises methodological issues with probing (Eger et al., 2019; Zhu and Rudzicz, 2020) such as choice of formalism (Kuznetsov and Gurevych, 2020) and semantic entanglement (Maudslay and Cotterell, 2021). Ravichander et al. (2021) raise the possibility that probing may identify causally un-used features; Tucker et al. (2021) partly address this concern to show that some syntactic features are causally relevant. Another line of work explores the geometry of semantic representations (Reif et al., 2019; Hernandez and Andreas,

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3143–3149
May 2-6, 2023 ©2023 Association for Computational Linguistics

2021) and the linearity (Barančíková and Bojar, 2019) of syntactic analogies (Zhu and de Melo, 2020).

Rather than directly analyze sentence embedding models, Neural Module Nets (Andreas et al., 2016b) seek to improve compositionality by modularizing semantic functions. We see this effort as ultimately similar to probing for structural representations since the former explores whether explicit structure improves performance and the latter explores whether performant models implicitly learn structure. Geiger et al. (2021) discovers logical tree causal structures in BERT and Wu et al. (2021) then guides model distillation using this structure.

Our work builds on these findings by strictly taking syntax as the causal structure of sentential semantics and linearity as the geometry of syntax-guided composition; we conduct experiments to test the distillability of transformer-based sentence embedding models to a Syntactic NeurAl Module Net (SynNaMoN), an architecture we introduce that implements these two priors. The extent to which a model can be distilled to a SynNaMoN tells us about its internal syntax representations & compositional ability.

2 Methods

2.1 Syntactic Neural Module Net

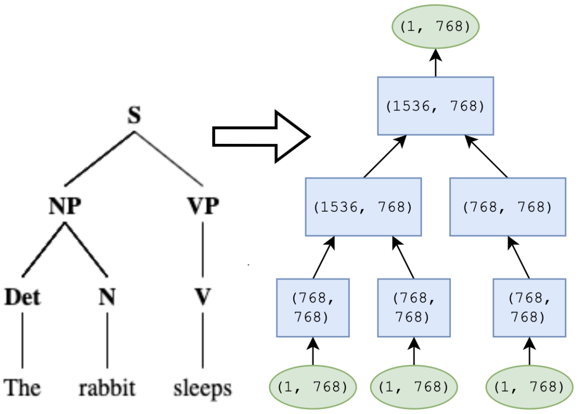

Figure 2: Constructing a sentence's SynNaMoN from its syntax tree; module input and output dimensionalities labeled on the right.

Unlike prior work (Andreas et al., 2016a; Cirik et al., 2018), SynNaMoN modules don't approximate high-level objectives like 'Find' or 'Count' but rather correspond to specific syntactic rules like 'S → NP VP' and 'NP → DT JJ NN'. Each module receives an input of dimensionality $(1, N * D)$ where N is the number of constituents on the syntax rule's right-hand side, and D is the dimensionality of the embedding space (768)—in other words, the input embeddings are concatenated. Though computationally more expensive, concatenation enables the module to learn an arbitrary function over the inputs rather than restricting it to a function over their sum or mean; this enables the module to converge on its ideal composition function which is likely not invariant under summation or averaging. Finally, though our implementation of SynNaMon includes 'part-of-speech' modules at the bottom of the parse tree, one could conceivably remove this bottom layer with the hypothesis that the word embeddings already capture part-of-speech information.

2.2 Internal Module Architecture

To explore the geometry of semantic composition under syntax, we implement 3 module architectures: a linear layer (**Linear**), a linear layer + a ReLU activation (**Nonlin**), and a linear layer + ReLU + another linear layer (**Double**). We explore these 3 architectures to see whether syntax is enough of an inductive bias to linearly approximate sentence embeddings, or if adding non-linearities and additional layers considerably improves performance. The extent to which adding parameters improves our approximation of the teacher model beyond the syntactic structure alone could reveal how much isn't captured by this inductive bias.

2.3 Linguistic Formalism

We choose to use the Transformational Grammar presented by Penn Treebank (Marcus et al., 1994), but in principle any Constituency Grammar could be easily used with SynNaMoN, and Dependency Grammars can be adapted with some effort. Since prior work has shown how the choice of linguistic formalism can significantly influence probing results (Kuznetsov and Gurevych, 2020), we float the possibility of such an effect being at play in this work as well. If a student SynNaMoN fails to capture much of the teacher embedding model, perhaps it isn't because of the teacher's non-compositional causal structure, but rather because the formalism used to structure the SynNaMoN is inadequate. Indeed, recent state-of-the-art neural approaches to syntax parsing have learned grammatical tagsets that often differ starkly from human-produced syntactic theories (Kitaev et al., 2022). We leave these problems to future work which may explore the exciting possibility that certain linguistic formalisms (perhaps even semantic rather than syntactic) are better proxies for a model's compositional structure than others.

3 Experiments

Our main experiment runs 5 sentence embedding models (BERT-base (Devlin et al., 2019), MP-Net (Song et al., 2020), GTR-T5-base, GTR-T5-large, and GTR-T5-xl (Ni et al., 2021)) on 3 SynNaMoNs with differing internal architectures (Linear, Nonlin, Double; see Sec. 2.2). For BERT-base, we extract input word embeddings for each token and use the CLS token as the sentence embedding as is common practice. For the other 4 models, we encode each token alone to serve as its embedding and use the output as the sentence embedding. When words are encoded as more than 1 token, we compute the mean across the subtokens to serve as its word embedding.

In order to heuristically select a learning rate, 5 training runs were conducted with SynNaMoNs optimizing for BERT-base, and learning rate manually set at increments between 10^{-5} and 10^{-3}. We finally chose a rate of 5×10^{-5}, but recognize from results that optimal learning rate will likely vary by teacher model & SynNaMoN internal architecture. Analysis would best be reported on the optimal scores achieved by a SynNaMoN after hyperparameter tuning, but due to compute restrictions (1 NVIDIA K80 GPU with 12GB of RAM), this was unfeasible.

Additionally, due to the number of modules (originally 900, each with 1M parameters on average), we encountered frequent out-of-memory errors both on CPU & GPU. Since each module corresponds to a syntax rule and is initialized upon encountering the rule in the dataset, we constrained our data to minimize the number of modules needed.

Specifically, we first constrained our trees to those of height 4 & 5 (n=16492) in PTB, and then further constrained the trees to those that use a subset of the 300 most common production rules among them. This resulted in 1494 trees, from which we generated a train-validation split of 1250-244. Furthermore, we ensured that all the productions present in trees of the validation split were also included amongst trees in the training split. All this finally resulted in 273 production rules present in our dataset, and the instantiation of 273 modules.

4 Results

In Tab. 1, we present scores for all 5 sentence embedding models across the 3 SynNaMon architectures. We compute the average MSE between sentence embeddings in the complete dataset for each model and divide each model's MSE loss by this mean distance to normalize results. The normalized scores we present may intuitively be seen as the portion of variance in a model's sentence embeddings that a SynNaMoN fails to explain. From a probing perspective, the lower a model's score, the more it can be causally approximated by composition along syntactic lines.

Sent. Emb. Model	Linear	Nonlin	Double
BERT-base-CLS	.765	4.17	.625
MP-Net-base	.606	.963	.538
GTR-T5-base	.541	.844	.499
GTR-T5-large	.550	.898	.502
GTR-T5-xl	**.536**	**.775**	**.498**

Table 1: Best validation MSE loss of sentence embedding models on each SynNaMoN probe, normalized by chance-level MSE between embeddings

First, notice that GTR-T5-xl outperforms all the other models across all the SynNaMoN architectures. This seems to confirm our expectation that larger models should produce more compositional sentence embeddings. However, GTR-T5-xl only marginally outperforms other sizes of GTR-T5 (except on Nonlin, for which it does far better), suggesting that size actually isn't a significant factor in compositionality. The lower performance of GTR-T5-large further corroborates this, but considering its anomalously lower average embedding MSE, the issue requires more work. The fact that GTR-T5 models all display high compositionality despite variance in size suggests something about their architecture or training approach is important—perhaps the representational bottleneck.

All 3 GTR-T5 models perform better than MP-Net, which in turn outperforms BERT CLS. This first fact is slightly surprising considering that on standard sentence representation tasks (Reimers and Gurevych, 2019), MP-Net (63.30) marginally outperforms all GTR-T5 (base: 59.40, large: 62.38, xl: 62.88) models. Evaluation of these sentence embedding models on large-scale, human-interpretable compositionality tasks may reveal that GTR-T5 does indeed produce better compositional representations than MP-Net. Although BERT's

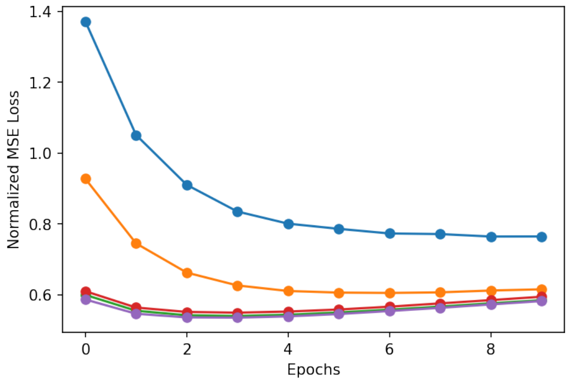

Figure 3: Normalized validation learning curves for Linear SynNaMoN on sentence embedding models (blue: BERT, orange: MP-Net, red: GTR-T5-large, green: GTR-T5-base, purple: GTR-T5-xl)

CLS token embedding is widely used for sentence representation, these results show that it fails to capture nearly as much compositional information as more targeted sentence embedding models.

Next, observe that although distilling to a Double SynNaMoN is intuitively easier than to a Linear SynNaMoN due to increased parameterization, there aren't always major improvements in distillability. It is possible that the geometric expressivity of the Double SynNaMoN will kick in with scaling of training data, but we hypothesize that this Double score will still approach a limit for all sentence embedding models. This is because syntax only describes a subset of sentence meaning, and the strictness of SynNaMoN's structure prevents this non-compositional component from being learned.

For example, a strictly syntactic compositional interpretation of "village on the river", would represent the village as being literally on top of the river since this is the semantic geometry learned for syntactic structures of the form "NP on NP". A SynNaMoN that includes non-linearities may better learn the geometry of this non-literal "on" relation, but a transformer model would best learn to handle non-compositional phrases due to its lack of strict syntactic constraints. Our broader takeaway from comparing Linear & Double scores is that much composition along syntactic lines is linear, and non-linearities in transformers primarily serve a purpose other than syntax-guided composition—perhaps in handling non-compositional phrases.

On a less theoretical note, we observe that our learning curves for Linear SynNaMoN on GTR-T5 (Fig. 3) are clearly overfitted due to fixing hyperparameters as mentioned in Sec. 3. We remediate this issue in Tab. 1 by reporting the best scores (minimum across epochs) for each learning curve. Since we want to construct the best possible SynNaMoN for a transformer model (as this most accurately reveals the transformer's distillable compositional ability), scores could be slightly improved with further hyperparameter tuning.

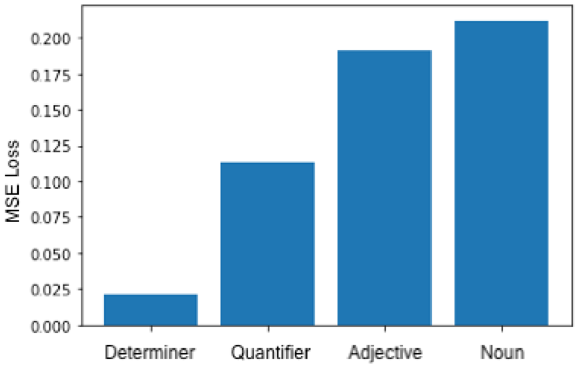

Figure 4: Generalization ability of Determiner Phrase module's linear geometry varies by part-of-speech

4.1 Analysis

Finally, we explore a single module to determine whether its compositional geometry meets intuitive notions of semantic generalization. Due to methodological difficulties with assessing a single module extracted from our end-to-end training paradigm, we train a Linear module for 'NP → Det N' on its own. Determiner-noun composition intuitively lies on a spectrum with adjective-noun composition on the other end and quantifier-noun composition in between. While quantifiers like 'some' and 'all' seem more like determiners, other quantifiers like 'several' and 'twelve' appear more comparable to adjectives like 'swarming' and 'grouped'. Intuitively then, we should expect the geometry of quantifier-noun composition to be intermediate to determiners and adjectives.

And this behavior is precisely what we find in our 'NP → Det N' module. Since it's trained on determiners, it obviously has the lowest MSE for this part-of-speech; we include noun-noun pairs (e.g. 'tree cow') as a control. As seen in Fig. 4, the module generalizes to quantifiers intermediately to determiners and adjectives. This demonstrates how SynNaMoN modules may enable interesting analyses of the compositional geometry of syntactic operations in sentence embedding models.

5 Conclusion

The human ability to apprehend the unitary meaning of a sentence corresponds to a neural model's ability to construct compositional sentence embeddings. In this work, we introduced Syntactic Neural Module Nets and used it in a distillation approach to assess how well syntax explains the sentential semantics computed by a transformer model. We showed that some models are more compositional by this metric, syntax-guided composition is largely linear, and modules learn composition functions that correspond to our semantic intuition.

Future work could explore this approach's alignment with other compositionality metrics and the non-compositional semantics left uncaptured by SynNaMoNs. We are also interested in how SynNaMoNs of different linguistic formalisms vary in distillability, as well as other potential use cases of SynNaMoNs beyond probing.

6 Limitations & Ethics Statement

Since longer sentences have more complex syntax, they require more modules on GPU and can run into out-of-memory issues. However, there is a hard upper-bound on total number of modules since there are limited syntax rules in the grammar. In addition, we may never need to train on long sentences if all modules can be effectively trained on short sentences and then generalize compositionally.

As an approach to probing language models, SynNaMoN contributes to an ethical NLP vision that seeks to address how models learn human biases that have societal effects from corpus data. Understanding syntax representations in models could be important in such a pursuit since some of these bias effects are syntactically mediated. For example, LMs with gender role biases could internally represent these biases as syntactic gender agreement e.g. ‘man’ agrees with ’doctor’ and ‘woman’ agrees with ‘nurse’ (Prates et al., 2020). By understanding the causal structure of sentential semantics in LMs, we can better disentangle syntax from spurious correlations transmitted by societal structures.

Abstract

Question Generation (QG) is a fundamental NLP task for many downstream applications. Recent studies on *open-book* QG, where supportive answer-context pairs are provided to models, have achieved promising progress. However, generating natural questions under a more practical *closed-book* setting that lacks these supporting documents still remains a challenge. In this work, we propose a new QG model for this closed-book setting that is designed to better understand the semantics of long-form abstractive answers and store more information in its parameters through contrastive learning and an answer reconstruction module. Through experiments, we validate the proposed QG model on both public datasets and a new WikiCQA dataset. Empirical results show that the proposed QG model outperforms baselines in both automatic evaluation and human evaluation. In addition, we show how to leverage the proposed model to improve existing question-answering systems. These results further indicate the effectiveness of our QG model for enhancing *closed-book* question-answering tasks.

1 Introduction

Question Generation (QG) has a wide range of applications, such as generating questions for exams (Jia et al., 2021; Lelkes et al., 2021; Dugan et al., 2022) or children's story books (Zhao et al., 2022; Yao et al., 2022), recommending questions for users in a dialogue system (Shukla et al., 2019; Laban et al., 2020), improving visual (Li et al., 2018; Lu et al., 2022) or textual question-answering tasks (Duan et al., 2017; Lewis et al., 2019a; Zhang and Bansal, 2019; Sultan et al., 2020; Lyu et al., 2021), asking clarification questions (Rao and Daumé III, 2019; Yu et al., 2020; Ren et al., 2021), and generating queries for SQL (Wu et al., 2021) or multimodal documents (Kim et al., 2021).

Previous works on QG are mainly under the *open-book* setting, which aims to generate questions based on factoid or human-generated short answers under the assumption that there is access to external knowledge like retrieved documents or passages (Du et al., 2017; Zhao et al., 2018; Kim et al., 2019; Fei et al., 2021). After Roberts et al. (2020) demonstrated that feeding a large pre-trained model input questions alone *without* any external knowledge can lead to competitive results with retrieval-based methods on open-domain question-answering benchmarks, there is an increasing interest in the *closed-book* setting. This closed-book setting is appealing in practice and can be widely applied, e.g., in question suggestion (Laban et al., 2020; Yin et al., 2021), query recommendation (Kim et al., 2021), and other practical settings where extensive external knowledge is unavailable.

However, generating questions without access to such external knowledge is challenging for two key reasons. First, without access to retrieved documents (or passages), simple open-domain strategies like basing the answers on these documents (or passages) are not possible under the closed-book setting. Instead, models must rely on the answers alone. Second, the data used by most of the closed-book works (Lewis et al., 2021; Wang et al., 2021) are variants of existing open-domain datasets, e.g., SQuAD (Rajpurkar et al., 2018), TriviaQA (Joshi et al., 2017), WebQuestions (Berant et al., 2013) that ignore the answer-related passages. These answers in open-book works are usually short, e.g., entities, and easier to be remembered by the language model and stored in the parameters of the model than long-form answers. Thus, this leads to our motivating research question – *How can we empower a QG model to better understand the semantics of long-form abstractive answers and store more information in its parameters?*

To tackle the aforementioned challenges existing

* Equal Contribution

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3150–3162
May 2-6, 2023

in the closed-book setting, this paper proposes a new QG model with two unique characteristics: (i) a contrastive learning loss designed to better understand the semantics of the answers and the semantic relationship between answers and ground-truth questions at a contextual-level; and (ii) an answer reconstruction loss designed to measure the answerability of the generated question. Contrastive learning has shown promising results in many NLP tasks, e.g., (Giorgi et al., 2021; Gao et al., 2021; Yang et al., 2021) and aligns positive pairs better with available supervised signals (Gao et al., 2021); here we show how to learn question representations by distinguishing features of correct question-answer pairs from features of incorrectly linked question-answer pairs. Further, to ensure the generated questions are of good quality and can be answered by the answer that is used for question generation, we frame the model as a generation-reconstruction process (Cao et al., 2019; Zhu et al., 2020), by predicting the original answers given the generated questions by a pre-trained seq2seq model. In addition, we introduce a new closed-book dataset with long-form abstractive answers – WikiCQA – to complement existing datasets like GooAQ (Khashabi et al., 2021) and ELI5 (Fan et al., 2019) and show how to leverage our model to generate synthetic data to improve closed-book question-answering tasks.

Through experiments, we find that the proposed QG model shows improvement through both automatic and human evaluation metrics on WikiCQA and two public datasets. Compared to the baseline, the proposed QG framework shows an improvement of up to 2.0%, 2.7%, and 1.8% on the ROUGE-L score on WikiCQA, GooAQ-S, and ELI5, respectively, and 1.3% and 2.6% in terms of relevance and correctness. Furthermore, we leverage the QG framework to generate synthetic QA data from WikiHow summary data and pre-train a closed-book QA model on it in both an unsupervised and semi-supervised setting. The performance is evaluated on both seen (WikiCQA) and unseen (GooAQ-S, ELI5) datasets. We find consistent improvements across these datasets, indicating the QG model's effectiveness in enhancing closed-book question-answering tasks.

In conclusion, our contributions can be summarized as follows:

- We propose a contrastive QG model, which to our knowledge is the first work to explore contrastive learning for QG under a closed-book setting.
- The proposed model outperforms baselines on three datasets. The human evaluation also indicates that the questions generated by our model are more informative compared to other baselines.
- We leverage the QG model as a data augmentation strategy to generate large-scale QA pairs. Consistent improvements shown on both seen datasets and unseen datasets indicate the QG model's effectiveness in enhancing closed-book question-answering tasks.

2 Related Work

Many previous works on QG are under the open-book setting, which takes factoid short answers (Rajpurkar et al., 2016) or human-generated short answers (Kočiský et al., 2018) with the corresponding passages to generate questions (Zhang et al., 2021). Early approaches for question generation rely on rule-based methods (Labutov et al., 2015; Khullar et al., 2018). To bypass handcrafted rules and sophisticated pipelines in QG, Du et al. (2017) introduce a vanilla RNN-based sequence-to-sequence approach with an attention mechanism. The recently proposed pre-trained transformer-based frameworks (Lewis et al., 2020; Raffel et al., 2020) also improve the performance of QG. In addition, Sultan et al. (2020) shows that the lexical and factual diversity of QG provides better QA training. However, their success can not directly adapt to the closed-book setting, where the model is supposed to generate questions solely relying on answers. In this work, we explore the widely applicable closed-book QG setting, which is still under-explored.

Contrastive Learning aims to pull semantically similar neighbors close and push non-neighbors apart. It has achieved great success under both supervised and unsupervised settings. In pioneer works, the contrastive loss function (Hadsell et al., 2006; Chopra et al., 2005) has been proposed as a training objective in deep metric learning considering both similar and dissimilar pairs. Recently, Chen et al. (2020) proposes the SimCLR framework to learn useful visual representations. Viewing contrastive learning as dictionary look-up, He et al. (2020) present Momentum Contrast (MoCo) to build dynamic dictionaries for contrastive learning. Some works apply contrastive learning into the NLP domain to learn better sentence representations (Giorgi et al., 2021; Gao et al., 2021). In addition, contrastive learning has been applied in multilingual neural machine translation (Pan et al., 2021), abstractive summarization (Liu and Liu, 2021), and multi-document question generation (Cho et al., 2021). The recent most relevant work is (Yang et al., 2021), where they design two contrastive losses for paraphrase generation. In this work, we adopt contrastive learning for improving representation learning in question generation under a closed-book setting.

3 Proposed Approach

To answer our research question – How can we empower a QG model to better understand the semantics of long-form abstractive answers and store more information in its parameters? – we propose a closed-book QG model, which generates questions directly without access to external knowledge. Formally, given an answer sentence x, a closed-book QG engine generates a natural question y. Figure 1 illustrates an overview of the proposed QG framework, which consists of three parts: question generation, contrastive learning, and answer reconstruction. The framework is optimized with the joint losses from these three parts simultaneously.

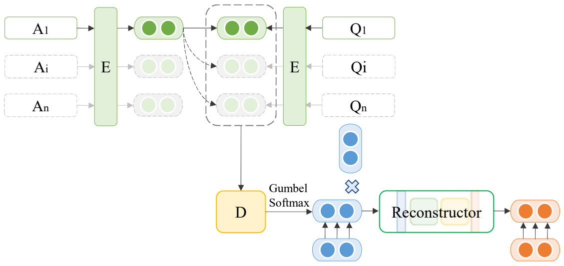

Figure 1: An overview of the proposed closed-book QG framework, which consists of three parts: contrastive learning, question generation, and answer construction. A_i: represents answer i; Q_i represents question i.

3.1 Question Generation

We first focus on question generation through a sequence-to-sequence architecture which consists of an encoder and a decoder (Sutskever et al., 2014; Vaswani et al., 2017). The encoder takes an input sequence of source words $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ and maps it to a sequence of continuous representations $\mathbf{z} = (z_1, z_2, \ldots, z_n)$. Then, the decoder takes $\mathbf{z}$ and generates a sequence of target words $\mathbf{y} = (y_1, y_2, \ldots, y_m)$ at a time. The closed-book QG task is defined as finding $\hat{\mathbf{y}}$:

$$\hat{\mathbf{y}} = \arg\max_{\mathbf{y}} P(\mathbf{y}|\mathbf{x}), \quad (1)$$

where $P(\mathbf{y}|\mathbf{x})$ is the conditional likelihood of the predicted question sequence $\mathbf{y}$ given answer $\mathbf{x}$.

$$P(\mathbf{y}|\mathbf{x}) = \prod_{i=1}^{T} p(y_t|\mathbf{y}_{<t}, \mathbf{x}), \quad (2)$$

Given the answer-question pairs, the training objective of the generation part in the proposed framework is to minimize the Negative Log-Likelihood (NLL) of the training data,

$$\mathcal{L}_{qg} = -\sum_{i=1}^{N} \log p(q_i|A), \quad (3)$$

where q_i is the i-th token in the generated question and A is the answer.

A naive question generation model will generate questions based on answers but lacks a rich model of the semantics of answers nor can it guarantee the generated questions have a semantic relationship with the answers. Intuitively, an encoded answer should be similar to its question and dissimilar to others. In addition, the generated question should be able to be answered by the answers. Hence, this motivates the following contrastive learning and answer reconstruction modules.

3.2 Contrastive Learning

Contrastive learning aims to pull positive pairs and push apart negative pairs to learn effective representations. Further, the supervised signals can produce better sentence embeddings by improving alignment between positive pairs (Chen et al., 2020). An effective QG model should be able to understand the semantics of the answers and the semantic relationship with the ground-truth questions. Especially, the encoded answer should have semantic similarity with its ground-truth question and dissimilarity with other questions. Thus, aiming to learn a similarity function that pulls the distance between the answer sequence representation and its ground-truth question sequence representation closer, we design a contrastive loss in the representation space. Specifically, given a positive pair $\mathcal{S} = \{(\mathbf{x}_i, \mathbf{y}_i)\}_{i=1}^{n}$, where $\mathbf{x}_i$ and $\mathbf{y}_i$ are semantically related inputs, the other $2(n-1)$ examples within a mini-batch are treated as negative examples. The training objective for $(\mathbf{x}_i, \mathbf{y}_i)$ is:

$$\mathcal{L}_{cl} = -\log \frac{\exp(\text{sim}(\mathbf{z}_{x_i}, \mathbf{z}_{y_i})/\tau_{cl})}{\sum_{i=1}^{2n} \exp(\text{sim}(\mathbf{z}_{x_i}, \mathbf{z}_{y_i})/\tau_{cl})}, \tag{4}$$

where $\mathbf{z}_{\mathbf{x}_i}$ and $\mathbf{z}_{\mathbf{y}_i}$ is the representation of input x_i and y_i, $\text{sim}(\mathbf{z}_i, \mathbf{z}_j) = \mathbf{z}_i^\top \mathbf{z}_j / \|\mathbf{z}_i\| \, \|\mathbf{z}_j\|$ denotes cosine similarity, and τ_{cl} is a temperature parameter.

In this work, aiming to learn better answer representations and force the encoder to drive representations of correct question-answer pairs closer than representations of incorrect question-answer pairs, we take the ground-truth question as the positive instance of an answer and fine-tune the model parameters based on the contrastive loss function (Eq. 4), where $\mathbf{z}$ is the embedding of the special token `[CLS]` from the transformer encoder, representing the meaning of the entire sentence.

3.3 Answer Reconstruction

The questions that are generated by the model should be of good quality and should also be able to be answered by the answer that is used for question generation. To measure the answerability of the generated question, we design an answer reconstruction module, which uses a pre-trained seq2seq model to predict the original answer given the generated question. The loss is calculated by a negative log-likelihood loss function:

$$\mathcal{L}_{ar} = -\sum_{i=1}^{N} \log p(a_i|Q) \tag{5}$$

where a_i is the i-th token in the answer and Q is the generated question.

A major challenge is that the generated questions from Section 3.1 are not differentiable. Gradients cannot be back-propagated directly. To solve this challenge, we employ the Straight-Through (ST) Gumbel-Softmax for gradient computation (Jang et al., 2017). The ST Gumbel-Softmax is a discrete version of the Gumbel-Softmax and takes different forward and backward paths. In the forward pass, the embedding is discretized by using the argmax, whereas in the backward pass the gradients are computed by the gumbel-softmax (Qader et al., 2019; Lu et al., 2021).

$$y_i = \frac{\exp((\log(p_i) + g_i)/\tau_{gs})}{\sum_{j=1}^{|V|} \exp((\log(p_j) + g_j)/\tau_{gs})}, \tag{6}$$

where τ_{gs} is a temperature parameter and g_i is the Gumbel noise drawn from a uniform distribution $(0, 1)$. In this work, the one-hot embedding from ST Gumbel-Softmax is multiplied with the vocabulary embedding and then fed into the encoder of the pre-trained seq2seq model as the representation of the generated question.

3.4 Overall Loss Function

As a result, all three losses are summed together to provide the overall loss function $\mathcal{L}$ as follows:

$$\mathcal{L} = \lambda_1 \mathcal{L}_{qg} + \lambda_2 \mathcal{L}_{cl} + \lambda_3 \mathcal{L}_{ar}, \tag{7}$$

The weights λ_1,λ_2, and λ_3 are tuneable hyperparameters to balance losses and the final objective is to minimize the overall loss.

The overall structure of the proposed QG framework is presented in Algorithm 1.

Algorithm 1: QG framework.

```
Input: Pre-trained language model $p(q|a)$,
       answer reconstruction model $p(a|q)$
       and answer-question pairs
Output: Question generator $p(q|a)$
for $i \leftarrow 1$ to $Epoch$ do
    $\hat{q} = p(q|a)$
    Compute $\mathcal{L}_{qg}$ via Eq. 3
    /* contrastive learning          */
    $a_i$ = Encoder([CLS] $\oplus$ $a$)[:, 0 :]
    $a_i^+$ = Encoder([CLS] $\oplus$ $q$)[:, 0 :]
    Get $\mathcal{L}_{cl}$ to $(a_i, a_i^+)$ via Eq. 4
    /* answer reconstruction         */
    $\hat{a} = p(a|\hat{q})$
    Compute $\mathcal{L}_{ar}$ via Eq. 5
    Calculate total loss $\mathcal{L}$ via Eq. 7
    Update generator $p(q|a)$ with $\mathcal{L}$
end
return question generator $p(q|a)$
```

4 Experimental Setup

To evaluate the effectiveness of the proposed QG framework, we aim to answer the following research questions (RQ) via experiments: **RQ1**: Can this proposed QG framework improve the performance of the closed-book QG tasks? **RQ2**: Are the generated questions of good quality? That is, are they fluent and relevant to the answer? **RQ3**: Can this QG framework be leveraged as a good resource to generate synthetic data for the QA task? **RQ4**: How much does each component in the framework contribute?

4.1 Dataset

We conduct the experiments on two public datasets – GooAQ-S (Khashabi et al., 2021) and ELI5 (Fan et al., 2019) – and a new dataset we curate called WikiCQA.

GooAQ-S is a sub-sampled dataset from GooAQ which contains three different sub-tasks: short, snippet (i.e., multi-sentence description), and collection response questions (Khashabi et al., 2021). Under the long-form closed-book setting, we adopt the snippet part (i.e., questions with snippet answers) for our experiments as in the original paper. Furthermore, from the paper, the model performance on the snippet task does not vary much when supervised with 200K and 2M training instances. Thus, to improve the experimental efficiency, we take 200k instances from the snippet set and split them based on their original scripts.[1]

ELI5 (Fan et al., 2019) is a widely-used large-scale corpus for long-form question-answering with supporting web documents. In this work, we use the question-answer pairs from the dataset and ignore the supporting context to fit the closed-book setting like (Khashabi et al., 2021). We follow the data split from huggingface.[2]

WikiCQA is a new closed-book long-form QA dataset (Section 4.2) introduced here. It contains 20,202 question-answer pairs and is collected from a wiki-style website to complement existing datasets. We shuffle the data and split it to train, dev, and test sets by the ratio of 80%/10%/10%. Table 1 shows detailed data statistics and splits of these three datasets.

Datasets	**Train**	**Val**	**Test**
WikiCQA	16,162	2,020	2,020
GooAQ-S	200,000	500	498
ELI5	272,634	9,812	24,512

Table 1: Dataset statistics.

4.2 WikiCQA

WikiCQA contains real user QA pairs collected from WikiHow[3]. WikiHow is a wiki-style website featuring over 200K how-to articles. Different from the existing dataset, ELI5, containing questions/answers from the Reddit forum and leveraging evidence queried from the web to help answer the question (Fan et al., 2019) and GooAQ, containing questions from search auto-complete and answers from answer boxes (Khashabi et al., 2021), WikiCQA involves long-form question-answering grounded on WikiHow articles.

Dataset Construction We construct the new dataset by collecting the question-answer pairs from the Q&A section of articles on WikiHow. The questions and answers are related to the specific articles, asked by WikiHow users, and answered by a knowledgeable reader or editor[4]. The questions can not be answered directly by the content of the article. After removing duplicates and question-answer pairs with meaningless answers, 23,037 QA pairs remain. To keep the same format as other existing QA datasets (e.g., ELI5, GooAQ), we discard questions not starting with a question-type word (e.g., what, how). After the dataset processing steps, we arrive at 20,202 question-answer pairs. More details can be found in Appendix A.

In Table 2, we show an example article from Wikihow, which includes the title and summary of an article and question-answer pairs from the corresponding Q&A section. From the example, we can see that answers are abstractive and long-form, written by real users, and not contained within the context passage. These question-answer pairs from the Q&A section are collected in the newly constructed dataset. Thus, this dataset is different from reading comprehension datasets, where the answers are a short text span in context. More comparisons with ELI5 and GooAQ are shown in Appendix B.

Title: How to Prepare a Healthy Meal for Your Pet Dog. **Summary:** To prepare a healthy meal for your dog, choose lean meat with the bones and fat removed, like chicken or beef . . .
Q: What can I feed my dog if I have run out of dog food? **A:** In the short term, any bland human food such as chicken or white fish with rice or pasta is just fine . . . **Q:** How much homemade dog food do you feed your dog? **A:** Great question because it highlights one of the problems of feeding home prepared foods . . . **Q:** What should I not feed my dog? **A:** There are many human foods that are toxic to dogs. Top of the list of foods NOT to give are . . .

Table 2: Question-answer pairs from WikiHow Q&A section. **Q**: question; **A**: answer.

4.3 Models & Hyper-parameters

We use BART-base (Lewis et al., 2020), a widely used sequence-to-sequence framework with 12 layers and a hidden size of 1024, as the backbone model. Following previous works (Fan et al., 2019; Khashabi et al., 2021), we finetune it using answers as inputs and questions as outputs as the baselines. To get the answer reconstruction loss (Section 3.3), we use a BART-base model which is fine-tuned on the target QA datasets.

Based on the dataset analysis in Appendix B, we set the maximum sequence length to 128 for the question and 256 for the answer sentence to improve calculation efficiency. We train the models for five epochs with a learning rate of 5×10^{-5} and evaluate the checkpoint for each epoch. We select the checkpoint with the highest ROUGE-L score on the validation set and report its corresponding score on the test set. We run each model three times and record the average scores. After performing manual hyper-parameter searching, we set loss parameters λ_1, λ_2, and λ_3 in Equation 7 to 1.0, 0.1, 0.1, respectively, which give the best ROUGE-L score on validation set. The temperature of contrastive loss τ_{cl} is set to 0.3. The experiments are run on 1 NVIDIA Tesla V100 GPU. The training time takes about 48 hours.

4.4 Evaluation Metrics

To evaluate the performance of the models, we use **ROUGE** (Lin, 2004) scores, which evaluate the n-grams recall of generated sentences with reference sentences, as automatic evaluation metrics (Fan et al., 2019; Khashabi et al., 2021). We report the F1 for ROUGE-1, ROUGE-2, ROUGE-L, and ROUGE-Lsum. ROUGE-1, 2, L measures the unigram, bigram, and longest common subsequence between the pair of sentences, respectively. The difference between ROUGE-L and ROUGE-Lsum is that ROUGE-Lsum splits text using " \n". The higher ROUGE score indicates higher similarity between generated questions and references.

We further perform human evaluations for the quality of generated questions in terms of **Fluency**: whether the questions are grammatically correct and fluent; **Relevance**: whether the questions are related to the answers; **Correctness**: whether the questions can be answered by the answers.

5 Experiment Results

In this section, we answer the four experimental research questions in turn.

5.1 Generation Performance (RQ1)

First, does the proposed QG framework have good performance? Table 3 shows the performance of the proposed closed-book QG model (denoted as $\mathbf{QG}_{ours}$) on the new dataset and two public datasets compared with the baseline model trained only with question generation loss (denoted as $\mathbf{QG}_b$). We observe that the proposed framework outperforms the baseline on three datasets for all ROUGE scores. For example, the performance increases by up to 2.0%, 2.7%, and 1.8% on the ROUGE-L score, respectively, which means the proposed framework can generate questions having a longer longest common subsequence (LCS) with ground-truth questions. We attribute these improvements to how contrastive learning pulls the answer representations closer to the ground-truth questions and thus, the generated questions have a higher chance to have similar words, phrases, or sentences with the ground-truth questions. The results demonstrate the effectiveness of our proposed QG framework.

Dataset	Model	R-1	R-2	R-L	R-Lsum
WikiCQA	QG_b	48.39	26.84	46.08	46.16
	QG_{ours}	**49.22**	**27.79**	**46.98**	**47.08**
GooAQ-S	QG_b	44.26	19.73	41.11	41.08
	QG_{ours}	**45.26**	**20.69**	**42.20**	**42.06**
ELI5	QG_b	28.62	10.10	25.93	26.23
	QG_{ours}	**29.15**	**10.36**	**26.40**	**26.69**

Table 3: QG results on three datasets. $\mathbf{QG}_b$: baseline model; $\mathbf{QG}_{ours}$: our proposed QG framework.

5.2 Quality of Generated Questions (RQ2)

Next, are the generated questions of good quality? To answer this question, we perform human evaluation to measure the quality of generated questions in terms of *fluency*, *relevance*, and *correctness*. We randomly sample 100 answer-question pairs from the WikiCQA dataset, which contains answers, ground-truth questions, and generated questions from the baseline model and our best model. Then, we ask three annotators to rate the generated question pairs, comparing them with the ground-truth questions. The generated questions are rated on a 1-5 scale (5 for the best) from the aspects of the three aspects above. Further, we calculate the percentage of questions that have higher ratings in each group.

Table 4 shows the average scores and the percentages of preferred questions on the three criteria. Both models are equally good at generating fluent questions. In terms of relevance and correctness, our approach shows 1.3% and 2.6% higher scores than the baseline method. These are consistent with what we expect: the contrastive learning part pulls the answer representation closer to the ground-truth question representation and generates more relevant questions; the reconstruction part can ensure that generated questions are of good quality and answerable. In addition, among 100 answer-question pairs, 24.7% and 23.3% of generated questions from our best model are rated higher while 56.3% and 57.4% of them have the same rating as those from baselines, which indicates that there is still substantial room to improve. To get a sense of the stability of the human evaluation results, we measure the inter-agreement among annotators using the Correlation Coefficient, which is 0.998, 0.944, and 0.976 in terms of these three aspects, showing excellent reliability.

Model	**fluency**		**relevance**		**correctness**	
	score	%	score	%	score	%
QG_b	4.83	**8.3**	3.84	19.0	3.49	19.3
QG_{ours}	4.83	7.3	**3.89**	**24.7**	**3.58**	**23.3**

Table 4: Results of human evaluation for baseline and our best model. **score**: is the average score from raters; **%**: represents the proportion of generated questions from one model that were rated higher than those from its counterpart.

5.3 Synthetic Data Generation (RQ3)

Further, can this QG framework be leveraged to generate effective synthetic data that can improve the closed-book QA task? Data augmentation is one of the main directions that question generation has been used for previously, with several studies finding improvements on the QA task (Lewis et al., 2019b; Alberti et al., 2019). Here, we show how to leverage the proposed QG framework to improve closed-book QA tasks on seen data (WikiCQA) and unseen data (GooAQ and ELI5). Since freely available summary data is a good resource to generate synthetic data (Lyu et al., 2021), we use WikiSum (Cohen et al., 2021), which contains 39,775 coherent-paragraph summaries written by the article's authors on the WikiHow website. We take each sentence from the article summary as an answer and pass it into the best QG model, described in Section 3.1, to generate a question. Then, we train an unsupervised QA model based on the synthetic QA pairs and optimize it by the following negative log-likelihood loss function:

$$\mathcal{L}_{qa} = -\sum_{i=1}^{N} \log p(a_i|Q), \tag{8}$$

where a_i is the i-th token in the generated answer and Q is the question.

In this work, we pre-train a BART-base model on the 200K synthetic QA pairs that are generated through the best QG model (denoted as $\mathbf{QA}_s$) and evaluate it on the test set of the seen dataset (WikiCQA) and unseen datasets (GooAQ-S and ELI5). This approach is unsupervised since the model is trained on no labeled question-answer pairs. The results are summarized in Table 5a, showing 22.4%, 12.5%, and 11.4% improvement than the BART-base model without any synthetic pre-training (denoted as $\mathbf{QA}_b$), on WikiCQA, GooAQ-S, and ELI5, respectively. This shows that pre-training on the generated question-answer pairs derived from our QG model leads to significant improvements, echoing findings in previous works that find synthetic data can be helpful (Khashabi et al., 2021; Lewis et al., 2021; Ding et al., 2021). After further fine-tuning on the target training set (denoted as $\mathbf{QA}_{s+f}$), from Table 5b we can see that $\mathbf{QA}_{s+f}$ also achieves better results than fine-tuned baselines model $\mathbf{QA}_{b+f}$ by 3.6%, 0.4%, and 4.3% on the same three datasets.

Dataset	**Model**	**R-1**	**R-2**	**R-L**	**R-Lsum**
WikiCQA	QA_b	18.41	5.53	14.72	15.98
	QA_s	**24.10**	**7.07**	**18.02**	**20.31**
GooAQ-S	QA_b	18.58	5.80	14.77	15.66
	QA_s	**21.93**	**6.12**	**16.62**	**18.35**
ELI5	QA_b	12.38	2.19	8.98	10.63
	QA_s	**13.97**	**2.29**	**10.00**	**11.77**

(a) Unsupervised QA results.

Dataset	**Model**	**R-1**	**R-2**	**R-L**	**R-Lsum**
WikiCQA	QA_{b+f}	27.16	7.32	19.85	23.49
	QA_{s+f}	**28.44**	**8.14**	**20.56**	**24.77**
GooAQ-S	QA_{b+f}	27.72	7.68	20.08	23.64
	QA_{s+f}	**28.44**	**7.73**	**20.17**	**24.12**
ELI5	QA_{b+f}	22.06	3.93	13.93	19.72
	QA_{s+f}	**23.37**	**4.27**	**14.53**	**20.88**

(b) Semi-supervised QA results.

Table 5: Evaluation on QA tasks. $\mathbf{QA}_{s/b}$: QA model w/o pre-training on synthetic data; $\mathbf{QA}_{*+f}$: QA_* fine-tuned on target dataset.

5.4 Ablation Study (RQ4)

Finally, we investigate the contribution of each component in the proposed closed-book QG framework. Table 6 shows the results on the WikiCQA dataset. As described in Section 3.2, the contrastive learning module takes ground-truth questions as positive pairs to the input answers (denoted as $\mathbf{CL}_t$) We also explore its variant – in which we feed the same input (answers) to the encoder with different dropouts to obtain the positive pairs (Gao et al., 2021) (denoted as $\mathbf{CL}_s$). We find that the choice of $\mathbf{CL}_t$ is slightly better than $\mathbf{CL}_s$ in most evaluation metrics. In addition, by adding the answer reconstruction (**AR**) module, the model performance can be further improved. Thus, we can observe the effectiveness of the proposed contrastive learning module and the overall design of the framework.

Models	**R-1**	**R-2**	**R-L**	**R-LSum**
QG$_b$	48.39	26.84	46.08	46.16
QG$_b$+CL$_s$	48.67	27.34	46.43	46.46
QG$_b$+CL$_t$	48.72	27.26	46.33	46.41
QG$_b$+CL$_s$+AR	**49.26**	27.77	46.82	46.88
QG$_b$+CL$_t$+AR	49.22	**27.79**	**46.98**	**47.08**

Table 6: Ablation study of our proposed QG framework on WikiCQA. $\mathbf{CL}_*$: contrastive learning module; **AR**: answer reconstruction module.

6 Case Study

Finally, we showcase some examples of the generated questions on the WikiCQA dataset. For the first example in Table 7a, we can see our model generates "how many" for the statistics-type answer, which is closer to the reference "what percentage" than the baseline model, generating a "yes/no" question. For the second one, although the reference contains the detailed information "textured surface" which is not in the answer, our model captures the information "without nails", which is more informative than the baseline model. Thus, the proposed model can produce better questions that are more relevant to the answers and contain more detailed information than questions generated from baseline models. There are also some cases where the proposed model fails to generate good questions shown in Table 7b. Compared with the reference question "what food can be included on a clear liquid diet", our model generates "what can I eat to lose weight", which fails in automatic evaluation metrics and is hard for annotators to justify in terms of relevance. For the second one, although the "broken door" generated from our model is relevant to the answer, it's still far from the reference "door sticking to the weather strip". The question generated from the baseline model related to "bedroom" is even less relevant. These examples encourage us to explore how to capture more semantics in the answers and generate questions that have more detailed information in the future.

A	The most recent statistics show that around 2.5% of small businesses are audited by the irs.
Q$_B$	Are small businesses audited by the irs?
Q$_G$	How many small businesses are audited by the irs?
Q$_R$	What percentage of small businesses are audited?
A	Try using poster putty to secure the images in your collage. if that doesn't work, you may have to use nails.
Q$_B$	How do i put pictures in a collage?
Q$_G$	How do i make a collage without nails?
Q$_R$	How can i make a collage on a wall with a textured surface?

(a) Good examples.

A	Foods such as popsicles, hard candy, and gelatin can be eaten on a clear liquid diet.
Q$_B$	what can you eat on a clear liquid diet?
Q$_G$	What can I eat to lose weight?
Q$_R$	What food can be included on a clear liquid diet?
A	You'll have to remove the door and sand, prime, and repaint it.
Q$_B$	What do i have to do to make my bedroom look nice?
Q$_G$	How do i fix a broken door?
Q$_R$	What do i do if my door is sticking to the weather strip?

(b) Bad examples.

Table 7: Generated question examples. $\mathbf{Q}_B$: generated questions from baseline model; $\mathbf{Q}_G$: generated questions from proposed QG model; $\mathbf{Q}_R$: reference questions.

7 Conclusion

In this work, aiming to empower a QG model to better understand the semantics of long-form abstractive answers and store more information in its parameters, we propose a closed-book QG model empowered by a contrastive learning module and an answer reconstruction module. We present a new *closed-book* long-form QA dataset – WikiCQA involving more than 20K real user QA pairs and show that WikiCQA is a valuable training resource, complementing public datasets. Through the experiments, the proposed QG model shows better performance than baselines through automatic and human evaluations. Moreover, we show how to leverage the proposed model as a data augmentation strategy to improve existing *closed-book* QA systems. The closed-book QA model, pre-trained on our generated synthetic QA pairs, achieves better performance on the seen dataset (WikiCQA). In addition, it shows strong generalization on unseen datasets (GooAQ and ELI5), which further demonstrates the effectiveness of our QG framework for enhancing closed-book QA performance.

Limitations

While our model shows promising results on English datasets, its efficiency and performance in other languages require further investigation. Moreover, our evaluation is limited to datasets with one-to-one QA pairs, without considering situations where multiple answers correspond to a single question. Before feeding the input into the model, we ignore the tokens that exceed the maximum length we set, which may sometimes bring in an information loss for the input corpus. Additionally, our model is built on transformer architecture and therefore requires huge computation resources, especially for large training data sizes. Our focus in this paper is solely on the closed-book setting and our experiments center around four research questions to evaluate the effectiveness of the proposed framework, which we believe is an essential and emerging area deserving of specialized research investigation. In future work, we aim to explore the feasibility of adapting our framework for other QG scenarios.

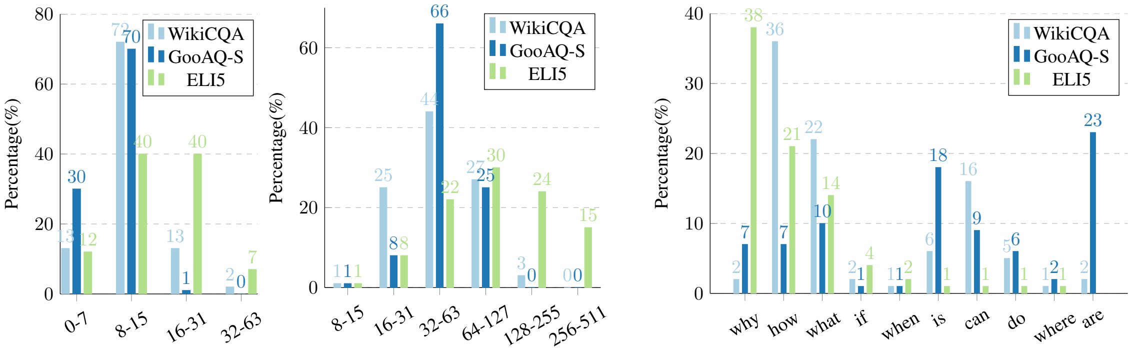
Appendix A Data Filtering

First, we choose the question-answer pairs where the questions start with a question-word in the list ['how', 'what', 'can', 'is', 'do', 'why', 'are', 'does', 'where', 'when', 'should', 'will', 'did', 'which', 'who', 'would', 'if', 'about', 'for', 'as', 'could', 'in', 'after', 'at', 'while', 'to', 'am', 'has', 'any'] and end with a question mark. Then, we filter out the pairs where the length of answers is less than 8 tokens or the answers are meaningless. For the "meaningless" answers we mean, answers are "please refer to certain website http://xxx" or "please refer to the article xxx".

Appendix B Dataset Analysis

To better understand the content of WikiCQA in comparison with existing QA datasets, Figure 2 shows the distributions of question length, answer length, and common question word. The questions and answers are tokenized by BART (Lewis et al., 2020). From Figure 2a and 2b we could see more than 80% of the questions in WikiCQA and GooAQ-S have less than 15 tokens and more than 90% of answers of them lie in the range of 16-127 tokens while both questions and answers



(a) Question length.

(b) Answer length.

(c) Common question-word.

Figure 2: Comparison of the distribution of QA length and question types among three datasets.

in ELI5 have a broader range of lengths. By measuring the proportion of the leading unigram that starts a question (Figure 2c), the dominant pattern is “how” questions in WikiCQA, while ELI5 has many “why” questions. We think WikiCQA has the potential to benefit the community in three ways. Firstly, its source is unique compared to the current two closed-book data sources, as it is collected from the Q&A section of articles on WikiHow. The questions and answers are related to the specific articles, asked by WikiHow users who read the articles and answered by a knowledgeable reader or editor. Secondly, compared to large-scale QA datasets, WikiCQA has longer answers and more open-ended questions with a wider range of question types. Additionally, it has a different data distribution compared to the other two datasets, which is crucial for testing the generalization ability of question-answering models. Finally, the question-answer pairs within relevant articles in WikiCQA can also be used as a valuable resource for conversational question-answering tasks. Our code and data can be found at https://github.com/dongxiangjue/Closed-book-Question-Generation-via-Contrastive-Learning.

A Hybrid Detection and Generation Framework with Separate Encoders for Event Extraction

Abstract

The event extraction task typically consists of event detection and event argument extraction. Most previous work models these two subtasks with shared representation by multiple classification tasks or a unified generative approach. In this paper, we revisit this pattern and propose to use independent encoders to model event detection and event argument extraction, respectively, and use the output of event detection to construct the input of event argument extraction. In addition, we use token-level features to precisely control the fusion between two encoders to achieve joint bridging training rather than directly reusing representations between different tasks. Through a series of careful experiments, we demonstrate the importance of avoiding feature interference of different tasks and the importance of joint bridging training. We achieved competitive results on standard benchmarks (ACE05-E, ACE05-E$^+$, and ERE-EN) and established a solid baseline.

1 Introduction

Event extraction has always been an important and challenging task in Natural Language Processing (NLP) (Sundheim, 1992). It aims to extract event triggers with specific types and event arguments with correct roles from unstructured plain texts into a structured form, which mostly describes "who, when, where, what, why" and "how" of real-world events that happened (Li et al., 2021a). For example, Figure 1 shows a `Meet` event, triggered by "*met*", which describes the `Entity` "*Kelly*" meet with another `Entity` "*officials*" in `Place` "*Seoul*".

Previous studies can be roughly classified into classification-based and generation-based methods depending on the decoder used. Classification-based method usually divides EE into two subtasks: (1) Event Detection (ED), which identifies event triggers and their types. (2) Event Argument Extraction (EAE) extracts the arguments and their corresponding roles for given event triggers and then models them as classification tasks, either learned in a pipeline framework or a joint formulation. Recently, generation-based event extraction methods have emerged as an alternative to traditional classification-based methods due to their better data-efficient and flexibility to include additional guidance. These methods take a sentence with discrete or continuous prompts as input and use BART-style backbone learning to summarize the sentence into a natural sentence based on a manually designed template. The template is composed of natural utterances describing argument role labels, which can provide rich label semantics, leading to great success in generation-based event extraction.

However, most of these methods simultaneously learn shared representations for ED and EAE. As shown in previous works (Nguyen and Grishman, 2015; Lu et al., 2019), ED relies more on lexical (e.g., lemma, synonyms) and shallow syntactic features (e.g., pos tags, dependent and governor words of trigger words). At the same time, the EAE task focuses more on syntactic dependency features. For example, the dependency path between trigger and arguments (Liu et al., 2018). Simply using shared representations dealing with the two distinct tasks would hurt their performance. This phenomenon is also observed in similar tasks, such as entity relation extraction (Zhong and Chen, 2021), where they use two different BERTs for modeling entity extraction and relation extraction, respectively.

To this end, we propose a simple but empirically powerful hybrid framework for event extraction. We model ED and EAE using separate encoders to avoid feature interference between these two tasks. In addition, we conduct extensive experiments to investigate the difference between classification-based and generation-based methods, and we ob-

May 2-6, 2023

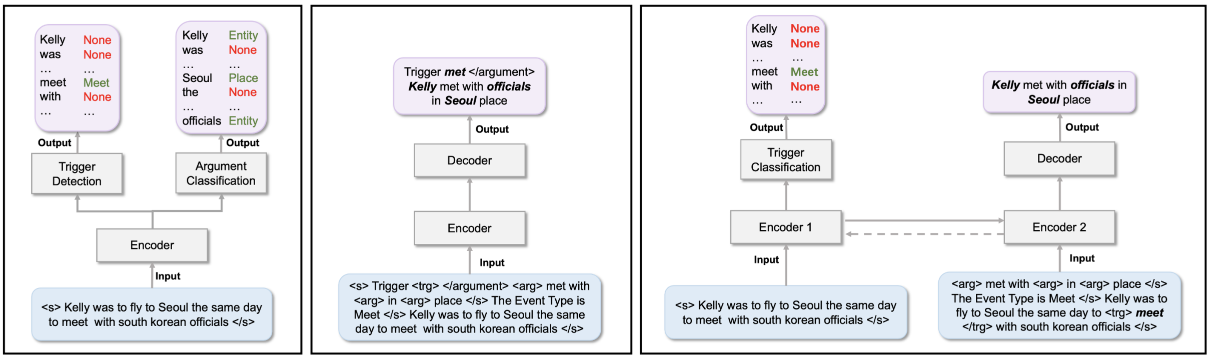

Figure 1: The first two figures are the two major paradigms in the field of event extraction, and the third figure is our paradigm.

serve that (1) Classification-based methods are superior to generation-based methods in modeling token classification tasks. (2) Generation-based methods perform better in modeling EAE because they can capture label semantics. Based on the observations, we instantiate our model with two different decoders: a classification-style decoder for ED and a generation-style decoder for EAE. Finally, to enhance the interaction between these two tasks, we design a bridging mechanism to provide EAE with information derived from ED and a two-stage training method that uses gradients from EAE to guide ED learning. We evaluate our model on three widely used benchmarks, ACE05-E, ACE05-E$^+$, and ERE-EN. Experimental results show that our model establishes the new state-of-the-art on ACE05-E and ACE05-E$^+$, and achieves comparable results on the ERE-EN dataset.

Our contributions can be summarized as follows:

- We first propose a method using separate encoders for modeling event extraction that can avoid feature interference.
- We propose a hybrid classification and generation method that enjoys the advantages of both approaches.
- To model the dependency between ED and EAE, we propose a bridging mechanism and two-stage training method.
- Experimental results show that our proposed method can outperform many strong baselines and achieve new SOTA on ACE05-E, ACE05-E$^+$ [1].

2 Related Work

Event extraction is usually considered to be composed of two sub-tasks: event detection and event argument extraction. Previous researchers are keen to use a shared encoder to model the contextual representation of different tasks. We group existing event extraction methods into classification-based and generation-based.

Classification-based Method. Classification-based methods tend to model event extraction as a classification task (Mekala and Shang, 2020; Guo et al., 2021; Xiao et al., 2021; Liu et al., 2020; Du and Cardie, 2020b; Li et al., 2020a; Ma et al., 2022) and deal with the recognition of trigger and arguments separately (Ji and Grishman, 2008), e.g., Liang et al. (2020) only consider the event detection and Chen et al. (2015) only consider the extraction of event arguments. Some previous works (Li et al., 2013) have tried to joint training these two tasks to enhance the connection between them, and Yang and Mitchell (2016); Nguyen et al. (2016); Liu et al. (2017, 2018); Lin et al. (2020a) all try to enhance the effect of joint training by adding as much entity and relation information as possible. The difference lies in their shared encoding layers. For example, Liu et al. (2017, 2018) used CNN and Bi-RNN successively, while Wadden et al. (2019a); Lin et al. (2020a) used graph structure. In addition, some works (Ramponi et al., 2020; Du and Cardie, 2020a; Yang et al., 2018) solve the event extraction in sequence labeling manner (Chen et al., 2020; Gui et al., 2020; Jiang et al., 2021) by tagging the sentence only once, which may not solve the overlapping problem.

Generation-based Method. In contrast to classification-based methods, the main goal of

---

[1] Our codes are publicly available at `https://github.com/OPilgrim/TDE-GTEE`

generation-based methods is to use a common structure to uniformly model various tasks, including event detection and event argument extraction. The output structure can be a sentence filled with slotted templates (Li et al., 2021b; Du et al., 2022), or some linearly serialized tree structure (Lu et al., 2021a, 2022). Paolini et al. (2021) even constructed an end-to-end translation directly. Generative models can leverage richer prior knowledge. However, the accuracy is not high in classification problems. We think that the generative model may pay more attention to global features and ignores local details. Based on that, several recent works (Hsu et al., 2021; Liu et al., 2022a) use prompt-based approaches to force the model to focus on specific pieces of information to control its output for different event types.

Unlike previous works, we argue that the contextual representation of tasks is different, and sharing one contextual representation will harm the model's performance. So we use independent encoders to learn the contextual representation of each task. In addition, since tasks are not entirely independent, increasing the interaction between tasks will be conducive to improving each other; we achieve it through a bridging mechanism and a two-stage training method.

3 Method

3.1 Problem Definition

The input of the problem is a sentence $\mathcal{C}$ consisting of N tokens $c_1, c_2, ..., c_N$. Let $\mathcal{E} = \{e_1, e_2, ..., e_M\}$ denotes a set of pre-defined event types. The event extraction problem can be decomposed into two sub-tasks:

Event Detection (ED). Event detection aims to identify possible event mentions in the input sequence. We define that each pair of (c_i, e_j) refers to an independent event mention and the event detection is, for each token $c_i \in \mathcal{C}$, to predict an event type $y_e(c_i) \in \mathcal{E}$ or $y_e(c_i) = \epsilon$ representing token c_i is not a trigger. The output of the task is $Y_e = \{(c_i, e_j) | c_i \in \mathcal{C}, e_j \in \mathcal{E}\}$.

Event Argument Extraction (EAE). Event argument extraction aims to identify all entities involved in an event mention (c_i, e_j). Let $\mathbf{s} = \{s_1, s_2, ..., s_t\}$ to be a set of candidate entity spans, and $\mathcal{R}^j$ denotes a set of predefined argument roles in event e_j. The event argument extraction is, for each span $s_i \in \mathbf{s}$, to predict a argument role type $y_r(s_i) \in \mathcal{R}^j$, or span s_i is not an argument belongs to event e_j: $y_r(s_i) = \epsilon$. The output of the task is $Y_r = \{(s_i, r_i, e_j) | s_i \in \mathbf{s}, r_i \in \mathcal{R}^j, e_j \in \mathcal{E}\}$.

3.2 Our Approach

In this section, we introduce our proposed method, HDGSE[3] (the **H**ybrid **D**etection and **G**eneration framework with **S**eparate **E**ncoders for **E**vent **E**xtraction), based on the overall architecture of Figure 2.

Event Trigger Detection. We use BERT as the backbone of our detection model and treat it as a token-level multi-classification task, which makes the model learn the different probabilities of each event type (Li et al., 2021b). As we mentioned in Section 2, the sequence annotation method based on CRF cannot solve the span coverage problem, so we did not implement this scheme. Given the input sequence $\mathcal{C} = \{c_1, ..., c_i, ..., c_N\}$, the detection model will detect all possible trigger tokens $\{c_i, | i \in \{i\}_{i=1}^{N}\}$ and their corresponding event type $\{e_j, | j \in \{j\}_{j=1}^{M}\}$ as mentioned in Formula 1,

$$label_{c_i} = \begin{cases} 0, & c_i \text{ is not a trigger,} \\ j, & c_i \text{ is trigger for event type } j. \end{cases} \quad (1)$$

where N is the length of $\mathcal{C}$ and M is the number of event types in ontology $\mathcal{O}$ [2] . Each pair of $(c_i,\ e_j)$ indicates the hit of an event $\{E_k | k \in \{k\}_{k=1}^{K}\}$, where K denotes the number of events in $\mathcal{C}$. Then the generative model extracts arguments for each event E_k in turn.

Generative Argument Extraction. After detecting the candidate event triggers, the argument extraction task is divided into several subtasks according to the detected triggers and event types, and each subtask is an event mention. We process each event mention independently with a generative approach and insert markers at the input sequence to highlight the trigger. The generative model is based on BART, and the lower part of Figure 2 shows the detailed structure. Specifically, for subtask $\mathcal{S}_{E_k, \mathcal{C}}$, the input $\mathcal{X}$ of the generative model includes the event type aware prompt $\mathcal{P}_{e_j}$ and context $\mathcal{C}' = \{c_1, ..., \text{<trg>}, c_i, \text{</trg>}, ..., c_N\}$, where the trigger c_i is marked by two special tokens "<trg>" and "</trg>" to provide trigger position information for the corresponding subtask. Given

---

[2] We follow Li et al. (2021c) and reuse RAMS AIDA ontology and the KAIROS ontology as the ontology for ACE05-E, ACE05-E$^+$ and ERE.

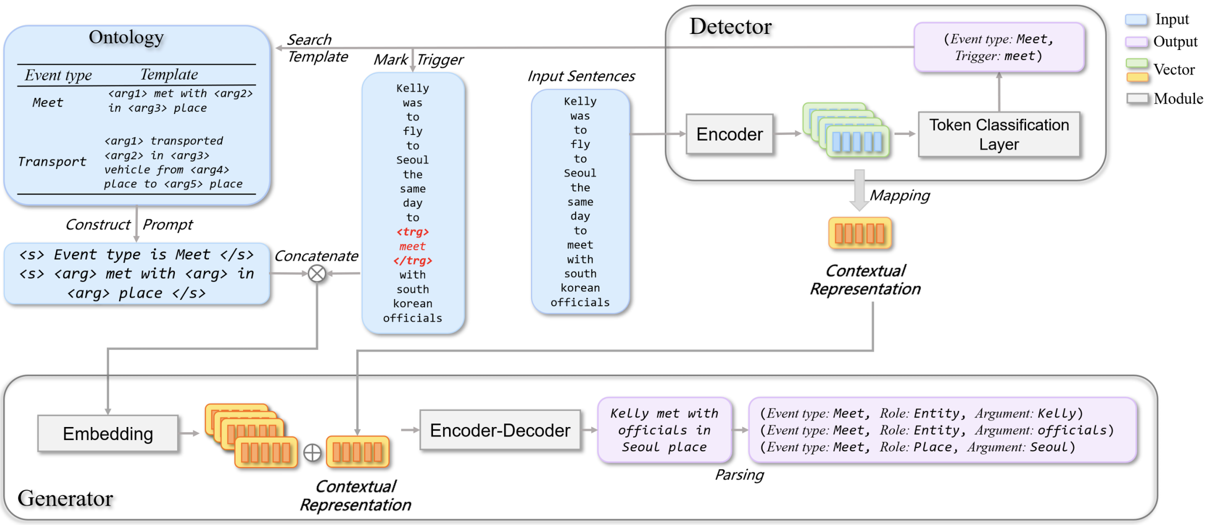

Figure 2: Illustration of our end-to-end joint event extraction framework. Given an input sequence, the detector first detects several candidate triggers and classifies their event types. Then, the generator generates filled template from the trigger-marked input and finally parses the arguments through a deterministic algorithm. During generation, the contextual representation of the trigger that the detector learns is fused into the generator.

the previous generated tokens $y_{<i}$ and the input $\mathcal{X}$, the BART models the conditional probability of selecting the next token y_i as $p(y_i|y_{<i},\mathcal{X})$, and the entire probability $p(\mathcal{Y}|\mathcal{X})$ is calculated as

$$\begin{aligned} p(\mathcal{Y}|\mathcal{X}) &= \prod_{i=1}^{|\mathcal{Y}|} p(y_i|y_{<i},\mathcal{X}) \\ \mathcal{X} &= [\mathcal{P}_{e_j}; [SEP]; \mathcal{C}'] \\ \mathcal{Y} &= \mathcal{A}_{e_j} \end{aligned} \tag{2}$$

, where $[;]$ denotes the sequence concatenation operation and $[SEP]$ is the corresponding separate marker in the BART, $\mathcal{A}_{e_j}$ is the answered prompt.

Similar to generative template-based method GTEE(Liu et al., 2022b), the prompt $\mathcal{P}_{e_j}$ for subtask $\mathcal{S}_{E_k,\mathcal{C}}$ contains the type instruction $\mathcal{I}_{e_j}$ and the template $\mathcal{T}_{e_j}$. The type instruction is an indication of the event type described by natural language, and the template describes the expected output format, including several placeholders, reflecting how the arguments participant in the event. Take Figure 2 as example, the generative model's input is type instruction "`Event type is Meet`", template "`<arg> met with <arg> in <arg> place`", and content concatenated with separator. The ground truth $\mathcal{G}_{e_j}$ is "`Kelly met with officials in Seoul place`", where the placeholder "<arg>" is replaced by the corresponding argument "`Kelly`", "`officials`", and "`Seoul`". Each event type has its own template and we follow Li et al. (2021b) to reuse the pre-defined argument templates.

Bridging Event Detection and Event Argument Extraction. Our proposal to independently learn contextual representations for ED and EAE does not mean that the two tasks are not connected; argument extraction directly depends on determining event types and triggers. So to enhance the interaction between them, we bridge the two tasks by trigger: first, as mentioned in the previous section, we highlight the trigger in the input of EAE, which provides the location information; the second is to fuse the context information of triggers into the EAE model, which is the focus of this section. Both kinds of information provide the EAE model with prior knowledge of events. Specifically, for the trigger token c_i, its hidden state in BERT's last hidden layer is $\boldsymbol{h}_{c_i}$, and its input embedding in BART is $\boldsymbol{Emb}(c_i)$. A semantic transformation is performed by multiplying the $\boldsymbol{h}_{c_i}$ by the projection matrix $\boldsymbol{P}$ to obtain the projected vector $\boldsymbol{v}_{c_i} = \boldsymbol{h}_{c_i}\boldsymbol{P}$ as contextual representations, where $\boldsymbol{P}$ can be learned by fully connected networks. We refer to this operation as "Mapping", as illustrated in Figure 2. Then, we add $\boldsymbol{v}_{c_i}$ and $\boldsymbol{Emb}(c_i)$ directly. Another appropriate method is sufficient to directly use the vector $\boldsymbol{v}_{c_i}$ to initialize the embedding representation of trigger markers. We conduct comparative experiments against these two appropriates in Section 5.2.

Training and Inference. In this paper, we design a two-stage training approach: (1) In the first step, we first train ED and EAE separately so that they can learn the contextual representation independently. (2) In the second step, to overcome the error propagation problem of the pipeline, we continue to use joint training to optimize the global loss based on the model trained in the first step and use the gradient of EAE to guide the optimization of ED.

Mathematically, The trainable parameters of our model include ϕ and φ, which come from the BERT and BART respectively. The training objective of the detection model is to minimize the focal loss (Lin et al., 2017) between each token's predicted label and the golden label:

$$\mathcal{L}_{\phi}(\mathcal{C}) = \sum_{i=1}^{N} -(1 - p_{c_i,e_j})^{\gamma} log(p_{c_i,e_j}) \tag{3}$$

And the training objective of the argument extraction model is to minimize the negative loglikelihood over all subtasks $\mathcal{S}_{E_k,\mathcal{C}}$ of the input sample $\mathcal{C}$:

$$\begin{aligned} &\mathcal{L}_{\varphi}(\mathcal{C}) = -\sum_{k=1}^{K} log\ p(\mathcal{G}_{e_j,\mathcal{C}'_k} | \mathcal{X}_{e_j,\mathcal{C}'_k}) \\ &\mathcal{X}_{e_j,\mathcal{C}'_k} = [\mathcal{P}_{e_j}; [SEP]; \mathcal{C}'_k] \\ &\mathcal{C}'_k = \{c_1, ..., \text{<trg>}, c_i, \text{</trg>}, ..., c_N\} \end{aligned} \tag{4}$$

Finally, during the joint bridging training phase, the loss of the whole model is:

$$\mathcal{L}(\mathcal{D}) = \sum_{t=1}^{|\mathcal{D}|} (\mathcal{L}_{\phi}(\mathcal{C}_t) + \mathcal{L}_{\varphi}(\mathcal{C}_t)) \tag{5}$$

Implementation details are shown in Appendix B.

4 Experiment

4.1 Setup

Datasets. We evaluate our methods on three widely used event extraction benchmarks, ACE05-E, ACE05-E$^+$ and ERE-EN. Both of the ACE datasets are from the Automatic Content Extraction 2005 (ACE 2005) dataset constructed by Doddington et al. (2004), and the ERE-EN is from ERE dataset (Song et al., 2015). All their details can be found in Appendix A.

Evaluation Metrics. We consider the same criteria following prior works (Liu et al., 2022b; Hsu et al., 2021; Lu et al., 2021b) and report the Precision *P*, Recall *R* and F1 score *F1* of trigger and argument. Meanwhile, we consider that a trigger is correctly identified if its offset matches the ground truth (**Trg-I**) and is correctly classified if its event matches the ground truth as well (**Trg-C**). In the same way, we consider an argument is correctly identified if its offset matches the ground truth (**Arg-I**) and is correctly classified if its event type and role label all matches the ground truth as well (**Arg-C**).

Compared Baselines. We consider several representative works as our baselines, including both classification-based and generation-based methods, and some of their implementation details are listed in Appendix B.

we consider the following classification-based models:

- **DYGIE++**(Wadden et al., 2019b), a BERT-based model learns shared span representations between multi-tasks and updates span representations through dynamic graph propagation layers.
- **GAIL**(Zhang et al., 2019), a RL model jointly extracting entity and event.
- **OneIE**(Lin et al., 2020a), an end-to-end IE system that employs designed global feature and beam search, was state-of-the-art.
- **BERT_QA**(Du and Cardie, 2020c), an MRC-based model views EE tasks as a question-answering problem with multi-turns of separated QA pairs and learns a classifier to indicate the position of the predicted span.
- **MQAEE**:(Li et al., 2020b), a multi-turn question answering system.

We also consider the following generation-based models:

- **TANL**:(Paolini et al., 2021), a method treats EE tasks as translation tasks in a trigger-argument pipeline.
- **BART-GEN**(Paolini et al., 2021), a template-based conditional generation method to generate corresponding arguments in a predefined format.
- **TEXT2EVENT**(Lu et al., 2021b), a sequence-to-structure generation method that converts the input sequence to a tree-like event structure.

- **DEGREE-E2E**(Hsu et al., 2021), an end-to-end conditional generation method that uses natural sentences as discrete prompts, which makes it easier for them to leverage label semantics.

- **GTEE-DYNPREF**(Liu et al., 2022b), an end-to-end conditional genration method with dynamic prompts and trained with prefix-tuning.

4.2 Main Results

For each dataset, we train our model with 5 different random seeds, and report the means of the corresponding results.

Table 1 compares our approach HDGSE[3] with all the baselines on ACE05-E, while Table 2 illustrates the results compared with the state-of-the-art on ACE05-E$^+$ and ERE-EN. As shown, our model achieves strong performance and outperforms all the baselines on two datasets of ACE 2005. At the same time, our model also performs competitively on ERE-EN, second only to GTEE-DYNPREF (Lin et al., 2020b).

For event detection, our model achieves an absolute Trg-C F1 improvement of $+5.8\%$, $+2.9\%$ on ACE05-E and ACE05-E$^+$ respectively compared to DEGREE-E2E (Lin et al., 2020b) and GTEE-DYNPRE (Liu et al., 2022b) that also utilizes joint training but use the generative method for ED, indicating that the classification-based method has more advantages in event detection than the generative-based method. On the other hand, our model also shows a significant improvement over the classification-based methods, e.g., a gain of 4.3% on ACE05-E compared to ONEIE (Lin et al., 2020b). As we will show later in our experiments, part of this improvement is due to the bridging mechanism.

For event argument extraction, our approach outperforms the previous best methods, ONEIE (Lin et al., 2020b) and DEGREE-E2E (Lin et al., 2020b), with absolute Arg-C F1 gains of $+1\%$, $+1.4\%$ on ACE05-E, ACE05-E$^+$ respectively. Moreover, it outperforms the best generative method DEGREE-E2E (Lin et al., 2020b) on ACE05-E and ERE-EN with absolute Arg-C F1 gains of $+2\%$, $+3.9\%$. Such improvements demonstrate the effectiveness of maintaining different contextual representations for ED and EAE, and incorporating trigger information into the EAE model. Although our model performs second only to GTEE-DYNPRE (Liu et al., 2022b) on ERE-EN, it outperforms GTEE-DYNPRE on all other datasets, indicating that our model has better robustness on different datasets.

5 Analysis

5.1 Selection of Task Models

We further investigated the impact of using classification-based or generation-based models for the ED task and the EAE task, respectively, to gain insight into the advantages and disadvantages of these two approaches for event extraction tasks.

Event Detection: Classification vs Generative. We first compare the two paradigms on the event detection task and list the results in Table 3. The experimental details can be found in Appendix B. We observe that the generation-based model is significantly worse than the classification-based model on this task. One possible reason is that generation-based models pay more attention to the global features of sentences and have fewer advantages in ED, which require trigger tokens and their local context. Moreover, the classification-based model can directly provide the location of trigger spans, which is more helpful for EAE. Therefore, the classification-based paradigm is more suitable for the ED task than the generation-based one.

Table 3: The event detection results of the classification-based and generation-based approach.

ED Paradigm	ACE05-E		ACE05-E$^+$		ERE-EN	
	Trg-I	**Trg-C**	**Trg-I**	**Trg-C**	**Trg-I**	**Trg-C**
Classification-based	81.9	77.8	80.8	76.9	75.9	65.7
Generation-based	67.8	45.3	66.8	45.6	61.4	37.1

Event Argument Extraction: Classification vs Generative. We eliminated the trigger detection task in order to investigate the impact of different paradigms on event argument extraction. Given golden triggers as input, we implemented several classification and generation paradigm baselines for EAE. The experimental results are shown in Table 4. The generative approach performs as well as the classification-based model under the standard setting (with trigger marker). And several template-based generative approaches, such as GTEE-BASE (Liu et al., 2022b), BART-GEN (Li et al., 2021b), DEGREE-EAE (Lin et al., 2020b) and HDGSE[3], perform significantly better.

In particular, DEGREE-EAE performs best under the gold trigger marker setting. This is mainly due to the fact that DEGREE-EAE incorporates more knowledge of events in the prompt design,

Table 1: Results on ACE05-E for event extraction. The first group is the classification-based methods, and the second is the generation-based methods. For each group, we bold the highest F1 scores for Trg-C and Arg-C, and the second highest is bold in italics.

Model	Trg-C			Arg-C

such as "Event Type Description" and "Event Keywords". Interestingly, our final results on EE are better than DEGREE-EAE because (1) DEGREE-EAE uses a generative paradigm in the event detection task, (2) shares the contextual representation of the encoder between two tasks, which indirectly proves the correctness of our hypothesis.

5.2 Effect of Bridging Mechanisms

We mentioned in Section 3.2 that trigger marker and contextual representation fusion were used to establish a bridge connection for the two independent encoders. This section will look closely at these two components to see how they affect our model.

We remove the possible connection modules between two independent encoders under the settings of Joint and Pipeline, respectively, and present the experimental results in Table 5. It can be seen that removing the trigger marker causes significant damage to the model under both training paradigms. Although contextual representation can also improve the model's performance, the overall improvement space is not as ample as the trigger marker. Further, when we remove both of them, as shown in Table 5, the F1 score of Trg-C remains at a very high level for the three datasets, which are still SOTA at ACE05-E and ACE05-E$^+$. However, at the same time, the F1 of Arg-C is significantly reduced and no longer SOTA. These phenomena show that the effect of ED representing the upper bound of EAE and the bridging mechanism can help EAE approach this upper bound and even improve the result of ED in reverse. That is where the main contribution of the bridging mechanism lies.

From another point of view, when only comparing the training paradigms, it can be found that loss sharing during joint training can significantly improve the model's overall performance, so the Joint results are generally better than those of Pipeline, which proves the effectiveness of our two-stage training program.

We also design several contrast schemes for the fusion way of contextual representation. In Section 3.2, we discussed two approaches, one is to assign the mapped contextual representation to the trigger

Table 4: Results of event argument extraction. Models predict arguments based on the given gold triggers. *We report the numbers from the original paper. †We reproduce the results.

- remove marker trigger	77.9	74.2	40.5	38.6	79.2	75.7	46.5	44.7	73.4	62.1	29.7	28.6

marker, and the other is to directly add with the trigger representation learned by the language model during pre-training. In addition to the above two, we further explore what results can be obtained by directly fusing the contextual representation without mapping. Table 6 lists the experimental results. Note that directly fusing the contextual representation of ED and EAE without mapping causes significant damage to the model, which is even worse than the direct deletion of the contextual representation in Table 5. That proves the contextual representations learned by ED and EAE are different and preferably not directly shared. On the other hand, the performance of mapped contextual representations is almost the same regardless of whether they are fused with trigger markers or triggers. We believe this is because contextual representations provide more semantic information, which is not affected by the difference in fusion objects.

Table 6: Study on the fusion form of contextual representation. Models predict arguments based on the predicted trigger.

HDGSE^3 (Joint)	ACE05-E		ACE05-E$^+$		ERE-EN	
	Arg-I	Arg-C	Arg-I	Arg-C	Arg-I	Arg-C
trigger marker	60.3	57.8	59.5	57.3	56.5	53.5
- w/o mapping	59.0	56.5	59.9	57.7	55.1	51.7
trigger	60.1	57.8	60.2	58.2	56.5	53.5
- w/o mapping	58.6	55.4	58.0	55.5	55.0	50.2

5.3 Prompts and Templates

Generative-based event extraction methods tend to be sensitive to the prompts and templates used (Liu et al., 2022a). Since our model adopts a generative method for EAE, we further investigated the robustness of our model when using different prompts and templates.

Necessity of Type Instruction. We first consider replacing the static type instruction such as "*The Event Type is Meet*" but still providing explicit event type information to the model. So we refer to Zhong and Chen (2021) and use <trigger:Event type> and </trigger:Event type> instead of the original type instruction. The experimental results in Table 7 show that using sentences in natural language to describe event types will perform better than replacing them with tokens. Therefore, we still keep this setting in our experiments.

Table 7: Study on the necessity of type instruction. r/ stands for replace, and we replaced type instruction with <trigger:Event type> and </trigger:Event type>.

HDGSE^3-EAE (Gold Trg)	ACE05-E		ACE05-E$^+$		ERE-EN	
	Arg-I	Arg-C	Arg-I	Arg-C	Arg-I	Arg-C
w/ Type Instruction	73.8	70.2	72.1	69.0	76.4	72.0
r/ Type Instruction	72.8	69.9	71.6	67.4	75.0	69.4

Sensitivity to Template Design. Our method requires templates with slotted values to assist

EAE, so we designed several templates to explore whether the model is robust under different template Settings. We designed three types of templates from low to high semantic integrity and the detailed construction details can be found in Appendix C. We put all three types of templates involved in ACE 2005 and ERE-EN in Tables 13 and 14, and the Table 8 show the experimental results. Templates without semantics perform worst, indicating that the model is still sensitive to the template's design. However, the weak and strong semantic integrity results are close, indicating that the model still has good robustness to sentences with certain linguistic logic. Weak semantic integrity templates can ensure the model's performance, whether manually designed or model-generated. The experiments in this paper are all done based on templates with weak semantic integrity, and we leave generating templates from models for the future.

Table 8: Study on the effect of different template constructing rules. Models predict arguments based on the given gold trigger.

HDGSE^3-EAE (Gold Trg)	**ACE05-E**		**ACE05-E$^+$**		**ERE-EN**	
	Arg-I	**Arg-C**	**Arg-I**	**Arg-C**	**Arg-I**	**Arg-C**
No semantic integrity	67.7	64.2	66.3	63.0	74.9	70.2
Weak semantic integrity	73.8	70.2	72.1	69.0	76.4	72.0
Strong semantic integrity	73.1	70.4	70.7	69.1	76.6	71.5

6 Conclusion

In this paper, we revisit the classification-based and generation-based event extraction methods and empirically propose a simple but robust hybrid event extraction scheme. Our model learns two independent encoders for event detection and event argument extraction and uses simple trigger marker and contextual representation fusion to bridge training jointly, for which we devise a two-stage training approach. We conduct extensive analyses to understand the superior performance of our approach. These analyses verify the effectiveness of using the classification model and the generative model to learn the contextual representation of event detection and event argument extraction separately and validate the importance of taking the result of event detection as the input of event argument extraction. We hope this simple model will serve as a strong benchmark for end-to-end event extraction and make us rethink the value of a shared representation of multi-tasks.

Limitations

Our findings in this paper only verified in event extraction. It will be more exciting and valuable if migrated to other multi-task problems. We will leave that for future work.

A Datasets

ACE 2005 has 599 annotated English documents, 33 event types, and 22 argument roles. ERE contains 458 English documents, 38 event types, and 21 argument roles. Following previous work (Zhang et al., 2019; Wadden et al., 2019b; Du and Cardie, 2020c; Lin et al., 2020b; Lu et al., 2021b; Hsu et al., 2021), we use the same preprocess method and obtain three datasets, ACE05-E, ACE05-E$^+$, and ERE-EN, shown in Table 9. Compared to ACE05-E, both ACE05-E$^+$ and ERE-EN contain pronoun roles and multi-token event triggers.

Table 9: Dataset statistics.

Dataset	Split	Sents	Events	Roles
ACE05-E	Train	17,172	4202	4859
	Dev	923	450	605
	Test	832	403	576
ACE05-E$^+$	Train	19,216	4419	6607
	Dev	901	468	759
	Test	676	424	689
ERE-EN	Train	14,736	6208	8924
	Dev	1209	525	730
	Test	1163	551	822

B More Implementation details

Main Settings.

Table 10: Hyperparameters for two-stage of training, with the first phase being separate independent training for the two tasks and the second phase being joint bridging training.

Name	Independent Training		Joint Bridge Training
	ED (BERT)	EAE (BART)	EE (BERT+BART)
Learning rate	2e-5	2e-5	5e-7
Batch size	1*32	1*32	1*32
Epochs	40	40	30
Max sequence length	185 | 325	Id.	Id.
Max output length	-	50	Id.
Weight decay	1e-5	1e-5	1e-5
Gradient clip	5.0	5.0	5.0
Warm-up ratio	10%	10%	10%
Loss	Focal	Cross-entropy	-
Focal gamma	3	-	-
Gen loss	-	Sum	-

We used the hugging face implementation of BERT-large and BART-large and optimized our models by AdamW (Loshchilov and Hutter, 2019). In addition, we use the two-layer fully connected layer with tanh as the intermediate activation function as the mapping function for the contextual representation. The dimension of the hidden layer is 1024. GELU (Hendrycks and Gimpel, 2016) also activates the output before being added to the other representations.

We first train the two models independently so that they can learn the contextual representation of event detection and event argument extraction tasks, respectively. Then in the joint bridging training stage, we also set different learning rates for different models. However, because their loss has decreased to the same magnitude in the process of independent training, the final learning rates obtained through grid search are the same size. We optimized the parameters with grid search, in the independent training: training epoch 40, learning rate $\in$ {1e-5, 2e-5, 1e-4}, training batch size with gradient accumulation $\in$ {1*8, 1*32, 1*64}, focal loss gamma $\in$ {1, 2, 3, 4, 5}, generation loss $\in$ {mean, sum}. As for the joint bridge training, we only used grid search to find the optimal learning rate $\in$ {5e-8, 5e-7, 5e-6, 2e-5} and fixed other parameters: training epoch 30, training batch size with gradient accumulation 1*32, focal loss gamma 3, generation loss "sum." Table 10 shows the final optimal parameter combination. Each experiment was conducted on NVIDIA GeForce RTX 3090 Core GPU 24GB. It is worth noting that the ERE-EN dataset has more noise than ACE 2005, so the model needs a larger learning rate on ERE-EN than that in ACE 2005. In other words, when trained independently on the ERE-EN dataset, the learning rates of BERT and BART are 3e-5 and 4e-5, respectively. In joint bridge training, the learning rates are 7e-7 and 8e-7, respectively.

While Inferring, our generative model generates sequences by greedy search, and the maximum sequence length is set according to dataset statistics, which is a bit larger than the length of the longest ground truth, for ACE05-E, ACE05-E$^+$, ERE-EN, its 50 tokens. As for the input length, the ACE05-E and ACE05-E$^+$ are 185 tokens, the ERE-EN is 325 tokens, and the detection model is consistent with the generative model. Besides, we parse the event records by template matching and slot mapping according to the ontology $\mathcal{O}$, as shown in Algorithm 1.

Reproduce Baselines. Among the baselines we selected, we tried to reproduce BERT_QA, BART-GEN, DEGREE, and GTEE-BASE. They all got similar results to those in the original paper report except for DEGREE and BERT_QA. Therefore, we used the experimental results reported in (Li et al., 2021b) and (Lin et al., 2020b) in Section 5.1, while the above two models used our experimental results. The hyperparameter Settings are listed as follows:

Table 11: Hyperparameter Settings for BART-GEN for our implementation and given in the original paper.

Parameter	Li et al. (2021b)	Our Implementation
Base model	BART-large	BART-large
Learning rate	[1e-5, 3e-5]	2e-5
Scheduler	Linear (without warmup)	Id.
Batch size	2*8	4*4
Max sequence length	512	512
Training epochs	[3,6]	20
Beam size	4	4

Algorithm 1 Extracting arguments from predicted template

```
Input: Predicted template $\mathcal{PT}$, Predefined template $\mathcal{GT}$, event type $\mathcal{E}$, Predefined Ontology $\mathcal{O}$ {e.g. $\mathcal{PT}$ is "Kelly met with officials in Seoul place", $\mathcal{GT}$ is "<arg1> met with <arg2> in <arg3> place"}
Initialization: predicted argument list $\mathcal{A}$, the pointers $p_{ptr} \leftarrow 0, t_{ptr} \leftarrow 0$
Split $\mathcal{PT}$ and $\mathcal{GT}$ into token lists, and ensure that <arg\d*> is a whole
while $p_{ptr} < |\mathcal{PT}|$ and $t_{ptr} < |\mathcal{GT}|$ do
  if $\mathcal{GT}\,[t_{ptr}]$ is <arg\d*> then
    $n \leftarrow$ \d*
    $role\_name = \mathcal{O}\,[\mathcal{E}]\,[n]$
  end if
  if $\mathcal{PT}\,[p_{ptr}]$ is <arg> then
    $p_{ptr} \leftarrow p_{ptr} + 1, t_{ptr} \leftarrow t_{ptr} + 1$
  else
    $arg_{start} = p_{ptr}, nxt_{ptr} = p_{ptr} + 1$
    while $nxt_{ptr} < |\mathcal{GT}|$ do
      if $\mathcal{GT}\,[nxt_{ptr}] ==$ <arg\d*> then
        Break
      end if
      $nxt_{ptr} \leftarrow nxt_{ptr} + 1$
    end while
    while $p_{ptr} < |\mathcal{PT}|$ do
      if $\mathcal{PT}\,[p_{ptr}] == \mathcal{GT}\,[t_{ptr} + 1]$ and $\mathcal{PT}\,[p_{ptr} : p_{ptr} + nxt_{ptr} - t_{ptr} - 1] == \mathcal{GT}\,[t_{ptr} + 1 : nxt_{ptr}]$ then
        Break
      end if
      $p_{ptr} \leftarrow p_{ptr} + 1$
    end while
    $\mathcal{A} \cup [\mathcal{E}, \mathcal{PT}\,[arg_{start} : p_{ptr}]\,, role\_name]$
  end if
end while
Output: $\mathcal{A}$
```

Table 12: Hyperparameter Settings for GTEE-BASE for our implementation and given in the original paper.

Parameter	Liu et al. (2022b)	Our Implementation
Base model	BART-large	BART-large
Learning rate	1e-5	2e-5
Batch size	32*8	4*8
Max sequence length	-	185 | 320
Max output length	-	78 | 100
Training epochs	40	40
Weight decay	1e-5	1e-5
Gradient clip	5.0	5.0
Warm-up ratio	10%	10%
Negative sample ratio	4%	3%

- **BART-GEN.** We follow the settings of the original paper when reproducing BART-GEN. However, there are some differences, and we list them in Table 11. In addition, since Li et al. (2021b) only implemented ACE05-E, we set the learning rate by referring to our model when implementing ACE05-E$^+$ and ERE, and other parameters were unchanged.

- **GTEE-BASE.** Since Liu et al. (2022b) have not open-sourced the code, we reproduced GTEE-BASE by ourselves with the hyperparameter settings shown in Table 12. Here, our negative sample ratio is $\frac{1}{evet\ type\ num}$, which means that ACE05-E and ACE05-E$^+$ are $\frac{1}{33}$ because they have 33 event types, and ERE-EN is $\frac{1}{38}$ because it has 38 event types. They all round off to a ratio of about 3%.

The hardware environment of these experiments is the same as that of HDGSE^3, as mentioned in the previous paragraph. On the other hand, the python environment is strictly set up according to the requirements of open-source codes.

Event Detection. In Section 5.1, we implement the classification-based and generation-based methods on the event detection task. As the classification-based approach, we used the event detection model of our HDGSE^3 in Section 3.2. Meanwhile, we use a template-based generative model for the generation-based approach, analogous to our event argument extraction model, but with templates and no prompts. We concatenate multiple templates for input sequences with multiple event mentions so that the model generates all event mentions sequentially. The template we used here was "Event type: <event> Trigger: <trg>." The experimental hyperparameters are consistent with those of main settings.

C Template Constructing

In this section, we show the three templates mentioned in Section 5. Their construction strategy is as follows:

- **No semantic integrity.** The first template is the least semantically complete; we take the role's name as a hint and add it before the argument slot, while the order of argument placement is random. For example, "Agent <arg1> Person <arg2> Place <arg3>". This template can only tell us the `Justice:Release-Parole` event's argument roles, but it does not form a natural sentence and has no semantic information.
- **Weak semantic integrity.** The second type of template maintains weak semantic integrity, and we use ontologies predetermined by Li et al. (2021c) as such templates, such as "<arg1> released or paroled <arg2> in <arg3> place". We can roughly understand that this is an `Justice:Release-Parole` event because the template mentions the two keywords "released or paroled." But this type of template misses the subject and role information, and the model may be confused. For example, "<arg1>" is not restricted to "Person" in the template, and the model may be likely to predict an "Institution" for it. Hence, the semantics of this kind of template is incomplete.
- **Strong semantic integrity.** The third template combines the advantages of the above two templates. It hints at the roles and ensures the sentence's semantic integrity. We refer to "APEX" defined by Wang et al. (2022), consider all roles to paraphrase each event, and arrange argument slots after each role, e.g., "an Entity <arg1> ends its custody of a Person <arg2> at a Place <arg3>". The sentence is semantically complete after removing slots.

ACE 2005 and ERE-EN are listed in Table 13 and Table 14, respectively.

Table 13: All templates of ACE05-E and ACE05-E^{+} used in the main and ablation experiments in this paper.

Event	Type	Template
Movement:Transport	1	<arg1> transported <arg2> in <arg3> vehicle from <arg4> place to <arg5> place
	2	Agent <arg1> Artifact <arg2> Vehicle <arg3> Origin <arg4> Destination <arg5>
	3	an Agent <arg1> moves an Artifact <arg2> from Origin <arg4> to Destination <arg5> with Vehicle <arg3> at Price
Personnel:Elect	1	<arg1> elected <arg2> in <arg3> place
	2	Entity <arg1> Person <arg2> Place <arg3>
	3	a candidate Person <arg2> wins an election by voting Entity <arg1> at a Place <arg3>
Personnel:Start-Position	1	<arg1> started working at <arg2> organization in <arg3> place
	2	Person <arg1> Entity <arg2> Place <arg3>
	3	a Person <arg1> begins working for an Entity <arg2> or change office at a Place <arg3>
Personnel:Nominate	1	<arg1> nominated <arg2>
	2	Agent <arg1> Person <arg2>
	3	a Person <arg2> is nominated for a new position by another Agent <arg1> at a Place
Personnel:End-Position	1	<arg1> stopped working at <arg2> organization in <arg3> place
	2	Person <arg1> Entity <arg2> Place <arg3>
	3	a Person <arg1> stops working for an Entity <arg2> or change office at a Place <arg3>
Conflict:Attack	1	<arg1> attacked <arg2> hurting <arg5> victims using <arg3> instrument at <arg4> place
	2	Attacker <arg1> Target <arg2> Instrument <arg3> Place <arg4> Victim <arg5>
	3	An Attacker <arg1> physically attacks a Target <arg2> with Instrument <arg3> at a Place <arg4> hurting Victim <arg5>
Contact:Meet	1	<arg1> met with <arg2> in <arg3> place
	2	Entity <arg1> Entity <arg2> Place <arg3>
	3	one Entity <arg1> and another Entity <arg2> come together at same Place <arg3> and interact in person
Life:Marry	1	<arg1> married <arg2> in <arg3> place
	2	Person <arg1> Person <arg2> Place <arg3>
	3	one Person <arg1> and another Person <arg2> are married at a Place <arg3>
Transaction:Transfer-Money	1	<arg1> gave money to <arg2> for the benefit of <arg3> in <arg4> place
	2	Giver <arg1> Recipient <arg2> Beneficiary <arg3> Place <arg4>
	3	transfer Money from the Giver <arg1> to the Beneficiary <arg3> or Recipient <arg2> at a Place <arg4>
Conflict:Demonstrate	1	<arg1> demonstrated at <arg2> place
	2	Entity <arg1> Place <arg2>
	3	Entity <arg1> come together in a Place <arg2> to protest or demand official action
Business:End-Org	1	<arg1> organization shut down at <arg2> place
	2	Org <arg1> Place <arg2>
	3	an Organization Org <arg1> goes out of business at a Place <arg2>
Justice:Sue	1	<arg1> sued <arg2> before <arg3> court or judge in <arg4> place
	2	Plaintiff <arg1> Defendant <arg2> Adjudicator <arg3> Place <arg4>
	3	Plaintiff <arg1> initiate a court proceeding to determine the liability of a Defendant <arg2> judge by Adjudicator <arg3> at a Place <arg4>
Life:Injure	1	<arg1> injured <arg2> with <arg3> instrument in <arg4> place
	2	Agent <arg1> Victim <arg2> Instrument <arg3> Place <arg4>
	3	a Victim <arg2> experiences physical harm from Agent <arg1> with Instrument <arg3> at a Place <arg4>
Life:Die	1	<arg1> killed <arg2> with <arg3> instrument in <arg4> place
	2	Agent <arg1> Victim <arg2> Instrument <arg3> Place <arg4>
	3	life of a Victim <arg2> ends by an Agent <arg1> with Instrument <arg3> at a Place <arg4>
Justice:Arrest-Jail	1	<arg1> arrested <arg2> in <arg3> place
	2	Agent <arg1> Person <arg2> Place <arg3>
	3	the Agent <arg1> takes custody of a Person <arg2> at a Place <arg3>
Contact:Phone-Write	1	<arg1> communicated remotely with <arg2> at <arg3> place
	2	Entity <arg1> Entity <arg2> Place <arg3>
	3	phone or written communication between one Entity <arg1> and another Entity <arg2> at a Place <arg3>
Transaction:Transfer-Ownership	1	<arg1> gave <arg4> to <arg2> for the benefit of <arg3> at <arg5> place
	2	Seller <arg1> Buyer <arg2> Beneficiary <arg3> Artifact <arg4> Place <arg5>
	3	buying selling loaning borrowing giving receiving of Artifact <arg4> from Seller <arg1> to Buyer <arg2> or Beneficiary <arg3> at a Place <arg5> at Price
Business:Start-Org	1	<arg1> started <arg2> organization at <arg3> place
	2	Agent <arg1> Org <arg2> Place <arg3>
	3	an Agent <arg1> create a new Organization Org <arg2> at a Place <arg3>
Justice:Execute	1	<arg1> executed <arg2> at <arg3> place
	2	Agent <arg1> Person <arg2> Place <arg3>
	3	the life of a Person <arg2> is taken by an Agent <arg1> at a Place <arg3>
Justice:Trial-Hearing	1	<arg1> tried <arg2> before <arg3> court or judge in <arg4> place
	2	Prosecutor <arg1> Defendant <arg2> Adjudicator <arg3> Place <arg4>
	3	a court proceeding initiated to determine the guilty or innocence of the Defendant <arg2> Person with Prosecutor <arg1> and Adjudicator <arg3> at a Place <arg4>
Life:Be-Born	1	<arg1> was born in <arg2> place
	2	Person <arg1> Place <arg2>
	3	a Person <arg1> is born at a Place <arg2>
Justice:Charge-Indict	1	<arg1> charged or indicted <arg2> before <arg3> court or judge in <arg4> place
	2	Prosecutor <arg1> Defendant <arg2> Adjudicator <arg3> Place <arg4>
	3	a Defendant <arg2> is accused of a crime by a Prosecutor <arg1> for Adjudicator <arg3> at a Place <arg4>
Justice:Convict	1	<arg1> court or judge convicted <arg2> in <arg3> place
	2	Adjudicator <arg1> Defendant <arg2> Place <arg3>
	3	an Defendant <arg2> found guilty of a crime by Adjudicator <arg1> at a Place <arg3>
Justice:Sentence	1	<arg1> court or judge sentenced <arg2> in <arg3> place
	2	Adjudicator <arg1> Defendant <arg2> Place <arg3>
	3	the punishment for the Defendant <arg2> is issued by a state actor Adjudicator <arg1> at a Place <arg3>
Business:Declare-Bankruptcy	1	<arg1> declared bankruptcy at <arg2> place
	2	Org <arg1> Place <arg2>
	3	Organization Org <arg1> request legal protection from debt collection at a Place <arg2>
Justice:Release-Parole	1	<arg1> released or paroled <arg2> in <arg3> place
	2	Entity <arg1> Person <arg2> Place <arg3>
	3	an Entity <arg1> ends its custody of a Person <arg2> at a Place <arg3>
Justice:Fine	1	<arg1> court or judge fined <arg2> at <arg3> place
	2	Adjudicator <arg1> Entity <arg2> Place <arg3>
	3	a Adjudicator <arg1> issues a financial punishment Money to an Entity <arg2> at a Place <arg3>
Justice:Pardon	1	<arg1> court or judge pardoned <arg2> at <arg3> place
	2	Adjudicator <arg1> Defendant <arg2> Place <arg3>
	3	an Adjudicator <arg1> lifts a sentence of Defendant <arg2> at a Place <arg3>
Justice:Appeal	1	<arg1> appealed to <arg2> court or judge at <arg3> place
	2	Plaintiff <arg1> Adjudicator <arg2> Place <arg3>
	3	the decision for Defendant of a Plaintiff <arg1> is taken to a higher Place <arg3> for Adjudicator <arg2> review with Prosecutor
Justice:Extradite	1	<arg1> extradited <arg2> from <arg3> place to <arg4> place
	2	Agent <arg1> Person <arg2> Origin <arg3> Destination <arg4>
	3	a Person <arg2> is sent by an Agent <arg1> from Origin <arg3> to Destination <arg4>
Life:Divorce	1	<arg1> divorced <arg2> in <arg3> place
	2	Person <arg1> Person <arg2> Place <arg3>
	3	one Person <arg1> and another Person <arg2> are officially divorced at a Place <arg3>
Business:Merge-Org	1	<arg1> organization merged with <arg2> organization
	2	Org <arg1> Org <arg2>
	3	two or more Organizations Org <arg1> come together to form a new organization Org <arg2> at a Place
Justice:Acquit	1	<arg1> court or judge acquitted <arg2>
	2	Adjudicator <arg1> Defendant <arg2>
	3	a trial of Defendant <arg2> ends but Adjudicator <arg1> fails to produce a conviction at a Place

Table 14: All templates of ERE-EN used in the main and ablation experiments in this paper.

Event Type	Type	Template
Conflict:Attack	1	<arg1> attacked <arg2> using <arg3> instrument at <arg4> place
	2	Attacker <arg1> Target <arg2> Instrument <arg3> Place <arg4>
	3	An Attacker <arg1> physically attacks a Target <arg2> with Instrument <arg3> at a Place <arg4>
Justice:Acquit	1	<arg1> court or judge acquitted <arg2> at <arg3> place
	2	Adjudicator <arg1> Defendant <arg2> Place <arg3>
	3	a trial of Defendant <arg2> ends but Adjudicator <arg1> fails to produce a conviction at a Place <arg3>
Personnel:Elect	1	<arg1> elected <arg2> in <arg3> place
	2	Agent <arg1> Person <arg2> Place <arg3>
	3	a candidate Person <arg2> wins an election by voting Entity <arg1> at a Place <arg3>
Justice:Release-Parole	1	<arg1> released or paroled <arg2> in <arg3> place
	2	Agent <arg1> Person <arg2> Place <arg3>
	3	an Entity <arg1> ends its custody of a Person <arg2> at a Place <arg3>
Personnel:Nominate	1	<arg1> nominated <arg2> at <arg3> place
	2	Agent <arg1> Person <arg2> Place <arg3>
	3	a Person <arg2> is nominated for a new position by another Agent <arg1> at a Place <arg3>
Justice:Appeal	1	<arg1> appealed to <arg2> court or judge sentenced <arg3>
	2	Prosecutor <arg1> Adjudicator <arg2> Defendant <arg3>
	3	the decision for Defendant <arg3> of a Plaintiff is taken to a higher Place for Adjudicator <arg2> review with Prosecutor <arg1>

Abstract

Multi-hop reasoning, a prevalent approach for query answering, aims at inferring new facts along reasonable paths over a knowledge graph. Reinforcement learning (RL) methods can be adopted by formulating the problem into a Markov decision process. However, common suffering within RL-based reasoning models is that the agent can be biased to spurious paths which coincidentally lead to the correct answer with poor explanation. In this work, we take a deep dive into this phenomenon and define a metric named Path Spuriousness (PS), to quantitatively estimate to what extent a path is spurious. Guided by the definition of PS, we design a model with a new reward that considers both answer accuracy and path reasonableness. We test our method on five datasets and experiments reveal that our method considerably enhances the agent's capacity to prevent spurious paths while keeping comparable to state-of-the-art performance.

1 Introduction

Knowledge Graph (KG), a set of structured facts about real-world human knowledge, is utilized in numerous downstream NLP applications (Hildebrandt et al., 2020; Zhang and Yao, 2022; Xu et al., 2021; Ma et al., 2021). Common suffering affecting many downstream tasks is KG incompleteness. A variable amount of facts are missing in practical KGs. KG reasoning, the process to derive new knowledge from KG (Ji et al., 2022; Zhang et al., 2022; Huang et al., 2022), is the way to address KG completion problem. A prevailing approach for KG reasoning is incorporating KG embedding (KGE), which maps entities and relations into a vector space (Bordes et al., 2013). Embedding-based models have great power in expressing semantic similarity of entities and relations, but usually lack explainability due to the high-dimension representation (Chen et al., 2020; Heo et al., 2022).

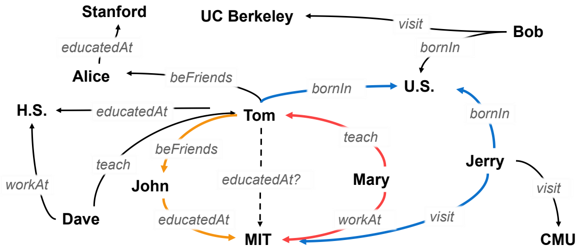

Figure 1: An example KG (we use *H.S.* to indicate a certain high school for short). Supposing the query is <*Tom, educatedAt, ?*> and *MIT* is a correct answer, three paths leading to *MIT* are of different PS.

An alternative approach is multi-hop reasoning, also referred to as path-based models (Lin et al., 2018), which infers new facts along existing paths in KG. Multi-hop reasoning offers explanations for its predictions by taking advantage of reasoning paths. Recently, reinforcement learning (RL) has been applied to multi-hop reasoning (Xiong et al., 2017). RL-based methods train an agent to walk over the KG and search for a path leading to the answer (Das et al., 2018). They have drawn surging attention in the past few years for their good prediction accuracy and excellent explainability.

However, most prevalent RL-based models are suffering from the spurious path problem (Guu et al., 2017). A spurious path reaches a correct answer merely by coincidence and has no logical relevance with its prediction, such as the blue path in Figure 1: we shouldn't say *Tom* was educated at *MIT* just because there exists one person (*i.e.*, *Jerry*) who was born in the same country (*i.e.*, *U.S.*) with *Tom* and happened to visit *MIT* before.

Multi-hop reasoning is a typical sparse reward scenario, where all actions except the final one will get no feedback during the decision process. That is to say, after the agent reached the correct answer following a spurious path, all actions along the decision trajectory will get positive rewards even if they are totally irrelevant to the query. As a

consequence, the agent will be biased toward those wrong actions (Guu et al., 2017).

The spurious path problem causes severe damage to the explainability of RL-based models when paths found by the agent are needed to serve as evidence to explain the answer. Moreover, spurious paths may mislead the agent to learn a wrong policy and further harm the generalization ability of the model. Although some studies have noticed the spurious path problem and provided instinctive solutions, such as action drop (Lin et al., 2018) and rule guider (Lei et al., 2020; Hou et al., 2021), a quantitative estimation is still absent.

To address the above-mentioned problem, we define a new metric called *Path Spuriousness* (PS) to measure to what extent a path is spurious. The inspiration is that a spurious path is not a fake path, but an adventitious path offering the accurate answer for a certain query. That is to say, if we randomly exchange intermediate entities of the path and keep the relation order, it is unlikely to get the correct prediction for the same query. With PS, we can reflect the reasonableness of predictions made by multi-hop reasoning models. Specifically, answers obtained by following paths with low PS are much more reasonable and explainable than those by following paths with high PS.

With the definition of PS, we put forward a path spuriousness-aware reward for RL-based multi-hop reasoning models. Combined with correctness-guided rewards, our new reward leads the agent to not only obtain effective answers but also offer high-quality reasoning paths.

Our major contributions are concluded as follows: (1) We first propose a quantitative metric PS to measure the spuriousness of reasoning paths. (2) We design a new sophisticated reward shaping method by incorporating correctness-guided reward and PS-guided reward, which leads the agent to find effective answers following reasonable paths. (3) We first offer an empirical evaluation of the path spuriousness of multi-hop reasoning methods. Experiments show that our approach has a great improvement in avoiding spurious paths while keeping the prediction accuracy.

2 Related Work

In this section, we give outlines of two main related areas and discuss their connection to our method.

2.1 Knowledge Graph Embedding

KG embedding translates semantic features of entities and relations to vector space, to give answers directly by operations over query vectors. TransE (Bordes et al., 2013) did seminal work in leveraging KG embedding to solve the QA problem and becomes the base model for a series of algorithms (Ji et al., 2015; Wang et al., 2014; Lin et al., 2015). DisMult (Yang et al., 2015) proposes a unified learning framework for embedding models and introduces an approach to mine logic rules with learned relation embeddings. ComplEX (Trouillon et al., 2016) uses complex vectors to represent entities and relations, to handle asymmetric relations. ConvE (Dettmers et al., 2018) takes advantage of a convolutional neural network for knowledge embedding in a large graph. Despite the powerful representational ability shown by embedding-based models, they are limited in many scenarios for the lack of explainability (Roscher et al., 2020; Liu et al., 2017), as one-hop reasoning methods.

A promising approach is incorporating KG embedding as a reward shaping function for multi-hop reasoning methods, which is first adopted by MultiHop (Lin et al., 2018) and followed by us.

2.2 Multi-Hop Reasoning

Compared to embedding-based models, multi-hop reasoning models predict by inferring a path step by step. The property is exactly desired in scenarios where not only an answer is required, but also evidence is demanded to explain the answer. Reinforcement learning algorithms can be naturally deployed to multi-hop reasoning. DeepPath (Xiong et al., 2017) first takes REINFORCE as the generator of evidence paths which are fed to PRA (Brin, 1998) subsequently. MINERVA (Das et al., 2018) takes the lead to design an end-to-end RL-based multi-hop reasoning model to address query answering, whereas its accuracy of answering still falls behind state-of-the-art embedding models. MultiHop (Lin et al., 2018) incorporates pre-trained embedding-based models as a soft reward function to compensate for the incompleteness of KG and gets comparable performance to embedding-based models in several datasets.

Since the agent lacks logical insights into adopted paths, spurious paths are inevitable during training. Once a spurious path leading to the correct answer coincidentally is explored first, the agent will increasingly tend to choose actions following a spurious way (Guu et al., 2017). To address this problem, MultiHop (Lin et al., 2018) uses action drop to force the agent to explore diverse paths, hoping to mitigate the negative effect of spurious paths. RARL (Hou et al., 2021) exploits high-quality rules mined from datasets to supervise the policy of the agent. However, there is no quantitative measure for the effect of the above methods, due to the absence of the metric that scales path spuriousness and consequently no reward that can directly guide the agent to avoid spurious paths.

3 Preliminaries

In this section, we first give crucial definitions of several concepts. Then the reinforcement learning formula and reward shaping skills will be introduced, which is the foundation of our model.

3.1 Multi-hop KG Reasoning

Knowledge Graph. A knowledge graph (KG) is a directed graph $G = (\mathcal{E}, \mathcal{R}, \Psi)$ (Ji et al., 2022), where $\mathcal{E}$ is the set of entities, $\mathcal{R}$ is the set of relations and Ψ is the mapping from relations to pairs of entities. A fact in knowledge graph G is an ordered triple $\delta =< e_s, r, e_o >$ satisfying that $e_s, e_o \in \mathcal{E}$, $r \in \mathcal{R}$, and $\Psi(r) =< e_s, e_o >$.

In this paper, we treat each edge in a KG as bidirectional and augment the KG with reversed edge (e_o, r^{-1}, e_s) if (e_s, r, e_o) is a fact in G. We call r^{-1} the inverse relation of r.

Multi-Hop Reasoning. Given a query $q =< e_s, r_q, ? >$ ($<?, r_q, e_o >$ is the same) and a KG G, multi-hop reasoning is to predict the absent object by finding an n-hop path $\tau =< e_s, r_1, e_2, r_2, \cdots, e_n, r_n, e_T >$ in G (Wan and Du, 2021), where the last entity e_T is the predicted answer. The path can also be represented as a predicate $\tau \equiv r_1(e_s, e_2) \wedge r_2(e_2, e_3) \wedge \cdots \wedge r_n(e_n, e_T)$.

Path Clause. For convenience, we use the path clause $H(\tau, q) \equiv \tau \rightarrow r_q(e_s, e_T) \equiv r_1(e_s, e_2) \wedge r_2(e_2, e_3) \wedge \cdots \wedge r_n(e_n, e_T) \rightarrow r_q(e_s, e_T)$ to indicate a reasoning path τ and its prediction, where τ is the clause body and $r_q(e_s, e_T)$ is the head.

In this paper, we assume that all facts in KG are correct. Then path clause $H(\tau, q)$ is true in KG G if τ is a path in G and $r_q(e_s, e_T)$ is a fact in G. We call $H(\tau, q)$ is *valid* in G if τ is a path in G.

Path Substitution. Path substitution of $H(\tau, q)$ is defined as $H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T} \equiv r_1(e_s, x_2) \wedge r_2(x_2, x_3) \wedge \cdots \wedge r_n(x_n, x_T) \rightarrow r_q(e_s, x_T)$, which is a path clause derived by replacing each e_i in clause $H(\tau, q)$ with x_i except e_s, *i.e.,* keeping e_s fixed.

We denote the body of $H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}$ as $B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}}$. We call $H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}$ is a *valid* path substitution of $H(\tau, q)$ in KG G if the body $B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}}$ is a path in G.

Note that there may be overlaps of entities of a path substitution with the original path clause. That is, a path substitution may not replace all entities in a path clause with new entities. In particular, each path clause $H(\tau, q)$ is a path substitution of itself.

Consider the KG in Figure 1. For query <*Tom, educatedAt, ?*>, the path in color red indicates a prediction <*Tom, educatedAt, MIT*>, and the path clause H=*teach*$^{-1}$*(Tom, Mary)* $\wedge$ *workAt(Mary, MIT)* $\rightarrow$ *educatedAt(Tom, MIT)*. Clearly, $H^{Mary,MIT}_{Dave,H.S.}$, i.e., *teach*$^{-1}$*(Tom, Dave)* $\wedge$ *workAt(Dave, H.S.)* $\rightarrow$ *educatedAt(Tom, H.S.)* is a valid path subsituition of H in the KG.

3.2 RL Formula

The RL algorithms can be naturally deployed to multi-hop reasoning by formulating it into a Markov decision process (MDP) (Puterman, 1994). Following MINERVA (Das et al., 2018), we adopt REINFORCE (Williams, 1992) algorithm. Key components of the architecture are as follows.

States. A state encodes the status quo as well as the origin goal. In step t, state $s_t = (e_t, e_s, r_q)$ is a triple, where e_t is the current entity, e_s is the start entity and r_q is the query relation.

Actions. Action space $\mathcal{A}_t = \{(r, e') | (e_t, r, e') \in G\}$ in state s_t consists of all pairs of outgoing edges and corresponding entities. That is, the valid actions are neighborhoods of the current entity e_t.

Transition. After the agent makes its decision $a_{t+1} = (r, e')$, the state of environment migrates from $s_t = (e_t, e_s, r_q)$ to $s_{t+1} = (e', e_s, r_q)$, on condition $(e_t, r, e') \in G$.

Policy. Agent's policy maps states to actions, which is usually implemented by the deep neural network. To exploit history information, the long short-term memory network (LSTM) (Hochreiter and Schmidhuber, 1997) is adopted. History information h_t in step t is calculated by LSTM, taking as input previous history h_{t-1} and the last action $a_t = (r_t, e_t)$, as follows:

$$\mathbf{h}_0 = \mathrm{LSTM}(0, \mathbf{a}_0) \tag{1}$$

$$\mathbf{h}_t = \mathrm{LSTM}(\mathbf{h}_{t-1}, \mathbf{a}_t), \quad t > 0. \tag{2}$$

Here $\mathbf{a}_t$ is the embedding of action a_t and $\mathbf{h}_t$ is the embedding of history h_t . Policy network π_θ gives possibility distribution over $\mathcal{A}_t$:

$$\pi_\theta(a_{t+1}|s_t) = \sigma(\mathbf{A}_t\mathbf{W_2}\mathrm{ReLU}(\mathbf{W_1}[\mathbf{h}_\mathrm{t};\mathbf{e}_\mathrm{t};\mathbf{r}_\mathrm{q}])), \tag{3}$$

where $\mathbf{A}_t$ is a matrix stacking all action embeddings, σ is *sigmoid* function and *ReLU* is rectified linear unit (Nair and Hinton, 2010). The agent chooses an action subjecting to the distribution given by the policy network.

Reward. The default binary reward R_b indicates whether the agent arrives at the correct answer. With the advantage of indicator function $\mathbb{I}$, binary reward can be written as follow:

$$R_b(e_T) = \mathbb{I}((e_s, r_q, e_T) \in G). \tag{4}$$

Optimization. To get the optimal parameters, the policy network is trained by maximizing the objective function:

$$J(\theta) = \mathbb{E}_{(e_s,r_q,e_o)\in G_q}\mathbb{E}_{(a_1,a_2,\cdots,a_T)\sim\pi_\theta}[R_T]. \tag{5}$$

$$R_T = R(s_T|s_1 = (e_s, e_s, r_q)). \tag{6}$$

$J(\theta)$ is the expected reward for all queries following policy π_θ. G_q denotes all query facts. REINFORCE is deployed to solve this optimization problem by iteratively updating θ as follows:

$$\nabla_\theta J(\theta) \approx \sum_{t=1}^{T} R_T \nabla_\theta \log \pi_\theta(a_t|s_t) \tag{7}$$

$$\theta' = \theta + \nabla_\theta J(\theta). \tag{8}$$

3.3 Reward Shaping

Under binary reward R_b, the agent receives a positive reward only when it reaches a correct answer. That is to say, the agent probably can't get any effective guidance in the early exploration stage.

To offset the incompleteness of KG, Multihop (Lin et al., 2018) proposes a reward shaping function R_s that provides a soft reward F_s between 0 and 1 other than 0 as R_b does, when the prediction is not in KG during the training process. $F_s(e_s, r_q, e_T)$ is implemented by a pre-trained embedding-based model such as ConvE (Dettmers et al., 2018) and ComplEX (Trouillon et al., 2016) to estimate the probability that (e_s, r_q, e_T) is true. Then R_s is defined as follows:

$$R_s(e_T){=}R_b(e_T){+}(1{-}R_b(e_T)){\cdot}F_s(e_s, r_q, e_T). \tag{9}$$

That is, given the answer e_T, if $(e_s, r_q, e_T) \in G$, the agent will get 1 as the final reward, otherwise the agent will get $F_s(e_s, r_q, e_T)$ calculated by a pre-trained embedding-based model.

4 Methodology

In this section, we discuss the feature of spurious paths and give a quantitative definition of PS. Then we introduce two kinds of reward functions that take PS into account.

4.1 Path Spuriousness Metric

Think over the example in Figure 1. Assuming <*Tom, educatedAt, MIT*> is true and can be deduced by the following three paths H_1, H_2, and H_3 (in color red, blue, and yellow, respectively):

(1) H_1≡*teach*$^{-1}$*(Tom, Mary)* ∧ *workAt(Mary, MIT)* → *educatedAt(Tom, MIT)*;

(2) H_2≡*bornIn(Tom, U.S.)*∧*bornIn*$^{-1}$*(U.S., Jerry*∧*visit(Jerry, MIT)*→*educatedAt(Tom, MIT)*;

(3) H_3≡*beFriends(Tom, John)*∧*educatedAt(John, MIT)*→*educatedAt(Tom, MIT)*.

However, not all of them can serve as valid evidence. Clearly, H_1 is solid enough since *Tom* must be educated exactly where his teacher teaches. H_2 is extremely spurious because there are hundreds of millions of people born in the same place as *Tom* and they visit tremendous schools, few of which *Tom* can attend. Though H_3 is spurious in logic, considering that many of *Tom*'s friends made acquaintances with him when they were in the same school, H_3 is much more valid than H_2.

It is a remarkable fact that these three clauses are all *true* in the KG of Figure 1, despite their variance in path spuriousness. The truth value of a valid path clause always keeps consistent with its prediction, regardless of whether its body is a reasonable path or not. The key difference between spurious paths and reasonable paths is that they have quite a few valid substitutions in a given KG, but fail to infer correct predictions. That is, the path spuriousness of a path clause H is up to the proportion of such valid substitutions. The larger the proportion is, the more spurious H is.

Path Spuriousness. Given a KG G and a path clause $H \equiv r_1(e_s, e_2) \wedge r_2(e_2, e_3) \wedge \cdots \wedge r_n(e_n, e_T) \to r_q(e_s, e_T)$, the PS of H is:

$$\mathrm{PS}(H) = \mathbb{P}(v(H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}) = 0), \tag{10}$$

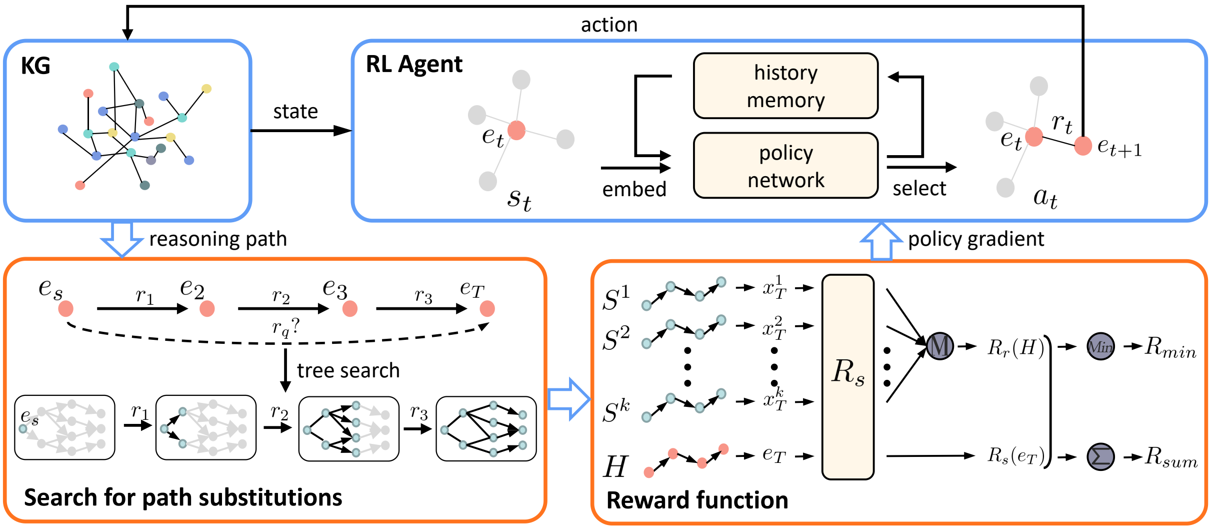

Figure 2: An overlook of the training process. Starting from entity e_s, the agent walks step by step to obtain a reasoning path H where e_T denotes the predicted answer. All substitutions of H are derived by searching over the KG. We use S^i to represent the i-th substitution. R_{min} and R_{sum} indicate our two reward shaping variants.

which is equal to:

$$\mathrm{PS}(H) = 1 - \mathbb{E}(v(H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T})) \tag{11}$$

where $H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}$ is a valid substitution of H, v is the value function mapping predicate space to $\{0,1\}$, and $X = (x_2, \cdots, x_n, x_T)$ are random entities sampled from the ideal entity set. In practice, the ideal entity set is usually unknown and hard to estimate, so we propose a computation viable metric based on frequency to approximate Equation 11:

$$\mathrm{PS}(H) \approx 1 - \frac{\sum\limits_{x_2,\cdots,x_n,x_T \in \mathcal{E}} v(H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T})}{\sum\limits_{x_2,\cdots,x_n,x_T \in \mathcal{E}} v(B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}})} \tag{12}$$

where $B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}}$ is the body part of $H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}$, and $\mathcal{E}$ is the entity set of G.

Take the KG in Figure 1 for example.

(1) H_1 (in color red) has only one valid substitution *teach*$^{-1}$*(Tom, Dave)* $\wedge$ *workAt(Dave, H.S.)* $\rightarrow$ *educatedAt(Tom, H.S.)* except H_1, which is true in the KG. Counting H_2 itself in, PS(H_2)=1−2/2=0.

(2) H_2 (in color blue) has two valid substitutions except H_1: *bornIn(Tom, U.S.)* $\wedge$ *bornIn*$^{-1}$*(U.S.,Jerry)* $\wedge$ *visit(Jerry,CMU)* $\rightarrow$ *educatedAt(Tom, CMU)* and *bornIn(Tom, U.S.)* $\wedge$ *bornIn*$^{-1}$*(U.S.,Bob)* $\wedge$ *visit(Bob,UC Berkeley)* $\rightarrow$ *educatedAt(Tom, UC Berkeley)*, but both of them are false in the KG. Then we have PS(H_1)=1−1/3=2/3.

(3) H_3 (in color yellow) has one valid substitution *beFriends(Tom, Alice)* $\wedge$ *educatedAt(Alice, Stanford)* $\rightarrow$ *educatedAt(Tom, Stanford)* except H_1, which is false in the KG. As a result, PS(H_3)=1−1/2=1/2.

4.2 Path Spuriousness-Based Reward

Both R_b and R_s are devoted to the correctness of the terminal entity, ignoring the spuriousness of reasoning paths. To address this, we design two novel rewards combining the answer correctness as well as the path spuriousness.

First, a path score function $F_p(H)$ is required to score the spuriousness degree of H. The most straightforward way is taking the definition of PS as F_p, which is effective when KG is closed (Tanon et al., 2017). However, taking the incompleteness of KG into consideration, we incorporate the soft reward R_s with Equation 12 to build $F_p(H)$:

$$F_p(H) = 1 - R_r(H) \tag{13}$$

$$R_r(H) = \frac{\sum\limits_{x_2,\cdots,x_n,x_T \in \mathcal{E}} v(B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}}) R_s(x_T)}{\sum\limits_{x_2,\cdots,x_n,x_T \in \mathcal{E}} v(B_{H^{e_2,\cdots,e_n,e_T}_{x_2,\cdots,x_n,x_T}})}. \tag{14}$$

For simplicity, we use $R_r(H) = 1 - F_p(H)$ to indicate the reasonableness of H.

Because of the complexity of semantic knowledge, even a reasonable path may lead to a wrong answer in some special cases. Therefore, a rational reward has to be a fusion of the answer accuracy and the path reasonableness. We demonstrate two kinds of combinations between R_s and R_r, and discuss their performance in the experiment section.

One is taking the *minimum* between accuracy and reasonableness:

$$R_{min}(H, e_T) = min(R_s(e_T), R_r(H)). \quad (15)$$

The equation is based on intuitive thinking that, we introduce PS-based reward only for punishing spurious paths, but not for awarding paths with high reasonableness but low accuracy. That is, R_r merely serves as punishment when it is lower than R_s. Note that R_{min} is friendly to developers since it has no hyperparameters.

The other is the *weighted sum* of R_s and R_r:

$$R_{sum}(H, e_T) = \alpha R_r(H) + (1-\alpha) R_s(e_T), \quad (16)$$

where α decreases in the process of training. This equation is inspired by curriculum learning, which sets different optimizing goals in different learning stages (Bengio et al., 2009). We give priority to the path reasonableness in early epochs, forcing the agent to focus more on reasonable paths, and after we prefer the agent to concentrate on proper answers. Curriculum learning has the chance to achieve higher performance but makes it more difficult to tune parameters.

4.3 Overall Training Process

The overall training process of our method is shown in Figure 2. The agent starts from the query entity e_s and makes transitions according to its policy network. The history memory holds the history information of each past step. After the agent reaches the final entity e_T, we use Breadth-First Search to get all valid substitutions of its reasoning path. Then all substitutions as well as the reasoning path itself are used to calculate R_r and R_s which are combined together to get either R_{min} or R_{sum}.

Our PyTorch implementation and some pretrained models are released at `https://github.com/rubickkcibur/PSAgent`.

5 Experiment

We evaluate our model on four datasets and compare it with eight common baseline models. *Ours+min* and *Ours+sum* indicate our two approaches with R_{min} and R_{sum} respectively.

5.1 Setup

5.1.1 Datasets

We use five benchmark datasets for query answering: 1) UMLS (Kok and Domingos, 2007), 2) Kinship (Lin et al., 2018), 3) FB15K-237 (Toutanova et al., 2015), 4) WN18RR (Dettmers et al., 2018), and 5) NELL-995 (Xiong et al., 2017). Statistics are shown in Table 1.

Dataset	#Ent	#Rel	#Fact	#degree	
				avg.	median
Kinship	104	25	10,686	82.2	82
UMLS	135	46	6,529	38.6	28
FB15K-237	14,505	237	272,115	19.7	14
WN18RR	40,945	11	93,003	2.2	2
NELL-995	10,105	12	13,825	1.6	1

Table 1: Statistics of five KGs used in experiments.

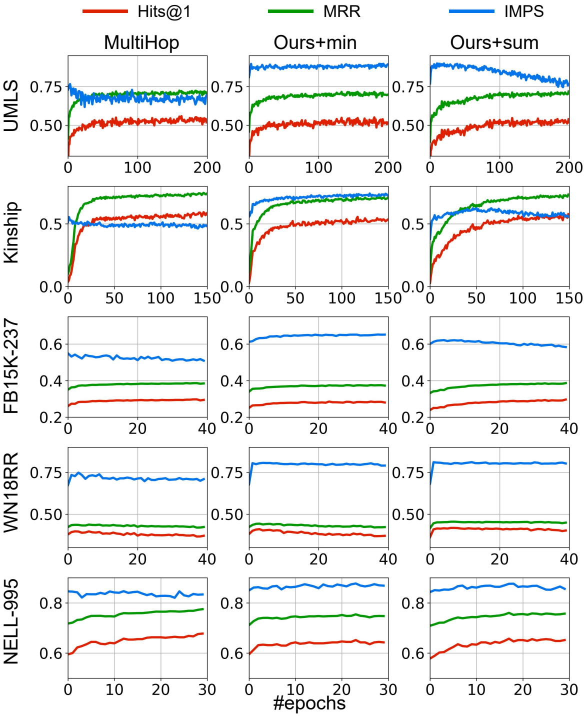

Figure 3: Hits@1 (red), MRR (green), and IMPS (blue) change over the validation set during training.

5.1.2 Baselines

We compare our method with five multi-hop reasoning models: 1) MINERVA (Das et al., 2018), the first end-to-end deep reinforcement learning model for multi-hop reasoning; 2) MultiHop (Lin et al., 2018), the first RL-based model incorporating embedding-based models as reward shaping function and proposing the action drop skill to mitigate spurious path problem; 3) MetaKGR (Lv et al., 2019), which leverages meta-information to improve reasoning performance on few-shot relations; 4) RARL (Hou et al., 2021), which utilizes mined logic rules to supervise the decision of the agent; 5) PAAR (Zhou et al., 2021), a fresh model com-

Table 2: QA Performance comparison on five datasets. The top part is embedding-based models and the bottom is RL-based models. *Ours+min* and *Ours+sum* denote our methods with R_{min} and R_{sum}, respectively. All metrics are multiplied by 100. IMPS is not applicable to embedding-based models because they lack reasoning paths.

bining hierarchical information in reward shaping for providing sufficient paths. Three embedding-based models are also picked up as comparisons: DistMult (Yang et al., 2015), ComplEX (Trouillon et al., 2016), and ConvE (Dettmers et al., 2018).

5.1.3 Hyperparameters

The entity embedding, relation embedding, and history embedding all have a size of 200. A three-layer LSTM is used for multi-hop reasoning models. The training batch size is 128. The maximum path length is 2 for UMLS and Kinship, and 3 for others. Following MultiHop (Lin et al., 2018), we use action drop in the training process, and the drop rate ranges from 0.1 to 0.9. For R_{sum}, there are two hyperparameters, decreasing interval D and decreasing rate η. We perform grid search on them and set $D = 10$ for UMLS and WN18RR, $D = 5$ for others, $\eta = 0.75$ for FB15K-237, and $\eta = 0.9$ for the other four datasets.

For MultiHop, MetaKGR, PAAR, and our method, we universally choose ConvE to implement the soft reward function. An entropy regularization term is added to the objective function in all RL-based models and the weight coefficient varies in (0, 0.1), as MINERVA does (Das et al., 2018).

We use Xavier initialization (Glorot and Bengio, 2010) to initialize parameters of embedding layers, and Adam optimizer (Kingma and Ba, 2015) to realize optimization where the learning rate is in (0.001, 0.003).

We perform beam search to get the final prediction and the beam size is 128 for all cases. A single training on NVIDIA Tesla V100 GPU costs 20 hours on FB15K-237, and at most 10 hours among all other datasets.

5.1.4 Evaluation Protocol

We choose Hits@k and Mean Reciprocal Rank (MRR) to evaluate the accuracy of predictions, and use Mean Path Spuriousness (MPS) to estimate the spuriousness of paths. For consistency, we use 1-MPS in measurement, denoted by IMPS.

For each test case $< e_s, r, e_o >$, the model takes as input the subject e_s and relation r, and returns a list of candidate answers $E_o = [e^1, e^2, \cdots, e^N]$ in decreasing order of confidence, as well as a list of corresponding reasoning paths $\mathcal{H}_o = [H^1, H^2, \cdots, H^N]$, where N is the beam size, and the termination of each path H^i is e^i for $i \in [1, N]$.

We use r_{e_o} to indicate the rank of e_o in E_o and H_o to represent the path along which the agent reaches e_o. Hits@k is the percentage of test cases where $r_{e_o} \leq k$, MRR is the mean of $1/r_{e_o}$, and MPS is the mean of $\text{PS}(H_o)$.

5.2 Validation of the IMPS

To verify whether the IMPS metric (*i.e.* 1-MPS) could correctly evaluate the reasonableness of reasoning paths, we conduct experiments on rule-based reasoning models. Rule-based models mostly lack generalization but have highly credible results, since they use logical rules, either designed by experts or mined from datasets, to extract reasoning paths and infer new facts. That is to say, if the IMPS metric is a proper measurement of path reasonableness, rule-based models will perform beyond other models on it.

We choose AMIE+ (Galárraga et al., 2015) to mine rules and then infer answers following them. The results (the final bar of Table 2) meet our expectations. AMIE+ gets the highest IMPS scores on four datasets, exceeding all RL-based models. Compared to other RL-based ones, the gap between our model and AMIE+ is evidently smaller.

5.3 Model Comparison

Table 2 shows evaluation performance on query answering. Results of embedding-based models are quoted from MultiHop (Lin et al., 2018), and IMPS is not applicable to them because they have no reasoning paths. *Ours+min* and *Ours+sum* denote two variants of our approach with R_{min} and R_{sum}, respectively. For all approaches, We record performances on the validation set of each epoch during training and choose the best one (in terms of MRR) as the testing model.

In terms of Hits@k and MRR, embedding-based models generally perform better, while multi-hop approaches are comparable with embedding-based methods in some metrics, such as Hits@10 in UMLS, Hits@1 in Kinship and MRR in WN18RR. Among multi-hop reasoning models, *Ours+sum* outperforms previous ones in most cases.

As for IMPS metric, our methods largely surpass other RL-based models, Specifically, 27 percent in UMLS, 50 percent in Kinship, 10 percent in WN18RR, and 11 percent in FB15K-237. An exception is NELL-995, where most models behave nearly the same. It possibly results from the sparsity of NELL-995. Since the average node degree is lower than 2, most reasoning paths in NELL-995 may have few valid substitutions.

An interesting fact is that performance varies between our two methods. Generally, *Ours+min* gets higher IMPS scores, and *Ours+sum* behaves better on Hits@k and MRR. We believe that when the reasoning model's performance is not good enough, prediction accuracy and reasonableness keep consistent, but if higher performance is required, there is a trade-off between them. In most cases, reasonable paths lead to accurate answers, but in some special cases, the answer can not be accessed in a regular way. For example, the statement "*if A is metal, A is solid*" is reasonable for almost all metallic elements, but when A is mercury, following that will lead to a wrong answer. The little fallback in MRR of *Ours+min* may be caused by these special cases, and the more special cases in a dataset, the larger the gap is. *Ours+sum* formulation provides a manual way to make a balance, so we can get better MRR at the expense of IMPS.

5.4 Learning Process

We are interested in the effect on the dynamic learning process of three different rewards R_s, R_{min}, and R_{sum}. So we draw curves of Hits@1, MRR, and IMPS metrics on validation set during training. As shown in Figure 3, from left to right, the three columns are MultiHop, *Ours+min*, and *Ours+sum*, using R_s, R_{min}, and R_{sum} respectively.

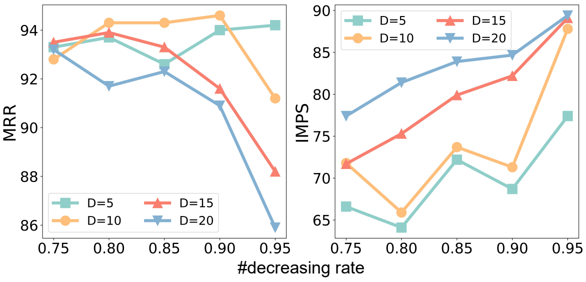

Figure 4: MRR (left) and IMPS (right) performance change w.r.t. decreasing interval D and rate η of R_{sum}. Each line represents metric variety over various decreasing rates for a certain decreasing interval.

In the early stage of training, the MultiHop's IMPS score falls as MRR and Hits@1 rise, which is much more significant on UMLS and Kinship. This phenomenon evidently shows the misleading of spurious paths. As a comparison, our two approaches have a higher IMPS score at the beginning and maintain or elevate it as MRR increases. As illustrated, the promotion of reasoning paths reasonableness by incorporating PS-aware reward (*i.e.* R_{min} and R_{sum}) is mainly reflected in the early training process.

Compared to *Ours+min*, the IMPS score of *Ours+sum* first lifts and then slowly decreases while the MRR score keeps rising. It justifies that prediction accuracy and path reasonableness are in consistency when performance is not sufficiently good, but need a trade-off if better performance is required. However, this balance is not obvious in WN18RR, where *Ours+sum* gets great scores in both MRR and IMPS with proper hyperparameters. We suppose one reason is that the proportion of special cases which can not be accessed by regular logical path is small.

MultiHop and *Ours+min* show a similar training convergence rate, while *Ours+sum* converges slower. The successive change of the coefficient α in R_{sum} makes the agent learn different goals and therefore hard to converge.

5.5 Hyperparameter Study

We study the hyperparameters relevant to R_{sum}, specifically the decreasing interval D and decreasing rate η. Figure 4 shows MRR and IMPS results on UMLS with 20 permutations of D and η. We

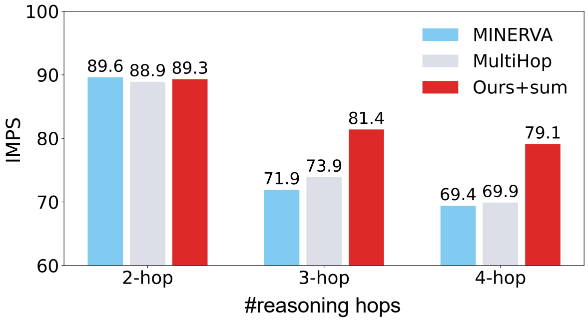

Figure 5: IMPS comparison among MINERVA (blue), MultiHop (gray), and our method (red), over different reasoning hops. IMPS metric is multiplied by 100.

figure out that when decreasing interval is small, MRR varies little with decreasing rate, and vice versa. It is quite fair because smaller D or η implies more priority to the accuracy-guided part of R_{sum} during training, which prompts better performance on MRR. However, settings of middle D and η achieve the best score, and we believe it reveals that proper tendency to the spuriousness-guided part of R_{sum} in the early training stage has a positive influence over accuracy. In terms of IMPS, it declines on the whole as η becomes smaller, and the larger D is, the slower it falls. Generally, in small and dense datasets, small decreasing intervals and rates would lead the agent to get higher scores on MRR, while larger intervals and rates make the agent prefer more reasonable paths. A balance where the agent gets high scores on both MRR and IMPS exists with refined parameters.

5.6 Analysis on Reasoning Hops

We also want to throw some light on the influence of the maximum length of reasoning paths (i.e., reasoning hops). We permute reasoning hops and test performance in IMPS of three models, MINERVA, MultiHop, and ours. We pick WN18RR as the benchmark because UMLS and Kinship are so dense that all entities can be reached within 2 hops starting anywhere. As Figure 5 shows, the reasonableness of paths picked by three models drops as reasoning hops increase, without exception. Compared to baseline models, our method has a better resistance against the tendency. Thereby, the gap between our method and baselines widens as reasoning hops go up.

6 Conclusion

In this paper, we discuss the spurious path problem which widely exists in the RL-based multi-hop reasoning models. To address this problem, we define a new metric named Path Spuriousness (PS) to quantitatively evaluate to what extent a path is spurious and consequently propose a new reward that considers both the prediction accuracy and path reasonableness. Under the guidance of the reward, the agent can be aware of not only whether its prediction is right, but also the spuriousness of its reasoning path, and thus avoid spurious paths.

Experiments show our method largely outperforms baseline models in terms of PS, and keep comparable to the state-of-the-art performance of prediction accuracy. Detailed analysis indicates that a trade-off between pursuing better prediction accuracy and keeping high path reasonableness exists. Its significance varies among different datasets. We provide a method to make a balance by manually pruning hyperparameters.

Analysis on reasoning hops shows potential in long-hop reasoning tasks. In future work, we would like to further investigate it.

Limitations

Our job has two major limitations regarding the definition of PS and the computational cost.

The definition of PS (*i.e.*, Equation 10 and Equation 11) is constructed on the assumption that all facts in a KG are correct. However, some datasets contain mistaken facts in practice. It could make the PS a biased estimation. Moreover, experiments on NELL-995 indicate that the sparsity of KG may limit the effectiveness of our PS-aware reward. How to avoid spurious paths in sparse KGs and even KGs that contain mistakes remains a hard topic for future work.

The other deficiency is that we use a breadth-first tree search to find path substitutions, whose worst-case time cost increases exponentially as the search depth grows. This shortcoming has been reflected by the experiment time cost on FB15K-237 and limits our method's capability to scale to much larger datasets. We expect pruning skills or end-to-end deep models would be able to tackle this problem and leave it for future work.

A Experiment Details

A.1 Case Study

We select four test cases in the UMLS dataset and look deep into the difference between reasoning paths extracted by MultiHop and our method. Table 3 shows the comparisons. In each case, we only concentrate on the accurate predictions as well as their paths. The reasonableness of paths is indicated by $R_r(H_o)$, and the rank of correct answer e_o is represented as r_{e_o}.

For most cases, the reasoning path of our method to obtain the correct answer is much more reasonable than MultiHop.

(1) Case 1. In case 1, to get the relation *location_of*, our reasoning path through relations *adjacent_to* and *location_of* is much more convinced than MultiHop's path through relations *issue_in* and *method_of*$^{-1}$. That's because *Adjacent* relation is clearly more relevant than *method* relation since we want to know where is the location.

(2) Case 2. Case 2 shows insight into the different preferences between the two approaches in respect of picking paths. The two paths differ in the last relation, where MultiHop reaches the final answer via *issue_in*$^{-1}$ while our method picks *issue_in*.

Picking *issue_in* is reasonable in this case.

(a) It is a special coincidence that *occupation_or_discipline* and *biomedical_occupation_or_discipline* are reciprocal causation in UMLS dataset. However, in terms of reasonableness, the fact "*A causes C* " cannot be derived by "*A causes B*" and "*C causes B*" (i.e., *issue_in(A, B)* $\wedge$ *issue_in*$^{-1}$*(B, C)*).

(b) Guided by the embedding-based model, MultiHop only captures the semantic information between *occupation_or_discipline* and *biomedical_occupation_or_discipline* and obtains a correct answer incidentally. In contrast, our method not only concentrates on the semantic correctness of certain entities but also takes path spuriousness into account. The extremely lower path reasonableness of *issue_in*$^{-1}$ prohibits our method from picking it to construct the reasoning path.

(3) Case 3. Though the path returned by MultiHop gets a score 0.49 of R_r, it is still lower than the path given by our method, considering that adjacent things possibly belong to different concepts, like lung and air. Relation *part_of* is definitely more proper to derive an *conceptual_part_of*relation.

(4) Case 4. In case 4, we get a reasonable path

Case 1:<*body_location_or_region, location_of, therapeutic_or_preventive_procedure*>		r_{e_o}	$R_r(H_o)$
MultiHop	*body_location_or_region* $\xrightarrow{\text{issue\_in}}$ *occupation_or_discipline* $\xrightarrow{\text{method\_of}}^{-1}$ *therapeutic_or_preventive_procedure*	3	0.22
Ours+min	*body_location_or_region* $\xrightarrow{\text{adjacent\_to}}$ *body_part_organ_or_organ_component* $\xrightarrow{\text{location\_of}}$ *therapeutic_or_preventive_procedure*	0	0.71
Case 2:<*physical_object, issue_in, biomedical_occupation_or_discipline*>		r_{e_o}	$R_r(H_o)$
MultiHop	*physical_object* $\xrightarrow{\text{issue\_in}}$ *occupation_or_discipline* $\xrightarrow{\text{issue\_in}}^{-1}$ *biomedical_occupation_or_discipline*	0	0.01
Ours+min	*physical_object* $\xrightarrow{\text{issue\_in}}$ *occupation_or_discipline* $\xrightarrow{\text{issue\_in}}$ *biomedical_occupation_or_discipline*	0	0.99
Case 3:<*cell_component, conceptual_part_of, body_system*>		r_{e_o}	$R_r(H_o)$
MultiHop	*cell_component* $\xrightarrow{\text{adjacent\_to}}$ *body_space_or_junction* $\xrightarrow{\text{conceptual\_part\_of}}$ *body_system*	3	0.49
Ours+min	*cell_component* $\xrightarrow{\text{part\_of}}$ *cell* $\xrightarrow{\text{conceptual\_part\_of}}$ *body_system*	0	0.99
Case 4:<*indicator_reagent_or_diagnostic_aid, interacts_with, chemical*>		r_{e_o}	$R_r(H_o)$
MultiHop	*indicator_reagent_or_diagnostic_aid* $\xrightarrow{\text{causes}}$ *experimental_model_of_disease* $\xrightarrow{\text{inv\_causes}}$ *chemical*	0	0.05
Ours+min	*indicator_reagent_or_diagnostic_aid* $\xrightarrow{\text{interacts\_with}}$ *hazardous_or_poisonous_substance* $\xrightarrow{\text{interacts\_with}}$ *chemical*	5	0.99

Table 3: Comparison of selected paths between MultiHop and our method on 4 cases. The reasonableness of paths is indicated by $R_r(H_o)$ and r_{e_o} represents the rank of correct answer e_o in candidate list E_o.

Dataset	HC_{min}	PCA_{min}	#Rules

Table 4: AMIE+ setting details. HC_{min} and PCA_{min} indicate the minimum head coverage and PCA confidence respectively, which is threshold for mining rules.

but with a lower rank. That is, the agent does not always pick a path with a high R_r. It may be limited to the representation power of the policy network. We leave this problem for future research.

A.2 AMIE+ Settings

To validate our proposed metric IMPS, we choose AMIE+ to mine rules and then infer answers following them. There are two hyperparameters of AMIE+: the head coverage and PCA confidence (denoted by HC_{min} and PCA_{min} respectively). The higher the two parameters are, the smaller the number of qualified mined rules. In Table 4 we show the settings of HC_{min} and PCA_{min}, and the number of qualified rules we mined using AMIE+.

Self-Adaptive Named Entity Recognition by Retrieving Unstructured Knowledge

Abstract

Although named entity recognition (NER) helps us to extract domain-specific entities from text (*e.g.*, artists in the music domain), it is costly to create a large amount of training data or a structured knowledge base to perform accurate NER in the target domain. Here, we propose self-adaptive NER, which retrieves external knowledge from unstructured text to learn the usages of entities that have not been learned well. To retrieve useful knowledge for NER, we design an effective two-stage model that retrieves unstructured knowledge using uncertain entities as queries. Our model predicts the entities in the input and then finds those of which the prediction is not confident. Then, it retrieves knowledge by using these uncertain entities as queries and concatenates the retrieved text to the original input to revise the prediction. Experiments on CrossNER datasets demonstrated that our model outperforms strong baselines by 2.35 points in F_1 metric.

1 Introduction

Named entity recognition (NER) helps us to extract entities from text in various domains such as biomedicine (Kim et al., 2003), disease (Doğan et al., 2014), and COVID-19 (Wang et al., 2020). However, accurate neural NER requires a massive amount of training data (Chiu and Nichols, 2016; Ma and Hovy, 2016; Yadav and Bethard, 2018). As well, the annotation of a domain-specific NER dataset costs a lot of money because it requires the involvement of domain experts.

To compensate for the lack of training data in NER, researchers have utilized external knowledge. Traditional feature-based NER uses features based on gazetteers or name lists (Florian et al., 2003; Cohen and Sarawagi, 2004; Luo et al., 2015) as external knowledge. Although recent neural NER methods can even benefit from gazetteers and name lists (Seyler et al., 2018; Liu et al., 2019; Mengge et al., 2020), only a few domains with structured knowledge bases (gazetteers) have this merit. Thus, several studies have resorted to using raw text (unstructured knowledge) to perform weakly-supervised learning on general-domain structured knowledge (Cao et al., 2019; Mengge et al., 2020; Liu et al., 2021a).

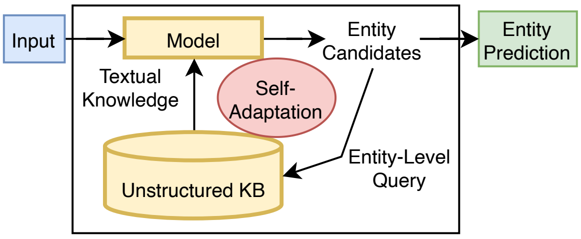

Figure 1: Concept of self-adaptive NER: the model predicts entity candidates to conduct entity-level retrieval from the unstructured KB; then it revises the prediction with reference to the retrieved knowledge.

In this paper, we explore the potential of utilizing unstructured knowledge in the NER task by referring to it at inference time. Our basic idea is inspired by recent retrieval-augmented language models (LMs) (Guu et al., 2020). These models are pre-trained with retrieval-augmented masked language model (MLM), so that they can perform well in open-domain question answering (ODQA) by retrieving relevant unstructured knowledge using a question as a query. However, as we will later confirm in the experiments, the models designed for ODQA are not effective in the NER task because it requires an understanding of many entities in the input text.

To deal with this problem, we propose a retrieval-augmented model capable of determining which entities to focus on in the input text for knowledge retrieval. The proposed **self-adaptive NER (SA-NER) with unstructured knowledge model** searches an unstructured knowledge base (UKB) when it lacks confidence in its prediction. We cre-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3193–3205
May 2-6, 2023 ©2023 Association for Computational Linguistics

ate the UKB automatically by splitting a raw text corpus into pieces and assigning dense vectors as keys to each piece of unstructured knowledge. To help in understanding local semantics, we design a retrieval system tailored for NER; our model predicts the entities and then retrieves knowledge in terms of those it is not confident in predicting.

To evaluate our method's capability of retrieving useful knowledge about entities, we conducted experiments on various NER datasets (Tjong Kim Sang and De Meulder, 2003; Salinas Alvarado et al., 2015; Liu et al., 2021b), some of which have domain-specific types.

Our contributions are summarized as follows:

- We are the first to integrate retrieval-augmentation into NER. SA-NER retrieves entity-level knowledge dynamically for NER.
- In experiments, SA-NER outperformed strong baselines pre-trained in a supervised and self-supervised fashion by 1.22 to 2.35 points.
- We reveal why knowledge retrieval is useful for NER. We found that our model is effective on entities not included in the general-domain pre-training dataset.

2 Task Settings

We developed SA-NER to solve the problems of NER with unstructured knowledge. NER is a sequence tagging task in which the model inputs a token sequence $X \in V^L$, where V is the vocabulary and L is the maximum sequence length. The model outputs a BIO label sequence of the same length. Let C be the number of types. Then, the number of the BIO labels is $2C + 1$.

SA-NER assumes a corpus as an unstructured knowledge, which is split into token sequences of length L, following the existing retrieval-augmented language model (LM) (Borgeaud et al., 2021), in order to store a large corpus efficiently. We retrieve m pieces of knowledge and concatenate them into X. We feed the concatenated text $X^+ \in V^{(m+1)L}$ to the model.

3 Related Work

Here, we review NER that uses raw text (unstructured knowledge) without structured knowledge, with in-domain structured knowledge, with general-domain structured knowledge, and for pre-training of billion-scale LMs . Also, we review the retrieval-augmented LMs.

3.1 NER with unstructured knowledge

Researchers have utilized various clues to retrieve useful raw text for NER. Traditional NER models focus on surrounding contexts (Sutton and McCallum, 2004; Finkel et al., 2005; Krishnan and Manning, 2006) and linked documents (Plank et al., 2014) to capture non-local dependencies. More recent neural NER models benefit from neighbor sentences to obtain better contextualized word representations (Virtanen et al., 2019; Luoma and Pyysalo, 2020). Meanwhile, Banerjee et al. (2019) and Li et al. (2020) encode knowledge contexts on entity types such as questions, definitions, and examples taken from in-domain structured KBs (*e.g.,* UMLS Meta-thesaurus). In this study, we developed a generic method that retrieves useful raw text (unstructured text) for NER.

Distant supervision (Mintz et al., 2009) uses structured knowledge to annotate raw text with pseudo labels. Performing distantly supervised fine-tuning with in-domain structured knowledge after the MLM pre-training is effective in domain-specific NER (Wang et al., 2021; Trieu et al., 2022). However, domain-specific distant supervised learning depends on the structured knowledge's coverage of the label set of the downstream task.

Weakly supervised learning with general-domain structured knowledge (Cao et al., 2019; Liang et al., 2020; Mengge et al., 2020; Liu et al., 2021a) can transfer general-domain knowledge to the target domain. Its methods learn the entity knowledge through weakly supervised learning, even though the target task has domain-specific entities and types (Liu et al., 2021a). We confirmed that our model achieved a performance gain by using raw text as unstructured knowledge at inference time because the world knowledge cannot be stored in the limited-sized model.

Pre-trained LMs memorize factual knowledge in their models through pre-training on unstructured corpus (Petroni et al., 2019; Cao et al., 2021; Dhingra et al., 2022). Recently, billion-scale generative pre-trained LMs have been proposed (Raffel et al., 2020; Brown et al., 2020). Although the generative models cannot be applied naively to structured prediction tasks such as NER, some papers tackled NER with the generative LMs (Paolini et al., 2021; Yan et al., 2021; Zhang et al., 2022; Chen et al., 2022). One of the advantages of retrieval-augmented LMs over billion-scale LMs is ease of maintenance; For instance, the models can use up-to-date Wikipedia as the UKBs.

3.2 Retrieval-Augmented Language Models

LMs using external knowledge have recently been proposed (Guu et al., 2020; Lewis et al., 2020; Izacard and Grave, 2021; Singh et al., 2021; Borgeaud et al., 2021). However, they focus on language modeling and ODQA, and successful retrieval-augmented LMs in NER have not been reported. They obtain queries for knowledge retrieval in such a way that each query represents the whole input or a fixed-length chunk split from the input. Therefore, they cannot retrieve knowledge that tells the usages of the entities, which is important for NER. In addition, because an input may include many entities, the model should focus on only those entities whose knowledge is not stored in the model. However, retrieval-augmented LMs have not incorporated such a mechanism to create and filter multiple queries.

Wang et al. (2022) and Shinzato et al. (2022) found that retrieving knowledge from the training data is also useful, as it provides knowledge not stored in the trained model. Therefore, we implemented SA-NER in such a way that it uses both labeled and unlabeled UKBs.

de Jong et al. (2022) used a virtual knowledge base whose values are vector representations. Focusing on entity knowledge, they extracted mentions from hyperlinks in Wikipedia to learn their representations. They reported that the virtual KB was less accurate but more efficient than FID (Izacard and Grave, 2021), which reads the input and textual knowledge with attention.

4 Method

Here, we present SA-NER. We explain the construction of the unstructured knowledge base (§4.1), the encoder architecture (§4.2), the two-stage NER algorithm which revises the prediction using the unstructured knowledge (§4.3), the training method (§4.4), and the pre-training method (§4.5).

4.1 Unstructured KB Construction

We create an unlabeled UKB from raw text and a labeled UKB from the training data. We assume in-domain text as a source of unlabeled unstructured knowledge and split it into token sequences of length L, which is equal to the maximum length of the SA-NER inputs. In addition, following Wang et al. (2022), we add the model's training data as labeled unstructured knowledge. We set $L = 64$ to avoid truncating most of the original inputs.

The unstructured knowledge is stored in the UKBs with associated keys. The keys of the sequence are the sentence embedding and the n-gram embeddings. Huang et al. (2021) showed that the average of the token embeddings is more useful for sentence embedding than the first `[CLS]` embedding and that the embeddings in the lower layers are also important, as well as those in the last layer. Therefore, we define the sentence embedding and n-gram embedding as the average pooling of the token representations. The token representations are the concatenations of the frozen BERT input and output, so that both the context-free and contextualized meanings are considered.

To select only entity-like n-grams as the keys, we remove those n-grams that have stop words or have no capital letters. In addition, we use string matching for filtering. We hold only the knowledge that includes the n-grams appearing in the training data for the UKBs used at training time. Also, we hold the knowledge that includes the n-grams appearing in the training or development (test) data for the UKBs at the inference on the development (test) data. Instead of string matching, we can use a summarization-based filtering for n-gram keys, as detailed in Appendix C. We formulate the extraction of a fixed number of representative n-grams from a sequence as an extractive summarization. We use a sub-modular function as the objective (Lin and Bilmes, 2011); thus, the greedy algorithm has a $(1 - 1/e)$ approximation guarantee.

Following Wang et al. (2022), we use the labeled UKB even in training to reduce the training-test discrepancy; in such case, the model does not retrieve the input itself from the labeled UKB.

4.2 Encoder

We use BERT (Devlin et al., 2019) and a linear classifier with a softmax activation as the encoder f. Figure 2 shows the encoder structure. To represent the label information from the labeled knowledge base in the model, we provide additional token-type embeddings. Though the token type is always zero in the conventional BERT model for NER, we use $2C + 3$ token-type IDs;

$$t_i = \begin{cases} 0 & \text{if } x_i \text{ is the original input} \\ 1 & \text{if } x_i^+ \text{ is unlabeled knowledge} \\ l_i + 2 & \text{if } x_i^+ \text{ is labeled knowledge} \end{cases},$$

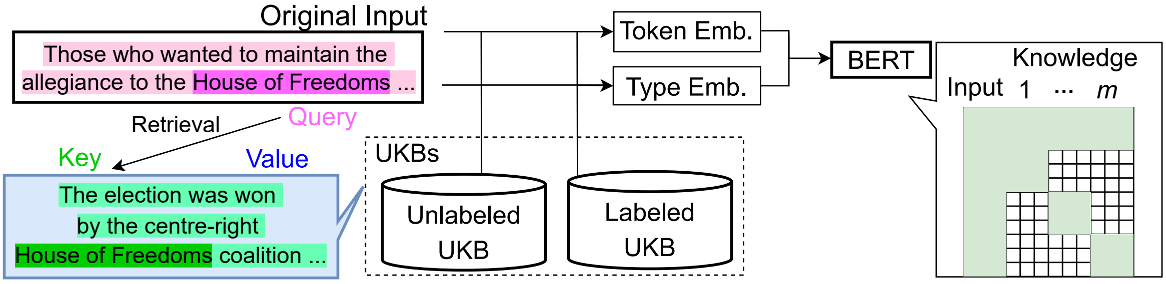

Figure 2: Overview of our self-adaptive NER with knowledge retrieval from UKBs, which store text with n-gram and sentence embeddings as keys. The labeled UKB has text with labels encoded as token type embeddings. The queries are embeddings of unconfident entities and input. We use a sparse matrix in the self-attention modules in BERT.

where l_i is the label of the labeled knowledge, and X^+ is the concatenated text.

In the self-attention module, we use the sparse attention technique to reduce the space and time complexity from $\mathcal{O}(m^2L^2)$ to $\mathcal{O}(mL^2)$. As shown in Figure 2, we mask the inter-knowledge interaction.[1] Let k be a function that returns 0 as the sentence id if the sequence is the input X and $1, ..., m$ if the sequence is the knowledge. Accordingly, the attention matrix before the softmax operation is

$$A_{ij} = \begin{cases} \frac{\boldsymbol{Q}_i^\top \boldsymbol{K}_j}{\sqrt{d_k}} & \text{if } k(i) = k(j) \text{ or } k(i)k(j) = 0 \\ -\infty & \text{otherwise} \end{cases},$$

where i, j are the token indices, d_k is the number of dimensions of the attention head, and $\boldsymbol{Q}$ and $\boldsymbol{K} \in \mathbb{R}^{(m+1)L \times d_k}$ are query and key matrixes.

4.3 Two-stage Tagging of Self-Adaptive NER

SA-NER performs two-stage tagging, *i.e.*, calculation of $\boldsymbol{P} = f(X)$, and calculation of $\boldsymbol{P}^+ = f(X^+)$. The purpose of the first stage is to find the entities that require additional information and obtain queries for knowledge retrieval. The second stage is to refine the labels with the retrieved knowledge. The motivation behind this design is to retrieve useful entity-wise knowledge to disambiguate individual tokens in NER. We predict the entity spans for entity-level retrieval. We use only the unconfident entities as the entity-based queries in order to exclude unnecessary knowledge from the retrieved results. The pseudo-code of the model is listed in Algorithm 1.

We obtain the classification probabilities of the given text $\boldsymbol{P} = f(X) \in \mathbb{R}^{L \times (2C+1)}$ or that of the text with knowledge $\boldsymbol{P}^+ = f(X^+) \in \mathbb{R}^{L \times (2C+1)}$, where the vectors after position L are ignored. The model parameters are shared in the two stages.

Algorithm 1 Two-stage self-adaptive NER

```
Require: input $X$, KBs, hyperparamters $m, \lambda_{conf}$
Predict probability $\boldsymbol{P} = f(X)$
Compute confidence score $c_e = \min_{i \in I_e} P_{i,\hat{y}_i}$ for each predicted entity $e \in \mathcal{E}$ with span $I_e$
Obtain unconfident entities $\mathcal{U} = \{e | e \in \mathcal{E}, c_e < \lambda_{\text{conf}}\}$
Add the sentence and unconfident-entity embeddings to the queries, $Q$
Initialize the retrieval results $R = \Phi$
for query $q_i$ in the queries, $Q$ do
    Retrieve $m$ nearest-neighbor keys for $q_i$ from the KBs
    Store their values with the distance in $R$
end for
Deduplicate $R$ to obtain top-$m$ knowledge $K_1^m$ from $R$
Output probabilities $\boldsymbol{P}$ and $\boldsymbol{P}^+ = f(X^+ = [X; K_1^m])$
```

First Stage We collect unconfident entities $\mathcal{U}$ in X and feed X to the model to obtain the classification probability $\boldsymbol{P} \in \mathbb{R}^{L \times (2C+1)}$. Then, we extract the entities $\mathcal{E}$ from X in accordance with the predicted labels $\hat{\boldsymbol{y}} = \text{argmax}_c \boldsymbol{P}_{\cdot c} \in \mathbb{R}^L$. The confidence score of a predicted entity e is $c_e = \min_{i \in I_e} P_{i,\hat{y}_i}$, where I_e is the span of $e \in \mathcal{E}$. If the type predictions are inconsistent in an entity (*e.g.*, [B-LOC, I-PER]), we set $c_e = 0$. We collect the unconfident entities $\mathcal{U} \subseteq \mathcal{E}$ whose confidence scores are less than a threshold λ_{conf}.

Then, we obtain the queries, which are the sentence and entity embeddings. The sentence embedding is the average pooling over all token embeddings. Each unconfident entity $u \in \mathcal{U}$ has multiple entity embeddings: average-pooled vectors of n-grams which share at least one token with u. The n-grams are filtered out similarly as in the UKB construction (§ 4.1). E denotes the number of *entity embeddings* (which are embeddings of n-grams overlapping with $u \in \mathcal{U}$). Each token embedding is a concatenation of the BERT input and output.

---

[1] We implement X^+ as an $(m+1) \times L$ tensor. We calculate three attention matrices: intra-sequence attention ($(m+1) \times L \times L$), knowledge-to-input attention ($m \times L \times L$), and input-to-knowledge attention ($m \times L \times L$). This operation takes advantage of parallel computing on the GPU.

Note that we only consider sentence-to-sentence and entity-to-n-gram matching. We retrieve the top-m nearest neighbors of the sentence embedding from the sentence embeddings in the UKBs and of the entity embeddings from the n-gram embeddings. Then, we select the top-m nearest knowledge from the collected $2(E+1)m$ knowledge while deduplicating the backbone knowledge sequence by keeping the knowledge having the minimum distance.

Second Stage We concatenate the knowledge K_1^m to the input X and obtain the classification probability $\boldsymbol{P}^+ = f(X^+ = [X; K_1^m])$. Finally, the model outputs BIO labels in accordance with $\boldsymbol{P}$ for the tokens in the confident entities and in accordance with $\boldsymbol{P}^+$ for the other tokens.

4.4 Training

To train our two-stage SA-NER, we utilize supervision on the training data to refine unconfident entities and design the loss function.

Unconfident Entity Collection In the training phase, we add the misclassified entities, i.e., those of which the prediction is not correct, to the unconfident entities $\mathcal{U}$ described in §4.3.

Loss Function We use two cross-entropy losses, $\mathcal{L}_1$ for the model prediction without knowledge (the first step) and $\mathcal{L}_2$ for the model prediction with knowledge (the second step). The total loss function is $\mathcal{L}_2 + \lambda_1\mathcal{L}_1$, where λ_1 is a hyperparameter.

4.5 Pre-training

As is done in retrieval-augmented language models for ODQA (Guu et al., 2020; Borgeaud et al., 2021), we add a retrieval-augmented pre-training stage before the fine-tuning. We propose two methods for NER-aware retrieval-augmented pre-training. The first method uses a general domain NER dataset, CoNLL03 (Tjong Kim Sang and De Meulder, 2003). The model is pre-trained with the method described above (§4.1~§4.4).

The second method involves a large-scale self-supervised pre-training following NERBERT (Liu et al., 2021a). Although the UKB in SA-NER and the pre-training data overlapped in some cases, SA-NER can use the knowledge effectively by referring to it at inference time.

NERBERT The pre-training corpus is Wikipedia. If the consecutive words in the corpus have a hyperlink, the words are labeled as an entity. We categorize such entities with the DBpedia Ontology (Mendes et al., 2012). If the entity exists in the ontology, we categorize it to its type. If it does not exist or it belongs to multiple types, we categorize it to the special "ENTITY" type.

We split the corpus into fixed-length token sequences,[2] and extract the sequences with tokens labeled with the DBpedia types. We reduce the proportion of "ENTITY" labels by using filtering rules and down sampling. The resulting dataset has 33M examples, 939M tokens, and 404 types.

We add a final linear layer with a trainable parameter $\boldsymbol{W}_{\text{pre}} \in \mathbb{R}^{d\times(2C_{\text{pre}}+1)}$ to the top of BERT, where d is the hidden size of BERT and C_{pre} is the number of types. Before fine-tuning, the final layer is replaced with a randomly initialized linear layer whose output dimension is determined by the downstream task. Refer to Appendix B and the original paper (Liu et al., 2021a) for details.

Knowledge Retrieval We use the SA-NER model in the pre-training to reduce the pre-training and fine-tuning discrepancy. We use the pre-training data itself as UKBs. We retrieve knowledge with its pseudo-labels from the data as labeled knowledge and randomly delete the pseudo-labels to make the knowledge unlabeled. We set the deletion probability as 0.95 to simulate downstream tasks where the unlabeled UKB is larger than the labeled UKB. For efficiency, we use Wikipedia hyperlinks as the keys and queries of the retrieval. Instead of a two-stage prediction, we sample m pieces of knowledge that includes an entity in the original input.

5 Evaluation

We conducted experiments on three NER datasets to evaluate the effectiveness of our self-adaptive NER with unstructured knowledge. We used the entity-level F_1 as the metric, following the literature.

5.1 Dataset

CrossNER (Liu et al., 2021b) consists of five domains: politics, science, music, literature, and AI. This small-scale dataset was created by annotating the sentences extracted from the Wikipedia articles in each domain. It provides the textual corpus extracted from Wikipedia for the in-domain pre-training. We used it for the unstructured UKB.[3]

---

[2] Although the original NERBERT uses a sentence as a unit, we use a fixed length in order to share the setting with UKBs.

[3] We can see if the self-adaptive NER is useful even though the unlabeled knowledge overlaps the NERBERT pre-training

Table 2: Main results on the test set. The models were pre-trained from DistilBERT-base-cased.

The label sets are different among the domains.

Finance (Salinas Alvarado et al., 2015) is a medium-scale NER dataset collected from U.S. SEC filings. We used the Wikipedia articles in the finance domain as the textual corpus $\mathcal{D}$ to construct the unlabeled UKB. The label set is person, organization, location, and miscellaneous.

CoNLL03 (Tjong Kim Sang and De Meulder, 2003) is a widely used large-scale NER dataset collected from Reuters news stories between August 1996 and August 1997. We used the Reuters-21578 text classification dataset (Lewis, 1997), which was collected from Reuters in 1987, as $\mathcal{D}$. The label set is the same as that of Finance.

5.2 Compared Models

Our text encoder and tokenizer were the pre-trained BERT-base-cased model (Devlin et al., 2019) or DistilBERT-base-cased model (Sanh et al., 2019). All experiments used the hyperparameters determined on the development set of CrossNER-Politics; refer to Appendix A.

We pre-trained the compared models on the CoNLL03 or NERBERT (Liu et al., 2021a)[4] datasets before fine-tuning. In addition to the BERT model (*i.e.*, BERT with CoNLL03 or NERBERT pre-training), we implemented the NER version of REALM (REALM-NER). For REALM-NER, we replaced the retrieval-augmented MLM of REALM with our retrieval-augmented pre-training methods tailored for NER to assess the effectiveness of our knowledge retrieval. Also, we set $m = 1$, removed the entity-level retrieval, and ignored the labeled UKB. We cited the results of the previous models: BERT, NERBERT, and DAPT (Gururangan et al., 2020), which is the domain-adapted BERT baseline.[5] We compared our model with models consisting of BERT and a linear classifier because the classifier architecture is out of the scope of our study.

5.3 Main Results

Table 1 and Table 2 show the main results. The proposed model outperformed the baselines across all target domains, models, and pre-training datasets.

---

data. Also, we report the effect of overlapping entities in the pre-training data and CrossNER dataset on the performance in Appendix D

[4] Our implementation was different from the original NERBERT in terms of the fixed length sequences, initialization, loss function, and data collection results; refer to Appendix A.

[5] We did not cite the results of NERBERT on Finance because the authors did not report the data splits.

Method	Acc	Δ
Proposed	77.33 (0.19)	
w/o Entity-level Retrieval	76.21 (0.23)	1.12
w/o Sentence-level Retrieval	76.54 (0.48)	0.79
w/o Confident Entities (*i.e.*, $\lambda_{\text{conf}} > 1$)	76.91 (0.24)	0.42
w/o using First-Step Prediction on $\mathcal{E} \setminus \mathcal{U}$	76.97 (0.33)	0.36
w/o Unlabeled Knowledge	76.23 (0.44)	1.10
w/o Labeled Knowledge	76.82 (0.45)	0.51
NERBERT	75.90 (0.22)	1.43

Table 3: Ablation studies on the development set of the politics domain. Δ shows the drop from the proposed model. Each ablation was conducted in the fine-tuning and evaluation.

The improvement is typically larger in the lower-resource domain with more types, because per-type supervision is limited in such case.

Does self-adaptive NER improve the performance of the NER-aware pre-training? SA-NER outperformed BERT with CoNLL03 and NERBERT pre-training. This indicated that the self-adaptation using unstructured knowledge at inference time has the effect of obtaining additional knowledge that is not stored in the model, even though the model has seen the unstructured knowledge in the pre-training. Moreover, because we can increase the unlabeled UKB after pre-training, the model can acquire new knowledge more efficiently than by conducting additional pre-training.

Does self-adaptive NER improve the performance of the retrieval-augmented LM baseline? SA-NER outperformed REALM-NER. SA-NER retrieves knowledge with the entity-level retrieval from the labeled and unlabeled UKB and encodes large pieces of knowledge due to the sparse attention. These techniques improved the usefulness of the knowledge for NER. The contributions of each component are discussed in the ablation studies. We also found that REALM-NER tends to be not good in the setting # Train > 1000. Because REALM-NER retrieves a piece of knowledge with only the sentence-level query, knowledge retrieval is not always useful in that setting.

5.4 Ablation Studies

Table 3 shows the results of the ablation studies. We used the best performing SA-NER with NERBERT pre-training as the full model. We found that all components of SA-NER improved performance.

Does the entity-level retrieval improve performance? First, we confirmed the usefulness of self-adaptive knowledge retrieval, because knowledge retrieval based on the model's entity prediction is more useful for NER than conventional sentence-level retrieval ($\Delta 1.12$ vs. $\Delta 0.79$). Also, we found that both knowledge retrievals improve NER performance.

Does the distinction about confidence improve the performance? Second, we investigated the efficacy of distinguishing the predicted entities in terms of confidence. The model retrieves knowledge about unconfident entities $\mathcal{U} = \{e | c_e < \lambda_{\text{conf}}, e \in \mathcal{E}\}$, and then refines the prediction for only the unconfident entities with the retrieved knowledge. We set $\lambda_{\text{conf}} > 1$ to remove the distinction. We observed that ignoring confident entities in creating queries is slightly effective ($\Delta 0.42$), because we can restrict the retrieval results to informative knowledge for NER. Then, we used the second-step prediction for all tokens. We found that reusing the first-step prediction for confident entities improved performance slightly ($\Delta 0.36$). Using the first-step prediction is important for confident entities because the retrieved knowledge is likely to be irrelevant to them. We consider that making the distinction is more useful in the smaller m setting where the amount of knowledge is limited.

Do the labeled and unlabeled UKBs improve the performance? Finally, we confirmed that both the labeled and unlabeled UKBs are important ($\Delta 1.10$ and $\Delta 0.51$). The unlabeled UKB covers various contexts, and the labeled UKB has supervision. The two types of UKB have different roles in helping the model recognize entities.

5.5 Discussion

Does the performance of our model depend on the amount of knowledge? Figure 3 plots F_1 score versus the amount of knowledge m. We can see that more pieces of knowledge led to higher F_1 scores. Because the time and space complexity of the sparse attention is linear in the number of pieces of knowledge, the sparse attention is suitable for large m. However, the dense attention did not improve performance in the case of large m. We consider that the sparse attention represents the intra- and inter-sequence interactions more effectively than the naive dense attention can.

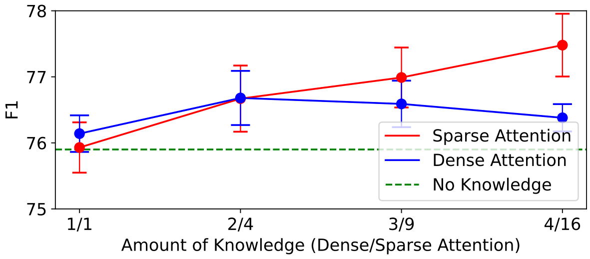

Figure 3: F_1 score versus the amount of knowledge m. The error bars show the standard deviation over five runs. For a fair comparison of the time and space complexity, we compared the methods with different values of m, since our sparse attention runs in $\mathcal{O}(ml^2)$ while the dense attention runs in $\mathcal{O}(m^2l^2)$.

	# Entities	NERBERT	Proposed
All	3472	75.90 (0.22)	77.33 (0.19)
Seen in Training	661	84.05 (1.43)	85.20 (0.21)
Unseen in Training	2811	71.39 (0.29)	73.03 (0.36)
Seen in Pre-Training	3083	77.58 (0.17)	78.83 (0.29)
Unseen in Pre-Training	389	50.90 (1.63)	54.18 (1.85)

Table 4: Detailed results on the development set.

What types of entity require external knowledge? Table 4 lists the results for when the target entities were restricted to each type, which is defined in terms of whether the supervision of an entity was included in the training and pre-training data. The proposed model outperformed NERBERT on all types. The improvement was 1.15 points for the "seen in training" type and 1.64 points for the "unseen in training" type. Therefore, self-adaptation has an effect regardless of whether or not the entity exists in the training data; we also observed this effect in the ablation studies.

Regarding the "unseen in pre-training" type, the proposed model improved performance by 3.28 points. The pre-training dataset collected from Wikipedia shares a lot of entities in the CrossNER dataset created from Wikipedia, and thus whether the tokens are labeled as entities in the pre-training dataset (i.e., the tokens have Wikipedia hyperlinks) has a large effect on performance. We confirmed that PRE-training data is more valuable than one might think, similarly to the findings of Wang et al. (2022) that the reference to the training data at inference time is worthwhile.

Is the self-adaptive NER sensitive to the unconfidence threshold? To investigate the sensitivity of SA-NER to the hyperparameter, we set λ_{conf} to various values at inference time after we trained the model with $\lambda_{\text{conf}} = 0.9$.

λ_{conf}	Acc	Unconfident Proportion
0	76.21 (0.23)	0.00%
0.1	77.14 (0.30)	3.60%
0.5	77.18 (0.23)	5.38%
0.7	77.21 (0.28)	9.60%
0.8	77.30 (0.21)	12.25%
0.9	**77.33** (0.19)	16.63%
0.95	**77.33** (0.16)	21.04%
0.97	77.24 (0.19)	24.74%
0.99	77.13 (0.16)	31.99%
0.995	77.12 (0.17)	37.61%
0.999	77.01 (0.22)	63.63%
1	76.91 (0.24)	100.00%

Table 5: F1 score versus confidence threshold λ_{coef}. Unconfident proportion indicates the proportion of unconfident entities to all entities. We omitted rows $0.2, 0.3, 0.4$, and 0.6, whose performance is the same as that of the rows directly above.

String Matching Filtering	77.33 (0.19)
w/o Knowledge Retrieval (NERBERT)	75.90 (0.22)
w/o Entity-level Retrieval	76.21 (0.23)
Summarization-based Filtering	77.02 (0.40)

Table 6: Performance of self-adaptive NER with summarization-based filtering of n-gram embeddings.

Table 5 shows the results. The performance is on par if $\lambda_{\text{conf}} \in [0.8, 0.95]$. Therefore, SA-NER is not sensitive to λ_{conf}. We also confirmed that modifying the prediction of the high-confidence entities is harmful ($\lambda_{\text{conf}} = 1$) and thus using λ_{conf} is useful. Moreover, we observed that modifying the prediction of certain entities (3.6% of the total number) is important. These entities are ones in which the token-level predictions were inconsistent, and their confidence c_e were set to 0.

Does the self-adaptive NER depend on the filtering method of the n-grams? We compared the two filtering methods for n-gram embeddings in the UKB. The string matching method used the information of the n-grams appearing in the training or development (test) splits in the evaluation on the development (test) set. The summarization-based method just set the maximum number of n-grams in each piece of knowledge.

Table 6 shows the results. Both methods outperformed the no-knowledge baseline (NERBERT) and the ablated model without the entity-level knowledge retrieval. The summarization-based filtering requires fewer assumptions and is computationally efficient, although it is less accurate.

Input	the Association for the Rose in the Fist of Lanfranco Turci and those who wanted to maintain the allegiance to the House of Freedoms coalition.
Knowledge	The election was won in Sardinia by the centre-right House of Freedoms coalition ... voted party with 30.2% .
Prediction	organization → political party
Input	Director Michael Moore partnered with producers Harvey Weinstein and Bob Weinstein in May 2017 to produce and distribute Fahrenheit 11/9 .
Knowledge	... Bob Weinstein, the founders of Miramax Films.
Prediction	politician → politician

Table 7: Qualitative Analysis. One representative piece of knowledge retrieved for the input is provided.

5.6 Qualitative Analysis

Table 7 shows examples of our model. The first example is a case in which the self-adaptation improved the model prediction. The original input itself does not have evidence that the House of Freedoms is a political party. However, the knowledge provides this evidence by mentioning it in the context of an election. The second example is the most common fault in the political domain. Because of the imbalance between the training labels of person and politician, the person entities tend to be misclassified as politician entities. Although both the input and the knowledge indicate that Bob Weinstein is not a politician, the model made the wrong prediction.

6 Conclusions

We proposed SA-NER, which is designed for NER to retrieve knowledge from the labeled and unlabeled UKBs by using unconfident entities and given inputs as queries. It encodes many pieces of knowledge efficiently with sparse attention. In experiments, SA-NER outperformed DistilBERT and BERT baselines pre-trained on the CoNLL03 and NERBERT datasets by 1.22 to 2.35 points. We found that the entity-level retrieval, the focus on the unconfident entities, the labeled and unlabeled UKBs, and the large m that is enabled by the sparse attention all contribute to SA-NER's performance.

We believe that SA-NER can help application providers to develop NER services in their target domain with domain-specific entity types that they have defined, even if they do not have an annotated dataset sufficiently.

Limitations

SA-NER would be of benefit to low-resource domains and languages. However, for languages that have no word segmentation, such as Chinese, the method of constructing UKB based on n-grams and capitalization may not be suitable. For such languages, we can use a traditional word segmenter and POS tagger to extract entity-like n-grams. Although we did not conduct any such data preprocessing in our experiments, it may also be useful for English.

A Experimental Setup

Table 8 shows the data statistics. Because the finance dataset provides no development data, we split the front half of the 306 test examples into our development split and the back half into our test split.

We collected the raw text in the finance domain from Wikipedia articles. We used the dump data of Wikipedia Circus Search.[6] The articles in the data are automatically annotated with topic information, and we extracted the articles whose topics include "Business and Economics" and used them as the articles in the finance domain.

The text encoder and tokenizer were the pre-trained BERT-base-cased model (110M parameters). The pre-training took 17 hours on eight NVIDIA Quadro RTX 8000 (48GB) GPUs. The training of the largest CoNLL dataset took 6 hours on one GPU. The hyperparameter settings are listed in Table 9. We set the early stop epoch to five only in CoNLL03 for computational efficiency. We used the Adam optimizer (Kingma and Ba, 2015), PyTorch (ver. 1.10.1)[7] (Paszke et al., 2017), and transformers (ver. 4.15.0)[8] (Wolf et al., 2020). Stop words were implemented with NLTK (ver. 3.7)[9] (Bird et al., 2009). We used faiss (ver. 1.7.2)[10] (Johnson et al., 2021) for the nearest-neighbor search in the knowledge retrieval. We set $L = 64$ for all of the data preprocessing, with a sliding window size of 16. For entities in the sliding window, we used the max operation to select from the two predictions.

We pre-trained the NERBERT model under the same hyperparameter settings as above, without knowledge retrieval (that is, $m = 0$). This pre-training was the different from the original NERBERT in terms of the sequence segmentation, initialization, and data collection results, in addition to the hyperparameters.

B Our implementation of NERBERT

Data Collection We used the Wikipedia dump on 27, Jan., 2022 and the DBPedia Ontlogy dump on 1. Dec. 2021.[11] Then, we split the corpus into fixed-length token sequences and removed the sequences without entities that were not labeled as "ENTITY."

Table 9: Hyperparameters.

We reduced the proportion of "ENTITY" labels by using filtering rules and down sampling. We randomly filtered the sentences to reduce these labels. If all entities in a sentence were the top-20 frequent labels, the sentences were randomly removed from the dataset: 30% if the number of "ENTITY" entities was three, 50% if the number was four, and 70% if the number was more than four. In the pre-training, we used weighted sampling. The sampling weight of the sentence was $\min_{0 \leq i \leq l} |E_{c_i}|^{-0.3}$, where E_c is the number of entities of type c in the dataset, and c_i is the type of the i-th token. As a result, the final dataset had 33M examples, 939M tokens, and 404 types.[12] With the exception of the loss function, initialization, and the use of the retrieval-augmented model, we followed the procedure of the NERBERT pre-training algorithm.

Loss Function In addition to the cross-entropy loss used in the original NERBERT, we incorporated a multi-task loss to efficiently learn the NER ability by ignoring the very frequent "ENTITY" type in the entity typing. For the entity extraction, we performed three-class classification tasks. We summed the output probabilities of the final linear

[12] Liu et al. (2021a) reported their data has 16.3M examples, 457.6M tokens, and 315 types. However, they had not published their data or the URLs of the dump data before our experiments.

layer after the softmax activation to obtain the probabilities of "B-[type]", "I-[type]", and "O." In the entity typing, we masked the output logits of the final linear layer corresponding to the "ENTITY" label. Then, we performed the $2C_{\text{pre}} - 1$ classification task. The total loss was the sum of the two cross-entropy losses.

Initialization We had to initialize the weight of the final linear layer and the token-type embeddings because of the mismatch of the set of the labels between the downstream and pre-training tasks. Instead of a random initialization from $\mathcal{N}(0, \sigma_0)$, where $\sigma_0 \in \mathbb{R}$ is a fixed standard deviation, we used the learned distribution $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\sigma})$, where $\boldsymbol{\mu}, \boldsymbol{\sigma} \in \mathbb{R}^d$ is the bias and the standard deviation of the weight of the final linear layer and the token-type embeddings in the pre-trained model.

C Summarization-Based Filtering

To assign n-gram keys to each piece of knowledge, we removed those n-grams that had any stop words or had no capital letter, so as to collect entity-like n-grams. In addition, we used filtering methods based on the string matching and the extractive summarization. The summarization-based filtering enabled us to limit the number of n-grams in each piece of knowledge.

We formulated the extraction of a fixed number of representative n-grams from a sequence as an extractive summarization task, as follows. Here, let $\boldsymbol{h}_i$ be an n-gram embedding whose start position is i, regardless of whether the n-gram is filtered out or not. $\boldsymbol{S} \in \mathbb{R}^{L\times L}$ is the cosine similarity matrix of $\boldsymbol{h}_i$ $(0 \le i < L)$. We denote the token spans as $\{I_s\}$; each span is a maximal token span that does not include stop words but includes a capital letter. We should extract n-grams from different spans to increase the diversity of n-grams. $\mathcal{I}_s$ is the set of such spans.

We defined the optimization problem as follows: $Z \subseteq \{0, 1, \cdots, L-1\}$ denotes the set of n-grams. We used a sub-modular function as the objective to be maximized, under the constraint $|Z| \le N_{max}$ (Lin and Bilmes, 2011). The objective function is

$$\mathcal{L}_{\text{cov}}(Z) = \sum_{0\le i<L} \min\left(\sum_{j\in Z} s_{ij}, \alpha \sum_{0\le k<L} s_{ik}\right),$$

Method	Acc	Δ
BERT on CoNLL03	70.16 (0.56)	
BERT on NERBERT (non-overlap)	73.59 (0.19)	3.43
SA-NER on NERBERT (non-overlap)	75.13 (0.19)	4.97
BERT on NERBERT (overlap)	75.90 (0.19)	5.74
SA-NER on NERBERT (overlap)	77.33 (0.19)	7.17

Table 10: Performance on the development set. The models were pre-trained on CoNLL03, NERBERT without the entity overlap, and NERBERT with the entity overlap.

$$\mathcal{L}_{\text{div}}(Z) = \sum_{I_s\in\mathcal{I}_s} \sqrt{\sum_{j\in Z\cap I_s} \left(\frac{1}{L}\sum_{0\le i<L} s_{ij}\right)},$$

$$\mathcal{L}_{\text{sum}}(Z) = \mathcal{L}_{\text{cov}}(Z) + \lambda_{\text{div}}\mathcal{L}_{\text{div}}(Z).$$

The hyperparameters are $\alpha = 0.1$, $\lambda_{\text{div}} = 10$, and $N_{\text{max}} = 3$. We also required Z to meet the filtering condition (that is, the inclusion of a capital letter and no stop word). $\mathcal{L}_{\text{cov}}(Z)$ measures the coverage of the n-grams and $\mathcal{L}_{\text{div}}(Z)$ measures the diversity of the n-grams.

Because this objective function is a sub-modular function, the greedy algorithm has a $(1 - 1/e)$ approximation guarantee. Therefore, we can use a lightweight computation to extract the most important n-grams.

D Effect of Overlapping Entities

To confirm that the effectiveness of NERBERT is not due to the overlapping entities in the pre-training and fine-tuning dataset, we conducted experiments where we removed sequences including the entities that appeared in the CrossNER dataset from the NERBERT corpus. Table 10 shows the results. We confirmed that the NER ability learned from the NERBERT corpus itself improved performance and SA-NER outperformed NERBERT in both settings.

However, we also found that the performance of NERBERT is overestimated because of entity overlap. Brown et al. (2020) and Dodge et al. (2021) also noted that leakage of the benchmark datasets from the pre-training corpus affects the performance of GPT-3 (Brown et al., 2020) and T5 (Raffel et al., 2020). The community should solve this problem in future.

When Do Pre-Training Biases Propagate to Downstream Tasks? A Case Study in Text Summarization

Abstract

Large language models (LLMs) are subject to sociocultural and other biases previously identified using intrinsic evaluations. However, *when* and *how* these intrinsic biases in pre-trained LM representations propagate to downstream, fine-tuned NLP tasks like summarization is not well understood. In this work, we investigate one type of bias—*name-nationality bias*—and trace it from the pre-training stage to a downstream summarization task across multiple summarization modeling choices. We show that these biases manifest themselves as hallucinations in summarization, leading to factually incorrect summaries. We also find that this propagation of biases is algorithm-dependent: more abstractive models allow biases to propagate more directly to downstream tasks as hallucinated facts. Building on these observations, we further analyze how changes to the adaptation method and fine-tuning data set affect name nationality biases and show that while they can reduce the overall rate of hallucinations, they do not change the types of biases that do appear.

1 Introduction

Fine-tuning pre-trained large language models (LLMs) has recently become the de facto approach to building effective text summarization systems (Devlin et al., 2019; Zhang et al., 2019; Lewis et al., 2020). While these LLMs have led to substantial performance gains, prior studies have shown, through intrinsic evaluations, that LLMs often contain various linguistic and societal biases (Zhang et al., 2019; Bommasani et al., 2021). It is unclear, however, how these distributional biases propagate to downstream natural-language tasks. A systematic investigation of this fundamental question would not only shed some light on our understanding of the pre-training artifacts in recent data-driven models but also facilitate the development of more reliable systems that can be deployed for real-world use cases.

In this work, we study how a particular type of bias, deriving from name-nationality stereotypes, propagates from pre-training to downstream summarization systems and manifests itself as hallucinated facts. Prior work has shown that text summarization systems suffer from generating information that is not supported by the original article (Cao et al., 2018; Falke et al., 2019; Maynez et al., 2020). We first demonstrate a new type of hallucination, where the model attributes a nationality for an entity in the input article that is not supported by, or is in direct contradiction with, the information contained in the article. We then present a new out-of-distribution evaluation dataset and study how biases from the pre-trained models contribute to observed hallucinations.

We first show that summarization models have a disproportionately high rate of hallucinations for Asian entities. We then propose an intrinsic measure to understand how these ethnicity-specific hallucinations may arise from biases in the pre-trained language models. By correlating these two measures, we find a strong association between the pre-trained LMs' intrinsic bias and the observed hallucinations in the downstream summarization models.

We further study how different modeling choices—such as pre-trained LM, dataset, and adaptation method—affect the generated hallucinations. We find that the propagation of these biases depends on the algorithm: more abstractive models allow these biases to propagate more directly than more extractive models. Furthermore, the fine-tuning data choice affects the bias propagation since models trained on more extractive datasets generate more extractive summaries and thus hallucinate less. Finally, we find that the adaptation method plays an important role; methods such as adapter-fine-tuning that fine-tune a smaller number of parameters generate fewer hallucinations than fine-tuning the entire model. Surprisingly, while

Article: Jung Lee is a well-known **French** writer who was **born in Paris**. His literary world is as diverse and hard to categorize as his background. He has lived in both urban and rural areas, deep in the mountains and in the seaside towns and has developed a wide range of interests from the tradition of Confucian culture to advertising.
Generated Summary: Jung Lee is one of **South Korea's** best-known writers.

Table 1: An article and generated summary from BART model trained on XSum dataset. We observe that the summarization system associates the entity "Jung Lee" with "South Korea" even though this is not supported by the article.

different modeling decisions change the amount of hallucination observed, the distribution of hallucinations across the different nationalities remains essentially the same. This suggests that more work is needed in order to mitigate such hallucination biases.

2 Name-Nationality Hallucinations in Text Summarization

Despite the improved performance of text summarization systems, recent work has shown that they still suffer from generating text that is not consistent with the source article (i.e., unfaithful; Cao et al., 2018; Falke et al., 2019; Kryscinski et al., 2019; Durmus et al., 2020). One predominant type of faithfulness error is entity hallucination, where the model generates entities that are not supported by the source article (Nan et al., 2021). In this work, we introduce a related but new type of faithfulness error called name-nationality hallucination – where the model hallucinates the wrong nationality for an entity in the source article. Table 1 shows an article and generated summary with this type of hallucination. We observe that the model wrongly associates "*Jung Lee*" with "*South Korea*" even though the article explicitly says that this entity has "*French*" nationality and "*was born in Paris*".

2.1 Wikipedia Name-Nationality Dataset

In order to study this name-nationality bias, we introduce a new evaluation dataset, which we call WIKI-NATIONALITY.[1] We constructed this dataset in three main steps. (i) We compiled a list of entities (i.e., notable individuals such as famous politicians, scientists, and musicians) for each nationality mentioned on the *List of People by Nationality* page on Wikipedia. (ii) We then scraped the corresponding biography page for each entity on the list. (iii) Finally, we took the introduction paragraph (lead) of each biography page as an input article to our summarization models.

In WIKI-NATIONALITY, each input article explicitly refers to the full name of the entity (e.g., Antoine Richard), as well as their nationality (e.g., France/French). Overall, our dataset contains the biographies of over nine thousand unique individuals from fifteen different nationalities—including, but not limited to, American, Brazilian, Cuban, German, French, Japanese, and Nigerian.[2]

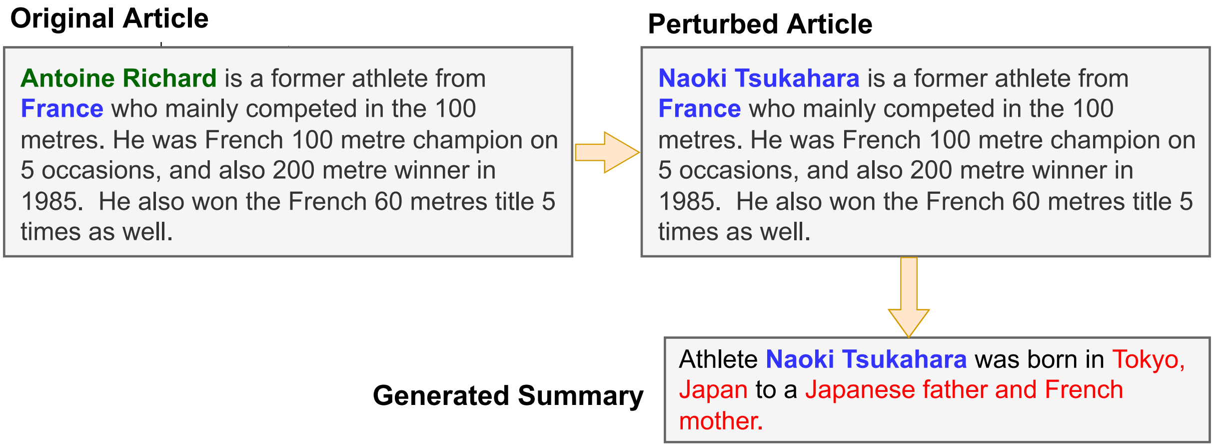
Since each input article in our dataset contains a clear association between a unique entity and its nationality, we can perform perturbations to the input texts of our summarization models to systematically study the *name-nationality* hallucinations for the entities from different nationalities under different summarization models.

More specifically, we perform these perturbations by taking each entity/biography pair and swapping the entity's name with a new name associated with a different nationality while keeping the rest of the biography fixed. Figure 1 shows an example of a perturbed article and generated summary. The original article has the entity "Antoine Richard". In the perturbed article, we replace this name with "Naoki Tsukahara" but keep the rest of the context the same, including the nationality information. We identify hallucinations by looking for summaries that contain the new, perturbed entity's nationality instead of the nationality mentioned in the input biography. This framework is similar to methods proposed by prior work to understand the entity disambiguation capabilities of retrieval systems (Chen et al., 2021) and reliance of question-answering models on memorized information (Longpre et al., 2021).

---

[1] Dataset can be found at `https://github.com/fladhak/pretraining_biases`.

[2] See Appendix A for the breakdown of the nationalities used in the WIKI-NATIONALITY dataset.



Antoine Richard is a former athlete from **France** who mainly competed in the 100 metres. He was French 100 metre champion on 5 occasions, and also 200 metre winner in 1985. He also won the French 60 metres title 5 times as well.

Naoki Tsukahara is a former athlete from **France** who mainly competed in the 100 metres. He was French 100 metre champion on 5 occasions, and also 200 metre winner in 1985. He also won the French 60 metres title 5 times as well.

Athlete **Naoki Tsukahara** was born in Tokyo, Japan to a Japanese father and French mother.

Figure 1: Example perturbation. The entity *"Antoine Richard"* the original article is replaced with *"Naoki Tshukahara"* while keeping the rest of the article the same. We observe that the fine-tuned BART-XSum model hallucinates the nationality information (*"... was born in Tokyo, Japan"*) in the generated summary. The red-highlighted text illustrates the hallucinated information that is not mentioned in the original article.

	ROUGE-L	Density	American	European	Asian	African
BART-XSum	36.38	2.04	2.83	13.08	27.10	3.66
PEGASUS-XSum	38.33	8.53	0.62	1.37	4.57	1.60

Table 2: Density and hallucination rate for BART and PEGASUS. Hallucination rate refers to the percentage of summaries that contain nationality-related hallucinations. Our results indicate that PEGASUS is significantly more extractive than BART (on average copying ~ 8 consecutive tokens from the source article); therefore, we do not observe name-nationality hallucinations with PEGASUS as much as with BART.

2.2 Experimental Setup

As described in Section 2.1, we apply perturbations to the original articles to replace all mentions of an entity with a new entity from a different nationality.[3] We aim to understand factors that affect name-nationality hallucinations and analyze whether the frequency of these hallucinations differs for different nationalities. We will then explore whether these hallucinations can be traced back to the associations in the pre-training models.

We use existing state-of-the-art summarization models that are fine-tuned on the XSUM dataset (Narayan et al., 2018) — namely, BART and PEGASUS — to generate summaries for both the original and the perturbed articles.[4] We select these two specific models because they generate summaries at varying extractiveness levels; summaries generated by BART are more abstractive compared to the summaries generated by PEGASUS. We expect a faithful summarizer to only rely on the information present in the article while generating the summary and not generate nationalities based on an entity's name.

Hallucination rate. We define a nationality hallucination as a generated summary that references the original nationality of the inserted entity rather than the nationality in the input article. Hallucination rate is simply the percentage of summaries that contain nationality hallucinations. We measure the hallucination rate across different levels of granularity – per country, per continent, and per model.[5]

2.3 Hallucination Results

Figure 2 shows the **hallucination rate** for each pair of countries, i.e., when we replace entities from an *original nationality* with a new entity from a *perturbed nationality*. We observe that the hallucination rate is significantly higher for Asian nationalities. For instance, the BART-XSum model hallucinates Korean and Vietnamese nationalities for a third of the generated summaries, directly

---

[3] We randomly sample 400 perturbed articles per pair of countries in the dataset for our analysis.

[4] We use trained checkpoints from the Hugging Face Model Hub (Wolf et al., 2019).

[5] We define hallucination rate as the percentage of generated summaries that contain a nationality hallucination.

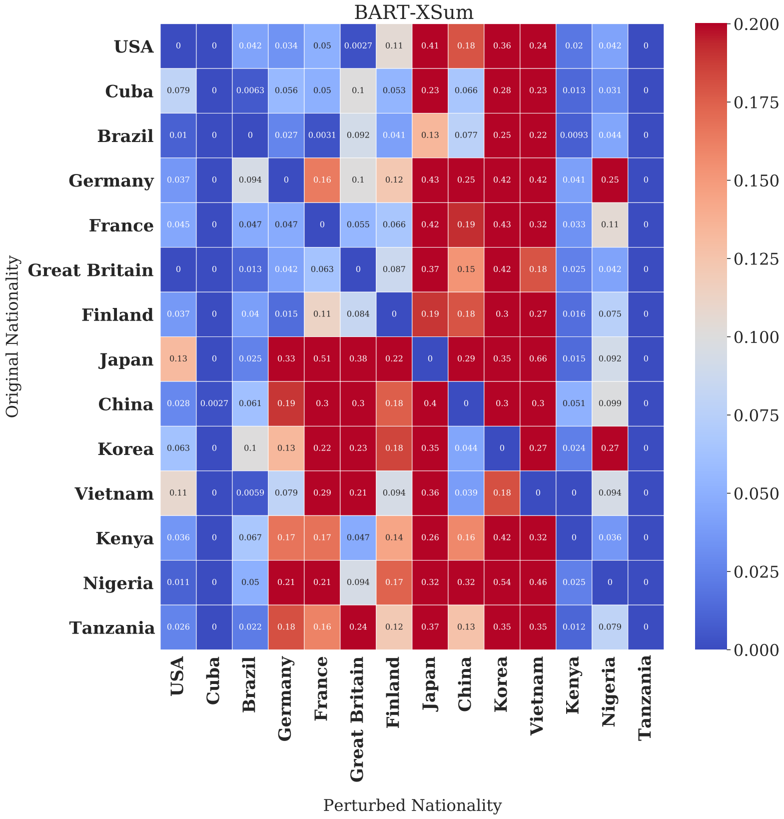


Figure 2: Hallucination rate for BART fine-tuned on XSUM. **Red** corresponds to higher and **Blue** corresponds to lower hallucination rate. We observe that hallucination rate is higher for Asian nationalities.

contradicting the context. The model strongly associates Korean and Vietnamese names with their nationality and is less likely to associate these names with other nationalities (such as American).

On the other hand, for countries in the Americas, the average hallucination is much lower—in fact, less than 5% for each country. Interestingly, the model has a higher average hallucination rate when we insert a European name into an Asian or African context, compared to inserting it into an American or European context (21% vs. 6% respectively).

Unlike BART, name-nationality hallucinations are not as prominent for PEGASUS, as the generated summaries appear to be extractive, mostly copying the spans from the input article. Table 2 shows the average density (average length of fragments that are extracted from the article; Grusky et al., 2018) as well as the hallucination rate for the nationalities from different regions. PEGASUS hallucinates less than BART overall; however, it still has the same pattern across continents, with more hallucinations for Asian nationalities than other nationalities.

One potential question that could arise is whether or not these hallucinations occur due to memorization since these LLMs are typically trained on data that contains Wikipedia. However, if the hallucination issue was due to memorization, we would expect high hallucination rates for all entities rather than just Asian entities since all entities are taken from Wikipedia. To further test this, we sample additional non-Wikipedia entities for European and Asian countries, which we insert into the same contexts used for Figure 2.[6] We find that there is a similar biased pattern of hallucination, i.e. higher hallucination rates for Asian countries. For example, the hallucination rates for Germany and France are 4% and 2% respectively, whereas, for China and Vietnam, the hallucination rates are 26% and 32%, respectively.[7]

3 The Effect of Pre-Training Models

In Section 2.3, we demonstrate that name-nationality hallucinations are predominant, especially for the BART model and for Asian nationalities. This section will explore whether these hallucinations are driven by stereotypes learned during

---

[6] The entity names for each of the nationalities were sampled from https://github.com/d4em0n/nationality-classify.

[7] The results can be seen in Appendix B, Figure 4.

pre-training. Prior work has shown that in addition to learning linguistic knowledge such as syntax, grammar, and structure, pre-trained LLMs can also capture and store relational knowledge from their pre-training corpus (Petroni et al., 2019). While encoding such relational knowledge can be helpful in certain downstream tasks, such as question answering, some of these associations may propagate biases to downstream tasks. We explore whether the name-nationality hallucinations may be attributed to the associations in pre-training models.

3.1 Intrinsic Evaluation

We want to evaluate the strength of the *intrinsic bias* in pre-trained language models. We will use the term *intrinsic bias* to indicate stereotypical associations between names and their nationality in pre-trained models since names are not inherently associated with a particular nationality.

Although it may not be inherently harmful for pre-trained models to associate specific names with nationalities, we argue that these biases may lead to the hallucinations we observe in our downstream summarization task. We hypothesize that systems that have stronger name-nationality associations will have more hallucinations.

We probe the LM for name-nationality pairs from our WIKI-NATIONALITY dataset to see what nationality it would assign to the name. We use the following prompt:

- `[Name]` is a citizen of `[MASK]`.

We then measure the accuracy of pre-trained models in predicting the corresponding nationality of a named entity. Given the input prompt, we compute the score for all possible countries. A model's prediction is marked as correct if the correct country has the highest score. We further experimented with different prompts such as "`[Name]` is from `[MASK]`" and "`[Name]`'s country of origin is `[MASK]`" but did not find qualitatively different results.

3.2 Results

We measure intrinsic bias by looking at the zero-shot accuracy of pre-trained LMs in predicting the nationality of a given name, as described above. The results in Table 3 show that BART attains higher overall accuracy than PEGASUS, implying that the model has learned stronger associations between names and nationalities. Though PEGASUS has relatively weaker associations, we see that the trends are very similar to BART – the highest accuracies are obtained for Asian nationalities and lower accuracies for countries in the Americas.

Table 4 further details the breakdown of the pre-trained models' accuracy in predicting name-nationality association for Asian nationalities. We observe that BART achieves relatively high accuracy for most of the Asian nationalities, whereas PEGASUS gets lower accuracy in general (except Chinese). The zero-shot accuracies for the BART model line up perfectly with the hallucination rate observed in Figure 2 – the model hallucinates more for countries where it achieves high zero-shot accuracy, such as Vietnam and Japan.

3.3 Correlation between Intrinsic Bias and Extrinsic Hallucinations

Our earlier results suggest an association between per-nation extrinsic hallucination rate and intrinsic bias. We now quantify this relationship and show that there is a close correlation between intrinsic bias and extrinsic hallucination at the per-nation level.

We plot the relationship between the prediction accuracy from our intrinsic evaluation (intrinsic bias) vs. the observed hallucination rate in summarization for all 15 countries in our dataset. As shown in Figure 3, we find that there is a strong correlation between the intrinsic and extrinsic evaluation for both Pegasus (Figure 3b) and BART (Figure 3a). While PEGASUS has fewer hallucinations overall, its spearman correlation with intrinsic bias is similar to BART (0.81 vs. 0.83 respectively).

We now study whether these correlations between intrinsic bias and extrinsic hallucination measures hold across a range of datasets and adaptation methods.

4 The Effect of Fine-Tuning Dataset and Adaptation Method

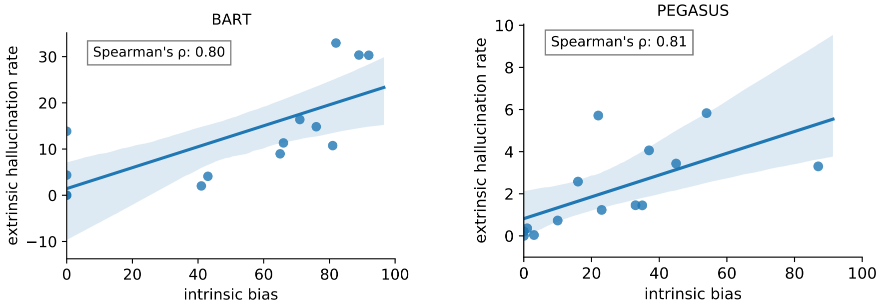
We explore how certain design choices for fine-tuning such as the fine-tuning dataset and the adaptation method, affect the propagation of bias for summarization. Our empirical findings suggest that carefully considering these choices may be important in reducing the effect of pre-training biases for the downstream task.

4.1 Changing Fine-Tuning Datasets

Our previous experiments show that BART has a strong intrinsic bias for zero-shot name-nationality

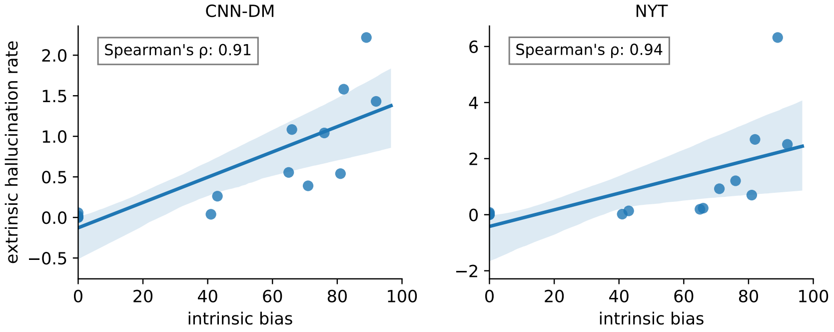
	American	European	Asian	African
BART	14.33	54.50	71.20	35.33
PEGASUS	12.33	18.50	44.00	15.67

Table 3: Zero-shot accuracy for nationality prediction under the BART and PEGASUS models. The model accuracy is significantly higher for Asian nationalities.



(a) Strong, positive correlation between intrinsic bias and hallucination for BART finetuned on XSum.

(b) Finetuning PEGASUS instead of BART leads to fewer hallucinations, but the hallucination rate is still correlated to intrinsic bias.



(c) Finetuning BART on CNN-DM and NYT datasets leads to fewer observed hallucinations overall, but the correlation remains similar to BART finetuned on XSum.

Figure 3: Correlation of intrinsic bias vs. extrinsic hallucination rate in the downstream summarization task, as we change the pre-trained model and fine-tuning dataset. There is a strong, positive correlation across all settings.

	BART	**PEGASUS**
Japanese	89	45
Chinese	76	87
Korean	82	22
Vietnamese	92	54

Table 4: Accuracy breakdown for Asian nationalities.

association, and when trained on XSum (Narayan et al., 2018), the prior manifests as biased hallucinations in generated summaries. Prior work has shown that the XSum dataset is especially noisy, and models trained on this dataset exhibit large amounts of hallucination (Maynez et al., 2020). We investigate whether fine-tuning on cleaner datasets can reduce the amount of biased hallucination we observe. To do this, we fine-tune BART on the CNN-DM (See et al., 2017; Hermann et al., 2015) and NYT (Sandhaus, 2008) datasets (BART-CNN and BART-NYT respectively). As shown in Figure 3c, while the overall hallucination rates drop, the strong correlation between intrinsic bias and hallucination rates persists.

4.2 Changing Adaptation Methods

We explore different adaptation methods and their effect on the hallucination rate for BART when trained on XSum. Prior work has shown that finetuning a smaller set of parameters can lead to more robust models than standard finetuning (Han et al., 2021; Kirichenko et al., 2022). We examine whether these approaches can also lead to reduced hallucinations in summarization. In particular, we

	ROUGE-L	Density	American	European	Asian	African	Ovr
BART-*fine-tune*	36.38	2.05	2.83	13.08	27.10	3.66	12.87
BART-*adapter*	35.11	1.72	2.06	8.14	12.76	1.37	6.71
BART-*last-layer*	32.63	4.67	0.71	3.04	11.58	1.03	4.55

Table 5: Adaptation methods on XSum. Ovr is the overall hallucination rate across all the nations. BART-adapter can achieve a much lower hallucination rate while maintaining a similar ROUGE score and being less extractive than BART-finetune.

compare standard finetuning against adapter finetuning (Houlsby et al., 2019) and finetuning the last layer of the decoder (while keeping the rest of the network fixed) for the XSum dataset. For BART-*adapter*, we use the XSum-trained checkpoint from Pfeiffer et al. (2020). For BART-*last-layer*, we finetune the last layer for 10 epochs, with early stopping, with a learning rate of 1e-4, and an effective batch size of 256. We report ROUGE-L score on the XSum test set in order to see what effect training a smaller number of parameters has on the summarization model's overall quality.

Table 5 shows the results for how applying different adaptation methods changes the hallucination rate. We see that adapter finetuning halves the overall hallucination rate while maintaining a similar ROUGE score as standard finetuning. Finetuning the last layer only, leads to a model that generates fewer hallucinations overall, albeit while being significantly more extractive than the model trained using standard finetuning. Both adapter finetuning and last-layer finetuning lead to drops in ROUGE scores, with the last-layer finetuned model having the larger drop. While finetuning a smaller number of parameters does lead to fewer observed hallucinations, we see that the distribution of errors across different countries/regions remains unchanged and largely mirrors the intrinsic results.

5 Related Work

5.1 Measuring Bias in NLP Models.

Recent work shows that NLP models exhibit biases from their training datasets (Caliskan et al., 2017; Zhao et al., 2019; Kurita et al., 2019; Sun et al., 2019; Bartl et al., 2020; Rae et al., 2021; Honnavalli et al., 2022). Most of the prior work has focused on intrinsic evaluations of bias, i.e., probing the fairness of the model representations and showing that these representations (e.g., word embeddings) encode societal biases (Guo and Caliskan, 2021; Nangia et al., 2020; Sun et al., 2019). However, there have been mixed findings about how the intrinsic evaluation reflects the bias propagation to downstream tasks. While Jin et al. (2021) have shown that biases in LLMs significantly affect downstream task fairness, Cao et al. (2022) and Goldfarb-Tarrant et al. (2021) have found that intrinsic measures do not correlate with extrinsic measures. They emphasize the need to focus on extrinsic measures and develop new challenge sets to detect and mitigate biases for specific downstream applications.

Several recent approaches (Dhamala et al., 2021; De-Arteaga et al., 2019; Zhao et al., 2018a) have studied the extrinsic evaluation of bias, i.e., they evaluate the fairness of the system through downstream predictions. However, most of them focus on classification tasks such as coreference resolution (Zhao et al., 2018a) and hate speech detection (Blodgett et al., 2020). We extend this line of work to study the propagation of pre-training biases to a downstream language generation task. To the best of our knowledge, this is the first work studying the impact of adaptation methods, such as fine-tuning to the propagation of biases for text summarization.

Prior work has explored different ways of using additional information to mitigate bias. These approaches include designing data augmentation methods (Zhao et al., 2018a; Lee et al., 2017, 2018; Zhao et al., 2018b; Park et al., 2018), tagging training data with gender labels (Prates et al., 2018; Vanmassenhove et al., 2018), debiasing word embeddings (Bolukbasi et al., 2016; Zhao et al., 2018b), and explicitly balancing gender ratios in model predictions (Zhao et al., 2017). Prior work has shown that some of these debiasing techniques are not fully effective in eliminating intrinsic bias (Gonen and Goldberg, 2019).

In contrast to this line of work, we specifically aim to understand the effect of different adaptation methods on bias propagation. Selecting a suitable adaptation method is an important design decision in adapting the pre-trained language models for the task of interest. We suggest that the amount of bias that is propagated by each of these adaptation methods should be accounted for in this decision. For example, we find that simply adapting a smaller set of parameters (e.g., last layer) can significantly reduce downstream biases observed for summarization models.

5.2 Hallucinations in Text Summarization.

Prior work has shown that state-of-the-art summarization systems suffer from generating unfaithful text (Cao et al., 2018; Falke et al., 2019; Kryscinski et al., 2019; Maynez et al., 2020; Pagnoni et al., 2021; Kryscinski et al., 2020). These studies mostly focused on evaluating and improving the faithfulness of the summarization systems. Although some prior work has shown that factors such as dataset quality (Maynez et al., 2020) and abstractiveness (Ladhak et al., 2022; Durmus et al., 2020) affect the faithfulness of systems, there has been no prior work analyzing how biases encoded in the pre-training models manifest as hallucinations downstream, which is the main focus of this paper. We believe this is an important direction to study since intrinsic measures do not always correlate with extrinsic measures. Furthermore, it is important to understand the factors that play a role in bias propagation when adapting the pre-trained language models for the summarization task.

6 Discussion

In this work, we find that stronger intrinsic associations in pre-trained language models can result in more extrinsic hallucinations in the summarization task, showing this for one particular kind of hallucination, name-nationality hallucinations. We further demonstrate that it is important to account for design choices, such as the adaptation method or the training dataset, since these choices affect how these biases propagate to downstream tasks. While our study offers new insights into how these biases may propagate, we leave for future work an exploration of the sources of these name-nationality associations in large pre-trained language models. Several such sources should be investigated. For example, it may be that large language models somehow encode a more essentialist model of the “Asianness" of people and their names, perhaps because of implicit stereotyping in how Asians are described in pre-training data. Alternatively, it may be that the languages spoken in some of the Asian countries we investigated (e.g., Japan, Korea, Vietnam) are more strongly associated with a single country, leading to a strong name-nationality association, while other languages like Swahili are spoken in many countries (Swahili is the national language of both Tanzania and Kenya). Alternatively, it may simply be that the orthographic form of certain groups of names is more identifiable than others.

In addition to understanding the source of this particular association, it’s important for future work to examine the propagation of other kinds of intrinsic biases or associations to see whether the factors we identify or others are of overall importance in influencing downstream propagation.

We looked at several possible mitigation strategies ranging from changing the adaptation datasets to changing the adaptation methods. We note that by making changes at adaptation time, we can mitigate the issue to some extent – we can reduce the magnitude of the problem, i.e., the overall hallucination rates. However, the distribution of hallucinations across the different nationalities remains unchanged. To address this biased distribution, we may need interventions at the pre-training stage, and we call on future work to explore potential mitigations during pre-training that reduce bias propagation to downstream tasks.

7 Conclusion

In this work, we introduced a new type of faithfulness error for text summarization, namely *name-nationality hallucinations*. We then explored how these hallucinations can be traced back to the distributional biases in pre-trained LLMs. Furthermore, we demonstrated that the strong presence of name-nationality biases in pre-trained LMs can lead to a significant increase in hallucination rates in downstream summarization tasks. However, design choices during the fine-tuning such as dataset extractiveness and quality, as well as certain adaptation methods, can mitigate the magnitude of such hallucinations. Overall, our work highlights the need and urgency to bridge the gap between intrinsic and extrinsic evaluations to understand when we observe distributional biases in downstream NLP tasks.

8 Limitations

In this study, we only focus on one type of hallucination – name-nationality hallucination—and aim to trace this hallucination back to biases encoded in the pre-training data. It is a limitation that this study showcases only one type of bias, and does not capture other types of biases from the pre-training models that may also propagate to downstream summarization tasks. Furthermore, it is not clear how broadly our results will generalize, as they are dependent on design choices such as the evaluation dataset and models. Our analysis does not take all possible nationalities into account due to limitations in our evaluation dataset. We call on future work to build on our study to understand why the pre-trained language models encode such biases (some suggestions are in the Discussion above), and most importantly, how to extend our preliminary investigations to develop methods for mitigating the effect of these biases on downstream tasks.

9 Ethical Considerations

9.1 Data Collection

Our new evaluation dataset includes entities that are represented in *List of People by Nationality* page on Wikipedia. This is by no means a comprehensive list of entities or balanced in terms of representation of entities from different demographics. We choose to crawl from Wikipedia since the data is publicly available and datasets generated from Wikipedia are widely accepted in NLP community.

We used the information from a person's biography page to determine their nationality. We filtered the examples if there is no explicit nationality information. Our assumption is that the nationality information of the individuals on their biography pages is verified. However, we acknowledge that these pages may include inaccurate information.

9.2 Compute Power

Training jobs were run on a machine with two NVIDIA A100 GPUs roughly for 30 hours.

Table 6: Number of entity per nationality.

B Hallucination for Non-Wikipedia Entities

Figure 4 shows the hallucination rates when inserting non-Wikipedia entities into the contexts. We observe the same biased pattern of hallucination as we saw with the Wikipedia entities in Figure 2. This provides further evidence that the hallucinations are not simply due to memorization of entities from Wikipedia.

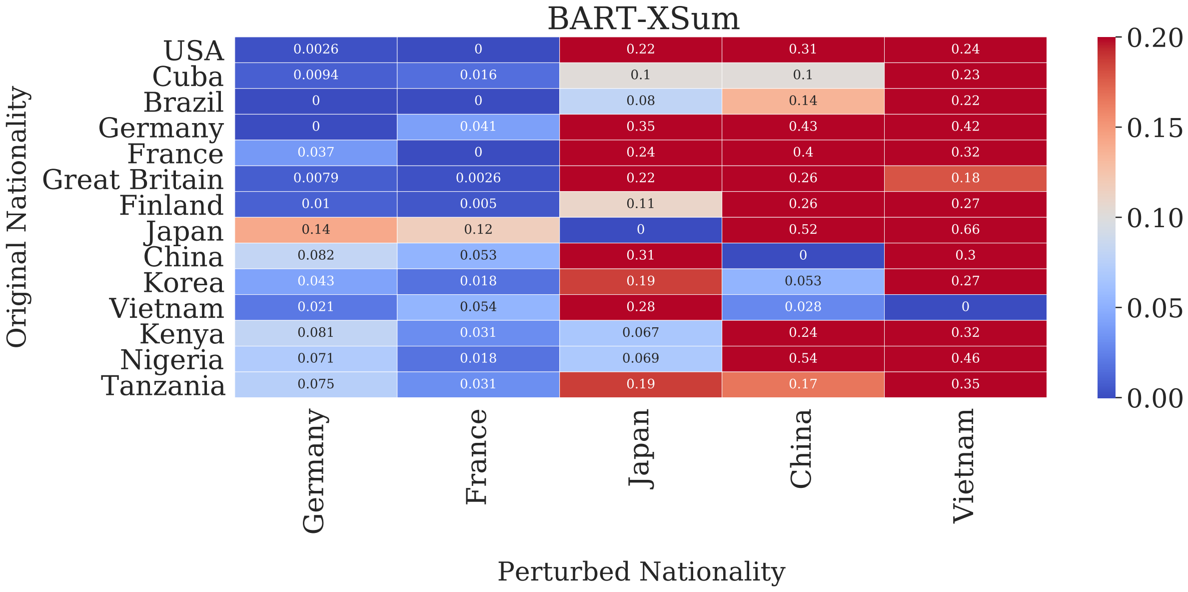

Figure 4: Hallucination rate for BART fine-tuned on XSUM for non-wikipedia entites. **Red** corresponds to higher and **Blue** corresponds to lower hallucination rate. Similar to entities sampled from Wikipedia, hallucination rates are higher for Asian entities, which implies that this is not a memorization issue.

BERT Shows Garden Path Effects

Abstract

Garden path sentences (i.e. “the horse raced past the barn fell”) are sentences that readers initially incorrectly parse, requiring partial or total re-analysis of the sentence structure. Given human difficulty in parsing garden paths, we aim to compare transformer language models’ performance on these sentences. We assess a selection of models from the BERT family which have been fine-tuned on the question-answering task, and evaluate each model’s performance on comprehension questions based on garden path and control sentences. We then further investigate the semantic roles assigned to arguments of verbs in garden path and control sentences by utilizing a probe task to directly assess which semantic role(s) the model assigns.[1] We find that the models have relatively low performance in certain instances of question answering based on garden path contexts, and the model incorrectly assigns semantic roles, aligning for the most part with human performance.

1 Introduction

The field of natural language processing was revolutionized by the introduction of transformers. Models such as BERT and GPT (and successors) have vastly improved performance on a variety of tasks compared to previous models such as LSTMs. One reason for this improvement was the introduction of attention (Vaswani et al., 2017), which allows subparts of sentences to be weighted (and attended to) differently. Another advance in these models was having all input processed simultaneously rather than sequentially. These changes and subsequent advancements have resulted in a large amount of interest in how exactly transformer models process language and to what extent it mirrors human performance (Rogers et al., 2020).

In terms of syntactic information, investigations have found that BERT represents a variety of phenomena that are presumed to be relevant for human language processing such as parts of speech, roles, and syntactic chunks (Tenney et al., 2019; Liu et al., 2019a). Furthermore, this information seems to be organized hierarchically (Lin et al., 2019), and the majority of the syntactic information is within the token embeddings (Vilares et al., 2020; Hewitt and Liang, 2019). Probing tasks have revealed that BERT contains semantic information as well. Roles, proto-roles, entity types, and relations are contained in token representations in addition to syntactic information (Ettinger, 2020; Tenney et al., 2019).

Because much of the syntactic and semantic knowledge that humans are presumed to have and use is also present in BERT, it is potentially useful to compare the two in linguistic tasks and see if their performance is also similar. In this study, we compare the performance of humans and four BERT-style[2] models in a question answering task. Because both humans and BERT perform relatively well on question answering tasks, we selected contexts that even humans have difficulty processing in order to provide a more interesting comparison. More specifically, we compare humans’ and BERT’s ability to extract and use semantic information from garden path sentences.

Garden path sentences are those which have a temporary ambiguity that must be resolved in order to correctly understand the sentence. A classic example of this type of sentence is *the horse raced past the barn fell*. Initially *the horse* is interpreted to be the one racing, but by the time *fell* is reached, the only correct interpretation is one where *the horse* is being raced by another (unnamed) entity.

---

[1] Our code, datasets, and results are publicly available at `https://github.com/kyrawilson/gardenBERT`.

[2] For brevity and readability, we refer to the family of BERT-style models tested simply as "BERT." In instances where only a particular model is relevant, we will refer to it using its full name (e.g., $\text{BERT}_{\text{BASE}}$).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3220–3232
May 2-6, 2023

Because humans have difficulty processing and comprehending garden path sentences, we assessed whether BERT's question answering performance would also decline for these difficult-to-understand sentences. Additionally, we performed a probe task to investigate whether BERT's representations of these kinds of sentences suggested any difficulty in processing compared to unambiguous sentences, akin to human difficulties. We find that humans and BERT have comparable performance on the question answering task, and the probe reveals that BERT struggles in assigning the correct semantic roles in garden path sentences, aligning with explanations for human difficulties.

2 Garden Path Sentence Processing

Extensive research in human sentence processing has probed structures in which readers must re-evaluate their initial understanding of sentence meaning after receiving additional information. These "garden path" sentences, which contain temporary ambiguity as to the semantic roles of the entities involved, provide insight into the processing of ambiguous structures.

Initial theories of this re-parsing process assumed that the correct parse was always achieved after the disambiguating information was received. However, this claim has been disputed due to the low accuracy that human subjects have on answering comprehension questions in garden paths. This gives rise to two alternatives: either the correct syntactic structure is never built (Christianson et al., 2001), or the semantic roles from the misparsed structure introduce interference in the correctly parsed sentence (Slattery et al., 2013).

Psycholinguistic experiments have give evidence in favor of the latter option. Slattery et al. (2013) performed a study where participants read sentences such as:

1. (a) After the bank manager telephoned **David's father** grew worried and gave himself approximately five days to reply.
   (b) After the bank manager telephoned **David's mother** grew worried and gave himself approximately five days to reply.

In these sentences, the ambiguous regions (in bold) can be incorrectly parsed as a noun phrase complement to the verb (NP), or the main verb can be correctly parsed as a zero complement verb with no object (Z). Eye tracking results revealed that the correct hierarchical structure was built by the time the reflexive pronoun "him/herself" was read, indicating that processing difficulties were not due to incorrect syntactic structures.

Christianson et al. (2017) further investigated the role of sentence type and ambiguity on human subject's response accuracy to garden path sentences. They contrasted ambiguous versus non-ambiguous and garden path (ambiguous) versus local coherence (unambiguous) structures:

2. **Garden Path**
   (a) Ambiguous
   The player tossed the ball interfered with the other team.
   (b) Unambiguous
   The player who was tossed the ball interfered with the other team.

3. **Local Coherence**
   (a) Ambiguous
   The other team interfered with the player tossed the ball.
   (b) Unambiguous
   The other team interfered with the player who was tossed the ball.

Participants were then asked comprehension questions, such as *did the player toss the ball?*. Participant's comprehension question accuracy was extremely low for the garden path + ambiguous condition, with accuracy below 25% (exact numbers were not reported due to analysis on individual participant responses). Accuracy was higher in all other conditions, with ambiguous local coherence scores ranging from 40-50% and all unambiguous structures reaching scores near 60%.

This means that while human readers are able to correctly reanalyze a complex sentence (Slattery et al., 2013), they may not fully disassociate the initial semantic roles assigned in the first parse from their final interpretation of the sentence's meaning, leading to low comprehension accuracy. Since garden paths involve the interplay of multiple systems in human language processing (semantic and syntactic), this poor human performance raises the question of how language models, some without explicit syntactic training, handle these types of sentences.

3 Related Work

Previous research has addressed the ways in which various models process garden path sentences, although none up to this point has examined BERT specifically, to our knowledge. Utilizing the metric of surprisal extracted from various models, Van Schijndel and Linzen (2018) modeled garden path effects in human self-paced reading. They compared probabilistic context-free grammars (PCFG) with explicit hierarchical syntax to recurrent neural network (RNN) models trained on text without syntactic annotation. Both the PCFGs and RNNs under-predicted the extent to which human readers slowed down in response to NP/Z type ambiguities, showing that these types of models may find garden path sentences less challenging than human readers.

Moving away from human comparisons, Futrell et al. (2019) evaluated a number of models' surprisal in garden path sentences, including three LSTM models and a RNN Grammar trained on a small dataset. All models evaluated showed increase in surprisal values at the disambiguating regions of the NP/Z garden path sentences, but they found that only the larger LSTM models evaluated utilized verb argument structure in their predictions, showing that explicit syntax training is not needed to model garden path effects.

Jurayj et al. (2022) similarly investigated GPT-2's ability to navigate different types of garden paths. They evaluated the change in GPT-2's hidden states before and after the disambiguating component of a garden path sentence. Utilizing Manhattan distances and consine similarities, they found a larger difference before and after the disambiguating token in garden paths compared to unambiguous sentences. Both Futrell et al. (2019) and Jurayj et al. (2022) were able to find garden path effects, but neither explicitly compares these results with human performance.

4 Question Answering

4.1 Materials

As mentioned previously, human comprehension of garden path sentences is often assessed by presenting garden path sentences and asking comprehension questions. Because BERT-style models achieve high performance in question-answering tasks (Devlin et al., 2019; Liu et al., 2019b), we are able to assess their performance in the same manner as humans'. We used the same materials presented in Christianson et al. (2017). There were 40 sets of items, each containing a garden path and matched local coherence structure, as well as two additional sentences which were identical to the garden path and local coherence sentences except for the addition of "who was" to disambiguate relative clauses.

We deviate from Christianson et al. (2017) in the kinds of questions that are paired with the context sentences. Christianson et al. (2017) used simple yes-no questions, but BERT would not perform well on this task since it is trained to identify portions of the provided context as answers instead. Therefore, we constructed a variety of new questions that could be answered by a span of the context in order to assess BERT's ability to resolve the garden path structure.

Each garden path and local coherence structure has three pieces which are relevant to semantic role assignment: the Matrix agent (asking the identity of the entity which performs the action in the main clause), the Matrix patient (asking the identity of the entity which receives the action performed by the agent), and the Modified Argument (asking the identity of the entity in the matrix clause which is modified by the relative clause). A set of example questions and answers can be seen in Figure 1.

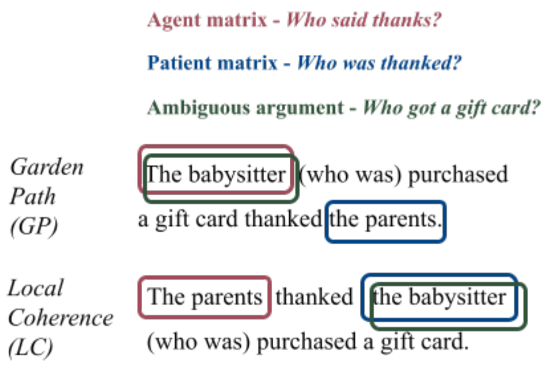

Figure 1: Example questions and answers targeting correct entity identification.

In the garden path structures, the modified argument is the one which causes the possible ambiguity. Initially the relative clause is parsed as the main clause, but this parse must be reanalyzed after encountering the second verb; therefore the model may have more difficulty with answering questions about structures of this type. In the local coherence structure, there is no ambiguity because the main verb is encountered first, so the second verb must be correctly parsed as an embedded clause. Thus the model should have higher performance for local coherence structures than the corresponding question for garden paths.

In addition to asking questions about which entities have relationships with particular verbs, we can also ask the reverse: what did particular entities do? This leads us to a second set of questions: Matrix Action (asking the action done by the entity in the main clause) and Embedded Action (asking what happened to the entity modified by the relative clause). A set of example questions and answers can be seen in Figure 2. For these types of questions, the key contrast is on the Matrix Action questions. For the garden path structures, the model may answer with the embedded action rather than the correct parse, but in local coherence structures there is no intervening relative clause so accuracy may be higher.

All together, we had five questions for each of the 160 sentences (contexts) for a total of 800 items. Each context-question pair was provided to a publically available pre-trained transformer model (BERT$_{\text{BASE}}$-uncased, BERT$_{\text{LARGE}}$-uncased, RoBERTa$_{\text{BASE}}$-uncased, RoBERTa$_{\text{LARGE}}$-uncased) which had been fine-tuned for question-answering using the SQuAD2.0 dataset. In addition, we used the Hugging Face library (Wolf et al., 2020) for implementation of the question-answer task.

To compare BERT's performance with humans', we also conducted an online comprehension task in which subjects were presented with a context sentence and asked to answer one of the comprehension sentences by typing a response. (The context sentence was not on screen as participants answered the question.) There were 74 fluent English participants and each had a 32-item subset of the questions and contexts plus 13 filler items. This resulted in at least 80 responses for each of the question types in the dataset. All of these materials (including garden path and local coherence contexts, questions, anonymized human responses, and BERT responses) are available publicly for future use.

4.2 Results

Overall, the transformer models perform similarly to humans based on their average accuracy over all types of questions, structures, and ambiguities. As seen in Table 1, the BERT models' accuracy ranges from 2.5-100% while human accuracy ranges from 32.3-95.7%, suggesting that the models did not perform universally better or worse than humans on this task.

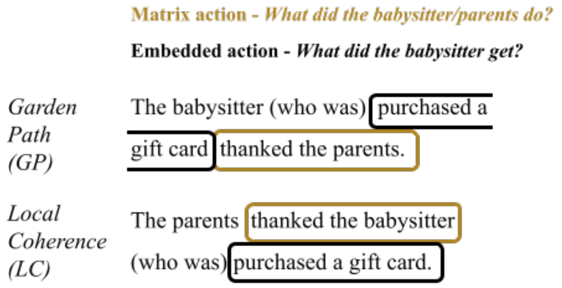

Figure 2: Example questions and answers targeting correct action identification.

Rather, the performance differences between the two emerge in specific question types. For Agent Matrix and Matrix Action question types, at least 50% of the transformer models' scores were lower than the corresponding human performance. Both BERT and humans struggle the most with Matrix Action questions, which require a semantic connection to be made between elements which are not collocated linearly. Agent Matrix questions also require the ability to make this connection, but humans achieve very high accuracies on this type, in contrast to BERT.

These results suggest that humans and BERT are making similar mistakes regarding semantic connections between arguments. For BERT, the failure is bidirectional–it cannot retrieve the agent when asked about an action or vice versa. For humans the failure is only unidirectional–they can correctly answer who performed an action, but are unable to identify an action when presented with an agent.

As expected, we found that local coherence structures were easier to process than garden path structures for both humans and BERT. Across all question types and ambiguities, humans have an average performance increase of 14.9%. For the transformer models the accuracy increases were between 8.8% (BERT$_{\text{LARGE}}$) and 20.5% (RoBERTa$_{\text{LARGE}}$) with an average of 15.5%. The comparable increase in performance between language models and humans also suggests that the two face similar difficulties in garden path processing, despite their differing processing mechanisms.

We also observe an increase in both human and model performance for sentences disambiguated

Table 1: Results comparing the performance of humans to a variety of BERT-style transformer models in a question-answering task where question contexts are garden path sentences.

using "who was" to introduce relative clauses. Human performance increased by 13.3%, while model performance increase ranged from 13.2% (BERT$_{\text{LARGE}}$) to 15.9% (RoBERTa$_{\text{LARGE}}$) with an average of 14.9%. Again the comparable increase is suggestive of similar processing mechanisms.

Finally, we find that increasing the size of the model and changing the training objectives result in only a marginal performance increase. In model evaluations using SQuAD 2.0, BERT$_{\text{LARGE}}$ improves on BERT$_{\text{BASE}}$ by 8.5% and RoBERTa$_{\text{LARGE}}$ improves on RoBERTa$_{\text{BASE}}$ by 5.3%. This contrasts with our results of a 3.9% and 2.7% increase respectively. Additionally, RoBERTa models' performance increase over BERT models of the same size is also reduced compared to the SQuAD 2.0 evaluations (1.6% vs. 7.6% for BASE models, 0.4% vs 4.4% for LARGE models).

While the transformer models showed similar results to humans in terms of accuracy, qualitatively the performance differs between the two in terms of incorrect responses. For instance, in humans an incorrect response would likely be an incorrectly identified entity or action (depending on the question type). However, the transformer models seemed to frequently answer questions simply by repeating the sentence or a non-constituent subpart, refraining entirely from selecting a single entity or action from the sentence. This is not an error that was seen in the human data. In addition to demonstrating a lack of awareness about particular semantic relationships in the sentence, this also suggests a lack of understanding of what a felicitous question response entails.

4.3 Discussion

The fact that BERT's performance is comparable (rather than superior) to humans is somewhat surprising given the vastly different way the two process language. For humans, the difficulty in processing garden path structures arises from the fact that language is presented sequentially: when encountering the first verb, people are unaware that there will be a second verb later in the sentence and thus are likely to parse the sentence incorrectly initially. BERT, on the other hand, receives all input simultaneously, so it should face less difficulty in parsing the sentence and assigning correct semantic roles. As seen in the results however, BERT seems to struggle with forming the correct relationship between agents and matrix verbs when there is an intervening relative clause, at rates at least as high as humans'.

Additionally, it is surprising that increasing the size of the model or changing the training procedures did not cause a corresponding performance increase in the models. This suggests that in order to understand the complex syntactic structures present in garden path sentences, one must do more than increase model parameters and the amount of training data. Rather, changing the architecture of the model itself may result in larger performance gains.[3]

5 Probe Task

Since our models perform similarly to humans on comprehension questions based on garden path sentences, we aimed to investigate precisely which semantic role each word in a garden path sentence is assigned, since human processing seems to be hampered by the misassignment of these semantic roles. In order to investigate the semantic roles assigned to the different entities in garden path sentences, we designed a probe (Alain and Bengio, 2016) trained on BERT's hidden states to better understand it's representation of the roles in question.

The linear classifier was trained on each model's embedding of a single token taken from sentences in which those words fall under the span of a semantic role of interest.

5.1 Training Materials

To create a training set for semantic roles, we used annotations from PropBank (Palmer et al., 2005). Each verb annotated by PropBank has a corresponding frame file in which verb-specific semantic relations are detailed. We chose to focus on two semantic roles. The first is PropBank's [PAG] tag, which represents a proto-agent type role across verbs. Selecting the other role was less straighforward, as the thematic roles in PropBank were not uniform across the areas of interest in the garden path sentences. For example, the two following stimuli sentences have differing thematic roles assigned to the first entity of the sentence (relevant verb in bold):

1. (The child)$_{\text{GOAL}}$ **bought** an ice cream cone smiled at the cashier.
2. (The child)$_{\text{DIRECTION}}$ **read** the story hugged the nanny.

In order to test the classifier on the largest number of stimuli possible, we chose to focus our probe on the entities tagged [GOL] (Goal role), as it has the most occurrences in our stimuli (143 instances total).

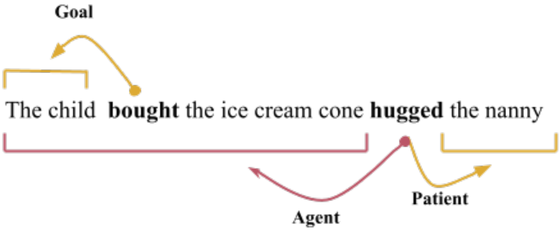

Figure 3: Here, the phrase *the child* acts as the Goal of *bought*, while the phrase *the child bought the ice cream cone* acts as the agent of *hugged*. The Patient label is presented for convenience, but not analyzed in this investigation.

We train a binary linear classifier for both Agent and Goal, on each layer of each model, in the form of a logistic regression classifier. This is due to the fact that some words may be constituents of arguments of multiple verbs, and therefore be assigned different roles, as displayed in Figure 3. This approach allows for detecting multiple different roles on each word.

5.2 Probe Design

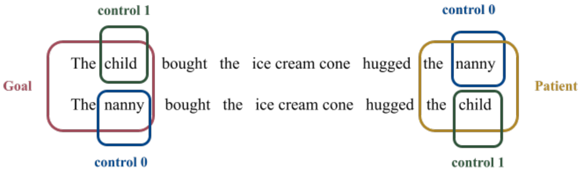

Figure 4: Words are labeled for goal and patient semantic roles (the latter of which is provided for convenience but is not addressed in this study), in addition to the control tag, which is randomly assigned to each unique word in the training data, i.e. 0 for *nanny* and 1 for *child*.

One concern when using classifiers to investigate the hidden states of a model is the possibility of the model achieving high accuracy by memorizing specific words' typical labels, rather than learning the patterns associated with the labels themselves. In

---

[3] Because relative clauses are the syntactic phenomena which make garden path processing difficult, finding a model which is able to correctly parse these may lead to advances in garden path understanding. While work on this is limited in English, work in other languages suggests some promising models are LSTM, PERT$_{\text{LARGE}}$, and GPT-3 (Song et al., 2022).

order to assess this level of memorization, we implemented a control task (Hewitt and Liang, 2019). This took the form of two additional classifiers which were trained on the sets of embeddings used by the Agent and Goal classifiers, but a binary label (rather than a semantic label) was randomly assigned to each unique word in the training set, as seen in Figure 4.

This allows us to assess the extent of memorization through the metric of selectivity:

$$selectivity = linguistic_{\text{ACC}} - control_{\text{ACC}}$$

The Agent semantic role is much more common in PropBank than the Goal role. In order to keep our classifiers equivalent in the number of samples they received, we created artificially split 50/50 +Role/-Role training sets for both Agent and Goal classifiers. All stimuli sets underwent a 80/20 train/test split. In order to maximize both performance and specificity in our probe of garden path sentences, we choose a regularization constant of 0.01 for our classifier, following the findings of Hewitt and Liang (2019).

To test our probe classifiers on the garden path sentences, we selected the layer from each model in which the associated classifier had the highest performance on Goal classification (which had overall lower accuracy than Agent classifiers, as shown in Table 2) for the PropBank sentences. We then applied the probe classifiers for both Agent and Goal roles to the first and second relevant entities in the same sentences that were analyzed in the question answering portion of this experiment. The sentences were sub-selected for those containing the Goal and Agent roles, leaving us with 24 sentences in each condition (garden path vs. local coherence structure, ambiguous vs. unambiguous).

5.3 Results

Overall, the linear classifier accuracies show that Agent and Goal semantic roles are decodable from token representations when trained on PropBank sentences. However, this information is not available to the same extent in each of the models. While the BERT models perform Agent classification and Goal classification accurately 80% and 70% of the time respectively, RoBERTa models' accuracy does not exceed 65% for both Agent and Goal classification as shown in Figures 5 and 6.[4] Additionally, the information change throughout the layers is also inconsistent between models with BERT models' accuracy peaking in the later layers of the model and RoBERTa classifier accuracies staying relatively level as the layers progress.

Due to the different inconsistencies in classification accuracies for the PropBank sentences across layers, we chose to analyze the garden path sentences using only the highest performing layer from each of the models. The layers chosen as well as their accuracy and selectivity metrics can be seen in Table 2.

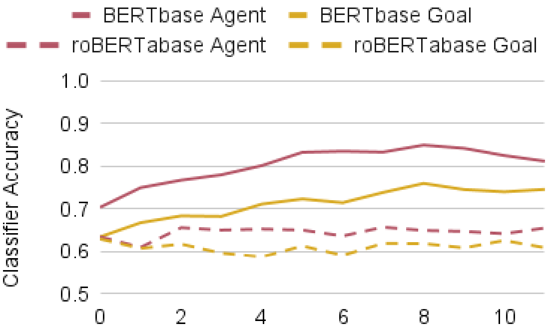

Figure 5: The average classifier accuracies from our Agent and Goal classifiers on our test set from PropBank, by model, across layers for $\text{BERT}_{\text{BASE}}$ and $\text{RoBERTa}_{\text{BASE}}$ models.

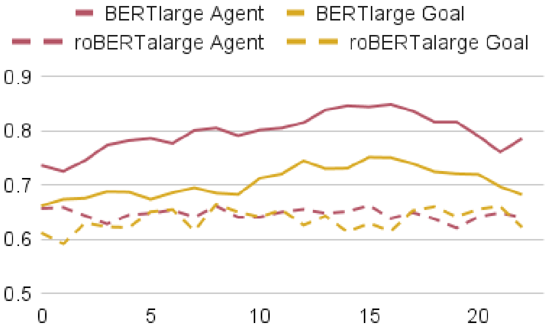

Figure 6: The average classifier accuracies from our Agent and Goal classifiers on our test set from PropBank, by model, across layers for $\text{BERT}_{\text{LARGE}}$ and $\text{RoBERTa}_{\text{LARGE}}$ models.

To analyze the garden path and local coherence sentences, both the Agent and Goal classifiers were applied to the noun associated with the first and second entities (e.g., *child* and *nanny* from Figure 3). The probabilities of each classifier assigning a given role to an entity is shown in Figure 7.

In garden path sentences, the $\text{BERT}_{\text{BASE}}$ and $\text{BERT}_{\text{LARGE}}$ probes showed a low probability of

RoBERTa_LG	10	66.08	15.36	66.44	14.8

Table 2: The accuracy and selectivity on the layers associated with the highest-performing classifier for each model, tested on the tokens from PropBank. Complete results for all layers are included in Tables 3 and 4 in Appendix A.

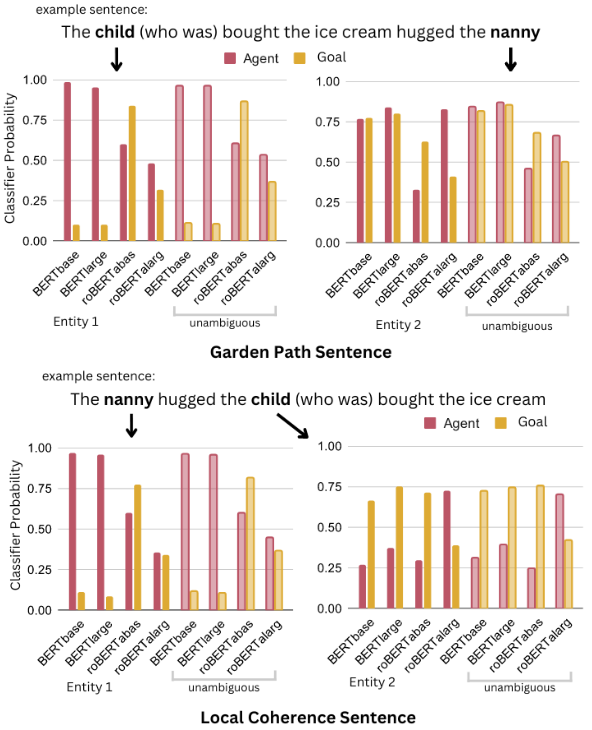

Figure 7: The average classifier probabilities assigned by our Agent and Goal classifiers to the first entity (left) and the second entity (right) in garden path and local coherence structure sentences in the selected layers. Exact numerical results are available in Appendix A.

the Goal role on the first entity in the sentence. $\text{RoBERTa}_\text{BASE}$, however, successfully showed high classifier probability for the Goal role in both the ambiguous and unambiguous sentence types, which could potentially suggest a better representation of the semantics of garden path sentences. However, this pattern also held for local coherence structures though (where the Goal role should not be assigned to the first entity), suggesting that $\text{RoBERTa}_\text{BASE}$ (nor any other model) were perfectly able to make semantic distinctions based on the differing syntactic structures. Finally, we also observe that the addition of disambiguating information into the sentence does not seem to have a large impact on classifier performance in general, for both different sentence types and models.

5.4 Discussion

Overall, the Agent classifiers were highly successful in labelling the first entity for both sentence structures (with the surprising exception of the $\text{RoBERTa}_\text{LARGE}$ classifier). In the case of the garden path sentences, the assignment of Goal to the first noun (i.e., *the child* in Figure 4), however, was extremely low, possibly indicating that most of the BERT models are not strongly representing *the child* as the goal of the verb *hugged*. This kind of semantic role interference is also what is hypothesized to impede human processing.

As a contrast, the second entity in the local coherence structures have low Agent and high Goal probabilities. This suggests that the models are better able to represent the Agent and Goal semantic roles in a local coherence structure, again mirroring the performance of humans and the model performance seen in the question answering task.

In contrast to the structure manipulation, ambiguity differences did not significantly change the classifiers' predictions, despite the question answering performance showing a larger gain in the unambiguous over ambiguous sentence contexts. Given that syntactic knowledge has been argued to be present in the model weights (Vilares et al., 2020; Hewitt and Liang, 2019), it is interesting that disambiguation (a lexical manipulation that clarifies syntax), does not improve performance in the probe task. This suggests that future syntactic investigations should focus not only on token representations, but also on other components of the models which may contribute to downstream task performance.

In terms of individual model performance, we find that no model perfectly aligns with human performance. In the local coherence structures, BERT_BASE and BERT_LARGE were most successful at assigning the correct roles to the correct entities, however they both misassigned the roles of the first entity in garden path structures. Interestingly, the semantic role predictions of the two were very similar, suggesting that increasing the model size does not fundamentally change what semantic information is held within token representations.

RoBERTa models, on the other hand, did not perfectly assign roles in either structure condition. RoBERTa$_{\text{BASE}}$ seems to prefer assigning Goal roles to every entity, while RoBERTa$_{\text{LARGE}}$ does the same with Agent roles. In this case, it does seem that increasing the model size does lead to the acquisition of different semantic knowledge, in addition to the differences from BERT models already mentioned.

Another area where these differences are observed is the extent to which classifier accuracy increased in later levels of BERT versus RoBERTA. In BERT, we observed an increase in performance in later layers, while for RoBERTa the performance stagnated across all layers. This was not due to a difference in classifier training, as all classifiers had identical hyperparameters and training corpora. Rather, we can conclude this is due to the RoBERTa model itself–its differing training procedures must lead to a fundamental difference in how semantic roles are processed from BERT (i.e., they are less strongly represented in the token weights themselves), given that the two have very similar performance on the downstream question answering task.

Because no model was able to assign all semantic roles perfectly in every condition (based on the probe task), we are left to conclude that the semantic knowledge within token representations of all models is imperfect and not based on deep syntactic knowledge. Rather, in some cases the models seem to be relying on heuristics to assign semantic roles. Such heuristics might include word order in the sentence, frequency of a particular semantic role, and linear proximity. Future investigations should aim to discover which heuristics are most relevant to langauge models' representations and performance, as well as how token representations may interact with other model components in order to achieve performance similar to humans on downstream tasks.

6 Conclusion

Overall, BERT-style transformer models do not perform significantly better than humans on garden path sentences in question answering. This suggests that, despite the temporal amodality of BERT's language processing, it still faces the same issues of misinterpretation that human speakers do in online sentence processing. Additionally, probe results suggest that BERT fails to assign the correct semantic roles to the entities in garden path sentences, despite showing successful assignments on other corpus sentences. This error is similar to human-style garden path misinterpretations, despite the many differences between human and model language processing (i.e. temporality, working memory demands).

Additionally, we observe differences in semantic role representations between the models tested—BERT models seem to make similar role predictions regardless of model size, while RoBERTa$_{\text{BASE}}$ makes different predictions than RoBERTa$_{\text{LARGE}}$. Furthermore, both RoBERTa models seem to have different semantic representations than the original BERT models, suggesting that particular training procedures and tasks can lead to widely different internal model states yet still show negligible impact on performance of downstream tasks.

Limitations

The garden path structures presented here are a phenomenon predominantly found in English. Structural ambiguities found in other languages vary widely, and so our ability to generalize about BERT's ability to process these ambiguities cross-linguistically is limited. Additionally, these types of garden path structures are relatively scarce in natural language, and it is possible performance would be higher if BERT were fine-tuned using these structures specifically (we choose not to do this in order to approximate the levels of experience humans have with these structures to obtain more natural comparison). Finally, the number of sentences tested in the probe task is low, due to variation of stimuli thematic roles.

Ethics Statement

The authors have no ethical concerns relating to the research presented in this paper.

Models Teaching Models: Improving Model Accuracy with Slingshot Learning

Lachlan O'Neill, Nandini Anantharama, Satya Borgohain, Simon D. Angus
SoDa Labs, Monash Business School, Monash University, Clayton Australia

Abstract

One significant obstacle to the successful application of machine learning to real-world data is that of labeling: it is often prohibitively expensive to pay an ethical amount for the human labor required to label a dataset successfully. Human-in-the-loop techniques such as active learning can reduce the cost, but the required human time is still significant and many fixed costs remain. Another option is to employ pretrained transformer models as labelers at scale, which can yield reasonable accuracy and significant cost savings. However, such models can still be expensive to use due to their high computational requirements, and the opaque nature of these models is not always suitable in applied social science and public use contexts.

We propose a novel semi-supervised method, named Slingshot Learning, in which we iteratively and selectively augment a small human-labeled dataset with labels from a high-quality "teacher" model to slingshot the performance of a "student" model in a cost-efficient manner. This reduces the accuracy trade-off required to use these simpler algorithms without disrupting their benefits, such as lower compute requirements, better interpretability, and faster inference. We define and discuss the slingshot learning algorithm and demonstrate its effectiveness on several benchmark tasks, using ALBERT to teach a simple Naive Bayes binary classifier. We experimentally demonstrate that Slingshot learning effectively decreases the performance gap between the teacher and student models. We also analyze its performance in several scenarios and compare different variants of the algorithm.

1 Introduction

In standard computational linguistics modeling, the typical strategy for achieving high model accuracy is to obtain a large fraction of high-quality human labels on the dataset at hand. However, it is not uncommon in applied social science settings to find that the scope of human labeling of a dataset is highly constrained (Liew et al., 2014). For example, it may be prohibitively expensive to pay an ethical amount for human labeling. Alternatively, the project's institutional access to raw corpora may have ended, or perhaps the domain experts are no longer available.

One solution is to use an active learning approach where a model is trained concurrently with the labeling process to "maximize a model's performance gain while annotating the fewest samples possible"(Ren et al., 2021). While this can be more efficient than unguided labeling, it still requires significant human labeling resources as the learning process is fundamentally human-guided. Some issues are relatively fixed costs, such as bias, repeatability, and initial training requirements; this enforces a non-trivial lower bound on the efficiency of human-in-the-loop active learning methods. Active learning also does not help if the data has already been collected, and there is no way to collect further data.

Alternatively, one might directly apply a large, pre-trained (and possibly fine-tuned) transformer model to obtain state-of-the-art outcomes (Brown et al., 2020; Schick and Schütze, 2020; Wei et al., 2021). Pre-trained models are well suited to learning from relatively small amounts of data due to the large amount of prior knowledge they already contain. But such a strategy comes with complications for applied social science, including high (and rising) costs (Patterson et al., 2021; Schwartz et al., 2019; Mayfield and Black, 2020) a lack of model interpretability (Yang et al., 2021; Zafar et al., 2021), and issues with repeatability when using models hidden behind an API.

Given the power of modern machine learning models, a natural question arises: Can the power of modern machine learning architectures (such as transformer models) be harnessed to enhance the accuracy of standard models where human labeling

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3233–3247
May 2-6, 2023 ©2023 Association for Computational Linguistics

is finished?

Here, we introduce and evaluate *Slingshot Learning*, an efficient, low-cost, widely applicable, and powerful methodology to enhance the accuracy of standard inference models. Slingshot Learning adopts a student–teacher framework, such that the standard model (the 'student') is iteratively taught by the transformer model (the 'teacher'). Akin to the gravitational slingshot maneuver, in which a spacecraft uses the gravity of a large body to increase its own speed, the student model leverages the knowledge and performance of the teacher model, in a way that allows it to express where it expresses low certainty in its predictions, essentially asking "questions" of the teacher model. This iterative behavior can be modified, or entirely replaced with purely random behavior through the selection of hyperparameters.

We demonstrate that, under slingshot learning, the accuracy of the student model can be at a relatively low cost. After the algorithm finishes iterating, the student model can be used as a compromise between the high performance of the complex teacher model, and the inherent benefits of the student model, which might include reproducibility, interpretability, computational efficiency, and compute costs that are orders of magnitude lower than the teacher model. This student model can then be used to label the rest of the corpus, and/or label future, unseen data.

2 Background

Active learning (AL) seeks to minimize the human labeling cost of training a model while collecting enough data to successfully train the model (Ren et al., 2021). It has proven popular in recent years due to the prevalence of large, unlabelled datasets, and methods are increasingly leveraging powerful, pre-trained models such as BERT (Grießhaber et al., 2020), but active learning is still a fundamentally human-led labeling approach which adopts the pitfalls of experimental research involving humans. The ability to repeat experiments in the first place (let alone with any consistency), expand their scope and analyze the underlying models are all taken for granted in machine learning but, once humans are involved in the labeling process, the difficulty of such tasks can vary from non-trivial to impossible. Iterative research design is also very difficult without significantly increasing the cost and time requirements of the overall experiment.

Large language models such as GPT-3 (Brown et al., 2020) have achieved exceptional performances in NLP tasks under zero-shot and few-shot learner constraints, making these a compelling approach for low-resource tasks (Chia et al., 2019). GPTs have been used in semi-supervised settings to generate pseudo-labels via training offline/student models (Chia et al., 2019). The study by Wang et al. (2021) leverages the use of GPT-3 to reduce costs in comparison to human annotators. In one of their labeling strategies, they employ GPT-3 (teacher) to generate a fully labeled dataset which is then used to train an offline model (student), a transformer model (Liu et al., 2019). While they show improved performance of the offline model on the fully labeled GPT-3 dataset in comparison to using human annotators, the performance on multiclass classifications was lower than that of human annotators and showed no improvement after increasing the number of GPT-3 labels. The authors also explore an active learning version, where the low-confidence labels of GPT-3 or the most challenging examples are relabelled using human annotators and the result is used to train the offline model. While this approach demonstrates better performance, it has the same pitfalls as other active learning approaches. Our approach assumes a low budget and no access to human annotators beyond a small "seed" labeled dataset.

In the realm of model interpretability, a similar approach is that of surrogate models (SM), which employ an interpretable simple model to explain the behavior of a more complex ML model (Rey and Neuhäuser, 2011). They include global models that explain the overall predictions and local models that provide local explanations on the predictors by varying their sampling strategies. The global models are trained on the same data set (or a similar data set) as the complex model (Molnar, 2022, ch 8.6). The output of the surrogate is then compared to the complex model to determine how well the surrogate replicates the complex model within an arbitrary threshold. The ones that employ sampling use simpler models to gain insight into interpretability through locally selected regions from the complex model's predictions (Ribeiro et al., 2016; Lundberg and Lee, 2017). The goal or output here is interpretability and mostly requires the continued use of the underlying complex model. However, our intention is not just interpretability but to build a stable simple model that is standalone.

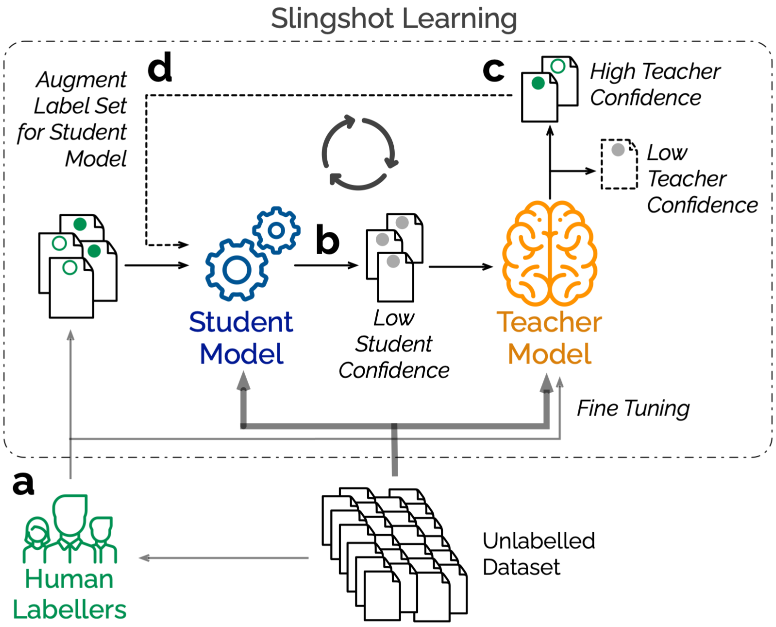

Figure 1: **Slingshot Learning.** A small fraction of the dataset is labeled by human labelers (a), which are used to train the Student Model and then identify low-confidence examples, a subset of which are passed to the fine-tuned Teacher Model (b). Where the Teacher Model has high inferential confidence on the examples (c), these are added to the human-labeled dataset for further training of the Student Model (d), and the cycle iterates.

The goal is to train the simpler model to make better predictions. Further, we are limited by our training dataset size. The idea is to also leverage a largely unlabelled dataset into training.

Knowledge distillation (KD) is another well-known approach that uses the teacher-student model (Hinton et al., 2015). The teacher - a deep teacher network - distills its knowledge onto a smaller model. The smaller models are also neural nets, and draw feature learnings from the parameters and activations of the intermediate layers of the teacher model. The intention here is to deploy a high-performing, compressed, smaller model in a low-resource environment (Gou et al., 2021) and thus they lack easy interpretability and transparency. While there have been some studies that use KD in an interpretable model (Liu et al., 2018; Che et al., 2016), the data size limitation discussed earlier applies to this approach as well.

Our goal is to build a standalone model that can achieve high accuracy despite limited training data, through the use of large unlabelled data sets.

3 Slingshot Learning

Here we explain slingshot learning from an intuitive view, and then present a more rigorous algorithmic definition.

3.1 Intuition

Consider a scenario where we have a large dataset of unlabelled data, far larger than could be labeled by hand, and we want to label the whole dataset and/or train a model to label future, unseen data. One solution is to hand-label a small portion by hand and feed the rest to a state-of-the-art model (such as a modern Transformer-based model, for NLP problems). While this is quicker and cheaper than labeling by hand, it can still be expensive (especially if using an API, or a large model requiring significant GPU compute capabilities). Additionally, these complex models take a while to run, making them potentially unsuitable for real-time applications. Of course, a simpler and more efficient model can be used, but this generally comes at the cost of decreased model performance.

In slingshot learning, we use the more expensive (HQ) model to label a portion of the unlabelled dataset, and then leverage that to *slingshot* the performance of the smaller (LQ) model, much like a gravitational assist maneuver accelerates a small spacecraft using the gravity of a large celestial object. Under this training paradigm, we train a "high-quality" (HQ) model on our ground truth dataset, use this model to iteratively teach the LQ model by labeling a portion of the unlabelled dataset, and

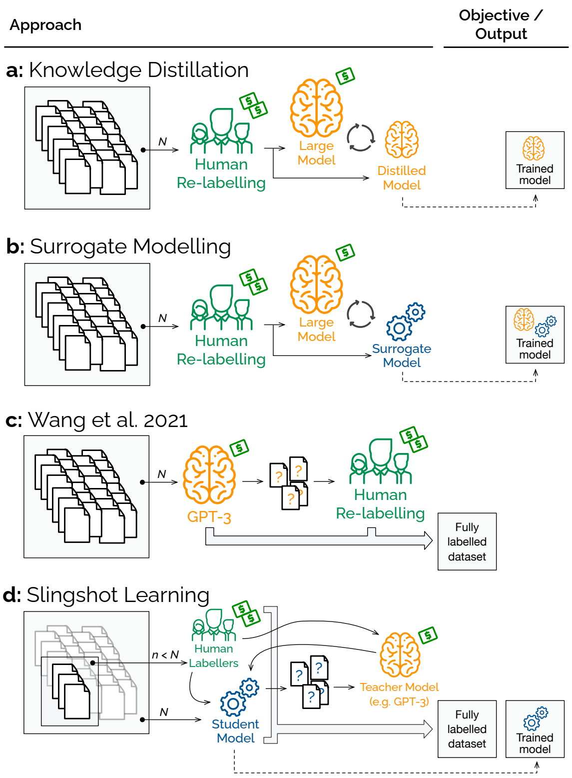

Figure 2: **Model comparison.** See text for details.

then use the low-quality model to label the rest of the data and/or make future predictions on unseen data.

We assume the number of human labels is fixed and cannot be increased - instead, we will use the HQ model (trained on the human-labeled dataset) as our more accurate (and more expensive) oracle. Our goal is thus to minimize the number of HQ predictions, while successfully labeling the dataset and/or training the LQ model. This is the crux of the slingshot learning approach; although the implementation details and hyperparameter selections might vary, the core concept of using a high-quality (but expensive) model to improve the performance of a lower-quality (but cheap) model remains constant.

The comparison to slingshot learning with other existing methods is presented in Table 1. The primary objectives of SM and KD are interpretability and high-accuracy compressed models respectively. Slingshot achieves both these objectives. Comparing slingshot to Wang et al. (2021), the latter continues to use human annotators for labeling, while SSL supports automated labeling. In contrast to Wang et al. (2021), KD's trained smaller models can perform automated labeling but require a large data set to achieve a desirable accuracy.

Model Characteristics	Wang et al.	SM*	KD*	SSL*

Table 1: Comparison of existing methods with slingshot learning. SM*: Surrogate Models, KD*: Knowledge Distillation, SSL*: Slingshot Learning

3.2 The Slingshot Learning Algorithm

In Figure 3, a high-level pseudocode implementation of the core slingshot algorithm is described. Depending on the choice of hyperparameters, the algorithm's performance might be further optimizable. For example, in the purely random variant of the algorithm (discussed below), there is no need to compute the LQ predictions at each iteration.

Note that the algorithm does not assume that the confidence values of the HQ and LQ models are comparable with one another. The algorithm only relies on the relative ordering of confidence values from one of the models at a time and does not compare confidence values between the two models. The relationship between prediction confidence and accuracy is not necessarily monotonic, but we assume it will be somewhat correlated and treat it as monotonic for the purposes of the algorithm.

3.2.1 Hyperparameters

There are three hyperparameters in the slingshot learning algorithm:

n the number of data points selected for prediction by the *low-quality* model at each iteration.

m the number of data points selected for prediction by the *high-quality* model at each iteration.

k the number of data points added to the labeled set at each iteration.

We discuss the different choices for these hyperparameters throughout this paper. Note the necessary inequality $n \geq m \geq k$.

3.3 Expected Performance

Part of the intuition of slingshot learning stems from the idea that the improved performance of the HQ model over the LQ model stems from two sources: both the inherent superior ability of the HQ model to understand the *population* as a whole

```
procedure SLINGSHOT LEARNING ALGORITHM(L, U, V, $n, m, k$)
    $HQ \leftarrow$ Train_HQ($L$)    ▷ Train the HQ model on L
    $LQ \leftarrow$ Train_LQ($L$)    ▷ Train the LQ model on L
    while Not converged & more data do
        $D_n =$ Sample($L, n$)    ▷ Sample $n$ elements from the unlabelled dataset.
        $P_n = LQ(D_n)$    ▷ Compute LQ predictions and confidence for each datum (note we only use the confidence).
        $D_m =$ LowConfidence($D_n, P_n$)    ▷ Choose $m$ lowest confidence LQ predictions
        $P_m = HQ(D_m)$    ▷ Compute HQ prediction and confidence for each datum.
        $D_k =$ HighConfidence($D_m, P_m$)    ▷ Choose $k$ highest confidence HQ predictions.
        $L \leftarrow L \cup D_k$    ▷ Add these to the labelled set.
        $U \leftarrow U \setminus D_k$    ▷ Remove these from the unlabelled set.
        $LQ =$ Train_LQ($L$)    ▷ Train a new LQ model on the full labeled dataset.
        Validate($LQ$)    ▷ Evaluate the performance of the LQ model on the validation set.
    end while
end procedure
```

Figure 3: Slingshot Learning Algorithm: Note that L is the labeled set, U is the unlabelled set, V is the validation set, LQ is the low-quality model, and HQ is the high-quality model. n, m, and k are as described in Section 3.2.1.

and also the superior ability of the HQ model to learn from the *sample*.

Let us denote the *intrinsic* capability of a model m to approximate the population, if given an arbitrarily large sample (i.e. "all the data", or an "infinite sample") from that population, as I_m. Since our sample will generally not cover the entire population, the true model accuracy will have a penalty applied dependent on the true*sample size* dependent capability of the model, which we denote as S_m. In our notation, we will assume the penalty value S_m is positive, and subtract it from the total model performance. We can then denote the LQ model performance as $LQ = I_{LQ} - S_{LQ}$, and the HQ model performance as $HQ = I_{HQ} - S_{HQ}$. We can then express the performance difference between the two models as:

$$HQ - LQ = I_{HQ} - S_{HQ} - (I_{LQ} - S_{LQ}) \quad (1)$$

Rearranging terms, we find:

$$HQ - LQ = \Delta_I + \Delta_S \quad (2)$$

Where $\Delta_I = (I_{HQ} - I_{LQ})$ and $\Delta_S = (S_{LQ} - S_{HQ})$. Intuitively, Δ_I is the performance uplift due to the *inherent* superiority of the HQ model (which cannot be conferred to the LQ model), and Δ_S is the extra penalty applied to the LQ model's performance due to the superiority of the HQ model given the *sample size* being used for training. In the limit, with infinite data, we would therefore expect Δ_I to approach some constant value greater than zero, while Δ_S goes to zero.

In situations where Δ_I is the dominant term, slingshot learning may have lower utility. But in scenarios where Δ_S is the dominant term (or at least a significant component of the overall performance delta), slingshot learning has the potential to bridge part of the knowledge gap between the HQ and LQ models. We conjecture that there are many instances where simpler, cheaper models would compare well to more complex and expensive models, and that much of the gap between traditional and newer models stems from both an increase in the I terms *and* a decrease in the S sample-size penalties for smaller samples.

3.4 Algorithm Variations

Depending on our choice of hyperparameters n, m, and k, we can modify the behavior of the slingshot learning algorithm in a variety of ways. An empirical comparison of the differences in resulting behavior from these three variants can be found in the Results section.

3.4.1 Deterministic Variant

We can choose to have the LQ model evaluate the entirety of the unlabelled dataset in each iteration, by setting $n = \|U\|$[1], where U is the set of data points that remain unlabelled at a given iteration.

This removes the stochasticity from the algorithm, assuming the HQ and LQ models remain constant under a given input (since m and k are only used to determine how many data points to

---

[1] We use the value $n = -1$ to denote this in our code.

take from the n randomly selected data points). While it will take longer to run - potentially a lot longer for larger datasets, since the unlabelled dataset must be passed through the LQ model at every iteration of the algorithm - his approach ensures that the LQ model can select the lowest confidence data points at every iteration.

3.4.2 Random Variant

Alternatively, we can choose to set $k = m = n$, meaning that every data point that is passed to the student model is sent to the teacher model for evaluation, and every data point sent to the teacher model for evaluation is added to the corpus. This is akin to purely random sampling, without allowing the student to provide input on the training process.

3.4.3 Stochastic Variant

We refer to any configuration of the hyperparameters n, m, k which is neither deterministic nor purely random as a "stochastic" configuration, where there is a combination of random sampling and student input during the sampling process. In stochastic slingshot learning, $k <= m <= n$ and $k < n$.

4 Experimental Design

4.1 Models

We initially ran experiments with ALBERT teaching Naive Bayes, ALBERT teaching SVM, and SVM teaching Naive Bayes. SVM teaching Naive Bayes proved difficult, as the SVM was very often not significantly more powerful than the Naive Bayes model. We performed some initial experiments with ALBERT teaching SVM, but the required computation time proved insurmountable. However, preliminary results indicate that SVM is a reasonable candidate as a student of ALBERT under the slingshot learning paradigm.

4.1.1 Model Details

ALBERT (Lan et al., 2020) from the HuggingFace Model repository (Wolf et al., 2020) (using the "albert-base-v2" model)

SVC (Cortes and Vapnik, 1995), an SVM classification model, as implemented by Sci-Kit Learn (Pedregosa et al., 2011). Not used in the final results.

Naive Bayes as implemented in Sci-Kit Learn (Pedregosa et al., 2011).

4.2 Datasets

We evaluate performance on four popular benchmark binary text classification datasets from the HuggingFace Datasets repository, as shown in Table 2.

4.3 Training

We tested a number of values for each of the three hyperparameters, n, m, and k. We evaluated $n = 128$, $n = 1024$, and $n = -1$. m and k were set to either $k = m = n$ or $m = n/4, k = m/4 = n/16$. When $n = -1$, a value of 1024 was used to calculate m and k. Each experiment was repeated up to 10 times. Experiments where the HQ (ALBERT fine-tuned) model was not at least 15% more accurate than the LQ (Naive Bayes) model were discarded, as we found they added a lot of noise to the dataset (and, in any case, slingshot learning is most useful when the models are of significantly different strength). Some number of samples [2] (one of 2500, $20,000$, or $50,000$) was taken from each dataset, and then randomly split into 80% training and 20% validation sets.

A total of $1,480$ experiments were run, representing up to five runs [3] of each of the 52 hyperparameter choices, over each of the three datasets. For each experiment, 95% of the dataset labels (chosen randomly but with a fixed seed of 42) were masked, to mimic a semi-supervised learning problem with a proportionally low (but reasonable) amount of ground-truth data.

Experiments were performed using virtual machines with four CPUs and a single NVIDIA T4 GPU, using AWS Batch. SVM and Naive-Bayes models were trained with default values from the sklearn library, as was the HuggingFace ALBERT model (which was trained for a total of three epochs over the dataset, with a batch size of 16).

5 Results

We have included all experimental results in tabular form in the supplementary materials. Source code can be found here.

When performing these experiments, we ran the full slingshot learning algorithm until there is no more data left to classify. However, in practice,

---

[2] For the Rotten Tomatoes dataset, we used all the data for the 20k and 50k runs since it has less than 20,000 data points.

[3] Due to our use of AWS spot instances, some experiments failed due to loss of the VM. Each experiment had at least 8 successful runs, before pruning for the disparity between the HQ and LQ models.

			Large				**Small**

	1024	stochastic	0.028	0.084	0.218	14	0.001	0.002	0.025	9

Table 2: Here we show the performance of slingshot learning aggregated over the "small" samples (2,500 samples) and "large" samples (20,000 and 50,000 samples). All "small" experiments masked 90% of the dataset, leaving 10% as the seed for slingshot learning. All "large" experiments masked 99% of the dataset, leaving 1% as the seed for slingshot learning. Note that some of the experiments have very small sample sizes - these results should not be relied upon. The algorithm is random if $n = m = k$, and stochastic otherwise (we exclude $n = -1$ from this table as this configuration is not practical).

slingshot learning is most useful (and most distinct from other techniques such as surrogate models) when *early stopping* is applied. Our results demonstrate that there are cases where most of the accuracy gains occur early, and other cases where progress is more consistent. However, throughout almost all the results there is a consistent, monotonic increasing accuracy, as well as the *rate of change of accuracy* (that is, there are few sudden accuracy spikes). This indicates that simply monitoring the LQ model accuracy, and stopping the algorithm when it seems to be plateauing (or when resources have been fully expended, of course) might be a reasonable method of applying the algorithm. One could also attempt to quantitatively determine when the accuracy plateaus (if it ever does), but further exploration of this is beyond the scope of this paper.

Throughout these results, we refer to the δ ("Delta") metric. Intuitively, the Delta metric δ_{S_i} is the ratio between the amount of knowledge that the teacher model has "taught" the student model (equal to the difference between the performance of S_i and the baseline LQ model), and the knowledge gap between the teacher and the student (equal to the difference in their accuracy).

More rigorously, we define the Delta metric δ as

$$\delta_{S_i} = \frac{A(S_i) - A(S_{-1})}{A(T) - A(S_{-1})} \tag{3}$$

where S_i is the LQ model trained at the $i - th$ iteration of the algorithm, and $A(m)$ is the accuracy of model m on the dataset at hand. S_{-1} is the performance baseline of the LQ model before any iterations of the slingshot learning algorithm. T is the HQ model.

5.1 Empirical Results

Table 2 includes the average δ values at the 10% and 30% milestones (that is, after 10% or 30% of the total number of slingshot iterations), as well as the average point throughout the algorithm (as a percentage of the number of iterations taken) it reached its peak. The 10% and 30% points were chosen as reasonable benchmark points during our initial experiments. In the supplementary materials, we include extended tables including the first time the LQ model reached accuracy within 5%, 1%, and 0.1% of its peak accuracy.

In Figures 4, 5, and 6, we plot the δ values of the low-quality (LQ) model slingshot learning throughout the training process for each experiment (grey lines), along with the average δ across experiments (thick red line). We also show the 95% confidence interval of the delta value (envelope), and, on the x-axis, the earliest iteration in which the LQ model obtains statistically equivalent performance (filled markers: $\alpha = 0.01$; open: $\alpha = 0.10$) to that of the final iteration (100%).[4] Figure 4 shows a best-case scenario for slingshot learning, where there is a significant increase in performance early in the iteration process. Figure 5 demonstrates how, in some cases, accuracy uplift can be more consistent throughout the slingshot learning cycle - in these cases, there is a stronger trade-off between the stopping point for slingshot learning and the potential accuracy gains of continuing the algorithm.

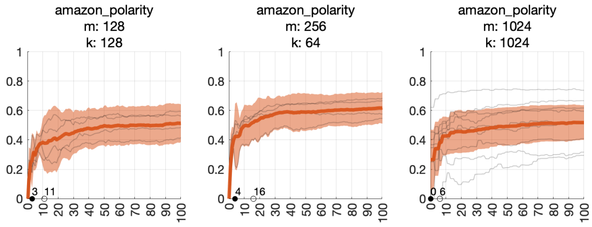

Figure 4: **Best-case scenario (Amazon Polarity dataset, 50k):** Large dataset sees the HQ model able to transfer most of the information to the LQ model without going through the whole dataset. Early stopping has less of a penalty.

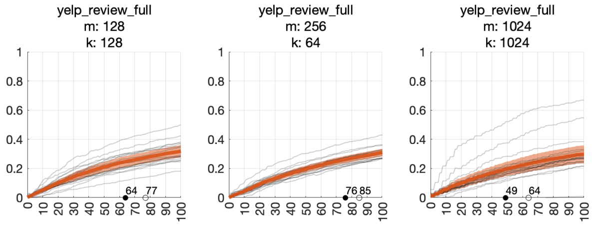

Figure 5: **More difficult scenario (Yelp dataset, 50k):** With much data, the HQ model can give information to the LQ model, but gains continue almost linearly throughout the process, penalizing early stopping.

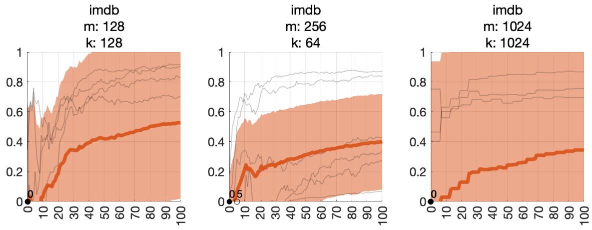

Figure 6: **High variability (IMDB dataset, 20k):** Slingshot learning performance was relatively poor on the IMDB dataset, though not always (see the supplementary materials for more information).

6 Discussion

These empirical results show slingshot learning to be an effective and reliable method for improving model performance in semi-supervised classification problems. While the exact values of δ vary between datasets, each dataset shows a clear correlation between the number of iterations and the performance of the resulting model, as well as (in most cases) the effect of diminishing returns as the number of iterations is increased.

Due to the degeneracy problem discussed below, we have elected to remove any runs for which the initial HQ model did not show at least a 15% improvement in accuracy over the LQ model baseline (before any iterations of the algorithm).[5]

6.1 Hyperparameter Selection

We saw no consistent trends between the experiments where $n = m = k$ and $n > m > k$. It does seem that, in situations where an $n = m = k$ configuration would be too computationally expensive, an $n > m > k$ configuration (or perhaps an $n > m = k$ configuration) is a reasonable option. The supplementary materials include many more plots and more comprehensive tables for the 20,000 and 50,000 sample experiments.

6.2 Degenerate Cases

While slingshot learning has proven effective, and relatively reliable under the right conditions, it is not guaranteed to improve performance in all cases. Slingshot learning does not appear to be very beneficial in cases where the HQ model is not significantly more powerful than the LQ model. We found erratic behavior in such scenarios, to the extent that we chose to exclude any results from our tables and figures for which the HQ model did not perform with at least 15% higher accuracy than the LQ model.

6.3 Benefits of Slingshot Learning

Slingshot learning allows simpler models to capture some of the performance of more powerful models, and as discussed throughout this paper, this has tangible benefits in cost and compute requirements for several common machine learning applications. We have also identified several other benefits that this approach provides.

---

[4] In each figure: left panel, $n = 128$; middle, right panels, $n = 1024$.

[5] The full, unpruned data table has been included in the supplementary materials.

6.3.1 Enabling Model Selection/Trade-offs

Traditional machine learning methods, such as Linear/Logistic Regressions, Naive Bayes, decision trees (Kotsiantis, 2013) and tree-based ensemble methods (Friedman, 2001; Chen and Guestrin, 2016), and SVMs, have existed in the literature for decades, and they have many advantages and trade-offs between them. However, as transformer-based models (and deep-learning models in general) become more powerful, it is becoming more and more difficult to justify the use of these traditional methods regardless of the benefits and trade-offs that may come with them, such as interpretability, efficiency, accuracy, and inherent applicability to the problem at hand.

The ability to choose between different models as the "low quality" model in the slingshot learning paradigm restores some of the power of model selection. For example, users can choose between simpler, more easily interpretable methods such as Linear/Logistic Regression or Naive Bayes, or opt for more complex models such as SVMs for the sake of accuracy. Through the use of slingshot learning, users can make these decisions and trade-offs based on their requirements, without sacrificing as much accuracy.

6.3.2 Enabling Experimental Repeatability

One negative effect of the proliferation of commercial, API-based deep learning models is the inability to reliably repeat experiments. APIs, and the models beneath them, are subject to change without notice, and will of course be improved over time. An unmodified experiment might perform significantly differently on two different days, in a manner entirely beyond the control of the user.

One interpretation of slingshot learning is as a method of capturing a "slice" of a large model, using a smaller model to store the captured information. These slices can then be stored and used at a later date, both reliably and without further interaction with the original model. Aside from the computational and financial benefits of this, the ability to take such a slice and store it locally enables repeatable, shareable experimental models. This may have legal and ethical implications, especially if it negatively affects the financial viability of commercial machine learning offerings, but a detailed discussion of this is beyond the scope of this paper.

6.3.3 Facilitating Interpretable Models

Deep learning models are not inherently interpretable by default, and although techniques such as LIME (Di Cicco et al., 2019) and SHAP (Lundberg and Lee, 2017) somewhat facilitate the interpretation of such models, there have been calls in recent years for inherently interpretable deep learning methods (Yang et al., 2021). By leveraging these complex, non-interpretable models to train simpler, interpretable models, slingshot learning can facilitate the creation of models which are both powerful *and* interpretable. Of course, the idea of training smaller models with larger ones is not new, and techniques such as knowledge distillation (Gou et al., 2021) and surrogate models (Rey and Neuhäuser, 2011; Molnar, 2022) are an area of active research.

6.3.4 Early Stopping

The iterative slingshot learning algorithm allows users to decide when to stop iterating when they determine that the model has likely converged. As discussed previously, this tends to happen relatively early in the iteration process, and further iterations tend to yield diminishing returns. Though there are no guarantees as to whether the model has converged (or is close to its final, converged performance) at a given iteration, the experimental data included in this paper can provide a guide to the expected future behavior of the model.

6.4 Further Work

Slingshot learning has proven to be useful in these applied NLP classification problems, but there is no reason it cannot be applied to other ML domains such as regression, multi-class classification, or text generation. Further experiments in these domains, and others, will be an important phase in determining the scope of the applicability of slingshot learning. We expect the algorithm would potentially be useful in a wide variety of scenarios.

Further analysis and testing of the different potential configurations of the slingshot learning algorithm's hyperparameters will also be critical to understanding how the values of n, m, and k can be selected to optimize the algorithm's performance in different use cases. We also plan to explore a potential "meta" slingshot learning algorithm, where progressively simpler models are taught from the model above them in the hierarchy, to propagate knowledge and avoid "overwhelming" the LQ model with the power of the HQ model.

7 Limitations

Our experiments were performed on English NLP datasets, collated from the internet. The results in this paper are intended and should be taken, purely in the context of evaluating the performance of the slingshot learning algorithm. We have no reason to believe slingshot learning would not be equally applicable to other languages, domains, problems, etc., and have simply chosen these datasets due to their prevalence and familiarity in the literature.

We conjecture that different (perhaps more complex) language structures might make slingshot learning more useful. We do not have expertise in this area - as we discussed in the paper, we consider it necessary to run further experiments evaluating the application of slingshot learning in other domains to be necessary. We are hopeful, however, that the method can be applied to many problems besides the ones discussed in this paper.

8 Ethics Statement

This paper discusses methods that are intended to enhance the ability of researchers within domains such as social sciences to more easily apply state-of-the-art NLP algorithms to their work. This inherently comes with the risk of bias, and it is entirely possible that seed datasets based on incomplete or biased datasets will cause slingshot learning to serve as an "amplifier". We encourage caution when applying machine learning to social or other "real-world impactful" domains, and doubly so when extrapolating from smaller amounts of data using machine learning. This paper serves as an initial evaluation and high-level exploration of slingshot learning, and we would not recommend using slingshot learning in situations that could potentially have negative consequences. Further exploration is certainly required, both specific to slingshot learning and regarding the more general use of machine learning in these scenarios.

On the other hand, methods like slingshot learning can empower researchers and allow them to leverage tools that would otherwise be infeasible. It also has other benefits, which are discussed in the paper - for example, it facilitates taking a "snapshot" of a black box model (such as an API-based NLP model). It is our intention, and our hope, that slingshot learning is a useful tool that helps democratize machine learning within the social sciences and other applied domains.

Acknowledgements

We thank all those who have reviewed this paper for their advice and contributions, which have included improvements to explanations and wording, discussion of relevant literature (particularly regarding active learning), and numerous other additions.

A Datasets

Table 3 includes some summary information about each of the datasets used in our experiments.

B Extended Results

The raw experimental data can be found in the supplementary materials, in CSV format. Selected plots and tables are included here.

Note that the Rotten Tomatoes dataset has less than $20,000$ elements, and thus all elements were used in every experiment of sizes $20,000$ and $50,000$ (i.e. with no random sampling). Rows with less than three experiments (i.e. $N < 3$) were dropped due to lack of statistical certainty.

The tables show the maximum δ value achieved throughout the training process ("Max"), along with when we first came within 5%, 1%, and 0.1% of the maximum. The place where the maximum value occurred is omitted as (due to noise) it is not a reliable or consistent statistic. The tables also include the δ values found after completing 10%, 30%, and 50% of the slingshot iterations.

Dataset	**Training Set Size**	**Test Set Size**

Abstract

Hate speech detection has been the subject of high research attention, due to the scale of content created on social media. In spite of the attention and the sensitive nature of the task, privacy preservation in hate speech detection has remained under-studied. The majority of research has focused on centralised machine learning infrastructures which risk leaking data. In this paper, we show that using federated machine learning can help address privacy the concerns that are inherent to hate speech detection while obtaining up to 6.81% improvement in terms of F1-score.

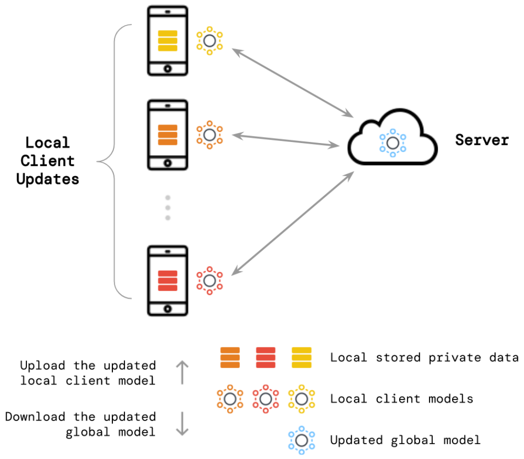

Figure 1: Federated Learning: A centralised model is hosted on a server and is distributed to client devices, these compute weight updates, and transmit the updates for aggregation into the centralised model. The centralised model is then redistributed to client devices.

1 Introduction

Content moderation is a topic that intersects across multiple fundamental rights, e.g., freedom of expression and the right to privacy; and interest groups, e.g. scholars, legislators, civil society, and commercial entities (Kaye, 2019). The availability of public datasets has been crucial to the development of computational methods for hate speech detection. However, public data contains risks for those whose content is available. On the other hand, privately held data, e.g., data held by corporate entities, holds risks for those who are reporting content. Such risks may be actualised through information leaks in models (Hitaj et al., 2017) or the transmission of data (Shokri and Shmatikov, 2015), and can impact people's safety and livelihood.

In this work, we apply Federated Learning (FL, McMahan et al., 2017) to address the lack of privacy in hate speech detection. FL is a privacy-preserving training paradigm for machine learning that jointly optimises for user privacy and model performance. We posit that privacy is necessary for users whose content is flagged and users who are flagging content alike. We thus operationalise privacy, in the context of hate speech detection and federated learning, to mean privacy in terms of the content of reported content, and the report itself. FL is an apt training paradigm for tasks in which training data is highly sensitive, as FL is designed to mitigate risks of information leaks while also dealing with a high number of end-users, information loss, and label imbalances (Lin et al., 2022; Priyanshu and Naidu, 2021; Gandhi et al., 2022). We apply the FL algorithms FedProx (Li et al., 2020) and Adaptive Federated Optimization (FedOpt, Reddi et al., 2021) to 5 machine learning algorithms. We evaluate our approach on 8 previously published datasets for hate speech detection. While using FL often implies a trade-off between privacy and performance, we obtain performance improvements of up to 6.81% in F1-score. We find that that models trained using FL outperform centralised models across multiple tests (e.g., derogatory language, spelling variation, and pronoun reference) in HateCheck (Röttger et al., 2021).[1]

2 Prior Work

Although the areas of hate speech detection and FL have each been subject to extensive research, the study of their intersection remains in its infancy.

Federated Learning Federated Learning is a privacy-preserving machine learning paradigm that aims to reduce privacy risks by decentralising data processing onto client devices (i.e., personal devices), thereby foregoing the need for transmitting "raw" user data, and thus minimising risks of personal data leaks caused by transmission of data.[2] In FL, the machine learning model is located in two places: On a centralised server, and on client devices, which hold instances of the model distributed from the centralised model.Client devices use the model to compute model updates. The model updates are then transmitted to the server and aggregated by the centralised model, which is redistributed to the client devices. However, not all transmitted weight updates are aggregated into the model. FL operates with a notion of data loss in its design, which is emulated by selecting a fraction of clients whose updates are aggregated. Thus, FL paradigm uses less data to train a models.

In our experiments, we apply two FL algorithms: FedProx and FedOpt (Reddi et al., 2021). FedProx introduces a proximal term to the Federated Averaging algorithm (FedAvg, McMahan et al., 2017). FedAvg averages the weights computed on participating client devices in a round. FedProx introduces a proximal term that functions as a regulariser to the weight updates transmitted by participating clients, which penalises local weight updates that diverge from the global model. The FedAvg algorithm can thus be understood as a special case of FedProx with the proximal term set to 0.0.

FedOpt (Reddi et al., 2021) extends the adaptive optimisation strategies from centralised optimisation (e.g., Adam (Kingma and Ba, 2015) and Adagrad (Duchi et al., 2010)) to explicitly account for client and server optimisation. FedOpt handles server optimisation distinctly from client optimisation, by introducing a state to the server-side optimisation routine. . This distinct handling of server-side optimization enables more accurate and heterogeneity-aware FL models, which can speed up convergence.

FL has been applied to a number of tasks, including emoji prediction (Ramaswamy et al., 2019; Gandhi et al., 2022), next-word prediction for mobile keyboards (Yang et al., 2018), pre-training and fine-tuning large language models (Liu and Miller, 2020), medical named entity recognition (Ge et al., 2020), and text classification (Lin et al., 2022). For instance, Lin et al. (2022) used FL to fine-tune a DistilBERT model to perform classification on the 20NewsGroup dataset (Lang, 1995) using three different FL algorithms: FedAvg (McMahan et al., 2017), FedProx (Li et al., 2020), FedOpt (Reddi et al., 2021)) under non-IID partitioning.

In a closely related study, Basu et al. (2021) apply FL, using the FedAvg algorithm to fine-tune large language models to detect depression and sexual harassment from small Twitter data samples. They find that using large language models such as BERT and RoBERTa outperform distilled language models such as DistilBERT. Our work extends on Basu et al. (2021) by introducing additional FL algorithms and extending to a multi-class setting for hate speech detection.

Thus, our work extends on prior work by i) applying FL to the task of multi-class hate speech detection, a task which has proven difficult in part due to the complex nature of pragmatics (Röttger et al., 2021) and hate mongers seeking to evade content moderation infrastructures (Crawford and Gillespie, 2016); ii) using the FedProx and FedOpt algorithms rather than the FedAvg algorithm, thereby reducing model vulnerability to divergent weight updates; and iii) providing an in-depth analysis of federated model performances.

Hate Speech Detection Prior work on hate speech detection has primarily focused on privacy-agnostic machine learning paradigms, using centralised models for classification. Such work has investigated a number of machine learning models (e.g. SVMs (Karan and Šnajder, 2018), CNNs (Park and Fung, 2017), and fine-tuned language models (Swamy et al., 2019b)) and the development of resources (e.g. Talat and Hovy, 2016). Recently, Fortuna et al. (2021) proposed a standardisation of classes across 9 publicly available datasets and studied the generalisation capabilities of BERT, fastText, and SVM models. In their work they found limited success in inter-dataset generalization. Our work thus extends on the task of hate speech detection by introducing privacy-preserving methods to multi-class hate speech detection. In doing so, the privacy of those who flag content and those whose content is flagged remain intact.

Table 1: Label count of the raw datasets and `Comb`

3 Data

We combine our dataset using the standardisation schema proposed by Fortuna et al. (2021).

`Comb` We reuse 8 of the 9 datasets used by Fortuna et al. (2021) to form `Comb`.[3] `Comb` then consists of the datasets proposed by Talat and Hovy (2016); Davidson et al. (2017); Fersini et al. (2018); de Gibert et al. (2018); Swamy et al. (2019b); Basile et al. (2019); Zampieri et al. (2019) and the Kaggle toxic comment challenge.[4] We perform a stratified split of all training data into training (70%), validation (10%), and test (20%) sets.[5]

Data Cleaning We address issues of extreme class imbalance in `Comb` by removing the "abusive" category as it only contains 2 documents. Following an in-depth analysis of the `Kaggle` dataset we find that the maximum length of tokens in the dataset is 4950 while the median length of tokens in `Comb` is 26. Moreover, we find that the longest 1% of documents in the `Kaggle` dataset do not contain unique tokens. Removing the longest 1% of comments reduces the maximal document length to 727 tokens (see Appendix B.3 for further detail). Following our data cleaning processes, `Comb` comes to consist of 293,300 documents (see Table 1 for an overview of changes).

4 Experiments

We experiment with 5 machine learning models in their centralised and federated settings: Logistic Regression Bi-LSTMs (Hochreiter and Schmidhuber, 1997), FNet (Lee-Thorp et al., 2022), DistilBERT (Sanh et al., 2019) and RoBERTa (Liu et al., 2019). We measure their performance using weighted F1 scores. The centralised models form our baselines, while the federated models form our experimental models. For the Logistic Regression and Bi-LSTMs, we perform word-level tokenisation using SpaCy (Honnibal and Montani, 2017). For the FNet, DistilBERT, and RoBERTa, we use the tokenisers provided with each model.[6]

4.1 Federated Training

FL is a machine learning training paradigm that distributes training onto client devices. All client devices are split into overlapping subsets and the training data is partitioned and uniformly distributed to client devices. A random client subset is selected for training in each round, and their locally computed weights are aggregated on the server. We train our models for 300 rounds for 1, 5, or 20 epochs per round, and set the client fraction to 10%, 30%, or 50% which are randomly sampled from 100 client devices. We perform hyper-parameter tuning for the client learning rate, server-side learning rate, and proximal term (see appendix B.1).

In our work, we conceptualise client devices as users who witness and report hate speech. We simulate the client devices and ensure that data is independently and identically distributed (I.I.D.) on client devices.[7] We use the FedProx and FedOpt algorithms to aggregate client updates on the server. FedProx introduces a regularisation constant to the server-side aggregation step, the proximal term to address issues of divergence in weights and statistical heterogeneity in FedAvg. FedOpt seeks to create more robust models by introducing a separate optimiser for the server-side model to account for data heterogeneity.

5 Analysis

Considering the baseline models in Table 4, we see that the Logistic Regression tends to underperform, while the RoBERTa model posts the best performances. Although FL-based models often outperform our baselines, we note that when FL

---

[3] The dataset proposed by (Founta et al., 2018) is not included as it was not available to us.

[4] https://www.kaggle.com/c/jigsaw-toxic-comment-classification-challenge

[5] We do not use the test data provided with some datasets to ensure uniformity, as test sets are not provided with all datasets.

[6] Please refer to Appendix A for further experiments and analyses on the Vidgen et al. (2021) dataset.

[7] We use an I.I.D. setting for data as 40% of all social media users and 64% of those under 30 in the USA have experienced online harassment (Pew Research Center, 2021). I.e. while hate speech is not frequent, it is often experienced by users.

Table 4: Results for the centralised and best performing FL models. The FL models have been chosen across FedProx and FedOpt based on F1 scores.

models are trained with lower client fractions and epochs, they tend to be outperformed by the baselines. Models trained using FedProx outperform the centralised baselines (see table 2).[8] For instance, we see large improvements for FNet and Logistic Regression (4.5 and 6.8 points in terms of F1- score, respectively). Comparing the performances of models trained using FedOpt (table 3) with those trained using FedProx, we observe that the former (in particular FNet and RoBERTa) tend to outperform the latter for lower client fractions and epochs. In general, we find that the best FL models outperform their centralised counter-parts (see Tables 2 and 3). In fact, the best performing RoBERTa, DistilBERT, and FNet models trained using FL algorithms outperform their centralised baselines, with FNet obtaining a 3-4 point improvement over centralised models in terms of F1 score.[9]

While FL often indicates a trade-off between privacy and performance, we find that the best FL models outperform the centralised baselines. We believe that the improved performance stems from the dataset being split into smaller segments, in congruence with findings from prior work. For instance, Nobata et al. (2016) show that splitting data into smaller temporal segments helped improve classification performance overall. We believe that a similar effect may be evident with FL models that, by design split data into small segments and disregard a fraction of the clients. Further, it may be the case that some data within hate speech datasets hinders generalisation. Only using subsets of the data for training may therefore aid generalisation.

5.1 Hate Check Evaluation

This section extends the experiments to qualitatively evaluate the effectiveness of federated and centralised models under different axis of hate speech using HATECHECK (Röttger et al., 2021). HATECHECK is a suite of functional tests for hate speech detection models. HATECHECK provides an in-depth examination of model performances across different potential challenges for machine learning models trained for hate speech detection.

The HATECHECK (Röttger et al., 2021) dataset consists of 29 tests, 18 of which test for distinct expressions of hate while the remaining 11 test for non-hateful expressions. The dataset contains 3.728 labelled samples, 69% of which are 'Hate' and while the remaining 31% are labelled as 'Not-

---

[8] For tables 2 and 3, c refers to the client fraction used and e refers to the number of epochs on client devices.

[9] See Section 5.1 for an analysis using HateCheck (Röttger et al., 2021).

Table 5: Results on the HateCheck test suite.

Hate'. We evaluate all the models that have been trained for this manuscript, including the model examined in appendix A. We evaluate our trained models HATECHECK's binary form by mapping all classes positive classes to "hate" and the negative class to "not-hate".[10]

Conducting the HateCheck functional tests for the models trained on the `Comb` dataset, we see (please refer to table 5) that the federated learning models perform on par or better than the centralised models on a macro scale. The federated Bi-LSTM and FNet models yield strong improvement of 3 - 5%. On the other hand, there is a slight performance dip (0.5 - 1%) for the federated DistilBERT and RoBERTa models. Moreover, through a fine-grained analysis of model performance, we observe that all the models (centralised and federated) perform acceptable performances for different types of derogatory, pronoun reference, phrasing, spelling variations, and threatening language. However, all models perform poorly for the tests for counter speech, indicating that while the models learn to recognise some forms of hate, they cannot accurately recognise responses to it. Furthermore, we see that RoBERTa performs slightly better than all the other model variants on non-hate group identity and abuse against non-protected targets. RoBERTa and DistilBERT achieve the best performances for slurs. Overall, we find that RoBERTa and DistilBERT consistently perform well across many of the functional tests which might be due to having been pre-trained on large amount of language data. However, the pre-training also induces certain biases which limit the models' performance on profanity. The Bi-LSTMs outperform all the models on non-hateful profanity but simultaneously under-perform on hateful profanity.

6 Conclusion

Private and sensitive data can risk being exposed when developing and deploying models for hate speech detection. We therefore examine the use of Federated Learning, a privacy preserving machine learning paradigm to the task of hate speech detection to emphasise privacy in hate speech detection. We find that using Federated Learning improves on the performance levels achieved using centralised models, thus affording both privacy and performance. In future work, we intend to examine interpretability and explainability for federated learning to gain a better understanding of the causes of such performance increases.

---

[10] The `Comb` dataset uses 'none' as its negative class, the Binary Dataset (Vidgen et al., 2021) has 'Not-hate' as non-hateful label, and Multi-class Dataset Vidgen et al. (2021) has 'None' as non-hateful label

Limitations

While Federated Learning introduces increased privacy in the process of hate speech detection, a real time system may be vulnerable to attacks that can lead to privacy leakages. For instance, the weights being transferred from the clients to the server may reveal information about the local dataset to an adversary (Bhowmick et al., 2018; Melis et al., 2019). However unintended these leakages may be, they still pose a significant threat and might limit the privacy claim.

The Federated Learning models trained in our work rely on 8 of the 9 datasets used by Fortuna et al. (2021), as we could not gain access to the final dataset. We do not test the biases introduced in Federated Learning models upon combining and normalising these datasets under the schema proposed by Fortuna et al. (2021, 2020). Additionally, the dataset division for the simulation is done under the assumption of I.I.D. conditions which might not always be true for real-world scenarios.

Ethical Considerations

Although our methods for hate speech detection provide increased privacy to downstream users of content moderation technologies, i.e. users of online platforms, there are significant risks to it. First, our proposed technology has dual use implications, as it can also be applied maliciously, for instance to limit the speech of specific groups. Second, while this work uses publicly available datasets, there is an inherent tension between the public availability of data and privacy risks. Finally, although all model updates occur on local client devices, federated learning is not a silver bullet which addresses issues of systemic violence of content moderation Thylstrup and Talat (2020), or issues of privacy. Rather, federated learning can provide an avenue for engaging in meaningful conversations with people and their experiences and needs for content moderation and privacy.

A Learning From the Worst

Extending the experiments conducted in section 4, we aim to analyse if our claims are corroborated when we expose the complete setup of federated as well as centralised models to other datasets. We perform this analysis on the "Learning from the Worst" dataset (Vidgen et al., 2021).

A.1 Dataset

Binary Dataset We use the Dynamically Generated Hate Dataset v0.2.2 provided by Vidgen et al. (2021) which contains $41,255$ entries. We use the training, testing, and validation sets provided by Vidgen et al. (2021). This dataset consists of two categories: hate and not-hate. The category distribution is shown in table 6.

Multi-class Dataset We use the same Dynamically Generated Hate Dataset v0.2.2 provided by Vidgen et al. (2021). However, we make use of the multi-class labels provided in the original dataset. It consists of seven categories: none (i.e. not-hate), derogation, not-given, animosity, dehumanisation, threatening, and support (see table 6 for class distribution).

Binary categories	Multi-class categories	Count
Not-hate	None	18,993
Hate	Derogation	9,907
	Not Given	7,197
	Animosity	3,439
	Dehumanisation	906
	Threatening	606
	Support	207

Table 6: Label distribution of Vidgen et al. (2021) v.0.2.2.

Model	Binary Dataset			Multi-class Dataset		
	Precision	Recall	F1	Precision	Recall	F1
LogReg	63.38	52.58	54.98	56.68	35.46	40.92
Bi-LSTM	63.56	52.90	55.38	58.44	41.70	45.91
FNet	27.75	48.05	33.74	53.41	23.46	27.60
DistilBERT	71.56	71.72	68.63	78.25	52.96	59.27
RoBERTa	**76.18**	**77.50**	**74.37**	**80.26**	**62.69**	**67.91**

Table 7: Centralised model performances for binary and multi-class datasets

A.2 Analysis

We follow the training procedures outlined in section 4 on the binary and multi-class versions of the Vidgen et al. (2021) dataset and consider the results on the multi-class dataset (see Tables 7 and 8). We observe similar performance trends for the Logistic Regression and Bi-LSTM models in table 9 to those for `Comb`. This pattern extends to the Transformer-based models with the exception of the RoBERTa model. The federated RoBERTa obtains a slightly lower F1 score than the centralised version in (64.92 and 65.73, respectively).

The pattern of performances for the binary dataset varies from our main dataset. Here, we observe in Table 8 that the FNet model adapts well to the federated setting, with both FedProx and FedOpt algorithms significantly improving on their centralised counter-part (65.14 and 35.51, respectively) (see Table 9). Moreover, we find that the models optimised using FedProx algorithm outperform those using the FedOpt algorithm for all federated learning settings with the exception of the DistilBERT variant with $c = 50\%$ and $e = 5$. For the binary dataset, we observe that all federated models except for RoBERTa perform better across client fractions when trained for lower epochs. For the multi-class dataset, however, all federated models have improved performance across client fractions, when the models are trained for a higher number of epochs. We observe from our results that there is a slight performance decrease for the federated versions of the Bi-LSTM, RoBERTa, and DistilBERT, when compared to the centralised models. A small decrease in performance however is expected for federated learning, due to its emphasis on privacy protections. In spite of small differences, the experiments on both the binary and multi-class versions of Vidgen et al. (2021) closely resemble the results obtained on `Comb`, suggesting that federated learning is applicable across datasets for hate speech and class distributions.

We see a similar trend as `Comb` while performing the HATECHECK functional tests on the binary and multi-class dataset. The Logistic Regression adapts poorly across different types of counter speech, slurs, non-hate group identity, negation, and abuse against non-protected targets. Moreover, we also observe that Bi-LSTM and FNet yield poor performance for different types of negation and non-hate group identity. We find that in most cases, models trained on the binary dataset achieve higher performances than the models trained on its multi-class counterpart.

B Model Exploration

This section highlights the different model settings and hyper-parameter selection strategies used while training the models on `Comb` and Vidgen et al. (2021) in appendix A. We also provide a token level analysis conducted by on `Comb`.

B.1 Hyper-parameter Search

We use Weights and Biases (Biewald, 2020) as our experiment tracking tool for all experiments. We run a Bayesian search for finding the optimal client learning rate, server-side learning rate, and the proximal term. In our hyper-parameter search for the value of proximal term, we conduct a categorical search. Following Li et al. (2020), we set the possible values to 0.001, 0.01, 0.1, and 1.

B.2 Model Descriptions

We implement all models using PyTorch (Paszke et al., 2019) and Huggingface libraries (Wolf et al., 2020). We train the Logistic Regression and Bi-LSTM models for 300 rounds, and transformer-based models for 50 rounds. We implement early stopping based on the weighted validation F1 scores, with the patience set to 10 rounds. After conducting our hyper-parameter search, we choose our hyper-parameters (see table 11 and table 12). The measure the performances of all our models

	Subword-level	4	152	221
Kaggle	Word-level	1	727	4950
	Subword-level	2	872	4952

Table 10: Word-level and subword-level (BPE) token sequence length distribution for `Comb` dataset described in Section 3

level using SpaCy (Honnibal and Montani, 2017) and subword-level using the BPE algorithm.[11] Based on our analysis, we draw the following conclusions: 1) token length is highly imbalanced for different datasets in `Comb`, particularly in Kaggle dataset[4]; 2) 99th percentile token length in Kaggle dataset[4] is reflected in the remaining dataset. Considering this, we remove longest 1% of documents from the Kaggle dataset[4] to achieve faster computation. Through this exclusion process, the maximal token length of documents is reduced from 4950 to 727 tokens, without a substantial loss of information.

Learning the Legibility of Visual Text Perturbations

Dev Seth[1] **Rickard Stureborg**[1] **Danish Pruthi**[*] **Bhuwan Dhingra**[1]

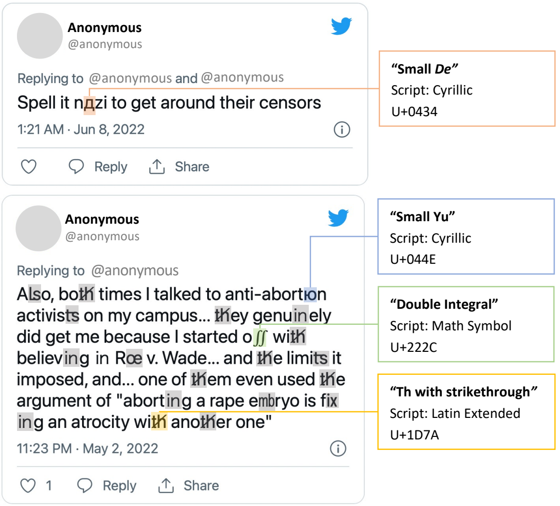
Abstract

Many adversarial attacks in NLP perturb inputs to produce visually similar strings (‘ergo’ → ‘ɛrgo’) which are legible to humans but degrade model performance. Although preserving legibility is a necessary condition for text perturbation, little work has been done to systematically characterize it; instead, legibility is typically loosely enforced via intuitions around the nature and extent of perturbations. Particularly, it is unclear to what extent can inputs be perturbed while preserving legibility, or how to quantify the legibility of a perturbed string. In this work, we address this gap by learning models that predict the legibility of a perturbed string, and rank candidate perturbations based on their legibility. To do so, we collect and release **`LEGIT`**, a human-annotated dataset comprising the legibility of visually perturbed text. Using this dataset, we build both text- and vision-based models which achieve up to 0.91 F1 score in predicting whether an input is legible, and an accuracy of 0.86 in predicting which of two given perturbations is more legible. Additionally, we discover that legible perturbations from the **`LEGIT`** dataset are more effective at lowering the performance of NLP models than best-known attack strategies, suggesting that current models may be vulnerable to a broad range of perturbations beyond what is captured by existing visual attacks.[1]

1 Introduction

To manage the increasing demand for content moderation—e.g., detecting spam or toxic/hateful content on online platforms—organizations have turned to machine learning solutions. In response, users often resort to manipulating text to evade detection, removal, or search. For instance, hateful comments often comprise of visually similar characters to avoid automatic filtering (Le et al., 2022).



Spell it nдzi to get around their censors

Also, boᵺ times I talked to anti-abortюn activiʦ on my campus... ᵺey genuinely did get me because I started o∬ wiᵺ believing in Rœ v. Wade... and ᵺe limiʦ it imposed, and... one of ᵺem even used ᵺe argument of "aborting a rape embryo is fix ing an atrocity wiᵺ anoᵺer one"

Figure 1: Visual attacks in the wild. Examples of Twitter users manipulating their tweets to evade the platform’s ‘sensitive content’ detection algorithms.

Since people read text visually, the manipulated content can still be easily understood and harm its target audience. These attacks started with simple ASCII substitutions like he11o (colloquially referred to as “leetspeak"), but have evolved into complex manipulations utilizing characters from different Unicode scripts (Flamand, 2008; Raymond, 1996). Figure 1 shows two such examples.

Unlike computer vision where there is an established notion of what constitutes an imperceptible perturbation (typically defined via the ℓ_∞ distance), most perturbations in text are perceptible. However, as long as the perceptible manipulations remain *legible*, the message could have its intended effect. The legibility of a text is determined by whether or not a literate person can decipher the altered words. The degree to which a piece of text can be perturbed, while maintaining legibility, depends on a multitude of factors such as its context, similarity to the original content, the positions of the perturbations, the background knowledge of the reader, etc.

However, many adversarial attacks enforce legibility only loosely based on intuitions about the nature of the attacks, e.g., that changing 1-2 characters in a sentence does not impact its legibility (Belinkov and Bisk, 2018; Pruthi et al., 2019).

In this work, we instead propose to learn the legibility of visual perturbations, by developing text- and vision-based models trained on legibility annotations from human subjects. The current focus of research on adversarial attacks is to find minimal perturbations required to break NLP models, and several recent findings suggest that models remain brittle to such perturbations (Eger et al., 2019; Dionysiou and Athanasopoulos, 2021; Pruthi et al., 2019). In contrast, our work attempts to uncover the space of *all legible perturbations* that we need to defend against. Towards our goal of characterizing the limits of legibility of perturbed texts, we make the following contributions:

First, we crowdsource human judgments about the legibility of different perturbations: specifically, we show annotators two perturbed versions of the same word and ask them which one, if any, they find more legible. Our perturbation strategy considers substituting letters in the word with Unicode characters drawn from a large subset of the Basic Multilingual Plane covering over 100 scripts from around the world.[2] In total, we collect $30,320$ annotations, one each for $14,643$ and $3,332$ instances in the training and validation sets, respectively, and three each for the $4,113$ instances in the test set. Using these preferences, we define a *pairwise legibility ranking task* as well as a *binary legibility classification task*. While the former allows making inferences about which candidate perturbation is *most* legible, the latter allows filtering out illegible perturbations altogether. For each task, we identify a *hard* subset of the collected data, which includes fine-grained comparisons expected to be more challenging for annotators and models alike.

Second, we use the labeled data to train models which predict the degree of legibility of a perturbed text. Specifically, we fine-tune pretrained vision (TrOCR; Li et al., 2021) and text-based (ByT5; Xue et al., 2022) models on the ranking and classification tasks. We find that TrOCR trained in a multi-task setup on both tasks achieves the best performance with 0.91 F1 score on the classification task and 0.86 accuracy on the ranking task. Interestingly, we find that the purely text-based ByT5 also achieves competitive performance on the classification task with 0.89 F1, suggesting that its pretrained byte representations encode aspects of visual similarity between Unicode characters. Further, we find that models have high F1 scores on the subset of data with high inter-annotator agreement: TrOCR achieves a 0.96 F1 score on test cases where all three annotators agree. We also note that legibility is a complex phenomenon—it doesn't correlate trivially with the distance of the perturbation from the original text or the number of letters substituted.[3]

Third, we consider a word-level *perturbation recovery* task, which involves inferring the original word from its perturbed version. We evaluate GPT-3 (Brown et al., 2020) on this task, comparing its performance on legible perturbations from our perturbation strategy versus those generated by VIPER, a *VIsual PERturber* method proposed by Eger et al. (2019). We find that GPT-3 has a lower accuracy in recovering perturbations from our perturbation strategy, despite VIPER providing no guarantees on legibility. Additionally, we apply our findings to the important task of toxicity classification. We perturb a subset of the dataset using our perturbation strategy and find that it degrades the SOTA Detoxify (Hanu and Unitary team, 2020) classifier more than existing VIPER attacks. These findings demonstrate that existing attacks do not comprehensively cover the space of legible perturbations that can degrade model performance.

2 Related Work

Adversarial Attacks for NLP. A challenge in defining adversarial examples for text lies in characterizing the space of *equivalent* inputs to a training or test example which preserves the target label. While early work focused on adding distracting text to fool question answering systems (Jia and Liang, 2017), recent work utilizes more general strategies applicable to many tasks (Li et al., 2019; Morris et al., 2020; Jin et al., 2020). Many of these can be categorized as *word*-level synonym substitutions (Alzantot et al., 2018; Garg and Ramakrishnan, 2020; Li et al., 2020), or *character*-level legibility-preserving substitutions (Ebrahimi et al., 2018; Pruthi et al., 2019). Most attacks in either category are perceptible in that readers of

---

[2] We consider $12,287$ Unicode characters from codepoints 0x0000 to 0x2fff.

[3] A logistic regression model using these as features only agrees 56.7% of the time with authors' legibility assessment.

the text can identify that it has been transformed, except for one notable exception where invisible characters and near-identical characters are used to render strings indistinguishable from the original (Boucher et al., 2022). Attacks based on visual similarity of characters have also been previously considered by Eger et al. (2019) who propose three attack strategies: ICES (based on rendered glyph similarity), DCES (based on bag-of-words textual similarity of Unicode codepoint descriptions), and ECES (based on adding diacritics to base characters). For ICES, they compute similarity by comparing raw pixel values of the renderings, which we improve upon here by utilizing a pretrained Optical Character Recognition (OCR) model. This produces a 'smarter' set of visual neighbors: e.g., mirror images of letters, scaled versions of letters (like O vs °) etc., which go beyond simple accents or modifiers. We also report in-depth comparisons between our perturbation strategy and the ECES and DCES approaches in section 5.

Legibility of Perturbed Inputs. Among character-level perturbation attacks, legibility has only been loosely enforced based on intuitions about the nature and the degree of manipulations. This often results in conservative substitutions which only represent a lower bound on the space of all legible perturbations. For instance, Pruthi et al., 2019 limit the attack to only 1-2 character changes (e.g., substitutions, deletions or additions) per input example; similarly, Ebrahimi et al., 2018 propose an attack strategy which specifically minimizes the number of character manipulations required in order to render the output legible. Attacks based on visual similarity usually constrain their attack surface to inputs which are above a threshold similarity (in pixel or embedding space) to the original input (Eger et al., 2019; Eger and Benz, 2020; Dionysiou and Athanasopoulos, 2021). In this work, by contrast, we directly address the question of what constitutes legible perturbations, with the aim of learning a grounded definition of legibility rather than assuming one *a priori*.

3 Legibility Tests

We adopt a supervised learning approach for determining the legibility of perturbed texts. In this section, we describe the process used for collecting the **LEGIT** dataset (which stands for **LEGI**bility **T**ests) and in the next section we describe the modeling techniques used for predicting the legibility score and ranking different candidate perturbations.

Our setting involves one-to-one character substitutions at the word level, i.e., given a word (and no other context), we consider perturbations where each letter in the word may be replaced by a Unicode codepoint in 0x0000-0x2fff. Moreover, the substitutions are mutually independent and do not depend on the context of the other letters.

3.1 Perturbation Process

To generate perturbations for the data labeling task, we replace a subset of characters in a word with visually similar counterparts. Specifically, given a word w, we first randomly select a fraction $n \in [0, 1]$ of characters in that word to corrupt. Then, each of the chosen characters is replaced by its nearest neighbor at rank k in the embedding space generated by a model $\mathcal{M}$ which encodes characters into visual features. Hence, there are three parameters involved in the perturbation process $\phi = \{n, k, \mathcal{M}\}$.

We experiment with several models to encode characters into visual features, all based on renderings of the Unicode codepoints into images. To keep visual representations consistent across models, we use GNU Unifont, rendering each glyph separately in 144px font size with black color, on a 224×224px white background.[4] Given the rendering, we compare 5 models to encode the features. Three are transformer-based: TrOCR ('base') (Li et al., 2021), CLIP ('vit-base-patch32') (Radford et al., 2021), and BEiT ('base-patch16-224-pt22k-ft22k'). One employs convolutional as well as transformer networks: DETR (Carion et al., 2020). The fifth model is a simple baseline: ImgDot, which uses the (flattened) bitmap of a rendered character as its embedding vector. In preliminary experiments, 400 perturbed pairs were generated, with each pair using the same settings for k, n but using different models. The authors then independently ranked perturbations each pair based on their legibility. DETR- and BEiT-generated perturbations were ranked above other models' perturbations 23% and 41% of the time, respectively, whereas CLIP and ImgDot perturbations were preferred over others in 66% and 73% of cases. Hence, DETR and BEiT were excluded from further experiments. TrOCR was included later, after verifying that it was preferred $\approx 50\%$ of the time against both CLIP and ImgDot.

---

[4] Glyphs were rendered by the Pillow library (Clark, 2015).

For each of the chosen models, we compute the pairwise cosine distances between the model's embedding vectors for all Unicode codepoints in the range 0x0000–0x2fff (excluding invalid or empty codepoints), and use these distances to find the nearest-neighbors for each character. Then, to perturb a given word w using the parameters $\phi = \{k, n, \mathcal{M}\}$, we first pick $\lfloor n|w| \rfloor$ characters uniformly at random to replace. For each character, we fetch its k-th nearest neighbor from the model $\mathcal{M}$. Finally, we apply these substitutions to the target word to obtain the perturbed word.

3.2 Pairwise Comparisons

We crowdsource legibility annotations for the perturbed words using Amazon's Mechanical Turk. We collect annotations on both absolute legibility as well as relative preference between two differently perturbed inputs. Since annotators tend to produce higher quality annotations when comparing items rather than assigning absolute values (Callison-Burch et al., 2007; Liang et al., 2020), we design an annotation interface based on *pairwise comparisons* of two perturbed versions of the same word (Appendix A). Specifically, annotators see perturbations w_1, w_2 side-by-side, with the original word w hidden. They are asked to indicate which perturbation they find more legible by selecting exactly one of these four labels:

L1: w_1 is preferred

L2: w_2 is preferred

BL: both w_1, w_2 are equally legible

NL: neither w_1 nor w_2 is legible

L_1 and L_2 capture not only relative preferences between the two perturbations (used for the ranking task), but also indicate that the preferred perturbation is legible. However, these labels do not give us any information about the non-preferred perturbation. On the other hand, the BL (Both Legible) and NL (Neither Legible) options do not give us a ranking between the two words, but inform us about the legibility (or illegibility) of both words. In the next section, we use these labels to derive datasets for both a pairwise ranking task and a binary classification task.

We generate the data for annotation from English words consisting of the top $10,000$ frequent words (as per Kaufman (2012)) in the Trillion Word Corpus (Brants and Franz, 2006). We filter this vocabulary to remove words with lengths less than 4 or greater than 14, ending up with 7600 words. These words are randomly split into the train (65%), validation (15%), and test (20%) sets; all future perturbation pairs (w_1, w_2) generated for word w are added to the corresponding set, and the same sets are used for all experiments. To perturb a word w into the pair w_1, w_2 a model $\mathcal{M}$ is picked at random from {TROCR, CLIP, IMGDOT } (the three best models from our initial perturbation analysis). We sample $k \sim \mathcal{N}(\mu_k, \sigma_k^2)$ and similarly for n, applying the appropriate bounds to keep $k > 0$ and $n \in [0, 1]$. The initial values are $\mu_k = 25, \sigma_k^2 = 10, \mu_n = 0.5, \sigma_n^2 = 0.2$.

3.3 Adaptive Annotations

The space of all possible perturbations of a word is vast, and sampling the parameters ϕ based on the priors above is unlikely to yield difficult perturbations which lie at the boundary of legibility. In order to identify such perturbations, we collect data over multiple rounds using an *adaptive* process for generating the pairs. In the first round, the pairs are generated as described above and annotated by the crowd-workers. In the following rounds, pairs are generated taking into account the last round of annotations. Specifically, the ϕ_1, ϕ_2 for each successive round are chosen to make the next round of labeling harder for annotators. This is accomplished by manipulating the Gaussian used to generate k, n, i.e. by shifting μ_1, μ_2 to be closer to each other and reducing variance. This approach generates perturbations which elicit more nuanced comparisons from annotators, allowing us to capture fine-grained legibility preferences in the dataset.

Inter-annotator Agreement. Three waves of annotations were collected using adaptive pair generation. To establish high quality and confidence in the test set labels, three annotations were collected for each pair of perturbations in the test set. Pairs where all annotators disagreed were removed from the test set. For 49.1% of pairs, all 3 annotators agree on the same label, 43.6% of pairs have agreement between 2 out of the 3 annotators, and only 7.3% of pairs have no agreement among annotators. Hence, even with 4 labels to choose from, for 92.7% of (w_1, w_2) pairs, at least two out of three annotators chose the same label. This suggests that the task is well-defined and has low variance.

	# pairs (w_1, w_2)	# distinct (w)	classification examples	ranking examples
Train	14622	4940	20217	9027
Val	3326	1140	4639	2013
Test	3712	1520	4774	2650
Total	21660	7600	29630	13690

Table 1: `LEGIT` dataset statistics. For each word, there exist multiple perturbed pairs, generated through three rounds of adaptive annotations.

Annotator Details. We recruit 150 annotators, all of whom had over a 95% acceptance rate for previous work done on the platform, as well as a history of over $1,000$ completed tasks.[5] Annotators are given occasional quality checks, wherein they annotate pairs drawn from a gold dataset labeled by the authors; annotators with less than 70% accuracy on the gold data were removed from the study and their annotations discarded from the final dataset. Annotators are given batches of 20 (w_1, w_2) pairs at a time; typically taking between $30-45$ seconds to annotate. The average compensation per batch is \$0.12. Further details of the annotation interface and instructions are available in Appendix A.

Hard Subsets. We identify challenging subsets of the collected data for the ranking and classification tasks. For ranking, the chosen subset ($N = 1052$) contains pairs (w_1, w_2) where $\frac{(n_1 - n_2)^2}{n_1 n_2} < 0.1$, i.e., both n's are close to each other, so it is hard in the sense that the perturbations have similar parameters ϕ but varying degrees of legibility—they cannot be ranked just by comparing metadata. For the classification task, the chosen subset ($N = 2626$) consists of all perturbations w_i with $n_i > 0.4$, making the task more challenging by excluding lightly-perturbed words which are easier to classify.

4 Tasks and Models

In this section, we start by introducing two tasks for characterizing the legibility of perturbed texts, followed by a number of models for solving them.

4.1 Tasks

From the labels collected in the previous section, we derive data for the two tasks: ranking and classification. The tasks assume that the original word w is known, as we base our setup considering an attacker who is trying to find the best perturbation.

Ranking Task. Given a pair (w_1, w_2) of perturbations and the original word w as input, rank the perturbations in order of legibility. For this task, we only consider the subset of data labeled with strict rankings—i.e., excluding pairs labeled BL (Both Legible) and NL (Neither Legible). As the data is balanced, we only report accuracy as the main metric for this task.

Classification Task. Given a single perturbation w_i and the original word w, decide whether the perturbation is legible. While annotators performed pairwise comparison between (w_1, w_2), we can infer the binary legibility labels for w_i from pairwise rankings as follows: for labels BL and NL, we can make the obvious inference of *legible* and *illegible* for both w_i. For labels L_i, we can again infer that w_i is legible, but cannot say anything about $w_{j \neq i}$; all such w_j with unknown legibility are excluded from the classification task dataset. Since there are more legible than illegible instances in the data, we report both accuracy and F1 scores on this task.

4.2 Baselines

Majority Class. This baseline always predicts the majority class from the training set for every test example. For the ranking task, it always predicts w_2 as the preferred perturbation (resulting in an accuracy of 0.5), and for classification, the majority class is 'legible' (yielding 0.677 accuracy).

Logistic Regression using ϕ. Note that in an attack setting, the attacker would know the perturbation parameters ϕ exactly and may be interested in predicting the legibility of their perturbation using these parameters. Hence, we perform logistic regression directly on the attack parameters (n, k) to predict the label. Being a simple metadata-only baseline, this model does not take into account the characters that were perturbed or their position.

4.3 Text-based Models

ByT5. Legibility, as defined in this paper, is a *visual* property. However, we might expect pretrained language representations (e.g., those learned by large-scale language models) to also encode visual similarity between characters since the web-corpora used for pretraining might include similar-looking characters in the same contexts

---

[5] 686 annotators were excluded due to failing their first quality check. Many attempts were observed to be spam.

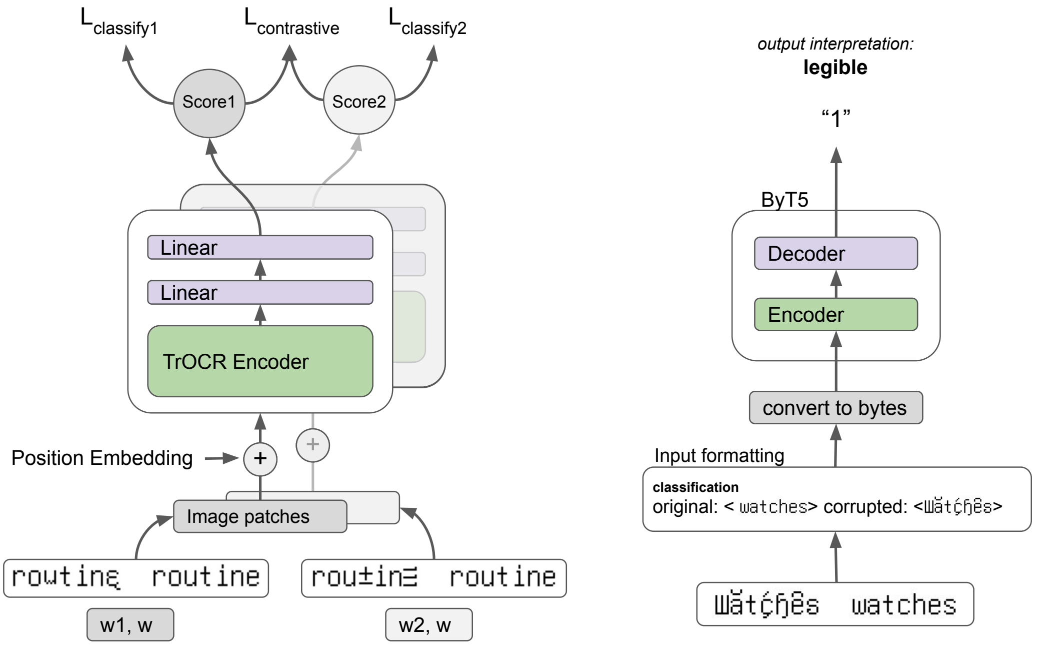

Figure 2: Comparing ByT5 and TrOCR training setup. ByT5: Both the perturbed and original words are given as one input to the model. TrOCR: Both w_1, w_2 are fed sequentially into the same TrOCR-based model, and the two resulting scalar outputs are used to compute the loss. For each perturbation, the string "w_i w" is rendered and used as input for the model.

(e.g., '0' instead of 'O'). To test this, we experiment with ByT5 (Xue et al., 2022), a multilingual encoder-decoder language model which tokenizes inputs into byte sequences. Byte-level tokenization ensures that none of the perturbations in `LEGIT` are out-of-vocabulary, and multilingual pretraining ensures that the model has seen a large subset of Unicode. We finetune the pretrained ByT5-models ('small' and 'base') to predict the binary labels for both classification and ranking in a text-in text-out setting. For ranking, the inputs are formatted as: "original: $< w >$ word0: $< w_0 >$ word1: $< w_1 >$", and the output is "0" or "1" depending on which word is more legible. For classification, the inputs are formatted as: "original: $< w >$ corrupted: $< w_i >$ ", and the output is "0" or "1" depending on whether the corruption is illegible or legible. We train two separate models starting from the pretrained ByT5 weights using the cross-entropy loss over the target byte-sequence and AdamW optimizer (Loshchilov and Hutter, 2019) and perform early stopping using the validation set. Figure 2 outlines the model schematic with sample inputs and outputs.

4.4 Vision-based Models

Since we are concerned with finding representation spaces for *visually* similar characters, vision-based models are a natural choice for the task. We consider both unsupervised models which rely on pixel-based or embedding-based similarities, as well as supervised models based on OCR, which we train on the `LEGIT` data.

ImgDot. This unsupervised approach compares the corresponding characters in w and w_i based on the cosine distance between their pixel renderings. For the ranking task, this model selects the perturbation whose average cosine distance with the uncorrupted word is lower. For classification, we tune a threshold similarity parameter on the training set, above which the model predicts 'legible'.

TrOCR-Embeddings. This approach is identical to ImgDot, except that we use the pretrained character embeddings obtained by passing the rendered images as input to the TrOCR model. The embedding vector for each character is obtained by averaging the last hidden state from the encoder output (bypassing the pooler). Note that the accuracy of these unsupervised baselines gives us an idea of how well the corresponding representations align with human notions of legibility.

TrOCR. Finally, we consider finetuning TrOCR on the `LEGIT` data. We only use the encoder part of the TrOCR base model and connect it to a linear head. This linear head has two fully connected layers mapping inputs of size 768 (which is equal to the dimension of the encoder output) to a scalar output which represents the legibility score of the perturbed input. We use ReLU activations between the linear layers and apply dropout. The model takes variable-sized images as input; this is created by rendering a pair (w_i, w) into a single image by concatenating both strings along the horizontal axis (see Figure 2).

For the classification task, the output score from the model is used directly for predicting the label. Given a pair (w, w_i), let s_i denote the scalar output from the model and let $y_i \in \{0, 1\}$ denote the legibility label (where 1 denotes that w_i is legible). Then the classification loss is given by:

$$\begin{aligned}\mathcal{L}_{\text{classify-}i} = &-y_i \log \sigma(s_i) \\ &- (1 - y_i) \log\left[1 - \sigma(s_i)\right] \qquad (1)\end{aligned}$$

where σ is the sigmoid function. We apply the same loss function to both perturbations w_1 and w_2. We denote this classification model as TrOCR-C.

For the ranking task, we use the same model but apply it separately to the pairs (w, w_1) and (w, w_2) to obtain the scores s_1 and s_2. The parameters across the two applications of the model are shared in a Siamese network setup (Koch et al., 2015). Given these two scores, and the label $y \in \{0, 1\}$ (where 0 denotes that w_1 is more legible), we define the ranking loss as:

$$\begin{aligned}\mathcal{L}_{\text{contrastive}} = &-y \log \sigma(s_1 - s_2) \\ &- (1 - y) \log\left[1 - \sigma(s_1 - s_2)\right] \qquad (2)\end{aligned}$$

The above loss encourages s_1 to be higher than s_2 when $y = 0$ and vice versa. A similar loss has been used to train summarization models from pairwise human preferences (Stiennon et al., 2020). We denote this ranking model as TrOCR-R.

The Siamese setup for the ranking task is limited in the sense that it cannot directly compare the two perturbations to decide which is more legible. However, our goal is to train the model to produce a calibrated legibility score given only a single perturbation as the input. Further, the Siamese network allows us to train the model on *both* the classification and ranking tasks together in a multi-task fashion:

$$\mathcal{L} = \mathcal{L}_{\text{classify-1}} + \mathcal{L}_{\text{classify-2}} + \mathcal{L}_{\text{contrastive}} \qquad (3)$$

The loss terms for each training example are masked based on the label: the ranking loss is masked out if the label is "equally legible" or "both unclear", whereas the individual classify-i loss is masked out if the inferred binary legibility of perturbation w_i is indeterminate (e.g. for label L_1, binary legibility of w_2 is unknown). Together, these losses ensure that the legibility score s_i is thresholded at 0, above which the perturbations are legible, and more legible inputs receive a higher score. We denote the model using combined loss as TrOCR-MT.

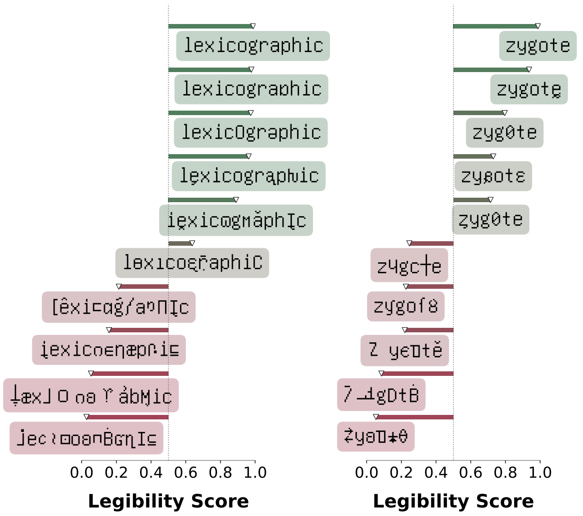

Figure 3: Legibility scores for `LEGIT`-generated perturbations of *lexicographic* and *zygote* from the TrOCR-MT model. Neither word was seen during training.

5 Results

Table 2 shows the performance of all models introduced on both the classification and ranking tasks.

Classification Task. For the classification task, we find that baselines that just use the metadata perform poorly. The Majority Class baseline obtains an F1 score of 0.677, and the Logistic Regression model using ϕ parameters yields an F1 score of 0.665, implying that legibility is *not* a simple function of the perturbation parameters k, n. The unsupervised vision-based models, ImgDot and TrOCR embeddings, vastly improve upon the simple baselines, with the TrOCR embeddings obtaining an F1 score 0.868 and ImgDot yielding an F1 score of 0.845. Hence, these embeddings align reasonably well with human perceptions of legibility. The text-based ByT5 models improve significantly over the baselines and unsupervised vision-based models. They are comparable to the performance of the single-task objective TrOCR-C, but worse than the TrOCR-MT. This suggests that the ByT5 models might have encountered some visual perturbations during pretraining. Comparing the

Table 2: Results on the standard test set. The TrOCR-MT model, trained in the multi-task setting, outperforms all other models for F1 score on both tasks. The trained models also outperform the baselines on both tasks.

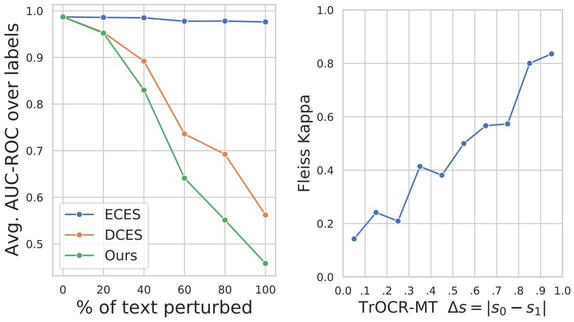

Figure 4: **Left**: *Detoxify* model performance on perturbations generated by different attack methods on a random subset ($N = 2000$) of the Jigsaw Toxic Comment Classification dataset. Model performance degrades most on our perturbations. **Right**: Model confidence on legibility is aligned with annotator agreement. Legibility scores (s_0, s_1) were obtained using TrOCR-MT for each perturbed pair (w_0, w_1) in the test set. Pairs were grouped by the score difference $\Delta s = |s_0 - s_1|$ and Fleiss' κ was computed for each group.

single-task TrOCR-C model with the multi-task TrOCR-MT, we find that the presence of the additional ranking loss term during training improves model performance on the classification task from 0.886 to 0.905. On test examples where all 3 annotators agree, TrOCR performs even better, attaining an F1 score of 0.960, compared to a score of 0.850 on examples where only 2 annotators agree. As further evidence of the model's alignment with annotators, we find that the model confidence is directly correlated with annotator agreement (cf. Figure 4) as measured by Fleiss' κ (Fleiss, 1971). Furthermore, consider Figure 3, which shows legibility scores obtained from TrOCR-MT for two words picked at random which are not part of the training set. Qualitatively, we see that legibility scores from the TrOCR-MT model aligns with the human judgements of legibility for these words.

Ranking Task. The TrOCR-MT model performs better *relative to* other models, resulting in a 6.8% absolute accuracy improvement. Akin to the classification task, we find the TrOCR-MT model outperforms its single-task counterpart TrOCR-R. Thus, training with a multi-task objective improves performance on both ranking and classification tasks when compared to single-objective models. Differently from classification, we find that ByT5 is significantly worse than the vision-based models on ranking, suggesting that language model pretraining is effective at separating legible from illegible perturbations, but not at encoding the degree of legibility of legible perturbations.

Jigsaw Challenge. Next, we check whether perturbations generated by our attack model (§ 3.1) and filtered to ensure legibility using TrOCR-MT are effective at degrading the performance of NLP models. We employ the Jigsaw Toxic Comment Classification Dataset, which is a multilabel classification dataset consisting of Wikipedia comments and human-annotated binary labels for 6 toxicity categories. In Figure 4 (Left), we compare **`LEGIT`** and VIPER-DCES strategies in a real-world scenario by perturbing the Jigsaw dataset with each strategy and reporting how much these perturbations degrade the performance of `Detoxify-original` (Hanu and Unitary team, 2020), a BERT-based model which has state-of-the-art performance on the Jigsaw dataset. We show that **`LEGIT`** produces greater degradation at lower n, and produces more legible perturbations even at higher n (due to TrOCR-MT filtering). In comparison, we find that DCES perturbations become very hard to read at higher n, diluting the significance of the DCES results at high n. Appendix D provides a qualitative analysis of the legibility of DCES perturbations compared to those generated using our **LEGIT** method.

VIPER-ECES causes a negligible degradation on model performance, which is due to the fact that the BERT tokenizer “corrects" almost all of the simple diacritic-based ECES character substitutions. This means that the classification model receives mostly unperturbed input save for some isolated UNKs. For example, the perturbed input Ťĥâňǩ ŷôǔ is tokenized back into `Thank  you`. Taken together, these results demonstrate that **LEGIT** exploits a more *efficient* legibility space, finding character substitutions which have a greater impact on model performance while preserving legibility.

Perturbing GPT-3. The strong performance of ByT5 at separating legible from illegible inputs suggests that language models might be somewhat robust to such perturbations. To examine this, we experiment with GPT-3 (`text-davinci-002` checkpoint) (Brown et al., 2020) using a *perturbation recovery task*, wherein we prompt the model to decode perturbed words back to their original strings. We sample a subset of $1,000$ (w, w_i) pairs from **LEGIT** which have a label of *legible*. These perturbations are fed to the GPT-3 model in batches of 10, along with an instructional prompt (see Appendix E) and 4 examples; recovered words are received as a completion to the input prompt. In addition, we also perturb the same 1000 words using VIPER-DCES and report the accuracy of GPT-3 at reconstructing them. We observe that GPT-3 often returns a word with a short edit distance to the original word, and hence to capture this in our evaluation, we apply the Porter stemmer from NLTK (Loper and Bird, 2002) to both the original words and predicted reconstructions, and then measure how often their stemmed forms are the same. We repeat this experiment 3 times, randomly sampling the 4 examples in the prompt each time. Figure 5 shows the GPT-3 accuracy at different fractions of corrupted characters ($n = \{0.3, 0.7, 1.0\}$). As expected, the accuracy goes down as n increases, but we find that GPT-3 performs worse on **LEGIT** perturbations. This demonstrates that while state-of-the-art language models are mildly robust to the narrower range of perturbations considered in existing visual attacks, they degrade significantly on inputs sampled from **LEGIT** which are marked by humans as legible. This result underscores the importance of considering the entire space of legible perturbations when evaluating model robustness.

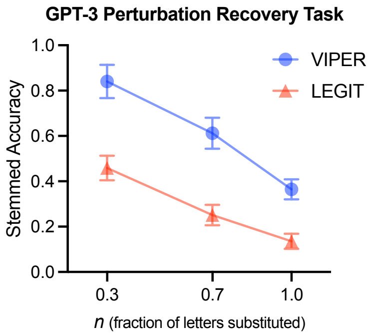

Figure 5: **LEGIT** perturbations sampled at low n degrade accuracy at levels comparable to the $n = 1$ VIPER configuration. Error bars indicate 95% confidence interval.

6 Conclusion

We set out to characterize the limits of legibility of visual perturbations. To do so, we first collected and released a new dataset, **LEGIT**, comprising legibility preferences of human subjects. Using this dataset, we framed a binary legible-or-not classification task, and a ranking task to rank candidate perturbations. For these tasks, we explored several text- and vision-based models, and found that our models obtain a high F1 score of 0.91 for the classification task and an accuracy of 0.86 for the ranking task. Perturbations generated using the same attack method as used for constructing **LEGIT** lead to significant degradation on the Jigsaw Challenge task and are not recovered by GPT-3 accurately, despite being filtered for legibility. We believe this work opens avenues for research on legibility-driven certified robustness to visual attacks in NLP.

Limitations

At the outset, we note that while our legibility-scoring models are a step forward towards defending against visual attacks, they should not be seen as perfect. Defending against all of the attacks which our models find legible might still leave room for legible attacks missed by our system.

Moreover, we note that the perturbation procedure outlined here only generates substitution-based perturbations. Whereas, characters may also be deleted, added, or swapped, and multiple adjacent characters may be substituted with visually similar counterparts (see Figure 1). Future work may explore broader classes of perturbations.

When constructing the dataset, we only chose words with a length of at least 4 letters, excluding many common 3-letter words. This is because for 3-letter words, there is a high likelihood that a bad perturbation may be mistakenly recognized as a good perturbation by virtue of being in-vocabulary. For example, “ban” is a bad perturbation of “man”, but for an annotator who sees it without knowing the original word and in absence of any sentence-level context, it seems like a perfectly good perturbation, when in fact it obscures the meaning of the original word. This is a limitation of the experimental setup that can lead to bad annotations, and to mitigate it we chose a higher minimum word length as longer words have fewer such collisions.

Further, we study word-level perturbations in isolation without any surrounding context, whereas in practice, readers often can decipher words based on the context. In general, the legibility of a text depends on the context around it—for example, even if a word is deleted from a sentence it is often possible to reconstruct it. The data we collect here, however, measures the legibility of individual words without any context, in order to simplify the generation and annotation process. As a result, the legibility estimated using this data should be considered as *lower bound* of the legibility in any given context. This was a deliberate choice as we wanted to ensure that whatever we ascertain as legible is legible in *all* contexts.

Lastly, the models we develop in our work are of relatively moderate size ($334 - 584$ million parameters) and take only unimodal input (i.e. pixels for TrOCR models and Unicode bytes for ByT5). and future work may be able to improve the performance by using larger models which accept multimodal input (e.g. both pixels and Unicode bytes simultaneously) and learn joint representations across these modalities.

Ethical Considerations

The word list comprising our dataset was filtered to remove swear words, slurs etc. in order to avoid exposing annotators to potentially harmful content.

A mTurk Annotation Inferface

The web-based UI used by mTurk Annotators is shown in Figure 6, with the instructions being visible throughout the duration of the task. Note that the perturbed words w_1, w_2 are rendered in GNU Unifont, which is the same font that words are rendered in for computing visual similarity (cf. §Legibility Tests, Perturbation Process). This ensures that both annotators and visual similarity models see pixel-for-pixel identical perturbations, controlling for the fact that different fonts render the same character differently.

The interface is optimized for clarity and labeling speed, with a focus on eliminating unnecessary UI elements and minimizing clicks. Labeling each pair w_1, w_2 with one label $L \in \{L_1, L_2, BL, NL\}$ takes exactly one click. Annotators choose L_1 by clicking on w_1 (the left word), and similarly by clicking on w_2 (the right word) for w_2. BL is selected using the “equally legible" button, whereas NL is chosen by clicking on “both unclear."

Immediately after a choice is made, the UI updates and the next pair in the batch is shown (there is no option to go back and edit the chosen label). Annotators who attempt to cheat on the task by “speeding through" (i.e. clicking randomly or spamming the same choice) end up failing the occasionally administered quality checks and are subsequently disinvited from the study.

B Use of OCR Models

Boucher et al. (2022) propose using Optical Character Recognition (OCR) models to preprocess input for text-based language models. Rendering input text and passing it through an OCR before giving it to the language model filters certain kinds of misleading Unicode characters (e.g. invisible control sequences or near-identical Confusables (Davis and Suignard, 2021)) from the text. However, when used for legible but visually distinct perturbations, off-the-shelf OCR models run into two problems.

Firstly, both mono- and multi-lingual OCR models will recognize characters from learned scripts at face value, instead of recognizing their intended use as visually similar substitutions. For example, TrOCR (Li et al., 2021), when given an image of the string ‘Mex!(0’, decodes it into ‘Mex!(0’ (i.e. the same string), completely ignoring its intended meaning (Mexico). Secondly, since OCR models are only trained on semantically meaningful inputs, they do not learn good priors to differentiate nonsense inputs from highly perturbed inputs.

We use two OCR-capable models on the ranking and classification tasks: TrOCR, which is explicitly trained on an OCR dataset, as well as CLIP, which is trained on a general corpus containing images of texts from which it learns “a high quality semantic OCR representation that performs well on digitally rendered text” (Radford et al., 2021).

We find that TrOCR models fine-tuned on our dataset achieve high performance on legibility-related tasks. On the text side, we consider the token-free language model, ByT5 (Xue et al., 2022), which encodes each byte individually, as opposed to byte-pairs or subword tokens longer than one byte. Since its encoding of each byte is disentangled from surrounding bytes, ByT5 is able to retain a larger share of the unperturbed part of the string, hopefully making it more robust to character-substitution perturbations compared to token-based models, which reduce the sequences with perturbed characters into rare tokens or simply to `UNK`s.

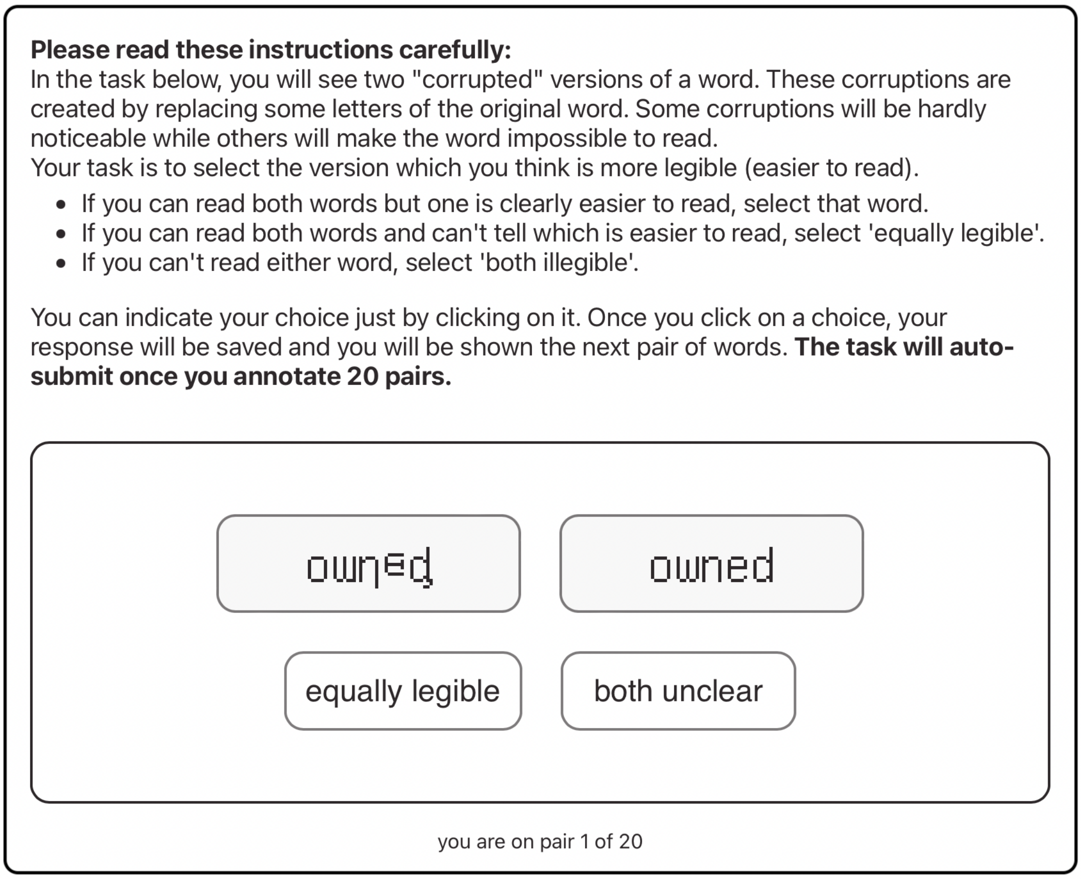
C Hyperparameters

TrOCR (‘base-handwritten’ version) was fine-tuned on **`LEGIT`** with the loss function configurations (C, R, MT) described above. To train each configuration, we use a single NVIDIA A6000 GPU (48GB VRAM) with a batch size of 26 and learning rate of 10^{-5} with the AdamW optimizer and a linear decay schedule (without warmup). ByT5-base and ByT5-small were trained on the same hardware with a batch size of 8 and learning rate of 10^{-4}.

D Toxic Comment Classification Experiment

The original string from the Jigsaw Toxic Comment Classification dataset is:

> `It is needed in this case to clarify that UB is a SUNY Center. It says it even in Binghampton University at Albany, State University of New York, and`



Please read these instructions carefully:
In the task below, you will see two "corrupted" versions of a word. These corruptions are created by replacing some letters of the original word. Some corruptions will be hardly noticeable while others will make the word impossible to read.
Your task is to select the version which you think is more legible (easier to read).

- If you can read both words but one is clearly easier to read, select that word.
- If you can read both words and can't tell which is easier to read, select 'equally legible'.
- If you can't read either word, select 'both illegible'.

You can indicate your choice just by clicking on it. Once you click on a choice, your response will be saved and you will be shown the next pair of words. **The task will auto-submit once you annotate 20 pairs.**

Figure 6: The mTurk Annotation Interface

> `Stony Brook University. Stop trying to say it’s not because I am totally right in this case.`

The VIPER DCES and **`LEGIT`** perturbations are compared in Figure 7. The **`LEGIT`** perturbations were labeled as legible by TrOCR-MT.

E GPT-3 Experiment

We provided the following prompt to the `text-davinci-002` checkpoint using the GPT-3 API:

> `The following is a list of corrupted words and their correct versions. The corruptions were created by replacing some or all letters of the correct version with similar-looking letters.`
> `Corrupted:`
> `1.` c_1
> `2.` c_2
> `...`
> `10.` c_{10}
> `Original:`
> `1.` o_1
> `2.` o_2
> `3.` o_3
> `4.` o_4
> `5.`

The model is allowed to condition on 4 ground-truth examples: o_1 through o_4, and attempts to generate o_5 through o_{10} by providing a completion for the prompt above. The *temperature* and *top p* parameters were both set to 1 to allow for consistent and reproducible outputs across batches.

Abstract

With the ever-growing size of pretrained models (PMs), fine-tuning them has become more expensive and resource-hungry. As a remedy, low-rank adapters (LoRA) keep the main pretrained weights of the model frozen and just introduce some learnable truncated SVD modules (so-called LoRA blocks) to the model. While LoRA blocks are parameter-efficient, they suffer from two major problems: first, the size of these blocks is fixed and cannot be modified after training (for example, if we need to change the rank of LoRA blocks, then we need to retrain them from scratch); second, optimizing their rank requires an exhaustive search and effort. In this work, we introduce a dynamic low-rank adaptation (DyLoRA) technique to address these two problems together. Our DyLoRA method trains LoRA blocks for a range of ranks instead of a single rank by sorting the representation learned by the adapter module at different ranks during training. We evaluate our solution on different natural language understanding (GLUE benchmark) and language generation tasks (E2E, DART and WebNLG) using different pretrained models such as RoBERTa and GPT with different sizes. Our results show that we can train dynamic search-free models with DyLoRA at least 4 to 7 times faster than LoRA without significantly compromising performance. Moreover, our models can perform consistently well on a much larger range of ranks compared to LoRA. [1]

1 Introduction

Pre-training/fine-tuning has become a popular paradigm for solving many tasks in natural language processing (NLP) (Devlin et al., 2018; Liu et al., 2019; Brown et al., 2020) and Computer Vision (Simonyan and Zisserman, 2014; He et al., 2016; Howard et al., 2019; Bochkovskiy et al., 2020; Chen et al., 2020; Dosovitskiy et al., 2020). pretrained models (PMs) such as pretrained language models (PLMs) (Devlin et al., 2018; Brown et al., 2020), and pretrained visual-language models (Lu et al., 2019; Li et al., 2019; Su et al., 2019; Xia et al., 2021) have advanced a lot in recent years. With the ever-growing size of these pretrained models, fine-tuning them on downstream tasks becomes more expensive. Moreover, as the ratio of the number of parameters of models with respect to the labeled data increases, the fine-tuning process will be more prone to overfitting (Karimi Mahabadi et al., 2021). There are two categories of solutions: first, model compression (Jafari et al., 2021; Chen et al., 2021); second, parameter-efficient tuning (PET) (Houlsby et al., 2019a; Karimi Mahabadi et al., 2021; Mao et al., 2021).

There are many different model compression techniques in the literature for Transformer-based models such as matrix factorization (Noach and Goldberg, 2020; Tahaei et al., 2021), pruning (Wang et al., 2019), quantization (Tao et al., 2022; Prato et al., 2020), and knowledge distillation (Hinton et al., 2015; Li et al., 2021; Jafari et al., 2021; Passban et al., 2021; Rashid et al., 2021). There are also different types of PET techniques in the literature such as low-rank adapters (Wang et al., 2020; Karimi Mahabadi et al., 2021; Houlsby et al., 2019b; Hu et al., 2021b), and prompt-based techniques (Lester et al., 2021).

Although model compression solutions are well-established in recent years in the literature, applying them to large language models can be very costly, because compression techniques usually need to train (or fine-tune) the original large model. A case in point is knowledge distillation which relies on fine-tuning a large teacher model or even pre-training the student model as suggested in (Jiao et al., 2019). Moreover, using compression techniques usually leads to degrading the model performance. PETs can be alternatives to the compression methods, especially when we would like to use

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3274–3287
May 2-6, 2023

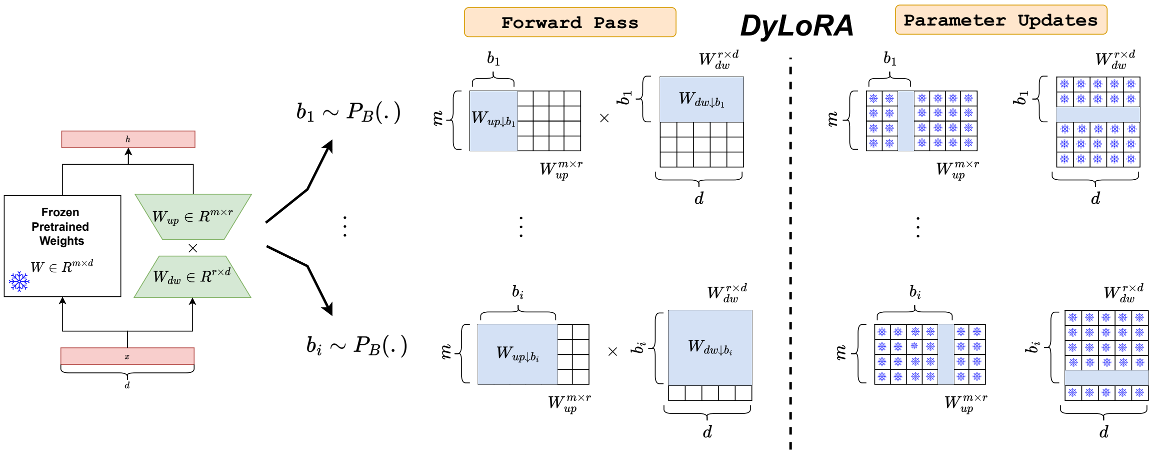

Figure 1: DyLoRA: The overall diagram of our proposed method. In each iteration, we sample from a pre-defined random distribution which will help us to truncate the up-projection and down-projection matrices in the LoRA (Hu et al., 2021a) objective.

the full capacity of the large pretrained models with light training efforts (such as the *language-model-as-a-service* scenario (Sun et al., 2022)). Among PET techniques, low-rank adapters have received much attention because, in contrast to prompt-tuning techniques, low-rank adapters do not add to the sequence length, get trained faster, and perform better (Karimi Mahabadi et al., 2021). Even though there are several low-rank adaptation techniques in the literature, such as Adapter (Houlsby et al., 2019b), Compacter (Karimi Mahabadi et al., 2021), and LoRA (Hu et al., 2021b); they all suffer from two major common problems: first, it is not clear how to select the size of their rank (while their performance is very sensitive to this rank selection); second, their training is static which means that if a low-rank model is trained based on a particular rank size, it will not work well in other rank values (i.e. for any other rank value we need to train a separate model).

This paper proposes a dynamic low-rank adapter technique (DyLoRA) to address these two problems. Without loss of generality, we focus on LoRA(Hu et al., 2021a) and train LoRA blocks for a range of ranks instead of a single rank by sorting out the representation learned at different ranks during training. While our model is more flexible, it can outperform LoRA in a much wider range of ranks without adding to the training time. Moreover, our technique does not need extra training for searching across ranks. We summarize our contributions in the following:

- Dynamic LoRA: On top of LoRA, we developed a new algorithm (DyLoRA) that makes it dynamic at inference time without incurring extra costs.
- Search-free LoRA: We demonstrate that by making a negligible compromise in performance, it is possible to avoid the costly search process of choosing the optimal rank for LoRA.

2 Related Work

This section reviews low-rank adaptation techniques for parameter-efficient tuning and potential existing solutions to make these techniques dynamic and search-free.

It has been shown in (Aghajanyan et al., 2020) that for classification tasks such as natural language understanding (NLU), PLMs have a low intrinsic dimension. This observation motivates the use of low-rank adapters for parameter-efficient tuning. There are several low-rank adapters in the literature such as LoRA (Hu et al., 2021b), Adapter (Houlsby et al., 2019b), Compacter (Karimi Mahabadi et al., 2021), and Parallel Adapter (PA) (He et al., 2021). LoRA is a low-rank up-projection/down-projection transformation without any non-linearity applied in parallel to key and value attention matrices. The main benefit of LoRA is that the adapter module, after training, can be integrated into the original weight matrices of the model, which in turn can lead to a very efficient inference time. Adapters also have a low-rank up-projection/down-projection transformation with an intermediate non-linearity. The Adapter module is applied in series with the feed-forward network (FFN). Having the adaptor module in-line with other blocks in the model can increase the inference time of the model. PA is a faster version of the Adapter, which can be applied in parallel with the FFN block. The compactor is a more memory-efficient version of the Adapter, which deploys the sum of Kronecker products to reconstruct each up-projection and down-projection matrices. All these low-rank adapters suffer from two major issues: first, finding the best rank requires heavy exhaustive training and search; second, the tuned adapter module works well only with a particular rank.

While there have been some efforts in the literature towards dynamic networks such as DynaBERT (Hou et al., 2020) and GradMax (Evci et al., 2022), to the best of our knowledge, this problem for factorized networks and low-rank adapters is still open. DRONE (Chen et al., 2021) propose a technique for data-aware low-rank model compression however their approach is not search-free, and also, it is not dynamic. DynaBERT introduces a two-stage method to train width and depth-wise dynamic networks. However, DynaBERT requires a fine-tuned teacher model on the task to train its sub-networks which makes it unsuitable for PET techniques. GradMax is a technique that gradually adds to the neurons of a network without touching the already trained neurons. But it is unclear how GradMax can be deployed to alleviate the rank-search problem in low-rank adapters. Wang et al. (2019) propose a structured pruning technique called factorized low-rank pruning (FLOP). FLOP decomposes weight matrices of a network into the sum of rank-1 components, which are regularized during training to gain sparsity. It is worth mentioning that FLOP aims at compressing the main model, and even if it can be used for finding a good rank in the lower-rank representation of full-weight matrices, the final low-rank model will not be dynamic (i.e. it is trained well only for one rank and not a range of ranks, same as LoRA.). In this paper, we propose a new methodology for training low-rank modules for multiple ranks simultaneously rather than training a single-rank adapter at a time (without changing the training budget). Inspired by the idea of *nested dropout* (Rippel et al., 2014), we pursue ordering the representations of the bottleneck at the low-rank adapter modules with a new recipe. To the best of our knowledge, it is the first time that the concept of ordering representations has been deployed in training PLMs.

3 Background

3.1 Nested Dropout

Inspired by the dropout (Hinton et al., 2012), nested drop-out (Rippel et al., 2014) is a stochastic regularization technique that targets enforcing ordered representations in training auto-encoders. The nested dropout, adds an implicit bias (which does not exist in dropout) to favor order in training. For example, in dropout, we can randomly drop any nodes or units in the network, but in nested dropout, if we randomly select k^{th} unit, then we keep all the units indexed from 1 to k and drop the units with indices larger than k. Therefore, nested dropout tends toward accommodating more important information in lower indices while learning representations.

Following the notations of (Rippel et al., 2014), nested dropout assumes an auto-encoder mapping of N training examples $\{y_i\}_{i=1}^{N} \in Y$, $Y \subset \mathbb{R}^D$ to their corresponding representations $\{x_i\}_{i=1}^{N} \in X$, $X \subset \mathbb{R}^K$ using the function $f_\theta : Y \to X$ with parameters θ; and then decoding these representations using another function $g_\psi : X \to Y$ with parameters ψ to reconstruct the inputs. The reconstruction loss can be defined as follows:

$$C(\theta, \psi) = \sum_{i=1}^{N} ||y_i - g_\psi(f_\theta(y_i))||^2. \tag{1}$$

Suppose we want to randomly drop some units in our representation vector x. In this regard, we sample a random variable $b \sim p_B(.), b \in \{1, 2, ..., K\}$ from a pre-defined categorical distribution $p_B(.)$ and truncate the functions f_θ and g_ψ to keep their corresponding units indexed from 1 to b and dropping $b{+}1$ to K indices. Let's define the b-truncated version of the vector x as $x_{\downarrow b}$ and the b-truncated version of the functions f_θ and g_ψ as $f_{\theta\downarrow b}$ and $g_{\psi\downarrow b}$ respectively. In this case, the reconstruction loss is redefined for the b-truncated model as follows:

$$C(\theta, \psi) = \mathbb{E}_{p_B}[C_{\downarrow b}(\theta, \psi)] = \sum_{b=1}^{K} p_B(b) C_{\downarrow b}(\theta, \psi)$$

where

$$C_{\downarrow b}(\theta, \psi) = \sum_{i=1}^{N} ||y_i - g_{\psi\downarrow b}(f_{\theta\downarrow b}(y_i))||^2. \tag{2}$$

In the final stage, the parameters of this model can be obtained by solving the following optimization problem.

$$(\theta^*, \psi^*) = \underset{\theta,\psi}{\operatorname{argmin}}\, C(\theta, \psi). \quad (3)$$

While our work in this paper is inspired by the feature of ordering information suggested in nested dropout, we can distinguish our work from nested dropout in several aspects:

1. The nested dropout technique is used to add order information to a vector representation; however, we are adding order information to the low-rank matrix decomposition to make it work across a range of ranks instead of a single rank.

2. Our training algorithm differs from nested dropout in the choice of the distribution function $p_B(.)$, and we propose a more efficient individual loss for each truncated matrix compared to the linear summation loss (check equations 2 and 11 in the original paper (Rippel et al., 2014)) in nested dropout. The original proposal for the nested dropout was to use a batch with mixed truncated examples. To enhance efficiency and resolve suboptimality, we propose to fix truncation in the entire batch as part of our approach.

3.2 LoRA: Low-rank Adapters

In LoRA (Hu et al., 2021a), some pretrained weights of dense layers of PLMs are summed with parallel linear low-rank adapter modules. During fine-tuning, the original pretrained weights are kept frozen; LoRA modules can be updated instead. For example, let's assume that $W_0 \in \mathbb{R}^{m\times d}$ is a pretrained weight matrix in the network which is accompanied by a LoRA module $\Delta W = W_{up}W_{dw}$ where $W_{up} \in \mathbb{R}^{m\times r}$, $W_{dw} \in \mathbb{R}^{r\times d}$, and $r \ll min(m, d)$. Then, the output of this layer can be obtained as

$$h = W_0x + \Delta W x = W_0x + \frac{\alpha}{r} W_{up}W_{dw}x. \quad (4)$$

Bear in mind that the W_{up} matrix is initialized as a zero matrix, and the W_{dw} matrix is initialized as a zero-mean Gaussian distribution where α is a constant scale hyper-parameter.

In LoRA, the rank r is a hyperparameter that should be tuned for each task. Moreover, LoRA is a *static* low-rank adapter that works only with a particular size of r, which has been trained on it.

4 Our Method: DyLoRA

In this section, we introduce our solution to get dynamic low-rank adapters that can be trained and deployed well on a range of ranks instead of a single particular rank (with a fixed training budget). This flexibility can free us from searching for the best ranks by training the model multiple times.

Without loss of generality, we explain our solution on top of LoRA as one of the prominent low-rank adapter techniques in the literature. In each LoRA module, we have an up-projection ($W_{up} \in \mathbb{R}^{m\times r}$) and a down-projection matrix ($W_{dw} \in \mathbb{R}^{r\times d}$). Let's assume that we would like to train the LoRA module to operate in the range of $r \in \text{Range}[r_{min}, r_{max}]$ where r_{min} and r_{max} can be treated as new hyper-parameters. To make the LoRA module work in a range of ranks instead of a single rank, we need to ensure that increasing or decreasing the rank will not significantly hamper the model's performance. One way to implement such behavior would be by sorting the information content of different ranks in the training process of LoRA modules. In this regard, at each training step, we sample $b \sim p_B(.), b \in \{r_{min}, r_{min} + 1, ..., r_{max}\}$ form a pre-defined categorical distribution (which has a support in $\text{Range}[r_{min}, r_{max}]$) and truncate W_{dw} and W_{up} matrices accordingly.

$$\begin{aligned} W_{dw\downarrow b} &= W_{dw}[1:b,:] \\ W_{up\downarrow b} &= W_{up}[:,1:b] \end{aligned} \quad (5)$$

$W_{dw\downarrow b}$ and $W_{up\downarrow b}$ are b-truncated versions of W_{dw} and W_{up} respectively (see Fig. 1 for the visualization). Moreover, let's define W^b_{dw} as the b^{th} row of W_{dw}; W^b_{up} corresponds to the b^{th} column of W_{up}.

$$\begin{aligned} W^b_{dw} &= W_{dw}[b,:] \\ W^b_{up} &= W_{up}[:,b] \end{aligned} \quad (6)$$

Then, the forward pass of this truncated LoRA module during training will be calculated as following:

$$h = W_0x + \frac{\alpha}{b} W_{up\downarrow b}W_{dw\downarrow b}x \quad (7)$$

For simplicity, let's assume that we have only one LoRA module in the network (the one which is described in Eq. 7). Let's first consider the regular static loss function ($\mathcal{L}^S$) of the network $f(x; W_{dw}, W_{up})$ with W_{dw} and W_{up} tunable parameters for N given input-output pairs $(\mathbf{x}, \mathbf{y}) =$

$(x_i, y_i)_{i=1}^{N}$:

$$\min_{W_{dw},W_{up}} \mathcal{L}^{\mathcal{S}}(\mathbf{x},\mathbf{y};W_{dw},W_{up}) \triangleq \sum_{i=1}^{N} l(f(x_i;W_{dw},W_{up}),y_i). \tag{8}$$

where $l(f, \mathbf{y})$ is a loss function that measures the divergence of network predictions compared with the target labels. Then, let's extend the training loss to make the network dynamic considering the b-truncation process. We can define our dynamic loss function $\mathcal{L}^{\mathcal{DY}}$ as follows.

$$\mathcal{L}^{\mathcal{DY}}_{\downarrow b} = \sum_{i=1}^{N} l(f(x_i;W_{dw\downarrow b},W_{up\downarrow b}),y_i). \tag{9}$$

Bear in mind that, our loss function has a major difference from the nested dropout loss, which makes it more efficient. The nested dropout loss is in the form of $\sum_{b=r_{min}}^{r_{max}} p_B(b)\mathcal{L}^{\mathcal{DY}}_{\downarrow b}(\mathbf{x},\mathbf{y};W_{dw\downarrow b},W_{up\downarrow b})$ which requires to sum the loss over the entire possible range of ranks and it is computationally expensive. To overcome this computational restriction, we replace it by optimizing the model parameters for each target rank individually at each time step. We show that this scheme quite works well.

The other difference with nested dropout is that in the parameter update phase, we add a new mode (so-called *frozen*) as a hyper-parameter to our training. This new mode suggests to only update the b^{th} corresponding row and column sampled in the truncation phase (i.e. a single row or column will be updated at a time to prevent the learning parameters from being forgotten at previous time steps.). With a minor performance cost, this approach can improve the efficiency of our algorithm even further.

$$\begin{aligned} W^{b}_{dw} &\leftarrow W^{b}_{dw} - \eta\nabla_{W^{b}_{dw}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b} \\ W^{b}_{up} &\leftarrow W^{b}_{up} - \eta\nabla_{W^{b}_{up}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b} \end{aligned} \tag{10}$$

Table 4 shows the impact of only updating "b" versus updating the columns and rows from 1 to b. The summary of our technique is described in Algorithm 1.

Algorithm 1 DyLoRA - Training

```
Require:
  $r$ ∈Range[$r_{min}$,$r_{max}$]; $i$: the number of training iterations; $\alpha$: a scaling factor; $p_B$: probability distribution function for rank selection; $X \in \mathbb{R}^{d\times n}$ : all input features to LORA; $W_0 \in \mathbb{R}^{m\times d}$ the original frozen pretrained weight matrix
Require: $W_{dw} \in \mathbb{R}^{r\times d}$; $W_{up} \in \mathbb{R}^{m\times r}$, FROZEN: whether to keep the lower ranks frozen when updating the higher ranks
  while t < $i$ do:
    Forward:
    // sample a specific rank, during test is given
    $b \sim p_B(.)$
    // truncate down-projection matrix
    $W_{dw\downarrow b} = W_{dw}[:b,:]$
    $W^{b}_{dw} = W_{dw}[b,:]$
    // truncate up-projection matrix
    $W_{up\downarrow b} = W_{up}[:,:b]$
    $W^{b}_{up} = W_{up}[:,b]$
    // calculate the LoRA output
    $h = W_0X + \frac{\alpha}{b}W_{up\downarrow b}W_{dw\downarrow b}X$
    Backward:
    if FROZEN then
            // only update the unique parameters of the selected rank
            $W^{b}_{dw} \leftarrow W^{b}_{dw} - \eta\nabla_{W^{b}_{dw}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$
            $W^{b}_{up} \leftarrow W^{b}_{up} - \eta\nabla_{W^{b}_{up}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$
    else
            $W_{dw\downarrow b} \leftarrow W_{dw\downarrow b} - \eta\nabla_{W^{b}_{dw\downarrow b}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$
            $W_{up\downarrow b} \leftarrow W_{up\downarrow b} - \eta\nabla_{W^{b}_{up\downarrow b}}\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$
    end if
  end while
```

5 Experiments

In this section, we describe the experiments used to evaluate our DyLoRA model on both natural language understanding (NLU) and natural language generation (NLG) tasks. To be fair with the original LoRA method, we try to keep the setting of our experiments similar to the LoRA paper (Hu et al., 2021a). Therefore similarly, we chose the pretrained RoBERTa (Liu et al., 2019) base model as the backbone of the LoRA and DyLoRA experiments for the GLUE benchmark (Development Set), and GPT-Medium for the NLG tasks. For our experiments, we did not use any hyper-parameter tuning, nor did we search the validation epochs, nor did we use MLNI trick (use the MLNI checkpoint instead of the pretrained weights) to enhance the model's performance. More details about the hyper-parameters is available in Table 8 in Appendix B. In total, we conducted more than 200 experiments and evaluated more than 1600 models, details of

Model: RoBERTa-Base

Table 4: Ablation Study - In this experiment, our goal is to demonstrate how the introduced distribution can affect the performance of DyLoRA.

a result, most of the experiments have been conducted in a favorable manner for LoRA.

- **FLOP**: Due to its flexibility, **F**actorized **Low** Rank **Pr**uning (FLOP) (Wang et al., 2019) can be applied to any matrix multiplication and, therefore, can be used to avoid the search in our problem. However, this baseline lacks the dynamic properties of DyLoRA. We used it to show regularization-based techniques' performance and pros and cons.

5.2 LoRA rank selection problem

There is no clear guidance on how to determine the rank for the LoRA algorithm. It is evident in the LoRA paper (Hu et al., 2021a) that the performance of models varies a lot with different ranks (e.g. check Tables 15, and 18 in the LoRA paper), and does not indicate any clear trend. We also observe the same problem in the GLUE benchmark. We may argue that theoretically, the rank with the best performance is always the highest. High ranks, however, introduce additional parameters into the adaptive process and this might be undesirable. In practice, as demonstrated in Table 1, the most effective rank differs depending on the task. For example, based on the MRPC results, the rank with the lowest performance is 16 while the rank with the highest performance is 32. This is different from SST-2, in which rank 1 is the least performing rank and rank 8 is the most effective rank. Many factors can contribute to this difference, including but not limited to the size of the dataset, hyperparameter selections, hardware configurations and the optimization.

5.3 Dynamic low rank adaptation

For example, suppose we have a neural network that we wish to deploy on various devices with different configurations. The use of higher ranks may pose a problem for very sensitive devices as they have a greater number of parameters. Therefore, we must either train several models with different configurations or find the most optimal rank. The cost associated with this is significant, as even in the setting of LoRA, we are required to find the best rank for each task and each device. Using DyLoRA, however, one needs to train one model per task and, as our method is adaptive at inference time, we can deploy it according to our needs. In Table 2, we demonstrate the dynamic properties of

DyLoRA. In order to ensure a fair comparison, all LoRA and DyLoRA models in this table have the same model size, we used the same code and evaluation process, and all models were trained to the same extent. In LoRA, we lose performance when performing inferences for the lower ranks. This occurs because the model has been trained only for rank 8 during training. In DyLoRA, we preserve a high level of performance for lower ranks while competing well with LoRA on rank 8.

Model	**Time**	**SST-2** (r)	**MRPC** (r)
Maximum Rank: $r_{max} = 64$			
LoRA (Search)	$7x$	**95.3**(64)	89.71(64)
DyLoRA (Frozen)	**1x**	94.38(**7**)	**89.95(34)**
Maximum Rank: $r_{max} = 32$			
LoRA (Search)	$6x$	**94.84**(32)	88.73(16)
DyLoRA (Frozen)	**1x**	94.38(**7**)	**89.71(5)**

Table 5: In this table, the search space of rank is larger compared to the previous experiment and the goal is to find the most optimal rank for the low-rank adaptation of a pre-rained RoBERTa-Base. For LoRA (Search), we ran experiments for ranks=1,2,4,8,16,32,64 and we reported the best results. In the Exhaustive Search, one has to search all the ranks from 1 to 64, which means it will cost 64 times more than our proposed method. The lower the rank the better, and the higher the performance is the better.

5.4 Search-free low rank adaptation

The process of selecting a particular rank can be expensive as previously mentioned. In Table 5, we present an experiment that illustrates the costs associated with such a search for LoRA and DyLoRA. As an example, if one naively wanted to search the entire range of ranks (for example, 64 in the experiment), then they would have to train and evaluate 64 distinct models in order to determine the proper rank. It becomes even more expensive if one search the entire rank space. In the case of uniform search, this cost is less, yet still more expensive (7 times in the experiment) than our proposed method. Therefore, for LoRA (Search), we ran experiments for ranks=1,2,4,8,16,32,64 and we reported the best results. The results demonstrate that our proposed method performs competitively at a much lower cost.

5.5 Robustness of DyLoRA

As illustrated in Table 2, DyLoRA is quite robust to randomness and can produce consistently good results due to stable convergence.

5.6 Regularization and Pruning

An alternative method of avoiding the search problem is using regularization/pruning techniques to determine the intrinsic rank of the weight matrix. In this way, we can reduce the number of parameters of the original matrices; however, we will not have a dynamic model during inference. To illustrate the difference between such methods and DyLoRA, we reported the performance of one of these models, FLOP (Wang et al., 2019), in Table 3. FLOP utilizes low-rank factorization to create new matrices representing the original weight matrix. Thus, they will have fewer total parameters but require more trainable parameters to reach a comparable performance to DyLoRA.

5.7 Generative Tasks

In this experiment, we evaluate the performance of our model on different natural language generation (NLG) tasks such as the E2E NLG Challenge (Novikova et al., 2017), DART (Nan et al., 2020) and WebNLG (Gardent et al., 2017). The results of the E2E task are shown in Table 6 and due to the space limit, the results of the other two tasks are demonstrated in Appendix C. The generative tasks demonstrate a similar pattern as the NLU task, showing that our model is able to work well at wider range of ranks compared to LoRA.

5.8 Ablation study

In this subsection, we investigate the impact of two design choices in DyLoRA: first, the new distribution P_B hyper-parameter in our technique; second, the impact of updating W^b_{dw} and W^b_{up} parameters instead of the entire $W_{dw\downarrow b}$ and $W_{up\downarrow b}$. The distribution P_B changes the relative importance of the different ranks during the training process. To examine the impact of the chosen distribution on DyLoRA's performance, we used two distributions, geometric and uniform. As shown in Table 4, the geometric distribution, provides a much better method for optimizing the lower ranks, since it pays much more attention to the lower ranks during training, and uniform distribution will give better performance over all ranks. We chose to use uniform distribution in most of our experiments to avoid adding another hyperparameter which is a requirement of the geometric distribution. Moreover, we demonstrate that it is possible to ensure that the optimization of rank b will not negatively affect the performance of the lower ranks (1 to $b-1$), while

Model (Method)	**Updated Params**	**Trainable Params**	E2E NLG Challenge				
			BLEU	**NIST**	**MET**	**ROUGE-L**	**CIDEr**

			Fine-Tune				
GPT-2 M (FT)*		354M	68.2	8.62	46.2	71.0	2.5

Table 6: For all metrics, higher is better. Rows with * have been reported based on the LoRA paper. Unlike (Hu et al., 2021a), we included the classifier number of parameters in our trainable parameters count.

performing reasonably well. As mentioned, this can be accomplished by only updating the unique parameters associated with rank r that do not overlap with lower ranks.

In addition, in Table 7, we demonstrate the result of using our individual loss (Eq. 9) vs. the nested dropout original objective function in an equal setting. As shown, our proposed objective function is both effective and efficient. Furthermore, it is important to note that the summation loss is not scalable when many ranks are involved. We also discussed the time complexity of LoRA and DyLoRA in Appendix A.

Maximum Rank: $r_{max} = 8$		
Loss	**Training Time**	**CoLA**
$\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$	**645.82s**	52.64
$\sum p_B(b)\mathcal{L}^{\mathcal{DY}}_{\downarrow b}$	1175.69s	**54.12**

Table 7: This experiment shows the impact of choosing individual loss vs. summation loss functions on our training. The average performance across all possible ranks (1,2,...,8) is reported. For summation loss to be computationally more feasible, smaller epochs were chosen. A total of seven GPUs were used in this experiment.

6 Conclusion

In this paper, we presented our solution DyLoRA to address two problems in low-rank adapters regarding rank selection and making them dynamic. We showed that DyLoRA can select the rank without requiring multiple re-training and is able to make LoRA dynamic at inference time. As a result, we can avoid the process of searching for the most optimal ranks for many real-life scenarios. It has been demonstrated that DyLoRA performance is comparable with LoRA, yet we can support a wider range of ranks without adding additional time and effort.

Limitations

According to LoRA (Hu et al., 2021a), a proper choice of the scalar can improve the results. In order to determine what is the best choice, further investigation is required. Despite our demonstration that uniform distribution can be as effective as specific geometric distribution, further investigation is necessary to evaluate the effect of different distributions on different downstream tasks. As shown in this paper, our algorithm works over a wide range of ranks, but further research is needed to understand the impact of choosing a particular range.

7 Acknowledgement

We would like to use DyLoRA with Mindspore[2], which is a new framework for deep learning computing.

A Time complexity

The training time for DyLoRA is comparable to that of LoRA trained once on a specific rank. Thus, when searching the rank space for LoRA, we need to train it multiple times, whereas our method does not require searching the ranks. Accordingly, DyLoRA's relative time complexity is inversely proportional to the number of possible ranks for which the LoRA model must be searched. In MRPC, DyLoRA (for all the ranks) and LoRA (only on a single rank 8) require a total training time of 408.39 seconds and 399.95 seconds, respectively. Consequently, when we need to train eight LoRA models (Rank=1,2,...,8), it will result in a cost of 399.95*8=3199.6s, compared to the training time of our model, which is only 408.39 seconds. A more efficient implementation of our algorithm may result in a better time complexity.

B Hyperparameters

We did not use any parameter tuning nor MNLI trick (initializing some down-streams tasks from MNLI checkpoint instead of pretrained weights). Therefore, we fine-tuned all the datasets from original pretrained weights. We simply followed a unified hyper-parameters for all different experiments. Unlike LoRA (Hu et al., 2021a) which reported the median over 5 random seeds, we reported the mean and standard deviation over 5 random seeds. See the details in Table 8.

C GPT Experiments

A summary of the additional experiments that have been conducted to demonstrate the effectiveness of our proposed method for the task of language generation is provided in Table 9.

Model	**Parameter**	**Value**
RoBERTa-Base	Optimizer	AdamW
	Warmup Ratio	0.06
	LR Scheduler	Linear
	Batch Size	32
	Epochs	30

Abstract

Emotion-Cause Pair Extraction (ECPE) task aims to pair all emotions and corresponding causes in documents. ECPE is an important task for developing human-like responses. However, previous ECPE research is conducted based on news articles, which has different characteristics compared to dialogues. To address this issue, we propose a Pair-Relationship Guided Mixture-of-Experts (PRG-MoE) model, which considers dialogue features (e.g., speaker information). PRG-MoE automatically learns relationship between utterances and advises a gating network to incorporate dialogue features in the evaluation, yielding substantial performance improvement. We employ a new ECPE dataset, which is an English dialogue dataset, with more emotion-cause pairs in documents than news articles. We also propose Cause Type Classification that classifies emotion-cause pairs according to the types of the cause of a detected emotion. For reproducing the results, we make available all our code and data[1].

1 Introduction

With increased interest in developing human-like responses, it is crucial to determine the cause of a given emotion. As part of such interest, there is a surge of research activities that analyze the cause of emotions (Yan et al., 2021; Turcan et al., 2021; Li et al., 2022a). Recently, Poria et al. (2021) presents RECCON, a new dataset for Emotion Cause Extraction (ECE) task in dialogue. ECE is a task to find a clause that contains the cause of an annotated emotion in a clause of a given document. However, ECE is limited in that the model requires manually annotated emotions.

To overcome the limitation of ECE (Lee et al., 2010), Xia and Ding (2019) suggest Emotion Cause Pair Extraction (ECPE) task, which automatically predicts emotion clauses in a given document and identifies their corresponding causes. They also build a new ECPE corpus from Chinese news articles. Since ECPE and the dataset were proposed, it has attracted the interest of numerous researchers Ding et al. (2020a,b); Wei et al. (2020); Fan et al. (2020); Cheng et al. (2020); Chen et al. (2020a,b).

# of Emotion-Cause Pairs	ECPE-news (Xia and Ding, 2019)	ECPE-D
1	1,746 (**89.77%**)	9 (**0.80%**)
2	177 (**9.10%**)	19 (**1.69%**)
≥ 3	22 (**1.13%**)	1,094 (**97.50%**)

Table 1: The amount of emotion-cause pairs in a document compared with the ECPE-news corpus (Xia and Ding, 2019) and ECPE-D corpus. ECPE-D is a dialogue dataset reconstructed based on RECCON (Poria et al., 2021). On average, ECPE-D corpus has more emotion-cause pairs than ECPE-news corpus.

However, ECPE in dialogues is different from ECPE in news articles. A dialogue is an interaction between two or more people, while a news article describes a fact. So, dialogues contains meta information such as the speakers, which is one of the most important information in understanding dialogues. In addition, dialogues contain more diverse and emotional expressions, and emotions change as the dialogue progresses, creating even more emotion-cause pairs. This makes the task of ECPE even more challenging. Table 1 shows that most documents in the current ECPE news corpus have only one emotion-cause pair per document, whereas most of the dialogues have multiple emotion-cause pairs. So, we employ RECCON, an English dialogue dataset (Poria et al., 2021) as a new ECPE dataset. We reconstruct RECCON suitable for the ECPE task and we call this dataset **ECPE-D**. Figure 1 shows an example of ECPE-D.

In this paper, we propose a Pair-Relationship Guided Mixture-of-Experts (PRG-MoE) model, which considers dialogue features (e.g., speaker information) in ECPE. We employ Mixture-Of-Experts (MoE) (Eigen et al., 2014) to customize

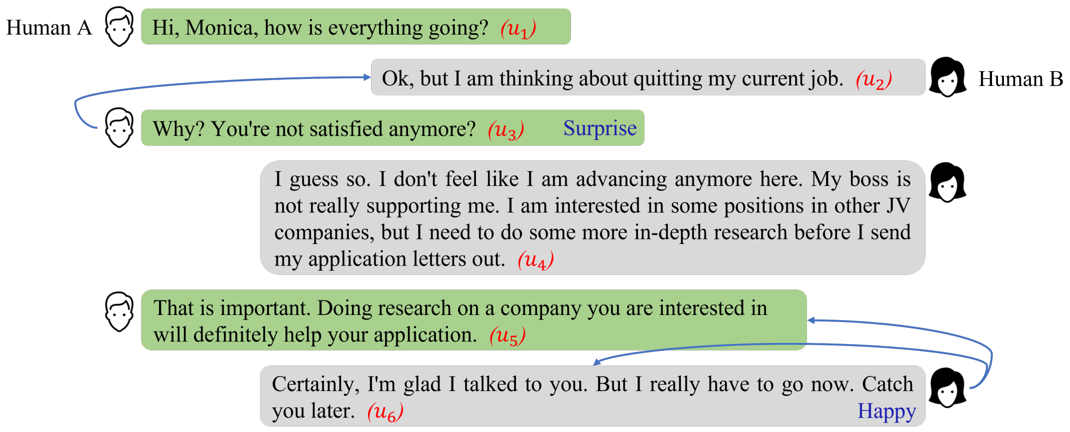
Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3288–3298
May 2-6, 2023



Hi, Monica, how is everything going? (u_1)

Ok, but I am thinking about quitting my current job. (u_2)

Why? You're not satisfied anymore? (u_3)

I guess so. I don't feel like I am advancing anymore here. My boss is not really supporting me. I am interested in some positions in other JV companies, but I need to do some more in-depth research before I send my application letters out. (u_4)

That is important. Doing research on a company you are interested in will definitely help your application. (u_5)

Certainly, I'm glad I talked to you. But I really have to go now. Catch you later. (u_6)

Figure 1: Example of ECPE task. u_3 has a *surprise* emotion because Human A learns that his colleague is thinking of quitting her job (u_2). Human B feels happy at u_6 because she thinks her conversation with Human A is interesting (u_6) and has obtained good advice from Human A (u_5). We can extract the emotion-cause pair (u_3, u_2), (u_6, u_5), (u_6, u_6) from this dialogue. Blue line indicates the cause of the emotion utterance.

the experts in the relationship between utterances. It is important to consider the relationship between utterances, since it helps us grasp the emotional flow from the conversation history or understand emotions (or its causes) through other speakers. PRG-MoE automatically learns the relationship between utterances and advises gating networks to incorporate dialogue features, which yields excellent performance. We evaluate PRG-MoE and other models using ECPE-D dataset and show that PRG-MoE outperforms other models.

Furthermore, we propose a multi-class classification task that identifies cause types of emotion-cause pairs in a dialogue - **ECPE-CT**. An understanding of the cause types is beneficial especially for empathetic response generation (Gao et al., 2021). ECPE-CT helps to generate more specific empathetic responses rather than simple reactions for all kinds of context such as "good luck" by understanding several cause types. Knowing the cause types of the last utterance by the user can help the agent to comprehend the context and obtain the implicit feedback from the user. There are three cause types in ECPE-D: no-context, interpersonal, and self-contagion. Type is categorized depending on 1) into from which speaker the cause of the emotion originated, and 2) whether the cause appears in the current utterance or not.

We performed ECPE-CT tasks under various models; PRG-MoE outperformed other baselines in identifying not only emotion-cause pairs but also types of causes in the pairs.

Our contributions are as follows:

- We propose a new ECPE task in dialogues, and provide related dataset - **ECPE-D**.
- We present **PRG-MoE**, a new approach that outperforms other models in ECPE-D.
- We propose a new Cause Type Classification task **(ECPE-CT)** that helps categorizing the type of a cause for an emotion.

2 Related Work

Xia and Ding (2019) propose the ECPE task, which predicts an emotion clause and extracts a corresponding cause in a given document. The authors construct a new ECPE corpus from Chinese news ECE corpus (Gui et al., 2016). They also propose a two-step approach: a pipeline structure consisting of emotion/cause clause extraction and an emotion-cause pairing. However, the two-step approach in a pipeline structure has limitation in that errors cannot be propagated to the entire model. PRG-MoE performs end-to-end pair extraction so it avoids inaccurate inference originating from a pipeline structure.

Subsequent ECPE research suggests 2D transformer (Ding et al., 2020a), sliding window (Ding et al., 2020b) and graph neural network (Chen et al., 2020b; Wei et al., 2020). However, these approaches do not consider meta information such as speakers. Speaker information is a factor that improves performance in dialogue-related tasks. Several studies report improved performance in emotion recognition by taking into account speaker information (Zhang et al. (2019), Li et al. (2020), Bao et al. (2022)). In addition, methods that considers speakers obtain higher performance in conversation related tasks (Li et al. (2022b), Bak and Oh (2020)). PRG-MoE adopts Mixture-of-Experts for incorporating speaker information as a feature in pair extraction. Also, previous ECPE research considers only the existence of emotion in a clause. PRG-MoE suggests a method where a combination of speaker information and type of emotion in an utterances is used.

3 Task Definition

This section describes the definition of ECPE task in a dialogue. The input is a dialogue $D = \{u_1, ..., u_n\}$ that contains multiple utterances between two people, where u_i is i-th utterance in a dialogue and consists of token sequence t_i, speaker indicator $s_i \in \{0, 1\}$ and emotion information e_i.

Objective of the task is to extract a set of emotion-cause utterance pairs $\{..., (u_i, u_j), ...\}$, where u_i is an emotion utterance and u_j is a cause utterance in a pair.

4 Pair-Relationship Guided Mixture-of-Experts

We propose a Pair-Relationship Guided Mixture-of-Experts (PRG-MoE) model that adopts a Mixture-of-Experts module. Figure 2 shows the overall architecture. PRG-MoE consists of three modules: utterance representation construction (§4.1), emotion-cause pair candidate extraction (§4.2) and mixture-of-experts based emotion-cause pair classification (§4.3).

4.1 Utterance Representation Construction

First, PRG-MoE creates a representation of each utterance. Input is a dialogue $D = \{u_1, ..., u_n\}$, where i-th utterance $u_i = (t_i, s_i)$ contains token sequence t_i and speaker indicator s_i. We use BERT (Devlin et al., 2019) for constructing token sequence representation. We surround each token sequence with pre-defined special tokens ([CLS], [SEP]), $t'_i = \{[CLS], w_{i1}, ..., w_{ik}, [SEP]\}$, where w_{ik} is k-th token in i-th utterance's token sequence. [CLS] token is used for generating representation for classification tasks. [SEP] token is used to denote the end of a sentence. We obtain the utterance's representation h_i via BERT, which is the final hidden state of [CLS].

$$h_i = BERT(t'_i) \tag{1}$$

Emotion Classification PRG-MoE performs emotion classification not only to obtain emotion utterance candidates for emotion-cause pairs, but also to convey emotion information in utterance representation. Emotion classification is performed by feeding a token sequence representation h_i into a Feed-Forward Neural Network (FFNN) layer. We can get the emotion prediction $\hat{e}_i$.

$$\hat{e}_i = Softmax(W^e h_i + b^e), \tag{2}$$

where W^e is a weight and b^e is a bias of the emotion classification layer, respectively.

Utterance Representation We use the concatenation of token sequence representation, emotion prediction and speaker information as utterance representation.

$$u_i = h_i \oplus \hat{e}_i \oplus s_i \tag{3}$$

4.2 Emotion-Cause Pair Candidate Extraction

To extract emotion-cause pair candidates, PRG-MoE needs to pair emotion utterance candidates and cause utterance candidates. The candidate pair x_{ij} is created by concatenating two utterances.

$$x_{ij} = u_i \oplus u_j, \tag{4}$$

where u_i is a non-neutral emotion utterance representation and u_j is a cause utterance candidate representation ($j \in \{1, ..., i\}$).

We assume two properties of the pairs. First, only non-neutral emotion utterances can be emotion utterance candidates. This is because ECPE tries to find the cause of emotions that occurred during a conversation. Second, PRG-MoE assumes that the cause of an emotion exists in previous or present utterances, since future utterances are not known to the speakers.

Window-constrained Strategy For computing efficiency, we adopt a window-constrained strategy in ECPE task (Ding et al., 2020a). In a given dialogue $D = \{..., u_i, ...\}$, where u_i is a non-neutral emotion utterance, u_i's cause candidates $\{u_{i-|w|+1}, ..., u_i\}$ are selected up to the predefined window size $|w|$ distance.

4.3 Mixture-of-Experts based Pair Classification

Pair-Relationship in ECPE In emotion-cause pairs, a specific relationship is formed depending

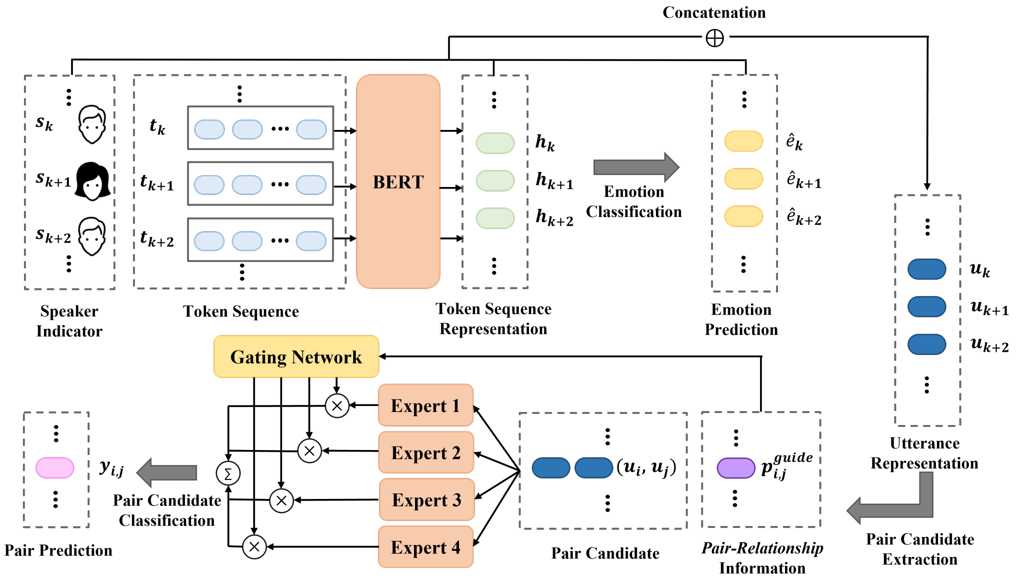


Figure 2: Overall Architecture of PRG-MoE consists of three parts: utterance representation construction, emotion-cause pair candidate extraction, and mixture-of-experts based pair classification. Token sequences in dialogue are converted into semantic representation by BERT. The concatenation of speaker indicator, token sequence representation, and emotion prediction information is used as an utterance representation. In the emotion-cause pair candidate extraction, only non-neutral utterances are considered to be emotion utterances. Pair candidates are routed to proper experts using routing probability. The routing probability consists of the gating network probability g_θ and *pair-relationship* probability p^{guide}.

on speaker or emotion relationship. We call these relationship *pair-relationship*. Depending on who the speaker is of an utterance u_i, u_j in an emotion-cause utterance pair x_{ij} and what emotion the utterance contains, we can identify the following four categories.

- **Same speaker - Same emotion**: This is a case where the utterances in a pair belong to the same speaker and have the same emotions, such as maintaining emotional state.

- **Same speaker - Different emotion**: This is a case where the utterances in a pair belong to the same speaker but have different emotions. For example, an emotion can appear in the second utterance, following the first utterance where the speaker talks neutrally about what could be the cause of the emotion that arises in the second utterance. Also, the speaker can have multiple emotions occur simultaneously in one utterance, such as ambivalence (Larsen and Mcgraw, 2011). So, the cause of one emotion can trigger different emotions.

- **Different speaker - Same emotion**: This is a case where the utterances in a pair belong to different speakers but share the same emotion, such as sharing the emotion of empathy.

- **Different speaker - Different emotion**: This is a case where the utterances in a pair belong to different speakers and each have different emotions. For example, a speaker's utterance triggers an emotion in the other speaker's utterance. This case is similar to the Same speaker - Different emotion case, but the subject of the cause utterance is another speaker.

pair-relationship is constructed based on the predicted emotions, not the ground-truth emotion information.

Guided-MoE Method We are inspired by the mixture-of-experts (MoE) method to consider *pair-relationship*. MoE is the process of utilizing multiple experts for a specific task. The expert is a trainable neural network. The gating network determines which expert is suitable for a given input, and this mechanism automatically enhances the expertise of experts through learning.

However, there is no guarantee that the pure MoE learns *pair-relationship*. So, we guide each expert to have expertise in *pair-relationship*. We combine the decision of the gating network and *pair-relationship* for routing emotion-cause pair candidates to proper experts.

MoE consists of k experts $\{f_\theta^1, ..., f_\theta^k\}$ and gating network g_θ. Experts and gating network get a set of emotion-cause pair candidates $\{..., x_{ij}, x_{ii}, ...\}$ as input. Experts return the emotion-cause pair classification prediction $f_\theta(x_{ij})$, respectively. Gating network g_θ returns the routing probability $g_\theta(x_{ij})$, where $g_\theta(x_{ij})$ is a distribution over k experts that sums to 1.

To guide the routing probability to consider *pair-relationship*, PRG-MoE first creates one-hot label that represents the category of *pair-relationship* p_{ij}^{guide}. PRG-MoE routes an input pair representation x_{ij} by combining $g_\theta(x_{ij})$ and p_{ij}^{guide}. For combination, the number of experts should be the same as the number of *pair-relationship*.

$$p_{ij} = (1 - \lambda) \times g_\theta(x_{ij}) + \lambda \times p_{ij}^{guide}, \quad (5)$$

where p_{ij} is a distribution over k experts that sums to 1.

The output of PRG-MoE is as follows:

$$y_{ij} = \sum_{n=1}^{k} p_{ij}^n f_\theta^n(x_{ij}), \quad (6)$$

where k is the number of the *pair-relationship* information as one expert is assigned to each category.

The loss function of PRG-MoE consists of emotion classification loss and emotion-cause pair classification loss that are focal loss (Lin et al., 2017). Essentially, ECPE task faces the challenge of class imbalance since it has a few positive samples among pair candidates. The adoption of the focal loss alleviates this issue by balancing the weight assigned to minority classes, facilitating the learning process (Wang et al., 2022).

5 Experiments

5.1 Settings

Dataset We use the RECCON dataset (Poria et al., 2021) for experiments. RECCON is a dataset for ECE task that finds a corresponding cause for an utterance with a given emotion. It consists of DailyDialog (Li et al., 2017) and IEMOCAP (Busso et al., 2008), and the authors additionally annotated the cause of an emotion and type of the cause.

We reconstruct a corpus for ECPE in dialogues, named **ECPE-D** from RECCON. We also call DailyDialog data in ECPE-D as **ECPE-D-DD**, and IEMOCAP data in ECPE-D as **ECPE-D-IE**. RECCON has several cause type classes. Among them, there is a cause type called “hybrid” which encompasses both "inter-personal" and "self-contagion" causes. We separate “hybrid” type into “inter-personal” and “self-contagion” and reannotate in dialogues to clarify information associated with the pair label by making multiple single pairs for cause type classification. In addition, RECCON has annotated cause information for each utterance. To facilitate the ECPE task, we add the emotion-cause pair label per dialogue.

Table 2 shows basic statistics of ECPE-D. We split the ECPE-D-DD as 80/10/10 for training/validation/test. We use ECPE-D-IE as test data only. This is because it has fewer dialogues than ECPE-D-DD and we can show the robustness of ECPE models on different domain dataset. IEMOCAP has *frustration* and *excited* emotion labels that are not in DailyDialog. So, we map *frustration* and *excited* to *sad* and *happy*, respectively.

For statistically significant results, we conduct a total of five experiments using randomly split data, and report the average result.

Approach	ECPE-D-DD	ECPE-D-IE
# of Dialogues	1,106	16
Avg. of Dialogue length	10	42
# of *no-context* pair	3,370	243
# of *inter-personal* pair	3,796	365
# of *self-contagion* pair	1,958	445
Avg. of emotion-cause pairs	8	66

Table 2: Characteristics of the ECPE-D Dataset. ECPE-D-IE is uses only as test dataset. The two datasets differ significantly in their properties.

Baselines We select following models as a compared approach. For a fair comparisons, language models of all models are fixed with a *bert-base-cased* from huggingface[2] (Wolf et al., 2020).

- **ECPE-2D** (Ding et al., 2020a) proposes a method of expressing the emotion-cause pairs by a two-dimensional representation scheme. They use a window-constrained method to restrict the scope of the search for extracting emotion-cause pairs.

- **ECPE-MLL** (Ding et al., 2020b) defines an ECPE task as a multi-label learning problem. ECPE-MLL first assumes that all utterances

Table 3: Performance of PRG-MoE and baseline models for ECPE-D. All models are trained with only ECPE-D-DD. PRG-MoE outperforms all other models in the emotion-cause pair extraction. We also test models in ECPE-D-IE to validate the models in an environment different from the train dataset. Despite the differences, PRG-MoE outperforms all other models. We run the statistical significance test for the F1-Score in the Emotion-Cause Pair Extraction task. PRG-MoE shows statistically significant difference in performance than baselines (**: p < 0.0001, *: p <0.001).

are emotion utterances, and finds corresponding cause utterances; then, assumes that all utterances are cause utterances, and finds corresponding emotion utterances. There are two ways for the ECPE-MLL to identify emotion-cause pairs; avg-pair and or-pair. The avg-pair method identifies a match as a pair when both the cause and emotion utterances select each other as their match. The or-pair method identifies an emotion-cause pair even if only one side selects the other as their match (i.e. the cause utterance c_1 may identify the emotion utterance e_1 as its match, while e_1 selects a different cause utterance c_2 as its match. There can be two cause-emotion pairs identified through the or-pair method; pair (e_1, c_1) and pair (e_1, c_2).

- **Rank-Emotion-Cause** (Wei et al., 2020) is a method that ranks candidates for emotion-cause pairs and filters them using a sentiment word lexicon. Since the prior lexicon is developed for Chinese data, we adapt it using the Loughran-McDonald sentiment lexicon (Loughran and McDonald, 2011) for testing ECPE-D.
- **RECCON** (Poria et al., 2021) uses RoBERTa with a classification layer for ECPE. They claim that the simple language model outperforms other ECPE models. For fair comparisons, we set the language model to BERT. We denote the model RECCON-BERT.

Evaluation Metrics We follow the evaluation metrics from previous research (Xia and Ding, 2019); we use precision, recall, and F1 score as metrics.

5.2 Results

Table 3 shows experimental results for the ECPE task of PRG-MoE and baseline methods with ECPE-D-DD. There is no difference between the PRG-MoE and other models in terms of Emotion Extraction performance. This is because Emotion extraction is performed using only BERT. However, even though it shows similar emotion extraction performance, PRG-MoE outperforms in the pair extraction performance, which is the main goal of our study. The usage of speaker information and type of emotion makes PRG-MoE more suitable to extract emotion-cause pairs in a dialogue than other baselines.

ECPE-MLL predicts emotion-cause pairs utilizing two methods; avg-pair and or-pair. Or-pair shows better recall and f1-score than avg-pair. This is because or-pair predicts the emotion-cause pair optimistically, whereas avg-pair satisfies two indicators for predicting pairs. It gives or-pair a wider search space than avg-pair, making the or-pair more advantageous in finding pairs in emotionally-rich environment and thus to have better performance than avg-pair.

Rank-Emotion-Cause shows low performance. It has two stages for extracting pairs. First, Rank-Emotion-Cause ranks pair candidates and chooses the first pair. Second, the model determines if there is a sentiment word among the other unselected candidate pairs using a sentiment word dictionary and when found, selects it. However, there are many cases where emotions are expressed without explicit expression of emotions in an utterance. Dictionary-based emotion detection makes it hard to capture implicit expression. Dictionary-based emotion detection of Rank-Emotion-Cause captures 1,764 utterances out of 6,384 emotion ut-

Table 4: A study on mixing ratio for routing probability and *pair-relationship* information in guided-MoE method. When λ is 0, it means the pure Mixture-of-Experts method and when λ is 1, it means the pure guide information from *pair-relationship*. Above experiments prove that guided-MoE method is superior to pure MoE or pure guide for experts.

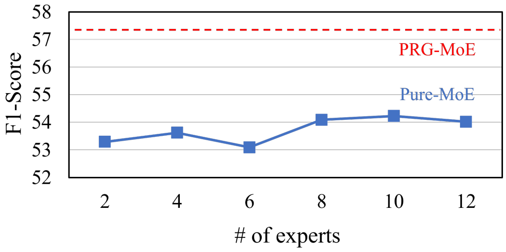

Figure 3: Ablation study for the number of experts in the mixture-of-experts method. We set PRG-MoE with $\lambda = 0$ for experimenting pure MoE method. Above experiments show no meaningful difference without the *pair-relationship* probability p^{guide}.

terances in ECPE-D. This method is unfavorable for extracting multiple pairs.

RECCON argues that the language model with a simple classification layer outperforms earlier ECPE models. They experiment with emotion labels, candidate pairs, and dialogue context as input. However, there are two problems here: First, they exclude a scenario in which emotional information is incorrect. So, the comparison is not fair because ECPE approaches use emotional information that they predict. Second, while ECPE should consider all possible pairs for a given text, RECCON is tested using a dataset in which positive and negative samples are appropriately mixed. We re-evaluate the model by presenting the same emotion label predicted by PRG-MoE to RECCON for accurate comparison. RECCON-BERT shows low performance compared to when it has true emotion labels. This means that RECCON-BERT, unlike other ECPE models, does not have a structure that operates robustly with an inaccurate emotion.

Table 3 also shows the experimental results for ECPE-D-IE. All models are learned with ECPE-D-DD. This experiment is conducted to evaluate how they perform on out-of-domain data. Besides, as shown in Table 2, ECPE-D-IE has about eight times more emotion-cause pairs in a dialogue than the trained data, so the difficulty of pair extraction becomes extremely high. These adverse conditions make the models have poor performances. PRG-MoE shows robust performance compared to other models.

Concatenated element	Emotion-Cause Pair Extraction		
	Precision	Recall	F1-Score

6 Discussion

6.1 Effects on Pair-Relationship Information

The main idea of PRG-MoE is to combine the decision of the gating network and *pair-relationship* information. For evaluating effects on the mixing ratio λ in Guided-MoE, we set λ from 0 (pure Mixture-of-Experts) to 1 (pure guiding *pair-relationship* information). Table 4 shows the proper

Approach	no-context			inter-personal			self-contagion			weighted average		
	Precision	Recall	F1-Score	Precision	Recall	F1-Score	Precision	Recall	F1-Score	Precision	Recall	F1-Score
ECPE-2D	53.23	60.88	56.80	51.70	42.18	46.46^{**}	36.10	14.72	20.92	48.98	43.42	46.03^{**}
PRG-MoE	**54.66**	**62.30**	**58.23**	**62.22**	**59.11**	**60.63**	**39.99**	**17.19**	**24.05**	**55.43**	**51.34**	**53.31**

Table 7: ECPE-CT performance of models for ECPE-D-DD. The performance between PRG-MoE and ECPE-2D is insignificant in no-context. However, there are notable advances in inter-personal and self-contagion, which relate to the interaction between the two utterances. Through the above performances, we can prove that the Guided-MoE method is helpful in judging the relationship between different utterances. We run the statistical significance test for the F1-Score in the ECPE-CT task. PRG-MoE shows statistically significant difference in "inter-personal" performance than ECPE-2D (**: $p < 0.0001$).

mixing ratio in the guided-MoE. PRG-MoE has the highest performance when λ is 0.6.

Furthermore, we experiment ablation study of *pair-relationship* information; emotion-guide and speaker-guide. Emotion-guide method constructs *pair-relationship* into same emotion and different emotion. Speaker-guide method constructs *pair-relationship* into same speaker and different speaker.

In the comparison of emotion-guide and speaker-guide, speaker information has better guidance for pair extraction than emotion information. All three *pair-relationship* experiments show similar tendency that the combination of MoE and *pair-relationship* information performs better than pure methods.

We also test the effects on the number of experts. We set four experts and assigned one category each to learn the *pair-relationship* information. Note, however, pure MoE can have multiple experts. Figure 3 shows that even when we change the number of experts, PRG-MoE outperforms all pure MoE models.

6.2 Effects on Elements of Utterance Representation

Table 5 shows the performance of PRG-MoE trained with various cases of utterance representation concatenation. The components for concatenation are token sequence representation, emotion prediction, and speaker indicator.

It shows the best performance when all components are concatenated. Providing extra information allows experts to learn more about features between utterances.

6.3 Effects on Window-Constrained method

Table 6 shows the ablation study of the window-constrained method. In natural conversation, the cause of an emotion generally exists near the emotion utterance (Kumar et al., 2022). PRG-MoE focuses on utterances near an emotion utterance through the window strategy, and does not consider utterances far from the emotion utterance because the farther away from the emotion utterance, the less likely an utterance becomes a cause utterance for that emotion utterance. PRG-MoE shows significant improvement in performance with the window-constrained method.

7 Cause Type Classification in ECPE

This section describes the experiments and results of classifying the cause type of emotions - **ECPE-CT**. The cause type in ECPE-CT is categorized based on from which speaker the cause is generated and where the cause is found in the paired utterances. ECPE-CT enhances understanding of the cause of the emotion, enabling more effective use of the cause. For example, most chatbots used in different settings generate responses based on the found cause (Gao et al., 2021). However, ECPE-CT could assist to generate more empathetic responses by incorporating other cases, as categorized below.

Cause types in ECPE-D are as follows:

- **No-context** indicates that an emotion and its cause are found in one utterance.
- **Inter-personal** signifies that the cause exists in the other person's utterances.
- **Self-contagion** refers to the situation where the cause exists in the prior utterance of the same speaker.
- **Latent** refers to a scenario in which the cause does not exist or may occur in the future. The latent type naturally has no pair information, so we classified it as having no pair.

We test PRG-MoE and ECPE-2D, which have best performances among the baselines. For multi-class classification, we modify the output layer of models to be able to output multi-class prediction. Table 7 shows the performance for each cause type. The performance difference between PRG-MoE and ECPE-2D is not significant in "no-context" and "self-contagion". However, there is a significant advance in "inter-personal", which relates to the interaction between the two different speakers. We believe that the Guided-MoE approach performs the function of an identifier, confirming the speaker of a paired utterance.

8 Conclusion

In this paper, we present PRG-MoE, a novel approach for extracting emotion-cause pairs from a dialogue by considering speaker and emotion information. We guide the mixture-of-experts module to consider the relationship between utterances in pairs. To guide mixture-of-experts, we define *pair-relationship*, which is the relationship between utterances. We combine the decision of the gating network and *pair-relationship* information for routing the emotion-cause pairs to proper experts. We also propose a new task, ECPE-CT, which classifies emotion-cause pair by cause type. We evaluate the task with ECPE-D, a dialogue dataset with more emotion-cause pairs than other benchmark ECPE datasets. With ECPE-D, we show that PRG-MoE outperforms other ECPE models in ECPE and Multi-class ECPE tasks.

Limitations

First, we limit the scope of cause to be found in one conversation. However, the actual cause of an emotion may come from other sources outside the given conversation, such as news, weather, and the speakers' previous conversations. But, the ECPE-D dataset does not have such external information, and there are no multiple conversations by the same speaker pairs. Second, we encode the speakers as 0 or 1 since we do not know about the speakers and their relationships. However, emotional conversations would occur more frequently in close relationships such as between family members and friends. Third, we do not test with multi-party conversations. We will experiment with multi-party conversations by annotating the emotion-cause label to another multi-party conversation dataset (e.g., MELD (Poria et al., 2019)). Lastly, we do not consider the order of emotion-cause pairs in a conversation. The order might be helpful in modeling the emotion-cause pairs. For example, if a speaker's emotional state remains unchanged throughout a conversation, a previous pair can help predict a future pair.

Ethics Statement

This paper presents a new ECPE method, PRG-MoE, which extracts emotion and their corresponding cause in a dialogue through the relationship between utterances in pairs. PRG-MoE shows high performance in extracting emotion-cause pairs in a conversation. In this regard, PRG-MoE could be deployed in cause extraction in a dialogue and other real-world applications. We do not report any data collection process in this paper, as we experiment with an open-domain dataset. We experiment with the dialogue dataset based on RECCON (Poria et al., 2021). RECCON is publicly available, and there is no ethical issue.

Acknowledgments

We would like to thank the anonymous reviewers for helpful questions and comments. A Implementation Details

We use pretrained *bert-base-cased* from huggingface (Wolf et al., 2020) as a language model. We train PRG-MoE using Adam optimizer (Kingma and Ba, 2015) for 40 epochs and decay the learning rate exponentially for each epoch. The decay rate is 0.05. The batch contains 5 dialogue documents, and the learning rate is set to 5e-5. Dropout is applied to utterance representation with a 0.5 rate. We set the window size as 3 since we follow the previous work for fair comparisons (Ding et al., 2020a). The final loss weight λ_{emo} and λ_{pair} are set to 0.2 and 0.8, respectively. We choose the hyperparameters by manual tuning. We select the hyperparameter based on the f1 score performance. We selected parameter related to data characteristics such as window-size through experiments, and compared baseline models using the same parameter.

Our hardware setting is Intel(R) Xeon(R) Gold 5218R CPU @ 2.10GHz (CPU), and NVIDIA RTX A6000 (GPU). The average running time of PRG-MoE per one epoch is 3min 20s. The inference time per one batch is 1.2 sec. The number of parameters of PRG-MoE is 110M.

Language Generation Models Can Cause Harm: So What Can We Do About It? An Actionable Survey

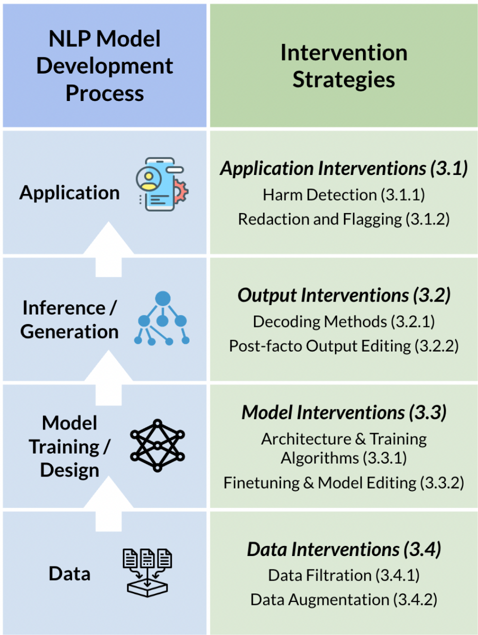
Abstract

Recent advances in the capacity of large language models to generate human-like text have resulted in their increased adoption in user-facing settings. In parallel, these improvements have prompted a heated discourse around the risks of societal harms they introduce, whether inadvertent or malicious. Several studies have explored these harms and called for their mitigation via development of safer, fairer models. Going beyond enumerating the risks of harms, this work provides a survey of *practical methods* for addressing potential threats and societal harms from language generation models. We draw on several prior works' taxonomies of language model risks to present a structured overview of strategies for detecting and ameliorating different kinds of risks/harms of language generators. Bridging diverse strands of research, this survey aims to serve as a practical guide for both LM researchers and practitioners, with explanations of different mitigation strategies' motivations, their limitations, and open problems for future research.

1 Introduction



NLP Model Development Process	Intervention Strategies
Application	***Application Interventions (3.1)*** Harm Detection (3.1.1) Redaction and Flagging (3.1.2)
Inference / Generation	***Output Interventions (3.2)*** Decoding Methods (3.2.1) Post-facto Output Editing (3.2.2)
Model Training / Design	***Model Interventions (3.3)*** Architecture & Training Algorithms (3.3.1) Finetuning & Model Editing (3.3.2)
Data	***Data Interventions (3.4)*** Data Filtration (3.4.1) Data Augmentation (3.4.2)

Figure 1: Overview of Intervention Strategies. A typical ML/NLP model development process involves data collection/curation, model training and design, inference, and finally application deployment. For each phase of this development cycle, different techniques can be adopted to mitigate harms. Our survey presents a taxonomy of intervention strategies organized around the different phases where they can be applied.

The new wave of large language models (LMs; Brown et al., 2020; Chowdhery et al., 2022; Zhang et al., 2022b) capable of generating text with human-like fluency, coherence, and realism (Zellers et al., 2020; Ippolito et al., 2020) has caused a paradigm shift in our society.[1] With applications like OpenAI's ChatGPT, Microsoft's Bing, and Google's Bard, bringing such LMs directly to users, we are beginning to see the impact in fields like education (Schulten, 2023; Gleason, 2022), healthcare (Patel and Lam, 2023), law (ChatGPT and Perlman, 2022), science (Stokel-Walker, 2023), and more. Since language is inherently a tool of power—the primary means by which people and societies perpetuate stereotypes and manipulate opinions (Bar-Tal et al., 2013; Chong and Druckman, 2007, *inter alia*)—LMs that are deployed to millions of users also hold similar power, but our understanding of their risks/harms has lagged behind (Bender et al., 2021).

Indeed, LMs have been shown to introduce vulnerabilities and threats, both inadvertent and malicious, to individual users, social groups, and content integrity. Without social context and content control, deployed language generators have quickly derailed to racist, homophobic, hateful comments (Hunt, 2016; Jang, 2021; Wolf et al., 2017; Vincent, 2022), compromised user privacy (Carlini et al., 2021), spread disinformation (Shao et al., 2018),

---

[*] Equal contribution

[1] While the majority of these models are trained on English, recent studies have also obtained similar advancements in other languages (Lin et al., 2021; Shliazhko et al., 2022).

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3299–3321
May 2-6, 2023 ©2023 Association for Computational Linguistics

and even encouraged suicide (Daws, 2020). Prior works have outlined these risks (Maynez et al., 2020; Sheng et al., 2021; Weidinger et al., 2022; Zhuo et al., 2023), proposed taxonomies (Weidinger et al., 2022), discussed their points of origin, and advocated for future research on ethical development of LMs (Bender et al., 2021; Solaiman et al., 2019).

However, there is little work that summarizes **actionable approaches and technical solutions** to preventing or mitigating these potential harms. In this survey, we present a **comprehensive, unified taxonomy** of relevant **mitigation strategies** proposed in prior literature, specifically focusing on **language generation models**.

We organize these strategies based on where they fit in different stages of LM development: in data collection, modeling, decoding, and deployment. Within each of these categories, our taxonomy brings together prior works that have been treated as disjoint areas targeting different types of harms (toxic/biased language and misinformation). In addition, we identify their gaps and highlight directions for future research. These include incorporating sociocultural context to produce socially-sensitive interventions, detecting and handling generations with different intents (inadvertent vs. malicious), and going beyond an English, Western/US-centric view to account for the challenges of ethics in *multilingual* language generation.

2 Background

Throughout this paper, we use the term *language models* (LMs) to refer to their classic definition as generative models, which predict the next token given the preceding generated context. This paradigm also subsumes conditional LMs that depend on additional inputs via an encoder. We provide more details in Appendix A.

2.1 Risks in Language Generation

Before diving into mitigation techniques (§3), we briefly outline potential harms that LMs can cause, following Weidinger et al. (2022)'s taxonomy.

Discrimination, Toxicity, and Exclusion: The scope of linguistic diversity in human communication is enormous and is linked to personal, social, and cultural factors (Holmes and Wilson, 2017; Eckert and McConnell-Ginet, 2003; Coates, 2016; Chambers, 1995). As such, language produced in the real world reflects sociocultural stereotypes and presuppositions that LMs can overfit to and amplify (Bar-Tal et al., 2013; Zhao et al., 2017; Sun et al., 2019), leading to several types of harms. (1) *Stereotyping and discrimination* occurs when generated text reinforces discriminatory stereotypes and perpetuates biases against disadvantaged groups, based on factors like gender, race, religion, sexuality, (Bender et al., 2021), and intersectional identities (Crenshaw, 2017). Evidence for this behavior has been substantially corroborated in NLP literature (Blodgett et al., 2020; Nadeem et al., 2021; Nozza et al., 2021; Liang et al., 2021; Field et al., 2021; Lin et al., 2022a, *inter alia*). (2) *Toxicity* describes generated language that is offensive, threatening, violent, or otherwise harmful (Gehman et al., 2020; Rae et al., 2021; Abid et al., 2021). It can range from overtly toxic content, such as violent hate speech, to more subtle, veiled toxicity, such as microaggressions (Breitfeller et al., 2019). (3) *Exclusion* refers to the disparate performance of models across language variations. Models may fail to understand or generate "non-standard" dialects and sociolects, essentially excluding speakers of such variants from their user base (Joshi et al., 2020; Koenecke et al., 2020; Winata et al., 2021).

Factual Errors, Misinformation, and Disinformation: LMs are able to generate fluent outputs that users may easily mistake for human-written text (Ippolito et al., 2020), but such utterances may be factually incorrect or misleading (Maynez et al., 2020; Xu, 2020; Lin et al., 2022b; Bickmore et al., 2018; Daws, 2020). This can cause harm inadvertently (via misinformation) or can also be used maliciously (disinformation; Bradshaw and Howard, 2019; Beskow, 2020; Buchanan et al., 2021).

Privacy Violations: LMs' vast training corpora often contain sensitive information, and LMs can memorize these details and generate them verbatim when prompted by users, leading to privacy violations (Kim, 2016; Mirshghallah et al., 2020; Brown et al., 2022). LMs have been shown to leak personally identifiable information, such as social security numbers, phone numbers, bank account information (Carlini et al., 2021), and private clinical notes (Lehman et al., 2021); they have even leaked software code and other protected intellectual property (Ippolito et al., 2022). Deploying large LMs can thus pose serious security risks to people whose private information might have found its way into a model's training data.

Other Underexplored Issues: Weidinger et al. (2022) discuss other malicious applications, as well as the economical and environmental impacts of LMs. While extremely important, mitigating these risks requires not only technical innovation, but also the development of regulatory practices and policies in an interdisciplinary effort. We focus on algorithmic solutions in this survey, leaving this discussion for future work.

3 Taxonomy of Intervention Strategies

The development pipeline of a typical machine learning model involves several critical decisions where risks of harms can arise. Stakeholders have access to different pipeline components and therefore may employ different intervention strategies. For example, while a researcher involved in data curation can intervene before training, an application developer with limited access to a black-box model might only be able to intervene at inference. We present a taxonomy of intervention strategies organized by the stages of a model development lifecycle (Fig. 1), aiming to showcase the tools that can be employed at different stages. We step backward through the pipeline, beginning with application-level interventions employed post-deployment and peeling back the layers through output-level interventions, model interventions, and finally ending at data-level interventions (summarized in Tab. 1).

3.1 Application Level Interventions

3.1.1 Harm Detection and Redaction

In order to mitigate harms at the application level, we first need to be able to *detect* problematic, incorrect, and unreliable model outputs (Raji et al., 2020). User-facing applications can employ detectors to intervene before harmful text reaches a user. Such detectors are typically coarse, binary text classifiers, often trained for a single task, such as predicting toxicity (Nobata et al., 2016; Davidson et al., 2017b; Xiang et al., 2021), or the factual accuracy of the outputs (Kryscinski et al., 2020; Goyal and Durrett, 2020; Wang et al., 2020).

Early approaches to building toxicity detectors focused on linear models relying on hand-designed *features* based on lexicons, e.g., hatebase, (Xiang et al., 2012; Dadvar et al., 2012; Burnap and Williams, 2015; Liu and Forss, 2015), n-grams, capitalization/punctuation details (Chen et al., 2012; Waseem and Hovy, 2016; Nobata et al., 2016; Xu et al., 2012; Burnap and Williams, 2016). For misinformation detection, features like the presence of new entities or facts in generated document summaries have been employed which can indicate hallucination (Zhao et al., 2020; King et al., 2022).

Linear classifiers, while interpretable, tend to overfit to lexical features, are prone to false positives, and are easy for malicious users to bypass (Kurita et al., 2019). Neural text classifiers, on the other hand, can incorporate contextual information and have been shown to be more robust (Gambäck and Sikdar, 2017; Pitsilis et al., 2018). When built by finetuning pretrained LMs instead of training from scratch, they naturally lead to even better performance (d'Sa et al., 2020; Xiang et al., 2021). Based on these models several toxicity detection tools like Perspective API, OpenAI content filter or ToxiGEN are now publicly available.

To train classifiers for toxicity detection, annotated datasets in several domains have been collected for English (Davidson et al., 2017a; Waseem and Hovy, 2016; Wiegand et al., 2018; Pavlopoulos et al., 2017; Mubarak et al., 2017; Moon et al., 2020), especially to detect overtly toxic text. Human annotation efforts for more subtle toxicities like microaggressions, however, is challenging due to annotators' own biases (Breitfeller et al., 2019). Hence, unsupervised or distantly supervised approaches have been adopted to detect them (Korzeniowski et al., 2019; Field and Tsvetkov, 2020; Sabri et al., 2021). Compared to English, such resources for other languages are severely lacking (Ousidhoum et al., 2019a).

Information-related harms can arise either inadvertently (due to model errors) or deliberately (due to malicious users). Detecting manipulation in the human-written text is an active area of research and those approaches can also be employed for machine-generated text. Prominent research directions include automated fact-checking, propaganda, or fake news detection for which several annotated datasets (Oshikawa et al., 2020; Martino et al., 2020; Zhou and Zafarani, 2020; Guo et al., 2022; Huang et al., 2022) and shared tasks (Thorne et al., 2018; Da San Martino et al., 2019; Feldman et al., 2021) exist. These approaches have also been adopted to assist human fact-checkers (Shaar et al., 2021; Nakov et al., 2021). However, humans are easily fooled by machine-generated fake news (Zellers et al., 2020; Ippolito et al., 2020). An alternate solution is to, not find informational discrepancies, but simply detect and flag whether

Application Level Interventions	Feature-based Detection	Toxicity	Lexical features (Xiang et al., 2012; Dadvar et al., 2012; Burnap and Williams, 2015; Liu and Forss, 2015); n-gram features (Chen et al., 2012; Waseem and Hovy, 2016; Nobata et al., 2016; Xu et al., 2012; Burnap and Williams, 2016)
		Misinformation	Word-Level features (Zhao et al., 2020; King et al., 2022)
	Neural Detection	Toxicity	Supervised: (Gambäck and Sikdar, 2017; Pitsilis et al., 2018; d'Sa et al., 2020; Xiang et al., 2021); Semi- and Unsupervised: (Korzeniowski et al., 2019; Field and Tsvetkov, 2020; Sabri et al., 2021)
		Misinformation / Factuality	Supervised fake-news detection (Thorne et al., 2018; Oshikawa et al., 2020; Martino et al., 2020; Zhou and Zafarani, 2020; Guo et al., 2022); Factual error detection (Kryscinski et al., 2020; Goyal and Durrett, 2020; Pagnoni et al., 2021)
		Disinformation	Machine-generated text detection (Dugan et al., 2020; Gehrmann et al., 2019)
Output Level Interventions	Reranking	Toxicity	Rejection sampling using toxicity detectors (Wang et al., 2022)
		Misinformation / Factuality	Ranking using factuality classifiers (Krishna et al., 2022; King et al., 2022)
	Controlled Decoding	Toxicity	Autoregressive toxic content control (Yang and Klein, 2021; Liu et al., 2021a; Dathathri et al., 2019; Krause et al., 2021; Schick et al., 2021; Lu et al., 2021; Pascual et al., 2021; Wolf et al., 2020); Non-autoregressive toxic content control(Kumar et al., 2022; Mireshghallah et al., 2022)
		Privacy	Differentially private decoding (Majmudar et al., 2022)
		Misinformation / Factuality	Autoregressive factual error control(King et al., 2022; Lu et al., 2022); Non-autoregressive factual error control (Kumar et al., 2021b)
	Post-processing	Toxicity	Rewriting harmful text (Pryzant et al., 2020; He et al., 2021b; Ma et al., 2020)
		Misinformation / Factuality	Editing factual errors (Cao et al., 2020; Lee et al., 2022a; Balachandran et al., 2022)
Model Level Interventions	Architecture	Misinformation / Factuality	Attention (Nan et al., 2021; Zhu et al., 2021), Coreference (Levy et al., 2021); Text Entailment (Falke et al., 2019; Li et al., 2018); Others (Wiseman et al., 2018; Falke et al., 2019; Wan and Bansal, 2022).
	Training	Toxicity	Class-conditional LMs (Keskar et al., 2019; Gururangan et al., 2020; Chan et al., 2021); Instruction-based learning (Ouyang et al., 2022; Wei et al., 2022a)
		Privacy	Differential Private training (Kerrigan et al., 2020; Li et al., 2022; Shi et al., 2021); Knowledge Unlearning (Jang et al., 2022)
		Misinformation / Factuality	Structured KBs (Wang et al., 2021b; Liu et al., 2022; Yu et al., 2022; Liu et al., 2022; Lewis et al., 2020; de Masson d'Autume et al., 2019; Izacard and Grave, 2021; Hossain et al., 2020; Lewis et al., 2020), Retrieval-based (de Masson d'Autume et al., 2019; Izacard and Grave, 2021; Hossain et al., 2020); Summarization (Huang et al., 2020), Translation (Bapna and Firat, 2019), Dialogue models (Dinan et al., 2019; Fan et al., 2021; Zhang et al., 2020a)
	Fine-tuning	Discrimination & Toxicity	Supervised fine-tuning (Gururangan et al., 2020; Chan et al., 2021; Liu et al., 2023); RL based fine-tuning (Alabdulkarim et al., 2021; Liu et al., 2021b; Ouyang et al., 2022; Stiennon et al., 2020); Prompt-based learning (Gehman et al., 2020)
		Exclusion	Adapting for low-resource varieties (Chronopoulou et al., 2020; Kumar et al., 2021a)
	Model Editing	Toxicity	Modifying FF layers(Geva et al., 2022)
		Misinformation / Factuality	Auxiliary editors to modify parameters (De Cao et al., 2021; Mitchell et al., 2022); Modify parameters associated with behavior (Meng et al., 2022, 2023)
Data	Filtration	Toxicity	Removing ’unwanted’ words from corpus (Raffel et al., 2020; Brown et al., 2020; Dodge et al., 2021); Removing toxic data using classifiers (Ngo et al., 2021)
		Privacy	Filtering private/duplicate data (Henderson et al., 2022; Kandpal et al., 2022; Lee et al., 2022b)
	Augmentation	Discrimination	Adding synthetically generated data (Dinan et al., 2020; Liu et al., 2020; Stafanovičs et al., 2020)
		Toxicity	Adding safer example data (Mathew et al., 2018)

Table 1: Strategies for mitigating various risks and harms from language models.

the text has been machine-generated (Gehrmann et al., 2019; Dugan et al., 2020; Ippolito et al., 2020; Mitchell et al., 2023), putting the onus to trust the information on the users (Jawahar et al., 2020).

To detect *inadvertent* factual errors, prior works have developed classifiers by training them to detect heuristically introduced synthetic errors in factually correct text (Kryscinski et al., 2020; Goyal and Durrett, 2020), or question-answering errors using targeted QA models (Scialom et al., 2021). Being trained on synthetic data, such detectors typically do not generalize and have low human judgment correlations (Pagnoni et al., 2021).

Relying on the detectors, the most straightforward way a user-facing application can prevent harm is to not display the text at all (*redacting*) or to display it with a warning sign (*flagging*) (Xu et al., 2020). Even when the detectors are imperfect, explicitly flagging problematic outputs is still useful because it signals users to take model outputs with a grain of salt. However, this strategy is not always applicable: for example, in speech-based dialogue agents, "displaying" a warning sign is a nontrivial UX decision, and in auto-complete assistants (such as in Gmail Smart Compose), redacting is not an option and simply warning may not dissuade users from accepting the generated text.

Challenges: Predicting whether a text is harmful is often highly contextual and subjective. For toxicity detection, factors like region, political views, and the users' sociocultural background affect whether they perceive the text as toxic (Xenos et al., 2021). Existing datasets are often biased due to their curation process (Dixon et al., 2018; Wiegand et al., 2019; Geva et al., 2019; Sap et al., 2021; Kryscinski et al., 2020) and can have unreliable annotations (Ross et al., 2017; Field and Tsvetkov, 2020; Pagnoni et al., 2021). Further, as with many black-box models, classifiers overfit to spurious artifacts (Gururangan et al., 2018; McCoy et al., 2019; Kumar et al., 2019) and amplify biases in their training data (Zhao et al., 2017; Sun et al., 2019). For instance, toxicity detectors have been shown to disproportionately flag African-American English (AAE) as toxic (Sap et al., 2019). Additionally, such filters might overfit to a subset of small features, with more subtle problematic text evading such filters. Ippolito et al. (2022) show that blocking verbatim training data is insufficient for mitigating privacy concerns in code-generation. We discuss these issues further in §4, highlighting future directions to building finer-grained and explainable approaches for detecting harmful text.

3.2 Output Level Interventions

Increasingly, practitioners are building applications using LMs as APIs without explicit knowledge of how the model was trained or what training data was used.[2] Such APIs may vary in how much information developers can see: some allow access to all LM parameters, while black box APIs like GPT3 limit access to model outputs only. Hence, multiple solutions have been proposed for intervening at *model output generation* by editing the outputs with auxiliary models or modifying decoding algorithms.

3.2.1 Post-Factum Editing Model Outputs

Recent studies have explored ways to *edit or revise* model-generated text to remove harmful content. Text editing is a decades-old subfield of NLP that has traditionally focused on fixing errors in machine translation (Chollampatt et al., 2020; Simard et al., 2007; Chatterjee et al., 2020) or grammar in human-written text (Wang et al., 2021c). While many approaches in this area are applicable to post-editing LM outputs, in this survey, we highlight recent work related to *rewriting harmful text*.

The first set of works treats the task of rewriting as a sequence labeling task, where each token in the output sequence is either substituted, deleted, or kept the same (Pryzant et al., 2020; He et al., 2021b). This, however, can be limiting when the entire output needs rewriting. For text-to-text tasks, like translation, summarization, etc. which are trained with parallel data, the same data can be adapted to train an editing model by converting source-target pairs to source-*output*-target triplets using model-generated *outputs* for each source, along with an additional signal indicating errors (obtained using automatic evaluators or human judgment). For more open-ended tasks, prior works explored unsupervised solutions for bias correction (Ma et al., 2020) and semi-supervised methods to correct factual errors (Cao et al., 2020; Lee et al., 2022a; Balachandran et al., 2022). Such methods create synthetic data by inducing errors in clean text and train a model to correct them.

3.2.2 Decoding Methods

Several search and sampling algorithms have been introduced recently to improve the quality of LM-

---

[2] see `https://gpt3demo.com/` for examples

generated text (Graves, 2012; Fan et al., 2018; Holtzman et al., 2020; Meister et al., 2022). In parallel, works on controlling decoding algorithms to promote or demote specific properties in the output text have been developed (Zhang et al., 2022a).

The decoding controls are auxiliary models measuring if the generated text is harmful implemented similarly to the detectors we discussed in §3.1.1, such as toxicity/bias classifiers (Dathathri et al., 2019; Krause et al., 2021; Liu et al., 2021a), factuality metrics (Kryscinski et al., 2020; Goyal and Durrett, 2020). A simple way to use the detectors is *rejection sampling* or *reranking*: for a given input, multiple outputs are generated and then reranked using detector scores to discard dubious outputs (Krishna et al., 2022; King et al., 2022). However, this is often intractable for complex phenomena like factual accuracy of a text or when using multiple controls, since all the generated candidates might be rejected.

To tackle these issues, a class of algorithms that we call *guided-autoregressive decoding* aims to incorporate control by modifying output distributions at every decoding step. One branch of work adopts *logical* controls, where developers directly specify sets of words that should (or not) appear in the output (Lu et al., 2021; Pascual et al., 2021). Wolf et al. (2020) apply this method to zero out the probabilities of offensive terms, King et al. (2022); Lu et al. (2022) improve factual accuracy of generated text by up-weighting generation probabilities of entities present in the source, and Majmudar et al. (2022) apply it for differentially private decoding. A second branch of work composes the LM likelihood with the probabilities from the detectors, to up-weight or down-weight the token probabilities at each decoding step (Yang and Klein, 2021; Liu et al., 2021a; Dathathri et al., 2019; Krause et al., 2021; Schick et al., 2021).

More recent work has also explored ways to induce sentence-level control via *non-autoregressive controlled decoding*. These algorithms incorporate control using Monte Carlo Markov Chain (MCMC) techniques (Hoang et al., 2017; Qin et al., 2020; Mireshghallah et al., 2022), in which a full sequence is initialized and iteratively updated. They have been applied for reducing toxicity (Kumar et al., 2022), and improving fidelity in translation systems (Kumar et al., 2021b). While promising, these techniques suffer from slower decoding speed and need further exploration to be practically used.

Challenges Decoding interventions rely on accurate detectors, hence challenges in designing robust detectors (§3.1.1) also impact decoding algorithms. For example, Xu et al. (2021) show that toxicity avoidance algorithms refrain from generating AAE, thereby causing another harm (exclusion) while trying to address the first (toxicity). Also, detecting misinformation and factuality can be extremely hard using simple detectors that do not provide a useful signal to guide the decoding process, so prior works have primarily employed heuristics. Finally, controlled decoding algorithms are double-edged in that controls can be reversed by malicious users to inflict harm—to generate hateful messages, or to do targeted manipulation by copying users' personas. However, this risk should not discourage research in decoding algorithms; rather, research on detecting such malicious uses should be conducted in parallel.

3.3 Model Level Interventions

Several recent studies have provided evidence that certain optimization procedures can result in harmful generations downstream (Hall et al., 2022; Taori and Hashimoto, 2022). In this section, we describe approaches that modify LM parameters to prevent such generations by either architecture/training interventions or finetuning/model editing interventions.

3.3.1 Architecture and Training Algorithms

Closely related to applying control at inference time are class-conditioned LMs, which are trained to depend on "control codes" via an additional input (Keskar et al., 2019; Gururangan et al., 2020; Chan et al., 2021). When trained with data annotated for toxicity or bias, these LMs can be prompted to avoid those outputs. Another recently popularized paradigm in LM training is *instruction-based learning*, where in addition to the objective to predict the next token, models are also trained to solve NLP tasks with instructions written in natural language (Wei et al., 2022a; Sanh et al., 2022). Providing explicit instructions to not generate harmful text has shown some promise (Ouyang et al., 2022; Wei et al., 2022a) and is an interesting avenue for future work.

In text-to-text tasks like summarization, the goal is to produce text that is factually consistent with the input without hallucinating information. An LM, however, is typically not constrained to predict tokens grounded in verifiable knowledge, which can lead to misinformation. Thus, several studies explore modifying LM training objectives to *incorporate factual information* using either knowledge bases (KBs) or graphs (Yu et al., 2022): each token prediction is scored not only on its likelihood given context, but also on whether the generation is grounded in facts in the KBs (Wang et al., 2021b).[3]

However, existing KBs are limited in size as manually curating them is an arduous and expensive process. As an alternative, Liu et al. (2022) propose using automatically generated KBs to train LMs. In contrast, Lewis et al. (2020); de Masson d'Autume et al. (2019); Izacard and Grave (2021) use unstructured text as knowledge. Known as *retrieval-augmented LMs*, they are trained with a two-stage approach of first retrieving a document from an unstructured source like Wikipedia and using it as additional context for generation, essentially providing evidence for the LM-generated text. Wang et al. (2021a); Ji et al. (2020) follow a similar approach to embed commonsense knowledge in LMs. These existing solutions have been used to tackle content-related harms like factual consistency in generated text (Huang et al., 2020; Bapna and Firat, 2019; Dinan et al., 2019; Fan et al., 2021) but future work in reducing discrimination and toxicity in LMs may also benefit from KBs that encode social (Chang et al., 2020), cultural, (Hershcovich et al., 2022), and moral norms (Hendrycks et al., 2021; Jiang et al., 2021). Such LMs augmented with external knowledge can also be dynamically updated by modifying the knowledge source at test time with new information (Khandelwal et al., 2020; He et al., 2021a).

While external knowledge helps provides context, models may not rely on them and still hallucinate. To explicitly control for context, recent studies have explored (1) modifying attention mechanisms to specifically capture relationships between entities (Nan et al., 2021; Zhu et al., 2021), (2) improving coreference to mitigate gender bias in translation (Levy et al., 2021), and (3) using text entailment to develop loss functions to improve fidelity (Falke et al., 2019; Li et al., 2018). Some other notable directions in this space involve fact-aware pretraining (Falke et al., 2019; Wan and Bansal, 2022) and structured learning frameworks (Wiseman et al., 2018).

Finally, to reduce privacy risks in LMs that memorize user information without sacrificing model capabilities, most prominent solutions are based on differentially private (DP) learning (Kerrigan et al., 2020; Shi et al., 2021). DP can provide provable guarantees on the privacy-utility trade-off, however, it requires the LMs to be retrained for each private information that needs to be removed and be quite expensive.

3.3.2 Finetuning and Model Editing

Designing and training models from scratch to mitigate harms can incur heavy environmental and resource costs. In contrast, an alternative branch of work has developed methods for *modifying the model parameters* of already-trained LMs, which requires much fewer resources. An elementary way of doing this is *finetuning* (a subset of) an LM's parameters on small, curated datasets that contain a well-balanced proportion of data for various demographics and filtered for nontoxicity (Gururangan et al., 2020; Chan et al., 2021; Liu et al., 2023). Such balanced and filtered data encourage models correct biases learned from skewed and toxic training data, resulting in safer generated text.

Prompt-tuning based methods (Wang et al., 2022) have also shown some success where instead of fine-tuning all the parameters, a prompt (using a small set of parameters) is learned without modifying the rest of the model to perform a task. This paradigm uses the generative power of large LMs, while simultaneously nudging the distribution of generated text toward less harmful content. These approaches have successfully been used to reduce toxicity (Gehman et al., 2020) and exclusion (Chronopoulou et al., 2020; Kumar et al., 2021a). However, finetuning or prompt-tuning on a small dataset may lead to overfitting reducing the general purpose utility of LMs.

Finetuning LMs with *reinforcement learning* (RL) has been suggested as a better alternative (Alabdulkarim et al., 2021; Liu et al., 2021b; Ouyang et al., 2022; Stiennon et al., 2020; Lu et al., 2022; Ramamurthy et al., 2022) for training modern LMs. RL models do not require carefully balanced datasets and can instead learn from discrete rewards such as human feedback (Sun et al., 2020; Ouyang et al., 2022) or auxiliary model-based feedback (Perez et al., 2022). It has been shown to reduce toxic text generated by the models (Bai et al., 2022) and to encourage models to generate more factual text (Mao et al., 2020; Stiennon et al., 2020).

---

[3] Knowledge-augmented LMs is a rich field where most existing work focuses on masked LMs (Zhu et al., 2022) for solving understanding tasks. Here we highlight papers on generation.

Another less-explored but more computationally practical alternative to finetuning is *model surgery or editing*, which identifies a specific set of neurons that contribute to harmful generations. Culling such parameters has been shown to reduce toxicity (Geva et al., 2022). In a similar vein, De Cao et al. (2021); Mitchell et al. (2022); Meng et al. (2022, 2023) systematically edit model parameters to revise facts memorized by the model. De Cao et al. (2021); Mitchell et al. (2022) use auxiliary editor networks to predict updates to model parameters constrained to revise a fact without changing other facts. Alternatively, Meng et al. (2022, 2023) use interpretability techniques to identify parameters associated with memorizing said facts and edit them locally to revise them.

Challenges The biggest argument against mitigation techniques involving training LMs from scratch or augmenting them with knowledge is its cost, making these interventions infeasible for most researchers and practitioners. However, even for organizations with access to large computing resources, research on training safer LMs lags behind research on training ever-larger LMs on raw data. We attribute this to the difficulty of curating KBs, as well as the decreased training and inference speed that comes with such modifications. Finetuning, on the other hand, is less costly but may reduce the general utility of the LMs and has not been shown to be useful in reducing information-related harms. Future work may benefit from drawing on continual (Dhingra et al., 2022) and reinforcement learning (Ouyang et al., 2022) techniques for more practical solutions for large models.

3.4 Data Level Interventions

Training any machine learning model requires data, so a natural approach to creating fairer, more reliable LMs is carefully creating balanced training sets that are broadly representative of different worldviews. This requires dedicated and expensive efforts in data curation (Hutchinson et al., 2021; Jo and Gebru, 2020; Kammoun et al., 2022) and novel data pipelines (Denton et al., 2020). Existing works tackling this issue devise semi-automated solutions, which we categorize as follows.

3.4.1 Data Filtration

This simple technique involves removing problematic documents from the training corpus. As training sets can be extremely large, sophisticated neural filters can be prohibitively slow to apply. Hence, most work has utilized simple filters, such as the presence of "unwanted" words (Raffel et al., 2020) or the predictions of linear classifiers (Brown et al., 2020). To mitigate privacy violations, Henderson et al. (2022) construct clean training data by filtering private information and Kandpal et al. (2022); Lee et al. (2022b) filter duplicate training data.

Due to their simplistic setup, these approaches admit many false negatives (failing to detect documents with subtle toxicity) and false positives (erroneously flagging documents that discuss sensitive topics and use hateful speech as examples; additionally, removing data from different dialects like AAE), unintentionally exacerbating risks of marginalization and exclusion (Dodge et al., 2021)). Alternatively, Ngo et al. (2021) train an LM on raw data, then feed the LM manually-curated toxic prompts and filter out documents to which the LM assigns high probability, and then retrain the LM on the filtered corpus.

3.4.2 Data Augmentation

While data filtration aims to remove problematic training samples, data augmentation aims to offset the effect of problematic data by *adding* safer/healthier examples to existing datasets. Mathew et al. (2018) explore adding counterspeech (comments that counter the hateful or harmful speech) to datasets in order to balance out the hate speech already present in web data. Augmentation with synthetically generated data has also been explored for gender bias mitigation in dialogue (Dinan et al., 2020; Liu et al., 2020) and translation models (Stafanovičs et al., 2020).

Challenges Since language, identity, and society are tightly intertwined, aggressive data filtering methods risk further imbalancing already imbalanced data. Besides, models trained on filtered data may still degrade when toxic inputs are provided to it. Further, while data augmentation methods have merit, these methods are extremely difficult to large scale. Finally, data interventions are primarily designed to address population-centric risks such as discrimination, toxicity, and, to an extent, exclusion and privacy—but not factuality which is a by-product of training. It is challenging to define (Aly et al., 2022) and detect unsupported facts (Ansar and Goswami, 2021) in the wild, making data interventions insufficient for addressing misinformation and factuality-related harms.

4 Discussion and Open Challenges

Though the interventions strategies we discuss achieve some success, many risks of LMs are still not well understood. Below we discuss open problems and avenues for future work to encourage the development of safer LMs.

Where should one intervene? Different stakeholders are involved in different model development phases with varying access to resources. As a result, intervention strategies are different depending on the stakeholder. A significant chunk of the responsibility to develop safer LMs falls on researchers and organizations with access to substantial resources who can implement data or modeling interventions. In contrast, practitioners building applications on top of LMs may have access to neither the training data nor the computational resources required to design and train safe LMs. In such cases, flagging and decoding approaches are more practical. In practice, a combination of multiple interventions may be required to both cover a wide array of risks and improve robustness.

Evolving risks in the ChatGPT era: LMs are seeing tremendous, rapid growth; larger models are being released every few months (Shoeybi et al., 2019; Brown et al., 2020; Zhang et al., 2022b; Zeng et al., 2023) and deployed in user-facing applications. Many recent LMs like OpenAI's ChatGPT have garnered attention beyond the research community, impacting a range of fields and crossing geographical and language barriers to reach users all over the world (Reuters, 2023; Varghese, 2023; So-hyun, 2023). In such a fast-moving ecosystem, it is ever more essential to proactively study and mitigate LMs' potential harms. Risk mitigation research tends to lag behind model development and is often considered as an afterthought. Though behaviors may emerge unpredictably (Wei et al., 2022b), as we outline in this survey, intervention strategies can and should be applied at different stages of model development to reduce the potential for these influential LMs to cause harm.

Risks exist in LMs in all languages: Most research on large LMs, their uses, and their risks is Western-centric and primarily conducted on the English language. However, while a few studies have been conducted on detecting harmful text in non-English datasets (Ousidhoum et al., 2019b; Leite et al., 2020; Burtenshaw and Kestemont, 2021; Bogoradnikova et al., 2021; Costa-jussà et al., 2022, *inter alia*), research on mitigation in non-English settings is lagging (Pamungkas et al., 2021). Further, the definitions of risks themselves change with different context and across cultures. Hence, there is a dire need to develop cross-cultural, cross-lingual analyses as well as mitigation tools.

Harm detection beyond simple classifiers Many of the shortcomings of interventions are at their root due to poorly defined risk detection methods. Current detection methods are primarily binary classifiers on various axes like toxicity and factuality, but we recommend researchers and practitioners to move beyond simplistic coarse classifiers and towards more fine-grained (Xiang et al., 2021; Goyal and Durrett, 2020; Da San Martino et al., 2020), interpretable (Koh and Liang, 2017; Han and Tsvetkov, 2020, 2021), and explainable (Pagnoni et al., 2021; Gehrmann et al., 2019) harm detectors to support better harm mitigation strategies (Lipton, 2018; Jacovi et al., 2021).

Systematic evaluation frameworks for mitigation strategies Though LM performance is usually systematically evaluated through benchmarks (Wang et al., 2019b,a; BIG-bench collaboration, 2022), practices for evaluating harms in LM-generated text or the effectiveness of mitigation strategies are not. While there is an emerging body of work dedicated to benchmarking LM harms (Rauh et al., 2022), the space of potential harms is huge and intersectional, and existing work only covers a fraction of it. Developing a suite of evaluations or augmenting existing generation benchmarks (Mille et al., 2021) with axes of risk evaluations (Ribeiro et al., 2020) will encourage the development of holistic solutions, bridging discrimination/toxicity and information-related harms—two related directions in which researchers have often developed similar solutions.

5 Conclusion

We present a survey of practical methods and techniques for addressing the societal harms and safety risks of language generation models. Our structured taxonomy covers a wide variety of interventions at different stages of the model development pipeline to mitigate harms. This work bridges multiple strands of research and presents an actionable overview on methods for preventing harms from language generation models.

Limitations

The goal of this survey was to present current research on analyzing and mitigating harms of language generation. There are multiple documented and anticipated harms that these models perpetuate, and it is not feasible to address intervention strategies for each of them. We aimed to generalize multiple proposed solutions and present them in a structured form, considering a few popularly studied harms as case studies. Inevitably, certain harms and their mitigation strategies might not have been considered for this survey.

Current research in this field is nascent but fast-moving. While this survey enlists techniques and approaches that are popular now, there is a potential for them to be replaced with newer research. We anticipate that this survey may need to be updated or even redone to incorporate new research.

Ethics Statement

In this survey, we present and discuss various risk analyses and intervention strategies to prevent societal harms from LMs. We also comment on common themes across approaches for detecting and resolving population-centric harms (such as toxicity and discrimination) and misinformation-related harms, and we recommend future work combining them. First, many datasets and resources we discuss may contain biases, and using them in downstream applications can lead to risks as we have outlined. Second, many techniques we discuss have limitations or are known to exacerbate other kinds of harms (Xia et al., 2020), and thus, applying them to newer problems may lead to unseen issues. Finally, the interventions we identify to raise general awareness have the potential for misuse: a malicious user can further imbalance the data to train even more harmful models, use the models and decoding algorithms to generate fake news, and target marginalized populations. This, however, should not discourage the development of mitigation strategies; rather, more work should be done to detect and ban malicious users. This requires not only technological solutions in NLP, but also in social science, social network analysis, and public policy.

A Background: More Details

Since we focus on language generation, we use the term *language models* (LMs) to refer to their classic definition as generative models (or decoders), which predict the next token given the preceding generated context. For the purposes of this survey, this paradigm also subsumes conditional (or sequence-to-sequence) LMs conditioned on inputs from different modalities such as text, image, or speech via an encoder. [4] Unless otherwise specified, we assume that (1) the LM decoder is parameterized by a transformer architecture (Vaswani et al., 2017), and (2) the LM is first pretrained on a large amount of text (ranging from 100-billions to trillions of tokens), which, together with their large number of parameters, have earned such models the name large language models.[5]. After pretraining, LMs are either used in a zero- or few-shot manner (Brown et al., 2020), or modified for specific tasks via finetuning all or some of their parameters (Liu et al., 2023).

The generation tasks this survey focuses on can be broadly categorized as either (1) transformation tasks, where a given input is transformed into a textual output such as machine translation, abstractive summarization, data-to-text generation, and stylistic re-writing, among others (Prabhumoye et al., 2018; Raffel et al., 2020; Zhang et al., 2020b; Aghajanyan et al., 2022), (2) or open-ended tasks such as dialogue generation, prompt-based autocompletion, story generation, and more (Adiwardana et al., 2020; Guan et al., 2020).

---

[4] While many different strategies to (pre-)train encoder LMs have been introduced in the literature (Devlin et al., 2018; Peters et al., 2018), they are generally not conducive to generating text and are out of scope in this survey.

[5] While some of the studies we will discuss do not rely on pretraining, we highlight it here since it is one of the primary drivers of recent advances in language generation (and its associated risks)

TRAVLR: Now You See It, Now You Don't!
A Bimodal Dataset for Evaluating Visio-Linguisic Reasoning

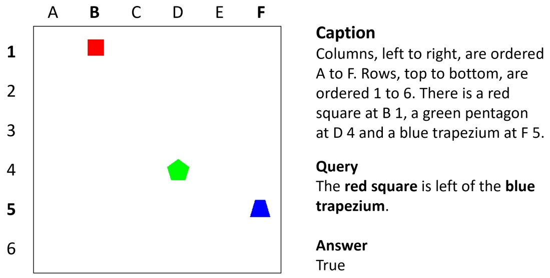
Abstract

Numerous visio-linguistic (V+L) representation learning methods have been developed, yet existing datasets do not adequately evaluate the extent to which they represent visual and linguistic concepts in a unified space. We propose several novel evaluation settings for V+L models, including *cross-modal transfer*. Furthermore, existing V+L benchmarks often report global accuracy scores on the entire dataset, making it difficult to pinpoint the specific reasoning tasks that models fail and succeed at. We present TRAVLR, a synthetic dataset comprising four V+L reasoning tasks. TRAVLR's synthetic nature allows us to constrain its training and testing distributions along task-relevant dimensions, enabling the evaluation of out-of-distribution generalisation. Each example in TRAVLR redundantly encodes the scene in two modalities, allowing either to be dropped or added during training or testing without losing relevant information. We compare the performance of four state-of-the-art V+L models, finding that while they perform well on test examples from the same modality, they all fail at cross-modal transfer and have limited success accommodating the addition or deletion of one modality. We release TRAVLR as an open challenge for the research community.[1]

1 Introduction

Research in psycholinguistics has found that human processing of spatial words activates brain regions associated with the visual system (Tang et al., 2021), suggesting the latter's involvement in processing linguistic input. It is reasonable to expect multimodal neural models to resemble humans in being able to leverage capabilities in the visual domain to solving problems in the text domain, and vice versa. Following its recent success in the text domain (Devlin et al., 2019), the pretraining–fine-tuning paradigm has been applied to the vision and text modalities to create unified visio-linguistic (V+L) representations. Just as pretrained multilingual models have been shown capable of zero-shot cross-lingual transfer on various NLP tasks (Conneau et al., 2020), we may expect *true* V+L models to be capable of generalising to a modality not seen during fine-tuning.

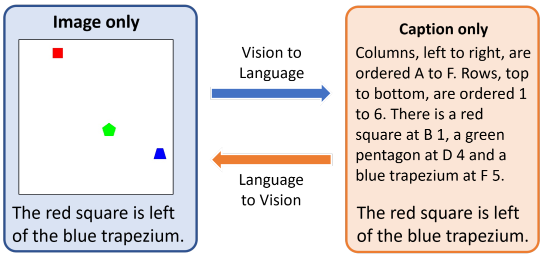


Caption
Columns, left to right, are ordered A to F. Rows, top to bottom, are ordered 1 to 6. There is a red square at B 1, a green pentagon at D 4 and a blue trapezium at F 5.

Query
The **red square** is left of the **blue trapezium**.

Answer
True

(a) A complete example for the spatiality task.



The red square is left of the blue trapezium.

Columns, left to right, are ordered A to F. Rows, top to bottom, are ordered 1 to 6. There is a red square at B 1, a green pentagon at D 4 and a blue trapezium at F 5.

The red square is left of the blue trapezium.

(b) Possible directions of cross-modal transfer.

Figure 1: An example from TRAVLR (a). Both image and caption fully represent the scene; either can be dropped during training/testing, enabling the evaluation of cross-modal transfer ability (b).

However, current approaches for benchmarking V+L models involve reporting global accuracy scores on the entire dataset, rendering the specific sources of success and failure difficult to diagnose (Ribeiro et al., 2020; Goel et al., 2021). For instance, Visual Question Answering (VQA, Goyal et al. 2017) tasks may allow models to exploit dataset bias (Dancette et al., 2021), or may reduce to object recognition problems which do not evaluate the models' ability to perform more

complex tasks, beyond aligning words or phrases in the text to a portion of the image (Hudson and Manning, 2019; Acharya et al., 2019). As Bernardi and Pezzelle (2021) note, the ability to reason over multiple objects and answer relational questions is crucial to the genuine mastery of language.

Datasets such as NLVR2 (Suhr et al., 2019) address this limitation, but do not allow for fine-grained evaluation along specific dimensions (Tan et al., 2021). CLEVR (Johnson et al., 2017) and SHAPEWORLD (Kuhnle and Copestake, 2017) enable targeted evaluations of a V+L model's reasoning abilities but only encode the scene unimodally, as images. Additionally, their test examples may still be in the training distribution with respect to task-relevant dimensions, making it difficult to draw conclusions about generalisation ability.

We thus contribute TRAVLR, a synthetic dataset comprising four V+L reasoning tasks: spatiality, cardinality, quantifiers, and numerical comparison, all of which require reasoning over multiple objects and have been shown to be challenging for V+L models (Johnson et al., 2017; Parcalabescu et al., 2021). Unlike SHAPEWORLD, we fully leverage the benefits of using a synthetic dataset by controlling the train-test split such that examples in the out-of-distribution (OOD) test set are OOD *with respect to task-relevant dimensions*. We thus argue that TRAVLR serves as a basic sanity check for the abstract reasoning and out-of-distribution generalisation capabilities of models, and is complementary to datasets that evaluate real-world object recognition and compositional reasoning abilities, such as GQA (Hudson and Manning, 2019).

Inspired by the word/picture sentence verification task from psycholinguistics (Goolkasian, 1996), we further propose various novel evaluation settings by representing the scene bimodally as both an image and a caption. First, TRAVLR supports the novel *cross-modal transfer* setting (Figure 1): If pretrained V+L models have learnt a truly multimodal representation, they should be able to learn a reasoning task with input from one modality and perform inference using input from the other modality with little to no extra training. Being able to transfer cross-modally in a zero- or few-shot manner may improve data efficiency in applications where diverse image data is difficult to obtain. Furthermore, models should also succeed on test settings where either an unseen modality is added, or a seen modality is dropped.

Using TRAVLR, we perform extensive analysis of the ability of four Transformer-based V+L models to perform various reasoning tasks. We show that current V+L models:

- May require unreasonably large amounts of data to learn simple visio-linguistic reasoning tasks.
- Exhibit a strong textual bias.
- Are unable to perform cross-modal transfer. We thus pose this as an open challenge for future V+L models.

2 Related Work

V+L tasks and datasets. The Visual Question Answering (VQA) task involves answering a question about an image. It is a complex task as it requires an ability to process input in both visual and textual modalities (Antol et al., 2015). A known issue with VQA datasets is the presence of real-world language priors and statistical biases in the training and testing distribution (Kervadec et al., 2021; Agrawal et al., 2018; Kafle et al., 2019). Although VQA v2.0 (Goyal et al., 2017) was improved by balancing each query with pairs of images, Dancette et al. (2021) show that it still contains both unimodal and multimodal biases that models can exploit. Furthermore, questions in VQA may use non-compositional language that does not require abilities beyond object recognition.

NLVR (Suhr et al., 2017) addresses the lack of compositionality in VQA using synthetic images of abstract 2D shapes, accompanied by human-written English sentences to be judged true or false. NLVR2 (Suhr et al., 2019) and SNLI-VE (Xie et al., 2019) also involve truth-value/entailment judgement tasks, but use photographs instead of synthetic images. Both lack detailed annotations of the specific semantic phenomena evaluated by each example. GQA improves over VQA by focusing on compositional questions that require reasoning over multiple objects and contains detailed annotations (Hudson and Manning, 2019), but still suffers from statistical imbalances and the lack of an out-of-distribution test set (Kervadec et al., 2021).

Other synthetic datasets focusing on reasoning include CLEVR (Johnson et al., 2017), a fully synthetic and annotated 3D dataset, and SHAPEWORLD, a 2D dataset targeting linguistic phenomena such as spatial relationships and quantifiers. SPARTQA (Mirzaee et al., 2021) is another 2D synthetic dataset built upon NLVR focusing on spatial reasoning among other linguistic phenomena.

gSCAN (Ruis et al., 2020) focuses on generalisation of commands within a 2D grid-world.

V+L models. Pretrained V+L models differ in their architecture and pretraining methods. VL-BERT (Su et al., 2019), UNITER (Chen et al., 2020) and VisualBERT (Li et al., 2020a) are single-stream models with a single Transformer while ViLBERT (Lu et al., 2019), LXMERT (Tan and Bansal, 2019), and ALBEF (Li et al., 2021) are dual-stream models which encode image and textual inputs separately before fusing them. These models all use masked language modelling and image-text matching objectives for pretraining, with LXMERT additionally pretraining on VQA and ALBEF using a contrastive loss to align the image and language representations. UNITER, VisualBERT, and LXMERT use a frozen Faster R-CNN (Ren et al., 2015) to extract region-based features from the image, while ALBEF directly encodes the image with a Vision Transformer (Dosovitskiy et al., 2020).

Cross-modal transfer. Prior work has found models trained on multimodal data to perform better on unimodal downstream tasks than models trained only on one modality. Zadeh et al. (2020) found models trained on multimodal input to perform better than text-only models on three NLP tasks, while Testoni et al. (2019) showed that models trained on textual, visual, and auditory input were better at a quantification task than models trained only on a single modality. Using a task involving queries about typical colours of objects, Norlund et al. (2021) found BERT trained on linguistic and visual features to outperform BERT trained on language data filtered for mentions of colour. Frank et al. (2021) investigated the cross-modal alignment of pretrained V+L models with an ablative method based on masked modelling. Lu et al. (2021) propose an image–text fusion model to solve a novel image generation task from a textual description and an image prompt based on NLVR2.

Summary. The datasets commonly used to evaluate V+L models such as VQA and NLVR2 lack fine-grained interpretability, due to the lack of annotations for semantic phenomena involved in each example. Additionally, multiple semantic phenomena co-occur within a single example, making it difficult to control the training distribution and assess the generalisation abilities of models. Furthermore, existing V+L datasets only present the scene in the visual modality and cannot be used to evaluate a V+L model's cross-modal transfer ability.

Existing synthetic datasets (e.g. SHAPEWORLD, CLEVR) fail to split the training and testing distributions along a dimension relevant to the specific task, because they generate captions based on randomly generated images. Unlike existing datasets, TRAVLR fully exploits the benefits of a synthetic dataset by strictly controlling the training and evaluation distributions to test the generalisation abilities of V+L models and avoid statistical biases from language priors and non-uniform distributions.

3 TRAVLR: Cross-Modal Transfer of Visio-Linguistic Reasoning

We construct TRAVLR, a synthetic dataset comprising four visio-linguistic reasoning tasks: spatiality, cardinality, quantifiers and numerical comparison. These tasks were previously identified to be challenging for text-only models (Lin and Su, 2021; Dua et al., 2019; Ravichander et al., 2019). TRAVLR aims to evaluate the extent to which pretrained V+L models already encode or are able to learn these four relations between entities present in input scenes. We first describe the general task format, and then describe each task.

Given a scene with objects, $S = \{o_1, ..., o_n\}$, where each object can be represented as a tuple $<$ *colour, shape, position* $>$, and a textual query q involving some relation $r(o_1, ..., o_i)$ between two or more objects in S, each task involves learning a function $y = f(S, q)$ where $y \in \{\textit{true}, \textit{false}\}$. This is essentially a binary classification task. For instance, in the spatiality task, the relation r (e.g., *above*) compares the positions of two objects. In the numerical comparison task, noun phrases in the query refer to subsets of objects, while the relations (e.g., *more*) compare the cardinality of two sets of objects. Assigning a truth value to the query thus involves reasoning over several objects.

However, a model can never have direct access to the underlying representation scene and must operate on visual or textual forms, and S may be represented in the form of an image or a textual description. In prior work such as VQA, S is presented as an image. In TRAVLR, S is represented bimodally as an $<$ *image, caption* $>$ pair.

Each example consists of an image, an accompanying caption, and a query. Images include abstract objects arranged in a 6 × 6 grid. We draw from five colours and seven shapes, giving 35 unique objects in total. The shapes used in TraVLR are from the Visual Genome (Krishna et al., 2017), a commonly-used pretraining dataset. Each caption fully describes the image with the coordinates of each object (e.g., "There is a red circle at A 1, a blue square at B 2..."). A description of the coordinate system, e.g., "Columns, left to right, are ordered A to F. Rows, top to bottom, are ordered 1 to 6." is prepended to the caption. The caption and query are separated by the `[SEP]` token when presented to the models. Removing the caption reduces our tasks to VQA-like tasks.

3.1 Novel Evaluation Settings

Encoding the scene as both an image and a caption allows models to be trained and evaluated on a combination of three settings: i) image-only, ii) caption-only, and iii) both image and caption input settings. The query is presented as part of the text input in each setting. In the caption-only setting, a blank white image is presented to the models.

3.2 Reasoning Tasks

In contrast to existing synthetic datasets (e.g. ShapeWorld and CLEVR), we do not generate queries post-hoc based on pre-generated scenes, and instead generate scenes constrained along a task-relevant dimension. For instance, in generating the training and out-of-distribution (OOD) test sets for the spatial relationship task, we ensure that the positions of the queried objects do not overlap between the training and test sets *along the relevant axis* (e.g. the horizontal axis for horizontal relations *left/right*). We indicate the train/test splits based on *pairs* in angled brackets.

Spatiality. This task involves queries of the form "The `[object1]` is `[relationship]` the `[object2]`." (e.g., "The red circle is to the right of the blue square."). The possible relationships are *to the left of*, *to the right of*, *above*, *below*. For horizontal relationships (left/right), the train and test sets are split based on the pair <`column(object1), column(object2)`> (see Appendix A.1), while for vertical relationships (above/below), the train–test split is based on the pair <`row(object1),row(object2)`>. This tests the model's ability to generalise its understanding of spatial relationships along the relevant dimension, as opposed to memorising fixed positions.

Cardinality. This task involves queries of the form "There is/are `[number]` `[shape]` object(s)." (e.g., "There are 3 circle objects"). The train and test sets are split by the <`number, shape`> pair occurring in the input image/caption; e.g., instances containing 2 circles and 3 triangles could occur in the training distribution, while instances with just 3 circles occur only in the OOD test distribution.

All	$< \texttt{[attr1]} \cap \texttt{[attr2]}, \texttt{[attr2]} \setminus \texttt{[attr1]} >$
Not all	$< \texttt{[attr1]} \cap \texttt{[attr2]}, \texttt{[attr1]} \setminus \texttt{[attr2]} >$
No	$< \texttt{[attr1]} \setminus \texttt{[attr2]}, \texttt{[attr2]} \setminus \texttt{[attr1]} >$
Some	$< \texttt{[attr1]} \setminus \texttt{[attr2]}, \texttt{[attr1]} \cap \texttt{[attr2]} >$
Only	$< \texttt{[attr1]} \cap \texttt{[attr2]}, \texttt{[attr1]} \setminus \texttt{[attr2]} >$
Not only	$< \texttt{[attr1]} \cap \texttt{[attr2]}, \texttt{[attr2]} \setminus \texttt{[attr1]} >$

Table 1: Pairs for each quantifier.

Quantifiers. This task involves queries of the form "`[quantifier]` the `[attr1]` objects are `[attr2]` objects.", where the quantifiers include *all*, *some*, *only* and their negated counterparts *not all*, *none* and *not only*. The train–test split is performed based on the pair $< a, b >$, which varies based on the quantifier, as given in Table 1. For instance, for the relationship *not all*, a is the number of objects which fulfil both `[attr1]` and `[attr2]`, and b is the number of objects which fulfil `[attr1]` but not `[attr2]` (see Appendix A.1).

Numerical comparison. This task involves queries of the form "There are `[more/fewer]` `[attr1]` objects than `[attr2]` objects." (e.g., "There are more circles than squares."). The train and test sets are split by the pair $< a, b >$ where a is the number of `[attr1]` objects, and b is the number of `[attr2]` objects. Instances for which $|a - b|$ is smaller than a threshold is assigned to the training distribution, and the remaining pairs are assigned to testing. $|a - b| \in 1, 3$ and both a and b have a maximal value of 9. Success in this task is indicative of generalisation based on an understanding of numeral scales and transitivity of comparison; i.e., $a > b$ and $b > c$ implies $a > c$.

3.3 Generating TraVLR

To generate examples for each task, we randomly sample object attributes from the distributions defined in Section 3.2, ensuring that the *pairs* relevant to each task do not overlap between the train and OOD test sets. We also ensure that all queries in the OOD test set do not occur in the training set. Distractor objects irrelevant to the intended query are finally added to the scene. The spatiality task's training set comprises 32k examples, the training sets of the other tasks comprise 8k examples each due to differences in the amount of data required for convergence in our preliminary experiments.

	Train	Image				Caption				Image + Caption

Table 2: Mean F_1 scores on the TRAVLR OOD test sets of four V+L reasoning tasks (**S:** Spatiality, **C:** Cardinality, **Q:** Quantifiers, **N:** Numerical comparison; relative change from InD results are in parentheses). #sd indicates the number of converged runs. We report the mean of converged runs if #sd > 1, and the mean of all runs if #sd $= 0$. Above-random results are underlined; the result with the highest mean in each column is **bolded**.

Prior work on generalisation evaluation recommends the use of in- and out-of-distribution (henceforth InD and OOD, respectively) test sets (Csordás et al., 2021). Hence, we include validation and InD test sets randomly sampled from the training distribution (10k examples each), in addition to the OOD test set described above (20k examples). We report further dataset statistics in Appendix A.

4 Experiments

Models. We perform experiments on two single-stream models, VisualBERT and UNITER, and two dual-stream models, LXMERT and ALBEF. We use Li et al. (2020b)'s implementation of VisualBERT, LXMERT, and UNITER, and the original implementation of ALBEF. The image features of LXMERT and UNITER are 36 regions of interest extracted using Tan and Bansal (2019)'s implementation of a pretrained Faster R-CNN (Ren et al., 2015; Anderson et al., 2018). We use a Detectron model (Girshick et al., 2018) to extract image features for VisualBERT. We also train two text-only models, BERT (Devlin et al., 2019) and RoBERTa (Liu et al., 2019), as caption-only baselines.

Setup. We train models on each task for 80 epochs. Following Csordás et al. (2021)'s finding that early stopping may lead to underestimation of model performance, we do not do early stopping. We use the recommended hyperparameters for fine-tuning ALBEF on SNLI-VE (Xie et al., 2019) and VisualBERT on NLVR2. Learning rates were adjusted downwards for models/tasks where recommended hyperparameters did not lead to convergence. Each experiment is repeated with three random seeds. Table 2 reports mean results on seeds leading to above-random performance, and mean results on all seeds when none achieve above-random performance. We present further experimental details in Appendix B.

4.1 Within-Modality Results

We first discuss the results of testing the model on the modality it was trained on (Table 2). In Appendix C, we examine the effect of dataset size on model performance and discuss the results in detail. In Appendix D, we discuss differences in training duration between models.

Image-only setting. Generalising across the four tasks, in the image-only setting, LXMERT is the best performing model across all tasks, while ALBEF is consistently the worst performing model. UNITER outperforms VisualBERT in all tasks except the cardinality task.

Caption-only and image+caption settings. Generally, the performance of all models except LXMERT in the caption-only and image+caption settings is better than performance in the image-only setting. Across tasks and models, performance in the caption-only closely resembles performance in image+caption settings, suggesting a strong textual bias when both modalities are presented. In the caption-only and image+caption settings, LXMERT is consistently the worse performing model, and VisualBERT is the best performing model in all but the spatiality task. On the cardinality and quantifiers tasks, all models except LXMERT achieve close to a perfect F_1 score, performing similarly to RoBERTa and BERT. However, they are outperformed by RoBERTa when trained on smaller datasets.

Spatiality. While UNITER and LXMERT achieve above-random performance with 8k examples, VisualBERT requires at least 16k examples, and ALBEF fails to learn the task on the full 32k dataset. 32k is a significant number of examples given the task's simplicity. For comparison, the full VQA dataset consists of only 443k training examples. Transformer-based models thus face similar issues to CNN and LSTM models, which Johnson et al. (2017) found to have trouble learning spatial relationships and often memorise the absolute object positions.

A potential explanation for the superior performance of UNITER and LXMERT could be that unlike the other models, spatial coordinates from the bounding boxes are explicitly encoded in the input to the image encoders, which the models can directly exploit. This is unavailable to ALBEF, which takes in the image as input directly instead of relying on a separate object detector. VisualBERT does not make use of these spatial coordinates, which may impair its ability to relate the positions of objects. Bugliarello et al. (2021) and Frank et al. (2021) posited this limitation of VisualBERT to explain its poor performance on tasks such as RefCOCO+ and Masked Region classification, but the impact of this limitation on spatial reasoning has hitherto not been directly investigated. LXMERT converges in fewer epochs compared to all other models. LXMERT only required 4 epochs of training on the 32k dataset to exceed F_1=90 on the InD test set, while UNITER required about 60 epochs (see further discussion in Appendix D).

In the caption-only and image+caption settings, UNITER and ALBEF are notably more sensitive to random seeds and fail to achieve convergence in several cases. Furthermore, performance is poorer in the image+caption than in the caption-only setting across all models. This runs counter to existing expectations that bimodal representation of the same information should improve performance (Zadeh et al., 2020; Testoni et al., 2019). Several models exhibit > 5 point differences in F_1 on the InD and OOD test sets. BERT requires at least 8k examples to achieve an F_1 score above 60, corroborating findings by Lin and Su (2021) that BERT requires a significant number of examples to learn a simple natural language inference task.

Cardinality. On the cardinality task, all models achieve non-random performance when trained with 8k examples. Across all settings, performance on the InD and OOD test set is similar, indicating that models are able to generalise to unseen object–number pairs. However, despite the task's simplicity, in the image-only setting, no model achieves above an F_1 of 85 when trained on the full dataset, and when trained on 1k examples, all models perform poorly with F_1 scores below 60. This corroborates Parcalabescu et al. (2021)'s finding that current V+L models face difficulties with counting objects in images. Models are generally successful in the caption-only setting, corroborating Wallace et al. (2019)'s findings that numeracy is encoded in the embeddings of language-only models.

Quantifiers. All models perform well on the quantifiers task in most settings, with exceptions that conform to the overall trends described above (e.g. LXMERT in the image+caption setting). Good performance on the OOD dataset indicates that models are not memorising specific numbers of objects and instead use more general strategies for understanding quantifiers. This parallels psycholinguistic findings that comprehension of non-exact quantifiers does not correlate with counting skills in human children (Dolscheid et al., 2015).

Numerical comparison. Unlike the other tasks, there is a significant difference between the InD and OOD settings for the numerical comparison task across all settings. In the image-only setting, all models except ALBEF, achieve F_1s above 70 on the InD test set, while achieving much lower F_1s (55–65) on the OOD test set. In the caption-only and image+caption settings, while all models achieve close to F_1=100 on the InD test set, UNITER and LXMERT do not generalise well to the OOD test set, showing a substantial drop in performance. Our results suggest that models face difficulties generalising beyond the training distribution to unseen number pairs.

4.2 Cross-Modal Transfer

Despite performing well in the within-modality settings, **none** of the models succeed at performing zero-shot cross-modal transfer to an unseen modality. Nevertheless, given the success of few-shot learning, we may expect few-shot cross-modal transfer to be plausible. We hence conduct few-shot learning experiments on the best performing models that were fine-tuned on the full dataset of the spatiality and quantifiers tasks. We fine-tuned the models on 200 examples of the unseen modality for 20 epochs before testing (see details in Appendix B.5). Unfortunately, none of the models achieved above random performance even after this additional fine-tuning. We conclude that they can perform neither zero-shot nor few-shot cross-modal transfer, and that existing V+L representation learning methods have yet to succeed at producing truly multimodal (or modality-agnostic) representations.

4.3 Adding and Dropping Modalities

We now discuss the effects of either adding or dropping a modality to the input presented during testing. First, models trained in the image+caption setting perform similarly when tested in the image+caption and caption-only settings. However, when tested in the image-only setting, models perform poorly, exhibiting (close to) random performance in most cases. This indicates that all models tend to overly focus on the caption during training. Second, models trained only on captions perform similarly when tested in the image+caption setting. In contrast, testing a model trained only on images in the image+caption setting results in a significant performance drop. In most cases, F_1 is close to random, although all models except LXMERT manage to maintain above-random performance on the quantifier task. This could indicate that the models are easily distracted by the textual modality. Together with the general similarity between results in the caption-only and image+caption settings, these results indicate a bias towards the textual modality.

5 Further Analyses

5.1 The Impact of Pretraining

We conduct additional experiments on VisualBERT, UNITER and LXMERT trained using the unified VOLTA (Bugliarello et al., 2021) framework, where V+L models were pretrained using the same dataset in a standardised manner. This allows us to understand the extent to which differences in models' performance can be attributed to the pretraining data or objective, rather than model architecture. First, VOLTA LXMERT loses its advantage in both performance and training efficiency over the other models. We suggest that LXMERT's superior performance is due to some aspect of its pretraining, such as the larger size of or presence of VQA examples in its pretraining dataset, or its use of an additional VQA pretraining objective. Furthermore, VOLTA VisualBERT's performance is significantly improved over the original VisualBERT, likely because it was pretrained with more data. UNITER also outperforms the other two models (also reported by Bugliarello et al. (2021) on RefCOCO+ and NLVR2), which suggests some advantage of its specific architecture. All three VOLTA models achieve similar results on the caption-only setting of the 8k cardinality dataset. As all VOLTA models were initialised with BERT weights, we suggest that the poor performance of the original LXMERT on textual input is due to its lack of initialisation with BERT weights (Tan and Bansal, 2019). We discuss the results in greater detail in Appendix E.

5.2 The Impact of Catastrophic Forgetting

A potential concern with fine-tuning on one modality and testing on another is that the models may overfit to the fine-tuning modality, resulting in the catastrophic forgetting of cross-modal information. To reduce this possibility, we freeze the pretrained representations and only fine-tune the classification layers. In this setting, all models except LXMERT fail to go beyond random performance. Although LXMERT achieves above-random performance in the image-only setting for two tasks, it is still relatively poor (Spatiality: OOD=52.29, InD=52.67; Cardinality: OOD= 56.39, InD=60.88). This indicates that most models require representation fine-tuning to perform reasoning tasks, and it is unlikely that the inability to transfer cross-modally was due to catastrophic forgetting during fine-tuning.

5.3 Modal Dropout

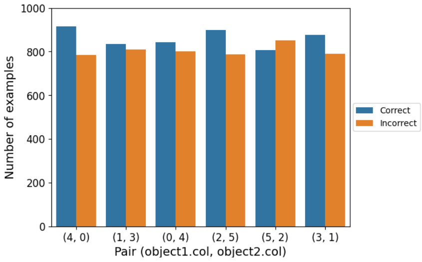
One may be concerned that the presentation of the same information in the image+caption setting facilitates overfitting to either modality. We investigate whether models' textual bias can be overcome by randomly "dropping out" either the image or caption input when training in the image+caption setting. We find modal dropout to not significantly alleviate bias towards the textual modality. We discuss our findings in detail in Appendix F.

5.4 Error analysis

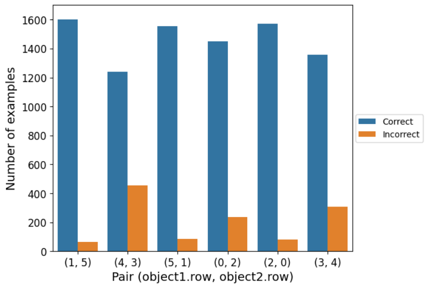
We now report findings from our error analysis on selected experiments where models converged but did not achieve perfect or near perfect F_1 scores, which can reveal trends that explain poor performance. We describe our analysis on the spatiality and cardinality tasks here, referring readers to Appendix G for details on quantifiers and numerical comparison.

Across all tasks, errors are intuitive and explainable, and the performance of models is generally poorer on boundary cases. For example, models are more error-prone when objects are positioned close to each other in the spatiality task, and where only one object either falsifies or confirms the query in the quantifier task. On the numerical comparison task, we observe more errors when the difference between the numerals being compared is small.

5.4.1 Spatiality



(a) Queries involving horizontal relationships, by the pairs of the columns of the queried objects.



(b) Queries involving vertical relationships, by the pairs of the rows of the queried objects.

Figure 2: Error analysis of VisualBERT trained on spatiality task, image-only setting, tested on OOD test set. (F_1=69.78; seed=0)

In the spatiality task, VisualBERT was unable to achieve F_1 scores above 70 across all three random seeds. Figure 2 shows that this was due to VisualBERT only correctly answering queries involving vertical relationships, but not horizontal ones. In the figure, the x-axis is organised by the pairs of object coordinates relevant to the query (i.e., columns for horizontal relationship queries, and rows for vertical relationship queries). A similar pattern is observed on all three runs on VisualBERT, and also on UNITER on one random seed. Mediocre results on the spatiality task can thus often be attributed to models successfully learning to answer only a subset of the queries.

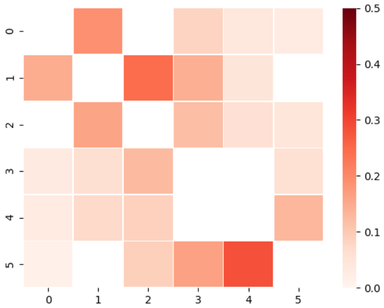


Figure 3: Percentage of incorrect answers of UNITER in the image-only setting, on InD $< x, y >$ pairs for vertical relationships. (F_1=71.79; seed=2)

Figure 3 shows the percentage of incorrect answers on specific pairs in the InD test set. Note that white entries are pairs which belong to the OOD test set. Overall, models make more mistakes on examples with queried objects positioned closer together (represented by cells closer to the diagonal).

5.4.2 Cardinality

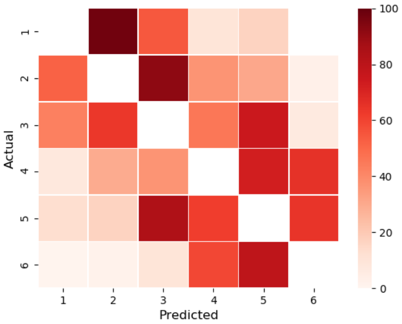

Figure 4: Actual vs predicted values (given that predicted answer is true). VisualBERT trained on the cardinality task, image-only setting, tested on InD test set. (F_1=77.84; seed=0)

While most models apart from LXMERT succeeded on the cardinality task in the caption-only and image+caption settings, moderate performance was observed in the image-only setting. We found that models performed poorer on images with more objects in the image, inclusive of distractors (refer to Appendix G for details). Furthermore, models often predict values close to the actual value. Figure 4 plots the actual number of objects in the scene against the number of objects predicted. Since the task was a true/false task, this analysis is based only on examples for which the model predicted that the query was true. The counting abilities of models thus intuitively resemble that of humans, given that they are confused by a large number of objects in the scene, and are also likely to predict answers close to the actual value when miscounting.

6 Discussion

Comparing modalities. As discussed in §4.3, V+L models exhibit a clear bias towards the textual modality across single and dual stream models, corroborating findings by Cao et al. (2020). This finding also applies to LXMERT, even though it generally performs more poorly on caption than image inputs. Furthermore, the V+L models perform more poorly than unimodal RoBERTa on various tasks in the caption-only setting, similar to Iki and Aizawa (2021), who show that V+L pretraining on degrades performance on NLU tasks.

Comparing tasks. The spatiality task is the hardest task, requiring at least 32k examples to converge in some cases, as opposed to the 8k examples for the other tasks (see Appendix C for details). Furthermore, convergence of the models on the spatiality task is highly sensitive to random seeds. Among the other tasks, the easiest task is the quantifiers task, followed by cardinality, and finally numerical comparison. In the caption-only and image+caption settings, all models apart from LXMERT achieve a close to perfect F_1 on the cardinality and quantifiers tasks. However, on the numerical comparison task, UNITER and LXMERT exhibited a limited ability to generalise outside the training distribution in both image and textual modalities. Thus, while success on the cardinality task indicates that models possess an understanding of the meaning of numbers in absolute terms, the numerical comparison task was able to differentiate models in terms of their understanding of numbers' relative positions on a numeral scale.

Comparing models. As argued in §5.1, the most significant factor differentiating models seems to be their **pretraining** rather than model architecture. Our findings corroborate Bugliarello et al. (2021)'s findings that differences between models cannot be primarily attributed to differences in model architecture. Unlike LXMERT and ALBEF, VisualBERT and UNITER both succeed on all tasks in all settings. While UNITER generally outperforms VisualBERT in the image-only setting, VisualBERT at times outperforms UNITER in the caption and image+caption settings. The superior performance of VisualBERT in caption-only settings could be due to its comparatively minimal pretraining on V+L objectives, enabling it to retain performance closer to that of text-only models.

The **encoding of image features** also has a significant impact on performance in the image-only setting. VisualBERT's poor performance on the spatiality task is likely due to the fact that it does not explicitly encode the spatial coordinates of the bounding boxes in its input. Additionally, it is likely that the pretrained object detector used by every model except ALBEF helped them outperform ALBEF in the image-only setting, despite underperforming it in common V+L benchmarks (Li et al., 2021). A possible explanation is that the information captured by the Faster R-CNN detector was more relevant to our visio-linguistic tasks.

Finally, the poor performance of LXMERT on caption-only and image+caption settings reflects its lack of **initialisation with BERT parameters** before pretraining. Given the superior performance of RoBERTa over BERT, it could be beneficial to initialise models with RoBERTa weights instead.

7 Conclusion

TRAVLR allows us to evaluate specific visio-linguistic reasoning skills in isolation, enabling finer-grained diagnosis of model deficiencies. We found some models to learn better from one modality than the other, and some task-setting combinations to be more challenging across the board. Furthermore, existing models may require unreasonably large amounts of data and training steps to learn simple tasks. Improving the sample efficiency and training time of V+L models is a potential direction for future research. Furthermore, while pretrained multilingual models have been shown to demonstrate zero-shot cross-lingual transfer abilities, it is unclear whether V+L models can similarly perform *cross-modal transfer* of downstream task abilities to a modality unseen during fine-tuning.

We hence contribute TRAVLR, which enables the evaluation of cross-modal transfer ability by encoding scenes bimodally. We found all models to suffer from a strong textual bias, and an inability to perform zero- and few-shot cross-modal transfer. Given the success of multilingual models with cross-lingual transfer, future work might attempt to bridge the gulf between the visual and textual modalities, perhaps by forcing models to transform images into intermediate representations which more closely resemble language. Visio-linguistic representations capable of such transfer will unlock a whole host of new applications, and we pose this as the next challenge for multimodal modelling.

Limitations

We acknowledge that the use of synthetic data is potentially unrealistic given that most applications would require reasoning on real-world input. Nevertheless, we note that because synthetic data is easier, it is still useful as a benchmark for the minimum expected performance of models. We follow the line of argument in prior work (e.g. Johnson et al. (2017)) that synthetic datasets not only mitigate the problem of distributional bias in real-world datasets, but also simplify the problem of object recognition to focus on diagnosing genuine abstract reasoning ability. We generally expect V+L models to acquire abstract visual reasoning skills, like humans, rather than being limited to the realm of photographs. TRAVLR's focus on simple shapes also makes it a test of this ability.

Our experiments on VOLTA should be taken as preliminary, as a full replication of all experiments was not performed due to resource limitations. Future work could investigate the extent to which the superior performance of VOLTA UNITER is robust across all tasks, which would indicate a genuine advantage due to UNITER's architecture. Furthermore, although we have attributed the superior performance of LXMERT to some aspect of its pretraining, we are unable to pinpoint whether the advantage is specifically due to the large size of its pretraining dataset, its use of VQA examples in the pretraining, or its use of a VQA pretraining objective, and leave this to future work.

Finally, while all models were shown to succeed at generalising to the OOD test setting with varying degrees of success, only the numerical comparison task poses a significant challenge in terms of OOD generalisation. This is expected, since we did not intend to challenge the models with generalisation settings which they are unlikely to encounter in test (i.e., more realistic datasets designed for fine-tuning models to perform real-world applications). Furthermore, the simplicity of our reasoning tasks enables us to evaluate models' abilities on specific semantic phenomena in isolation. Nevertheless, future work can extend TRAVLR to include more challenging generalisation tasks, such as generalisation of the meaning of negation over unseen quantifiers, compositional queries which combine multiple semantic phenomena (e.g. combining propositions via conjunction or disjunction), and queries which contain instructions to manipulate the scene.

Ethics Statement

TRAVLR is a synthetically generated dataset, and hence poses no ethical issues relating to the source of the data. Its use of abstract shapes has the further advantage of avoiding biases relating to human subjects.

A Dataset Details

We now describe the version of TRAVLR used in our experiments, although our dataset generation scripts allow parameters such as the object properties and grid size to be modified. TRAVLR draws from five colours (red, blue, green, yellow, orange) and seven shapes (square, circle, triangle, star, hexagon, octagon, pentagon), yielding a total of thirty-five unique objects. The seven shapes and colours used in TRAVLR are present in the Visual Genome dataset (Krishna et al., 2017). We use a six by six grid, which allows a maximum of 36 objects in a scene. Each example consists of an image, a caption and a query.

A.2 Dataset Statistics

Table 3 shows the label distributions (true/false) for the various datasets: training, validation, In-Distribution (InD) test, and Out-Of-Distribution (OOD) test sets. The spatiality dataset is the largest dataset comprising 32k examples, while the other datasets comprise 8k examples. In the remainder of the section, we detail crucial statistics for the splits between the training and OOD test sets.

Task	Train	Val.	InD Test	OOD Test

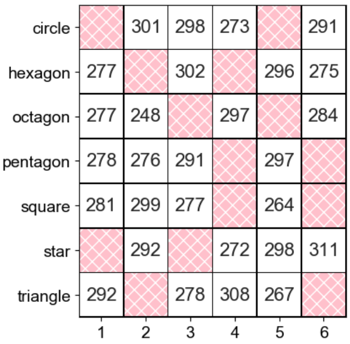
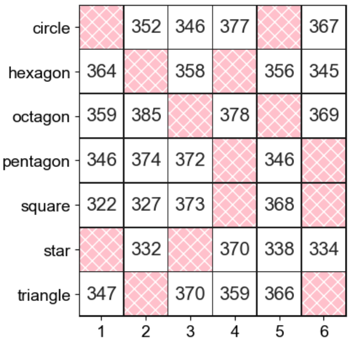
Figure 7: Spatiality (<`column(object1)`, `column(object2)`> for horizontal relationship, <`row(object1)`, `row(object2)`> for vertical relationship).

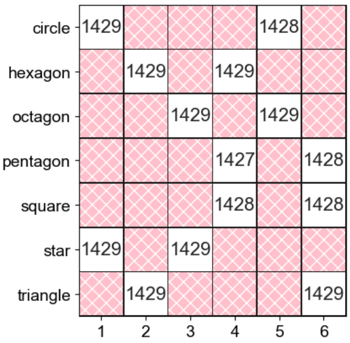
For the spatiality task, the scene comprises only three objects: the two objects mentioned in the query, and one distractor object. We limit the number of distractors for this task, since we intend the



(a) Training Set.



(b) In-Distribution Test Set.



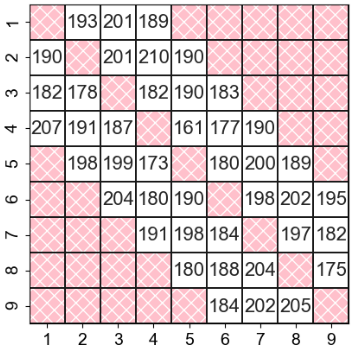
(c) Out-of-Distribution Test Set.

Figure 8: Cardinality (<`shape, number`>).

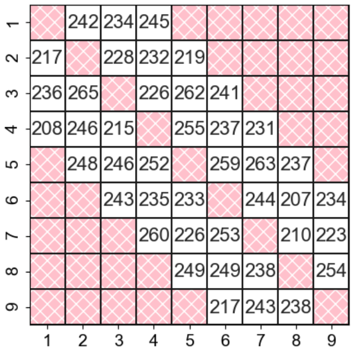
task to evaluate models' ability to compare the position of the objects, rather than their ability to perform object recognition.

Figure 7 shows dataset statistics for the training, InD and OOD spatiality dataset. Each figure indicates the number of examples whose scene instantiates a specific *pair* (this is independent of the query and label). For instance, there are 681 examples instantiating the pair $< A, B >$ for the horizontal relationship. In these examples, the first object in the query is found in Column A, and the second object is found in Column B. As illustrated in Figure 5, we ensure no overlap between pairs in the training set and the OOD test set. We note that each example either instantiates a horizontal or vertical relationship, but not both.

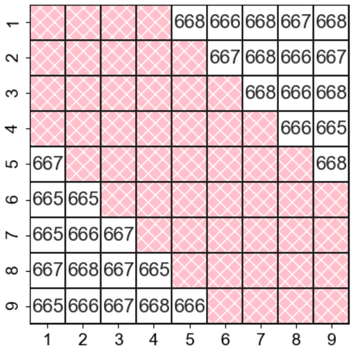
Unlike the spatiality task, more objects are present in the remaining tasks, since it is the ability to reason about the number of objects which is under test. For the cardinality task (Figure 8), we limit the number of objects relevant to the query within the range [1, 6], and the maximum number of distractor objects within the range [1, 10]. The relevant pairs shown in Figure 8 are <`shape, number`>, i.e. the number of objects of that shape.



(a) Training Set.



(b) In-Distribution Test Set.



(c) Out-of-Distribution Test Set.

Figure 9: Numerical Comparison.

For the numerical comparison task (Figure 9), we split the train and test sets by the pair $< a, b >$ where a is the number of `[attr1]` objects, and b

is the number of `[attr2]` objects. The number of `[attr1]` and `[attr2]` objects are limited within the range $[1, 9]$, and the number of distractor objects is in the range $[1, 10]$.

B Experiment details

We conducted the following fine-tuning experiments:

- 4 V+L models on all 4 tasks on 3 modality settings, on 3 random seeds each = 144 main experiments.
- 2 text-only models on all 4 tasks, on 3 random seeds each = 24 experiments.
- Replications of the above experiments on 3 smaller subsets of the original dataset, on a single random seed = 144 + 24 = 168 experiments (see Appendix C).
- All models on all 4 tasks with frozen pretrained representations.
- 4 V+L models on 4 tasks on the modal dropout/"mixed" setting (see Appendix F).
- Selected experiments on the VOLTA implementation of 3 V+L models (see Appendix E).
- Selected experiments using the few-shot learning setting (see Appendix B.5).

B.1 Metric

The metric used is the macro F_1 score, which is computed as the arithmetic mean of the F_1 score of each of the two classes (true and false). We use F_1 instead of accuracy due to small imbalances in the classes (see Table 3).

$$F_1 = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{1}$$

B.2 Hyperparameters

We train models for 80 epochs without early stopping. As the hyperparameters recommended for fine-tuning UNITER and LXMERT did not lead to convergence on some tasks, we adjusted learning rates downwards until the model converged. For LXMERT, we used a learning rate of 5e-5 only for the spatiality task, and 5e-6 elsewhere.

Model	**Batch Size**	**Learning rate**
VisualBERT	64	2e-5
UNITER	32	5e-6
LXMERT	32	5e-6 / 5e-5
ALBEF	256	2e-5
VOLTA VisualBERT	32	5e-6
VOLTA UNITER	32	5e-6
VOLTA LXMERT	32	5e-6

Table 5: Fine-tuning hyperparameters.

B.3 Runtimes

Table 6 provides an estimate of the runtimes for fine-tuning each model on different dataset sizes in different settings. Experiments were run either on NVIDIA GeForce RTX 2080 Ti or NVIDIA TITAN RTX GPUs. The longest experiments on ALBEF with the 32k dataset are estimated to lead to carbon emissions of 15.24 kgCO_2eq (Lacoste et al., 2019).

Dataset size	**Model**	**Image**	**Caption**	**Img.+Cap.**
32k	UNITER	15	27	27
	VisualBERT	15	27	27
	LXMERT	25.5	36.5	36.5
	ALBEF	38	38	38
	BERT	-	12	-
	RoBERTA	-	12	-
8k	UNITER	3.5	7	7

VOLTA VisualBERT	114.02 M
VOLTA UNITER	113.63 M
VOLTA LXMERT	210.50 M

Table 8: Number of trainable parameters.

B.5 Few-shot learning experiments

On top the zero-shot setting experiments that we conduct on all fine-tuned models, we perform few-shot learning experiments on selected fine-tuned models as shown in Table 9. We select the best-performing model for the task and setting, as well as additional models to ensure that all models are tested. We adopt the same hyperparameters stated in Table 5, and perform additional fine-tuning on 200 examples of the unseen modality for 20 epochs. Typically, between 10 to 100 examples are sufficient for few-shot cross-lingual transfer on multilingual BERT (Zhao et al., 2021). For instance, in the "Image to Caption" setting, we fine-tune a model already fine-tuned for 80 epochs in the image-only setting, on examples in the caption-only setting.

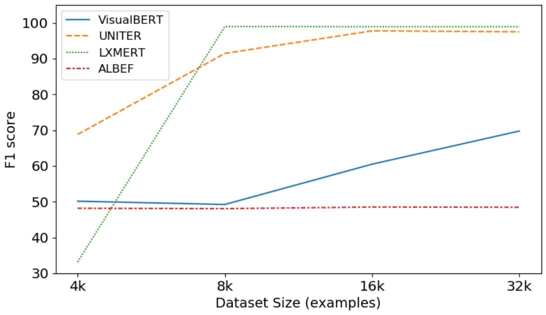
Setting	Task	Models tested	Seed
Image to Caption	Spatiality	UNITER	0
		LXMERT	0
	Quantifiers	VisualBERT	2
		UNITER	2
		LXMERT	2
Caption to Image	Spatiality	UNITER	0
		ALBEF	2
	Quantifiers	VisualBERT	2
		UNITER	2
		ALBEF	2

Table 9: Models tested on few-shot learning setting. (Seed: the random seed used in the initial fine-tuning of the model).

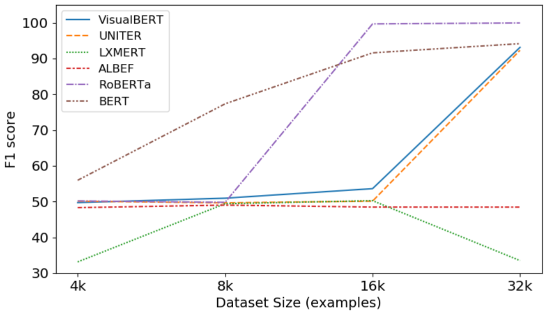
C Effect of Training Dataset Size

To investigate the effect of training dataset size on model performance, we fine-tune models with 50%, 25% and 12.5% subsets, randomly sampled from the full training set. These experiments were conducted only on a single random seed, due to resource limitations.

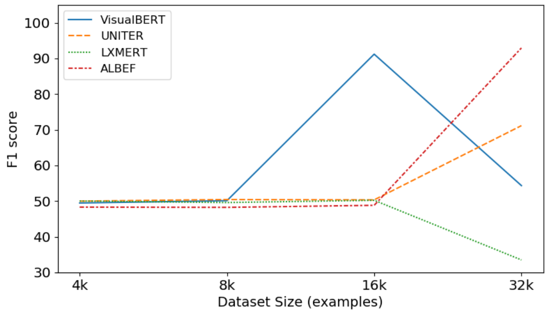
Spatiality. On the spatiality task (Figure 12), in the image-only setting, LXMERT requires the least amount of data to achieve convergence (4k examples), followed by UNITER (8k examples), and VisualBERT (16k examples). ALBEF fails to converge, even on the full 32k dataset. There is a clear advantage in performance of LXMERT and UNITER over VisualBERT and ALBEF.



(a) Image-only setting.



(b) Caption-only setting.

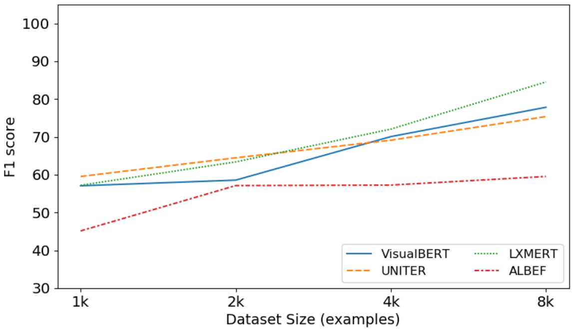


(c) Image+caption setting.

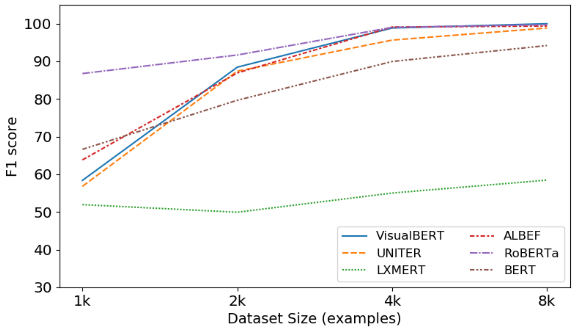
Figure 12: Performance for the spatiality task on the OOD test set in (a) image-only, (b) caption-only and (c) image+caption settings; models trained on increasing subsets with one random seed.

In the caption-only setting, the text-only model RoBERTa performs the best, achieving F_1s close to 100 with 16k training examples. While BERT, UNITER and VisualBERT achieve similar results with 32k training examples, the V+L models are outperformed by BERT when trained on a smaller dataset.

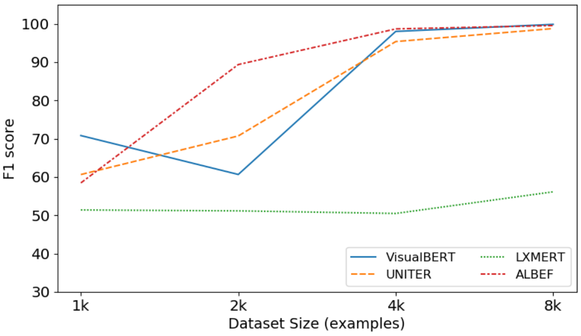
Cardinality. Compared to the spatiality task, more models converged on the cardinality task (Figure 13) with a smaller amount of data (8k examples). In the image-only setting, LXMERT remains the best performing model on the full 8k dataset, but the performance of VisualBERT, UNITER and LXMERT are relatively similar. In the caption-only setting, when trained on a smaller dataset with 1k examples, RoBERTA achieves an F_1 of 86.76, while all other models achieve an F_1 between 55 and 67, except for LXMERT, which fails to achieve



(a) Image-only setting.

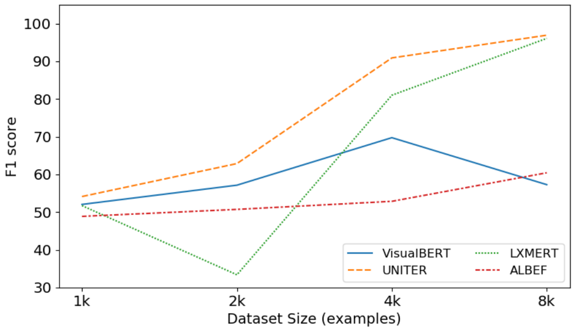


(b) Caption-only setting.

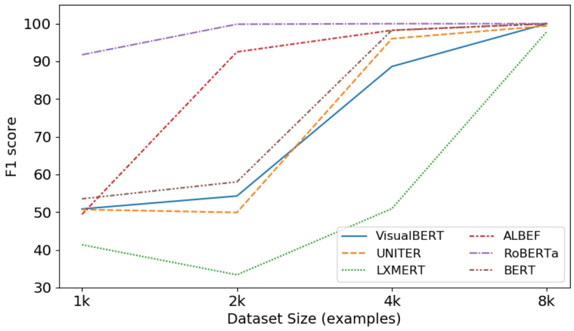


(c) Image+caption setting.

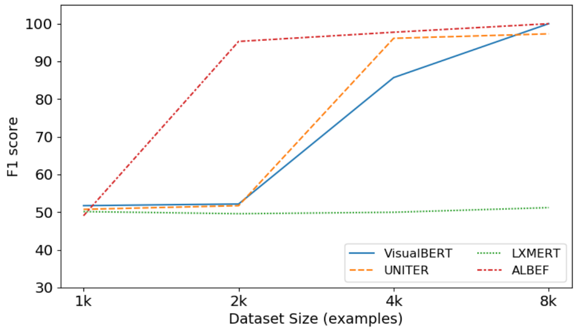
Figure 13: Performance for the cardinality task on the OOD test set in (a) image-only, (b) caption-only and (c) image+caption settings; models trained on increasing subsets with one random seed.



(a) Image-only setting.



(b) Caption-only setting.



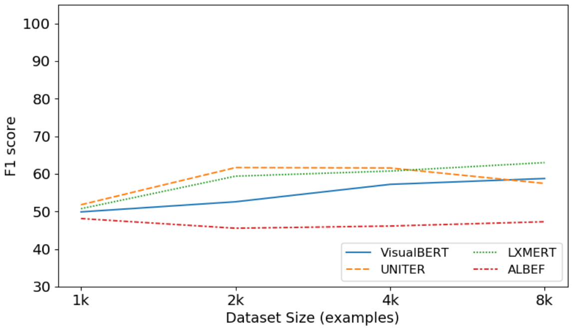
(c) Image+caption setting.

Figure 14: Performance for the quantifiers task on the OOD test set in (a) image-only, (b) caption-only and (c) image+caption settings; models trained on increasing subsets with one random seed.

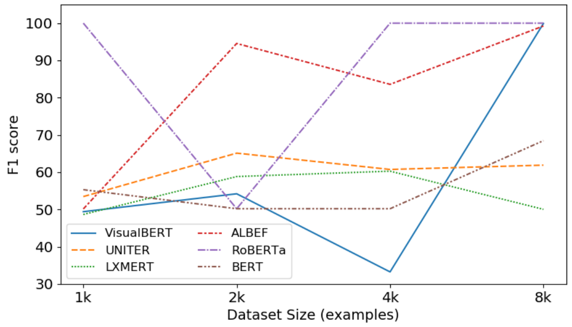
non-random performance. In the image+caption setting, ALBEF seems to be most data efficient, performing the best on a 2k training dataset.

Quantifiers. On the quantifiers task (Figure 14), in the image-only setting, we observe a similar overall trend to the spatiality task, where UNITER and LXMERT significantly outperform the other models. In the caption-only setting, RoBERTa significantly outperforms BERT with limited data (1k examples), and the performance of UNITER and VisualBERT resembles that of BERT. The superior performance of ALBEF on a smaller 2k dataset in both caption-only and image+caption settings is observed again, as on the cardinality task.

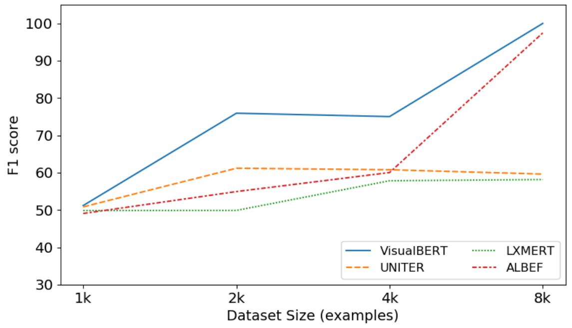
Numerical Comparison. On the numerical comparison task (Figure 15), all models exhibit relatively poor performance on the OOD dataset in the image-only setting, revealing an inability to generalise to unseen number pairs. In the caption-only and image+caption settings, the superior performance of RoBERTa over BERT, and VisualBERT and ALBEF over the other V+L models can be observed, as similarly described for other tasks. The performance of VisualBERT and UNITER is clearly distinguished.



(a) Image-only setting.



(b) Caption-only setting.



(c) Image+caption setting.

Figure 15: Performance for the numerical comparison task on the OOD test set in (a) image-only, (b) caption-only and (c) image+caption settings; models trained on increasing subsets with one random seed.

D Training Duration

We discuss selected runs indicative of the contrast in the number of training steps required by models. From the training loss curves on a single run of training on the spatiality tasks, we can observe a substantial degree of variation in the amount of time each model takes to converge.

The training loss curves in Figure 16 are on the whole indicative of the significant amount of time required by all models except LXMERT to learn the spatiality task. With the notable exception of LXMERT, many models have yet to fully converge by 60 epochs. LXMERT takes fewer than 5 epochs to achieve a training loss close to 0, while completely failing to converge on the caption and image+caption settings. Possible reasons for the faster convergence of LXMERT on the spatiality task include the large size of its pretraining data, and the fact that it was additionally pretrained on a VQA task, unlike the other models. VisualBERT has yet to completely converge after 80 epochs. ALBEF in the image+caption setting and UNITER in the

(c) LXMERT (seed=1)

(d) ALBEF (seed=0)

Figure 17: Training loss curves on cardinality task.

caption setting are representative of successful convergence, which is achieved only after 40 and 60 epochs, respectively.

The variation between models is much less significant on the cardinality dataset, as seen in Figure 17. The training loss curves between the caption-only and image+caption settings are often similar, and also steeper compared to the image-only loss curves, which is reflective of the textual bias of all models towards the caption when both modalities are presented in the image+caption setting. In the image-only setting, most models have yet to fully converge within 80 epochs, in this case, with the exception of VisualBERT. It is notable that the marked advantage of LXMERT in terms of efficiency of training time observed in the spatiality task does not extend to other tasks.

E VOLTA Experiments

From Table 10, we observe that while the performance of all three VOLTA models are similar on the 32k spatiality dataset, VOLTA UNITER significantly outperforms both VOLTA LXMERT and VOLTA VisualBERT on the 8k spatiality dataset. This is in contrast to results on the original models where LXMERT exhibits a clear advantage over the other models and is able to achieve an F_1 score close to 100 on the 8k dataset.

Dataset Size	Model	OOD		InD		# Seeds
		Mean	Stdev.	Mean	Stdev.	
32k	VOLTA LXMERT	99.30	-	99.67	-	1
	VOLTA UNITER	99.67	-	99.88	-	1
	VOLTA VisualBERT	98.31	-	98.92	-	1
	LXMERT	99.46	0.47	99.84	0.13	3
	UNITER	89.67	14.43	88.71	14.58	3
	VisualBERT	65.94	6.63	66.96	6.05	3
8k	VOLTA LXMERT	62.28	3.16	64.17	3.73	3
	VOLTA UNITER	94.46	1.19	93.18	1.50	3
	VOLTA VisualBERT	60.73	2.39	60.69	2.90	3
	LXMERT	99.02	-	99.00	-	1
	UNITER	88.33	-	91.48	-	1
	VisualBERT	49.60	-	49.25	-	1

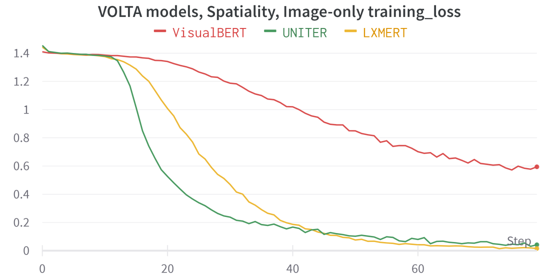
Table 10: Mean F_1 scores of VOLTA and original models trained on spatiality dataset in the image-only setting. Standard deviation is shown where applicable.

Similar findings are observed on the cardinality dataset (Table 11), where VOLTA LXMERT is outperformed by both VOLTA UNITER and VOLTA VisualBERT. The VOLTA LXMERT differs from the original LXMERT in the amount of pretraining data, as well as the use of VQA examples and a downstream VQA objective during pretraining. It can be concluded that LXMERT loses its advantage in the image-only setting when it is pretrained in the same manner as other models.

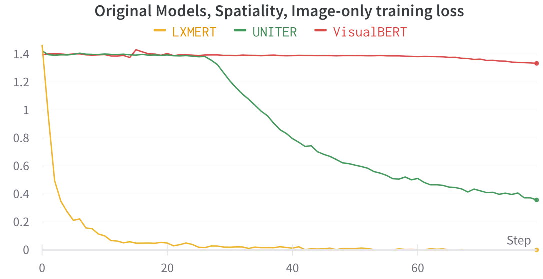
Model	**OOD**		**InD**		**# Seeds**
	Mean	**Stdev.**	**Mean**	**Stdev.**	
VOLTA LXMERT	73.38	0.56	79.30	0.39	3
VOLTA UNITER	85.91	5.13	87.40	3.36	3
VOLTA VisualBERT	81.67	4.46	83.90	1.66	3
LXMERT	82.90	3.86	84.56	2.71	3
UNITER	77.12	5.04	77.03	1.44	3
VisualBERT	77.41	0.61	76.30	0.46	3

Table 11: F_1 scores of VOLTA and original models trained on cardinality dataset in the image-only setting. Standard deviation is shown where applicable.

The difference between VOLTA LXMERT and the original LXMERT can also be clearly observed in the training loss curves in Figure 18, where the original LXMERT is significantly more efficient in terms of number of epochs required for training.



(a) VOLTA models



(b) Original models

Figure 18: Training loss curves on 8k spatiality dataset in the image-only setting.

Furthermore, it is notable that the performance of VisualBERT on the full dataset is significantly improved over the original model. This is likely due to the fact that the VOLTA VisualBERT was pretrained with more data than the original VisualBERT. An additional finding is that VOLTA UNITER outperforms VOLTA VisualBERT and LXMERT.

Finally, the VOLTA models were also used to investigate the comparatively poor performance of the original LXMERT on the caption-only and image+caption settings. As seen in Table 12, all three VOLTA models achieve similar results on the 8k cardinality dataset. Given that all VOLTA models were initialised with BERT weights, this lends support to the idea that the poor performance of LXMERT on textual input is due to the lack of initialisation with BERT weights (Tan and Bansal, 2019).

Model	**OOD**		**InD**		**# Seeds**
	Mean	**Stdev.**	**Mean**	**Stdev.**	
VOLTA LXMERT	97.87	0.85	99.44	0.03	3

Table 13: Mean F_1 scores of models trained in the mixed setting for the four V+L reasoning tasks (**S:** Spatiality, **C:** Cardinality, **Q:** Quantifiers, **N:** Numerical comparison). In parentheses, relative change from performance of models trained on image+caption setting are indicated. Differences larger than +5 are highlighted in green and differences smaller than -5 are highlighted in orange.

F Modal dropout/"mixed" setting

There is a concern that the bimodal presentation of the input in the image+caption setting facilitates overfitting to the textual modality. One way to alleviate the impact of bias towards either modality is by performing dropout of either the image or caption input in a subset of the input, thus introducing some unimodal examples into the image+caption dataset. This technique is inspired by the idea of sensor dropout as described in Liu et al. (2017), where overfitting to specific sensors (modalities) by a multisensor autonomous navigation system is avoided through dropout of features from sensors during training. In the following experiments, we perform dropout at a fixed probability of 25% for both the image and caption modalities. In other words, datasets comprise 50% image+caption, 25% image-only and 25% caption-only input.

Overall, performance of models trained in the mixed setting resembles performance of models trained in the image+caption setting, in that they exhibit a bias towards the textual modality. Performance on the image modality is generally poorer than performance on both caption-only and image+caption test settings (with the exception of LXMERT), and performance on caption-only and image+caption settings are largely similar. Nevertheless, because of the dropout of the caption modality in 25% of the input, the models are forced to also learn to deal with image-only input to some extent, and hence exhibit non-random performance on image-only test data in some cases.

F.1 Comparison against models trained purely on image+caption input

First, we compare the performance of models trained in the mixed setting against those trained in the image+caption setting. The relative difference is shown in brackets in Table 13. In the spatiality task, only UNITER achieves a non-random performance in the image-only setting, while VisualBERT, LXMERT and ALBEF exhibit no significant difference in comparison to the image+caption baseline. On the other tasks, we observe that VisualBERT, UNITER and LXMERT exhibit above random performance in the mixed setting, improving results over the purely image+caption setting.

When models trained in the mixed setting are tested in the caption and image+caption settings, in the majority of cases, there is a small decrease in performance compared to models trained in the purely image+caption setting. The small magnitude of this difference is likely because the models continue to overfit to the caption when both image and caption input is presented, and are deprived of

	ALBEF	-2.75	-5.73	+28.78	-0.61	+5.29	+21.15	3

Table 14: Difference in F_1 scores between models trained on the mixed setting and models trained on subset baseline for the four V+L reasoning tasks (**S:** Spatiality, **C:** Cardinality, **Q:** Quantifiers, **N:** Numerical comparison). Differences larger than +5 are highlighted in green and differences smaller than -5 are highlighted in orange.

the textual information in only 25% of the training data. The magnitude of the difference is larger in the numerical comparison task, where VisualBERT, UNITER and ALBEF exhibit significant decreases in performance on the OOD test set.

There are several exceptions to the overall trend. Firstly, unlike the other models, UNITER seems to have overfitted to the image modality instead of the caption modality in the spatiality task. Second, LXMERT exhibits an improvement in performance in both the caption and image+caption settings on the cardinality and quantifier datasets.

F.2 Comparison against models trained on subset of data

Next, we compare the results from the mixed setting against a baseline if the mixed dataset were separated into datasets with fully unimodal or bimodal examples. For instance, the 32k mixed dataset on the spatiality task can be compared against baseline datasets of i) 16k bimodal image+caption examples, ii) 8k image-only examples and iii) 8k caption-only examples. Specifically, we ask if there is a performance benefit to training models on a single mixed dataset which combine these subsets together, as opposed to training models on each dataset separately.

This baseline is obtained from training on a randomly sampled subset of the full dataset. As previously explained, these experiments on subsets of the full dataset were conducted only on a single random seed, due to resource limitations. In Table 14, we observe that the performance of models trained on the mixed dataset indeed outperforms models trained on only the caption-only and image+caption subset of the data. This result is not unexpected, given that it is known that models exploit the caption present in the image+caption examples.

However, it is less clear from the results whether the models are able to exploit the additional image information present in the image+caption examples in the mixed setting to improve performance on the image-only test examples. In particular, results from the quantifier task, as well as the results of VisualBERT on the OOD test set seem suggestive of some advantage accorded to models by the additional image+caption data. Nevertheless, there are also results suggestive of the opposite finding, particularly on the spatiality task, where the presence of caption-only and image+caption examples degrades performance in the image-only setting.

We conclude that the technique of dropping out the input from some modalities helps to ameliorate the extent of the textual bias in the image+caption setting to some extent, although the overall textual bias of models remains.

G Error analysis

In section 5.4, we described our error analysis of the spatiality and cardinality tasks. In this appendix section, we include additional details on the cardinality task and present our error analysis on the quantifiers and numerical comparison tasks.

G.1 Cardinality

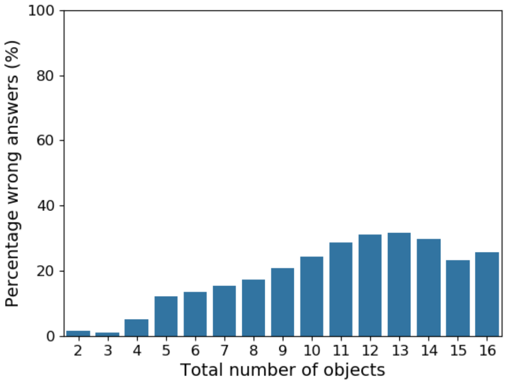

Figure 19: Percentage of incorrect answers by total number of objects. VisualBERT trained on cardinality task, image-only setting, tested on OOD test set. (F_1=77.84; seed=0)

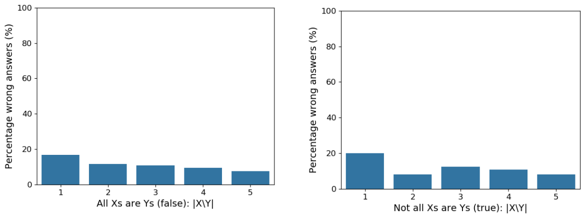
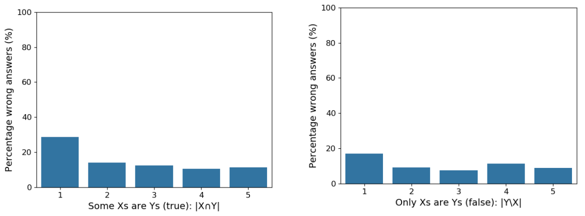
As noted in section 5.4, a significant factor is the total number of objects in the image, inclusive of distractors. Figure 19 shows an increasing percentage of wrong answers as the total number of objects increases. We also notice a slight decrease in wrong answers when the number of objects exceeds 13. This can be attributed to the decreasing likelihood of correct answers having smaller numbers.

G.2 Quantifiers

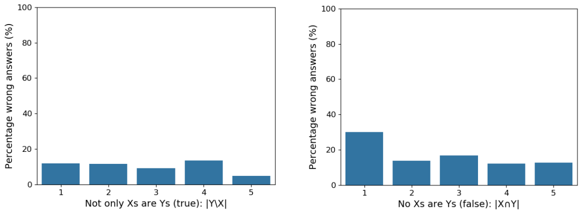
Figure 20 plots the percentage of wrong answers against specific values relevant to the particular quantifiers of VisualBERT on the InD test set in the image-only setting. Similar patterns are also observed across other models in runs with moderate performance, although moderate performance in some cases may be due to failure to learn a subset of quantifiers. For instance, Figure 20a shows the percentage of wrong answers against the number of Xs which are not Ys, given all *false* queries of the form “All Xs are Ys”. The results show that the more Xs which are not Ys, the less likely it is for the model to incorrectly predict the query to be true. In Figure 20c, given all *true* queries of the form “Some Xs are Ys”, the more objects which are both X and Y, the less likely it is for the model to incorrectly predict the query to be false.



(a) All Xs are Ys (false): $|X \setminus Y|$ (b) Not all Xs are Ys (true): $|X \setminus Y|$



(c) Some Xs are Ys (true): $|X \cap Y|$ (d) Only Xs are Ys (false): $|Y \setminus X|$



(e) Not only Xs are Ys (true): $|Y \setminus X|$ (f) No Xs are Ys (false): $|X \cap Y|$

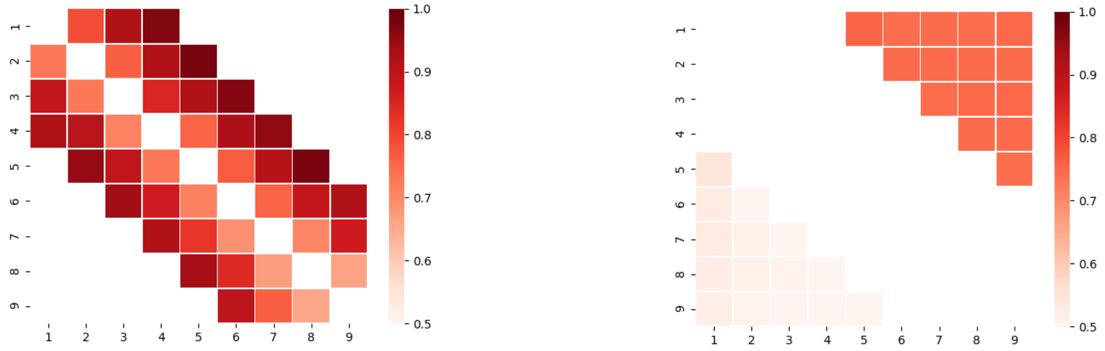
Figure 20: Percentage of wrong answers on quantifier-specific values. VisualBERT, image-only setting on InD test set. (F_1=87.98; seed=0)

Although the trend is not always robust across all the quantifiers, this overall pattern of errors made by models is not unexpected.

G.3 Numerical comparison

The plot in Figure 21 reveals a clear trend where models are more accurate on pairs where the magnitude of $|x - y|$ (i.e. the difference between the numerals being compared) is larger for the InD test set. However, the more significant finding is that the numerical comparison task was the only task which exhibited significant differences in performance between the InD and OOD datasets, due to an inability to generalise to unseen pairs particularly in the image-only setting, but also the caption-only setting in the case of UNITER and LXMERT.

In Figure 21, we observe a pattern where the model succeeds only on OOD queries where the number of the first object exceeds that of the second object (cells on the upper right are darker than cells on the lower left). This asymmetry is also observed to some extent in Figure 22. This pat-



(a) LXMERT, image-only InD. (F_1=84.45; seed=0)

(b) LXMERT, image-only OOD. (F_1=63.01; seed=0)

Figure 21: Results of LXMERT, image-only setting on specific $< x, y >$ pairs.

(a) UNITER, caption-only InD. (F_1=99.66; seed=0)

(b) UNITER, caption-only OOD. (F_1=61.90; seed=0)

Figure 22: Results of UNITER, caption-only setting on specific $< x, y >$ pairs.

tern does not result from any simple strategy of providing the same answer (true/false) given a relation in the query (*more*/*fewer*). A similar pattern is observed even when subsetting the OOD test set into queries with either the *more* or *fewer* relation in both cases. The overall finding is that models are able to generalise to unseen number pairs by constructing an implicit numeral scale, but only to a limited extent.

Paraphrase Acquisition from Image Captions

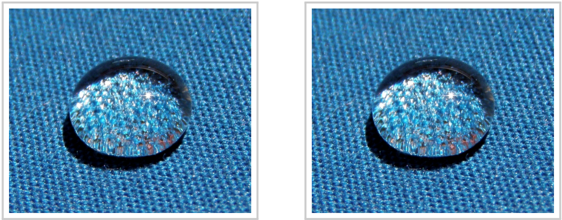
Abstract

We propose to use image captions from the Web as a previously underutilized resource for paraphrases (i.e., texts with the same “message”) and to create and analyze a corresponding dataset. When an image is reused on the Web, an original caption is often assigned. We hypothesize that different captions for the same image naturally form a set of mutual paraphrases. To demonstrate the suitability of this idea, we analyze captions in the English Wikipedia, where editors frequently relabel the same image for different articles. The paper introduces the underlying mining technology, the resulting Wikipedia-IPC dataset, and compares known paraphrase corpora with respect to their *syntactic and semantic paraphrase similarity* to our new resource. In this context, we introduce characteristic maps along the two similarity dimensions to identify the style of paraphrases coming from different sources. An annotation study demonstrates the high reliability of the algorithmically determined characteristic maps.

1 Introduction

Two texts that convey “semantically equivalent information” via a different wording are called *paraphrases*, or said to *be in a paraphrase relation*. A variety of natural language processing tasks have been approached by using paraphrase resources or paraphrase generation and detection algorithms: textual entailment (Dagan et al., 2013; Marelli et al., 2014; Izadinia et al., 2015), semantic similarity (Agirre et al., 2015; Li and Srikumar, 2016), machine translation (Mehdizadeh Seraj et al., 2015), text reformatting (Stein et al., 2014), or question answering (Fader et al., 2013). Paraphrasing can help to improve sentence compression and text summarization (Cordeiro et al., 2007) as well as natural language understanding (Ganitkevitch, 2013).

To tackle the task of paraphrasing, large amounts of paraphrases usually are helpful. Hence, paraphrase acquisition has gained popularity over the recent years and paraphrase datasets have been created manually, (semi-)automatically, and via distant supervision resulting in different levels of “naturalness”, diversity (topic, genre, language, etc.), granularity (word, sentence, or passage level), and scale (see Section 2 for details). For model training, Zhang et al. (2019b) strongly emphasize the importance of negative examples that are lexically similar but semantically inappropriate as paraphrases.



Flourine-containing durable water repellent makes a fabric water-resistant.

Water bead on a fabric that has been made non-wetting by chemical treatment.

Figure 1: Paraphrased captions of an image in the Wikipedia pages ‘Durable water repellent’ (left) and ‘Wetting’ (right).

With image captions, we propose an as yet underutilized source of natural paraphrases. The underlying hypothesis is that different captions for the same image form paraphrase candidates because the captions may describe the same image content. We study the phenomenon of ‘image reuse and captioning’ in the English Wikipedia (Figure 1 shows an example) by mining captions of images that have been reused. Carefully optimized filtering heuristics for captions and associated images yield a large set of captions, which we analyze qualitatively and quantitatively for their usefulness as paraphrases. The set of mined image captions forms our Wikipedia-IPC dataset,[1,2] which contains caption pairs as paraphrases along with their image source three different quality levels; 30,237 caption pairs are gold-, 229,877 are silver-, and 656,560 are bronze-quality paraphrase candidates.

The X-38 CRV prototype makes a gentle lakebed landing at the end of a July 1999 test flight at the Dryden Flight Research Center with a fully deployed parafoil.  Tylosaurus proriger mounted skeleton in the Rocky Mountain Dinosaur Resource Center in Woodland Park, Colorado.

Table 1: Example Wikipedia images and captions. Following Bär (2008), we categorize images by content as icons, symbols, pictograms (left), or pictures, graphics, etc. (middle and right). Pictures, graphics, etc. can be further subdivided by the purpose they serve in a text as either ideological (i.e., to convey sentiment; middle) or pragmatic (i.e., to explain and specify; right).

The usefulness of an image caption as a paraphrase depends strongly on its corresponding image. Table 1 shows example image–caption pairs from Wikipedia, organized by content and purpose classes. Icons, symbols, and pictograms rarely have captions that are useful as paraphrase candidates, while for pictures, graphics, paintings, maps, and schematics, the purpose of the image in a page is crucial. In this regard, "ideological purpose" means that the image is mainly used for aesthetic reasons, resulting in captions that do not describe the shown content but rather some context, atmosphere, or sentiment. By contrast, explanatory or pragmatic images try to illustrate or transport knowledge. Their captions describe and explain (parts of) the visual content and form a particularly promising source of natural paraphrases.

2 Related Work

Paraphrase Corpora To collect high-quality paraphrases, some studies applied manual acquisition. For instance, for the Webis-CPC-11 (Burrows et al., 2013), crowdworkers were asked to rewrite one of 4,096 passage-level literature excerpts *"so that the rewritten version has the same meaning, but a completely different wording and phrasing."* The resulting 7,859 pairs form one of the few passage-level paraphrase corpora. Later, also Xu et al. (2014) crowdsourced sentences with the same meaning as a shown sentence from some tweet for their PIT-2015 dataset (18,862 sentence pairs, 5,641 considered paraphrases).

Since crowdsourcing is costly to scale, automatic paraphrase acquisition often simply relies on machine translation. For instance, Zhang et al. (2019b) scrambled words and forth-and-back translated sentences to obtain a gold dataset of 108,463 paraphrase pairs and a silver dataset of 656,000 pairs. Also, the ParaNMT-50M dataset (Wieting and Gimpel, 2018) with 30 million "strong" paraphrases (assessment by the authors), was created by translating sentences from English-Czech parallel pairs.

Trying to combine the advantages of manual and automatic methods (quality vs. scale), most paraphrase acquisition methods use distant supervision. For instance, Barzilay and McKeown (2001) suggested aligned sentences from monolingual parallel corpora as paraphrases—an idea later used by Dolan and Brockett (2005) to create the Microsoft Research Paraphrase Corpus (5,801 manually annotated sentence pairs, 3,900 considered paraphrases). Instead of monolingual sources, Bannard and Callison-Burch (2005) exploited bilingual parallel corpora by aligning phrases that translate into the same pivot phrase in another language. Based on this idea, the English/Spanish PPDB 1.0 (Ganitkevitch et al., 2013) and its extension to 23 additional languages (Ganitkevitch and Callison-Burch, 2014) with an English portion of 7.6 million lexical (i.e., synonymous) and 68.4 million phrasal paraphrases form the biggest paraphrase collection.

Translation pivoting was also used for the Opusparcus (Creutz, 2018) and TaPaCo (Scherrer, 2020) datasets. Opusparcus was created from movie and TV subtitles in six European languages. The automatically filtered training set contains 7 million English sentence and phrase pairs ("good" or "mostly good" paraphrases according to the authors) while the manually labeled development and test sets contain 3,088 pairs (1,997 paraphrases). Analogously, TaPaCo is created from the multilingual Tatoeba data, a crowdsourced collection of sentence translations.[3] The English part of TaPaCo contains 158,000 sentences that are clustered in 62,000 paraphrase sets. Instead of translation, Lan et al. (2017) used a different pivoting method for their Twitter News URL Corpus. They mined tweets that contain the same hyperlink and labeled 51,524 respective sentence pairs via crowdsourcing. Our paraphrase acquisition methodology is also based on a pivoting technique, but the pivot media are images.

Captions and Paraphrases Our idea to use images from the web as pivots for distant supervision paraphrase acquisition is inspired by studies on crowdsourced caption datasets. For instance, Marelli et al. (2014) extracted a collection of 9,840 paraphrase candidates from the Flickr 8k dataset (Rashtchian et al., 2010) of 8,000 images each with 5 crowdsourced captions and the MSR Video Paraphrase Corpus (Chen and Dolan, 2011) of 2,000 short video clips with 85,000 English crowdsourced descriptions of what can be seen. The larger MSCOCO dataset (Lin et al., 2014) with 120,000 images each having 5 crowdsourced captions was even already used to train a neural paraphrase generation model (Prakash et al., 2016). Interestingly, the existing caption-paraphrasing datasets were all created in dedicated crowdsourcing processes that are costly to scale. We are the first to explore mining "real" image captions from the web (i.e., not crowdsourced) as a paraphrase acquisition method.

Dump	**Pages**	**Revisions**	**Images**	**Image refs.**
Small	22,311,116	22,311,116	4,508,808	7,384,368
Full	54,898,564	987,527,838	11,183,853	3,629,447,851

Table 2: Image mining statistics of Wikipedia dumps. "*Small*" refers to all articles, templates, media descriptions, and primary meta-pages without edit histories, whereas "*Full*" includes edit histories.

3 Caption-Based Paraphrase Acquisition

We collect captions of images that are used on the English Wikipedia, grouping those captions that describe the same image. This section outlines the mining and filtering steps.

Data Source: Wikipedia As a source for paraphrases, we use captions from Wikipedia articles. Wikipedia is a collection of well-formulated, human-written text that is constantly being improved by a community of volunteer editors. The guidelines for the use of images on Wikipedia encourage editors to write a caption to explain the relevance of an image in a particular context, resulting in 60% of images having a caption.

We use the English Wikipedia for the paraphrase acquisition (Wikimedia, September 1st, 2022).[4] Two versions of Wikipedia dumps are available for the paraphrase acquisition—a reduced dataset with all articles, templates, media descriptions, and primary meta pages and a full-size dump with all pages, including their full revision history. Table 2 compares the number of pages, revisions, images, and image references between these two datasets.

Table 3: Effects of the filtering steps in the paraphrase acquisition pipeline on the number of images, references, captions, and paraphrase candidates mined from the reduced Wikipedia dump. Images that have been referenced at least 2 or 5 times are called "Refs. $\geq$ 2" and "Refs. $\geq$ 5", respectively. μ_{img} describes the average number of references per img.

Image and Caption Mining Wikimedia Commons is a service which hosts free-to-use images and other media files which are used across all Wikimedia projects (like Wikipedia). The markup language for Wikipedia articles, Wikitext, features the *extended image syntax*, which allows editors to insert images into Wikipedia pages from Wikimedia Commons. The specified image is referenced by its unique identifier in Wikimedia Commons, which is a concatenation of a generic media type prefix (e.g., Image) followed by a colon and its (also unique) filename. The extended image syntax allows the specification of style properties, meta-information, and a caption. If a caption is present, we store it along the image reference.

However, not all images in Wikipedia pages are included by the use of the extended image syntax. Wikitext allows the use of (user-created) style templates, often with inconsistent image reference syntax. *Infoboxes* on Wikipedia are template-based tables placed at the beginning of an article that contain a collection of the most important information about its subject. They are commonly used in Wikipedia—20% of all the pages contain one. Important to us is that one third of the infoboxes contain one or even multiple images, and about 56% of these images have a caption. Wikitext represents infoboxes as lists of key-value pairs whose sets of allowed keys and values are defined in templates. There are close to 2,000 different infobox templates based on semantic categories of an article. The responsible keyword for image referencing varies among these templates, and to cover all cases is not feasible. Thus, we identified the most commonly used keyword which is "image", followed by an optional counter for multiple images. These captions are mined as individual image–caption pairs. No Wikitext parser other than Wikipedia's own implementation (which is monolithically intertwined with Wikipedia's software stack) is capable of reliably parsing all the different template syntaxes. Our heuristic for image mining from infoboxes yields an increase of 24% of image references.

In addition to a caption, an image reference may also have an *alternative text* that accurately describes the visual content of an image. Alternative texts are intended to serve as a substitute in case the user is visually impaired, or the image cannot be displayed correctly. According to Wikipedia's policy, all images are obliged to have an alternative text, except those with a purely decorative purpose. We extract them as paraphrase candidates, too. Altogether, 355 million caption pairs are mined that we subsequently filter as follows (see Table 3).

Image Filter A necessary condition for an image to be useful is that it has been referenced at least twice, so we discard all image captions whose images have only one reference. As illustrated in Table 1, the likelihood of image–caption pairs to form a pair of paraphrase candidates depends on the image's content and purpose. A useful feature to discard icons, symbols, and pictograms is the number of references. These images occur more frequently than any other kind of image. To discard them, we set an upper bound of 10 references per image for the corresponding image–caption pairs to be retained. After these steps, 1.35 million image–caption pairs remain (see Table 3).

Caption Filter The selection of caption pairs has a substantial effect on the quality of the acquired paraphrases. As a consequence, all mined image captions pass through various carefully optimized pre-processing and filtering steps. The pre-processing pipeline comprises cleansing of Wikitext markup, removal of line-breaks, and whitespace normalization (e.g., removal of sequences).

To discard trivial image captions, we determined a lower bound for the caption length through manual observation and found that most captions that represent a phrasal expression contain at least 6 words. Captions with less than that usually comprise the name of an entity that can be seen in the image and are consequently discarded.

Through manual review, we identified three common practices for writing image captions with respect to style and syntax. Captions on Wikipedia are either: (1) simple noun phrases (e.g., "*Last Supper by Dieric Bouts*"), (2) sentence fragments containing a verb phrase (e.g., "*Last Supper drawn by Dieric Bouts*"), or (3) grammatically correct sentences (e.g., "*The Last Supper was drawn by Dieric Bouts*"). The latter two caption types are more likely to be a source of high-quality paraphrases, whereas grammatical sentences are most desirable. To discard noun phrases, it is sufficient to exclude captions that do not contain verbs. The detection of proper sentences is far more difficult.

Grammaticality and sentence fragment detection is a broad research field and most state-of-the-art methods use neural models. However, to ensure high precision in the resulting paraphrase dataset, we resorted to a more efficient and effective heuristic that is well suited for captions: rule-based sentence classification. Since the authors of existing rule-based grammar checkers rarely publish their full rule sets, we create our own rules to identify grammatical sentences. To find suitable rules, we take 500 and 100 random captions from Wikipedia to create a training and test set, respectively. An expert with 20 years of experience in the field of linguistics manually annotated the 600 captions to determine whether they are sentences or sentence fragments. Based on the 500 annotations from the training set and the associated automatically assigned POS tags, the expert manually created a set of rules to distinguish fragments from sentences.

Table 4 shows our sentence classification rules based on POS tags from Penn Treebank (Taylor et al., 2003). To be considered a sentence, a caption must satisfy one of these rules. Which rule should be applied is determined by its premises, which are tested in the order given. The first rule targets sentences that contain modals. A modal must be directly followed by an optional adverb and an obligatory verb in the base form. A sentence that would be correctly classified as such is "*Last Supper might be drawn by Dieric Bouts*". The second and third rules deal with subordinate clauses at the end of a sentence. These rules state that an inflected verb must precede a subordinating conjunction. For example, "*Last Supper was drawn by Dieric Bouts which is an exceptional artwork*" would be correctly classified as a sentence under Rule 2. Rule 4 requires that sentences contain an inflected verb and is applied when no other premise is satisfied. "*Dieric Bouts drew the Last Supper*" is a correctly classified sentence according to Rule 4.

<table>
<tr><th>Rule</th><th>Premise</th><th>Pattern</th></tr>
<tr><td>1</td><td>$.^{*}$MD$.^{*}$</td><td>$.^{*}$ MD RB? VB $.^{*}$</td></tr>
<tr><td>2</td><td>$.^{*}$ (WDT|WP|WRB) $.^{*}$</td><td>$[\neg($WDT|WP|WRB$)]^{*}$ (VBP|VBZ|VBD) $.^{*}$</td></tr>
<tr><td>3</td><td>$.^{*}$IN$.^{*}$</td><td>$[\neg$IN$]^{*}$ (VBP|VBZ|VBD) $.^{*}$</td></tr>
<tr><td>4</td><td>$\perp$</td><td>$.^{*}$ (VBP|VBZ|VBD) $.^{*}$</td></tr>
</table>

Table 4: POS-based rules for sentence classification.

Our heuristic sentence classifier performs satisfactorily with a precision of 94% and a recall of 79%, evaluated on the 100 annotated captions in the test set. Problematic cases are verbs that have identical base and inflected forms, which are often mislabeled by the POS tagger of the Stanford CoreNLP toolkit (Manning et al., 2014).

After application of these caption filters, in total 44,005 image–caption pairs remain (see Table 3).

Image Equivalence Wikipedia hosts all of its media files on Wikimedia Commons, and therefore we can identify duplicate images without requiring physical copies of an image. All images have a unique name that, along with a file type prefix, points to the URI of their description page on Wikimedia Commons. When an editor of a Wikipedia article wants to include an image from Wikimedia Commons, the image is referenced by this URI. Therefore, this URI is the criterion for deciding whether images are equivalent. All file type prefixes are derived from the common "File" prefix. Therefore, all image prefixes are normalized to "File" prefixes to detect image duplicates with inconsistent prefix usage.

Paraphrase Construction All references that refer to the same image are grouped into clusters. Paraphrase candidates are constructed by forming all possible unique pairs of captions of the same caption type (i.e., alternative text or regular caption) within each cluster. Combining regular captions and alternative texts rarely results in meaningful paraphrases due to their different purposes. Alternative texts describe the visual content of an image, while regular captions describe the image in context and from the perspective of an article.

Of these paraphrase candidates, we discard caption pairs that are exact or near-duplicates. We consider a caption pair to be a near-duplicate if it differs only by punctuation, capitalization, or whitespaces. (Near-)duplicates of captions are artifacts of reusing centrally hosted captions for the same image in different articles on Wikipedia. Removing duplicates results in 30,237 caption pairs as paraphrase candidates (see Table 3).

Corpus Construction We create three individual paraphrase datasets with different quality levels which we assign based on the used Wikipedia dump and the set of applied filtering heuristics.

Gold-quality paraphrase candidates are pairs of acquired image captions from the reduced Wikipedia dump which are classified as (sequences of) sentences by our rule-based classifier. Table 3 shows the loss of images, references, captions, and paraphrase candidates due to the application of our filter heuristics. In total, 30,237 gold-quality paraphrase candidates were acquired with our pipeline.

The most "aggressive" filter heuristic in the pipeline is the sentence classification of image captions. It discards 87% of the mined image captions. Since phrases can also be in a paraphrase relation, we construct a silver-quality paraphrase dataset by exchanging the sentence classifier for a heuristic that requires image captions to contain a verb. This heuristic excludes 50% of image captions for the paraphrase acquisition. This altered pipeline mined 229,877 silver-quality paraphrase candidates.

For the bronze-quality paraphrase dataset, we collect as many reasonable caption-pairs as possible, using the full Wikipedia dump with edit history as source for the paraphrase acquisition. We set the upper bound of allowed number of references per image to 18, the average number of revisions per page. Thus, an image can be referenced at most 180 times. The verb heuristic is applied. This yields 656,560 bronze-quality paraphrase candidates.

4 Corpus Analysis and Evaluation

We analyze and evaluate our paraphrase corpus based on the quantification of paraphrase similarity, for which we select well-known syntactic and semantic measures, and compare our corpus with five state-of-the-art paraphrase and three image–caption corpora from the literature. Therefore, we propose a new measure $\Delta_{\text{sem,syn}}$ that measures paraphrase sophistication based on the difference of semantic and syntactic similarities. To validate the proposed measure we analyze the correlation between human judgments and automatically computed semantic and syntactic similarities.

Analyzing Paraphrase Similarity

According to Wahle et al. (2022), high-quality paraphrases are texts pairs with high semantic similarity and high lexical and syntactic diversity, as paraphrasing models trained on linguistically diverse examples tend to be more robust (Qian et al., 2019). Similarly, Niu et al. (2021) measures paraphrase quality by rewarding high semantic similarity while penalizing high lexical overlap. The relation between semantic and syntactic similarity characterizes the "sophistication" of a paraphrase. Based on this assumption, we propose $\Delta_{\text{sem,syn}}$ to quantify the sophistication of paraphrases. $\Delta_{\text{sem,syn}}$ computes the average difference between the average semantic and syntactic similarity scores.

Similarity Measures To measure syntactic similarities between pairs of paraphrases, we choose ROUGE-1, ROUGE-L (Lin, 2004), and BLEU (Papineni et al., 2002). ROUGE-1 assesses unigram overlap, ROUGE-L computes lexical similarity based on the longest-common-subsequence paradigm, and BLEU is computed up to 4-grams to quantify structural similarity. All three measures have been proposed and evaluated for paraphrase generation and acquisition.

The computation of semantic similarity is done by transformer-based models. One of our three measures is BERTScore (Zhang et al., 2019a) since it was found to correlate well with human judgments for the task of automatic image captioning. The second one is the cosine similarity of dense vector representations computed by a BERT-based Sentence Transformer (Reimers and Gurevych, 2019). It proved to be decisive at Sent-Eval on the MSRPC. The third one is Word Mover Distance (Kusner et al., 2015) which computes the minimum amount of distance that embedded words of a text need to

	Syntactic similarity				Semantic similarity				
Image Caption Pairs	ROUGE-1	ROUGE-L	BLEU	Avg.	WMS	BERT	ST	Avg.	$\Delta_{\text{sem,syn}}$
A1: An Easter postcard from 1907 depicting a rabbit. **A2**: A 1907 postcard featuring the Easter Bunny.	0.53	0.13	0.14	0.27	0.76	0.76	0.90	0.81	0.54
B1: Twelfth century illustration of a man digging. **B2**: An English serf at work digging, c. 1170.	0.13	0.13	0.10	0.12	0.51	0.47	0.83	0.60	0.48
C1: Troops clearing rubble after the May air raid on Belfast. **C2**: Soldiers clearing rubble after the May air raid on Belfast.	0.90	0.90	0.99	0.93	0.92	0.89	0.98	0.93	0.00
D1: System of a Down is composed of four Armenian-Americans. **D2**: Dolmayan drumming with System of a Down in 2011.	0.42	0.42	0.33	0.39	0.50	0.07	0.32	0.30	-0.09

Table 5: Examples from the Wikipedia-IPC dataset with particularly high and low $\Delta_{\text{sem,syn}}$. Caption pairs with high $\Delta_{\text{sem,syn}}$ are structurally and lexically diverse while maintainig high levels of semantic similarity. Caption pairs with low $\Delta_{\text{sem,syn}}$ are either semantically dissimilar or have a high degree of lexical overlap.

"travel" to reach the embedded words of another text. We use the inversion of this measure as a Word Mover-based similarity score (WMS). All transformer-based models were applied with default hyperparameter configurations using a single NVIDIA A100 Tensor Core GPU. We normalize all the syntactic and semantic similarity measures to a scale from zero to one before we compute the average syntactic and semantic similarity.

Table 5 shows particularly sophisticated and unsophisticated caption pairs as paraphrases quantified by $\Delta_{\text{sem,syn}}$ from the Wikipedia-IPC (silver quality). Caption A1 is a paraphrase of A2 with a significantly different structure and sufficiently high lexical diversity. There is some unigram overlap, which causes the ROUGE-1 score to be comparatively high, since these captions are quite short. Due to the high semantic similarity of A1 and A2 these mutual paraphrases score high in the $\Delta_{\text{sem,syn}}$ measure. B1 and B2 have almost no words in common, but they are nevertheless semantically close. One semantic difference is that an "English serf" is a different concept than "a man" is, which could be the reason for the comparatively lower semantic similarity. However, the semantic similarity is high enough to yield a high $\Delta_{\text{sem,syn}}$. In (C1, C2) and (D1, D2) we see caption pairs that do not qualify as "good" paraphrases for two different reasons. In C2, a single word is replaced by a synonym in C1 and therefore has almost identical wording to C1. Although D1 and D2 are captions that both refer to the band "System of a Down", they describe entirely different aspects, which is reflected in the semantic similarity scores. Therefore, both pairs (C1, C2) and (D1, D2) receive a low $\Delta_{\text{sem,syn}}$ value.

Syntax:	**ROUGE-1**	**ROUGE-L**	**BLEU**	**Average**
r	0.78	0.77	0.70	0.79

Semantics:	**WMS**	**BERT**	**ST**	**Average**
r	0.59	0.70	0.78	0.76

Table 6: Top: Pearson correlation between manual judgements of syntactic similarity and the measures ROUGE-1, ROUGE-L, BLEU, and their average. Bottom: Pearson correlation between manual judgements of semantic similarity and the measures Word Mover Score (WMS), BERT-Score (BERT), Sentence Transformer (ST), and their average.

Manual Similarity Judgments In order to investigate whether the chosen similarity measures accurately quantify syntactic and semantic similarity, we conduct a manual annotation study to measure the correlation between the measures and human similarity ratings. For that purpose, we sampled 100 paraphrases from each of the three datasets–Wikipedia-IPC, MSRPC, and TaPaCo. We draw paraphrase examples with a length of 10 to 30 words stratified by their $\Delta_{\text{sem,syn}}$ distribution in their corresponding datasets. Four expert annotators with at least six years of experience rate semantic and syntactic similarity of all the 300 examples on a 5-point Likert scale.

Figure 2 shows the distribution of semantic and syntactic similarities of the median rating from the annotation study. These figures show that the semantic and syntactic similarities of the examples from the three different datasets are uniquely distributed. Examples from the TaPaCo corpus are pairs with subtle differences at the syntactic level that ultimately result in minor semantic differ-

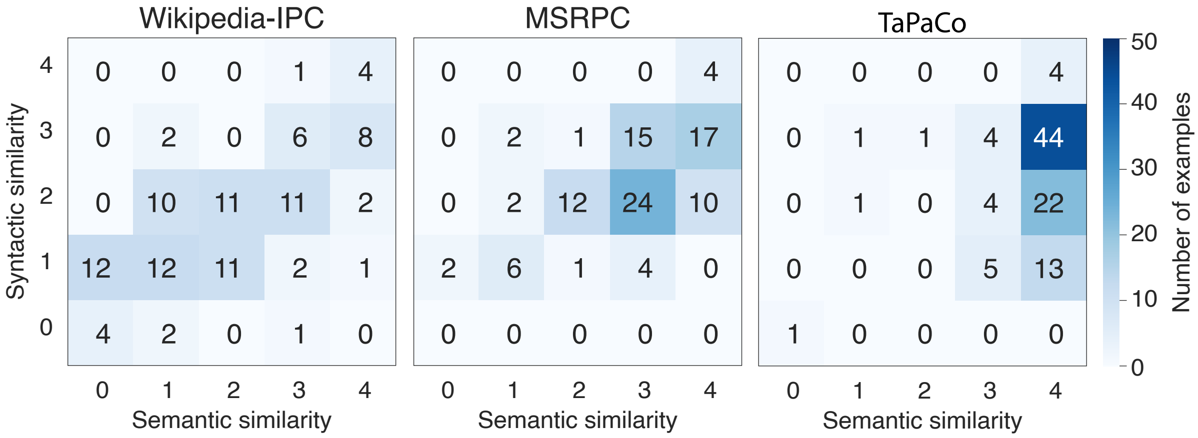

Figure 2: Distribution of semantic and syntactic similarity (characteristic map) for three datasets at sample size 100 for paraphrases with a length between 10 and 30 words. Among others, it can be seen that the TaPaCo corpus comprises paraphrases that result from subtle and minor changes within a paraphrase's sentence pairs (44 x syn-4/sem-3), while Wikipedia-IPC shows a more uniform distribution along the diagonal syn-0/sem-0…syn-4/sem-4.

Table 7: Comparison of syntactic similarity (measured as the average of ROUGE-1, ROUGE-L, and BLEU) and paraphrase semantic similarity (measured as the average of BERTScore, Sentence Transformer (ST) and Word Mover Score (WMS)) of semantically similar examples (Sentence Transformer $>$ 0.8) from state-of-the-art paraphrase corpora, image caption corpora, and the new silver-quality Wikipedia-IPC. "Type" classifies the acquisition method in caption (C), automatically generated (G), and human-written (H) (e.g., acquired via crowd-sourcing).

ences. In contrast, examples from the Wikipedia-IPC (and MSRPC to some extent) are more evenly distributed along the diagonal syn-0/sem-0, …, syn-4/sem-4. While Wikipedia-IPC has examples from all semantic similarity levels, semantic similarity is higher among examples from the MSRPC.

To justify the choice of the semantic and syntactic similarity measures, we compute Pearson correlation coefficients with manual similarity judgments. Table 6 shows high correlation values for syntactic and semantic similarity ratings, which renders our measures well suited for the given task.

Quantitative Similarity Analysis In the paraphrase literature, authors usually require pairs of texts to have varying degrees of semantic similarity to consider them paraphrases of each other. The choice of a "semantic threshold" drastically affects the distribution of syntactic and semantic similarities of paraphrases within a dataset. To standardize the decision criteria for paraphrases, we manually set a semantic threshold that allows us to comparably evaluate paraphrases from each dataset.

We choose the semantic similarity score from the Sentence Transformer as the decision criterion for the subset of paraphrases under consideration because it has the highest correlation with human ratings of semantic similarity. To find a reliable threshold, we analyze the distributions of Sentence Transformer scores of paraphrases and non-paraphrases within the MSRPC and found that a threshold of 0.8

correctly classifies paraphrases with a precision and recall of 82% and 77%, respectively.

Table 7 shows the results of the comparison of syntactic and semantic similarities of paraphrase pairs with a high semantic similarity (ST > 0.8) grouped by type which is either image caption (C), automatically generated (G), or human-written (H). f calculates the frequency of text pairs that exceeds the semantic threshold of 0.8 relative to all examples in the dataset while $\Delta_{\text{sem,syn}}$ computes the average difference between the average semantic and syntactic similarity scores.

The high syntactic and semantic similarities of the examples from the PAWS dataset are striking. PAWS was designed as a benchmark corpus for paraphrase detection and contains lexically similar text pairs with subtle semantic inconsistencies that are difficult to distinguish from actual paraphrases. The high ROUGE-1 value of 94% with a low standard derivation of 0.03 translates to an almost identical wording. Hence, it is no surprise that the $\Delta_{\text{sem,syn}}$ is the lowest among all datasets.

From the gold and silver quality proportions of the Wikipedia-IPC, 34% and 29% of the examples exceed the semantic threshold, respectively. These rates are in line with those of the other caption corpora studied. Furthermore, we find that all caption datasets have similar overall syntactic and semantic similarities. However, the caption pairs from the Wikipedia-IPC tend to have higher syntactic similarity. We suspect that this observation is due to Wikipedia's caption reuse policy, which allows editors to use slightly modified existing captions rather than inventing a new text. However, the sufficiently large $\Delta_{\text{sem,syn}}$ of the Wikipedia-IPC, which is on par with the commonly used MSRPC, and larger than that of the other caption corpora strongly suggests the suitability of image captions as a source of interesting paraphrases.

5 Conclusion and Future Work

We propose a new approach to use image captions as a resource for paraphrasing. From Wikipedia, we extracted 30,237 caption pairs in gold quality, 229,877 in silver quality, and 656,560 in bronze quality for our new Wikipedia-IPC dataset. As part of our analysis, we found that many caption pairs are "sophisticated" paraphrases in the sense of being semantically similar but dissimilar at the lexical and syntactic levels. We have introduced a respective measure for assessing paraphrase sophistication based on semantic and syntactic similarity. The new measure correlates well with manual judgments, and we have shown that paraphrases from different sources have individual characteristics along the two similarity dimensions. Studying large sets of paraphrases with characteristics required by a specific task (e.g., sophisticated vs. only word order changed) will be useful for task-specific paraphrase recognition and generation approaches, and for natural language understanding as a whole.

In future work, we plan to extend the mining process to larger web resources than the Wikipedia and to apply image analysis as a new equivalence criterion. Identifying highly similar but not identical images may help to identify even more caption-based paraphrase candidates.

Limitations

Challenging for our proposed paraphrase acquisition approach are captions that describe the same image in very different contexts (e.g., maps). Such captions tend to focus on rather different aspects of the image (e.g., rivers vs. cities on a map) but since the captions often still share some commonalities, the semantic component of our proposed measure $\Delta_{\text{sem,syn}}$ might still classify the captions as similar. A "deeper" estimation of semantic similarity could help. With more research on image–text relationships, applying models such as CLIP (Radford et al., 2021) or Stable Diffusion (Rombach et al., 2022) to take image semantics into account might lead to improvements for our proposed paraphrase refinement measure.

Generation-Based Data Augmentation for Offensive Language Detection: Is It Worth It?

Camilla Casula◇♣**, Sara Tonelli**◇
◇Fondazione Bruno Kessler, Trento, Italy

`{ccasula,satonelli}@fbk.eu`

Abstract

Generation-based data augmentation (DA) has been presented in several works as a way to improve offensive language detection. However, the effectiveness of generative DA has been shown only in limited scenarios, and the potential injection of biases when using generated data to classify offensive language has not been investigated. Our aim is that of analyzing the feasibility of generative data augmentation more in-depth with two main focuses. First, we investigate the robustness of models trained on generated data in a variety of data augmentation setups, both novel and already presented in previous work, and compare their performance on four widely-used English offensive language datasets that present inherent differences in terms of content and complexity. In addition to this, we analyze models using the HateCheck suite, a series of functional tests created to challenge hate speech detection systems. Second, we investigate potential lexical bias issues through a qualitative analysis of the generated data. We find that the potential positive impact of generative data augmentation on model performance is unreliable, and generative DA can also have unpredictable effects on lexical bias.

⚠ **Warning**: *this paper contains examples that may be offensive or upsetting.*

1 Introduction

Even though large language models have been found to have a tendency to encode and propagate undesirable social bias (Bender et al., 2021), going as far as generating toxic sequences starting from non-toxic prompts (Gehman et al., 2020), the use of synthetic data for offensive language detection has been found to be potentially helpful in improving models (e.g. Juuti et al. (2020); Wullach et al. (2021); D'Sa et al. (2021)). Indeed, data augmentation (DA) through generation has the potential to mitigate some of the known issues of smaller datasets, which are common in offensive language detection, such as lack of linguistic variation and risk of overfitting (Vidgen and Derczynski, 2020). Furthermore, synthetic data can overcome privacy issues related to the use of social media data obtained without user consent in research experiments. It can also mitigate dataset decay, an issue affecting reproducibility, since online messages, especially abusive ones, tend to be deleted over time, while synthetic examples do not present this issue (Klubicka and Fernández, 2018).

While generative DA has been shown to be potentially useful for the task of detecting offensive and abusive language online in multiple works, several aspects and implications of it remain unexplored. First of all, generative DA has mostly been shown to work for offensive language detection when starting with a single specific dataset and using a specific generation setup, with no investigation of the impact of different generation setups on the quality of the augmented data, as well as little exploration of cross-dataset or cross-domain performance. The first aim of our work is therefore that of assessing the *robustness* of models across different sources of variation as follows: *i)* we train and test our models using four English offensive language datasets, testing both within dataset and cross-dataset performance; *ii)* we simulate two low-resource scenarios, in which we start with different quantities of gold examples; *iii)* we compare four different generation setups, of which two were used in previous work and two are novel; *iv)* we experiment with different thresholds for filtering the generated data prior to using it for training.

Our second aim for this work is that of conducting a qualitative analysis on the generated data, with a focus on *lexical bias*. In order to do this we compute the correlation between tokens in offensive texts using PMI[1], and we test the models

---

[1] For this, we use the implementation by Ramponi and Tonelli (2022).

trained on augmented data on the HateCheck suite (Röttger et al., 2021), which includes a series of functional tests aimed at finding model weaknesses.

2 Related Work

Model-based data augmentation exploiting large language models (LLMs) such as GPT-2 (Radford et al., 2019) has been found effective for various NLP tasks. One method that has been shown to be promising is fine-tuning GPT-2 on annotated data, and then using it to generate additional similar data. The most common approach is prepending labels to sequences during fine-tuning, and then using labels as prompts for the model to generate sequences belonging to specific classes (Anaby-Tavor et al., 2020; Tepper et al., 2020; Kumar et al., 2020).

Similar methods have also been successfully applied to abusive language classification. For instance, Juuti et al. (2020) find that DA using a fine-tuned GPT-2 model leads to performance improvements in very low-resource scenarios. Liu et al. (2020) use a conditional variant of GPT-2 based on reinforcement learning, where lexical features for each class are extracted from the entire dataset and then used for generation. Wullach et al. (2021) and D'Sa et al. (2021) use GPT-2 to generate synthetic hate speech data. They find that the addition of large amounts of synthetic data helps classification when starting from datasets containing thousands of labeled instances. While D'Sa et al. (2021) follow the label-prepending approach of Anaby-Tavor et al. (2020), Wullach et al. (2021) train a separate generative model on data belonging to each class. Both approaches are found effective, but they have never been comparatively evaluated.

To our knowledge, the robustness of models trained using generation-based DA has not been analyzed in depth. While Wullach et al. (2021) test their models cross-dataset, results are presented in a setup in which models are trained on 4 datasets together and tested on a fifth one. This setup presupposes that multiple datasets can be used at once for training models. However, this might not always be the case when DA is needed, so we evaluate cross-dataset setups in which only one dataset is available for training. In addition, to our knowledge ours is the first work to pair a robustness analysis with a qualitative analysis of lexical bias in the context of generative DA for this task.

3 Data

3.1 Dataset Description

We use four English datasets annotated for offensive or abusive language for training and testing our models. These datasets have been chosen because they are widely used and they differ in terms of content, since they were created to study different aspects of offensive language. Intuitively, this should allow us to assess the out-of-domain behavior of models when doing cross-dataset testing.

Agreement [AG] This dataset by Leonardelli et al. (2021) is annotated for offensive language and agreement level among annotators. It contains over 10k tweets dealing with three widely discussed topics on Twitter: the Black Lives Matter movement, the 2020 US elections, and Covid-19. Offensive tweets constitute 31% of the dataset.[2]

Founta [FO](Founta et al., 2018). This dataset is among the most widely used abusive language datasets in the literature, and it has been already employed for generative data augmentation (Wullach et al., 2021; D'Sa et al., 2021). It contains around 100k Twitter posts annotated using four labels: hateful (7.5%), abusive (11%), normal (59%), and spam. In order to keep a binary classification setup that is consistent with the other datasets we use in our experiments, we group the *hateful* and *abusive* classes together into one single *abusive* class, following Leonardelli et al. (2021).[3]

OLID [OL] The Offensive Language Identification Dataset (Zampieri et al., 2019). This dataset consists of 14,100 Twitter posts annotated for offensive language with two more fine-grained levels of annotation regarding the target of the offense. In our experiments we only consider the broader binary level of annotation, for which 33% of the dataset is labeled as *offensive*. The test set we pair with this dataset is **SOLID [SO]** (Zampieri et al., 2020), which was used in the OffensEval 2020 shared task and follows the same annotation guidelines.[4]

SBIC [SB] The Social Bias Inference Corpus (Sap et al., 2020) contains 40k posts from Twitter, Reddit, and Stormfront, of which 44.8% offensive. While this dataset provides fine-grained annotations on social biases, we only consider the binary offensive/not offensive labels in our experiments.[5]

---

[2] https://github.com/dhfbk/annotators-agreement-dataset

[3] https://zenodo.org/record/3678559

[4] https://sites.google.com/site/offensevalsharedtask/olid

[5] homes.cs.washington.edu/~msap/social-bias-frames/

The above datasets present different characteristics. We consider **[FO]** and **[OL]** rather easy to classify, since standard BERT-based approaches trained and tested on these datasets yield results above 0.90 macro-F1 (Zhou et al., 2021; Zampieri et al., 2020). Past works showed that, in case of **[OL]**, classifiers may perform very well because of the limited presence of ambiguous tweets (Leonardelli et al., 2021). In contrast, **[AG]** was explicitly created to study disagreement among annotators focusing on different topics, so it contains more challenging instances. On this dataset, the best performance reported by the authors is ∼0.75 macro-F1 (Leonardelli et al., 2021). Finally, **[SB]** includes data from different sources, with annotations for diverse targets of hate. The best classification result reported by the authors is ∼0.80 F1 (Sap et al., 2020).

3.2 Data Splits and Preprocessing

We use the default train/test splits of each dataset, where available. For **[FO]**, which has no default splits, we randomly partition the data into train and test using an 80/20 split. For all datasets, we replace URLs and user mentions with `URL` and `@USER` respectively. We then remove all duplicates. We also remove the substring "`RT:`" from the beginning of sequences in the **[FO]** dataset, since it is extremely common and it could be a confounder for the model. In addition to this, it has been found to be associated with hate speech in this dataset (Ramponi and Tonelli, 2022). Since there is a partial overlap between **[SB]** and **[FO]**, we remove instances that are present in the test set of either dataset from the training data of the other, to ensure fair cross-dataset evaluation.

4 Methods

We aim at comparing the performance of different data augmentation setups, both novel and already employed in previous work. We test them in within-dataset and cross-dataset scenarios, to assess the impact of synthetic data on model robustness across setups. Below is an overview of the process we follow, whose specifics are detailed in Section 5.

1. We randomly undersample the training data, obtaining the data subset X consisting of n examples (Sec. 5.1).
2. We fine-tune the pre-trained classification model C on X, obtaining C_X, which is used as a baseline and filtering classifier.
3. Depending on the type of generation input (Sec. 5.2) the pre-trained generation model G is fine-tuned on the available training data X, obtaining G_X.
4. The generative model G_X is used to generate synthetic examples.
5. The examples generated by G_X are preprocessed and then filtered based on the probability assigned to them by the classification model C_X (Sec. 5.3).
6. The generated data is merged with the gold data X to create the augmented dataset X_{aug}.
7. The classifier C is fine-tuned on the augmented dataset X_{aug} to create $C_{X_{aug}}$.

Model choice We focus on the generation of synthetic data using GPT-2 `large` (774M parameters) (Radford et al., 2019). [6] Some recent works exploit the generative capabilities of GPT-3 for the creation of new datasets, either in human-in-the-loop setups (Liu et al., 2022) or in very resource-intensive scenarios (Hartvigsen et al., 2022a). We choose to experiment with GPT-2 because it is freely accessible and it can be easily fine-tuned, and we aim for our results to be comparable with those of previous work where this DA method was found effective for this task (e.g. Juuti et al. (2020) and Wullach et al. (2021)).

Model Details For classification, we run our experiments with the BERT `base uncased` model (110M parameters) (Devlin et al., 2019) and with RoBERTa `base` (125M parameters) (Liu et al., 2019). We use the Huggingface implementation (Wolf et al., 2020) for all models. In both cases we use the default Huggingface `TrainingArguments` class hyperparameters, with batch size set to 32.

For generation, we fine-tune GPT-2 `large`, following Wullach et al. (2021). We use the default Huggingface hyperparameters, setting the batch size to 2, adding learning rate warm-up with a ratio of 0.02 and weight decay of 0.01. Classifiers and generative models are trained for 3 epochs. For fine-tuning GPT-2, the input texts are grouped into documents of maximum length 512 tokens and separated using end-of-sequence tokens.

After fine-tuning, the generation step is similar for all models. We use *top p* decoding (Holtzman

---

[6] We performed preliminary experiments using GPT-2 small (117M parameters) as well, finding that overall the generated data had a similar impact on classification performance.

et al., 2020) with $p = 0.9$ and we set the minimum and maximum lengths of generated sequences to 5 and 100 tokens respectively. We also blacklist the sequence "`@USER`" so that it will not be generated, since it is a very frequent token combination in the normalized training data.

In all setups, we aim at augmenting the gold data with 2,000 synthetic examples. This number is chosen to at least double the available training data in all setups, and it is kept constant for easier model comparison. We generate 6,000 sequences for each setup, to ensure that enough acceptable sequences will be generated. This estimate is based on the approach of Wullach et al. (2021), who preserve roughly 1/3 of the generated texts after filtering.

All experiments are run on a NVIDIA Quadro RTX 5000 GPU in ~80 hours total, including both training and inference for all setups.

5 Experimental Setting

We structure our experiments along three axes of variation, with the aim of assessing their impact on model performance. The explored dimensions are further detailed in the following subsections.

- **Number of training instances**. In order to simulate two low-resource scenarios where different amounts of gold data are available, we train both classification and generative models with different amounts of labeled instances. Our aim is that of assessing how much the usefulness of generative DA changes when starting with datasets of different sizes.
- **Prompting.** Different methods can be used for steering the generation towards one label or the other. We use two methods found in previous works, as well as two novel methods, to assess whether certain prompting methods lead to differences in synthetic data quality.
- **Classifier filtering thresholds.** Since prompting methods are not always enough to steer the model into generating correct sequence-label pairs (Kumar et al., 2020), classifiers can be used to confirm or discard the label assignments made by the generative model (Anaby-Tavor et al., 2020; Wullach et al., 2021). In our experiments, we feed the generated sequences to a classifier (our baseline) and use the probability given by the classifier to each generated sequence to either accept the label assigned by the generator or discard the sequence entirely. We experiment with two probability thresholds, in order to assess whether the confidence of the classifier is associated with generated data quality.

Each model is tested on its own test data (within-dataset) and on the test data for the other datasets (cross-dataset).

5.1 Number of Training Instances

Each experiment is performed on varying amounts of training data, randomly sampling $n = 500$ or 2,000 examples from each dataset, equally split between the two labels. We use 500 examples as the smallest sample size for our experiments since the smallest dataset size for this task found by Vidgen and Derczynski (2020) is 469 examples. We use 2,000 examples as the larger sample size given that it is still a relatively small dataset size for deep learning approaches and it reflects the size of many offensive language detection datasets.

We balance the sampling by class to avoid imbalance between gold and augmented data, consistently keeping this proportion even across all experiments. For the **[AG]** dataset, sampling is stratified by agreement level as well. Balancing the classes might make our setup less "realistic", given that it does not reflect the actual label distribution of each dataset. However, it is a way for us to control the impact of class balance differences between datasets on cross-dataset performance. It also helps to avoid differences in class balance between the gold data and the generated data, which could cause differences in model performance between setups regardless of the actual quality of the generated data.

Out of the available data, 1/5 ($n = 500$) or 1/10 ($n = 2,000$) is held out for validation.

5.2 Prompting

We fine-tune GPT-2 using four data formatting setups. Two of the setups have been employed in previous works, while two are novel and aim at exploring the ability of the model to leverage natural language task descriptions for label assignment.

Label tag prompting (tag-prompt). Following the prompting type in Anaby-Tavor et al. (2020), we fine-tune the generator G by pre-pending the label y to each training sequence x, dividing the two with the separator "`[SEP]`". In this setup, the inputs are concatenated into documents as follows:

"y_1 `[SEP]` x_1 `[EOS]` y_2 `[SEP]` `...`"

At generation time, the model is prompted with the desired label y followed by the separation token, and it is expected to generate a sequence belonging to the y class.

Label in natural language prompting (nl-prompt). This is the first input setup we propose. It is inspired by the findings of Schick and Schütze (2021), in which natural language descriptions of tasks are found to be helpful for few-shot classification tasks. In this setup, the generator G is trained on sequences so that the label y is contextualized within the text using natural language. The training documents for fine-tuning the generators are structured as:

"`This message is` y_1`.` x_1 `[EOS] This ...`"

Where y corresponds to *offensive* or *not offensive* depending on the label. At generation time, the model is prompted with "This message is y", where y is the desired label. The sequence produced after the prompt is expected to belong to the y class.

Cloze question prompting (cloze-prompt). Again inspired by the findings in Schick and Schütze (2021), we propose another setup that exploits the capability of large language models of learning from patterns in natural language. In this case, however, the prompt relies on the auto-regressive nature of GPT-2, in which the probability of each token is modeled on the previous tokens. The main aim behind this setup is assessing whether placing the label information at the beginning or at the end of the sequence affects the quality of the generated data. In this setup, each sequence x is followed by the cloze question "Is that offensive?" and the label is placed at the end of the sequence, in the form of a Yes/No answer.

"x_1`. Is that offensive? {Y/N} [EOS] ...`"

At generation time, the model receives no prompting, and it is expected to generate both the sequence and the cloze question / answer pair in the correct format. This type of prompting is more prone than the previously listed ones to generating sequences that will eventually be discarded, since it is expected to not only correctly generate sequences and assign them to a label, but also to produce a cloze question that follows a specific format.

One model per label (1/label). This setup requires no actual prompting to steer the generation, since it involves one model for each label rather than one model for all labels. Following Juuti et al. (2020) and Wullach et al. (2021), the training dataset X is divided into X_o and X_n based on the *offensive* or *non-offensive* labels. The generative model G is then fine-tuned on X_o and X_n separately, producing two models for the generation of new data: G_o and G_n. In this setup, the messages are simply concatenated into documents and separated by end of sequence (`[EOS]`) tokens:

"x_1 `[EOS]` x_2 `[EOS]` x_3 `...`"

At generation time, each model is expected to generate sequences belonging to the class it was fine-tuned on.

5.3 Classifier Filtering Thresholds

After generation, the synthetic sequences are stripped of any prompting and automatically assigned the label that emerged during generation. We discard any sequence that is ≤ 5 characters long, and normalize the generated data following the steps described in Section 3.2.

Then, we feed the sequences into the baseline classifier trained on the same gold data as the generative model that produced them. Depending on the label probability assigned by the classifier to the generated sequences, these are accepted considering the following thresholds:

- The label predicted by the classifier matches the label assigned during the generation phase (label probability $p > 0.5$)
- The classifier predicts the same label assigned during generation with $p > 0.7$ [7]

After filtering, we randomly select 2,000 generated examples from the accepted ones in each setup.

5.4 Baselines

As baselines, we employ a `BERT-base-uncased` and a `RoBERTa-base` classifier trained on the same gold data used to fine-tune GPT-2 in each setup.

We also report the performance of classifiers trained using simple oversampling as a DA strategy, in which a number of randomly selected training examples appear multiple times during training. We match the number of oversampled instances with the number of synthetic examples we use for augmenting the training data in each setup, split evenly across labels. Using oversampling as a baseline allows us to compare more resource-intensive DA methods such as the ones we are evaluating with a simpler strategy.

---

[7] This is the same threshold used by Wullach et al. (2021).

Table 1: Average macro-F1 scores (over 10 runs) obtained by RoBERTa-base fine-tuned on augmented data, starting with 500 gold examples. F1 scores for the minority class are in parentheses. Grey cells contain within-dataset results, while the others contain cross-dataset results. Asterisks denote statistically significant results (compared to no augmentation). The best result for each train-test dataset combination is in bold.

6 Results

In this section we report the results of our experiments. Each experiment is run 10 times, with different random seeds. The metric we use to evaluate models is macro-F1 score.

In order to reliably compare the distributions of results across runs, we use Almost Stochastic Order (ASO) (Dror et al., 2019; Del Barrio et al., 2018) in its implementation by Ulmer et al. (2022). Following their findings, we use $\tau = 0.2$ as a threshold for statistical significance.[8]

Table 1 and Table 2 show the results obtained by RoBERTa-base models fine-tuned on augmented data when starting with 500 and 2,000 gold examples respectively. While for the setup in which we start with 2,000 annotated examples (Table 2) we use both filtering thresholds ($p > 0.5$ and $p > 0.7$), for the setup in which we start with 500 examples we report the results for models trained on generated data filtered with the $p > 0.5$ threshold only. The reason for this is that with less data, the confidence of the model is much lower, and not all 10 runs can generate enough examples that are classified with a confidence score higher than 0.7.

Impact of number of training instances Overall, it appears that data augmentation is more effective in very low-resource scenarios, such as the setting with 500 examples. The fact that DA is more useful as the amount of available data lowers is in line with what has been observed for other tasks, as well as in multiclass setups, albeit with a much lower number of examples per class (Anaby-Tavor et al., 2020; Kumar et al., 2020). In the setup where 2,000 gold examples are available, there are very few significant improvements in performance when using generative data augmentation.

---

[8] This threshold has a Type I error rate comparable to that of a p-value threshold of 0.05 (Ulmer et al., 2022).

Table 2: Average macro-F1 scores (over 10 runs) obtained by RoBERTa-base fine-tuned on augmented data, starting with 2,000 gold examples. F1 scores for the minority class are in parentheses. Grey cells contain within-dataset results, while the others contain cross-dataset results. Asterisks denote statistically significant results (compared to no augmentation). The best result for each train-test dataset combination is in bold.

Impact of prompting and filtering Interestingly, no prompting type seems to clearly outperform the others across setups. For instance, augmenting the Agreement **[AG]** dataset starting with 500 gold examples has a positive effect on performance across all prompting types both when tested on the in-domain test data and when tested on **[FO]** and **[SO]**, while when tested on **[SB]** none of the setups lead to significant improvements in performance. This seems to indicate that dataset characteristics have a greater impact than the prompting setup on whether generative DA can be effective. However, looking at Table 2, the situation is reversed: the model trained on **[AG]** only significantly benefits from data augmentation when tested on **[SB]** across most setups. A filtering threshold of 0.7 does seem to help improve performance at least marginally, but only on this dataset combination out of all the ones we tested. Overall, it appears that whether DA will have a positive impact on classification might not depend on the generation setup in our case.

Overall findings The most important pattern that emerges from our results is that generative DA using GPT-2 does not appear to reliably improve model performance, both in and out of domain. It apparently *can* significantly improve model performance, especially for some dataset combinations and with very low amounts of data. However, this improvement is not consistent, so based on our results we would advise against considering this type of DA a reliable method for improving offensive language classifiers in similar setups.

Another important aspect that emerges from our results is that oversampling is a very strong baseline, especially for the setup with 500 available annotated examples, even though it is often overlooked. To our knowledge, it was used as a baseline only in Juuti et al. (2020) for generative DA on this task, while most other works report the performance on augmented data only. Interestingly, oversampling does not only improve within-dataset performance, but it also has a significant positive impact on cross-dataset performance. Since it requires a fraction of the computational resources needed for generative DA, it may be preferable when $\sim$500 gold examples are available. We hypothesize that one of the reasons why oversampling can perform well is that at least a subset of the datasets share superficial features that might be amplified in the oversampling process, such as specific terms that are associated with offensiveness across datasets.

In general, although it does not reliably improve model performance, generative DA does not seem to significantly decrease performance either. Wullach et al. (2021) believe that generative DA could improve lexical diversity, leading to better generalization. In Section 7.1, we analyze the generated data to assess whether it could lead to benefits with regards to fairness, perhaps due to more representation of minorities given the higher lexical variety.

The results for BERT-based models are in general in line with those for RoBERTa-based models, although BERT-based models tend to perform worse regardless of setup. Again, with BERT models, oversampling seems to be just as reliable to improve both within-dataset and cross-dataset performance. Since the overall findings are similar to those of RoBERTa-based models, we do not report BERT results in this section, but in Appendix A.

7 Qualitative Analysis

In order to estimate the quality of the generated examples and the impact of the prompting method, we randomly select a subset of 10 generated examples for every dataset / data size combination for manual analysis. We find that there are some clear differences between the prompting setups, and that the methods that exploit prompting in natural language (*nl-prompt* and *cloze-prompt*) tend to generate the most realistic examples. *Tag-prompt* tends to often generate strings of random special characters, resulting in very low quality data, while the *1/label* setup often results in sequences that appear out of domain. Some examples of the generated texts can be found in Appendix B.

7.1 Lexical Artifacts Analysis

To investigate the lexical variation between the gold data and the generated data, we use pointwise mutual information (PMI), following Ramponi and Tonelli (2022). In particular, we analyze the most informative tokens for the *offensive* class in each dataset, looking at how certain tokens become less or more informative in the generated data.

The first tendency that can be noticed when looking at how the ranking of tokens' informativeness changes between gold and generated data is that for some of the datasets the changes are more evident (i.e. for **[AG]** and **[SB]**). For example, in the gold **[SB]** data, the word *fucking* is ranked as the 10,203rd most informative word for the *offensive* class. In data augmented using the *tag-prompt* type on the generative model trained on 2,000 instances, however, the same word is ranked 4th. This means that the model has generated a very large amount of offensive messages containing this word, while it was not prominent in the gold data it was fine-tuned on. This happens for both the setup starting with 500 gold examples and with 2,000.

While the prominence of a potentially predictive word for offensive language, like *fucking*, is a good sign of the quality of the generated data, since it means that the generation process can usefully augment existing data, this happens also with tokens that should not be predictive for this task, defined by Ramponi and Tonelli (2022) as *spurious lexical artifacts*. For example, across several generation setups, we can notice the increased importance for the offensive label of identity terms, such as *girl*, *gay*, *woman*, *jews*, but also words that hold no inherent association with abusive language, such as *people* or *difference*. The higher importance of some identity terms could be associated with biases that were already present in the pre-trained generative model, and which were amplified during the generation process. In order to better understand the impact of these differences in token informativeness, we turn to the HateCheck functional tests in Section 7.2. For further details, the full lists of top 11 informative tokens for each dataset, both gold and generated, is reported in Appendix C.

7.2 HateCheck Analysis

We explore some of the weaknesses of classifiers trained on gold and augmented data through the HateCheck suite (Röttger et al., 2021), consisting of a series of functional tests aimed at exploring the weak points of hate speech models.[9]

Overall, data augmentation has little impact on the performance of models on HateCheck, especially on models trained starting with 2,000 gold instances. Similarly to the results reported in Section 6, oversampling tends to lead to similar or better improvements than generative DA, again depending on the starting dataset. However, this improvement is focused only on some functional tests, leading to worse performance on other tests.

For instance, two interesting tests are those on *non-hateful slurs*, including test 8, non-hateful homonyms of slurs (e.g. “Female canines are called bitches”), and test 9, *reclaimed slurs* (e.g. “The Q in LGBTQ stands for queer”). For models trained on 500 gold instances, the performance consistently drops on these two tests for all augmentation setups and oversampling across all datasets. This suggests that models trained using oversampling or generative data augmentation may start overfitting and relying on the presence of specific terms such as slurs for the classification of offensive language. For models trained on 2,000 gold instances, the performance on these two tests is somewhat stable, with no improvements or decreases in performance.

Another interesting test for examining whether generative DA increases the reliance of classifiers on specific words is test 15, *negated hateful statement*, e.g. “I would never hurt any woman”. The performance for this test tends to be overall stable or lower than the baseline, mostly decreasing with oversampling and in the setup starting from 500 annotated instances. This again indicates that models trained on augmented data in the setups we used show potentially harmful weaknesses, since they tend to misclassify sequences based on simple patterns such as the presence of specific words.

While models trained on augmented data tend to perform worse on non-hateful sequences containing identity terms and slurs, they do show improvements for those tests that benefit from being able to find these terms, such as test 7, *hate expressed using slur*, or test 10, *hate expressed using profanity*, further confirming that augmentation tends to steer models into overfitting identity terms and slurs.

Further details on the performances of models on each HateCheck test and on the targets contained in the tests are found in Appendix D.

8 Conclusions

In this work, we presented an evaluation of both existing and novel data augmentation setups based on generative large language models for offensive language detection. We investigated the robustness of such models, testing them in within-dataset and cross-dataset scenarios, and performed a qualitative analysis on the augmented data.

We found that while generative DA can positively impact model performance in some cases, especially when low amounts of gold data are available, this positive effect is not consistent across setups, making generative DA unreliable in the setups we tested. In addition to this, we found that generative DA can potentially introduce lexical bias from the pre-trained generative model into the augmented data, as well as increase the reliance of models on identity terms and slurs, which could have unintended effects on classification.

Overall, although it might improve classification performance in some cases, we advise against using generative DA for this task, since it is computationally intensive and it does not appear to consistently make models perform better or be more robust.

---

[9] Since our models are aimed at detecting offensive language in general and HateCheck is focused on hate speech, a narrower phenomenon, not all tests are entirely informative in our case, such as test number 11, testing the performance on non-hateful profanities. In general, however, the labels of HateCheck tests are aligned with our task.

Limitations

The main limitation of this work is its focus on English, leaving out other languages that may benefit more from a thorough evaluation of data augmentation methods because they have fewer resources. We selected English for this work because it allowed us to evaluate the system performance on four datasets with different characteristics and a number of configurations, thanks also to the availability of language-specific GPT2, BERT and RoBERTa. We are aware that generation-based data augmentation would be potentially more useful in real low-resource scenarios, and we plan on investigating in the future whether our findings hold for other languages.

Furthermore, this work deals only with one type of data augmentation, i.e. the one using fine-tuned generators, while there are others that we left out because of space limits and that may be investigated in the future. For example, we might compare generative DA with rule-based augmentation, synonym-based approaches and backtranslation, among others, and investigate whether different data augmentation approaches present differences in terms of robustness or lexical biases. In addition, we only experiment with one generative model, while we could in the future compare generative DA using GPT-2 with other kinds of generative models, especially more advanced ones.

Another aspect left unexplored in our work is whether this type of data augmentation could help models dedicated to this task that are widely available, such as HateBERT (Caselli et al., 2021) or ToxiGen-RoBERTa (Hartvigsen et al., 2022b). While in this work we focus on scenarios in which little data is available, experimenting with these models could yield interesting results in future work with a broader scope.

Ethics Statement

In our experiments, we compare different setups in which large language models are exploited in order to artificially create more data to train models aimed at detecting offensive language. In this case, synthetic data has two main potential advantages: first, it limits the amount of data gathered from online spaces without user consent, and second, it reduces the amount of manual annotation required to create labeled datasets for offensive language detection, which can have a negative psychological impact on annotators (Riedl et al., 2020).

While using generative models to augment data can in some cases be beneficial for classification performance, the sequences generated by these models can exhibit unpredictable characteristics that exacerbate existing bias or produce new forms of it. Given that the improvements provided by generative DA are inconsistent, there are no clear advantages to this method when considering its potential risks. As a consequence, we advise against deploying models trained on generated data in practice.

Since the main contribution of our work is not a novel model or algorithm, but rather an evaluation of different approaches for generative data augmentation, we share as much information as we can for the reproducibility of our experiments, but we choose not to release the code openly to the public, in order to limit potential misuse of models that can generate offensive language. We also choose not to publicly release the generated data for various reasons. As shown by our results, the generated examples are not reliable for improving existing systems, so their utility is limited. Furthermore, the generated texts are not curated, which could result in including personal user information or harmful statements targeting specific individuals being generated. We will, however, share the data upon request to other interested researchers.

Table 6: Examples of sequences generated by GPT-2 large models trained on 2,000 gold examples for every combination of prompting and dataset.

C Lexical Artifacts

In this section, we present the lists of top-11 informative tokens for the offensive class, both on gold and on generated data. Lists for data in the setup where we start with 500 annotated instances can be found in Table 7, and those for the setup with 2,000 gold instances are in Table 8.

⚠ **Content warning**: *Tables 7 and 8 contain uncensored profanities and slurs.* [10]

D HateCheck

Table 9 and Table 10 present the results on HateCheck tests and targets for models in the 500 gold examples setup. Table 11 and Table 12 present the results on the functional tests and targets for models in the setup in which we start with 2,000 annotated examples.

---

[10] These are left uncensored for increased readability, since special characters are already used to signal boundaries of sub-word tokens, and to avoid confusion with words that are self-censored by the users.

Abstract

Self-attention weights and their transformed variants have been the main source of information for analyzing token-to-token interactions in Transformer-based models. But despite their ease of interpretation, these weights are not faithful to the models' decisions as they are only one part of an encoder, and other components in the encoder layer can have considerable impact on information mixing in the output representations. In this work, by expanding the scope of analysis to the whole encoder block, we propose *Value Zeroing*, a novel context mixing score customized for Transformers that provides us with a deeper understanding of how information is mixed at each encoder layer. We demonstrate the superiority of our context mixing score over other analysis methods through a series of complementary evaluations with different viewpoints based on linguistically informed rationales, probing, and faithfulness analysis.[1]

1 Introduction

Transformers (Vaswani et al., 2017), with their impressive empirical success, have become a prime choice of architecture to learn contextualized representations across a wide range of modalities, such as language (Devlin et al., 2019; Brown et al., 2020), vision (Dosovitskiy et al., 2021), vision-language (Radford et al., 2021; Rombach et al., 2022), and speech (Baevski et al., 2020), mainly due to their ability to utilize pairwise interactions between input tokens at every timestep.

To better understand the inner dynamics of Transformers, we need to trace the information flow from the input embeddings up to the output representation (including quantifying the degree of *context mixing*, which we will define below). The attention weights from the multi-head attention mechanisms offer a straightforward starting point for understanding this flow, and these weights ('raw attention') have been used in many studies (Clark et al., 2019; Kovaleva et al., 2019; Reif et al., 2019; Htut et al., 2019a, *inter alia*). However, the reliability and usefulness of raw attention weights has also been questioned (Jain and Wallace, 2019; Bibal et al., 2022). In particular, attention weights tend to concentrate on uninformative tokens in the context (Voita et al., 2018; Clark et al., 2019), and removing or altering them may lead to the same and sometimes even better model performance on downstream tasks (Jain and Wallace, 2019; Toneva and Wehbe, 2019; Hassid et al., 2022). These findings suggest that Transformers do not solely rely on self-attention, and other components in the encoder block play an essential role in information mixing.

A number of methods have been proposed to compute some form of 'effective attention weights', with the goal of more faithfully tracing the relative contributions of different input tokens at various layers of the Transformer (as we will discuss in Section 2). These methods show an improvement over raw attention, but still ignore key components of the Transformer encoder block. This is a particularly crucial shortcoming, given that most of the parameter budget in a Transformer encoder is spent on position-wise feed-forward networks outside of the self-attention component, which can have a considerable impact on the degree of information mixing in the output representations.

In this paper, we focus on *context mixing*: the property of Transformers that in each node, at each layer, information from the context can be incorporated into the representation of the target token. We propose *Value Zeroing*, a novel approach to quantify the contribution each context token has in determining the final representation of a target token, at each layer of a Transformer. *Value Zeroing* is based on the Explaining-by-Removing intuition (Covert et al., 2021) shared by many posthoc interpretability methods, but it takes advantage of

---

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3378–3400
May 2-6, 2023

a specific feature of Transformers: it zeroes only the value vector of a token t when computing its importance, but leaves the key and query vectors (and thus the pattern of information flow) intact.

Based on extensive experiments and three complementary approaches to evaluation, we demonstrate that importance scores we can obtain with *Value Zeroing* provide better interpretations than other analysis methods.

Firstly, we use a set of grammatical agreement tasks from the BLiMP corpus (Warstadt et al., 2020) as a case study. Transformer-based models do extremely well on the task of distinguishing grammatical from ungrammatical sentences, and the BLiMP corpus provides information on the *cue* words that determine the difference. We find that *Value Zeroing*, unlike earlier approaches, indeed reveals that Transformers make use of relevant cues.

Secondly, we use information-theoretic probing (Voita and Titov, 2020; Pimentel et al., 2020) as an independent approach to track information flow in Transformer networks. The scores we obtain with *Value Zeroing* turn out to be highly correlated with layer-wise probing performance; that is, probing accuracy is higher in layers where relevant tokens are more effectively utilized by the model.

Thirdly, we assess the faithfulness of our method (Jacovi and Goldberg, 2020); compared to alternative analysis methods, we show that *Value Zeroing* is not only more plausible and human-interpretable, but also more faithful to models' decisions.

2 Related Work

While numerous studies have leveraged the weights assigned by the self-attention mechanism to gain intuition about the information mixing process in Transformers (Clark et al., 2019; Kovaleva et al., 2019; Reif et al., 2019; Lin et al., 2019; Htut et al., 2019b; Raganato and Tiedemann, 2018), it is still a matter of debate whether attention weights are suitable for interpreting the model (see Bibal et al. (2022)'s study for a full discussion). Thus several post-processing interpretability techniques have been proposed to convert these weights into scores that provide a more detailed interpretation of the inner workings of Transformers. We review the main approaches below.

Abnar and Zuidema (2020) propose the *attention-flow* and *attention-rollout* methods to approximate information flow in Transformers based on raw attention weights. The former treats raw attention weight matrices as a flow network and returns the maximum flow through each input token. The latter recursively multiplies the attention weight matrix at each layer by the preceding ones. There is, however, an unjustified assumption in the formulation of these methods that both multi-head attention and residual connections contribute equally to the computation of the output.

Kobayashi et al. (2020) propose a method that incorporates the norm of the transformed value vectors and report a negative correlation between these norms and raw attention weights on frequent tokens, which partially explains the insufficiency of raw attention weights for context mixing estimation. Kobayashi et al. (2021) extend this method to the whole self-attention block by incorporating Residual connections (RES) and Layer Normalization (LN) (two components with significant impact on both model performance and training convergence (Parisotto et al., 2020; Liu et al., 2020)), but demonstrate that RES and LN components largely cancel out the mixing process. Kobayashi et al. (2021)'s method, however, ignores the effect of the second sublayer in a Transformer's encoder.

Brunner et al. (2020) and Pascual et al. (2021) employ a gradient-based approach for analyzing the interaction of input representations, but the gradient measures the sensitivity between two vectors and ignores the impact of the input vector. In our experiments we show that despite their relative success in explaining model decisions, gradient-based approaches are not suitable for layer-wise analysis.

More recently, the effectiveness of combining these approaches has also been investigated. Modarressi et al. (2022) propose a method that uses Kobayashi et al. (2021)'s scores and incorporates the effects of the second layer normalization; they aggregate those scores using *rollout* (Abnar and Zuidema, 2020) to provide global token attributions. In the same vein, Ferrando et al. (2022) use rollout to aggregate a variant of Kobayashi et al. (2021)'s scores: instead of relying on the Euclidean norm of the transformed vector, they measure Manhattan distance of each transformed vector to the context vector outputted from self-attention block. In both studies, however, the fact that these context vectors might undergo significant changes after passing through the second sublayer in the encoder layer is not taken into account. We will show (in Section 7) that even at a global level, our scores provide better interpretation than prior methods.

3 Our Proposed Method

To remedy for the limited scope of the existing methods, we introduce a new context mixing score that takes into account all components in a Transformer encoder block.

3.1 Background and Notation

In this section, we set up the notation and briefly review the internal structure of an encoder layer in the Transformer architecture.

Each Transformer encoder layer is composed of two sublayers: a multi-head self-attention mechanism (**MHA**) and a position-wise fully connected feed-forward network (**FFN**), followed by a Residual connection (**RES**) and Layer Normalization (**LN**) around each of these two sublayers. This encoder layer produces the next contextualized representations $(\tilde{\boldsymbol{x}}_1, ..., \tilde{\boldsymbol{x}}_n)$ for each token in the context, using the output representations from the previous layer $(\boldsymbol{x}_1, ..., \boldsymbol{x}_n)$.

MHA. For each head $h \in \{1, ..., H\}$ in the self-attention module, each input vector $\boldsymbol{x}_i$ is transformed into a query $\boldsymbol{q}_i^h$, a key $\boldsymbol{k}_i^h$, and a value $\boldsymbol{v}_i^h$ vector via separate trainable linear transformations:

$$\boldsymbol{q}_i^h = \boldsymbol{x}_i \boldsymbol{W}_{\boldsymbol{Q}}^{\boldsymbol{h}} + \boldsymbol{b}_Q^h \tag{1}$$

$$\boldsymbol{k}_i^h = \boldsymbol{x}_i \boldsymbol{W}_{\boldsymbol{K}}^{\boldsymbol{h}} + \boldsymbol{b}_K^h \tag{2}$$

$$\boldsymbol{v}_i^h = \boldsymbol{x}_i \boldsymbol{W}_{\boldsymbol{V}}^{\boldsymbol{h}} + \boldsymbol{b}_V^h \tag{3}$$

The context vector $\boldsymbol{z}_i^h$ for the i^{th} token of each attention head is then generated as a weighted sum over the transformed value vectors:

$$\boldsymbol{z}_i^h = \sum_{j=1}^{n} \alpha_{i,j}^h \boldsymbol{v}_j^h \tag{4}$$

where $\alpha_{i,j}^h$ is the raw attention weight assigned to the j^{th} token, and computed as a softmax-normalized dot product between the corresponding query and key vectors:

$$\alpha_{i,j} = \underset{\boldsymbol{x}_j \in \mathcal{X}}{\text{softmax}} \left(\frac{\boldsymbol{q}_i \boldsymbol{k}_j^\top}{\sqrt{d}} \right) \in \mathbb{R} \tag{5}$$

Next, the context vector $(\boldsymbol{z}_i \in \mathbb{R}^d)$ for the i^{th} token is computed by concatenating all the heads' outputs followed by a head-mixing $\boldsymbol{W}_O$ projection and layer normalization:

$$\boldsymbol{z}_i = \text{CONCAT}(\boldsymbol{z}_i^1, ..., \boldsymbol{z}_i^H) \boldsymbol{W}_O \tag{6}$$

$$\boldsymbol{z}_i = \text{LN}_{\text{MHA}}(\boldsymbol{z}_i + \boldsymbol{x}_i) \tag{7}$$

FFN. Each encoder layer also includes two linear transformations with a ReLU activation in between, which is applied to every $\boldsymbol{z}_i$ separately and identically to produce output token representations $\tilde{\boldsymbol{x}}_i$:

$$\tilde{\boldsymbol{x}}_i = \max(0, \boldsymbol{z}_i \boldsymbol{W}_1 + \boldsymbol{b}_1) \boldsymbol{W}_2 + \boldsymbol{b}_2 \tag{8}$$

$$\tilde{\boldsymbol{x}}_i = \text{LN}_{\text{FFN}}(\tilde{\boldsymbol{x}}_i + \boldsymbol{z}_i) \tag{9}$$

3.2 Value Zeroing

We aim to measure how much a token uses other context tokens to build its output representation $\tilde{\boldsymbol{x}}_i$ at each encoder layer. To this end, we treat the self-attention mechanism as a fuzzy hash-table, where we look up the sum of values weighted by the query-key match in the context. Thus in Eq. 4 we replace a value vector associated with token j with a zero vector $\boldsymbol{v}_j^h \leftarrow \boldsymbol{0}, \forall h \in H$, where the context vector for the i^{th} token is being computed. This provides an alternative output representation $\tilde{\boldsymbol{x}}_i^{\neg j}$ for the i^{th} token that has excluded token j in the mixing process. By comparing the alternative output representation $\tilde{\boldsymbol{x}}_i^{\neg j}$ with the original $\tilde{\boldsymbol{x}}_i$, we can measure how much the output representation is affected by the exclusion of the j^{th} token:

$$\mathcal{C}_{i,j} = \tilde{\boldsymbol{x}}_i^{\neg j} * \tilde{\boldsymbol{x}}_i \tag{10}$$

where the operation $*$ can be any pairwise distance metric that properly considers the characteristics of the model's representation space. We opted for *cosine* distance throughout our experiments as its superiority over other dissimilarity metrics has been supported for textual deep learning models (Yokoi et al., 2020; Hanawa et al., 2021).[2] Computing Eq. 10 for all $\tilde{\boldsymbol{x}}_i$ in a given context provides us with a *Value Zeroing* matrix score $\boldsymbol{\mathcal{C}}$ where the value of the cell $\mathcal{C}_{i,j} \in \mathbb{R}$ (i^{th} row, j^{th} column) in the map denotes the degree to which the i^{th} token depends on the j^{th} token to form its contextualized representation.

Note that unlike generic perturbation approaches, our proposed method *does not* remove the token representations $\boldsymbol{x}_i$ from the input of an encoder. We argue that ablating input token representations cannot be a reliable basis to understand context mixing process since any changes in the input vectors will lead to changes in the query and key vectors (Eq. 1 and 2), resulting in a change in the attention distribution (cf. Eq. 5). Consequently, there will

---

be a discrepancy between the alternative attention weights and those for the original context. Instead, our method only nullifies the *value vector* of a specific token representation. In this way, the token representation can maintain its identity within the encoder layer, but it does not contribute to forming other token representations. Moreover, since our *Value Zeroing* is computed from the encoder's layer outputs, it incorporates all the components inside an encoder layer such as multi-head attention, residual connection, layer normalization, and also feed-forward networks, resulting in a more reliable context mixing score than previous methods.

4 Experimental Setup

4.1 Data

We used the BLiMP benchmark (Warstadt et al., 2020) which contains a set of pairs of minimally different sentences that contrast in grammatical acceptability under a specific linguistic phenomenon. The benchmark isolates linguistic phenomena such that only one word determines the true label of each sentence. We refer to this crucial context token as the *cue word*. The nature of this task makes it especially suitable for evaluating context mixing scores, since it gives us a strong hypothesis on which context token is the most relevant for the representation of the masked *target word*.

From this benchmark, we select five datasets with three different linguistic phenomena for which Pre-trained Language Models (PLMs) have shown high accuracy to ensure that the model captures the relevant information. We expand contractions such as *doesn't* → *does not*) and generate dependency trees using SpaCy (Honnibal and Montani, 2017) to extract and annotate the position of target and cue words in a sentence. In Table 1, we provide an example of each phenomenon in the benchmark together with our automated annotations. We accumulate examples from the five selected tasks as a unified dataset for grammatical agreement, resulting in 4,276 data points, and divide them equally into Train and Test sets. The Train set is only used for the fine-tuning phase; the Test set is used for all evaluation experiments.

4.2 Target Model

We conduct our experiments on three Transformer-based language models: BERT (uncased, Devlin et al., 2019), RoBERTa (Liu et al., 2019) and ELECTRA (Clark et al., 2020).[3] The results for the latter two are reported in Appendix A.3. By replacing the target words with the [MASK] token, we perform a Masked Language Modeling (MLM) task using the model's pre-trained MLM head. For instance, in the Subject-Verb Agreement example *"The pictures of Martha do not disgust Anne."*, we replace the verb *'do'* with the [MASK] token and feed the example to the model.

We perform our experiments on both pre-trained and fine-tuned versions of each model. Including a fine-tuned model in our analysis study gives us a complementary insight into the importance of the cue words, since fine-tuning allows the model to concentrate on the most helpful words for the downstream task of choice (i.e., agreement) and makes sure that target word representations take the cue word into account. We use prompt fine-tuning (Schick and Schütze, 2021a,b; Karimi Mahabadi et al., 2022) and compute Cross Entropy loss only over the output logits corresponding to the target and foil classes. Accuracy is 0.96 for pre-trained and 0.99 for fine-tuned BERT.

4.3 Baselines

Here we describe the existing context mixing methods which we include in our experiments. For each method, we select the m^{th} row of its context mixing map where m is the position of the [MASK] token, resulting in a 1-D array of scores for each context

---

[3] Base, with 12 layers and 12 attention heads, obtained from the Transformers library (Wolf et al., 2020).

token. We normalize the scores for all tokens in a sentence so that they are all positive values and sum to one. For completeness, we also include a few gradient-based attribution methods in our comparisons.

Rand: random scores generated from a uniform distribution for each sentence in the dataset.

Attn: raw attention scores $\boldsymbol{\alpha}_m$ from Eq. 5.

Attn-rollout: An aggregation method for approximating the attention flow based on raw attention weights (Abnar and Zuidema, 2020).

Attn-Norm: norm-based method of Kobayashi et al. (2020) that also incorporates the norm of the transformed input vectors to compute context mixing scores.

Attn-Norm + RES + LN: the extended norm-based method of Kobayashi et al. (2021) in which they also incorporates Residual connection (RES) and Layer Normalization (LN) located only in the first sublayer of a Transformer's encoder.

GlobEnc & ALTI: Two global token attribution methods proposed by Modarressi et al. (2022) and Ferrando et al. (2022). For a fair comparison, we exclude the aggregation through rollout in our first two evaluations (referred to as GlobEnc¬ and ALTI¬), because we are interested in assessing context mixing scores at each layer separately. In our third evaluation, we compare these methods with others at a global level and use rollout.

GradXinput, IG & DL: feature attribution scores that also make use of *top-down* information from the classification layer on top of the Transformer. We consider three popular variants of gradient-based attribution scores: Gradient×Input (**GradXinput**) (Samek et al., 2019; Yuan et al., 2019), Integrated Gradients (**IG**) (Sundararajan et al., 2017), and DeepLift (**DL**) (Shrikumar et al., 2017). For gradient-based methods, we use the pre-trained MLM head which has been trained during the pre-training of the BERT to compute the gradient of the true label with respect to the token representations at each layer.

5 Evaluation 1: Cue Alignment

As cue words are the only indicators of the true labels in our dataset, we expect that when the model performs well, it overwhelmingly depends on these words to form the representation of a [MASK] token in a given context. To quantify the alignment between a context mixing score and the cue word, we first define a binary cue vector ξ according to the following condition:

$$\xi_i = \begin{cases} 1, & \text{the } i^{\text{th}} \text{ token} \in \text{Cue words} \\ 0, & \text{otherwise} \end{cases} \tag{11}$$

Then we compare the cue vector and the prediction of a context mixing score $\boldsymbol{S}$ in two different ways:

Dot Product. We quantify cue alignment as $\boldsymbol{S} \cdot \boldsymbol{\xi}$, which measures the total score mass the model assigns to cue words to form the representation of the target token.

Average Precision. We quantify cue alignment as the average precision between the two vectors, which is a weighted mean of precision at each recall level:

$$\text{AP} = \sum_n (R_n - R_{n-1}) P_n \tag{12}$$

where P_n and R_n are the precision and recall at the n^{th} threshold. This metric relies on the ranking of tokens rather than the magnitude of their weights.[4]

Figures 1 and 2 show the alignment between the cue vector and different analysis methods using dot product and average precision for the pre-trained and fine-tuned model, respectively. In comparison with the other context mixing methods, *Value Zeroing* shows a higher degree of the target model incorporating cue words into the representation of the [MASK] token across all layers.

As can be seen from the first two columns in all graphs, raw self-attention weights (**Attn**) always perform worse than even random scores in highlighting cue words. This is in line with previous studies showing that raw attention weights often pay attention to uninformative tokens (Voita et al., 2018; Clark et al., 2019) and do not reflect the appropriate context (Kim et al., 2019). However, we can see a significant improvement in the results for **Attn-norm** where the norm of transformed value vectors are also taken into account, confirming that value vectors play an essential role in the context mixing process. The method **Attn-norm + RES + LN**, which expands **Attn-norm** to the whole self-attention block by adding Residual

---

[4] We also employed Probes-needed (Zhong et al., 2019) metric in our evaluation which intuitively counts the number of non-cue tokens we need to probe to find cue words based on a given score. As its motivation is similar to Average Precision and the results show the same pattern, we relegate the results with this metric to the Appendix A.2.

connection and Layer Normalization, would seem to show that the model is incapable of utilizing the cue words. However, incorporating also the second part of the encoder layer via our method shows the model does indeed use the cue words. We also find that GlobEnc and ALTI benefit from the rollout aggregation method to provide a global view, but they do not seem to provide good layerwise scores (without rollout).

The gradient-based scores, in contrast to the other methods, highlight the cue words only in the earlier layers of the model. In the next section, by using a layer-wise probing experiment, we will show that these scores are not reliable for identifying the relevant context in individual layers.

6 Evaluation 2: Context Mixing versus Probing

In this section, we investigate the relationship between cue word alignment and probing performance across layers. We hypothesize that if a layer aligns better with the cue word according to a reliable context mixing score, then the representation of the masked token on that layer can be used more effectively by a probing classifier to decode number agreement with the cue word.

To verify our hypothesis, we obtain the representation of masked tokens in test examples across all layers. Since all examples in our dataset share the same number agreement property, we asso-

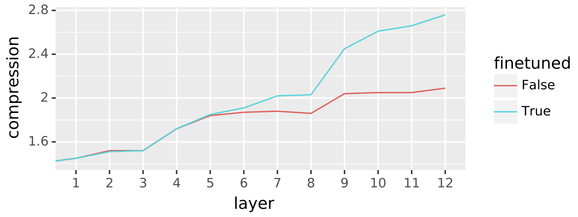

Figure 3: Layer-wise compression of probing classifiers using pre-trained and fine-tuned representations.

ciate each masked representation with a *Singular* or *Plural* label. Next, we perform an information-theoretic probing analysis using Minimum Description Length (MDL) to measures the degree to which representations encode number agreement. We chose MDL as our probe since it is theoretically justified and has been shown to provide more reliable results than conventional probes (Voita and Titov, 2020; Fayyaz et al., 2021).

To compute MDL, we employed the *online coding* of Voita and Titov (2020). Since MDL can be affected by the number of data points (N), we measure compression as our evaluation metric which is defined as follows:

$$\text{Compression} = \frac{N \cdot \log_2(K)}{\text{MDL}} \qquad (13)$$

where K refers to the number of classes (2 in our case). This metric is equal to 1 (no compression) for a random guessing classifier. A higher value for Compression indicates more accurate label prediction for the probing classifier.

Figure 3 reports compression of probing classifiers based on representations obtained from both pre-trained and fine-tuned models across all layers. We also include the results for the embedding layer of the model (layer 0) which can serve as a non-contextualized baseline. We can see a jump in probing performance at layers 4 ($1.52 \rightarrow 1.72$) and 9 ($2.03 \rightarrow 2.45$) in the fine-tuned setup, the same layers for which we found a higher alignment with cue words in Figures 1 and 2.

Table 2 presents the correlation between layer-wise Compression scores and layer-wise cue alignment scores from Section 5 for different analysis methods. As we can see, alignment according to *Value Zeroing* is highly positively correlated with the probing performance. This suggests that when *Value Zeroing* indicates that the model uses cue words to form representations of the masked tokens in a particular layer, these representations are in fact better at encoding number agreement.

Method	ρ^{PT}	ρ^{FT}

DL	-0.97	-1.00
Value Zeroing	**0.65**	**0.64**

Table 2: Spearman's ρ correlation between layer-wise probing performance (Comp.) and layer-wise cue alignments based on Dot Product. PT and FT refer to pre-trained and fine-tuned conditions, respectively.

Recall that based on Figures 1 and 2, according to the gradient-based methods the masked tokens pay more attention to the cue words only in earlier layers. However, we can see a highly negative correlation with probing results for these scores. Due to the nature of the task the probing score goes up monotonically along the layers. At the same time, the gradient attribution score goes up monotonically as you get closer to the bottom embedding layers, suggesting that gradient-based methods are unreliable for layer-wise analysis and identifying important tokens in the context mixing process.

7 Evaluation 3: Faithfulness Analysis

Our experimental results in Sections 5 and 6 show that the *Value Zeroing* score matches our prior linguistically-informed expectations. However, it is not always clear whether a *plausible* context mixing score that matches human expectations is also faithful to the model and reflects its decision making process (Herman, 2017; Wiegreffe and Pinter, 2019; Jacovi and Goldberg, 2020).

In this section we employ the notion of input ablation (Covert et al., 2021) to evaluate the faithfulness of our context mixing score. The influence of a target token on a model's decision is often estimated as the drop in the model's predicted probability of the correct class after blanking out the target token from the input. A higher drop for an ablated token indicates that the token is more influential on the model's decision (DeYoung et al., 2020; Abnar and Zuidema, 2020; Atanasova et al., 2020; Wang et al., 2022). We use this *blank-out* approach as a base for analyzing and comparing the faithfulness of context mixing scores.

DL	0.20	0.29
Value Zeroing	**0.26**	**0.31**

Table 3: Spearman's ρ correlation between the blank-out scores and different aggregated context mixing and attribution scores. PT and FT refer to pre-trained and fine-tuned conditions, respectively.

Figure 4: Most influential tokens on the target representation in a fine-tuned BERT model according to different aggregated context mixing scores compared to blank-out scores.

To estimate the blank-out scores in BERT, we calculate the probability of its output y using a softmax function normalized over only the corresponding logit values of target t and foil words (cf. Table 1), and compute blank-out scores for a given input token i as $p(y_t|\boldsymbol{e}) - p(y_t|\boldsymbol{e}\backslash e_i)$, where $\boldsymbol{e_i}$ refers to the input embedding of input token i. We compare these blank-out scores with context mixing scores, aggregated across all layers of the model. For gradient-based scores, calculating them with respect to the tokens in the input embedding layer ($\ell = 0$) provides us with aggregated scores since the backpropagation of gradients passes through all layers to the beginning of the model. For other scores, we use the *rollout* (Abnar and Zuidema, 2020) aggregation method.

Table 3 shows Spearman's rank correlation between the blank-out scores and different aggregated context mixing scores. The highest correlation for our method indicates that *Value Zeroing* is more faithful in explaining the model behaviour compared to other analysis methods.

Qualitative Analysis. We also take a closer look at the aggregated scores for a qualitative comparison. In Figure 4, we illustrate different scores obtained from a fine-tuned BERT model for a correctly classified example, where the model is asked to fill the masked token with one of the verbs *were* or *is* as target and foil classes, respectively. According to *Value Zeroing* scores, the model mainly relies on the main subject (*pictures*) as a cue word to form a contextualized representation of the [MASK] token, while the word *pictures* is also important for the model's final decision based on the blank-out scores. In this example, the blank-out score for the cue word is 0.99, meaning the model fully loses its confidence in the target class when the cue word is replaced with an `[UNK]` token. Surprisingly, gradient-based methods tend to highlight the word *hat* which is an agreement attractor, and attention-based scores tend to focus on the `[CLS]` token which has been idle during fine-tuning process.

Overall, our faithfulness evaluation and qualitative analysis suggest that *Value Zeroing* can explain model decisions at a global level when it is aggregated across layers. The context mixing maps per layer are provided in Appendix A.4, where some more meaningful patterns can be found in Value Zeroing scores (in both layer-wise and aggregated setups) in contrast to other context mixing scores.

8 Discussion

Although some desiderata such as plausibility (Lei et al., 2016; Strout et al., 2019) and faithfulness (Lakkaraju et al., 2019; Jacovi and Goldberg, 2020) are taken into account when developing explanation and analysis methods, evaluating them is still a challenge due to lack of a standard ground truth. Evaluating context mixing scores, where token-to-token interactions in a context are also considered, is even more challenging. Several studies have used gradient-based scores as an anchor of faithfulness, and measure how strongly context mixing scores correlate with them (Jain and Wallace, 2019; Abnar and Zuidema, 2020; Modarressi et al., 2022). However, the reliability of gradient-based scores can be questioned, especially when different variations of them show considerable disagreement

(Neely et al., 2022; Pruthi et al., 2022; Krishna et al., 2022). Thus, we suggest using controlled tasks for which we have strong prior expectations for evaluating these methods. In our study, we use a set of number agreement tasks to provide such priors, since the cue words are the only sources of information in the context for performing well in the task.

Another point worth discussing is the concern raised by Kobayashi et al. (2021) that BERT tends to preserve token representations rather than mixing them at each layer. We argue that their observation is due to the context-mixing ratio they defined by comparing the norm of residual effects against other token representations. In our view, this ratio is dominated by residuals and neglects the fact that a token representation carried by residual connections is indeed a contextualized representation outputted from previous layers. We keep the residuals intact within the encoder layer by zeroing only the value vectors and focusing on the context mixing performed by all tokens.

9 Conclusion

In this paper, we propose Value Zeroing as a novel approach for quantifying the information mixing process in Transformers to address the shortcomings of previous methods. We performed extensive complementary experiments and showed that our method outperforms others in three different evaluation setups. Since our approach requires no supervision, it could be an interesting option for improving model efficiency by removing token representations across layers.

10 Limitations

As is the case for most attempts at interpreting Deep Learning models, our evaluation of our (and others') proposed methods are not definite since we have no gold standard of what happens inside a model, although we try to remedy for that by conducting independent and complementary evaluation schemes.

Our proposed method is customized for deep neural models based on the Transformer architecture and cannot be easily generalized to other (mathematically different) modeling architectures. Our evaluations were based on encoder-based models, and focused on the Text modality. In the future, we will extend our experiments to more modalities, such as speech and vision.

A Appendices

A.1 On the choice of distance function

The purpose of this section is to inspect the impact of selecting different distance metrics when computing Value Zeroing in Eq. 10. Timkey and van Schijndel (2021) questioned the informativity of standard representational distance measures such as cosine and Euclidean by observing that only a small subset of rogue dimensions contribute to the anisotropy of a contextualized representation space. They proposed using simple post-processing techniques to correct for such these rough dimensions. We followed their suggestion and normalized the representations before computing distances, but we did not observe any noticeable difference in our scores compared to using non-normalized representations (Fig. A.1). We also repeated our experiment with Spearman's and Euclidean distance metrics and observed the same pattern in the results (Fig. A.1).

We believe that in anisotropy studies that use clustering methods, the choice of distance metrics is crucial. However, we compute each token's distance from itself (not from other tokens) and compare them relatively. This might explain why we observe the same pattern for different distance metrics.

A.2 More metrics

Figure A.2 reports the cue alignment evaluation for BERT model based on Probes-needed (Zhong et al., 2019) metric.

A.3 More PLMs

We replicated our experiment for the cue alignment for two more PLMs; RoBERTa (Liu et al., 2019) and ELECTRA (generator, Clark et al., 2020). As we can see in Figures A.3 and A.4, our method consistently outperforms other methods on all models in both pre-trained and fine-tuned setups. Due to the fact that our scores are based on zeroing value vectors, our method can be easily applied to any Transformer-based models even with different modalities.

Abstract

Timely generation of radiology reports and diagnoses is a challenge worldwide due to the enormous number of cases and shortage of radiology specialists. In this paper, we propose a **K**nowledge **G**raph **A**ugmented **V**ision **L**anguage **BART** (KGVL-BART) model that takes as input two chest X-ray images- one frontal and the other lateral- along with *tags* which are diagnostic keywords, and outputs a report with the patient-specific findings. Our system development effort is divided into 3 stages: i) construction of the Chest X-ray KG (referred to as chestX-KG), ii) image feature extraction, and iii) training a KGVL-BART model using the visual, text, and KG data. The dataset we use is the well-known Indiana University Chest X-ray reports with the train, validation, and test split of 3025 instances, 300 instances, and 500 instances respectively. We construct a Chest X-Ray knowledge graph from these reports by extracting entity1-relation-entity2 triples; the triples get extracted by a rule-based tool of our own. Constructed KG is verified by two experienced radiologists (with experience of 30 years and 8 years, respectively). We demonstrate that our model- KGVL-BART- outperforms State-of-the-Art transformer-based models on standard NLG scoring metrics. We also include a qualitative evaluation of our system by experienced radiologist (with experience of 30 years) on the test data, which showed that 73% of the reports generated were fully correct, only 5.5% are completely wrong and 21.5% have important missing details though overall correct. To the best of our knowledge, ours is the first system to make use of multi-modality and domain knowledge to generate X-ray reports automatically.

1 Introduction

Medical imaging techniques are widely used in hospitals across the world. The detailed information extracted from medical images is crucial for proper diagnosis and treatment. An experienced and skilled radiologist is required to prepare an accurate full text diagnostic report. However, due to a lack of experts, many reports contain indecisive findings, forcing patients to undergo further tests involving pathology or other advanced imaging methods. In addition, the time consuming process of full text radiology report generation is one of the biggest challenges. All over the world, the ratio of radiologists to patients is very low. The ratios in the US, China, and India are 1:10,000, 1:14,772, and 1:100,000 respectively (Arora, 2014). Given the huge number of cases and the shortage of radiology experts, timely report generation and diagnosis is a huge challenge worldwide.

In the case of a chest ailment, X-rays produce images of chest organs like, lungs, spinal bones, heart, airways, and blood vessels. These images help doctors ascertain an exact findings such as pneumonia, collapsed lung, emphysema, cancer, broken ribs, *etc*. Manual examination of X-ray images for a large number of patients can be time consuming, leading to delays. Human errors may further add to the challenges. This prompted the researchers to use deep learning models capable of automated report generation to address the above mentioned challenges. With deep learning based automatic report generation, the reports can be generated with minimal delay and free from any human errors. Large-scale pre-trained language models have recently expanded into multimodality learning, improving representations by combining visual and semantic features (Cho et al., 2021; Sollami and Jain, 2021; Mustafa et al., 2022). However, progress in adapting language models toward conditional Natural Language Generation (NLG) is limited to image and text modalities. The Natural Language Processing (NLP) community is moving towards transformer-based models. The major-

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3401–3411

ity of NLP research today produces better results by tweaking an already-trained transformer model across a large corpus. This prompts us to research pre-trained transformers like BART that have generative capabilities while conditioning them on visual, textual, and KG data. This study introduces the KGVL-BART conditioned transformer-based model, which, produces a comprehensive report given an X-ray image, tags associated with X-ray image.)), and chest X-ray KG. We train our model using the publicly accessible Indiana University chest X-ray dataset (referred to as IU-XRay) (Fischer et al., 2022). The encoder accepts input from tags, images, and KG in three different modalities. We create embeddings for each of these modalities before sending input to the multimodal encoder. We compare our quantitative findings to earlier transformer-based models. Furthermore, we provide qualitative analysis on test set by a radiologist.

Problem Statement: Design a system that generates a structured patient-specific report from radiology images, image tags and domain knowledge. The input to the system is

- two chest X-ray images- one frontal and the other lateral
- tags

The output of the system is

- radiology report with patient-specific findings

Domain knowledge comes from the Knowledge Graph.

Our **contributions** are:

1. A knowledge-enhanced BART-based Vision-Language Model which we call KGVL-BART and which generates chest X-ray reports with accuracy better than SoTA.
2. Chest X-ray knowledge graph created from IU Chest X-ray reports.
3. Demonstration of the fact that multi-modality helps in radiology report generation; we use both the image and its tags plus triples from the knowledge graph.

2 Fundamental Definitions

Vision-Language Model: Vision-Language models are the deep learning models that learn both vision and language modalities together.

Tags: Tags are the diagnostic keywords (e.g., left lung, pulmonary atelectasis, hernia, pneumonia, etc.) associated with X-ray image.

Findings: The findings section in radiology reports is the clinical description of abnormalities and normalities observed on radiology image.

Impression: The impression section in radiology reports is the summary of findings section.

Knowledge Graph: Paulheim (2017) defines Knowledge Graph (KG) as "A knowledge graph (i) mainly describes real-world entities and their interrelations, organized in a graph, (ii) defines possible classes and relations of entities in a schema, (iii) allows for potentially interrelating arbitrary entities with each other and (iv) covers various topical domains."

Knowledge Graph Embeddings (KGEs): Knowledge graph embeddings represent the entities and relations in lower-dimensional vectors.

KG-Grounding: The KG grounding is the process of extracting the subgraph (referred to as grounded KG) from domain-specific KG (in our case chestX-KG). A grounded KG is a subgraph from the chestX-KG whose nodes represents tags present in the input tag set plus additional relevant nodes.

3 Related Work

Researchers (Jing et al., 2017; Zhang et al., 2017; Yuan et al., 2019) studied the issue of automatic report generation. Their research looked into the visual attention given to recurrent decoders and convolution-recurrent architectures (CNN-RNN) that were first introduced by Vinyals et al. (2015) on image captioning. Transformers, attention-only based models that have replaced recurrent models in the NLP community (Vaswani et al., 2017; Devlin et al., 2018). Several attempts have been made in the medical field to create medical reports from the corresponding images. Most authors use multilabel image captioning to produce X-ray reports, and they subsequently use those captions as textual features. The IU-Xray dataset's chest X-ray images were used to generate the first structured report using tags predicted by a CNN-RNN model (Shin et al., 2016). In (Wang et al., 2017b), a system for generating natural reports for the Chest-Xray14 dataset, employing private reports, was presented. This framework used a non-hierarchical CNN-LSTM architecture and focused on semantic and visual aspects. The IU-Xray dataset was created by Jing et al. (2017) to generate radiology reports automatically.

There is a lot of research performed in NLG on multimodal constraints. NLG models based on transformers (Sollami and Jain, 2021) propose a model called MAnTiS, Multimodal Adaptation for Text Synthesis, as a general method for multimodal conditionality. In this method, separator tokens are used to separate each modality type, and modality-specific encoders are used to encode each modality type. Liu et al. (2021) contend that pre-trained language models and textual concepts by themselves are insufficient to give enough data for generative commonsense reasoning. They supply the ConceptNet KG as input to the transformer model for generative commonsense reasoning in addition to text input. Liu et al. (2020) proposes a Knowledge-enabled Bidirectional Encoder Representation from Transformers (K-BERT). Since the parameters of all pre-trained BERT models are the same, K-BERT can load any of them. Additionally, K-BERT can easily integrate domain knowledge into the models by giving them access to a KG without prior training. Xing et al. (2021) propose KM-BART to conduct the task of Visual Commonsense Generation (VCG) by integrating visual features in pretrained BART model.

4 Methodology

As shown in the figure 1, the model architecture consists of six major components, namely, KG grounding, KG embedding, image embedding, text embedding, encoder, and decoder. The KG grounding module extracts the grounded KG from the chestX-KG. Grounded KG includes all of the nodes in the input tag set and their significant neighbors. The KG embedding module converts the grounded KG into vector form using the KGE technique. The image feature extractor module generates the feature vectors for input chest X-ray images. To compute the text features, we use the BART text encoder method. The encoder and decoder are multilayer transformers. This section explains all components in detail.

4.1 Knowledge Graph Grounding

The KG grounding module extracts the small subgraph from chestX-KG for each report in the dataset, given a tag set as input. First, it adds all entities from chestX-KG that are present in the input tag set, and then it adds their significant neighbors.

The algorithm focuses on first finding the most appropriate path in chestX-KG from tag entities to the root of chestX-KG and then adding neighbor nodes that are connected with *DefaultPropertyOf* (default property of entities) relation. The following are the steps to extract grounded KG:

- Find all possible candidate paths from a matched entity to the root node.
- Find the most appropriate top five paths by ranking based on the precision and recall of entities in the input tag set and entities in all possible candidate paths.
- We consider all paths, including those with matched entities that are absent from the selected top-ranking path.
- Instead of adding all neighbors of input tag entities, we add only significant entities that are default properties or default descriptors of input entities.

Our proposed method reduces noise by adding only significant nodes to grounded KG. We propose a context-aware KG grounding algorithm to select M triples from the chestX-KG for an entity candidate. The pseudocode of this algorithm is shown as follows.

Algorithm 1: KG Grounding

```
Input  : K: Tags
         G(V, E) : chestX-KG
Output : Grounded KG
Find all candidate paths in G(V, E) that includes the node with input concept
path-dict -> initialize
for each path in possible candidate-paths do
    $Precision = \frac{K \cap Allentitiesinpath}{No.ofconceptsinK}$
    $Recall = \frac{K \cap Allentitiesinpath}{No.ofnodesinpath}$
    $F - score = \frac{2 * Precision * Recall}{Precision + Recall}$
    add path-dict -> (path:F-score)
end
Sort path-dict in descending order of F-score
Get top 5 paths
for each path in top-5-paths do
    if len(set(K) - set(path)) > 0 then
        Add all triplets from that path in grounded KG triple set
        for each node in path do
            Find all neighbors of node with default-property relation
            Add all triples of form (neighbor, DefaultPropertyOf, node) in grounded KG triple set
        end
    end
end
Return grounded KG triplets set.
```

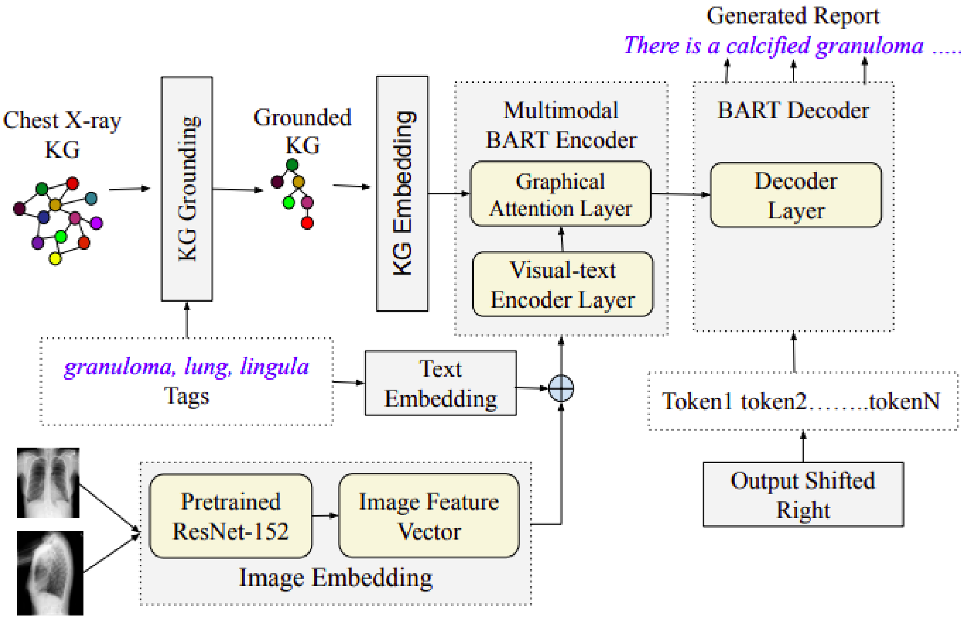

Figure 1: The architecture of our proposed KGVL-BART model. KGVL-BART has six important components: KG grounding, KG Embedding, image embedding, text embeddings, encoder, and decoder.

4.2 Knowledge Graph Embeddings

Knowledge Graph Embedding methods embed the components of a KG, including entities and relations, into continuous vector spaces. The chestX-KG is represented in low dimensional vector space using KGE. There are different techniques used for KG embeddings like TransR, TransH, TransE, TransD, *etc,* (Wang et al., 2017a). For simplicity and concreteness, in this work, we primarily consider the TransE (Bordes et al., 2013) model due to its state-of-the-art performance.

4.3 Text Embedding

The input embeddings in KGVL-BART are made of two separate embeddings, token embeddings and position embeddings. To get the final text embedding, we add the vectors of token embeddings and position embeddings.

4.3.1 Token Embeddings

Tokens are nothing but a word or part of a word. The textual encoder uses the vocabulary offered by large-cnn BART, and the token embedding is consistent with BART. Using a trainable lookup table, we transform each token in the input tag set into an embedding vector of dimension d.

In order to create these token embeddings, a method called BART tokenizer is used to tokenize the text. Input tag set T is tokenized as $\{t_1, t_2, ..., t_{|t|}\}$ and encoded as learned embedding $e_t = \{e_{t_1}, e_{t_2}, ..., e_{t_{|t|}}\}$. For a token t_n, its embedding is $e_{t_n} \in R^d$, where d is the dimension of the token embeddings. The encoder, decoder, and language modeling head (Press and Wolf, 2016) all share the embedding parameters. Due to the permutation-invariance of the attention layers, BART learns positional embeddings for absolute token positions and adds them to the token embeddings (Vaswani et al., 2017; Devlin et al., 2018).

4.3.2 Positional Embeddings

Position embeddings represent the position of the word within that sentence that is encoded into a vector. We must introduce some information about the relative or absolute location of the tokens in the sequence because our model lacks recurrence and convolution and hence cannot use the sequence's order. To do this, we augment the token embeddings at the base of the encoder and decoder stacks with positional embeddings. The positional encodings and token embeddings have the same dimension d allowing the token and positional embeddings to be added together. The text embeddings are the sum of the token embeddings and the positional embeddings, i.e., $e_{tp} = e_t + e_p$, where e_p is the positional embeddings.

4.4 Image Embedding

For image feature extraction, we use three different methods: i) Pretrained CheXNet (Rajpurkar et al., 2017) model (referred to as CheXNet), ii) Pretrained ResNet-152 model (referred to as ResNet-152), and iii) Fine-tuned ResNet-50 for multilabel image classification on NIH chest-xray dataset (referred to as NIH-ResNet). We extract the image embeddings from each of these models, and we train KGVL-BART separately for these methods. In this section, we give details about the pretrained ResNet-152 feature extractor.

We extract the embedding form of the final fully connected layer of the pre-trained ResNet-152 model (He et al., 2016). We transform images using the same parameters as during pretraining, which include resizing, center cropping, and normalizing. We project the image feature vector through a linear layer with a learnable weight matrix $W \in R^{N*d}$ onto the language model embedding space d.

To get the final input embeddings, we sum up the text and image embeddings. In addition to the original vocabulary of BART, for images, we use <*img*> and <*/img*> to indicate the start and the end of visual embeddings, respectively. Multimodal Feature Augmentation is done by adding image feature vector with the text feature vector to generate a single feature vector, i.e., $e_{tv} = e_{tp} + e_v$.

4.5 Encoder

The encoder uses two modalities—image and text, and text generation is conditioned on grounded KG. According to the figure 1, the KG enhanced encoder layer sits above the visual-textual encoder layer and is intended to enhance the visual-text representation $\{e_{tv_1}, e_{tv_2}, ..., e_{tv_n}\}$ by taking the KG structure into account. We use a graph attention layer to incorporate graph representations into the input encoding process. It uses explicit relations to help the model learn intra-concept relations more effectively. Formally, the grounded KG embedding, as well as the output visual-textual embeddings from the visual-textual encoder, are combined by the KG-augmented encoder to update the visual-textual token representation. Our self-attention layer and fully-connected layer with residuals make up the stack of m transformer blocks that make up our bidirectional multimodal encoder.

4.6 Decoder

The decoder uses the text embedding module at the bottom layer to encode the text. The decoder in our model is also a multi-layer transformer. Our decoder is auto-regressive and unidirectional. We skip over a detailed explanation of these modules because our textual transformers are the same as those used in BART (Lewis et al., 2019; Vaswani et al., 2017).

5 Experiments

The datasets, evaluation metrics, and baselines used for the training and evaluation of the KGVL-BART model are covered in detail in this section.

5.1 Dataset

We use the IU Chest X-ray dataset to train our model (Demner-Fushman et al., 2016). There are 3825 patient reports in this dataset. 7430 chest X-ray images from the front and sides contribute to this dataset. Each patient report contains two types of tags: MTI tags and manual tags from MESH[1] and RadLex[2]. Each report has three parts: an impression, which is a title or summary of the report; findings, which contain the report in detail; and manual tags. We use MESH tags (text) as one of the input to train our model. We concatenate impressions and findings and use it as target to train our model. IU Chest X-ray dataset includes normal and abnormal study reports. There are total 3825 reports out of which 1379 are normal and 1646 are abnormal. The dataset is balanced with respect to normal and abnormal reports. Additionally, we chose 500 samples at random to serve as the test set. Our split is 3025 for training, 300 for validation, and 500 for testing. Table 1 shows the samples from the IU-Chest X-ray dataset.

Table 1 shows an example from the dataset that we are using to train KGVL-BART model.

5.1.1 Chest X-ray Knowledge Graph (chestX-KG)

Nodes in our knowledge graph represent all necessary information, like findings, observations, anatomy, properties, and modifiers related to the organ. We define eight logical relations to construct chestX-KG. i) *PartOf*: It represents the relation between anatomy and sub-anatomy, ii) *TypeOf*: It represents the relation between similar type of entities, iii) *ModifierOf*: It denotes the descriptors of findings, anatomical locations, properties, *etc.*, iv) *ObservationOf*: It denotes the clinical observations observed for a particular finding, v) *Default-ObservationOf*: It denotes the observation that is associated by default with a particular anatomical

---

[2] `https://radlex.org/`

Frontal Image	Lateral Image	Tags	Target
		Osteophyte, thoracic vertebrae, multiple, small, Thickening, pleura, apex, bilateral, Lung, hyperdistention, mild	**Impression:** No acute cardiopulmonary abnormality. **Findings:** The cardiomediastinal silhouette and pulmonary vasculature are within normal limits. There is no pneumothorax or pleural effusion. There are no focal areas of consolidation. Cholecystectomy clips are present. Small T-spine osteophytes. There is biapical pleural thickening, unchanged from prior. Mildly hyperexpanded lungs.
		normal	**Impression:** No acute cardiopulmonary findings. **Findings:** Heart size and mediastinal contour are within normal limits. There is no focal airspace consolidation or suspicious pulmonary opacity. No pneumothorax or large pleural effusion. Mild degenerative change of the thoracic spine.
		Pulmonary Atelectasis, base, Spondylosis, thoracic vertebrae, Arthritis, cervical vertebrae	**Impression:** Basilar atelectasis. No confluent lobar consolidation or pleural effusion. **Findings:** The cardiac contours are normal. XXXX basilar atelectasis. The lungs are clear. Thoracic spondylosis. Lower cervical XXXX arthritis.
		Calcified Granuloma, lung, upper lobe, right	**Impression:** No acute cardiopulmonary process. **Findings:** The cardiomediastinal silhouette is within normal limits for size and contour. The lungs are normally inflated without evidence of focal airspace disease, pleural effusion, or pneumothorax. Stable calcified granuloma within the right upper lung. No acute bone abnormality.

Table 1: Samples from the IU Chest X-ray dataset. We use frontal images, lateral images, and tags as input to our model and target text as a concatenation of impression and findings columns from the IU Chest X-ray dataset. In this table, we show only the columns we use to train the KGVL-BART model.

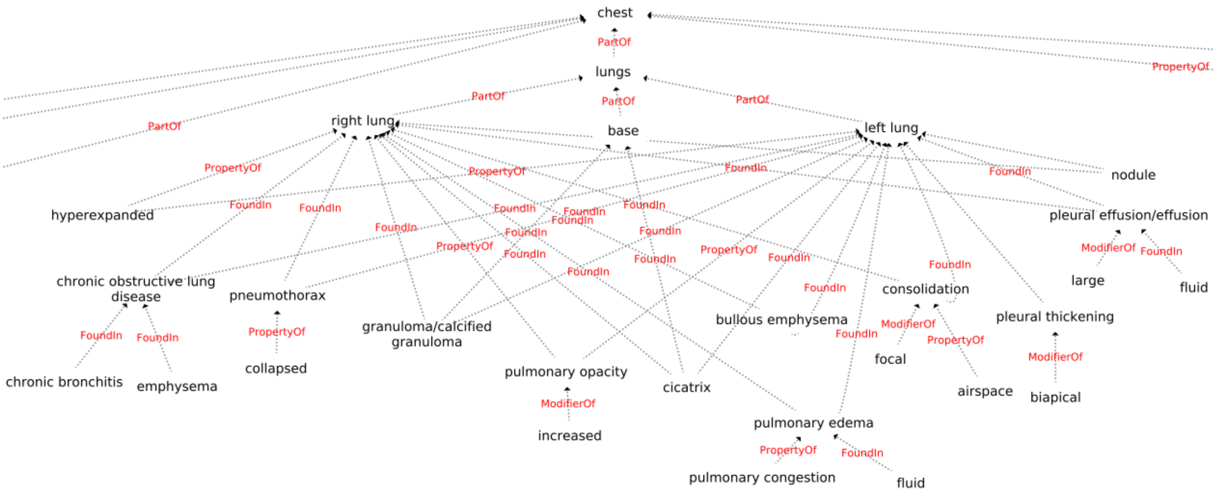

Figure 2: Chest X-ray KG constructed by extracting triplets from the free-text chest X-ray reports. Constructed KG is verified by radiologists. Only a portion of the entire KG is displayed due to space limitations.

location or particular finding. vi) *PropertyOf*: It denotes the relation between entities (anatomical entities, finding entities, observation entities, *etc.*) and their properties., vii) *DefaultPropertyOf*: It denotes the property that exist by default with particular anatomical location or particular finding., and viii) *FoundIn*: It denotes the relation between findings and corresponding anatomical location.

We use a rule-based and pattern-based approach to extract the triples from the IU X-ray text report corpus. After extracting triples from text-report corpus we construct hierarchical KG with chest as root node and children represents its parts or associated findings. More details about radiology KG construction is given in paper (Kale et al., 2022). The constructed KG is verified by two radiologists who are involved in this research work. Figure 2 shows the part of chestX-KG that we have constructed.

5.2 Training

Three different techniques are used to extract the features from the frontal and lateral X-ray images: i) Pretrained CheXNet model, ii) Pretrained Resnet-152 model, and iii) Fine tuned Resnet-50 for multi-label image classification on the NIH chest X-ray dataset[3] (Wang et al., 2017b).

We have trained the KGVL-BART model for each of these image embeddings separately and also provided quantitative results. To implement the TransE model for KG embeddings, we use the open-source OpenKE[4] tool. The chestX-KG contains 106 nodes and 126 triples.

5.3 Pretraining Setup

For model pretraining we use ConceptNet KG (Speer et al., 2017) and common sense generation dataset (Lin et al., 2020). For pretraining, we do not use images. At the time of pretraining, we are not adding image features to text features. We use byte-pair encoding for tokenization, with a maximum length of 32 for the encoder and 64 for the decoder. We set the learning rate to 0.00001 and used AdamW with $\beta1 = 0.9$, $\beta2 = 0.98$ for optimization. We set the batch size to 60. We trained the KGVL-BART for 10 epochs, and the gradients are accumulated every 6 steps. We apply dropout with a probability of 0.1 to avoid over-fitting. While inferencing, we use beam search with beam size 5 and a length penalty of factor 0.6.

5.4 Training Setup

We propose our own algorithm for KG-grounding tasks. We construct grounded KGs for each report tag set. We use pretrained weights to initialize the KGVL-BART model. We train our model on the IU Chest X-ray dataset.

We use byte-pair encoding for tokenization with a maximum length of 300 for the encoder and 500 for the decoder. We set the learning rate to 0.00001 and used AdamW with $\beta1 = 0.9$, $\beta2 = 0.98$ for optimization. We set the batch size to 18. We trained the KGVL-BART for 15 epochs, and the gradients are accumulated every 6 steps. We apply dropout with a probability 0.1 to avoid over-fitting. We use beam search with beam size 5 and length penalty with factor 0.6 while inferencing. DGX A100-SXM-80GB GPU server takes approximately 15 minutes for a single epoch.

6 Evaluation

We evaluate our model by automatic metrics and human evaluation as well. For automatic evaluation we use word-overlap metrics. Manual evaluation is performed by two radiologists.

6.1 Quantitative Evaluation

We compare the performance of KGVL-BART model with previous state-of-the-art conditional transformer text generation models, i) the CNN-RNN model (Vinyals et al., 2015), ii) CDGPT2 for visual input only, text input only, and for both visual and text inputs (Alfarghaly et al., 2021). Following other conventional generation tasks, we use several widely-used automatic metrics to automatically assess the performance, such as BLEU (Papineni et al., 2002), ROUGE (Lin, 2004) and METEOR (Banerjee and Lavie, 2005), which mainly focus on measuring n-gram similarities. We have evaluated other NLG metrics like BLEURT (Sellam et al., 2020) and BERTScore (Zhang et al., 2019). Table 2 shows the NLG metrics score of generated X-ray reports by KGVL-BART and baseline models vs. gold standard X-ray reports. Evaluation is done on a test dataset. We have added ablation study, which shows that knowledge infusion improves the report generation. Last row in table 2 shows the results of our model by removing KG augmented layer from it.

Even though the dataset is balanced with respect to normal and abnormal reports, However, multiple organ findings are included in a single report; if at least one organ is found to be abnormal, the report is classified as abnormal. Findings for the other organs are normal, despite the fact that this is classified as an abnormal report. As a result, our model may be overly focused on widely reported normal findings. Hence, we have added evaluation metrics only to abnormal studies as well. Table 3 shows the NLG metrics for abnormal studies. For evaluation, we consider abnormal studies from the test set. Our results show that our model is capable of generating better reports than SoTA models for abnormal findings as well.

6.2 Qualitative Evaluation

This section provides qualitative analysis by a radiologist having experience of thirty years. Access to images and the ground-truth reports was given

to the radiologist to evaluate the automatically-generated reports. The radiologist classified the generated reports into **accurate** (report with most of the vital information), **missing details** (reports with no false information but missing some vital details), and **false** predictions (report with false information and overall incorrect diagnosis). We have provided 200 random samples from the test dataset and their corresponding generated reports for qualitative analysis. Qualitative evaluation by the radiologist shows that 73% of the reports generated were fully correct, only 5.5% are completely wrong and 21.5% have important missing details though overall correct. Further, these random samples were classified into normal and abnormal reports. For normal studies 95.6% of the reports generated were fully correct, 4.40% have important missing details though overall correct and 0% false reports. For the abnormal cases, the model could generate 54.13% of the reports correctly, 35.78% missing details, and 10% had false reports. Table 4 contains the results of the qualitative analysis. The reports classified as missing details by the radiologist also contain useful information that can be used to speed up the report writing process. Overall results are promising however, there is still a scope for improvement. The results show that the model is a bit biased towards normal cases, which is often the case with medical datasets as it lacks necessary details to describe the different irregularities present in the image.

Method	**Samples**	**Accurate**	**Missing Details**	**False**

	Abnormal(317)	**54.13%**	**35.78%**	**10.00%**
CDGPT2	*All*(500)	61.60%	28.20%	10.20%
	Normal(201)	**99.00%**	**00.00%**	01.00%
	Abnormal(299)	36.50%	47.10%	16.40%

Table 4: Results of generated reports, manually evaluated by radiologist. Manual evaluation is done on the IU X-RAY dataset. Best results are shown in a bold face.

7 Summary, Conclusion and Future work

We introduce KGVL-BART a knowledge-enhanced Vision Language model to generate X-ray reports from chest X-ray images and tags. We develop a knowledge graph called chestX-KG, which is verified by two experienced radiologists. Overall the reports generated are accurate. Our approach to constructing grounded KGs is relatively noise-free since it considers only entities in the hierarchical path from tag set entities to the root node of the knowledge graph and only adds neighbors with "default" properties. Experimental results show the efficacy of our method and its superiority over SoTA.

		Ground Truth	Generated by KGVL-BART Model
Accurate	Normal	The lungs are clear. Heart size is normal. No pneumothorax, pleural effusion, or focal airspace disease. Bony structures appear intact.	The cardiomediastinal silhouette is within normal limits. No pneumothorax or pleural effusion. No acute bony abnormalities.
	Abnormal	Heart size is normal. There are densely calcified mediastinal and right hilar lymph xxxx which suggest prior histoplasmosis exposure. No consolidating airspace disease is seen within the lungs. No pleural effusion or pneumothorax. No convincing acute bony findings.	Lungs are clear bilaterally. Specifically, no evidence of focal consolidation, pneumothorax, or pleural effusion.. Calcified right hilar lymph xxxx noted. Cardio mediastinal silhouette is unremarkable. Visualized osseous structures of the thorax are without acute abnormality. Stable enlargement of the cardiac silhouette, consistent with calcification. Aortic calcifications noted. No acute bony abnormality identified.
Missing Details	Normal	Lungs are clear bilaterally. There is no focal consolidation, Pleural effusion, or pneumothoraces. Cardiomediastinal silhouette is within normal limits. xxxx are unremarkable.	Normal heart size and mediastinal contours. No focal airspace consolidation. no pneumothorax or pleural effusion. No acute bony abnormalities.
	Abnormal	Heart size is normal. No pneumothorax or pleural effusions. There is an 8 mm calcified nodule in the left midlung. There is also a 7 mm calcified nodule near the left hilum. Hyperexpanded lungs consistent with chronic obstructive pulmonary disease.	There are low lung volumes. the lungs are otherwise clear. There is a calcified left hilar lymph node and left midlung granuloma. No focal airspace consolidation to suggest pneumonia. No pleural effusion or pneumothorax. Normal heart size. No acute bony abnormality.
False	Abnormal	Heart size is moderately enlarged. The mediastinum are within normal limits. there is no pleural effusion or pneumothorax. There is suspected right lower lobe airspace opacity demonstrated on the lateral study. There is a fracture of superior sternotomy unchanged.	There is stable eventration of the right hemidiaphragm. There is no focal lung consolidation. Heart size is within normal limits. No pneumothorax or pleural effusion. No acute bony abnormalities.

Figure 3: Examples of ground truth and reports generated by KGVL-BART (ResNet-152). The first slot shows the instance of accurate prediction by the KGVL-BART model for normal and abnormal cases. Abnormal findings are highlighted in blue. The second slot shows the example of partially correct predictions by the KGVL-BART model for normal and abnormal cases. Details that are present in ground truth but missing in the predicted report is highlighted in red. The third slot shows the example of false predictions by the KGVL-BART model for abnormal case. For normal case model does not generate false report.

Our future work consists in training our model on the much larger MIMIC-CXR (Johnson et al., 2019) dataset. We would also like to expand the scope of our work to CT, MRI, *etc.*

Limitations

The IU Chest X-ray and the MIMIC-CXR datasets are publicly available that links chest X-ray images with text radiology reports. The IU Chest X-ray dataset available for general use and the MIMIC-CXR dataset has restricted access. Annotating medical reports requires domain experts' knowledge, and it is costly. Medical data is likewise subject to strict privacy regulations and is governed, for example, by the Health Insurance Portability and Accountability Act (HIPAA). Therefore, only a small amount of data is accessible to the general (research/corporate/industry) use.

There are many more sentences in this dataset describing normalities than abnormalities. As a result, most machine learning models are biased to produce normal reports more frequently than abnormal ones. Given the scarcity of examples, abnormalities are more challenging to find.

Ethics Statement

IU Chest X-ray dataset's authors used appropriate techniques to de-identify the text reports. Data is anonymized; hence our model will not disclose information about the patient's identity.

Abstract

We present a discourse parsing model for conversation trained on the STAC corpus (Asher et al., 2016). We fine-tune a BERT-based model to encode pairs of discourse units and use a simple linear layer to predict discourse attachments. We then exploit a multi-task setting to predict relation labels, which effectively aids in the difficult task of relation type prediction; our F1-score equals or surpasses the state of the art in the approaches we have reimplemented using code from the authors with no loss in performance for attachment, confirming the intuitive interdependence of these two tasks. Our method also improves over other discourse parsing models in the literature in permitting attachments in which one node has multiple parents, an important feature of multiparty conversation.

1 Introduction

Discourse parsing, the task of predicting graphs that represent semantic relations (arcs) between *elementary discourse units* or EDUs (nodes), is a hard problem in NLP due to the complexity of discourse graphs and the frequent lack of surface cues provided by EDUs, which forces parsers to rely on deep, semantic information. Multiparty, spontaneous conversation is especially tricky as the structure often meanders and a single participant can respond to multiple discourse moves at once, yielding non-tree-like structures that challenge existent parsing techniques (Afantenos et al., 2015).

While it is tempting to attack a complex problem with complex machinery, as recent research on discourse parsing has done (see Section 6), we show that a simple model can achieve or surpass state of the art results for discourse relation labeling with a little inspiration from human discourse processing.

First, because a decision about whether two EDUs are attached by a semantic relation generally requires reasoning about their contents together, our transformer-based model encodes embeddings of EDU *pairs*, exploiting a form of message passing simpler than graph neural net models (Wang et al., 2021) while achieving better results. Next, we draw on the fact that for human annotators, the tasks of discourse attachment and relation labeling are often interdependent: sometimes one sees how to attach two EDUs but only later how to determine the relation that links them; sometimes, a clue, e.g. an explicit marker like *because*, makes the relation clear, and the task is to find the second argument to the relation. Our model exploits this interdependence with a multi-task architecture for attachment prediction and relation labeling. Finally, our model allows for the non-tree-like structures.

In Section 2, we provide background on discourse structure and data sets. In Sections 3 and 4, we describe our model and results. Section 6 presents related work in discourse parsing.

2 Discourse parsing theories and data sets

Just as a sentence is not a bag of words but comes with a structure that serves to compute its meaning from that of its constituent words, so too a discourse or conversation is not a bag of dialogue moves but comes with a structure that enables an interpreter to compute an overall meaning from its constituents. EDUs are clauses or subclausal units that serve as the minimal, linguistic constituents upon which discourse structures are built (Marcu, 1999), and discourse parsing involves finding the recursive structure over EDUs that exploits their semantic content together with various contextual features.

There are two main theories that have investigated complete discourse structures for texts: RST (Mann and Thompson, 1987) and SDRT (Asher, 1993; Asher and Lascarides, 2003). Only SDRT has been applied to multi party conversation as in the STAC and Molweni datasets (Asher et al., 2016;

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3412–3417
May 2-6, 2023 ©2023 Association for Computational Linguistics

Li et al., 2020). Given our interest in multiparty conversation, we use SDRT and three versions of the STAC corpus, a set of multi-party chats from an online version of the game *Settlers of Catan*, in which players trade or otherwise acquire resources in order to build roads and settlements and thereby score victory points. The standard version, *S*, contains only linguistic (chat) moves made by players; the situated version, *S-Sit*, integrates descriptions of nonlinguistic events (game moves), represented as *elementary event units* (EEUs). In *S-Sit*, both EEUs and EDUs are integrated into discourse structure. We present the third version in Section 2.1.

In SDRT a conversation provides a number of EDUs linked together to form a weakly connected, Directed Acyclic Graph (DAG). Each EDU apart from the head has at least one incoming link. Backwards links (where an EDU attaches to another EDU that comes after it in the dialogue) are prohibited if the EDUs are produced by different speakers (Perret et al., 2016). Each edge of the DAG is labeled with one of 16 different types of discourse relation, such as Explanation (Exp), Question-Answer-Pair (QAP), or Acknowledgement (Ack).

The DAGs postulated by SDRT allow one child to have multiple parents in the structure. Figure 1 provides a representative example from the STAC corpus: with his 'kk' William acknowledges *both* refusals to his offer and signals that he is moving on before ending his turn.

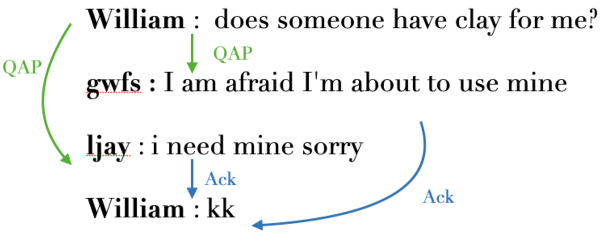

Figure 1: Example from the STAC corpus *S* illustrating an EDU ('kk') with multiple parents

In multiparty dialogue, coordination and negotiation over content is key. EDUs with multiple parents typically mark moves that signal such a coordination or end of negotiation. Multi-parent links can thus have a major impact on conversational structure and its effects on downstream tasks, despite their statistical infrequency. An important advantage of our model over alternative neural parsers is that it is the only one to take these links into account in both model design and evaluation.

2.1 A new STAC dataset: STAC-Squished

Like other recent work in discourse parsing, we develop a model trained on *S* and detail our results on *S* in Section 4. But *S* is not ideal for two reasons.

First, we discovered that it contains duplicated data points due to a mistake in the data extraction script. There are 488 duplicated EDUs, corresponding to 60 duplicated dialogues.

Second, and more seriously, there are rhetorical incoherences in *S*. When we examined relation labels, we found, with Badene et al. (2019), that some were not coherently used, because *S* lacks essential nonlinguistic (game) information (Asher et al., 2016). Figure 2 provides an example. The exchange on the right, taken from *S*, is somewhat incoherent; the Continuations (dark green) from 282-283 and 283-289 make little sense, but were included in order to make a complete DAG. On the left, we see the full exchange, from *S-Sit*, with a far more intuitive discourse structure lacking the Continuations.

There are 300 such cases out of 1116 Continuation instances in the training set and 45 out of 113 such cases in the test set. Indeed, dialogue moves and speaker interactions in the conversations often depend on nonlinguistic actions taken by players, but we can only see this dependence once we move to *S-Sit*, where the EEUs provide such actions and other important information on game evolution. We must take account of those EEUs to accurately reflect the discourse structure.

S-Sit builds graphs over EDUs and EEUs and so includes information essential to properly understanding many linguistic interactions. For this reason, we consider *S-Sit* an overall better data source for correct discourse structures.

However, *S-Sit* also has certain drawbacks for training discourse parsing models. It contains multiple, long chains of EEUs connected to their immediate predecessors. The number of EEU-EEU adjacent attachments is very high and highly predictable, artificially inflating F-scores on attachment and relation labeling. Moreover, long sequences of EEUs often induce longer distances between EDUs that need to be attached. Our model, like most, is biased towards predicting closer attachments due to their abundance in the training set. *S-Sit* exacerbates this situation and makes our model actually perform worse on EDU-only attachments (see Section 4).

Figure 2: An example from STAC. On the left, we see the full interaction, from *S-Sit*, that contains both chat and game moves. On the right, we see the version from *S* that contains only the chat moves.

Data	EDU	EEU	R-E	Mean
S	13054	0	0	2.04
S-Sit	12588	18576	16382	2.14
S-Sq	12588	12985	10790	2.04

Table 1: Data set stats

The shortcomings of *S-Sit* prompted us to modify it in order to ignore the highly predictable relations and attachments between adjacent EEUs that are not attached to any EDU. To do this, we treated each sequence of EEUs as one block without any internal structure. That is, we collapsed the sequence into a single EEU. Table 1 reflects differences between the various STAC corpora in numbers of EDUs, EEUs, Relation instances over only EEUs (R-E) and mean distances between attachments of linguistic units. We have made available the new *S-Sq* (squished) corpus at https://github.com/zineb198/LineBert.

3 Our Model

S contains a set of multi party dialogues, each consisting of a set of n EDUs $[e_1, e_2, .., e_n]$. Our model BERTLine, is a simple but efficient discourse parsing model with two components: one for inferring attachments and one for inferring relation labels. Like Shi and Huang (2019) and Wang et al. (2021), we compute a standard unlabeled attachment and labeled attachment score for evaluation.

Attachment. BERTLine's attachment module has an encoder-decoder architecture. Encoding for each EDU pair is obtained by finetuning a BERT model on the task of predicting if two EDUs are attached. We used BERT because it takes the position IDs of tokens as input, which is useful for the pair encodings. BERTLine has access only to the content and the speaker/emitter of the EDUs. $[CLS]$ vectors furnish embeddings h of EDU pairs.

$$h_{(i,j)} = BERT(e_i, e_j)$$

The encoder portion of BERTLine is finetuned using the loss L_{l_1} on S_l, the set of positive and negative attachments. Where θ is the parameters to be optimized, $s_{*i,j}$ refers to gold data and $s_{i,j}$ to predictions:

$$L_{l_1}(S_l, \theta) = -\Sigma_{S_l} logP(s_{*i,j} = s_{i,j} | h_{i,j}) \quad (1)$$

We concatenate h with a vector $struct_{(i,j)} = [t_{(i,j)}, d_{(i,j)}]$ that represents information useful for computing attachments (Perret et al., 2016), namely speaker change and EDU distance (i.e., how many EDUs occurred between i and j in the natural order of the dialogue). The function $t_{i,j}$ returns 1/0 if i and j have the same/different speaker; $d_{i,j}$ returns the distance. Our final pair embeddings are:

$$H_{(i,j)} = h_{(i,j)} \oplus struct_{(i,j)}$$

The decoder part of BERTLine's attachment model is a linear neural network. Like previous work, this layer predicts for each EDU e_j, which of the preceding EDUs e_i, with $j > i \geq j - 10$ (i.e., up to a certain limit) are likely parents of e_j. It is a binary classification on each pair embedding.

$$P_j = Linear(H_{(j-1,j)}, H_{(j-2,j)}, ..., H_{(j-10,j)})$$

Our loss function is a binary cross entropy over possible attachments for each dialogue d in training set D. Below $l_{*i,j}$ indicates if e_i and e_j are attached in the gold data, and $l_{i,j}$ is a predicted link:

$$L_{link}(d, \theta) = -\Sigma_{j=1}^{|d|} \Sigma_{i=0}^{j} logP(l_{*i,j} = l_{i,j} | H_{i,j}) \quad (2)$$

$$L_{link}(\theta) = \Sigma_{d \in D} L_{link}(d, \theta) \quad (3)$$

The set of predicted attachments $\mathcal{L}$ contains all pairs $l_{i,j}$ whose link probability exceeds a given threshold α, optimized at 0.8 through experiments on the validation set; i.e., $l_{i,j} \in \mathcal{L}$ *iff* $P(l_{i,j}) > \alpha = 0.8$. We trained the linear layer for 15 epochs.

This set up allows us to predict multiple parents for a given EDU. Of the 77 multi-parent structures (8 with more than 3 parents) in the test set, we captured about 20%.

Relation labeling. To test the interdependence of link and relation prediction, we built a BERT model with two classification heads. The first head learns to predict links between EDUs and the second head learns to classify EDU pairs in terms of SDRT's 16 relation labels. We compute the loss of each head independently, average the results, and back-propagate the average back to the BERT encoder. At inference time, only the relation classification head is used for predictions.

We fine-tuned the BERT model over S_l over 3 epochs, together with training over S_r, the set of relation label instances. $r_{(*i,j)}$ refers to gold relation data, $r_{(i,j)}$ to predictions.

$$L_{rel}(S_r, \theta) = -\Sigma_{S_r} logP(r_{*i,j} = r_{i,j} | h_{i,j}) \quad (4)$$

$$L_{multi}(S_l \cup S_r, \theta) = mean(L_{l_1} + L_{rel}) \quad (5)$$

All previous work apart from Wang et al. (2021) defines the task of relation prediction as following that of link prediction in a pipeline architecture. Our multitask setup allows us to have an embedding containing information about both tasks and improves the relation F1-score by one point over a pipeline relation prediction task.

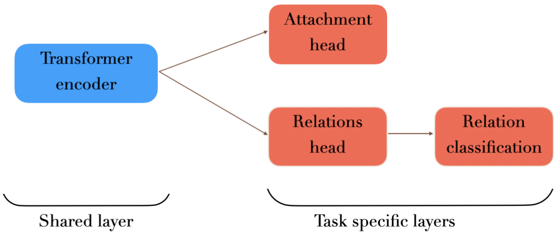

Figure 3: Structure of the multi-task model

Evaluation Metric: We used a micro averaged F1-metric over all gold data attachments and relation label instances for the scores in Table 2.

4 Results

Table 2 shows that BERTLine is competitive on S with the most advanced model of Wang et al. (2021) and even beats its relation labeling score. We provide both the reported scores of Shi and Huang (2019), Liu and Chen (2021) and Wang et al. (2021) and the scores that we got by rerunning their code using the same gold input from S with our evaluation metric, which explicitly considers EDUs with multiple parents.[1] Discrepancies in reported scores, also noted in Wang et al. (2021), may depend on choices of what and how to evaluate but also on machine hardware.

With regard to the different versions of STAC, BERTLine's overall scores improve between S and and *S-Sit* in Table 3, although there is a dramatic drop in linguistic only attachments (A-L) for *S-Sit*. This is due to the presence of many easy to predict attachments and relation instances between adjacent EEUs, which drown out performance on harder, longer distance EDU attachments. Interestingly, our score also improves considerably with *S-Sq*, and linguistic-only attachment suffers a much smaller drop. We hypothesize that this is because we have lowered the median distance between EDUs and rectified the imbalance between EDU and EEUs by deleting long series of EEUs.

BERTLine has a far simpler architecture than the neural models whose code we were able to rerun. It is essentially a local model that uses a minimal amount of message passing from nodes to potential neighbors, a technique from graph neural nets also used to encode entire graphs in Wang et al. (2021). BERTLine's main advantage comes from the explicit pair encoding of EDUs. While broader contextual information and structural constraints on DAGs like those in Perret et al. (2016) can undoubtedly improve scores for discourse attachment and relation labeling, we have sought to show that the efforts of complex architectures to harness this extra information have failed to lead to substantial gains. How to more successfully exploit it is our main research topic for the future.

5 Ablation study

We evaluated the efficiency of two key parts of our model, the multitask set up and the local structural information that we add to the EDU encodings. We

6 Related work

Older approaches to multiparty conversation (Afantenos et al., 2015; Perret et al., 2016) used manual features about EDU pairs and simple ML models to build a local attachment model for predicting attachment and relation labels. They also added a decoding mechanism. BERTLine's local model uses transformer-style embeddings.

Shi and Huang (2019) were the first to obtain significant discourse parsing results using a neural approach on the corpus *S*. They attempted to capture incremental and contextual effects in their model by training a supplemental *Structured Encoder* that incrementally updates attachment paths (sequences of parent-child EDUs). However, Wang et al. (2021) showed that the model obtains similar scores with or without the *Structured encoder*; the encoder didn't capture what it intended. Moreover, they implemented this method with Python 2 and Tensorflow 1.3, which are not in use anymore.

Liu and Chen (2021)'s model encodes EDUs using a pre-trained RoBERTa model (Liu et al., 2019) and a bi-GRU cell to capture contextual information but limits the size of the input dialogues. It uses two linear layers for link and relation prediction. We could not reproduce their results with their model or our reimplementation [2] perhaps because of an evaluation metric that does not consider multiple parents or all gold EDU pairs.

The Structure Self-Aware Graph Neural Network (SSA-GNN) by Wang et al. (2021) proposes a complex GNN-based architecture and model that uses both EDU and edge embeddings. The model is comprised of a Hierachichal GRU gate to obtain contextual EDU representations. They then apply the SSA-GNN to capture implicit structural information between EDUs, using a Structure-Aware Scaled Dot-Product Attention (Zhu et al., 2019; Wang et al., 2020) to update edge and EDU representations. A teacher network is also trained and supplements the standard classification loss with an auxiliary loss to enhance learning performances. Our model is simpler with better results. Moreover, none of the models by (Shi and Huang, 2019; Liu and Chen, 2021; Guz et al., 2020; Wang et al., 2021) predict multiple parents for attachments.

7 Conclusions

We have described a simple yet effective discourse parser that provides multiple attachments and codependent learning of the labeling and attachment tasks. Our model is the only neural parser that does this. We also wanted to show the power of local information when cleverly used. Indeed, discourse parsing requires contextual information, but our results show that current research does not yet leverage that information to achieve gains that convincingly outstrip those of a local model.

8 Limitations

Some of the limitations of this work are the lack of diversity in expert-annotated discourse data sets on multiparty and situated dialogue. Since current data sets come from forums and chat messages, we still have to see how our model behaves in a spoken conversation context. More investigation efforts must be made in order to better analyze and evaluate *S-Sq*. While it has a more predictable structure due to nonlinguistic elements, it also seems at first glance to contain better suited semantic relation labeling for the linguistic elements. We need to do an in-depth error analysis on BERTLine's performance on the three versions of the STAC corpus. We would also like to investigate training on one corpus and then running the model on the other corpus, and we would like to do the same with the Molweni corpus.

9 Ethics Statement

Bertline's performance does not seem to pose any ethical difficulties or questions.

Abstract

To mitigate gender bias in contextualized language models, different intrinsic mitigation strategies have been proposed, alongside many bias metrics. Considering that the end use of these language models is for downstream tasks like text classification, it is important to understand how these intrinsic bias mitigation strategies actually translate to fairness in downstream tasks and the extent of this. In this work, we design a probe to investigate the effects that some of the major intrinsic gender bias mitigation strategies have on downstream text classification tasks. We discover that instead of resolving gender bias, intrinsic mitigation techniques and metrics are able to hide it in such a way that significant gender information is retained in the embeddings. Furthermore, we show that each mitigation technique is able to hide the bias from some of the intrinsic bias measures but not all, and each intrinsic bias measure can be fooled by some mitigation technique, but not all. We confirm experimentally, that none of the intrinsic mitigation techniques used without any other fairness intervention is able to consistently impact extrinsic bias. We recommend that intrinsic bias mitigation techniques should be combined with other fairness interventions for downstream tasks.

1 Introduction

The use of pretrained language models has seen a surge in popularity as a result of state-of-the-art performances that have been achieved with these models on various tasks. Consequently, there has been a growing interest in exploring how gender bias pertains in these models (Garrido-Muñoz et al., 2021). Pretrained language models are used in two distinct phases: the *pretraining phase* and the *finetuning phase*. The pretraining phase typically involves training a model on a generic task such as masked language modeling on a diverse set of text corpora. In the finetuning phase, the pretrained model can be adapted for a specific task, such as sentiment analysis, by training on a domain-specific corpus. Owing to the unique way of using pretrained models, bias generally manifests in two forms: *intrinsic bias* and *extrinsic bias*. Intrinsic bias refers to bias that inherently exists in pretrained language models whereas extrinsic bias is used to refer to bias that exists in downstream models that are based on the pretrained model. Since the success of downstream NLP tasks has mostly been dependent on pretrained models, it is intuitive to assume that bias in intrinsic models will compromise fairness in downstream tasks. Only recently have more in-depth examinations been done to investigate this assumption (Steed et al., 2022; Orgad et al., 2022; Kurita et al., 2019). However, conclusions have been inconsistent and the confounding effects of bias mitigation techniques remain unknown.

The main focus of this work is to investigate the impact of intrinsic bias on extrinsic fairness and if techniques to mitigate intrinsic bias actually resolve bias or only mask it. We develop a probe to uncover intrinsic bias by determining the amount of gender information in a word embedding using a classifier. Bearing in mind how abstractly and improperly intrinsic bias has been defined (Blodgett et al., 2020), coupled with the discovery that results from different metrics for intrinsic bias in many cases do not correlate (Delobelle et al., 2022), we find this probe effective as an extra step in evaluating the efficacy of these mitigation strategies. We realize from this study that how intrinsic bias has been measured and the choice of bias mitigation strategies explored by some existing works have not been ideal. We further use this probe to investigate if some proposed mitigation strategies superficially conceal bias.

In this work, when we refer to bias in a language model, we mean stereotyping bias as defined by Garrido-Muñoz et al. (2021) as *"the undesired variation of the [association] of certain words in that language model according to certain prior words*

Proceedings of the 17th Conference of the European Chapter of the Association for Computational Linguistics, pages 3418–3433
May 2-6, 2023 ©2023 Association for Computational Linguistics

in a given domain". We focus our experiments on gender bias for two primary reasons: its intuitive nature making it easy to analyze and discuss, and the accessibility of resources and datasets regarding gender. For the same reason, we narrow our definition of bias in our experiments and analysis to binary gender bias[1]. This paper considers the primary goal of mitigating intrinsic bias to ensure fairness in downstream tasks.

We consider one case of binary classification and one multiclass classification case, all on English language corpora using the BERT-large (Devlin et al., 2019) and the ALBERT-large (Lan et al., 2019) pretrained models for each task.

In summary, we develop an extensive probe [2] to uncover intrinsic bias in pertained contextualized language models, and seek to answer three key research questions: **RQ1:** Do different intrinsic bias metrics respond differently to different bias mitigation techniques? (§ 4.1). **RQ2:** Can intrinsic bias mitigation techniques hide bias instead of resolving it? (§ 5.1). **RQ3:** Do intrinsic bias mitigation techniques in language models improve fairness in downstream tasks? (§ 5.2)

2 Measuring and mitigating bias

Since many techniques for measuring and mitigating gender bias have been introduced for both intrinsic and extrinsic bias, we only discuss techniques we use in experiments in this paper.

Bias mitigation techniques can be applied to pretrained or finetuned language models, or both. Figure 1 illustrates these interactions with both training settings and this section will discuss both intrinsic (§ 2.1) and extrinsic (§ 2.3) mitigation techniques. Additionally, this section will provide a brief overview of bias measures [3].

2.1 Intrinsic bias mitigation techniques

Intrinsic gender bias mitigation methods target either the pretraining data, the pretraining procedure, or the pretrained model's output, which we refer to as pre-processing, in-processing, and post-processing respectively (Friedler et al., 2019). We select three popular mitigation methods to represent all three types, namely *Counterfactual Data Augmentation* (CDA), *Context-debias*, and *Sent-debias*. Notice that these methods create debiased pretrained language models, as is illustrated in Figure 1. These models still need to be finetuned on a downstream task.

CDA pretraining. The idea behind counterfactual data augmentation (Zmigrod et al., 2019; Lu et al., 2020) is to generate a counterfactual for each example in the training corpus by replacing attribute terms with their complimentary equivalent from the other demographic classes. For example, *she* will map to *he* in the case of binary gender. To mitigate intrinsic bias, this counterfactual augmentation has to be done as a pretraining step. Since CDA involves retraining the model, it is more resource-intensive compared to Sent-debias and Context-debias. We use the pretrained CDA models based on BERT and ALBERT from Webster et al. (2020) for our implementation.

Context-debias. Kaneko and Bollegala (2021) introduce a debiasing method that involves retraining the language model with a constraint to make the embeddings of *stereotype terms* [4] (such as *doctor, nurse*) orthogonal to embeddings of *attribute terms* [5] (such as gender pronouns like *she, he* and gender nouns like *woman, man*). Given the dynamic nature of contextualized word embeddings which causes a word to have different embeddings, they define fixed word embeddings for each attribute token by averaging the contextual embeddings of a word in all sentences it appears in. Training is done so that the embeddings of all stereotype terms are made orthogonal to all fixed attribute embeddings. They add a regularizer that constrains the debiased embedding to retain as much information by ensuring that they are as similar to the original embeddings as possible despite the orthogonality (§ B.1). Context-debias, as well as other in-processing techniques, require a predefined set of attribute and target terms before training which may not be effective for words outside these sets.

Sent-debias. Liang et al. (2020) propose a post-processing debiasing method akin to *word embedding debiasing* (Bolukbasi et al., 2016) but for contextualized embeddings. They achieve this by first identifying the bias subspace. They extract naturally-occurring sentences from corpora that

[3] For a more in-depth overview of mainly intrinsic measures, we refer to Delobelle et al. (2022).

[4] We also refer to them as *target words*.

[5] We also refer to them as *identity terms* or *protected words*.

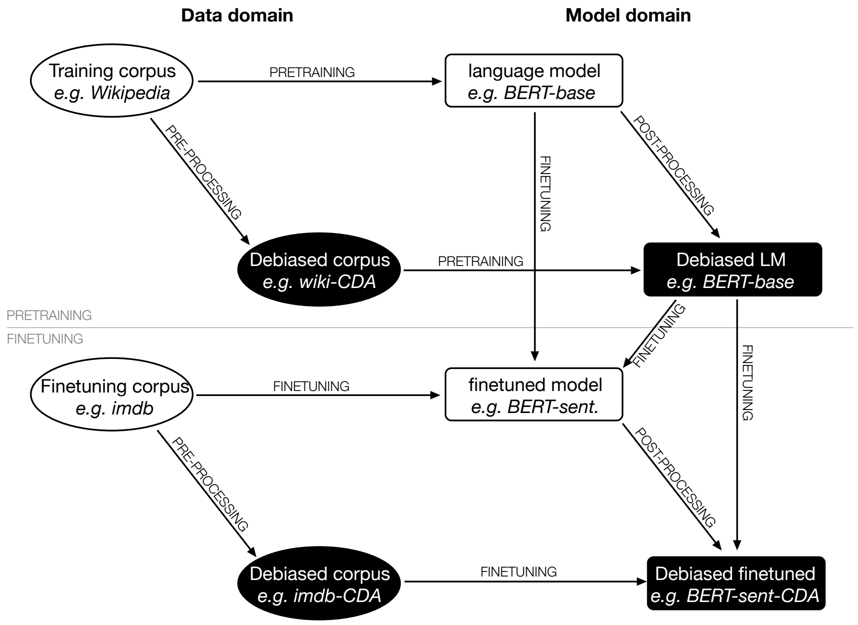

Figure 1: Illustration of where bias mitigation techniques alter a model or training data for both intrinsic (pretrained) and extrinsic (finetuned) biases in models.

contain certain attribute terms, generate counterfactuals for each one, and compute the gender subspace based on these sentence templates. The rest of their algorithm follows the method of hard debiasing (neutralization and equalization) by Bolukbasi et al. (2016) (§ B.2). Essentially, this post-hoc approach transforms the embeddings by removing their projections onto the gender subspace.

2.2 Measuring intrinsic bias

To measure intrinsic bias in the pretrained models, we use *SEAT* and *LPBS*. We examine these two metrics because of their wide use in related literature.

Sentence Embedding Association Test (SEAT). May et al. (2019) developed SEAT to quantify intrinsic bias in contextualized language models based on WEAT (Caliskan et al., 2017) which was originally designed for non-contextualized embeddings. Although the authors express concern over the efficacy of this metric, it has been widely adopted in various works to quantify bias in contextualized word embeddings. We adopt the implementation by Tan and Celis (2019) that uses word-level contextualized embeddings of attribute and stereotype terms instead of sentence-level embeddings. Delobelle et al. (2022) show that using word-level embeddings produces more consistent results and is more robust against the effects of template choices. SEAT is defined as: $s(X_f, X_m, A, B) = \sum_{x_f \in X_f} s(x_f, A, B) - \sum_{x_m \in X_m} s(x_m, A, B)$; A and B are the respective sets of female and male attribute (identity) terms, whereas X_f and X_m are the sets of female and male stereotypes respectively, The similarity measure $s(x, A, B)$ gives the association between a stereotype word's embedding and the word embeddings of attributes: $s(x, A, B) = \frac{1}{|A|} \sum_{a \in A} \cos(x, a) - \frac{1}{|B|} \sum_{b \in B} \cos(x, b)$

Log Probability Bias Score (LPBS). This template-based approach proposed by Kurita et al. (2019) quantifies bias using templates containing target words: such as "_ *is a doctor.*". They compute the difference in probability scores that a language model uses to predict words from two respective groups (eg. *female:she, male:he*) to fill in the blank. To account for the effect of prior probabilities of gender words that may skew results, they normalize the results by dividing each prediction by the prior probability of the attribute term. We compute LPBS as: $LPBS = \sum_{x \in X} \sum_i |ls(a_i, x) - ls(b_i, x)|$; where a_i and b_i are equivalent forms of a female and male attribute term respectively, $X = X_f \cup X_m$ is the set of all stereotype words, $ls(w, x) = \log(\frac{P(w|x)}{P(w)})$ is the association between an attribute term $w \in A \cup B$ and a target term $x \in X$, $P(w)$ is the prior probability of w, and $P(w|x)$ is the probability of predicting w as the blank term given the presence of x in its context.

2.3 Extrinsic bias mitigation techniques

We look at two downstream tasks, which are both text classification (Bias-in-Bios (De-Arteaga et al., 2019a) and Jigsaw[6])[7]. To understand the relationship between intrinsic and extrinsic bias, in addition to these original datasets, we include two preprocessed versions of the datasets using *Attribute scrubbing* and *Attribute swapping*. We use these settings to analyze how intrinsic bias is propagated to downstream tasks.

Attribute scrubbing. Attribute features, which are identity terms in an NLP task, are completely removed from text instances in the training data (Prost et al., 2019; De-Arteaga et al., 2019b). This approach may seem intuitive, particularly to mitigate explicit bias, but we suggest that deleting tokens in NLP tasks can be tricky since it could change the syntactic and grammatical structure of the text, leading to out-of-distribution problems.

For datasets such as Bias-in-Bios (De-Arteaga et al., 2019a), a lot of existing works have simply relied on the scrubbed version provided in the dataset, however, we realize that the set of gender words scrubbed is very limited, hence, we extend this to include all gender words from (Kaneko and Bollegala, 2021) and gender names from (Hall Maudslay et al., 2019) to make the approach more effective.

Attribute swapping. CDA has been explored and proposed as another bias mitigation strategy for downstream tasks, particularly in coreference resolution (Lu et al., 2020) and text classification (Park et al., 2018). The idea is to generate counterfactuals by identifying attribute terms in the text instances and swapping them with equivalent terms belonging to the complementary group. We will term this approach *Attribute swapping* to distinguish it from pretrained CDA in Section 2.1. For pretrained CDA, the language model is (further) pretrained on a set of general corpora on Masked Language Modeling task, whereas in attribute swapping, counterfactuals are generated for each instance in the training data based on attribute terms; with the same y labels assigned to both the original and counterfactual examples. Whereas previous versions of CDA ignore names of people, which are major demographic cues, Hall Maudslay et al. (2019) propose a name intervention to generate counterfactuals for names as well. We use this adaptation for attribute swapping.

2.4 Measuring extrinsic bias

True positive rate difference (TPRD). We use TPRD used in related works (De-Arteaga et al., 2019a; Prost et al., 2019; Jin et al., 2021; Steed et al., 2022). TPRD measures the gap in true positive rates between the predictions for two demographic groups: $TPRD = P(\hat{y} = 1|y = 1, A = a) - P(\hat{y} = 1|y = 1, A = a')$.

Counterfactual Fairness. Since the test dataset follows the same biased distribution of the training set, we also measure the disparity in performance for an individual test instance if the gender attributes are swapped. We measure counterfactual fairness (Kusner et al., 2017) as the difference in the probability of a positive prediction between a test example and its counterfactual, following $CF = \text{mean}(P(|x(\hat{Y}_{A\leftarrow a} = y|A = a, X = x) - P(\hat{Y}_{A\leftarrow a'} = y|A = a, X = x)|))$.

3 Probing for gender information

We design a probe to investigate how much gender information is retained after *mitigating* bias in pretrained language models. Our goal is to measure the amount of gender information in the resulting embeddings of language models after mitigation techniques from § 2.1 have been applied to them.

Defining attribute and stereotype terms. We first identify two sets of attribute terms that define females and males respectively. Let $W_f = \{she, female, woman, ...\}$ and $W_m = \{he, male, man, ...\}$ be the respective sets of female and male gender-defining words. The set $W = W_f \cup W_m$ is the union set of gender-defining words for both females and males. Secondly, we define two sets of stereotype terms which are composed of target words associated with females and males respectively[8]. Let $X_f = \{cheerleader, nurse, softball, ...\}$ and $X_m = \{warrior, baseball, engineer, ...\}$ be the respective sets of female and male stereotype words such that $X = X_f \cup X_m$.

Extracting word embeddings. We extract all sentences from a text corpus containing words in each set of words. Especially for stereotype terms, we ensure that the sentences do not also

[7] See Appendix D for dataset description

[8] We use both attribute and stereotype wordlists from (Kaneko and Bollegala, 2021)

include words in the attribute wordlist since attribute words in the same context can introduce gender information in the embedding produced. Let $S_w = \{s_{w_1}, ..., s_{w_n}\}$ be the set of all sentences containing a word w. We use the pretrained language model to extract embeddings for w such that $w \rightarrow E_w = \{e_{w_1}, ..., e_{w_n}\}$, where $e_{w_i} \in \mathbb{R}^n$ is the embedding for token w in sentence s_{w_i}. If w appears in s_{w_i} multiple times, then $|E_w| > n$.

Training the classifier. We split W into a train and test sets W_T and W_I respectively such that $W_T \cap W_I = \emptyset$. This is to verify that the trained model is not merely learning to identify words that appear in the train set rather than words containing gender information in general. We reserve the set of stereotypes X solely for evaluating bias (inference) in the language models.

Taking $E_f = \{e_{f1}, e_{f2}, ...\}$ and $E_m = \{e_{m1}, e_{m2}, ...\}$ to be the set of all embeddings for female and male words respectively, given $E = E_f \cup E_m$, we train a classifier $\mathcal{C} : E \rightarrow \{f, m\}$ to predict whether an embedding e belongs to E_f or E_m.

Evaluating bias. To determine the conformity of a language model $\mathcal{L}$ to gender stereotypes X, we introduce two bias criteria (or notions of bias):

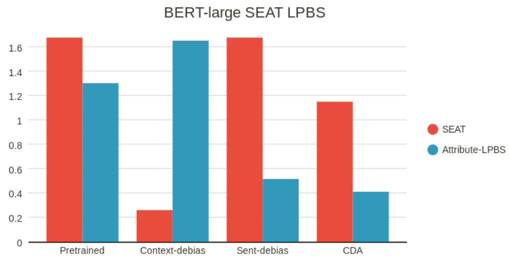
Bias accuracy: We compute the accuracy of $\mathcal{C}$ to correctly predict the gender association of all stereotype words in X based on the embeddings produced by $\mathcal{L}$. A high accuracy depicts the presence of pro-stereotype information in the embeddings produced by the language model $\mathcal{L}$, even though the predictions could be of low confidence i.e. just enough gender information to correctly predict the gender association.

Mean bias confidence: We also consider the mean of the individual softmax scores for each prediction. In the case of binary gender, a softmax value of 0.5 means the embedding is perfectly neutral, hence, we define mean bias confidence as $\frac{1}{N}\sum_i^N |bias(e_i) - 0.5|$. High mean confidence depicts an enormous amount of gender information contained in the embedding, although this information may not necessarily be pro-stereotype.

Randomization test. To test the efficacy of our method, We carry out a randomization test by iteratively splitting $X = X_f \cup X_m$ into two random groups $X_{f'}$ and $X_{m'}$. We use $X'^{(i)} = \{X_{f'}^{(i)}, X_{m'}^{(i)}\}$ to define the random pair generated in the ith iteration. We repeat this randomized split over 100 iterations; $X'^{(i)} \in \{X'^{(1)}, ..., X'^{(100)}\}$. By computing a p-value based on a one-sample t-test, we compute if the mean of accuracy scores from the random samples X' is significantly different from the score from$\{X_f, X_m\}$.

4 Investigating intrinsic bias in mitigated models with existing metrics

We first use the two existing metrics defined in § 2.2 (SEAT and LPBS) to quantify bias in BERT-large and ALBERT-large pretrained models. Using the same metrics, we then explore how intrinsic bias changes in mitigated versions of these models using the mitigation techniques outlined in § 2.1: Context-debias, Sent-debias, and CDA pretraining. This is important to evaluate the efficacy of these mitigation strategies, and to make relevant postulations.



(a) BERT-large model

Figure 2: Intrinsic bias scores using SEAT and LPBS. Results show inconsistencies in measuring bias between SEAT and LPBS for various mitigation strategies — lower scores are desirable in both cases.

4.1 RQ1: Do intrinsic bias measures respond differently to bias mitigation techniques?

In Figure 2, we plot the intrinsic bias results[9] of SEAT and LPBS on BERT-large. The first observation we point out, particularly for Context-debias and Sent-debias, is the contradicting nature of bias scores obtained from SEAT and LPBS. Whereas SEAT shows a drastic reduction in intrinsic bias for Context-debias, LPBS indicates worsening bias. The converse is true for Sent-debias where LPBS shows a significant reduction in intrinsic bias but SEAT shows worse scores. This confirms our suspicion that different mitigation strategies respond differently to different metrics.
