Quality of visual prediction. Another question on M2KT-VPN is whether the visual prediction network can provide grounded visual features. To answer this question, We measured each model's Median rank score (Elliott and Kádár, 2017) on the **2016** test data. We first average true and predicted features over their regions to get every single representative vector. The predicted representative vector is compared against the true representative vectors in the test data using the cosine similarity function to produce a ranked order of the true representative vectors. The Median Rank score reports the median value of the ranks for the gold representative vector compared to the predicted representative vector.

Model	2016	2017	mscoco	2018	Average
Transformer	55.77 / 76.91	47.48 / 70.77	38.95 / 64.12	33.11 / 60.37	43.83 / 68.04
mTransformer	56.42 / 77.57	48.54 / 72.31	40.50 / 65.56	34.31 / 61.67	44.94 / 69.28
IMAGINATION	57.11 / 77.85	49.53 / 72.68	40.75 / 65.95	35.12 / 62.84	45.63 / 69.83
M2KT-VPN	**57.49** / **78.15**	†**50.19** / **73.43**	†**41.28** / **66.44**	†**35.58** / **63.06**	†**46.13** / **70.27**

Table 3: The BLEU / METEOR scores of the text-only models and MMT models in each test set for English–French translation using English–Czech as the grounded language pair. "†" indicates statistical significance of the improvement over the IMAGINATION model.

Fusion Module	VPN	BLEU	METEOR
Attention		44.79	69.27
Concatenation	✓	6.43	19.29
Gate	✓	44.88	69.42
Attention	✓	46.13	70.27

Table 4: The average BLEU and METEOR scores over all test splits for variants of M2KT-VPN.

Model	Median Rank
IMAGINATION	45.5
M2KT-VPN	47.0
Elliott and Kádár (2017)	11.0
Random	$\sim$ 500

Table 5: Median rank of randomly selected vector (Random) and model's predictions.

Model	COMET
Transformer	0.7629
mTransformer	0.7651
IMAGINATION	0.7679
M2KT-VPN	0.7698

Table 6: The averaged COMET scores over all test splits for the English–French translation.

Model	2016	2018	Average
Transformer	55.85	47.54	51.69
mTransformer	57.01	49.85	53.43
IMAGINATION	57.99	50.14	54.07
M2KT-VPN	57.78	50.79	54.28

Table 7: The METEOR scores of the text-only and MMT models in each test set for English–Czech translation

Our M2KT-VPN model returns a median rank of 47.0, which is clearly better than the random baseline. This indicates that our model is learning visually grounded representations. However, Elliott and Kádár (2017) reported a median rank of 11.0 for their RNN-based model that predicts holistic features. This difference poses another challenge to predicting region-based visual features using VPN. We would like to improve the prediction quality and explore its impact on the translation quality in our future work.

Neural-based evaluation. Table 6 shows the average COMET score over all test splits. We can see the same trend as BLEU and METEOR in Table 3. While neural-based evaluation metrics would better align with human preference than those based only on surface characteristics, this pattern may vary (Freitag et al., 2021). A human evaluation may rather be conducted to reveal which metrics align better with the text of captions, where the text is usually shorter and simpler than those in the WMT evaluation task.

Multilingualism. The multilingualism of the M2KT-VPN model is another concern. Table 7 shows the METEOR score for the English–Czech translation. The consistent improvement over the text-only baseline for both English–Czech and English–French indicates that the M2KT-VPN model is capable of performing multilingual translation.

5.2 Probing

Input degradation. We examine the model's capability of handling incomplete textual modality. Intuitively, a better MMT model can recover the content in the flawed source text from the visual modality. Following Caglayan et al. (2019) and Li et al. (2022a), we

[6] "man", "woman", "people", "mean", "girl", and "boy".

Vanilla	a	young	girl	standing	···	a	yellow	cat
Color	a	young	girl	standing	···	a	[v]	cat
Entity	a	young	girl	standing	···	a	yellow	[v]
Char.	a	young	[v]	standing	···	a	yellow	cat
Prog.	a	young	girl	standing	···	[v]	[v]	[v]

Table 8: An example of textual degradation. "Vanilla" shows the original text without degradation. "Char." and "Prog." stand for character and progressive masking, respectively. "Color" deprivation replaces words that refer to colors with a special token [v]. "Entity" and "Char." mask out the visually depictable entities and character words[6], respectively. "Prog." masking all words except the first K words. The tokens at "[v]" are masked during both training and inference.

Model	Vanilla	Color	Entity	Char.
mTransformer	77.57	71.85	61.11	70.73
M2KT-VPN	78.15 (0.03)	72.28 (-0.13)	61.49 (-0.32)	70.78 (0.04)

Table 9: The METEOR scores on vanilla, color-deprivation, entity-masking, and character-masking test sets. The scores in the parenthesis show the METEOR changes when the MMT model takes random shuffled images as its input.

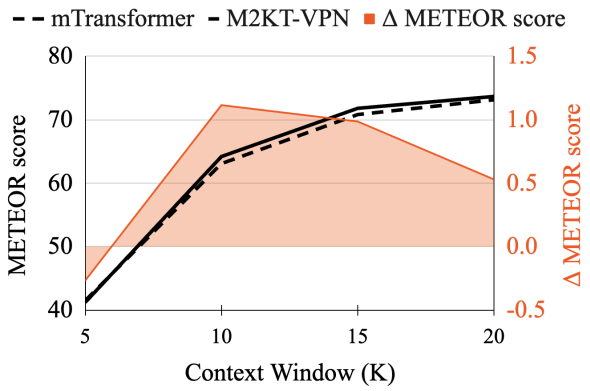

Figure 3: Evaluation with progressive masking of the context size of $\{5, 10, 15, 20\}$.

conducted four kinds of textual degradations: color deprivation, entity masking, character masking, and progressive masking. Table 8 shows examples of a complete text ("Vanilla") and its degraded ones. As entity masking is available only for the **2016** test set, we report all scores only for **2016** test set. Both the training and the test data are degraded.

Table 9 shows the BLEU and METEOR scores of the mTransformer baseline and M2KT-VPN model for vanilla, color-deprived, entity-masked, and character-masked **2016** test sets. The M2KT-VPN model outperforms the mTransformer baseline for color and entity degradation scenarios, while we see almost no change for character degradation. The possible cause of this difference is the nature of the **DETR** model we used to extract the feature. As the labels that **DETR** learns to predict contain only one word ("person") to stand for characters but more words for entities, an MMT model incorporating **DETR** would be capable of recognizing entities more precisely rather than characters. Table 10 also supports this idea. While the sentence's third [v] (corresponding to "bench") is correctly translated into "vif", the first masked entity (corresponding to "woman") keeps being mistranslated. As shown in the image, the **DETR** feature provides useful information to distinguish the "bench" from the "chair". However, it is not informative to identify the gender of the person in the image.[7]

Figure 3 compares the METEOR scores of the mTransformer baseline and an M2KT-VPN model for progressive-masked **2016** test sets with different context windows (K). The MMT model outperforms the baseline for $K = \{10, 15, 20\}$. The gap between the baseline and MMT model widens at $K = \{10, 15\}$ and narrows at $K = \{5, 20\}$. This observation for $K = \{10, 15, 20\}$ is consistent with a previous work of Li et al. (2022b), which claims the gap widens as the context window is reduced, while that for $K = 5$ is contrary to the claim. This suggests that the visual prediction network could fail to provide rich visual information when the textual context is extremely limited.

Visual awareness. We also examine the reliance of the model on the visual modality. To

[7]We found all three trained text-only systems failed to translate [v] corresponding to "bench", and all M2KT-VPN models successfully translate it.

	Vanilla	the woman in the brown shirt is sitting on a bright red bench .
	Entity	the [v] in the brown [v] is sitting on a bright red [v] .
	References	la femme en t-shirt marron est assise sur un banc rouge vif .
	mTransformer	l'homme en t-shirt marron est assis sur une chaise de couleur vive . (the man in the brown t-shirt is sitting on a brightly colored chair.)
	M2KT-VPN	l'homme en t-shirt marron est assis sur un banc rouge vif . (the man in the brown t-shirt is sitting on a bright red bench.)

Table 10: Translation examples of the baseline and MMT model. The bounding boxes in the image are the prediction of the **DETR-ResNet-50-dc5** model and have a score of above 0.8. We use DeepL to translate each hypothesis into English and show it in each parenthesis.

this end, we compute the performance deterioration when a model receives incongruent images instead of congruent images (Elliott, 2018). The scores with parenthesis in Table 9 show the performance changes when the model takes incongruent images. Without surprise, the MMT model is not aware of images for vanilla, color-deprived, and character-masked test sets, as the **DETR** model does not provide rich information about color and character in an image. Meanwhile, the model is sensitive to the input image when the entities in the source text are masked out; the MMT model readily uses **DETR** feature to disambiguate the masked entities.

5.3 Visual Feature Selection

Selecting a proper visual feature has been proven to affect MMT model performance (Li et al., 2021).

In Table 11, we compare the M2KT-VPN models using different visual features extracted by different vision backbones.

- **ResNet** (He et al., 2016): An image recognition model trained to classify an image into one of the 1,000 ImageNet classes. **ResNet-50** and **ResNet-101** comprise 50 and 101 layers, respectively. We extract the local features of each ResNet model and feed them into the MMT models.
- **Faster R-CNN** (Anderson et al., 2018): An object detection model trained to segment an image into 36 salient image regions and predict the object in each region.
- **DETR** (Carion et al., 2020): A transformer-based object detection model trained to segment an image into 100 regions and predict the object in each region. We used four different backbones: **ResNet-50**, **ResNet-50-DC5**, **ResNet-101**, and **ResNet-101-DC5**.
- **CLIP** (Radford et al., 2021b): A vision and language model trained on various image and text pairs in a self-supervised way. We examined three CLIP models using different backbones: **ResNet-101**, **ViT-B/16**, and **ViT-B/32**. We use the visual encoder of each CLIP model to encode images; no textual modality is involved in the extraction process.

10 out of 11 MMT models outperform the mTransformer model in both BLEU and METEOR scores. This shows that M2KT-VPN models are capable of incorporating various kinds of visual features. The only feature that deteriorates the model performance is ResNet-101; the feature extracted by ResNet-101 would be highly optimized for image classification and not suitable for machine translation.

Among all features, **DETR** with the **ResNet-50-DC5** backbone serves as the best feature extractor for the M2KT-VPN model. On the other hand, the model using **CLIP** features obtains almost equal performance to those using **ResNet** features. This observation is partially contrary to the previous works claiming that enhanced vision features obtain superior performance compared with low-level vision features (Li et al., 2022a).

We also observed that **DETR** with **DC5** backbone outperforms the non-DC5 counterparts. As **DC5** models provide the feature with higher resolution, the MMT model can receive richer information about small objects in an image. Consequently, the MMT model can better understand and translate those small objects more accurately.

Feature	BLEU	METEOR
None (mTransformer)	44.94	69.28
ResNet-50	45.34	69.67
ResNet-101	44.79	69.29
Faster R-CNN	45.72	69.65
DETR (ResNet-50)	45.79	70.01
DETR (ResNet-50-DC5)	**46.13**	**70.27**
DETR (ResNet-101)	45.49	69.84
DETR (ResNet-101-DC5)	45.81	69.91
CLIP (ResNet-101)	45.19	69.47
CLIP (ViT-B/16)	45.64	69.88
CLIP (ViT-B/32)	45.36	69.64

Table 11: The averaged BLEU and METEOR scores over all test splits of M2KT-VPN models using different visual features. The models in the parentheses are backbone models.

Grounded	BLEU	METEOR
→ Czech	46.14 (↑1.12)	70.27 (↑0.93)
→ German	45.95 (↓2.04)	69.95 (↓1.16)
→ Japanese	42.34 (↓2.53)	68.25 (↓0.99)

Table 12: The scores over all test splits of the M2KT-VPN model using different grounded language pairs. Each "→ X" stands for English → X as the grounded language pair. The scores in parenthesis are the changes from the text-only counterpart.

5.4 Grounded Language Pairs

The ability of a model to transfer multimodal knowledge between grounded and zero-shot language pairs is another key research question for this task. To answer this question, we compare three grounded language pairs for English–French zero-shot cross-modal translation.[8]

Shown in Table 12, the translation performance of using English–Czech as a grounded language pair is better than those of using English–German and English–Japanese.

The observation of using English–German contradicts our intuition that the more similar two language pairs are, the better one serves as a grounded language pair for another. As English–German training data is generated with no involvement of images, this indicates that M2KT-VPN requires image-aware training data to transfer multimodal knowledge.

English–Japanese also contains visual-aware translations, but it does not improve the performance of English–French. We found that M2KT-VPN translated the 1.43% of entire test examples into Japanese regardless the decoder is conditioned to generate French translation[9]. This ratio is much higher than that of the text-only counterpart (0.27%) and M2KT-VPN using English–Czech (0.26%) or English–German (0.28%). We conclude that grounded and zero-shot pairs should not be too distant.

6 Related Work

Multimodal machine translation. This task has been developed along with the creation of multimodal parallel corpora. After the first multimodal parallel corpus, namely Multi30K for English–German translation, emerged at the first conference of machine translation (Bojar et al., 2016), many publicly available datasets have been proposed: the English–French version of Multi30K and new test sets at 2017 (Elliott et al., 2017), the English–Czech version of Multi30k (Barrault et al., 2018), and the English–Japanese version of Multi30k (Nakayama et al., 2020). More recently, Guo et al. (2022) proposed a private expansion of Multi30K, including Hindi, Turkish, and Latvian translations. They examined a multilingual MMT model on their dataset and investigated the multilingual ability of the model. We put the step forward and investigate the zero-shot cross-modal translation capability in an MMT task.

Predicting a visual feature from textual modality is a well-established approach for improving multimodal machine translation systems. Elliott and Kádár (2017) first divided the multimodal machine translation task into two subtasks: translation task and visual grounding task. Similarly, Zhou et al. (2018) employed a latent space learning task as their visual grounding task to bridge textual and visual modalities. Recently, Li et al. (2022b) proposed to utilize the feature prediction from a visual prediction network. We make use of the model for the visually grounding task and propose to incorporate the prediction as a pseudo-visual feature with MMT models.

[8]We retrieved Japanese translations from Flickr30kEnt-JP (Nakayama et al., 2020)

[9]We used Google's language-detection library.

Zero-shot cross-lingual machine translation. Zero-shot *cross-lingual* machine translation aims to perform a translation with zero-resource where the considering language pairs do not have any parallel corpora (Firat et al., 2016; Johnson et al., 2017; Chen et al., 2017; Lample et al., 2018; Artetxe et al., 2019). The previous works have proved the zero-shot cross-lingual translation capability.

In a multimodal setting, we are only aware of two previous efforts on zero-shot transfer. Huang et al. (2020) simulated that no parallel corpus exists between the language pair and proposed utilizing the image as the pivot and performing a zero-shot cross-lingual translation. Besides, Long et al. (2021) trained a generative adversarial network (GAN) (Goodfellow et al., 2014) for generating the visual features for text-only language pairs. Both approaches use images for training, and evaluate models on a single text-only translation direction. Unlike these works, our work (i) tests MMT models with complete multimodal inputs and (ii) takes advantage of a multilingual model.

7 Conclusion

In this paper, we proposed a new task, **zero-shot cross-modal machine translation**, aiming to evaluate MMT systems from the perspective of the cross-lingual transferability of multimodal knowledge learned from grounded language pairs into language pairs with only text data during training.

Our proposed MMT model shows promising results, suggesting that the VPN mitigates the modality mismatch between training and inference steps for zero-shot language pairs. The analysis shows the importance of selecting a proper visual feature and the necessity of image-aware translations, both of which should be key properties of MMT models.

Limitations

Although our M2KT-VPN model has shown the zero-shot cross-modal translation capability, some limitations exist. While the well-established visual features are informative for some object entities, they do not benefit the translation of character and color words. Besides, the importance of language similarity between grounded and zero-shot pairs limits the language pairs we can apply M2KT-VPN for. In future work, we will extend our M2KT-VPN model to relax this limitation.

Abstract

Gender biases in language generation systems are challenging to mitigate. One possible source for these biases is gender representation disparities in the training and evaluation data. Despite recent progress in documenting this problem and many attempts at mitigating it, we still lack shared methodology and tooling to report gender representation in large datasets. Such quantitative reporting will enable further mitigation, e.g., via data augmentation. This paper describes the GENDER-GAP Pipeline (for **G**ender-**A**ware **P**olyglot Pipeline), an automatic pipeline to characterize gender representation in large-scale datasets for 55 languages. The pipeline uses a multilingual lexicon of gendered person-nouns to quantify the gender representation in text. We showcase it to report gender representation in WMT[1] training data and development data for the News task, confirming that current data is skewed towards masculine representation. Having unbalanced datasets may indirectly optimize our systems towards outperforming one gender over the others. We suggest introducing our gender quantification pipeline in current datasets and, ideally, modifying them toward a balanced representation.[2]

1 Introduction

Despite their widespread adoption, Natural Language Processing (NLP) systems are typically trained on data with social and demographic biases. Such biases inevitably propagate to our models and their generated outputs, e.g., by over-representing a given demographic group and under-representing others. It is, therefore, critical to measure, report, and design methods to mitigate these biases, before they can be encoded and potentially amplified during training (Foulds et al., 2020; Wang and Russakovsky, 2021).

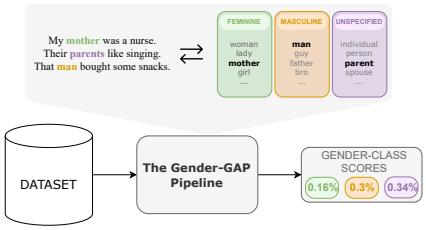

Figure 1: The Gender-GAP Pipeline works by identifying gendered lexical terms and reporting statistics on these lexical matching.

This paper focuses on quantifying gender representation in highly multilingual data (see Figure 1), in particular, for the task of machine translation. Gender is a complex concept that can be defined in many ways depending on the field of study, language or culture (Chandra et al., 1981; Hellinger and Bussmann, 2001; Kramer, 2020). We discuss and define gender in Section 3.1. However, briefly, we define gender bias as the systematic unequal treatment based on one's gender (Blodgett et al., 2020; Stanczak and Augenstein, 2021). Gender bias, when it impacts training data, may decrease the performance of the system on certain gender groups (Hovy et al., 2020). When impacting evaluation data, it may push the system designers to deploy a system that causes harm by favoring one group over others (Mehrabi et al., 2021). For example, a system that translates text that includes feminine nouns more poorly than text with masculine nouns may lead the end users to miss important information or misunderstand the sentence (Savoldi et al., 2021). A system that inaccurately translates a gender-neutral sentence in English e.g. *they are professors* to a sentence with a masculine noun *ils sont professeurs* in French may also lead to serious representational harm.

We propose the GENDER-GAP pipeline to quantify gender representation bias of multilingual texts

[1] http://www2.statmt.org/wmt23/

[2] The GENDER-GAP pipeline is available at https://github.com/facebookresearch/ResponsibleNLP/tree/main/gender_gap_pipeline

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 536–550
December 6–7, 2023.

using lexical matching as a proxy. Our pipeline can be seen as two main modules.

First, we build a multilingual gender lexicon: starting from a list of about 30 English nouns extracted from the HolisticBias dataset (Smith et al., 2022), split into 3 gendered classes—masculine, feminine, and unspecified. We manually translate them and reassign them to the appropriate gender class for each target language (e.g. "grandfathers", masculine in English, becomes "abuelos", masculine and unspecified in Spanish). Our list is restricted to nouns that refer to people (e.g. man, woman, individual) or to kinship relationships (e.g. dad, mom, parent). Most languages, including genderless languages (Prewitt-Freilino et al., 2012) (e.g. Finnish, Turkish) encode genders through kinship relationships and person terms (Savoldi et al., 2021). For this reason, focusing on a restricted list of kinship and person nouns allow us to scale our lexicon to 55 languages.

Second, we arrive at a straightforward and easily comparable gender distribution by using a word matching counter. Based on our newly collected multilingual lexicon, our pipeline segments each input sentence at the word-level using Stanza (Qi et al., 2020), a state-of-the-art word segmentation tool, and counts the number of occurrences of words in each gender class. As a result, we obtain a gender distribution across 55 languages. In summary, our contribution is threefold:

- We collect and release an aligned multilingual lexicon that can support measurement of the representation of genders in 55 languages.
- We introduce the Gender-Aware Polyglot pipeline (GENDER-GAP), a lexical matching pipeline, and describe the gender distribution observed in popular machine translation training and evaluation data. On average, all three analyzed datasets are biased toward the masculine gender. We find the gender representations to be domain- and language-specific. Additionally, using the GENDER-GAP pipeline, we can discover sentences that have been translated with a gender bias.
- We release our pipeline and recommend the reporting of gender representations in machine translation training and evaluation datasets to improve awareness on potential gender biases.

2 Related work

The study of biases in text has become more important in recent years, with Large Language Models (LLMs) displaying bias against people depending on their demographics and identity. As a testament to the importance of this topic, many recent papers, including those introducing GPT-3 and 4 (Brown et al., 2020; OpenAI, 2023), PaLM 1 and 2 (Chowdhery et al., 2022; Anil et al., 2023), LLaMa 1 and 2 (Touvron et al., 2023a,b), analyze how such biases affect their model outputs. Some works even discuss frequencies of gendered terms in their pretraining corpora (Anil et al., 2023; Touvron et al., 2023b), as this can affect downstream generation. Despite this acknowledgment of the issue, general purpose tools to measure demographic biases are still fairly rare, and so far have mainly been in English.

However, some have begun to measure demographic biases beyond English. Smith et al. (2022) built a comprehensive analysis dataset covering 13 demographic groups and Costa-jussà et al. (2023) extended it to the multilingual setting. Specific to Machine Translation, Savoldi et al. (2021) discussed best practices in reporting gender bias. Several works (Stanovsky et al., 2019; Prates et al., 2020; Renduchintala et al., 2021; Renduchintala and Williams, 2022) have explored metrics for exposing failures in automatically translating pronoun and occupations, and some have even explored MT model training (Escudé Font and Costa-jussà, 2019; Stafanovičs et al., 2020) or fine-tuning (Saunders et al., 2020; Corral and Saralegi, 2022; Costa-jussà and de Jorge, 2020) or both (Choubey et al., 2021) to lessen the effect of gender-related biases. More than this, there are initiatives that provide toolkits to generate multilingual balanced datasets in terms of gender (Costa-jussà et al., 2019) from Wikipedia and even balanced in gender within occupations (Costa-jussà et al., 2022).

However, despite the progress made, most of these resources only cover a handful of languages—the community still lacks easy to use, open-source toolkits to measure biases across a large number of languages. In this work, we address this need by showcasing, GENDER-GAP, a lexical matching pipeline to measure gender distribution across 55 languages.

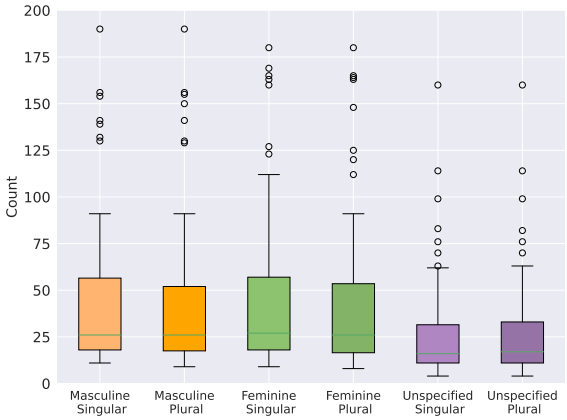

Figure 2: Distribution of the number of words in our proposed multilingual gender lexicon per language across gender-classes and number (i.e. singular and plural)

3 Proposed Data Collection and Pipeline

3.1 Defining Gender

Gender is a complex topic that can be defined in many different ways depending on the field of studies and the context (Hellinger and Bussmann, 2001). In this work, we approach gender from two perspectives:

First, linguistic gender (Corbett, 2013; Cao and Daumé III, 2020; Kramer, 2020; Stanczak and Augenstein, 2021) corresponds to the classification of linguistic units, such as words, into categories based on the gender information they provide. Linguistic gender refers to overlapping notions, such as *grammatical*, and *semantic* gender, depending on the properties of the language. Grammatical gender implies the classification of nouns, adjectives, and other parts of speech into categories based on their morphosyntactic properties. In many languages, grammatical gender morphology appears on all nouns, regardless of whether they refer to persons, animals, plants, or inanimate objects (e.g., "il libro" *the book* is a masculine noun in Italian). Semantic gender (Corbett, 1991) refers to the existence of lexical units whose meaning is associated with a specific cultural notion of peoples' gender(s). For instance, in English, the word "men" associated with masculine traits, "woman" with feminine ones, etc. Semantic gender then may be present in languages that do not morphologically mark grammatical gender, such as English, Turkish, or Mandarin Chinese. In languages that do mark grammatical gender, grammatical and semantic gender do not always match: for example, in German, the word for girl "Mädchen" is grammatically neuter, but refers to a person which would fall into our 'feminine' class based on its meaning. For our purposes, we use semantic gender classes in our multilingual lexicon, since we are interested in gender representation.

Our goal is to build and foster inclusive NLP technologies that do not carry, replicate, or amplify social gender biases, which can impact end users and societies negatively by affecting representations of specific groups. However, there are social meanings of gender that are not readily accessible in text, so, we use semantic gender on human words as a proxy for social gender.

Social gender refers to gender as a social construct based on cultural norms and identity (Ackerman 2019; Cao and Daumé III, 2020; Stanczak and Augenstein, 2021; Duignan, 2023). As highlighted by Ackerman 2019, social gender is defined as the internal gender experienced by a given human individual. For this reason, data-driven analysis of genders in large corpora can only relate to social gender indirectly through linguistic notions of gender(s).[3] We assume for our purposes that a list of gendered words can be used to approximate some important aspects of social gender for the purposes of measuring representation disparities.

3.2 Aligned Gendered Multilingual Lexicon

To measure gender distribution across 55 languages, we first build a multilingual lexicon. We want this lexicon to be as aligned as possible across languages while also encoding language-specific gender linguistic phenomena.

Languages Our lexicon is available in 55 typologically and phylogenetically diverse languages such as English, Finnish, Zulu, Vietnamese, Ganda, Japanese or Lithuanian, spanning 15 distinct scripts. We report the complete list of languages in Figure 6.

Gender Classes We define three semantic gender classes: masculine, feminine and unspecified. The unspecified class aggregates nouns of different sorts. It mainly capture nouns that do not explicitly encode any particular gender (e.g. "person" is considered unspecified in English). For this reason,

[3]We recall that gender is distinct from sex which refers to collections of biological properties of individuals such as genes (e.g., chromosomes), phenotypes (e.g., anatomy) (Council of Europe, 2023). See Butler (2011) for a discussion of additional factors that complicate this view.

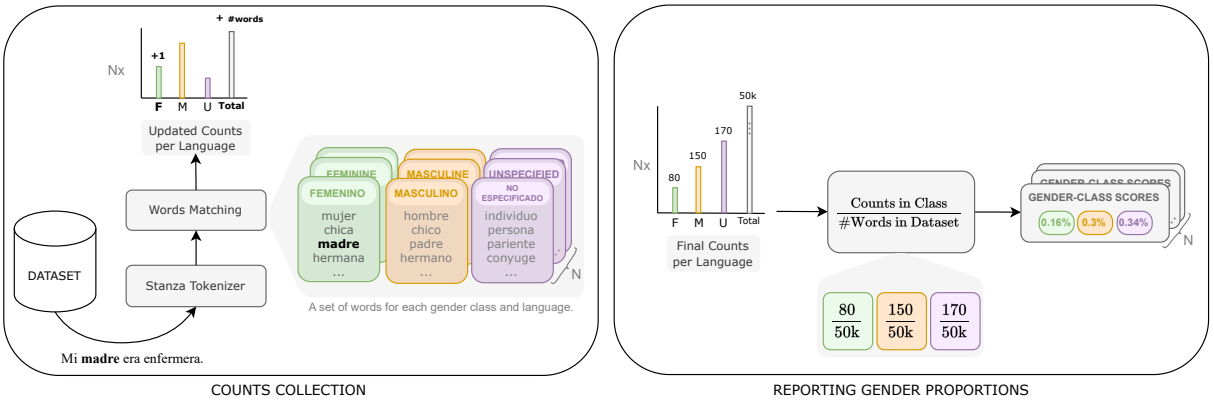

Figure 3: Diagram of the GENDER-GAP pipeline. In the first stage, we process each sentence of the 55 supported languages of the dataset and count the word matches for each category. Once this step is completed, we compute a gender-class score which corresponds to the proportion of gendered noun matched within all the words in the dataset.

"unspecified" can be seen as aggregating masculine, feminine and non-binary genders (Herdt, 2020).

While there exist more complex gender lexica as discussed in Stanczak and Augenstein (2021), they are focused on English and are not always easily translated. Because our goal is to provide a methodology that can be used to evaluate bias across multiple languages, we take a more pared down lexical approach.

Lexicon creation We start by defining a list of about ten, high frequency person nouns per gender class in English. Each noun is found in both its singular and plural form. To find a list of nouns that is as universal as possible, we restrict this list of persons such as masculine "man", feminine "woman", and "person" and synonyms (e.g. "individual") that we complement with kinship terms classified by gender (e.g., masculine "father", feminine "mother", neutral "parent"). Our list corresponds to the one defined in the previous work of HolisticBias (Smith et al., 2022), which is only available in English.[4]

We then translate these nouns into the other languages by reassigning them to the appropriate gender class. A noun in a given gender class may be part of another class (or multiple other classes) in another language. For instance "grandparents" (masculine, plural) becomes "abuelos" in Spanish which is both masculine and unspecified genders.

The English-language source list is passed on translators who are native speakers of the target language, with language proficiency at CEFR[5] level C2 in the source language. For all languages, translators are asked to provide equivalent singular and plural terms in their respective native language, except if any of the source concepts do not exist in the language. For example, not all languages use a distinctive, gender-agnostic term such as the English term *sibling*, distinctively from either *brother* or *sister*. We also consider that the reverse can be true (i.e. that the target language may have more than one term to translate one of the English terms in the source list), and give the translators the possibility to provide additional translations in such cases. For instance, when we translate *women* into Korean we get : "여성들" and "여인들".

Additionally, translators are asked to consider the terms in the source list as lemmas (or headwords in dictionary entries) and, if applicable to the given language, to provide relevant morphologically derived forms, including cases and gendered forms. Finally, translators are also encouraged to provide terms covering all language registers, which is necessary because some languages (e.g., Thai or Korean, among others) use several different terms at various levels of formality.

We are cognizant of the fact that this approach presents several limitations. The first limitation occurs when a term could be said to fall into both the unspecified and one of the gendered categories. For example, the term Spanish *padres* can be used to mean both *fathers* or *parents*. Some speakers also use the singular form to mean *parent* (and not necessarily *father*). The second limitation applies to

[4]We use the gender noun list v1.1 from HolisticBias

[5]https://coe.int/en/web/common-european-framework-reference-languages/level-descriptions retrieved 2023-07-24

languages that are closer to the synthetic end of the analytic-synthetic spectrum; i.e. languages that are agglutinative or highly fusional (e.g., Zulu, Uzbek, Estonian). This approach may not allow for the detection of many agglutinated or fused word forms. Finally, due to the templated, context-free nature of the lexicon, one term was particularly difficult to disambiguate: *veteran*, which can be used to refer to a soldier or a seasoned professional.[6] Cultural differences also had to be considered in addition to the above ambiguity; for example, Japanese translators mentioned the fact that the Japanese equivalent of the term was infrequently used with the first meaning cited above.[7]

Lexicon statistics In Figure 2 we can see the obtained data distribution across number and gender for the different languages. We notice a few outliers. As described above, translators are asked to provide relevant morphologically derived forms. This makes the number of nouns in Estonian to be 7 times larger than the average. For instance, "woman" is translated into *naine* "a woman", *naise* "of a woman", *naisele* "to a woman", etc.

3.3 Proposed Pipeline

Figure 3 shows a diagram of the GENDER-GAP pipeline. In the first stage or the counts collection, we work at the sentence level for the NTREX and FLORES-200 and at the document level for Common Crawl. We segment each sample at the word level using `Stanza` tokenizer available in the given language (Qi et al., 2020) except for Cantonese (yue) for which we reuse the model available for simplified Chinese (zh-hans) and Thai for which we use `PyThaiNLP`.[8] For the rest of the languages we use simple `nltk`[9] typographic tokenizer (based on white-space and punctuation marks). We then count and increment a gender-class counter anytime we match a word in the list of words representative of this class. For instance, in the sentence "my mother was a nurse" the pipeline will add +1 to the feminine counter (due to lexical match of "mother").

Once this process has been done for each sentence in the dataset we move to the second stage

Figure 4: Gender Representation in % of the total tokens in the FLORES dataset dev split.

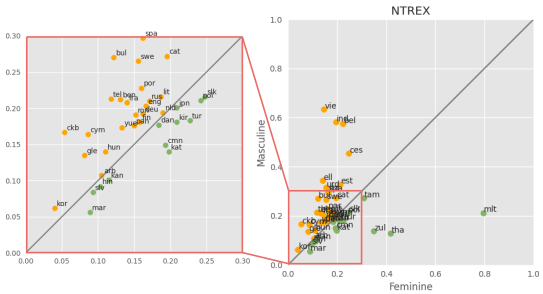

Figure 5: Gender Representation in % of the total tokens in the NTREX dataset.

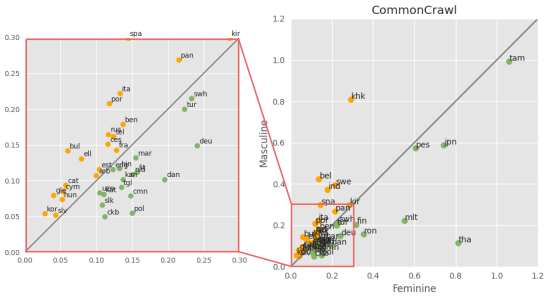

Figure 6: Gender Representation in % of the total tokens in the Common Crawl dataset.

or the reporting of gender proportions where we define a score for each gender-class by dividing the gender-class count by the total number of words in the dataset. By doing so, the final gender score does not depend on any defined linguistic macro-unit such as sentences or documents lengths but only on the word-level tokenization.

4 Experiments

To showcase GENDER-GAP, we run it on Common Crawl raw data and two popular machine translation evaluation datasets: FLORES-200 (NLLB Team et al., 2022) and NTREX-128 (Federmann et al., 2022). FLORES is a Wikipedia-based dataset including 3001 sentences translated from English to 200 languages. NTREX-128 is made of 1997

Table 1: % Gender Distribution in WMT Evaluation dataset. We report the English distribution and the average across all languages (standard deviation indicated between parenthesis). The full table is available in the appendix Table 3-5. We **bold** the most represented gender class, and underline the second most represented gender class. We define the the gender gap Δ defined as the absolute difference between the Feminine and Masculine scores. %doc. refers to Coverage.

sentences from news documents originally collected for WMT 2019 (Barrault et al., 2019) translated from English into 128 languages. Both these datasets are part of the corpora provided by the WMT shared task. In addition, we run the pipeline on a sample of Common Crawl.[10] Common Crawl is a snapshot of crawlable web data that is widely used in the NLP community thanks to the release of the CCNET corpora (Wenzek et al., 2020), the OSCAR corpus (Ortiz Suárez et al., 2019) and the C4 corpus (Raffel et al., 2019). It is used to train NLP systems like language and machine translation models. We run our pipeline on 100k documents for each language. Our pipeline supports 55 languages, and we run it on the intersection of these datasets with the set of supported languages.

5 Analysis

5.1 Quantitative Analysis

We report the average coverage and gender distribution in Table 1 along with the complete tables for the 55 languages in Table 3-5.

Coverage We first look at the number of samples for which at least one noun is found (cf. %doc in Table 1). We find that, on average, about 10% of samples match with at least a noun (between 10.1 and 13.4% depending on the dataset). We find that the coverage is the largest for Vietnamese (with up 45.7% of samples matched) and Thai (28.9% of samples matched) and the smallest for Korean (between 1.7% and 2.5% depending on the dataset). This shows that even though our lexicon is restricted to person nouns and kinship relationships, we are still covering a very large number of samples based on which we measure gender representations.

Gender Distribution Table 1 shows gender representation for masculine, feminine and unspecified. For better visualization, Figures 4, 5 and 6 report the % of masculine and feminine representation of the total tokens in FLORES, NTREX, and Common Crawl respectively.

On average, the masculine gender is more represented than the feminine in all three datasets. We find that NTREX is the dataset with the highest bias toward the masculine gender on average. Accounting for uncertainty, using the standard error to define a confidence interval,[11] we find that 30/45 languages are biased toward the masculine gender for NTREX. This includes languages like English, Arabic, French, Spanish, Vietnamese, and Panjabi. The rest of the languages are either balanced between masculine and feminine (i.e. Δ(|Fem.-Masc.|) is inferior to the confidence interval length) or biased toward the feminine gender. In addition, we find 16/54 languages biased toward the masculine gender for all three datasets suggesting an inherent gender bias in these languages. This includes several romance languages such as Spanish, French, Catalan and Italian along with Belarusian, Indonesian, and Panjabi.

Impact of Domains We find that 14/55 languages for which, the gender representation changes drastically across the different datasets. For instance, the gender differences are much larger in NTREX than in Common Crawl data. More specifically, in Lithuanian the distribution is skewed toward the masculine class for NTREX data, while it is skewed toward the feminine for Common Crawl data. For Danish, the gender representation is balanced for NTREX but skewed toward the Feminine class for Common Crawl data. This shows that domains highly impact gender representation. NTREX is based on news data, while

[10] https://commoncrawl.org/

[11] We consider that a given dataset in a language is biased toward a specific gender when the gap Δ(|Fem.-Masc.|) is higher than two times the standard error (ste.). This is equivalent to defining a confidence interval as $[r_g - 2ste, r_g + 2ste]$ given the gender score r_g with $g \in \{masc., fem.\}$. If Δ(|Fem.-Masc.|) is inferior to $2ste$, we consider the dataset to be gender balanced. ste is defined as $\frac{\sigma(fem-masc)}{\sqrt{n}}$ with n the number of words in the dataset and σ the standard deviation. See (Bulmer, 1979) for more details on these definitions.

Sentence 1: Omission of words/lexical variation	
Eng: shark injures 13-year-old on lobster dive in california	`masc.+= 0`
Spa: tiburón hiere a un **niño** de 13 años que buceaba en busca de langostas en california	`masc.+= 1`
Cat: un tauró fereix un **nen** de 13 anys mentre buscava llagostes a califòrnia	`masc.+= 1`
Sentence 2: Multiple translations and variation in part of speech	
Eng: [...] something increasingly demanded by younger shoppers.	`unspecified.+= 0`
Cat: [...] un aspecte cada cop més demanat pels consumidors més **joves**.	`unspecified.+= 1`
Sentence 3: Robust to typographic differences	
Eng: **mother**-of-three willoughby and **husband** dan baldwin have been close to jones and his **wife**	`fem.+= 2,masc.+= 1`
Cmn: [...]个孩子的母亲的威洛比及其丈夫 dan baldwin 十年来与琼斯及其妻子 tara保持[...]	`fem.+= 2,masc.+= 1`
Sentence 4: Synonyms	
Eng: [...] the owner of the lloyds pharmacy chain, for £125m, three years ago.	`masc.+= 0`
Vie: [...] chù sõ hũu cũa chuõi nhà thuòc lloyds, vói giá 125 triẽu bàng vào **ba** năm trùózc.	`masc.+= 1`

Table 2: Selected examples of gender representation across parallel sentences between English and multiple target languages (based on the NTREX dataset). Detected gendered nouns in bold/underlined. We indicate the counter incremented by the pipeline for the three gender classes (feminine, masculine and unspecified) next to each sentence when there is at least a match in one of the languages.

Common Crawl includes a large diversity of domains from the Web.

Comparing Genders across Languages In addition, we find a large variability across languages. Some languages like Belarus (`bel`) and Swedish (`swe`) are highly skewed toward the Masculine gender class, while other languages are much more balanced such as Mandarin Chinese (`cmn`) or Hindi (`hin`).

We note that gender distribution cannot be compared across languages quantitatively. Indeed, first, our lexicon is based by design on nouns that are not entirely parallel across languages. Second, our metric highly depends on the number of words in each dataset, which is not comparable across all languages due to their differences in morphology and syntax. However, as discussed below (§ 5.2), our pipeline allows us to highlight qualitative differences in how gender is encoded in different languages.

5.2 Qualitative Analysis: Gender representation variation in parallel data

To understand the cause of these gender representation differences across languages, we present several examples in Table 2. We dicuss them here:

- Omission of words: When comparing English with Romance languages, we observe cases where the gendered word is omitted in English while being translated as a masculine noun in the target language, like Spanish or Catalan. This leads to larger gender representation gaps in these languages.
- Multiple translations and part-of-speech: Sentence 2 shows the impact of how a single English word corresponds to multiple words in other languages. The unspecified word "kid" is translated in 10 words in Catalan: unspecified "jove, criatura"; feminine "minyona, menuda, nena, marreca"; masculine, "minyó, menut, nen, marrec", augmenting the coverage in that second language. In addition, some words in Catalan have multiple part-of-speech, like "jove, menuda, menut" which can act as nouns or adjectives.
- Sentence 3 illustrates that even with typologically different languages such as English and Mandarin Chinese, our lexical matching approach successfully highlights cases where gender is preserved across languages.
- Finally, in Sentence 4, we illustrate the limit of the context-free approach. Indeed, the noun “ba” means both *father* and *three* in Vietnamese, leading to over-estimating the masculine class on some samples.

In summary, the differences in gender representation across languages point to four distinct phe-

nomena: First, the inherent limit of our context-free lexical approach. Gender is, in some cases, incorrectly estimated by a by-design restricted lexical-matching method (e.g., Sentence 4). Second, different domain distributions may lead to diverse gender representation. As reported in the previous section, for some languages, the gender scores highly vary depending on the domains (e.g., News vs. Web crawled data). This suggests that when we analyze non-parallel data, the domain may be a prevalent factor that explains gender representation differences across languages. Third, as we observe when analyzing parallel data, gender representation differences may come from biases in the translation itself. For instance, in Sentence 1, the translation explicitly encoded the masculine gender in Spanish and Catalan while being gender unspecified in English. Other translations could have preserved the gender. Fourth, the way gender is encoded is, partly at least, unique to each language. Some languages are inherently biased toward the masculine gender (e.g. "padres", which may mean both *fathers* and *parents* in Spanish). Other languages do not always have genderless nouns. For instance, *siblings* can only be translated onto Lithuanian as "broliai ir seserys" *Brothers and Sisters*.

6 Conclusion

In this work, we presented GENDER-GAP, a large scale multilingual pipeline to compute gender distribution across 55 languages. We find that broadly used datasets are biased toward masculine gender. Based on this finding, our primary recommendation for multilingual NLP practitioner is to report the gender distribution along with the performance score. This allows reader and systems adopters to be aware of these biases in order to integrate this in their system deployment. Secondly, based on our multilingual lexicon, many directions could be taken to mitigate biases in the performance of the systems (due to biases in the data). Qian et al. (2022) developed a perturbation-based technique to build NLP systems that are less biased toward specific group. We envision using our multilingual lexicon to adapt this technique beyond English.

Limitations

English-centric We designed the list of gendered nouns starting from the English language and then scaled it to multiple languages. This means that our approach may cover incompletely the nuances in different language families regarding gender or only cover them partially and from an English-centric perspective.

Non-Binary Gender Modeling To favor scalability across 55 languages, we chose to use a three gender class lexicon. However, this restrict our approach to binary genders (masculine and feminine) and we only measure imperfectly non-binary genders distribution (Haynes et al., 2001; Herdt, 2020) with the "unspecified" class. We leave for future work the refinement of our lexical categories in order to measure more granularly genders across languages.

Lexical Matching The core assumption of this work is that our predefined lexicon defined in Section 3.2 gives us a proxy to account for gender distributions in large datasets. Although our lexicon is obviously not exhaustive, it is simple enough to scale to highly multilingual environments. Future work could consider other types of nouns (beyond family relations or persons) such as gendered occupations nouns, pronouns, etc.

Abstract

In this paper we propose a novel approach to automatically classify the level of formality in Japanese text, using three categories (formal, polite, and informal). We introduce a new dataset that combine manually-annotated sentences from existing resources, and formal sentences scrapped from the website of the House of Representatives and the House of Councilors of Japan. Based on our data, we propose a Transformer-based classification model for Japanese, which obtains state-of-the-art results in benchmark datasets. We further propose to utilize our classifier to study the effectiveness of prompting techniques for controlling the formality level of machine translation (MT) using Large Language Models (LLM). Our experimental setting includes a large selection of such models and is based on an En→Ja parallel corpus specifically designed to test formality control in MT. Our results validate the robustness and effectiveness of our proposed approach and while also providing empirical evidence suggesting that prompting LLMs is a viable approach to control the formality level of En→Ja MT using LLMs.

1 Introduction

Communication by way of natural language often includes indicators for respect to acknowledge the hierarchy, interpersonal relationship, and power dynamics of the participants in a conversation or written text. In this context, formality or honorifics refers to the set of linguistic features used to establish the degree of respect and deference conveyed in a given context.

Naturally, these phenomena exhibit significant variation across different languages and cultures (Biber and Conrad, 2019). While many European languages emphasize formality through the use of standard grammar, more complicated sentence structures (active, passive, use of clauses, etc.), or more advanced and complex choice of vocabulary and phrases, the Japanese language has its own formality system. This system, named Keigo (敬語), requires users to identify the status or the relationship with the interlocutor, is strict, following a standard grammar format (Fukada and Asato, 2004), and can generally be divided into four different categories (Aoki et al., 2007), as follows.

- **Regular (jyotai,** 常体**)**: a form that is often used in, but not limited to a daily conversation with only people one is familiar with or people who are in the equivalent social status.
- **Polite (teineigo,** 丁寧語**)**: a form that is generally used throughout the whole Japanese society to create some distance between one another. Although this form does not indicate the amount of respect one holds toward others, it helps deliver messages in a polite way that will not be offensive on any occasion.
- **Respectful (sonkeigo,** 尊敬語**)**: a form that shows extensive respect, which is used to maximize the preeminence of the interlocutor.
- **Humble (kenjyougo,** 謙譲語**)**: a form that specifies humbleness, which is used by the Japanese speakers to minimize their own value in order to highlight the greatness of the interlocutor.

In this context, what makes Japanese formality stand out is that it allows to convert any sentences from one style to another by simply adjusting the tense of the verb (Aoki et al., 2007), while maintaining the original meaning, word choice, and sentence structure.

Additionally, the system follows one additional rule (Aoki et al., 2007), where one can always mix the four forms together in one paragraph. The more respectful form one uses in a sentence or a paragraph, the more courtesy one states toward one's interlocutor. Similarly, the more humble form

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 551–560
December 6–7, 2023.

one uses, the more modest one is in the conversation. However, it is also emphasized that when containing too many formal terms in a sentence, the sentence will become annoying and considered inappropriate in Japanese social rules (Aoki et al., 2007).

Given the importance of formality in language generation systems such as machine translation (MT), the ability to control formality and honorifics is a critical factor in achieving accurate and appropriate results. In particular, for the Japanese language, failure in recognizing and incorporating levels of formality can result in unnatural, impolite, or disrespectful translations, which can impede effective communication across diverse linguistic and cultural contexts (Fukada and Asato, 2004). We therefore think that developing and refining MT models that can accurately control honorific levels is crucial for this language. Although formality-controlled machine translation (FCMT) has gained popularity for languages like English (Niu and Carpuat, 2020), there is a substantial lack of resources to tackle the formality problem for Japanese, which extends to the more fundamental task of formality detection.

In light of this issue, we focus on developing resources to improve formality detection in Japanese. We begin by uncovering several flaws on existing corpora for the task, including issues such as the presence of ungrammatical sentences, as well as wrong formality labels. To alleviate these issues, we introduce new resources for Japanese formality detection which consists of manually-labeled sentences annotated with three formality classes (informal, polite, and formal). We propose this three-way setting in opposition to existing resources which are annotated using binary labels, to better approximate the nature of formality of the Japanese language. As existing resources (Nadejde et al., 2022; Liu and Kobayashi, 2022) lacked data for the formal label, a part of our dataset is constructed with sentences sampled from these sources and with text obtained from meeting minutes from committees of the House of Representatives and the House of Councilors of Japan [1].

Furthermore, as language generation models based on Large Language Models (LLMs) have recently been able to attain substantial performance improvements on language generation benchmarks, we note that the lack of a consistent evaluation method makes it difficult to verify to what extent such models can perform formality control. In MT, current studies mainly rely on human assessment or simple models. For example, Feely et al. (2019) and Nadejde et al. (2022) use rule-based methods where lists of grammatical rules are combined with pattern-matching to perform classification. Though formality-level classifiers for Japanese based on machine learning have been proposed in the past (Rippeth et al., 2022; Liu and Kobayashi, 2022), so far this has been without focus on MT or lacked proper evaluation.

In consideration of the above issue, in this paper we propose a novel approach, based on machine learning, to evaluate the ability of En→Ja MT models to perform formality-control. Concretely, we use our dataset to train a robust Transformer-based classifier that leverages a masked-language model, which is able to obtain state-of-the-art performance on our dataset and on existing Japanese formality detection benchmarks. Following recent work relying on machine learning models to evaluate language generation, such as BERTScore (Zhang et al., 2019), and MT models, such as COMET (Rei et al., 2020a), we present an empirical study using our classifier to evaluate the zero-shot ability of several state-of-the-art LLMs to perform formality control.

Our results validate the effectiveness of our proposed approach and show that, compared to existing evaluation techniques that rely on rules and expression-matching, it offers a robust, reliable, and accurate evaluation metric for formality-controlled MT systems. We further demonstrate the ability of LLMs to generate sequences with varying levels of formality through the use of well-designed prompts, concretely showing that both GPT-3 and ChatGPT can attain a formality control accuracy of approximately 90%, and ultimately suggesting that prompting LLMs can result in better formality control performance than fine-tuned MT models. We release or data and trained models[2] to encourage further research on this topic.

2 Related Work

To the best of our knowledge, previous work on formality detection for Japanese is relatively recent and limited in scope, with only two existing resources. On the one hand, we find the Japanese portion of the CoCoA-MT (Nadejde et al., 2022)

[1] https://kokkai.ndl.go.jp/

[2] https://github.com/epochx/japanese-formality

dataset, which was released for the 2022 Shared Task on Formality Control at IWSLT (Anastasopoulos et al., 2022) and contains a total of 1,600 parallel English-Japanese sentences (1,000 for training, and 600 for testing). The source data for this corpus comes from Topical-Chat4 (Gopalakrishnan et al., 2019), as well as Telephony and Call Center data, containing text-based conversations about various topics. For each segment, one reference translation for each formality level (formal and informal) were collected. For the Japanese translations, informal was mapped to jyoutai, and formal was mapped to teineigo, sonkeigo and/or kenjyougo.

On the other hand, we find the recently-released KeiCO corpus (Liu and Kobayashi, 2022), which has a total of 10,007 examples across the four forms of the Japanese formality system (Levels 1 to 4, according to the paper). It additionally contains detailed information about the presence of level-related honorifics —a sentence may contain markers for multiple levels of politeness— the social relationship between the speaker and the listener, and conversational situations or topics. To obtain this data, 40 native Japanese volunteers were asked to regenerate a total of 3,000 sentences coming from machine translation, dialogue systems, and semantic analysis systems, by filling in blanks with honorifics.

The two datasets mentioned above have been used to train Transformer-based classifiers. Liu and Kobayashi (2022) rely on Japanese-BERT (Suzuki and Takahashi, 2021), while the submission of Rippeth et al. (2022) for the 2022 Shared Task on Formality Control at IWSLT relied on XLM-R (Conneau et al., 2020).

Our work is also related to FCMT. In this context, recent approaches have relied on formality-annotated parallel corpora such as CoCoA-MT, early work on this task resorted to other resources such as rule-based generation of synthetic data for English-Japanese (Feely et al., 2019) and English-German (Sennrich et al., 2016), as well as synthetic supervision by means of multi-tasking (formality classification and machine translation). We also find that these studies rely on rule-based simple approaches to measure the accuracy of formality control in the translation, or directly perform human assessment. For example, the FSMT approach English-French by Niu et al. (2017) conducted a human study in which they assigned translation pairs for human annotators. Neural CFMT models for English-Japanese (Feely et al., 2019) and English-German (Sennrich et al., 2016) depend on rule-based classifiers, where grammatical rules for the language are listed and matched.

The recent rise of LLMs has enabled models to perform certain language generation tasks in zero-shot or few-shot manner (Brown et al., 2020), or by means of prompts. Some of these capabilities have been further enhanced by means of prompt-based training (Sanh et al., 2022), where zero-shot generalization is induced by explicit multitask learning. This work is relevant to our paper, as we test the ability of several such models to perform zero-shot FCMT. Our study also considers multilingual efforts in Neural MT, admittedly also a kind of LLM, where we look at M2M100 (Fan et al., 2021) and NLLB200 (Costa-jussà et al., 2022)

Finally, we also find recent work on using few-shot prompting-based techniques to control the formality level of English-German Machine Translation (Garcia et al., 2023). Also, Pu and Demberg (2023) recently performed an in-depth study of the capabilities of ChatGPT to generate text in different styles, including formal/informal labels, showing that the model sometimes incorporates factual errors or hallucinations when adapting the text to suit a specific style.

3 A robust classifier for Japanese Formality

3.1 Data

The size and quality of the datasets are vital requisites to maximize the performance of the machine learning models (Mohri et al., 2018). As one goal of our work is to train a robust classifier for Japanese formality, we look at two main issues. In contrast to existing resources, which either offer limited flexibility by simplifying the dynamics of Japanese formality into two classes (Nadejde et al., 2022), or are too specific by exactly following the grammar (Liu and Kobayashi, 2022), we propose a compromise between these and divide the Japanese language into three categories based on the four formality levels and their corresponding applied situations: (1) “Informal” (for regular tense), (2) “Polite” (for polite tense or teineigo), and (3) Formal (for respectful and humble tenses). Below, we detail how we transformed existing datasets for our purposes, created new resources when necessary, and how we constructed a final curated corpus to train our model.

RECOCOA-MT As we divided Japanese formality into 3 classes, this suggested that the re-utilization of the Japanese portion CoCoA-MT corpus required a transformation of the labels, so we began by analyzing the data. During this stage, we found that many of the examples of the parallel corpus contain broken sentences, while in many cases other sentences do not have an understandable Japanese meaning. Based on these observations, we decided to re-annotate the data and recruited volunteer Japanese native speakers to proceed[3]. During the re-annotation procedure, we confirmed that 44 out of the 1,000 training examples were mislabeled. After re-annotation and filtering, 520 sentences are labeled as informal, 464 sentences as polite, and 12 sentences as formal.

KOKAI As seen above, the re-annotation of COCOA-MT showed that the label distribution in this dataset was heavily skewed away from the formal label, which suggested that more data for this particular level of formality was required. Noting that Japanese political committees tend to rely on language that is considered formal, or at least polite, with very little informal syntax, we proceeded to collect all the meeting minutes from the Japanese Congress (House of Representatives of Japan and the House of Councilors of Japan) from 1947 to 2022. In total, we obtained 64,630 sentences with 23,672 paragraphs, excluding 11,805 broken sentences which are mostly the names, dates, or titles of the committees or the list of participants. We surmise some of these broken sentences, as well as the informal sentences that we observed upon close examination, are likely interrupted utterances that occurred during the sessions. Despite the overall formal nature of the source of data, to ensure the quality of the labels we use for training, we randomly selected 1,360 examples from the raw data and ask our volunteer Japanese native speakersfootnote:annotators to annotate the examples following the same procedure as before. As a result, we obtain 137 informal examples, 760 polite examples, and 463 formal examples.

DAILY We collected 200 sentences sampled from Japanese news, novels, textbooks, business letters and academic documents. The dataset is well-balanced across our three labels with 65, 67, and 68 sentences for the informal, polite, and formal classes, respectively. We use this small corpus mainly for preliminary experiments, but also include these examples in the data used to train our model, as explained below.

KEICO We note that according to Liu and Kobayashi (2022), both respectful and humble tenses are used for the proposed formality Levels 1 and 2. We therefore simply map these two classes to our formal class, to make the annotations compatible with our setting

Using these sources of data except the KEICO, we prepared a first training set consisting of 1,000 examples (426 informal, 501 polite sentences, and 273 formal), leaving a total of additional 200 examples left for development purposes. Though KOKAI has been collected to specifically cover for the lack of annotated data for the formal label in RECOCOA-MT, because the contents are highly related to politics and other related domains, we hypothesize that by only utilizing examples derived for this dataset for training may lead to models that may fail to generalize well to other situation where the respectful and humble tenses are also utilized. To that end, for the initial training set we purposely omit examples from KEICO, which contains formal examples from a diverse set of domains, and build a second training set that relies on examples taken from this corpus to balance the topic distribution. We take a total of 2K examples from KEICO (with 530, 503, and 967 sentences for informal, polite, and formal classes, respectively.)

3.2 Model

Drawing from the success of classifiers based on BERT (Devlin et al., 2019), which have achieved excellent performance in a large selection of downstream tasks, and following Liu and Kobayashi (2022), we propose to use Japanese-BERT (Suzuki and Takahashi, 2021) to train a formality classifier for Japanese formality. The input text is preprocessed and tokenized using the MeCab morphological parser (Kudo, 2005), which is what Japanese-BERT utilizes. For training, we used the AdamW (Loshchilov and Hutter, 2019) optimizer, with a learning rate of 10^{-5}, a batch size of 16 and, and train for a maximum of 20 epochs.

We evaluate our model in the test portions of existing datasets, namely, COCOA-MT and KEICO.

[3]We recruited 30 native Japanese speakers within 20 and 30 years old. All annotators are currently undergraduate or graduate students of a university in Tokyo, Japan. Furthermore, these annotations were double-checked with the help of Japanese dictionaries by 3 additional native Japanese speakers who are graduate students of the same university.

For the former, our analysis reveals that out of 600 examples in the test set, only 594 have been made available, which we utilize in our study. For the latter, since no official test splits are provided, we try to follow the experimental setting proposed by Liu and Kobayashi (2022)[4] and randomly selected 20% of the examples to test.

To contextualize our contributions and put the performance of our classifier in context, we consider a selection of baselines taken from previous work, as well as our implementations of newly-introduced models, and use F1-Score for evaluation.

On CoCoA-MT, we consider the rule-based classifiers proposed by Nadejde et al. (2022) and Feely et al. (2019), as well as our Transformer-based classifier. To test our model in this dataset, which is a binary classification setting, we either train another Transformer-based model on binary labels, or simply convert the prediction of the 3-way models into binary classification by considering all the other 3 tenses except for regular form as formal.

For this dataset, we additionally propose a new rule-based classifier for Japanese formality, which we adapt from Feely et al. (2019). Concretely, we propose ways to mitigate some limitations that were identified in the existing model. For example, the original rules assigned "ない (negative - present tense)" and "なかった (negative - past tense)" to the polite class, while we consider that both of them should be the regular form. In our approach, we label all sentences that are not classified as belonging to the "Polite" and the "Formal" class as "Informal".

We omit results by Rippeth et al. (2022), who fine-tune XLM-R on binary classification between formal and informal classes, but only report accuracy on the development set, defined as the last 50 paired contrastive examples from each language, which we regard as too small and incompatible with our setting. Their model obtains an accuracy of 98% on both the formal and informal classes on this set.

For the KEICO dataset, we compare the performance of our Transformer-based and rule-based classifiers against the BERT-based classifier proposed by Liu and Kobayashi (2022). Since this classifier is trained on a different label set compared to our approach, we proceed as follows: (1) we compare the average F1-score for the respectful and humble term detection task in (Liu and Kobayashi, 2022) against the F1-score of our classifier on the formal label, which we regard as a roughly-equivalent setting, (2) as our approach directly collapses Levels 1 and 2 in Liu and Kobayashi (2022) to our formal label, while Level 3 (which uses teineigo) and Level 4 (no honorifics) perfectly match our polite and informal class, respectively, we compare F1-scores as-is against the overall classification performance.

[4]Their reported metrics are the result of 10 runs with different initialization, and each time 20% of the examples are randomly chosen for the evaluation.

Model	Precision	Recall	F1-score
Nadejde et al. (2022)	0.70	0.49	-
Feely et al. (2019)*	0.87	0.83	0.83
Rule-based*	**0.98**	**0.98**	**0.98**
no KEICO samples			
Transformer 3-way*	0.97	0.97	0.97
Transformer 2-way	0.97	0.97	0.97
with KEICO samples			
Transformer 3-way*	0.97	0.97	0.97
Transformer 2-way	0.97	0.97	0.97

Table 1: Performance formality-level classifiers for Japanese on CoCoA-MT, where * indicates models that were originally designed for 3-way classification, but adapted for binary formality labels by considering polite, respectful, and humble forms as Formal. Precision and recall values from (Nadejde et al., 2022) are based on M-Acc score, and are computed on a 300-example subset of the data. F1-scores were not reported, so we omit them.

3.3 Results

As can be seen in Table 1, both our rule-based and Transformer-based models are able to outperform previous work on CoCoA-MT by substantial margins. We further notice that both models are able to attain very similar, and extremely high performance of 97% F1-score, and that neither the change in label setting, nor the addition of examples from KEICO have any effect on the performance. We think these results are compelling evidence suggesting the limited quality of the examples in this dataset. Based on this, we recommend researchers to consider other benchmarks instead.

Table 2 shows our results on the KEICO dataset. We see that our Transformer-based classifier obtains an overall F1-score of 0.84, surpassing of the classifier proposed by Liu and Kobayashi (2022). By contrast, our rule-based classifier only obtains

Model	F1-score	
	Formality	Hon. Level
Liu and Kobayashi (2022)	0.802	0.727
Rule-based	0.620	-
no KEICO samples Transformer	0.550	0.604
with KEICO samples Transformer	**0.840**	**0.810**

Table 2: Summary of results on the KeiCO dataset. The "Formal" column refers to the accuracy of the model to detect formal terms, while the "Level" column indicates the performance of detecting the level of honorifics.

an F1-score of 0.620, showing that rule-based methods, as comprehensive as they may be, offer limited reliability in multi-domain scenarios.

We also observe that the addition of examples from the KEICO dataset to the training data has a substantial impact on the performance of our model. It is only when these examples are added that our Transformer-based model is able to outperform the baseline. We think this result validates our domain-shift hypothesis, suggesting that examples from KOKAI offer only a narrow variety of expressions of Japanese formality, which do not allow the model to generalize well to more general domains.

Overall, our results suggest that the KEICO dataset offers a more compelling and real-like arena to evaluate the accuracy of Japanese formality classifiers.

4 Empirical Study

Having demonstrated the abilities of our Transformer-based classifier of Japanese formality, we now turn to a more practical issue, and tasks ourselves with testing the proposed approach in a real scenario. We examine formality abilities of English to Japanese machine translation using a zero-shot prompting approach. To the best of our knowledge, our work is the first one to study this issue.

4.1 Experimental Setup

Data We utilize the COCOA-MT En→Ja test set for our experiments. As mentioned earlier, examples in this dataset exhibit numerous flaws, including incomplete and semantically meaningless sentences, but since no other suitable dataset exists, we resort to this dataset nonetheless. We assume the existence of tuples $(x, y_{\text{formal}}, y_{\text{informal}})$ where x is the input sentence in English, and y are the target sentences in Japanese at different formality levels. Using the original 594 English sentences, below we show how we prompt our selection of models to produce both informal and formal Japanese translations.

Models We utilize large multilingual MT models trained on massive parallel corpora, specifically, M2M100 (Fan et al., 2021) and NLLB200 (Costa-jussà et al., 2022). Additionally, we experiment with M2M100 models of different sizes, including the 418M and 1.2B models. For each MT model, we use the English sentences from COCOA-MT as input, and concatenate them with a prefix prompt $p \in P = \{\text{formal}, \text{informal}\}$ which is added using square brackets. Thus, the input to the models is expressed as "$[p]; x$," where ; denotes white-space-based concatenation.

Moreover, as LLMs have shown good performance on MT when provided with an appropriate prompt, we also experiment using GPT-3 (Brown et al., 2020) and ChatGPT. We use similar prompts to those used for the MT models, but suggest more clearly to the models to perform the formality control task by using "Translate English to p Japanese: x". For ChatGPT, as the official API was not yet available at the time of our experiments, so we manually input a total of 1,188 examples (594 examples for each informal and formal setup) into the web client of ChatGPT Plus[5]. We also consider the recently-released llama2 models (Touvron et al., 2023), specifically the chat versions, which have been optimized for dialogue. We utilize the 7B-parameter and 13-B models, the latter we quantize to 4-bits using QLoRA (Dettmers et al., 2023) in order to fit our GPU memory. We follow the approach by the original paper to create our prompt, and test two settings (1) a zero-shot approach where the model is directly asked to generate translation, and (2) a one-shot setting, where we incorporate a source-target translation example for the given formality target. We construct this example manually, making sure it has minimum overlap with the examples from our data.

Finally, we also consider the Transformer-based model by Nadejde et al. (2022) as a baseline. This model is a 20-layer encoder and 2-layer decoder Transformer trained from scratch on the COCOA-MT, with the help of data augmentation techniques.

ChatGPT	98.9	**0.868**	20.63	0.83 (0.25)	**0.91**	**0.91**	**0.91**

Table 3: Performance of our experiments with formality-controlled En→Ja MT, including results MT models (Nadejde et al., 2022) fine-tuned on the data, and zero-shot approaches using pre-trained MT models and LLMs. Here, T-3 and T-2 indicate the proposed 3-way and binary Transformer-based classifiers, and Cmp. is short for Compliance, showing the percentage of output that contained valid translations. For M-Acc (Nadejde et al., 2022), we also show the coverage of the matched sentences between parenthesis, as this evaluation metric model overlooks examples that do not match its rules.

Evaluation We perform evaluation in terms of the quality of the generated translations, and in terms of the ability to perform formality control. For the former, we follow previous work and report and BLEU scores (Papineni et al., 2002) relying on the sacrebleu[6] implementation (Post, 2018), and also consider COMET (Rei et al., 2020b) using the "wmt22-comet-da" model, which has multilingual support. For the latter, we rely on Matched-Accuracy (M-Acc) (Nadejde et al., 2022) which is a rule-based corpus-level metric for CoCoA-MT. M-acc works by checking if the hypothesis contains: a) any of the formality-marking phrases annotated in the formal reference and b) none of the phrases annotated in the informal reference (or vice versa). Crucially, sentences that are not matched are simply skipped. This metric was shown by Nadejde et al. (2022) to be relatively reliable for Japanese, obtaining a precision and recall of 0.7 and 0.49, respectively, when tested on a random sample of 300 sentences that were manually annotated by two professional translators. Finally, we utilize our proposed rule-based and Transformer-based classifiers. Finally, we also measure the zero-shot or few-shot ability of LLMs to "comply" with the given prompt by generating plausible translations. Based on the provided instruction, we use heuristics to parse and extract the translation from the text generated, and report the percentage of output that our heuristics are able to parse successfully.

4.2 Results

Table 3 summarizes our results on the formality control in En→Ja MT performance of all the models considered. We see that zero-shot prompting techniques work much better on LLMs than on pre-trained multilingual MT models, with the former attaining the best performance overall. In particular, we see that zero-shot techniques based on prompting lead to substantially low BLEU scores and formality control accuracy when tested on pre-trained multilingual MT models, which are also outperformed by the fine-tuned models by (Nadejde et al., 2022). This suggests that pre-trained multilingual MT models may simply lack the ability to be prompted for formality control.

In terms of model compliance, we notice that prompting LLMs leads to unstable behavior, with models often not following the provided instruction. This therefore leads them to not generate a valid translation, or to do so in a what such that it is not feasible to find the translation automatically in the model output. For example, some models do not follow the input-output pattern described in the prompt, while others tend to explain their translations in some cases. Finally, llama2 models sometimes refused to provide a translation for

[6] https://github.com/mjpost/sacrebleu

safety reasons, as they detected words regarded as rude or potentially harmful in the input.

Moreover, our results shed light on the reliability issues of M-Acc which, due to its hard matching approach, ends up ignoring many of the translations generated by the systems we test. We observe that across all our tested systems, its coverage lies between 0.18 to 0.25. M-acc is in principle designed to work only for the CoCoA-MT dataset. While this is allegedly a strong limitation already, we think the coverage issue we observed suggests that the approach may be even more limited.

In contrast to these results, we observe that both our Transformer-based and rule-based approaches offer no coverage issues, while also agreeing with each other and with the overall M-acc scores. We think these results validate our techniques as valid alternatives for the evaluation of formality-controlled MT, setting a potential direction for future developments.

5 Conclusions

This paper explores new alternatives to evaluate the ability of En→Ja MT models to perform formality control, proposing classifiers based on rule-based methods and a machine learning approach using HuggingFace Transformers[7] (Wolf et al., 2020).

To build robust models, we focus on developing resources to improve formality detection in Japanese, uncovering several flaws on existing corpora for the task, and introducing new annotated datasets. In contrast to prior work approaching formality using binary labels, we use three classes (informal, polite, and formal) to better approximate the ways honorifics are used in the Japanese language. Extensive experiments on benchmark datasets show that our proposed models offer state-of-the-art performance.

Finally, we empirically show that our machine-learning approach is superior to existing evaluation techniques for formality-controlled MT systems, offering a reliable and accurate evaluation solution. The study also demonstrates the ability of LLMs to generate sequences with varying levels of formality through well-designed prompts, resulting in state-of-the-art results in En→Ja formality-controlled MT. Our findings provide a valuable contribution to the NLP field by presenting a new approach to evaluate formality-controlled MT systems and highlighting the effectiveness of LLMs in this task.

[7] https://huggingface.co/docs/transformers

Limitations

In this work, we have introduced both data and models to tackle the task of formality detection in the Japanese language. Though our results suggest that we have been able to build a robust classifier that obtains good performance, we offer no empirical evidence to suggest how well these capabilities could generalize to untested domains or situations.

Moreover, as some of our experiments involved black-box models that are only accessible through an API, such as GPT-3 and ChatGPT, we are unable to offer reliability in replicating those results. Upon acceptance, we will be releasing the output we obtained from these models for the sake of reproducibility of our experiments.

Finally, we also utilize pre-trained models either as baselines or to initialize our proposed classifier, and we think this is an important driver of the performance we observed. This may be an issue where access to pre-trained models is limited.

There's no Data Like Better Data: Using QE Metrics for MT Data Filtering

Jan-Thorsten Peter* **David Vilar*** **Daniel Deutsch**
Mara Finkelstein **Juraj Juraska** **Markus Freitag**
Google
{jtp,vilar}@google.com

Abstract

Quality Estimation (QE), the evaluation of machine translation output without the need of explicit references, has seen big improvements in the last years with the use of neural metrics. In this paper we analyze the viability of using QE metrics for filtering out bad quality sentence pairs in the training data of neural machine translation systems (NMT). While most corpus filtering methods are focused on detecting noisy examples in collections of texts, usually huge amounts of web crawled data, QE models are trained to discriminate more fine-grained quality differences. We show that by selecting the highest quality sentence pairs in the training data, we can improve translation quality while reducing the training size by half. We also provide a detailed analysis of the filtering results, which highlights the differences between both approaches.

1 Introduction

In the times of statistical machine translation, a well-known motto was "there's no data like more data". Experimental results seemed to confirm this, with the performance of the systems steadily improving as more data was made available. Web crawling has proven to be a valuable source of data for training translation systems, with projects like Common Crawl[1] or ParaCrawl (Bañón et al., 2020) providing numerous parallel sentences with which to train MT systems. Inevitably, when crawling huge amounts of data, noise will be present. Taking the web as an example, the quality of available texts varies greatly between websites. There are sources which reliably produce high-quality text, e.g. large circulations newspaper websites usually contain text written and proof-read by professional journalists. But by its open nature, the web also contains texts of dubious quality (both in style and in content) which may pollute the collected texts.

When considering bilingual data collection, an additional difficulty comes into play, namely the alignment of segments between two or more languages. Sentence alignment algorithms (Gale and Church, 1993; Moore, 2002; Sennrich and Volk, 2011; Thompson and Koehn, 2019) are bound to make mistakes, resulting in pairing of sentences that are not necessarily translations of each other. Even if the correspondence between sentences may be correct, the quality of sentences may differ greatly between languages. While one source may provide high quality text in its original language, the available translations may be of sub-par quality due to a variety of reasons (Freitag et al., 2022b). In addition, given the increased availability (and quality) of machine translation engines, MT output is expected to be part of the crawled data, thus contaminating the training material.

Statistical systems were robust against such type of noise (Goutte et al., 2012). The maximum likelihood estimators of phrase probabilities (and related models) were based on relative frequencies, with the consequence that noisy translation units, while being available to the system at translation time, had a low chance of being used. In fact, works on filtering data dealing with statistical systems, e.g. Johnson et al. (2007) were more concerned with the efficiency of the systems, rather than with quality.

With the advent of neural machine translation, the situation has changed, and the quality of the data has a major impact in the resulting quality of the translation system. Neural networks have a great ability of memorizing (parts of) the training data (Arpit et al., 2017; Feldman and Zhang, 2020). Whereas for phrase-based models the noise was diluted in the abundance of better-quality data, in neural models such outliers may have a critical effect on the output of the system. Therefore data filtering has become increasingly important, even spawning dedicated shared tasks (Koehn et al., 2018, 2019,

* Equal contribution.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 561–577
December 6–7, 2023.

2020). Research in this area has allowed NMT systems to take advantage of big amounts of training data. As an example, initial versions of ParaCrawl degraded translation quality when adding them unfiltered to the training data of MT systems (Junczys-Dowmunt, 2018b; Schamper et al., 2018), whereas nowadays it is one of the main data sources used in WMT for the languages where it is available.

Thanks to these filtering techniques, huge amounts of parallel sentences are available for several languages, in some cases reaching up to hundreds of millions of sentences. But as noted above, not all texts are of the same quality. It is only natural to ask the question, once the training data reaches a size which is "big enough", if all the available text is useful for training NMT systems, or if the lower quality sentences are hindering the system. Note that most data filtering systems are focused in detecting noise or problems in the translation (e.g. under- or overtranslation). In very wide strokes, most systems answer the question "Is sentence A a translation of sentence B?", without looking (too much) into the quality.

Judging the quality of translations is the focus of the Quality Estimation (QE) field of machine translation. It can be considered an extension of machine translation evaluation, where references are not available. In the last years, the use of neural models has improved the results in this area dramatically. Would it then be possible to use quality estimation methods for filtering data and improve the quality of a neural machine translation system, which has been trained on already cleaned data? In other words, can we do a more fine-grained data selection beyond discarding "obvious" errors, focusing on selecting the best data that can be found in the training corpus? We explore these questions in this paper.

Our scientific contributions are:

- We show that neural QE metrics are effective methods for data filtering.
- We analyze the differences between the sentences filtered by the methods and find out that QE methods are more sensitive toward quality differences, being able to detect bad quality translations or fine grained translation errors (e.g. wrong named entities in a perfectly valid translation).
- We show that on the other hand QE filtering cannot account for some actual noise problems. Thus a "traditional" method for filtering the raw data coming from crawls is still needed as a first step.

2 Related Work

Already in the early days of the popularization of statistical methods for machine translation, the potential of mining data from the web was recognized by Resnik (1999). In contrast to other data sources at the time (e.g. Canadian Hansards, European Parliament Proceedings) which consisted largely of clean data, the necessity of including additional "quality assurance" steps were recognized in this work. As pointed out above, statistical systems were robust against noisy input data (Goutte et al., 2012), and as such, the topic of "corpus filtering" was mainly focused on selecting subsets of data closer to a given domain (Axelrod et al., 2011). Nevertheless Taghipour et al. (2011) shows that statistical systems may also benefit from careful curation of the training data.

The situation changed dramatically with the advent of neural machine translation, as such systems are much more sensitive to noisy input data (Khayrallah and Koehn, 2018). A clear reflection of this fact was the creation of a new dedicated shared task in the WMT yearly conference (Koehn et al., 2018, 2019, 2020) in the years 2018 to 2020.[2]

Junczys-Dowmunt (2018a) was the best performing system in the first edition of the filtering shared task, using a cross-entropy approach between two translation systems trained on clean data. In the next edition, the focus was moved towards low resource conditions. That year Chaudhary et al. (2019) presented the best performing system, using a system based on LASER embeddings (Schwenk and Douze, 2017).

The 2020 edition continued the focus on low-resource languages. At that evaluation, three were the best performing systems: Lu et al. (2020) and Lo and Joanis (2020) both use pre-trained multilingual models as a key component of their filtering systems. Esplà-Gomis et al. (2020) used an improved version of BICLEANER, their submission for the 2018 campaign (Sánchez-Cartagena et al., 2018). The authors further improved their system (Ramírez-Sánchez et al., 2020), including an extension using neural models (Zaragoza-Bernabeu et al., 2022). This latest version is considered state-

[2] In this year's WMT there is a new related shared task: "Parallel Data Curation".

of-the art and it is that which we take as baseline for comparing our method.

Of course, this is just but a very rough overview of the best performing systems in each evaluation campaign. We refer to the reports of each campaign for a more detailed overview of the methods explored each year. Bane et al. (2022) provide one more recent overview of data filtering methods. In this work, the authors sample 5M sentences from original training data and added 1M noise samples manually. They show that a two-stage approach can be beneficial for improving the quality of a translation system.

All of these methods have a common focus on detecting the type of noise that may originate from crawled data. This type of noise has been analyzed in Khayrallah and Koehn (2018), and Herold et al. (2022) build on their work and carry out a comparison of the efficiency of different filtering methods on various types of noise. Kreutzer et al. (2022) also provide an extensive analysis on the noise present in several widely used corpora.

Most similar to our work Carpuat et al. (2017) start with already clean data and analyze the effect of semantic divergence on translation quality. They are able to effectively select a subset of the training data and improve translation quality measured in BLEU. Bernier-Colborne and Lo (2019) use YiSi-2, also a quality estimation metric as a component in their corpus filtering system for the WMT 2019 shared task. Lo and Simard (2019) extend this idea by including BERT (word) alignments in the YiSi pipeline. We follow a conceptionally similar approach to these papers, using state-of-the-art QE metrics and provide a more in-depth comparison to other corpus filtering methods more oriented towards noise detection.

Quality estimation is again its own area of research, with dedicated shared tasks, e.g. (Zerva et al., 2022), that measure how well metrics can predict word- and sentence-level quality scores. In contrast to traditional MT evaluation, QE aims to assess the quality of the output texts without the use of a reference translations. The most successful QE metrics learn to jointly predict word- and sentence-level scores, like COMETKIWI (Kepler et al., 2019; Rei et al., 2022). Another possibility is to modify the input to a learned reference-based metrics like BLEURT (Sellam et al., 2020) or COMET (Rei et al., 2020) to use the source segment instead of a reference translation to predict sentence-level quality scores (Rei et al., 2021). We follow the latter approach and train a QE version of BLEURT that predicts sentence-level quality scores (see Section 3) that are used for data filtering.

3 From BLEURT to BLEURTQE

The QE metric that we propose for data filtering is a learned MT evaluation metric that is based on a BLEURT-style architecture (Sellam et al., 2020). BLEURT is a reference-based regression metric that is trained to predict a quality score for a hypothesis translation given a reference. The hypothesis and reference are concatenated together with a special token in between, then fed as input to the metric, which predicts a floating point quality score.

Our QE metric is a modification of the original model. To make it a QE metric, we pass the source segment as input to the metric instead of the reference. Then, we follow the winning submission to the WMT'22 Metrics Shared Task (Freitag et al., 2022a), MetricX, and use a modified version of the mT5 encoder-decoder language model (Xue et al., 2021) as our network architecture. Not that these is a multilingual model, so the same system can be used for a variety of languages. The source and hypothesis are passed as input to the encoder, and an arbitrary logit from the first step of the decoder is trained to predict the hypothesis quality score.

The QE metric is trained on the direct assessment quality judgments that were collected as part of the WMT Metrics Shared Task from 2015-2020 (Bojar et al., 2015, 2016, 2017; Specia et al., 2018, 2020; Fonseca et al., 2019) for all available language pairs. To (meta-)evaluate the metric we measure its correlation with ground-truth translation quality ratings using the benchmark MQM dataset from WMT'22 (Zerva et al., 2022) that includes 3 language pairs: en-de, zh-en, and en-ru. Since our metric is used to score individual segments and not systems, we report the segment-level correlation between our metrics' scores and the gold MQM scores using Pearson's r and Kendall's τ, shown in Table 1. The correlations are competitive to the top QE submissions to the WMT'22 Metrics Shared Task.

A (more refined) version of this metric has been submitted to this year's QE shared task (Juraska et al., 2023), and has been open sourced. We refer the reader to the system description for a more fine-grained discussion of the details of the metric.

Metric	en-de		en-ru		zh-en	
	r	τ	r	τ	r	τ
UniTE-src	0.40	0.29	0.39	0.34	0.40	0.43
COMETKIWI	0.43	0.29	0.39	0.36	0.51	0.36
BLEURTQE	0.38	0.29	0.41	0.39	0.38	0.35

Table 1: Segment-level Pearson's r and Kendall's τ on the WMT'22 MQM ratings for our QE metric, BLEURTQE and the top-performing metrics in the WMT'22 Metrics Shared Task, COMETKIWI (Rei et al., 2022), UniTE-src (Wan et al., 2022).

4 Experiments

We report experiments on three language pairs: English ↔ German, Japanese ↔ English and Chinese ↔ English. Our starting point is the full training data as provided by the WMT evaluation campaign. Corpus sizes can be found in Table 3. As can be seen in that table, we are working on a medium-to-large data condition, with the smallest language pair already having over 30M sentence pairs.

One thing to note is that these datasets have already undergone a cleaning process by the WMT organizers. I.e. a system trained on the entirety of this data is already able to obtain very good performance. In fact, many of the systems participating in the WMT evaluations take the available data as-is.

For each language pair we will consider different ways to reduce the size to 50% of their original size. This value was chosen in preliminary experiments on the English to German data, and it is comparable to previous work (Bane et al., 2022). Fixing the target size beforehand also allows a fair comparison between all the methods.

4.1 Filtering Approaches

We will consider three different filtering approaches for our experiments.

4.1.1 Random Selection

The most straightforward method to reduce the size of the training data is to just randomly select the desired amount of sentence pairs. We do not expect this method to perform well, but it constitutes the most direct baseline for data size reduction.

4.1.2 BICLEANER

As a representative for the "noise-detection" corpus filtering methods we chose to use BICLEANER AI.[3] This tool is an extension of the previous BICLEANER tool. The underlying method is based on a classifier that predicts if a sentence is a translation of another. BICLEANER AI substitutes the original classifier, based on handcrafted rules and extremely randomized trees, with a neural classifier based on XLM-RoBERTa. Zaragoza-Bernabeu et al. (2022) provide a detailed description of the tool and present an extensive experimental comparison showing state of the art results for filtering ParaCrawl.

It is also worth noting that BICLEANER is part of the pre-processing pipeline for generating the ParaCrawl dataset.

4.1.3 Quality Estimation for Filtering

For testing the performance of QE metrics for filtering we use two state-of-the-art metrics, COMETKIWI[4] (Kepler et al., 2019) and BLEURTQE[5] as described in Section 3. For each sentence pair in the training data, we compute the QE score for the translation from English into the foreign language. We use these scores for filtering for both translation directions, i.e. the resulting parallel data is the same for English → Foreign than from Foreign → English. We are aware that this may introduce a certain bias, as the performance of the QE metrics is not symmetrical. However scoring the full training data is a costly operation as we have to run big neural models on tens or hundreds of millions of sentence pairs. We still expect to see improvements even when using the wrong direction for data filtering. The only exception may be the backtranslated portion of the Chinese ↔ English dataset: As the starting data is Chinese, the filtering method may miss low quality backtranslations produced by an automatic system.

4.2 Experimental Setup

For all the filtering methods (except random selection), we compute the score of each sentence pair, and then select a threshold as to keep 50% of the original data. We then train an NMT system from scratch using the resulting training data sets.

Our translation system is a transformer-based encoder-decoder model based on PaxML[6], very similar to most of the systems participating in the WMT evaluation campaign. It consists of 6 encoder

[4] https://unbabel.github.io/OpenKiwi

[5] The tool will be open-sourced with the publication of the shared task system description.

[6] https://github.com/google/paxml

and 6 decoder layers, a model dimension of 1024, hidden dimension of 8192 and 16 attention heads. GELUs with gated activation are used as activation functions. We use a 32k shared vocabulary for each language pair, and limit the maximal sentence length to 128 tokens. The model has a total of 551M parameters.

We removed all sentences which have more than 128 tokens, but did not perform any other filtering or preprocessing of the data. All models are trained until they converged and we selected the checkpoint with the best BLEURT score on the WMT 2022 test sets.

In the discussion of the results we focus on the evaluation using COMET22. Traditional metrics like BLEU and CHRF are consistently outperformed by neural metrics in the WMT metrics shared task (Freitag et al., 2022a), thus we favor the use of such new metrics. We chose COMET22 over BLEURT in order to avoid overfitting on this last metric, as our proposed BLEURTQE model is based on it, and it also guides the checkpoint selection. Nevertheless, BLEURT, BLEU and CHRF scores are given in Appendix B.2 and confirm the trends reported here.

4.3 Test Data

In order to test on a variety of domains we use test sets from the WMT and IWSLT evaluation campaigns. We use the WMT 2019 (where available) consisting of news data, and the WMT 2022 and WMT2023 test sets, which are composed of a mix of different domains each. Additionally we experiment on the IWSLT'21 test set, sourced from TED talks (Anastasopoulos et al., 2021), and the IWSLT'23 dev set[7], which is based on ACL talks presentations (Agarwal et al., 2023).

Following the training data settings, we also filtered the test sentences longer than 128 tokens. As the WMT 2023 test set includes paragraph level evaluation, its size is reduced for en → de from 557 segments to 404 and for de → en from 549 to 468. All other test sets are barely affected (see Table 6 in Appendix A).

4.4 Experimental Results

Translation results for the English ↔ German language pair are shown in Table 2a. For en → de we can see that randomly selecting data hurts performance by 1 point on the WMT23 test set. Using each of the other filtering methods we are able to improve performance over using the full training dataset. For BICLEANER the improvement is rather modest, around 0.4 points for most test corpora. Note however that BICLEANER was already applied to the ParaCrawl dataset, which constitutes a big portion of the available training data for this language pair. As such it is understandable, or even expected, that translation quality is not improved by applying it again. The QE metrics perform similarly to each other, with a slight advantage of BLEURTQE over COMETKIWI. Using BLEURTQE we are able to achieve an improvement of up to 1.7 points on the WMT23 test set.

The results for de → en majorly confirm the previous observations. The best results are again achieved in this case on the WMT'23 data, with an improvement of 1.3 points achieved by both QE methods. For the WMT'22, IWSLT'21 and IWSLT'23 test sets, the translation performance basically stays constant for all filtering methods.

Results on English ↔ Japanese, shown in Table 2b also show similar trends. In this case the biggest improvement comprises 2.3 points on the WMT'23 test set[8], obtained by BLEURTQE. However for the ja → en translation direction we find an outlier, where no filtering achieves improvements over the baseline on the IWSLT'23 data.

Lastly, Table 2c shows the results for the Chinese ↔ English language pair. Again we can confirm the same trends as for the other two language pairs. The QE metrics are able to improve up to 2.8 points for the WMT'23 test set. The IWSLT'23 dataset again fails to achieve improvements, and in this case BICLEANER deteriorates translation quality, while the QE metrics are able to keep the performance.

Overall, we see that the QE metrics are effective in improving translation quality while retaining just half of the training data. The improvements can rage up to more than 2 COMET22 points, depending on language pair and test set. For IWSLT'23, having a more specialized technical domain, the QE metrics are not able to improve quality, for several language directions. But except for the case of English → Japanese, they also do not hurt performance. Additional results differentiating between the single domains of the WMT'22 and WMT'23 corpora can be found in Appendix B.1. In Ap-

[7]We use the dev set for IWSLT'23, since the test set is currently not publicly available.

[8]A slightly bigger improvement of 2.4 is obtained for WMT'22, but we skip this as we used this corpus to choose the best checkpoint during training.

Table 2: COMET22 scores all experiments. For each language direction, systems marked with stars are statistically significantly better than systems with fewer stars (pairwise permutation test (Koehn, 2004) with p=0.05). "Random" was excluded from the significance computation.

Language pair	Full	Filtered	Common
de ↔ en	292.8M	146M	105M
en ↔ zh	55.2M	27.6M	17.5M
en ↔ ja	33.9M	16.9M	10.4M

Table 3: Amount of sentences before filtering, after filtering, i.e. 50% of the original corpus size, and number of sentences kept by both BLEURTQE and BICLEANER. All language directions include ParaCrawl data. English ↔ Chinese includes around 19.7M backtranslated Chinese sentences, as provided by the WMT organizers.

pendix B.2 we also report the results of the same experiments using BLEU, CHRF and BLEURT. These metrics confirm the observations presented in this section.

Koehn et al. (2020) mentions that on average metrics that select shorter sentences performed better on Parallel Corpus Filtering. Contrary to that we observed that dropping 50% of the data with the proposed method led to on average slightly longer sentences e.g. from 14.4 to 15.5 words per sentence for BLEURTQE on English ↔ German.

5 Analysis

In this section we provide an in-depth analysis of the differences between the BLEURTQE-based and the BICLEANER filtering methods. Table 3 shows the amount of sentence pairs that are kept by both methods, which is roughly two thirds of the filtered sentences for all language pairs. Thus, it is clear that both methods do indeed perform quite different filtering. We will first report on manual inspection of the most striking divergences between both methods. In Section 5.2 we will then provide a more quantitative analysis of the behaviour of the methods using synthetic data.

5.1 Human Inspection

We will now analyze the difference in the filtering methods by looking into the sentences that are selected by each method. To this end, we select the sentences where one method filters it but the other does not. In addition we use automatic clustering methods in the spirit of (Aharoni and Goldberg, 2020) in order to get insights about topic distribution. We limit our analysis to the German–English language pair[9], but as the methods are largely language independent, we feel confident that our findings will generalize to the other language pairs. Also, due to the fuzzy and partially subjective nature of this investigation, we are unable to provide exact statistics about each kind of effect.[10]

We have encountered the following major differences in the working of the methods. For each of these categories it is easy to find an abundance of examples (easily in the thousands) in the filtered data.

Single Entity Mistranslations When looking into the parallel data available for training, one can find a big amount of "templated texts", i.e. sentences that have a common structure, but that differ in one or few components, frequently named entities or numbers. Some examples can be found in Table 4a. The first entry in this table is a typical example. In the travel domain, there is a big amount of sentences of the form "Flights from *cityA* to *cityB*", "Hotels in *city*" or similar formulations. One frequent source of sentence alignment errors originates from sentences that follow the same template, but have different instantiations. Although the travel domain is one of the biggest representative of these type of sentences, it is by no mean the only one, as the other examples in Table 4a show, including the financial and the technical domain.

In these type of sentences, the QE metric seems to be more sensitive to alignment errors. All the sentences shown in Table 4a (and many others) are selected by BICLEANER, while BLEURTQE discards them.

Low Quality Translations In this category we include training examples where one or both sides are of low quality. Examples can be found in Table 4b. We can see that the language quality of the examples is borderline at best. Strictly speaking, the translations are "correct" in the sense that they preserve the structure of the sentence. As such BICLEANER gives them a relative high score and are kept in the training corpus. BLEURTQE, on the other hand, is explicitly trained to flag such erroneous sentences (as they might very well originate from MT engines), and thus these examples are filtered out.

Bad Related Sentence Alignments As pointed out above, sentence alignment is also an automatic process. While both methods perform quite well when detecting clearly bad aligned sentences (see Section 5.2), we found that there are cases where

[9] None of the authors are speakers of Japanese or Chinese.

[10] If we were able to develop such statistics in an automatic way, we would be able to improve the filtering methods by including the same approaches!

(a) Single Entity Mistranslations. Templated texts where the specific instantiation is different in both languages. BLEURTQE filters out these examples, while BICLEANER keeps them.

Unnatural language on both sides.
It really is fast, easy, free and additionally to attempt.	Es ist schnell, Schnell, gratis und am besten von allen zu try.	Incorrect sentences in both languages.

(c) Examples of wrong sentence alignment, although the sentences are related to each other. BLEURTQE filters out these examples, while BICLEANER keeps them.

English	German	Translated German
Could you help me? Help to improve my English and French language	Ja, ich möchte gern mein Deutsch mit Dir verbessern.	Yes, I want to improve my German with you.
We, therefore, guarantee that you will get daily updates on office spaces to rent in Hong Kong.	Wir können Ihnen deshalb versichern, dass Sie bei uns täglich einen aktuellen Überblick über den österreichischen Markt erhalten.	We can guarantee that you will get an up-to-date daily overview about the Austrian market.
This implies that the law is either repealed or not enforced.	Darüber hinaus wird sichergestellt, dass bestehende Gesetze nicht dupliziert oder konterkariert werden.	In addition, it is ensured that existing laws are not duplicated or counteracted.

(d) Examples of sentence pairs originating from the Bible. BLEURTQE filters them out, probably due to archaic language, while BICLEANER keeps them.

English	German
19 Behold, my belly is as wine which hath no vent; it is ready to burst like new bottles.	19 Siehe, mein Bauch ist wie der Most, der zugestopfet ist, der die neuen Fässer zerreißet.
7:16 Those who went in, went in male and female of all flesh, as God commanded him; and Yahweh shut him in.	7:16 und das waren Männlein und Fräulein von allerlei Fleisch und gingen hinein, wie denn Gott ihm geboten hatte.

Table 4: Example sentences where the filtering methods diverge.

the source and target sides are related and the BICLEANER system seems to get confused by this proximity. Some examples are given in Table 4c. It can be seen that in all three examples the German side is clearly related to the English text, with probably a overlap big enough to get an acceptable score from the translation system underlying BICLEANER. Again, as BLEURTQE is trained to distinguish fine-grained differences between translations, it is more robust against this kind of problems.

Religious Texts One shortcoming we found for the BLEURTQE method is that many sentences originating from the Bible corpus (or similar religious texts) are filtered out, while BICLEANER keeps them. Some examples are given in Table 4d. This is probably due to the language being archaic, very different to the type of sentences BLEURTQE has been trained on. Such style would be heavily penalized in an evaluation, as a more modern language would be preferred.

5.2 Noise

In the previous section we saw several examples where BLEURTQE outperforms BICLEANER for data selection. However we should not forget that BICLEANER was developed with a (related but) different goal, namely the cleaning of raw data. In fact, our starting datasets, as made available for the WMT evaluation have already undergone a cleaning process, and are already at a pretty high quality level.

If we were dealing with crawled data directly, we would need to address different phenomena. In this section we study how the filtering methods perform when dealing with the typical noise found on crawled data. We follow Herold et al. (2022) for the categorization of different noise types, which in turn is based on Khayrallah and Koehn (2018). We create synthetic data for the English → German translation direction containing the following noise categories:

Misaligned Sentences created by shuffling the target side of the corpus.

Misordered Words created by reordering the words in either the source or the target sentences.

Wrong Language created by taking parallel sentences corresponding to another language pair.

Untranslated created by copying one sentence into the other direction i.e. each sentence pair in the corpus has a copy of the source sentence as a "target" sentence (or the reverse direction).

Over/Undertranslation created by truncating either the source or the target side.

We refer the reader to Herold et al. (2022) for a more detailed description and justification of these categories. We omitted the "Short Segments", "Raw Crawled Data" and "Synthetic Translations" categories, as it was not clear how to define the correct filtering strategy in those cases.

For each of the studied categories, we generated 200K synthetic noise examples by randomly selecting a subset of the training data. For these experiments we re-tuned the threshold for each method by computing the scores for the original sentences and the noise examples, and computing the median. In this way, we filter exactly half of the data and a perfect system would be able to completely separate the original examples from the noisy ones.

Results can be found in Table 5. It can be seen that for most categories BICLEANER clearly outperforms BLEURTQE. This is specially the case for the "Wrong Language" and "Untranslated" categories, where BICLEANER can detect all the noisy examples. In fact, one of the practical advantages of BLEURTQE is at the same time one of its weaknesses. As its backbone model is a multilingual model, it is able to handle a wide number of languages, but it does not have a way to differentiate between them.

For "Misordered Words" we find an interesting asymmetry. BLEURTQE is much stronger in detecting problems when the target side is reordered, undoubtedly due to this being the "natural" direction for which it was trained. BICLEANER also shows this behavior, with its target side performance being superior to that of BLEURTQE, but inferior in the opposite direction. BICLEANER is also clearly better at detecting Over- and Undertranslations.

5.3 Combination of Filtering Methods

Since BLEURTQE and BICLEANER based filtering both improve translation quality, and they filter different sentences, it is only natural to try to combine both. As can be seen in Table 3, the amount of available data dropped to roughly one third when combining both methods. The result

Noise type	BLEURTQE	BICLEANER
Misaligned Sentences	8.1	**5.6**
Misordered Words (src)	**24.3**	39.1
Misordered Words (tgt)	10.3	**6.3**
Wrong Language	43.8	**0.0**
Untranslated (src)	47.6	**0.0**
Untranslated (tgt)	63.8	**0.0**
Overtranslation	35.2	**13.9**
Undertranslation	13.4	**7.5**

Table 5: Percentage of sentences being kept as valid for each of the synthetic noise categories. 0% means that all noisy sentences have been filtered out, i.e. perfect performance.

only slightly degraded in the English to German direction compared to just using BLEURTQE (0.3 BLEURT points on WMT'22), but degraded more in the German to English direction (0.6 BLEURT points on WMT'22). Combining the two methods is thus too aggressive with our setup, and hurts translation performance. Adapting the thresholds for the combination, may result in better performance. Note however that ParaCrawl already used BICLEANER in its pipeline (Esplà et al., 2019), thus we have already implicitly been using a combination of both methods.

6 Conclusions

In this paper we have shown that filtering data using QE metrics is an effective way of improving translation quality. In contrast to "traditional" data filtering methods that focus on detecting noise in the data, QE methods focus on selecting the best translation examples. Analyzing the differences between the two different methods, we see that QE metrics are not as effective at detecting certain types of noise, e.g. untranslated sentences, but are much better at identifying more fine grained problems in the data, like small translation errors or grammatical mistakes. Therefore, when starting with already cleaned data, we can obtain a boost in performance by focusing the NMT system training on the best sentences.

Our results show that the improvements obtained generalize across different domains, as measured by a variety of metrics. Even for more distant domains, like the ACL Talks of of the IWSLT'23 corpus, the performance of the systems remains largely constant. QE estimation is a very active field of research. Using this approach, the improvements obtained in this area can have a direct impact on improving the quality of NMT systems.

Limitations

Better results could have been obtained by tuning the threshold for each method individually, but this would also increase the computational cost massively.

A more in-depth comparison could be carried out starting from the raw web-crawled data. However in this study we chose to start from conditions similar to what most participants in the WMT evaluation use.

Ethics Statement

BLEURTQE and COMETKIWI scoring all the training data is computationally expensive, and may be a limiting factor of the method for small institutions.

Appendices

A Test Data Statistics

Table 6 shows statistics of the test data sets after filtering the sentences with a length of over 128 tokens.

	test set	lines	filtered
WMT'22	en → de	2037	2036
	de → en	1984	1981
	en → ja	2037	2037
	ja → en	2008	2007
	en → zh	2037	2037
	zh → en	1875	1849
WMT'23	en → de	557	404
	de → en	549	468
	en → ja	2074	2073
	ja → en	1992	1988
	en → zh	2074	2073
	zh → en	1976	1948

Table 6: WMT test set sizes. All test sets are filtered to use less than 128 tokens. This mainly reduced the en ↔ de WMT'23 test set since this was a paragraph level task. The effect on all other test sets is minimal.

B Additional Results

B.1 WMT Data: Domain-specific Evaluation

The WMT'22 and WMT'23 test sets are comprised of text originating from different domains. The scores reported in the main text correspond to the evaluation of the corpora as a whole. In Tables 7 to 12 we show the results for each individual domain. It can be seen that the improvements are achieved over all separate domains. There are only two cases where training on all data performs slightly better than filtering with BLEURTQE (ecommerce de → en in Table 8, and manuals zh → en in Table 10).

B.2 Other Metrics

In this appendix we report the COMET22, BLEURT, BLEU and CHRF scores for the experiments reported in Section 4. Table 13 shows the results for German → English, Table 14 for English → German, Table 15 for English → Japanese, Table 16 for Japanese → English, Table 17 for English → Chinese and Table 18 for Chinese → English. The additional metrics support the conclusions of the paper.

	WMT'22				WMT'23			
	conversation	ecommerce	news	social	mastodon	news	speech	user review
None	87.9	87.4	86.4	83.1	82.5	80.8	80.9	82.0

Abstract

This paper presents the results of the WMT23 Metrics Shared Task. Participants submitting automatic MT evaluation metrics were asked to score the outputs of the translation systems competing in the WMT23 News Translation Task. All metrics were evaluated on how well they correlate with human ratings at the system and segment level. Similar to last year, we acquired our own human ratings based on expert-based human evaluation via Multidimensional Quality Metrics (MQM). Following last year's success, we also included a challenge set subtask, where participants had to create contrastive test suites for evaluating metrics' ability to capture and penalise specific types of translation errors. Furthermore, we improved our meta-evaluation procedure by considering fewer tasks and calculating a global score by weighted averaging across the various tasks.

We present an extensive analysis on how well metrics perform on three language pairs: Chinese→English, Hebrew→English on the sentence-level and English→German on the paragraph-level. The results strongly confirm the results reported last year, that neural-based metrics are significantly better than non-neural metrics in their levels of correlation with human judgments. Further, we investigate the impact of bad reference translations on the correlations of metrics with human judgment. We present a novel approach for generating synthetic reference translations based on the collection of MT system outputs and their corresponding MQM ratings, which has the potential to mitigate bad reference issues we observed this year for some language pairs. Finally, we also study the connections between the magnitude of metric differences and their expected significance in human evaluation, which should help the community to better understand and adopt new metrics.

Table 1: Official ranking of primary submissions to the WMT23 Metric Task. The final score is the weighted average correlation over 10 different tasks. Starred metrics are reference-free, and underlined metrics are baselines. See Table 18 for the pairwise comparisons from which the ranks were derived.

1 Introduction

The metrics shared task[1] has been a key component of WMT since 2008, serving as a way to validate the use of automatic MT evaluation metrics and drive the development of new metrics. We eval-

[1] https://wmt-metrics-task.github.io/

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 578–628
December 6–7, 2023.

uate reference-based automatic metrics that score MT output by comparing the translations with a reference translation generated by human translators, who are instructed to translate "from scratch" without post-editing from MT. In addition, we also invited submissions of reference-free metrics (quality estimation metrics or QE metrics) that compare MT outputs directly with the source segments. All metrics are evaluated based on their agreement with human rating when scoring MT systems and human translations at the system and sentence level. The final ranking of this year's submitted primary metrics is shown in Table 1. Below are some key details and changes for this year's metric shared task:

- **Language Pairs**: For this year, we focus on three main language pairs: (i) One language pair with paragraph-level test sets: English→German (en→de), (i) one low-resource language pair with sentence-level test sets: Hebrew→English (he→en), (iii) one high-resource language pair with sentence-level test sets: Chinese→English (zh→en).

- **Human Evaluation**: Like last year, we collected our own human ratings for our three language pairs from professional translators via MQM (Lommel et al., 2014; Freitag et al., 2021). We released and uploaded[2] all MQM annotations, and we recommend using Marot[3] for looking into this data.

- **Meta Evaluation**: This year's meta-evaluation is significantly streamlined from last year's. Instead of 201 tasks, we use just 10, designed to capture complementary ranking and linearity properties at system- and segment-level granularity. We replace Kendall's tau at the segment level with a version of pairwise accuracy that gives metrics credit for correctly predicting ties in human scores, while automatically calibrating for each metric's natural scale (Deutsch et al., 2023). Instead of averaging per-task ranks to derive an overall score for each metric, we simply average correlation/accuracy scores across tasks. This places metric scores on an absolute scale, and makes them independent of the performance of other metrics. Finally, we compute top-level significance clusters to provide a clearer global ranking of participating metrics.

- **Synthetic Reference**: The MQM scores for the human reference translation for zh→en were unexpectedly low, ranking humans below almost all WMT submissions. We investigate the impact of bad reference translations on reference-based metrics and propose a novel approach to create a synthetic reference translation from all WMT submissions and their corresponding MQM scores.

- **Challenge Sets Subtask**: For the second year, we include a decentralized sub-task on challenge sets, in which test sets are submitted by different research teams targeting to reveal metrics' abilities or the weaknesses in evaluating particular translation phenomena. We received three challenge sets covering a wide range of translation errors and linguistic phenomena in more than a hundred translation directions.

- **Understand Magnitude of Score Difference**: This year, we include two analyses to understand the meaning of the score differences that metrics present with respect to the statistical significance of MT system rankings according to human annotations and metric scores. These analyses provide additional assistance for MT researchers to build an intuition on the relationship between the magnitude of metric score differences and the reliability of the improved translation quality.

- **MTME**: Similar to last year, all the data has been uploaded to MTME[4], and all results in this paper are calculated with this analysis tool. We encourage every metric developer to use MTME to calculate contrastive scores to enhance consistency and comparability going forward.

Our main findings are:

- XCOMET-Ensemble is the winner of the WMT23 Metrics Shared Task (Table 1).

- High correlations between automatic metrics and human judgments at the segment level do not necessarily guarantee high correlations at the system level (Figure 5).

[2] https://github.com/google/wmt-mqm-human-evaluation

[3] https://github.com/google-research/google-research/tree/master/marot

[4] https://github.com/google-research/mt-metrics-eval

- Reference quality matters: The low quality reference for zh→en significantly lowered the correlation of all metrics with human judgement (Section 8).
- We determined the magnitude of score differences required to produce a statistically significant difference in human judgment for each metric, revealing that even minor score differences of the top performing metrics can be statistical significant with high probability (Section 7).
- Results from the challenge sets independently agreed with our findings that the quality of reference matters. Developing reference-free metrics is worth further exploration, and metric researchers are advised to investigate into the influence of language-agnostic multilingual embeddings on MT evaluation. It is equally important for metric researchers to test the performance of metrics in diverse collection of linguistic phenomena and wider landscape of translation quality in order to minimize unexpected behaviours of metrics (Section 10).

The rest of the paper is organized as follows: Section 2 describes the test data and additional MT systems that we trained. Section 3 presents an overview of the conducted expert-based human evaluation. Section 4 describes the metrics evaluated this year (baselines and participants). Section 5 describes the conducted meta-evaluation. Section 6 reports our main results. Section 7 interprets and evaluates metrics' scores beyond correlations. Section 8 analyses the impact of bad reference translations on the various metrics. Section 9 summarizes our results for additional WMT23 Translation task language-pairs based on their Direct Assessment human evaluation. Section 10 presents a description of the submitted challenge sets along with their findings. Finally, Section 11 presents our most relevant conclusions.

2 Translation Systems

Similar to previous years' editions, the source, reference texts, and MT system outputs for the metrics task are mainly derived from the WMT23 General MT Shared Task. In addition to the MT system outputs from the WMT evaluation campaign, we included translations from two additional MT systems which we deemed interesting for evaluation.

2.1 WMT Test Sets

We use test sets prepared by the WMT23 General MT Shared Task (Kocmi et al., 2023). For our three main language pairs, the test sets contain 557 en→de, 1910 he→en, and 1976 zh→en segments. This year, the test sets cover up to five domains from the following list: news, conversational, user reviews, manuals, and social. Each language pair contains a comparable number of sentences from each domain, resulting in reasonably balanced test sets.

English→German contains four balanced domains: news, social, conversational, and user reviews. In contrast to other language pairs, segments are paragraphs rather than sentences.

Hebrew→English contains only news and user reviews domains. This language pair has two human references, but one of them (refA) is suspected of being a post-edited Online-B system output.

Chinese→English contains news, user reviews, and manuals. The first two domains contain around 750 sentences, while manuals contains around 500.

The reference translations provided for the test sets are produced by professional translators.

For more details regarding the news test sets, we refer the reader to the WMT23 General MT Shared Task findings paper (Kocmi et al., 2023).

2.2 Additional MT Output

Similar to last year, we made an effort to expand the pool of translations beyond the WMT submissions, which can potentially be quite similar to each other. We added translations which we expected to differ in two main ways from the submissions: 1) by using a massively multilingual model; and 2) by generating with MBR decoding;

For our multilingual model, we selected the 3.3B parameter NLLB200 model (NLLB Team et al., 2022) via the huggingface (Wolf et al., 2020) interface. We found NLLB200 to significantly outperform the M2M100 (Fan et al., 2021) that we used last year.

Minimum Bayes Risk (MBR) decoding has recently gained attention in MT as a decision rule, with the potential to overcome some of the biases of MAP decoding in NMT (Eikema and Aziz, 2020; Müller and Sennrich, 2021; Eikema and Aziz, 2021; Freitag et al., 2022; Fernandes et al., 2022). MBR decoding centrally relies on a reference-based utility metric: its goal is to identify a hypothesis with a high estimated utility (expectation

under model distribution) with the hope that a high estimated utility translates into a high actual utility (with respect to a human reference). In practice, this means generating several candidate translations and finding the translation that is most similar to the rest of the candidate translations.

We produced both the top-1 greedy translation and MBR outputs. For MBR, we sampled 100 translation candidates from the model via Epsilon sampling (Hewitt et al., 2022; Freitag et al., 2023). We used `epsilon_cutoff=0.02` and `eta_cutoff=0.0`. This year, we used sentence-level BLEU from sacreBLEU (Post, 2018) with the default 'a13' tokenizer and the 'floor' smoothing method as utility function only.

3 MQM Human Evaluation

Automatic metrics are usually evaluated by measuring correlations with human ratings. The quality of the underlying human ratings is critical, and recent findings (Freitag et al., 2021) have shown that crowdsourced human ratings are not reliable for high quality MT output. Furthermore, an evaluation schema based on MQM (Lommel et al., 2014), which requires explicit error annotation, is preferable to an evaluation schema that only asks raters for a single scalar value per translation. Similar to last year, we decided to conduct our own MQM-based human evaluation on a subset of submissions and language pairs that are most interesting for evaluating current metrics.

MQM is a general framework that provides a hierarchy of translation errors which can be tailored to specific applications. Google and Unbabel sponsored the human evaluation for this year's metrics task for a subset of language pairs using either professional translators (English→German, Chinese→English) or trusted and trained raters (Hebrew→English). The error annotation typology and guidelines used by Google's and Unbabel's annotators differ slightly and are described in the following two sections.

3.1 English→German and Chinese→English

Annotations for English→German and Chinese→English were sponsored and executed by Google, using 18 professional translators (10 for English→German, 8 for Chinese→English) having access to the full document context. Each segment gets annotated by a single rater. Instead of assigning a scalar value to each translation, annotators were instructed to label error spans within each segment in a document, paying particular attention to document context. Each error was highlighted in the text, and labelled with an error category and a severity. Segments that are too badly garbled to permit reliable identification of individual errors are assigned a special *Non-translation* error. Error severities are assigned independent of category, and consist of *Major*, *Minor*, and *Neutral* levels, corresponding respectively to actual translation or grammatical errors, smaller imperfections and purely subjective opinions about the translation. Since we are ultimately interested in scoring segments, we adopt the weighting scheme shown in Table 2. For more details, exact annotator instructions and a list of error categories, we refer the reader to Freitag et al. (2021) as the exact same setup was used for the previous two metrics tasks.

Severity	Category	Weight
Major	Non-translation	25
	all others	5
Minor	Fluency/Punctuation	0.1
	all others	1
Neutral	all	0

Table 2: Google's MQM error weighting.

3.2 Hebrew→English

The annotations for the Hebrew→English language pair were sourced from Unbabel, who engaged four professional native language annotators possessing extensive translation experience. Much like Google's approach, these annotators were provided with the full document context, comprising up to ten segments. Their task was to identify and classify errors by highlighting them, following Unbabel's MQM 3.0 typology[5].

The annotators were instructed to classify the errors based on severity, with Unbabel's classification encompassing not only "Minor" and "Major" error severities (analogous to Google's criteria) but also a "Critical" error severity. However, to ensure consistency in our evaluation process, we opted to align with the Google methodology outlined previously. Specifically, we treated all annotated "Critical" errors as "Major" errors, and we applied a weighting scheme for punctuation errors, as detailed in Table 2.

[5]see Unbabel Annotation Guidelines - Typology 3.0

3.3 Human Evaluation Results

Due to the fact that we ran our own human evaluation, we were only able to evaluate a subset of the test segments. In Table 3, you can see the number of segments and documents for each language pair and test set that we used for human evaluation. We followed a simple and consistent approach to downsample the data: we considered each document, while only keeping the first 10 sentences of each document. By doing this, we did not need to discard most of the documents and only needed to crop longer documents. The English→German test is on the paragraph-level, and we had to discard two documents as the first paragraph already contained more than 10 sentences. In all cases, the MQM score for a segment is the sum of the scores for the errors in that segment, and the MQM score for a test set is the average of the MQM scores of the segments that were annotated.

The results of the MQM human evaluation can be seen in Table 4. Most of the reference translations are ranked first, except for refA for Chinese→English. Not ranking the human evaluation on top of the MT output is usually a signal for a corrupt human evaluation. We double-checked the annotation for refA and can confirm that the reference translation indeed contained many errors.

4 Baselines and Submissions

We computed scores for several baseline metrics in order to compare submissions against previous well-studied metrics. We will start by describing those baselines, and then we will describe the submissions from participating teams. An overview of the evaluated metrics can be seen in Table 5.

4.1 Baselines

SacreBLEU baselines We use the following metrics from SacreBLEU (Post, 2018) as baselines:

- **BLEU (Papineni et al., 2002)** is based on the precision of n-grams between the MT output and its reference weighted by a brevity penalty. Using SacreBLEU we obtained sentenceBLEU values using the `sentence_bleu` Python function and for corpus-level BLEU we used `corpus_bleu` (both with default arguments[6]).

- **F200SPBLEU (NLLB Team et al., 2022)** are BLEU scores computed with subword tokenization done by the standardized FLORES-200 Sentencepiece models. We used the command line SacreBLEU to compute the sentence level F200SPBLEU[7] and we average the segment-level scores to obtain a corpus-level score.

- **CHRF (Popović, 2015)** uses character n-grams instead of word n-grams to compare the MT output with the reference. For CHRF we used the SacreBLEU `sentence_chrf` function (with default arguments[8]) for segment-level scores and we average those scores to obtain a corpus-level score.

BERTSCORE (Zhang et al., 2020) leverages contextual embeddings from pre-trained transformers to create soft-alignments between words in candidate and reference sentences using cosine similarity. Based on the alignment matrix, BERTSCORE returns a precision, recall and F1 score. We used F1 without TF-IDF weighting.

BLEURT (Sellam et al., 2020) is a learned metric fine-tuned on Direct Assessments (DA). Unlike COMET, BLEURT encodes the translation and the reference together and utilizes the `[CLS]` token as an embedding to represent the pair. We employed the BLEURT20 checkpoint (Pu et al., 2021), which was trained on top of RemBERT using DA data from previous shared tasks spanning from 2015 to 2019, along with additional synthetic data created from Wikipedia articles.

COMET (Rei et al., 2022a) is a learned metric fine-tuned using DA from previous WMT Translation shared tasks. This metric relies on sentence embeddings from the source, translation, and reference to produce a final score. We utilized the default model `wmt22-comet-da` provided in version 2.0.2 of the `Unbabel/COMET` framework. This model employs XLM-R large as its backbone model and is trained on data from the 2017 to 2019 WMT shared tasks, in combination with the MLQE-PE corpus (Fomicheva et al., 2022).

COMETKIWI (Rei et al., 2022b) is a reference-free learned metric that functions similarly to

Table 4: MQM human evaluations for generalMT2023. Lower average error counts represent higher MT quality. Systems above any solid line are significantly better than those below, based on all domains with $p < 0.05$.

BLEURT, but instead of encoding the translation along with its reference, it uses the source. We utilized the `wmt22-cometkiwi-da` model, which was a top-performing reference-free metric from last year's shared task. This reference-free metric is fine-tuned on the same data as `wmt22-comet-da` using the version 2.0.2 of the `Unbabel/COMET` framework.

DOCWMT22COMETDA (Vernikos et al., 2022) is the document-level version of `wmt22-comet-da`, which computes the BERT embeddings using multi-sentence context instead of just the single sentence.

DOCWMT22COMETKIWIDA is the document-level version of WMT22-COMETKIWI-DA (QE) which computes the BERT embeddings using multi-sentence context instead of just the single sentence.

MS-COMET-QE-22 (Kocmi et al., 2022b) is built on top of COMET by Microsoft Research using proprietary data. This metric is trained on a several times larger set of human judgements compared to COMET-baseline, covering 113 languages and 15 domains. Furthermore, the authors propose filtering of human judgement with potentially low quality to further improve the model. The metric calculated scores in quality estimation fashion with only source segment and MT hypothesis.

PRISMREF and PRISMSRC (Thompson and Post, 2020a,b) PRISMREF is the reference-based PRISM that uses a multilingual MT model in zero-shot paraphrase model to score the candidate translation conditioned on the reference sentence, and the reference sentence conditioned on the candidate translation, and averages the two scores. PRISM-SRC is the source-based (i.e. QE as a metric) PRISM that uses a multilingual MT model to force-decode and score the candidate translation conditioned on the source sentence.

RANDOM-SYSNAME is a random metric that takes the system name as the only parameter. For each translation system, the metric computes the mean value X as $sha256(sysname)[0]\%10$. It uses discrete scores. Segment-level scores follow

Table 5: Baseline metrics and primary submissions for the metrics task. We categorize metrics into 3 major classes: lexical, embedding similarity and fine-tuned metrics. Regarding fine-tuned metrics we have metrics that use human quality scores such as DA or MQM and metrics that use synthetic labels for fine-tuning (3rd column).

Gaussian distribution around mean value X (in a range 0-9) and standard deviation of 2.

YiSi-1 (Lo, 2019) is a MT evaluation metric that measures the semantic similarity between a machine translation and human references by aggregating the IDF-weighted lexical semantic similarities based on the contextual embeddings extracted from pre-trained language models (e.g. RoBERTa, CamemBERT, XLM-RoBERTa, etc.).

4.2 Metric Submissions

The rest of this section summarizes the participating metrics.

CALIBRI-COMET22 and CALIBRI-COMET22-QE apply a post-processing approach to ratings provided by COMET. It uses `Unbabel/wmt22-comet-da` as the backbone for the referenced CALIBRI-COMET22 and `Unbabel/wmt22-cometkiwi-da` as the backbone for the unreferenced CALIBRI-COMET22-QE metric. The information whether a translation is error-free from MQM ratings (e.g. under Google's MQM error weighting, error-free translations have a score of 0) can be recovered. It then aims to calibrate the scores of the backbone model with respect to this binary error-freeness label using isotonic regression. During test time, it takes the samples for a given tuple (lang-pair, test-set, domain, ref, system-id) and employs a heuristic strategy to select samples from previous years that match the test sample score distribution. It then fits an isotonic regression model to the selected samples and transforms the test scores accordingly. The main idea is that in this way, the averaged system-level score can be interpreted as the fraction of error-free translations.

COMETOID22 (Gowda et al., 2023) is a reference-free metric created using knowledge distillation from reference-based metrics. Using COMET-22 as a teacher metric, it scores the MT outputs submitted to the WMT News/General Machine Translation task since 2009. A student metric, called COMETOID22, is then trained to mimic the teacher scores without using reference translation. The student metric has the same architecture as COMET-QE, and is initialized with pretrained weights from InfoXLM, a multilingual language model. We submit three variants: COMETOID22-WMT{21,22,23}, where the suffix indicates the training data cut-off year.

COMETKIWI XL/XXL (Rei et al., 2023) shares the same architecture as the COMETKIWI baseline but replaces InfoXLM with XLM-R XL (3.5B) and XXL (10.7B). In terms of training data, these models are trained on the same dataset as COMETKIWI, along with newly released Direct Assessments (DA) for Indian languages, which were introduced as additional training data for this year's Quality Estimation (QE) shared task (Blain et al., 2023).

EBLEU (ElNokrashy and Kocmi, 2023) String-based metrics such as BLEU and CHRF depend on string similarity as proxy for meaning similarity between candidate and target sentences. EBLEU stands for 'Embedded BLEU' and is loosely inspired by it. In EBLEU, we match candidate and target tokens approximately using non-contextual word embeddings and a word-to-word similarity map in a form we have dubbed "relative meaning diffusion tensors".

EMBED_LLAMA (Dreano et al., 2023a) relies on pretrained Llama2 embeddings, without any fine-tuning, to transform sentences into a vector space that establishes connections between geometric and semantic proximities. This metrics draws inspiration from Word2vec, and utilizes cosine distance for the purpose of estimating similarity or dissimilarity between sentences.

GEMBA-MQM (Kocmi and Federmann, 2023) is a LLM-enabled metric for error quality span marking. It uses three-shot prompting with the GPT4 model. In contrast to EAPrompt (Lu et al., 2023), it does not require language specific examples and requires only a single prompt.

HWTSC-EE-METRIC and KG-BERTSCORE (Wu et al., 2023) EE stands for Entropy Enhanced MT Metrics and aims at achieving a more balanced system-level rating by assigning weights to segment-level scores produced by MT metrics. The weights are determined by the difficulty of a segment determined by the entropy between the hypothesis-reference pair. This year, the COMET metric is utilized as the backbone of our EE metrics. The model we use is WMT22-COMET-DA.

KG-BERTSCORE incorporates multilingual knowledge graph into BERTSCORE and generates the final evaluation score by linearly combining the results of KGSCORE and BERTSCORE, in which

we use COMET-QE to calculate BERTSCORE this year.

MATESE (Perrella et al., 2022) leverages transformer-based encoders to identify error spans in translations, and classify their severity between Minor and Major. Differently from last year's version, MATESE is now based on DeBERTa for evaluating translations towards English, and InfoXLM for German and Russian. Furthermore, it has been re-trained using also the MQM data released at WMT2022.

MBR-METRICX-QE (Naskar et al., 2023) MBR decoding with neural utility metrics like BLEURT is known to be effective in generating high quality machine translations. We use the underlying technique of MBR decoding and develop an MBR based reference-free quality estimation metric. Our method uses an evaluator machine translation system and a reference-based utility metric (specifically BLEURT and METRICX) to calculate a quality estimation score of a model. We report results related to comparing different MBR configurations and utility metrics.

MEE4 (Mukherjee and Shrivastava, 2023) is an unsupervised, reference-based metric (an improved version of MEE) focusing on computing contextual and syntactic equivalences, along with lexical, morphological, and semantic similarity. The goal is to comprehensively evaluate the fluency and adequacy of MT outputs while also considering the surrounding context. Fluency is determined by analysing syntactic correlations, while context is evaluated by comparing sentence similarities using sentence embeddings. The ultimate score is derived from a weighted amalgamation of three distinct similarity measures: a) Syntactic similarity, which is established using a modified BLEU score. b) Lexical, morphological, and semantic similarity, quantified through explicit unigram matching. c) Contextual similarity, gauged by sentence similarity scores obtained from the Language-Agnostic BERT model.

METRICX-23 and METRICX-23-QE (Juraska et al., 2023) are learned reference-based and reference-free (respectively) regression metrics based on the mT5 encoder-decoder language model. They further fine-tune the mT5-XXL checkpoint on direct assessment data from 2015-2020 and MQM data from 2020 to 2021 as well as synthetic data. There are two contrastive submissions, "b" and "c", for both the reference-based and QE metrics. The "b" variant additionally trains on MQM data from 2022 and the "c" variant uses the PaLM-2 language model (Anil et al., 2023) to initialize the metric instead of mT5.

MRE-SCORE (Viskov et al., 2023) is a trained metric that is based on the encoder part of mT0-large model. We use a concatenation of source, reference and hypothesis texts for input. Additionally, some of the variants of the model uses contextual embeddings from LaBSE.

SESCOREX (Xu et al., 2023b) and INSTRUCTSCORE (Xu et al., 2023c) SESCOREX is an improved version of SESCORE2 (Xu et al., 2023a). Building upon the established strengths of SESCORE2, we utilize its framework for synthetic data generation to pre-train our scoring model. To further elevate the performance of SESCOREX, we introduce two key modifications: fine-tuning human rating data and transitioning the scoring backbone model to the MT5-xl model. INSTRUCTSCORE is an open-source, explainable evaluation metric for text generation. Utilizing explicit human guidelines and GPT4's implicit knowledge, we fine-tune an Llama model to provide evaluation metrics along with diagnostic reports that align with human assessments. Unlike traditional neural metrics, INSTRUCTSCORE evaluates text generation by providing a quality score based on detailed error explanations.

SLIDE (Raunak et al., 2023) Building metrics explicitly for document-level MT quality estimation has been challenging owing to the lack of large-scale document-level human annotated datasets. In this submission, we present a metric named SLIDE (Sliding Document Evaluator), which operates at the span of multiple sentences or paragraphs by way of an overlapping sliding window. SLIDE feeds each chunk into a source-based COMET model, with scores over overlapping chunks accumulated to produce a system-level score. SLIDE is motivated by two ideas: (1) Since COMET's underlying encoder is trained on wider contexts, we might observe generalizable evaluation behaviour beyond typical sentences-level lengths, within certain length limits and (2) since a sentence's evaluation will differ at different positions within a document, it may be helpful to evaluate each sentence in multiple different contexts.

TOKENGRAM_F (Dreano et al., 2023b) is an F-score-based evaluation metric for machine translation that is heavily inspired by CHRF++. By replacing word-grams with token-grams obtained from contemporary tokenization algorithms, TOKENGRAM_F captures similarities between words sharing the same semantic roots and thus obtains more accurate ratings.

XCOMET-XL/XXL (Guerreiro et al., 2023) is a new COMET (Rei et al., 2020) model that is designed to identify error spans in sentences and generate a final quality score, making it a more interpretable learnt metric. This metric is optimized for both regression and sequence tagging, and it can be used with or without references. XCOMET-QE submission results from the same model but running inference without a reference. These models utilize XLM-R XL or XXL as their backbone models, with XCOMET-XL having 3.5B parameters and XCOMET-XXL having 10.7B parameters. The training process for this metric occurs in stages, starting with DAs and then is fine-tuning on MQM data. XCOMET-ENSEMBLE is an ensemble between 1 XL and 2 XXL checkpoints that result from the different training stages.

XLSIM (Mukherjee and Shrivastava, 2023) is a supervised reference-based metric that regresses on human scores provided by WMT (2017-2022). Using a cross-lingual language model XLM-RoBERTa, we train a supervised model using a Siamese network architecture with cosine similarity loss.

5 Meta Evaluation

Our main goal in evaluating metrics is to establish a ranking that reflects a metric's performance across a range of settings and applications. Combining results from different settings is challenging because correlations with human gold scores have different ranges and may be subject to differing degrees of noise. There are also many ways of measuring correlation, with different strengths and weaknesses, and it is often not clear which is best in a given setting.

Last year, our approach was to define a large number of "tasks" (201 in total) that varied along dimensions such as language pair, domain, granularity, correlation statistic, etc. For each task, we used pairwise significance tests to establish a dense clustered ranking of participating metrics (e.g., 1, 1, 1, 2, 3, 3, ...). Motivated by theoretical results pertaining to combining rankings from different knowledge sources (Colombo et al., 2022; Dwork et al., 2001), we established an overall ranking by simply averaging the per-task ranks.

This approach has several disadvantages. First, it is difficult to incorporate new metrics into the comparison, since this requires not only computing the score of a new metric on 201 tasks, but also comparing it to all existing metrics on each task using expensive resampling significance tests. Adding a new metric also has the undesirable effect of potentially causing other metrics to swap places in the overall rankings. While rank averaging has theoretical underpinnings, as noted above, these apply to settings in which the constituent tasks provide only ranking information themselves. In order to take advantage of richer information available from correlation statistics, we derived dense ranks from pairwise significance tests, but this relies on an ad hoc clustering algorithm, and it is not clear to what extent our average ranks are supported by the original theory. They also lack confidence information, making it difficult to quantify conclusions about the overall superiority of one metric over another.

This year we adopted a much simpler approach in order to address these difficulties. We use just 10 main tasks, and compute an overall score by taking a weighted average of results from each task. We perform significance tests on each pair of metrics for each task as before, but also do so for each pair of metrics on the overall average score, allowing us to establish a clearer global ranking. The average score for a new metric can be computed relatively quickly, and it does not affect the scores of other metrics. Significance tests still require the expensive step of comparing to all other metrics, but they are no longer necessary for computing a metric's raw overall score.

We acknowledge that this approach is not perfect. One problem is that we need to combine correlations and accuracies that may have different dynamic ranges. For example, the mean Pearson correlation across all metrics for en→de at the system level is 0.88 with standard deviation 0.24, while at the segment level it is 0.39 with a standard deviation of 0.17. Averaging system-level and segment-level correlations will therefore effectively upweight the system-level contribution. We experimented with different weightings to compensate for this, but found that they did not make a large differ-

language	ref used	scored ref
en→de	A	–
he→en	B	A
zh→en	A	–

Table 6: Use of reference translations.

ence, and decided to use equal weights for simplicity. Another problem is that we do not account for dependencies among tasks. Although all tasks are at least somewhat complementary, many–such as system-level and segment-level correlations—are based on the same underlying data, and thus violate the assumptions of our hypothesis tests. We leave more sophisticated inference approaches such as proposed by Dror et al. (2017) or Hagmann and Riezler (2023) for future work.

5.1 Task Attributes

Tasks are identified by unique value assignments for each of the following attributes: language, level, and correlation statistic. Unlike last year, we no longer have tasks specific to different domains, as domains differ across languages this year. We also drop the "include-human" vs "no-human" distinction, and always score reference translations that are not used by the metrics. As shown in Table 6, Hebrew→English is the only language pair for which such a reference is available. Finally, last year we used three different averaging methods for each correlation statistic at the segment level; this year we choose only one method for each segment-level correlation.

Attributes are as follows:

Language

Language pairs include those for which we have MQM ratings—English→German, Hebrew→English, and Chinese→English—plus *all*, which indicates all pairs pooled together.

Level

We computed correlations at the *system* level and the *segment* level. For English→German, segments are paragraphs; for the two other language pairs, they are sentences. System-level scores for human ratings and for all metrics that did not supply an explicit system-level score are averages over segment-level scores.

Correlation/accuracy

We computed three correlation/accuracy statistics selected to provide complementary information:

task	lang	level	correlation	wt
1	all	system	accuracy	3
2	en→de	system	Pearson	1
3	en→de	segment	Pearson	1
4	en→de	segment	acc^*_{eq}	1
5	he→en	system	Pearson	1
6	he→en	segment	Pearson	1
7	he→en	segment	acc^*_{eq}	1
8	zh→en	system	Pearson	1
9	zh→en	segment	Pearson	1
10	zh→en	segment	acc^*_{eq}	1

Table 7: Tasks and weighting.

- System-level pairwise ranking *accuracy* (as proposed by Kocmi et al., 2021). This is computed over data pooled across all three language pairs.
- Segment-level pairwise ranking accuracy with tie calibration (as proposed by Deutsch et al., 2023). We use the acc^*_{eq} variant to compare vectors of metric and gold scores for each segment, then average the results over segments.
- System- and segment-level Pearson correlation. At the segment level, we flatten matrices of system × segment scores into vectors before comparing them.

5.2 Tasks and Weighting

Table 7 shows the complete list of tasks and their weights. All tasks receive a weight of 1, except for system-level accuracy, which has a weight of 3 because it combines data from all three language pairs.

To compute a global score for each metric across all tasks, we first map Pearson correlations from their natural range of $[-1, 1]$ into the $[0, 1]$ range of the accuracy scores, then take a weighted average of the results.

5.3 Rank Assignment

For each task, we assign ranks to metrics based on their significance clusters. To do so, we compare all pairs of metrics and determine whether the difference in their correlation scores is significant, according to the PERM-BOTH hypothesis test of Deutsch et al. (2021). We use 1000 re-sampling runs and set $p = 0.05$. As advocated by Wei et al.

(2022), we divide the sample into blocks of 100, compute significance after each block (cumulative over all blocks sampled so far), and stop early if the p-value is < 0.02 or > 0.50.

The acc^*_{eq} statistic creates a problem for significance testing because it optimizes a latent tie threshold for each metric on each test set (just one threshold for all item-wise score vectors). Since the permutation test for comparing two metrics creates two new vectors by randomly swapping elements of the original vectors on each draw, this necessitates the very expensive step of finding two new tie thresholds for each draw. To reduce the expense, we used the following approximate procedure. First find an optimal threshold for each input metric on the current test set, then create all pairs of item-wise scores and assign a correct/incorrect status to each pair by examining whether the metric's ranking matches the human ranking. Then perform the permutation test on these pairwise status vectors rather than the original score vectors. This approximation has more degrees of freedom than the original test, and can sample pairs that would never result from swapping the original score vectors, but our experiments showed that it is a reasonable proxy for the correct procedure.

To compute overall p-values based on weighted average scores of two metrics across all tasks, we cache the results of the draws for the per-task significance tests. In all cases, these are vectors of K pairs of correlation or accuracy statistics. Where $K < 1000$ due to early stopping, we duplicate elements to get 1000 examples. Then for i in 1..1000 we compare the weighted average of the pairs from the ith draw across all tasks, and record the results to produce an overall p-value.

Clustering

Given significance results (p-values) for all pairs of metrics, we assign ranks as follows. Starting with the highest-scoring metric, we move down the list of metrics in descending order by score, and assign rank 1 to all metrics until we encounter the first metric that is significantly different from any that have been visited so far. That metric is assigned rank 2, and the process is repeated. This continues until all metrics have been assigned a rank. Note that this is a greedy algorithm, and hence it can place two metrics that are statistically indistinguishable in different clusters.

6 Main Results

As we have seen in Section 5, the main results are the overall scores by taking a weighted average of the results from the ten main tasks, including system-level and segment-level tasks in different translation directions. Similar to last year, since the main use case of automatic metrics is to rank systems, system-level accuracy has a 1/4 weight on the final score with the remaining 3/4 distributed over 9 different settings.

Table 1 shows the official scores and rankings of all baselines and primary submissions. Table 8 and 9 show the scores and rankings of each individual task at system level and segment level, respectively. Similar to last year's results, neural metrics perform significantly better than lexical metrics. Of the 32 evaluated metrics, BLEU, F200SPBLEU and CHRF are ranked 28th, 24th and 29th respectively. On the other hand, fine-tuned neural baseline metrics, like COMET and BLEURT-20, remain ranked higher than several of the new primary submissions. They are surpassed only by submissions relying on significantly larger models.

It is worth noting that the best-performing baseline, COMETKIWI, along with four of the seven top-performing primary submissions, are reference-free. As we will elaborate on in a later section (Section 8), there are quality issues with human reference translations. This highlights the challenge of ensuring robustness to poor-quality references for reference-based metrics. In cases where a high-quality human reference is not available, reference-free metrics can serve as more robust alternatives.

Overall, XCOMET-Ensemble is the best performing metric in terms of average scores over the 10 meta-evaluation settings, with a statistically significant advantage over all other metrics. It consistently correlates best with human MQM scores at segment level for all translation directions, and it is ranked at worst in the 2nd significance cluster for all system-level meta-evaluation tasks.

Figure 1 shows the correlation scores split by translation direction. There are two key observations: 1) a majority of the metrics have higher correlations for en→de among the three translation directions, except for MRE-SCORE-LABSE-REGULAR and EBLEU, that perform substantially better for he→en, and YISI-1 and BERTSCORE, that perform equally in en→de and he→en; 2) reference-based metrics struggle for zh→en due to the reference quality, except for XCOMET-

Table 8: Results on system-level tasks for main language pairs. Rows are sorted by the overall average correlation across all 10 tasks (leftmost column). Starred metrics are reference-free, and underlined metrics are baselines.

ENSEMBLE and SESCOREX. The reason for the significant drop in correlation for he→en is unclear. This drop is observed across almost all metrics, whether they are trained or untrained, reference-free or reference-based, and they exhibit varying degrees of degradation.

We continue to be interested in metrics' ability to generalise across domains. In Figure 2, 3 and 4 we present the performance of each metric across different domains in each translation direction. Most metrics perform well in evaluating translation in the user reviews domain across translation direction, despite lacking annotated data in that domain. Further investigation is required to understand whether this is because the translation quality of MT output is more diverse in the user reviews domain, making it easier for metrics to accurately discriminate.

Figure 5 shows the average correlations of metrics when grouped separately by system-level and segment-level tasks. Many metrics fall into the same significance cluster when evaluated on the system-level, as we only have a limited number of MT systems. Although most of the metrics compute the system-level score by averaging their segment-level scores, we observe that high correlations between automatic metrics and human judgments at the segment level do not necessarily guarantee high correlations at the system level. For example, PRISMSRC is in the middle of the pack and has moderate Pearson's correlation at segment level for en→de. However, it is negatively correlating with human judgements when evaluating the same language pair at system level.

7 Understanding metrics' scores beyond correlation

In the past few years, we demonstrated that new metrics correlate better with human judgments than BLEU does. Some new baseline metrics even consistently outperform BLEU for consecutive years across translation directions and domains. How-

ever, the research community is still reluctant to adopt newer and better automatic MT evaluation metrics in practice. One of the reasons is that MT researchers have established some "common beliefs" about the relationship between BLEU and actual translation quality, and similar intuitions about new metrics have yet to crystallize. Thus, this year, we conduct two additional analyses beyond correlation with human to understand the meaning of the score differences that metrics present with respect to the statistical significance of MT system rankings according to human annotations and metric scores. Our results should *NOT* be used as arguments to forego significance tests or appropriate human evaluation. These analyses only support an intuitive sense of metric score meanings to encourage broader adoption of new automatic MT evaluation metrics.

7.1 Correspondence to MQM scores significance

First, we follow Lo et al. (2023a) to study the relationship between statistically significant differences in human scores and the magnitude of metric differences. Specifically, we run a one-sided paired t-test with an equal variance assumption for each system pair on segment-level MQM scores. After that, we fit the corresponding metric score differences and the p-values of the t-test on the MQM scores to an isotonic regression (Robertson et al., 1988), that predicts whether the human MQM score difference will be significant given the metric's score difference. Isotonic regression produces a non-decreasing function where the classifier output can be interpreted as a confidence level.[9] We set $p_{mqm} < 0.05$ as the significance level of MQM

[9] https://scikit-learn.org/stable/modules/isotonic.html

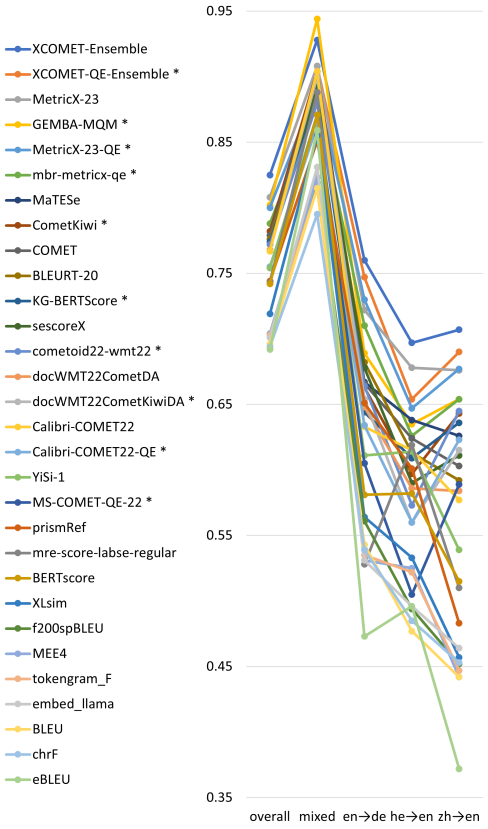

Figure 1: Average metrics' meta-evaluation scores in tasks grouped by translation direction. The "mixed" group is the accuracy score of the metrics in task 1.

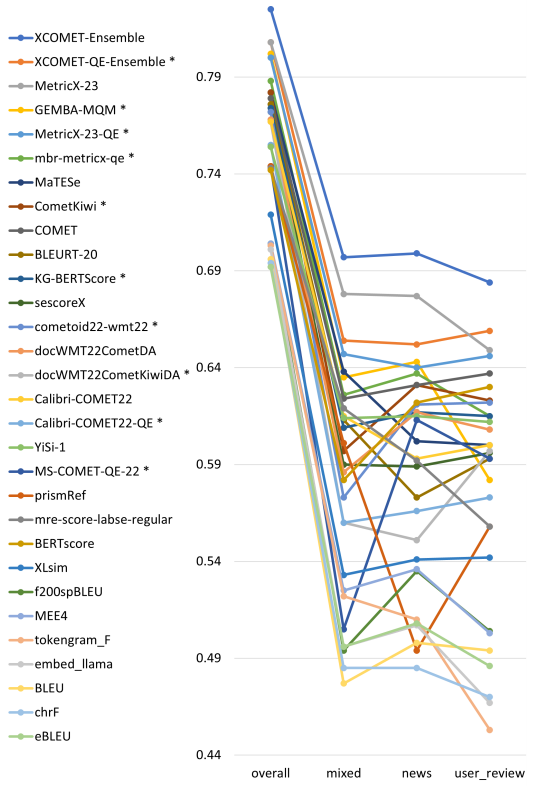

Figure 3: Average metrics' correlation with human in tasks grouped by domain in he→en. The "mixed" group is the average correlation in all he→en tasks.

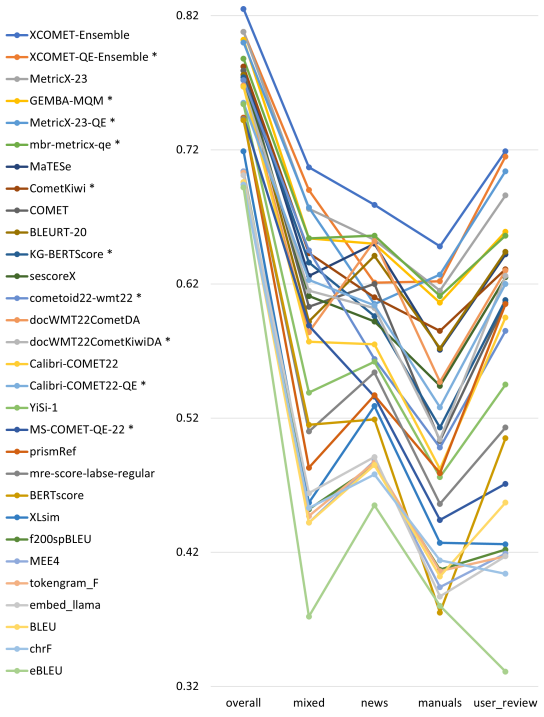

Figure 4: Average metrics' correlation with human in tasks grouped by domain in zh→en. The "mixed" group is the average correlation in all zh→en tasks.

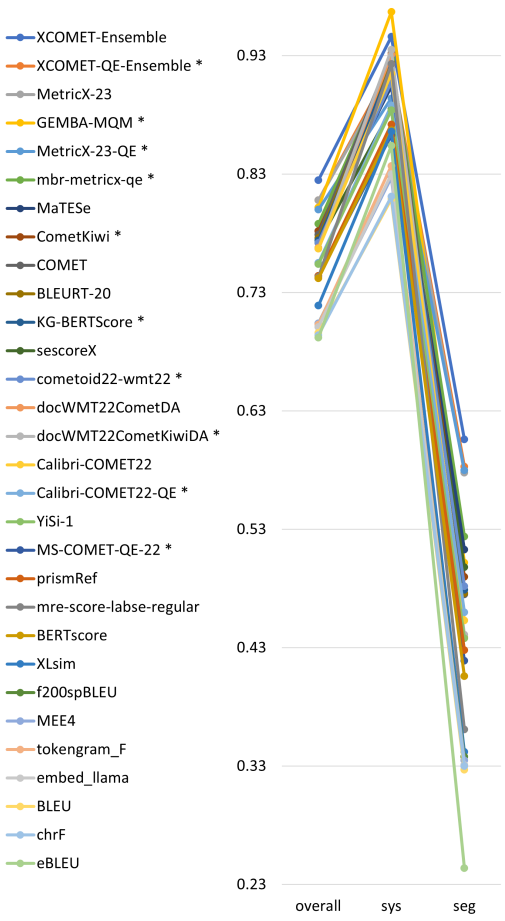

Figure 5: Average metrics' correlation with human in tasks grouped by granularity level.

scores. Thus, the output of the isotonic regression function can be viewed as $Pr(p_{mqm} < 0.05|\Delta M)$ where p_{mqm} is the p-value of the t-test on the MQM scores for each system pair and ΔM is the metric score difference.

Figure 6 shows the (log) p-value of one-sided paired t-test on the MQM scores against the corresponding BLEU and COMET score difference for each system pair in en→de. Figures 9-14 in appendix D, show the same analyses for all metrics and translation directions. For each metric, we can choose a particular level of confidence (i.e., a point along the y-axis on the right) to give metric score difference cut-offs (i.e., a point along the x-axis) that this metric difference reflects significant MQM score differences. Drawing a horizontal line from the confidence level, say 80%, to the red line enables us to find the minimum metric difference cut-off required at the corresponding x-value down from the red line, i.e. 11 for BLEU in Figure 6. Using this lookup method, Table 10 shows the cut-offs of ΔM when $Pr(p_{mqm} < 0.05|\Delta M) = 0.8$ for each metric and translation directions.

We run the leave-one-system-out cross validation and Table 10 shows that the range of precision in the cross validation are consistently high across metrics, with the exception of BLEU, CHRF, PRISMSRC, RANDOM-SYSNAME and SLIDE. This means the metric cut-offs we find using the regression model are reliable.

Contrary to the common belief that 2 BLEU improvement represents "significant" or "notable by human" improvement in the actual translation quality, our analyses show that 2.2 BLEU is the minimum required improvement for a high confidence (80%) that MQM annotators to mark significant differences in the translation output for one translation direction (zh→en) and that threshold would be as high as 11 BLEU for en→de. Table 10 serves as a reference between BLEU differences and differences in some of the modern metrics, and assists metric users in understanding scores provided by modern metrics. For example, when evaluating he→en translation quality, we see that a BLEU difference of 3.5 corresponds to 80% confidence that the metric's ranking of the two MT systems will match with the decision made by human annotators with a significant difference. Meanwhile, a COMET score difference of 0.014 would have the same 80% chance of human judged significant difference.

7.2 Correspondence to metric scores significance

Inspired by Marie (2022), we run a study similar to that in the previous subsection but on the relations between statistically significant differences in metric scores and the magnitude of metric differences. Instead of one-sided t-test on MQM, the p-values are now obtained by running statistical significance tests with bootstrap resampling on the metric scores for each system pair. Similarly, we fit the corresponding metric score differences and the p-values of the significance test to an isotonic regression for predicting whether the translation quality improvement as indicated by the metric will be significant given the metric score difference. We set $p_M < 0.05$ and thus, the output of the isotonic regression function is now $Pr(p_M < 0.05|\Delta M)$, where p_M is the p-value of the significance test on the metric scores for each system pair and ΔM is the metric score difference.

Figure 7 shows the (log) p-value of the signifi-

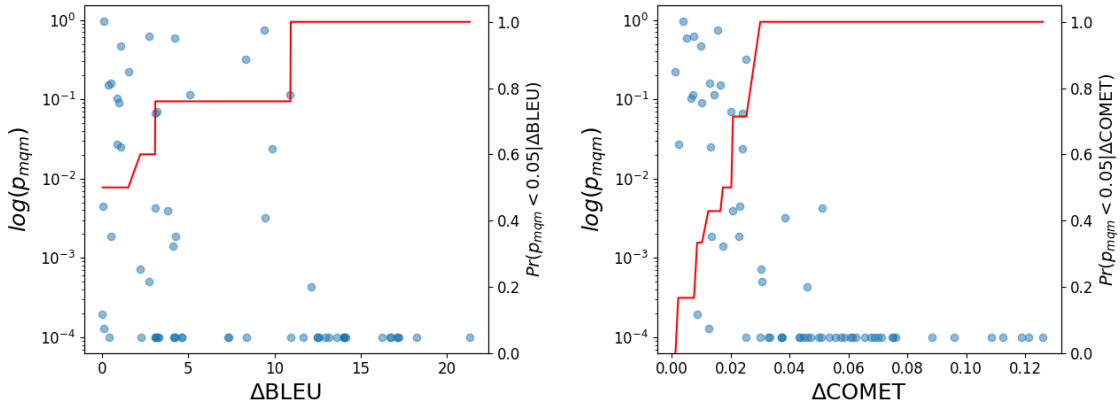

Figure 6: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the metric (left: BLEU, right: COMET) score difference for each system pair in en→de. The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

Table 11: Minimum ΔM when $Pr(p_M < 0.05|\Delta M) = 0.8$ for each metric in different translation directions round to 2 significant figures, and the range of precision for the isotonic regression model in leave-one-system-out cross validation.

tion, and Table 11 shows that the range of precision in the cross validation are consistently high across metrics. This means the metric cut-offs we find using the regression model are reliable.

Our results, agreeing with Marie (2022), show that to claim significant differences ($p_M < 0.05$) in BLEU with high confidence (80%), the BLEU differences should be greater than 1.1 BLEU for en→de. Table 11 serves as a reference of metric differences with respect to statistical significance with high confidence. For example, when evaluating en→de translation quality, we see that a BLEU

difference of 1.1 corresponds to 80% confidence the difference is statistical significant. Meanwhile, a COMET score difference of 0.0038 would have the same 80% chance of statistical significance.

We have to emphasize again that our result should *NOT* be interpreted as evidence to forego significance tests or appropriate human evaluation. Instead, we are only providing assistance to build an intuition on the meaning of the scores provided by the new metrics to encourage the transition away from BLEU.

8 Synthetic Reference Translations

Reference-based metrics compare machine translations of source segments to human translations of those same source segments to determine how good they are. The quality of the underlying human translation is crucial and can impact the quality of the predicted scores more than the choice of metric (Freitag et al., 2020). Motivated by the low human ratings of refA for Chinese→English (Table 4) and the relatively high rankings of reference-free metrics (in comparison to other language pairs) for this language-pair, we investigate a method for generating a synthetic reference translation based on the MT output and the corresponding MQM ratings.

8.1 Synthetic Reference Generation

The main idea is straightforward: Given the set of translations of WMT23 General MT Shared Task (generalMT2023) from the WMT campaign and their corresponding MQM ratings, we generate a new synthetic reference translation by choosing for each segment the translation that received the lowest MQM error score as the selected reference. The original human reference translation (i.e. refA) is considered as one of the possible translations in this process, and MQM score ties are broken randomly. Table 12 shows the resulting MQM score of the synthetic reference translations. We were able to reduce the MQM score to below 1 for both tested language pairs (en→de and zh→en), which corresponds to an average of less than one minor error per segment. While this may seem like a significant improvement, we must caution the reader that this is in essence "cherry-picking" based on the MQM ratings and may therefore introduce many hidden issues.

It is also interesting to understand how many segments come from each of the individual MT systems in this selection process. Table 13 shows the number of segments contributed by each system to the generated synthetic reference translations. Unsurprisingly, the top performing MT systems are also the main contributors to the selected synthetic reference translation. For en→de, refA (the original human-generated reference translation) provided the majority of the selected translations, while for zh→en GPT4-5shot is the main contributor, reflecting that the human-generated reference refA for zh→en was indeed error-prone. However, it is interesting to note that despite the overall low quality of this human-generated reference, our method still selected 209 segments from this translation as the lowest-error translation. This would appear to indicate that these human-generated reference translations are not uniformly bad, and only a subset of the translations were unreliable and contained major errors. A possible explanation could be that multiple translators worked on the reference, however, we confirmed with the sponsor translating zh→en that all segments were translated with the same translator.

8.2 Impact on Metrics

Figure 8 compares the segment-level and system-level Pearson correlations of all submitted metrics

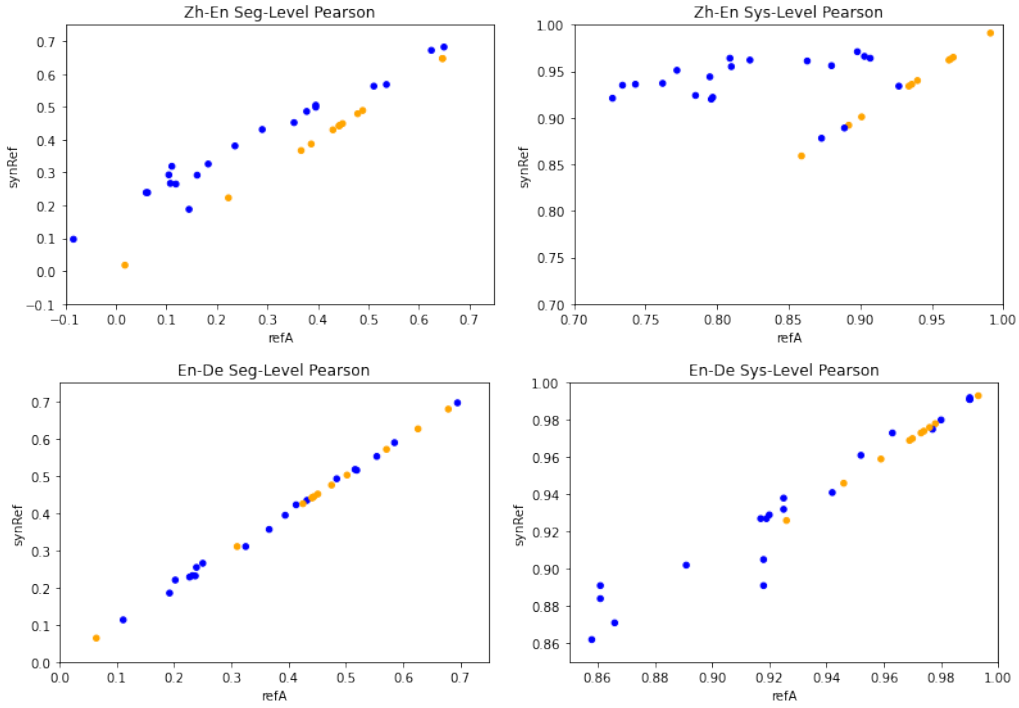

Figure 8: Pearson Correlation when using either the synthetic ref or the original human translation as reference translation. QE metrics are coloured in yellow; ref-based metrics are coloured in blue.

when using either the original or the synthetic reference translation. Reference-based metrics are coloured in blue, while QE metrics are coloured in orange. Obviously, as QE metrics do not use reference translations, their correlations are exactly the same. For Chinese→English, replacing the human-generated reference translation by the synthetic reference translation has a dramatic impact. All reference-based metrics increased their correlation levels with human judgements at both the segment-level and the system-level. This clearly indicates how critically important a high quality reference translation is for reference-based metrics, but moreover, it also highlights the advantages of QE metrics in cases where human-generated references have major quality issues. For the English→German language pair, the human-generated reference translation is of higher quality than any submitted MT system. Consequently, the synthetic reference translation had almost no impact on the segment-level correlations and only a mixed impact on the system-level correlations.

The main takeaways from this study are (i) poor human-generated reference translations can dramatically hurt the performance and reliability of your metric, (ii) strong QE metrics can be better alternatives in such scenarios, and (iii) generating a synthetic reference translation from all system outputs can be used to mitigate bad reference translations, although it assumes obtaining MQM annotations and suffers from cherry-picking bias.[10]

An open unanswered question remains: is it always necessary for a reference translation to be of higher quality than the translation generated by the MT system, in order to have a reliable reference-based metric? This would imply that generating a synthetic reference translation with any errors is problematic, since for any reference-based automatic metric, these synthetic references would become useless for evaluating any MT system that generates translations that surpasses the reference in quality.

9 DA+SQM Human Evaluation

In addition to our MQM annotations and as a contrastive evaluation to cover more language pairs, we look into the performance of metrics when compared to the human evaluation campaign conducted by the WMT23 General MT Shared Task (Kocmi et al., 2023), who ran human evaluation for all 14 translation directions and all WMT23 submissions.

In contrast to previous years, they no longer use

[10]Among other issues, any practical strategy for creating synthetic references would need to have a way of avoiding bias toward systems that are similar to the ones used for reference creation.

MTurk neither reference-based evaluation for into-English language pairs. They no longer use z-score normalization because the user interface decision to not track users (i.e., only maintaining HIT information) means that the z-scores are likely to be influenced by the distribution of system quality in the HITs rather than only annotator variation.

They employ the Direct Assessment Scalar Quality Metrics (DA+SQM) technique as presented in Kocmi et al. (2022a).

DA+SQM asks bilingual raters to annotate system translations against original sources on a 0–100 labelled scale. The scale is marked with seven points representing expected quality.

At the time of writing, the WMT23 General MT Shared Task had collected data only for 8 translation directions: Chinese↔English (zh↔en), German↔English (de↔en), Japanese↔English (ja↔en), English→Czech (en→cz), and Czech→Ukrainian (cz→uk).

We present system-level accuracy results for both MQM and DA+SQM in Table 14. There are many factors that could affect the ranking. Apart from using a different human annotation protocol, MQM compares 3 translation directions whereas the DA+SQM compares 8 translation directions, containing also the non-English low-resource pair of cz→uk. There is an overlap of only two translation directions between the two: en→de and zh→en. The main difference in ranking is for metrics XCOMET-Ensemble and MetricX-23 ranking significantly lower than for MQM. Investigating system-level Pearson's correlation for individual languages in Tables 19 to 27 shows that both metrics are performing considerably lower across all languages (except en→cz and cz→uk) and we do not see any pattern behind the drop in performance.

Table 14: Comparison between system-level pairwise accuracy using MQM and DA+SQM gold scores. MQM results pool data from our 3 main language pairs; DA+SQM results pool data from the 8 language pairs for which DA+SQM scores are available. Rows are sorted by MQM accuracy, with the pure rank order indicated in brackets. Starred metrics are reference-free and underlined metrics are baselines.

10 Challenge Sets Sub-task

For the second year, we included a sub-task on challenge sets. This sub-task is inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017) which aimed at testing the generalizability of NLP systems beyond the distributions of their training data. Whereas the standard evaluation of the shared task runs on test sets containing generic text from real-world content, the challenge set evaluation is based on test sets designed with the aim of revealing the abilities or the weaknesses of the metrics on evaluating particular translation phenomena. In order to shed light on different perspectives on evaluation, the sub-task takes place in a decentralized manner, where, contrary to the main metric task, the test sets are not provided by the organizers but by different research teams, who are also responsible for analysing and presenting the results.

This subtask is made of three consecutive phases; 1) the *Breaking Round*, 2) the *Scoring Round* and 3) the *Analysis Round*:

1. In the *Breaking Round*, every challenge set participant (*Breaker*) submits their challenge set S composed of contrastive examples for different phenomena, where every example $(s, \hat{t}, t, r) \in S$ contains one source sentence s, one incorrect translation $\hat{t}$, one correct translation t and one reference r.

2. In the *Scoring Round*, the organizers decompose the S into a blind test set S', where each example includes either an incorrect translation $(s, \hat{t}, r)$ or a correct translation (s, t, r) along with the source and the reference. The separated contrastive examples are shuffled, and the golden truth of which samples are correct or incorrect is kept in a separate set. The

MSLC23	4	low quality MT	9345	Lo et al. (2023b)	nrc-cnrc/MSLC23

Table 15: Overview of the participation at the metrics challenge sets sub-task

metrics participants from the main task (the *Builders*) are asked to score with their metrics the translations in the given blind test set without knowing which ones are correct or incorrect. Also, in this phase, the organizers score all data with the baseline metrics.

3. Finally, after having gathered all metric scores, the organizers return the respective scored translations to the *Breakers* for the *Analysis round*, where they look at which metrics are able to correctly rank the correct translations higher than the incorrect ones for the phenomena being tested.

There were 3 submissions this year, covering a wide range of phenomena and 146 different translation directions. An overview of the submitted challenge sets can be seen in Table 15. A short description of every submission follows:

ACES Challenge Set The Translation Accuracy ChallengE Set (ACES, Amrhein et al., 2023) consists of 36K examples representing challenges from 68 phenomena and covering 146 translation directions. The phenomena range from simple perturbations at the word/character level to more complex errors based on discourse and real-world knowledge. We benchmark the performance of segment-level metrics submitted to WMT 2023 using ACES. For each metric, the authors provide a detailed profile of performance across the ten top-level accuracy error categories in ACES as well as an overall *ACES-Score* for quick comparison. They also measure the incremental performance of the metrics submitted to both WMT 2023 and 2022.

They find that:

- there is no clear *winner* among the metrics submitted to WMT 2023,
- neural metrics also tend to focus more on lexical overlap than semantic content,
- reference-free metrics using language-agnostic multilingual embeddings struggle with detecting untranslated or sentences translated in the wrong direction, and
- performance change between the 2023 and 2022 versions of the metrics is highly variable.

The authors' recommendations are similar to those from WMT 2022. Metric developers should focus on: building ensembles of metrics from different design families, developing metrics that pay more attention to the source and rely less on surface-level overlap, and carefully determining the influence of multilingual embeddings on MT evaluation.

DFKI Challenge Set The submission by DFKI (Avramidis et al., 2023) employs a linguistically motivated challenge set that includes about 21,000 items extracted from 155 machine translation systems for three language directions (de→en, en→de, en→ru), covering more than 100 linguistically-motivated phenomena organized in 14 categories. The metrics that have the best performance with regard to our linguistically motivated analysis are the COMETOID22-WMT23 for de→en and METRICX-23-C for en→de and en→ru. Some of the most difficult phenomena for the metrics to score are *passive voice* for de→en, *named entities, terminology* and *measurement units* for en→de and *focus particles, adverbial clause* and *stripping* for en→ru.

MSLC23 Challenge Set The Metric Score Landscape Challenge (MSLC23; Lo et al., 2023b) data set aims to gain insight into metric scores on a broader/wider landscape of MT quality. Recent development of MT evaluation metrics has focused on improving their correlation with human judgment on translations of high-quality systems (e.g., participants in the WMT News/General MT Shared Tasks). This means that metric performance may be untested on low- to medium-quality MT output. MSLC23 provides a collection of low- to medium-quality MT output on the news portion of the WMT23 General MT Shared Task test set. Together with the high quality systems submitted to the General MT Shared Task, this enables better interpretation of metric scores across a range of different levels of translation quality. With this

wider range of MT quality, the authors also visualize and analyse metric characteristics beyond just correlation.

The authors find that the smaller variations in segment-level scores given by some metrics at the low end of quality could indicate that these metrics struggle to discriminate between low-quality MT systems. This is further shown by the observation that some metrics rank the low-quality systems in reverse order at system level. A "universal score" phenomenon for some metrics, where a small subset of non-minimum/maximum distinct scores are assigned to a variety of translation output, has been discovered. There is also an observation of diverse behaviours from different metrics on empty string translation. These results highlight the need for metric researchers to check their metrics' performance on a wider landscape of translation quality, or to indicate to potential users that they should be cautious about using their metric on a wide range of quality.

11 Conclusion

This paper summarizes the results of the WMT23 shared task on automated machine translation evaluation, the Metrics Shared Task. We presented an extensive analysis on how well metrics perform on our three main translation directions: English→German, Hebrew→English and Chinese→English. The results, based on 10 different tasks, confirm the superiority of neural-based learned metrics over overlap-based metrics like BLEU, SPBLEU or CHRF. These results are confirmed with DA+SQM human judgement. We also found that reference-free metrics were strong contenders this year, partly because they do not rely on the quality of reference translations, an increasingly important issue as MT systems under evaluation become better. In addition, we continued the challenge set subtask, where participants had to create contrastive test suites for evaluating metrics' ability to capture and penalise specific types of translation errors.

12 Ethical Considerations

MQM annotations and additional reference translations in this paper are done by professional translators. They are all paid at professional rates.

Organizers from the National Research Council Canada and Unbabel have submitted to this task the frozen stable versions of their metrics (YiSi and COMET) dated before this year's shared task and publicly available. Newer versions of COMET were developed without using any of the test set, test suite or challenge sets. We ensured that the metrics co-authored by Tom Kocmi were implemented without using any privileged test sets or insider information.

13 Acknowledgments

Results for this shared task would not be possible without tight collaboration with the organizers of the WMT23 General MT Shared Task. We are grateful to Google and Unbabel for sponsoring and overseeing the human evaluation.

Ricardo Rei is supported by the Portuguese Recovery and Resilience Plan (PRR) through project C645008882-00000055, Center for Responsible AI.

Eleftherios Avramidis is supported by the German Research Foundation (DFG) through the project TextQ (grant num. MO 1038/31-1, 436813723), and by the German Federal Ministry of Education and Research (BMBF) through the project SocialWear (grant num. 01IW2000).

A Correlations with MQM for all metrics

Tables 16 and 17 contain system- and segment-level results for all metrics (including contrastive submissions) on the 10 standard tasks described in Table 7. No pairwise significance tests were carried out for these results, so the per-task ranks only indicate each metric's order on that task, rather than its significance cluster as in Tables 8 and 9.

Table 18: Results of pairwise metric significance tests for primary submissions using permutation resampling. Each value gives the 100 $\times$ estimated probability of the null hypothesis that the average correlation of the metric in the current row is $\leq$ the average correlation of the metric in the current column. Starred metrics are reference-free, and underlined metrics are baselines.

B Significance comparisons for main results

Table 18 contains the results of pairwise comparisons for the results in Table 1.

C Correlations with WMT DA-SQM for all metrics

Tables 19 to 27 give correlations with WMT direct assessment (DA-SQM) scores on all 8 translation directions for which those scores are available. In all cases, reference A was used, and no additional metrics were available to be scored by the metrics. We evaluate metrics on a task setup similar to that of Table 7: one system-level pairwise accuracy task involving all languages (with a weight of 8), and system-level Pearson, segment-level Pearson, and segment-level acc^*_{eq} tasks for each translation direction (24 tasks in total, each with a weight of 1). Each table shows overall average correlation, along with the results for the tasks for one translation direction. Metrics that did not participate in all tasks do not have an average correlation, and are displayed at the end of each table.

We wish to emphasize that the DA+SQM is considerably noisier than MQM. This increased variability may influence the outcomes observed in the following spotlight evaluation. Consequently, readers should exercise considerable caution when drawing conclusions from these results.

Table 27: Correlations with WMT DA-SQM scores for all metrics on zh→en data. Rows are sorted by the overall average correlation across all 25 tasks (leftmost column). Starred metrics are reference-free, underlined metrics are baselines, and italicized metrics are contrastive submissions.

D Additional figures

Figures 9-14 show the (log) p-value of one-sided paired t-test on the MQM scores against the score difference of each metric for each system pair in each translation direction. Figures 15-20 show the (log) p-value of significance test with bootstrap resampling on the metric scores against the score difference of that metric for each system pair in each translation direction.

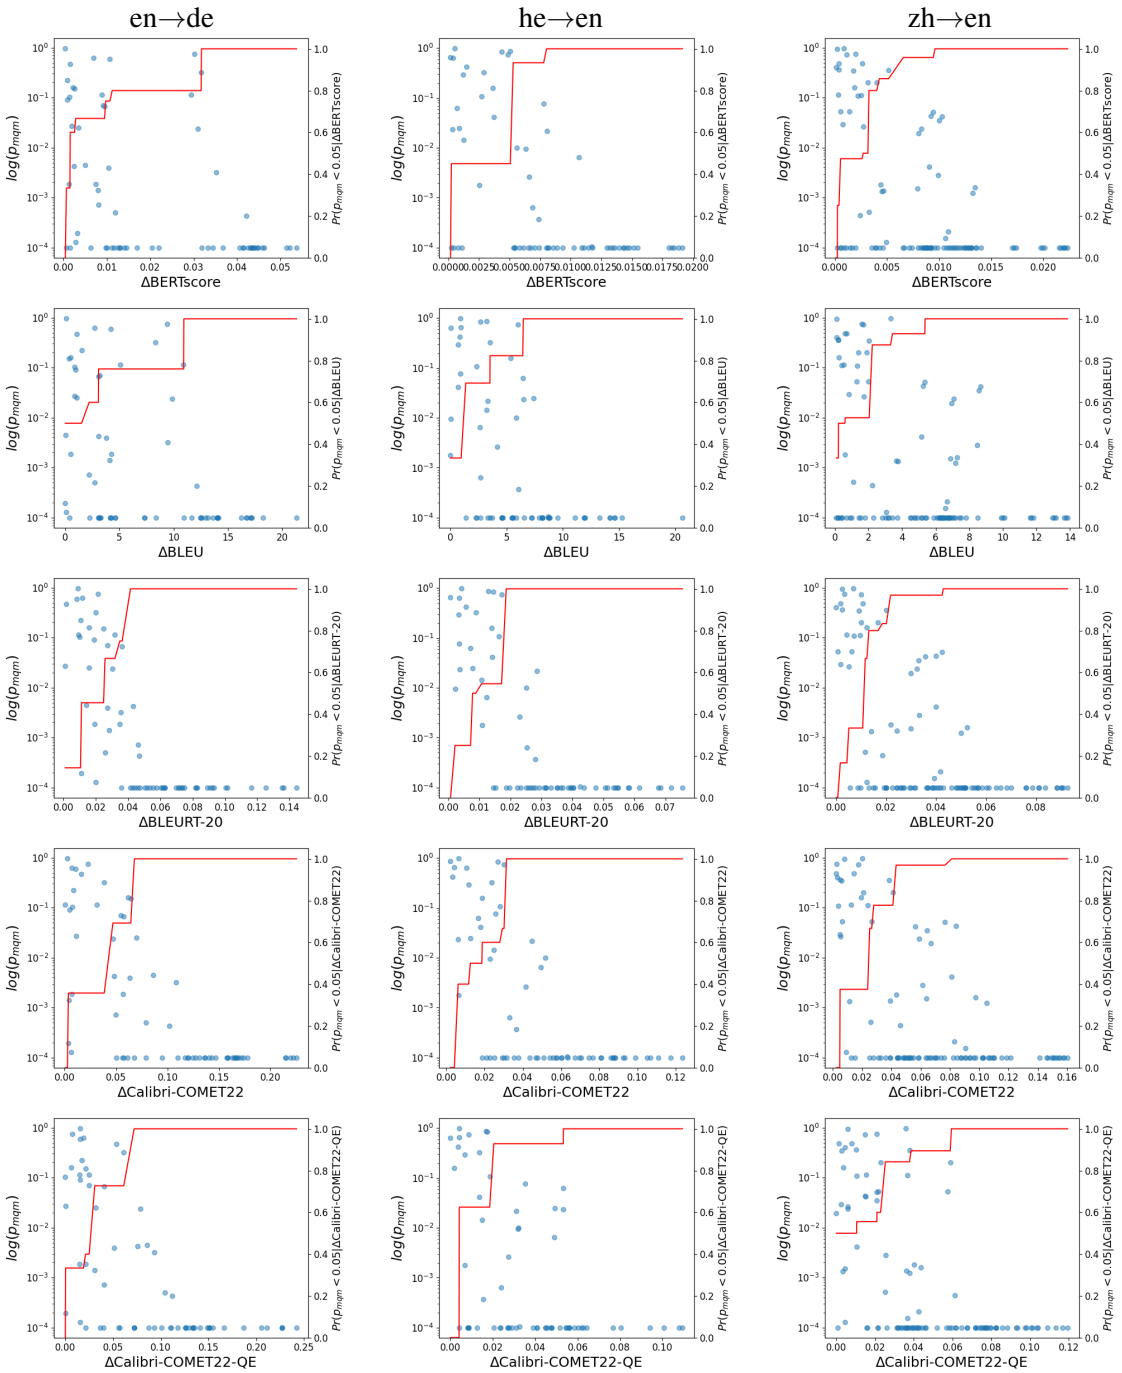

Figure 9: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: BERTScore, BLEU, BLEURT-20, CALIBRI-COMET22, CALIBRI-COMET22-QE) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

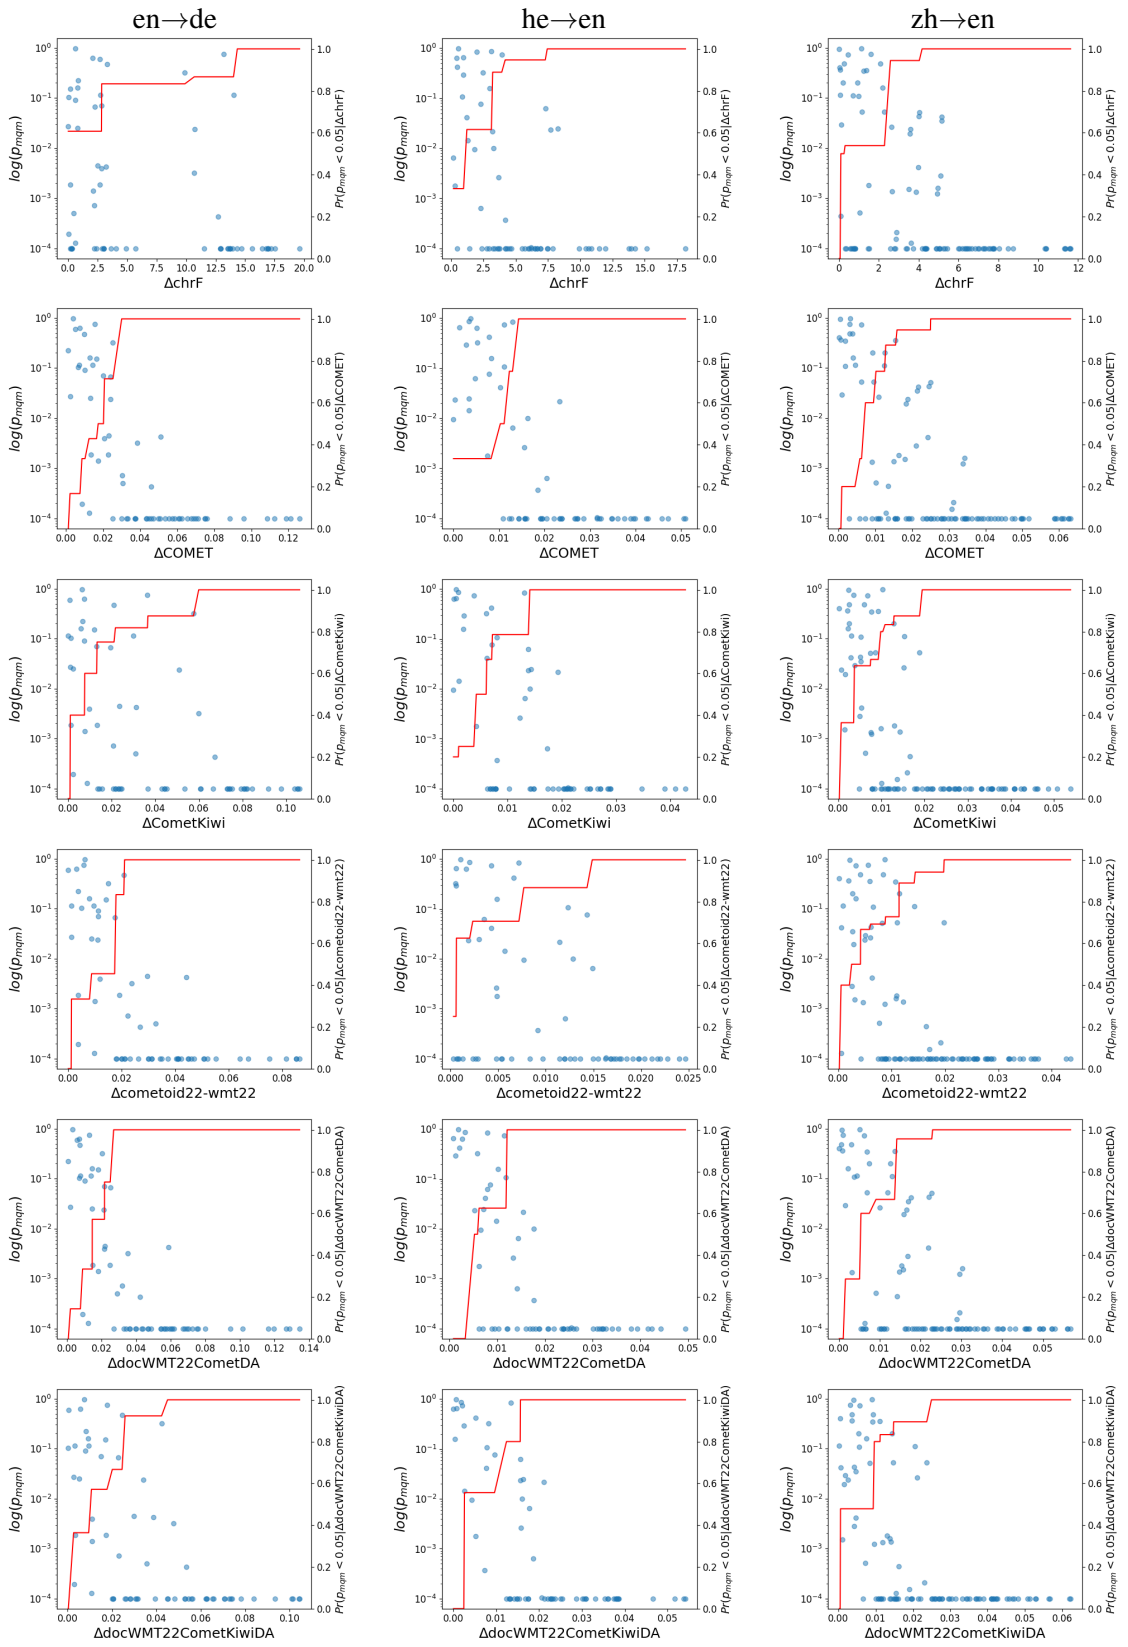

Figure 10: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: CHRF, COMET, COMETKIWI, COMETOID22-WMT22, DOCWMT22COMETDA, DOCWMT22COMETKIWIDA) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

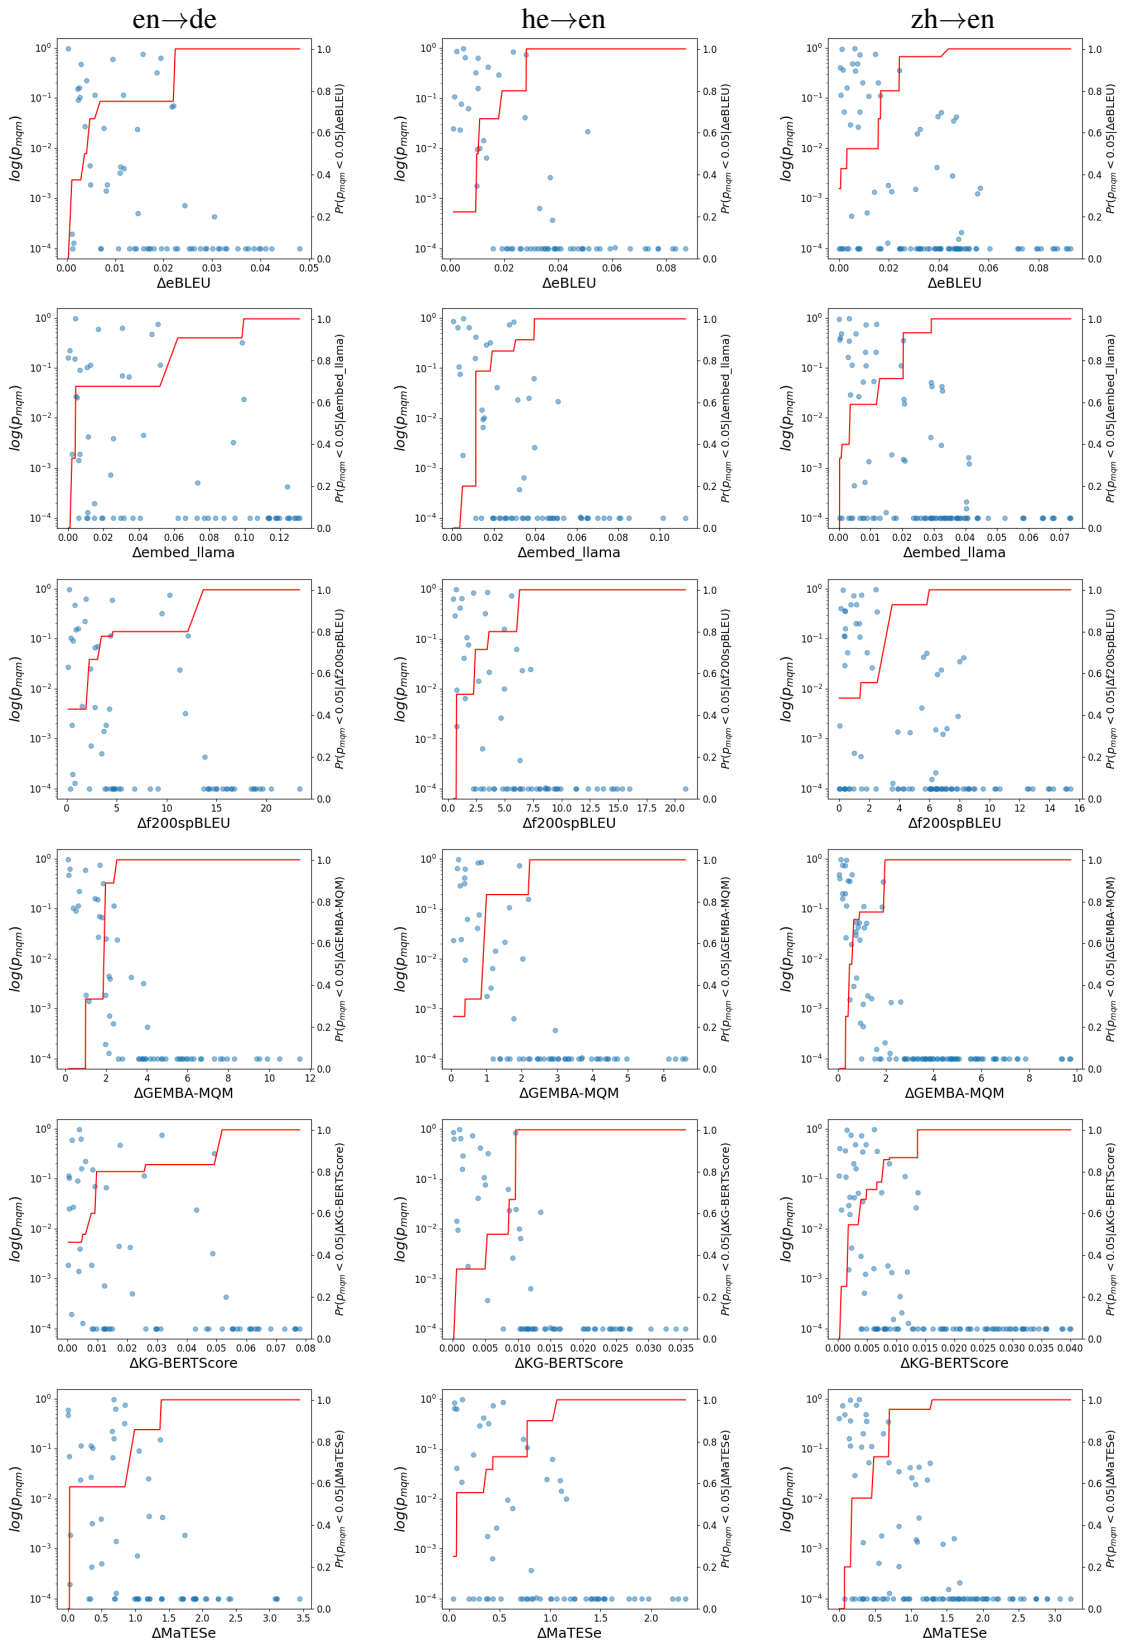

Figure 11: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: EBLEU, EMBED_LLAMA, F200SPBLEU, GEMBA-MQM, KG-BERTSCORE, MATESE) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

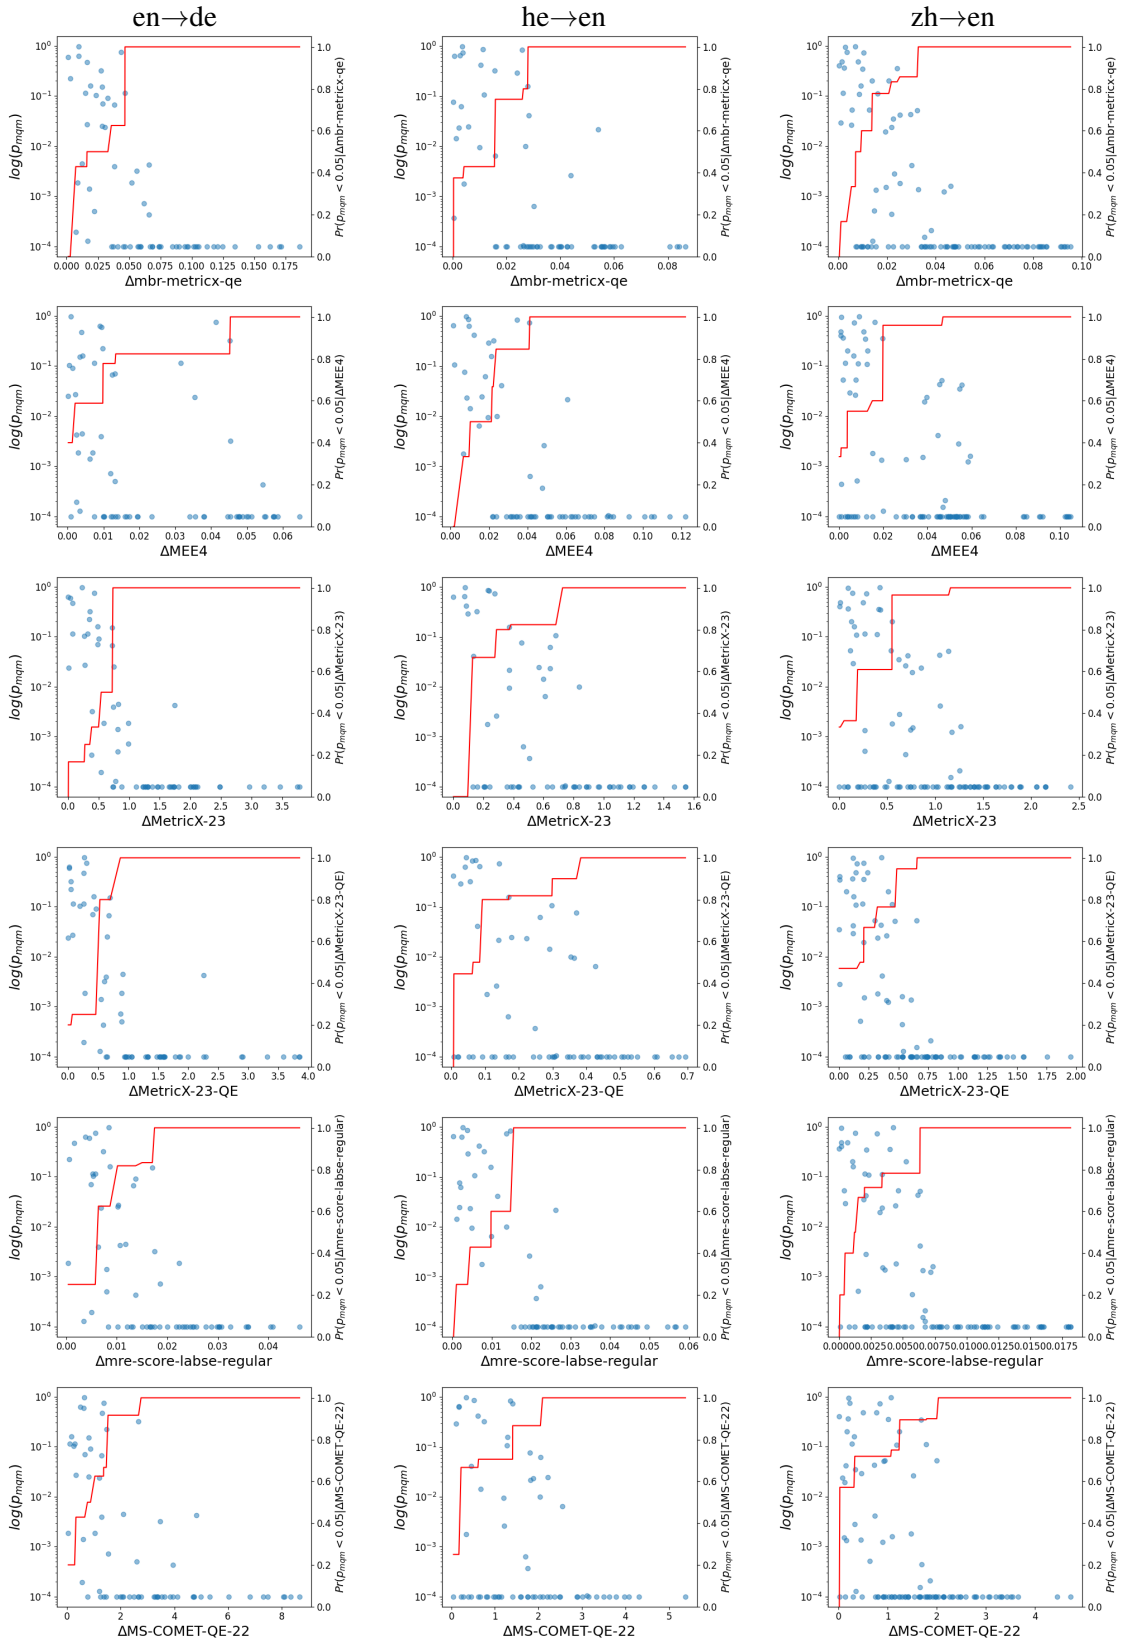

Figure 12: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: MBR-METRICX-QE, MEE4, METRICX-23, METRICX-23-QE, MRE-SCORE-LABSE-REGULAR, MS-COMET-QE-22) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

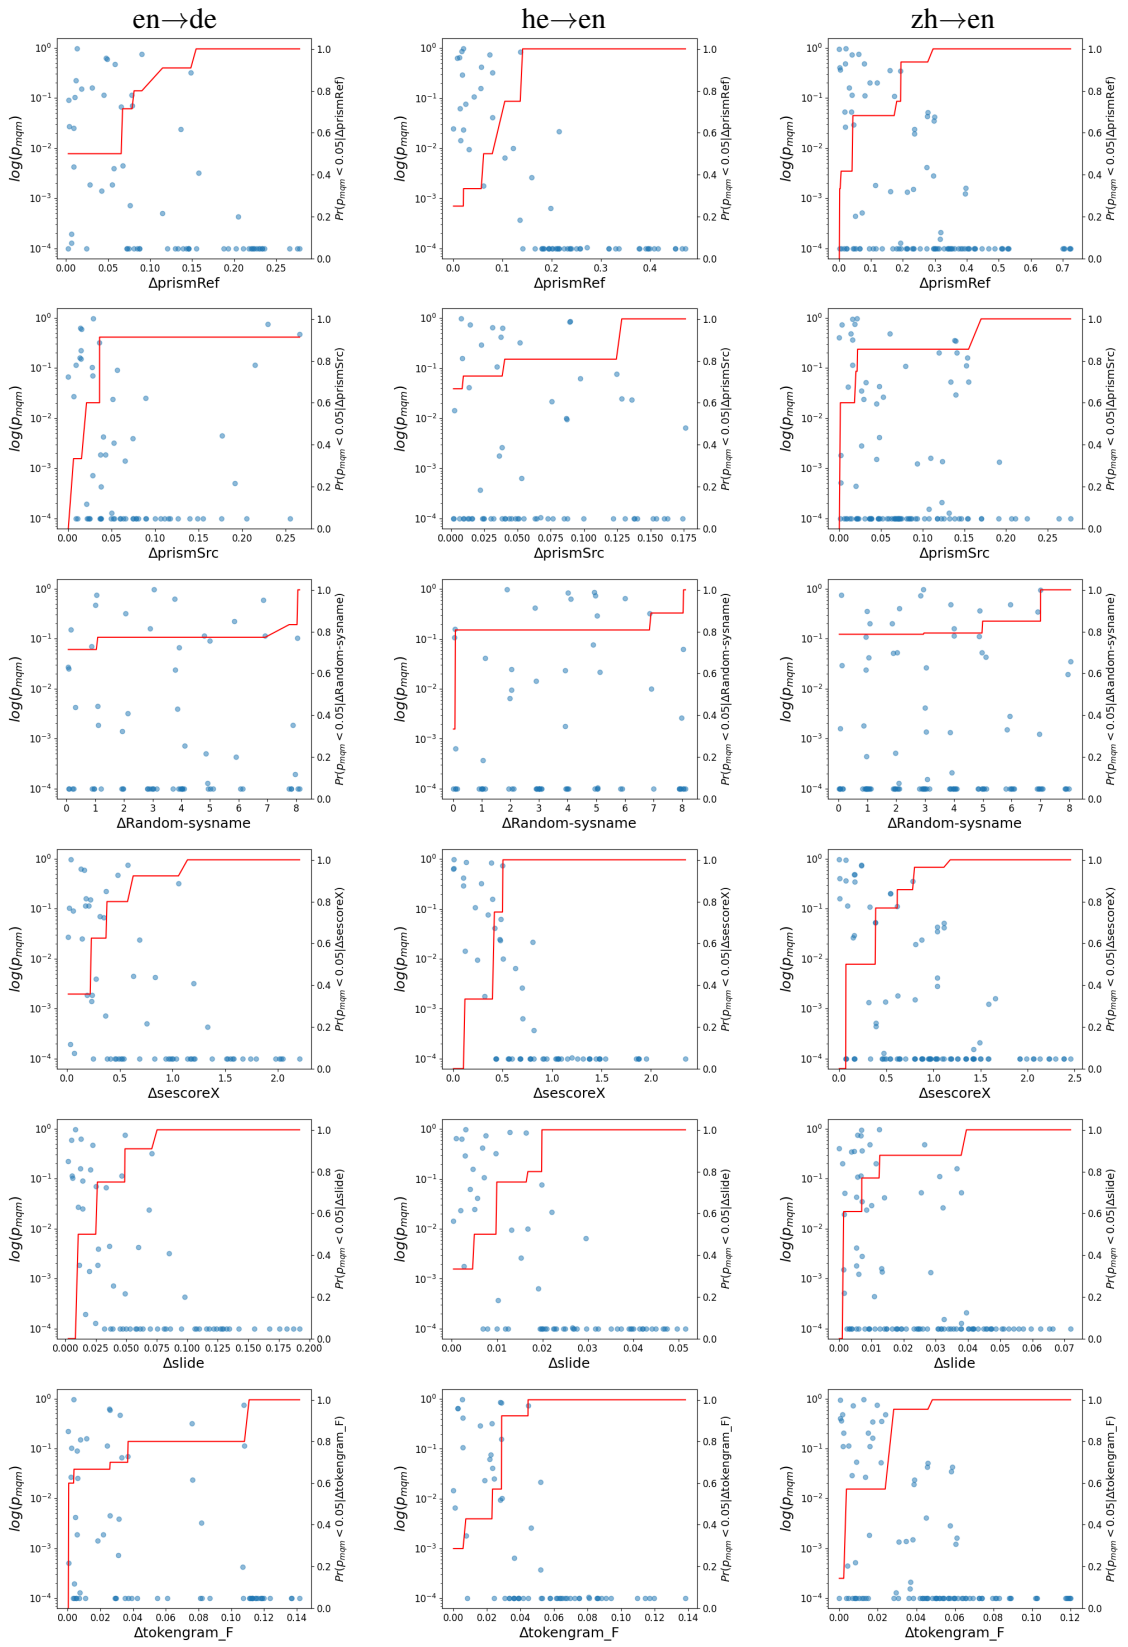

Figure 13: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: PRISMREF, PRISMSRC, RANDOM-SYSNAME, SESCOREX, SLIDE, TOKENGRAM_F) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

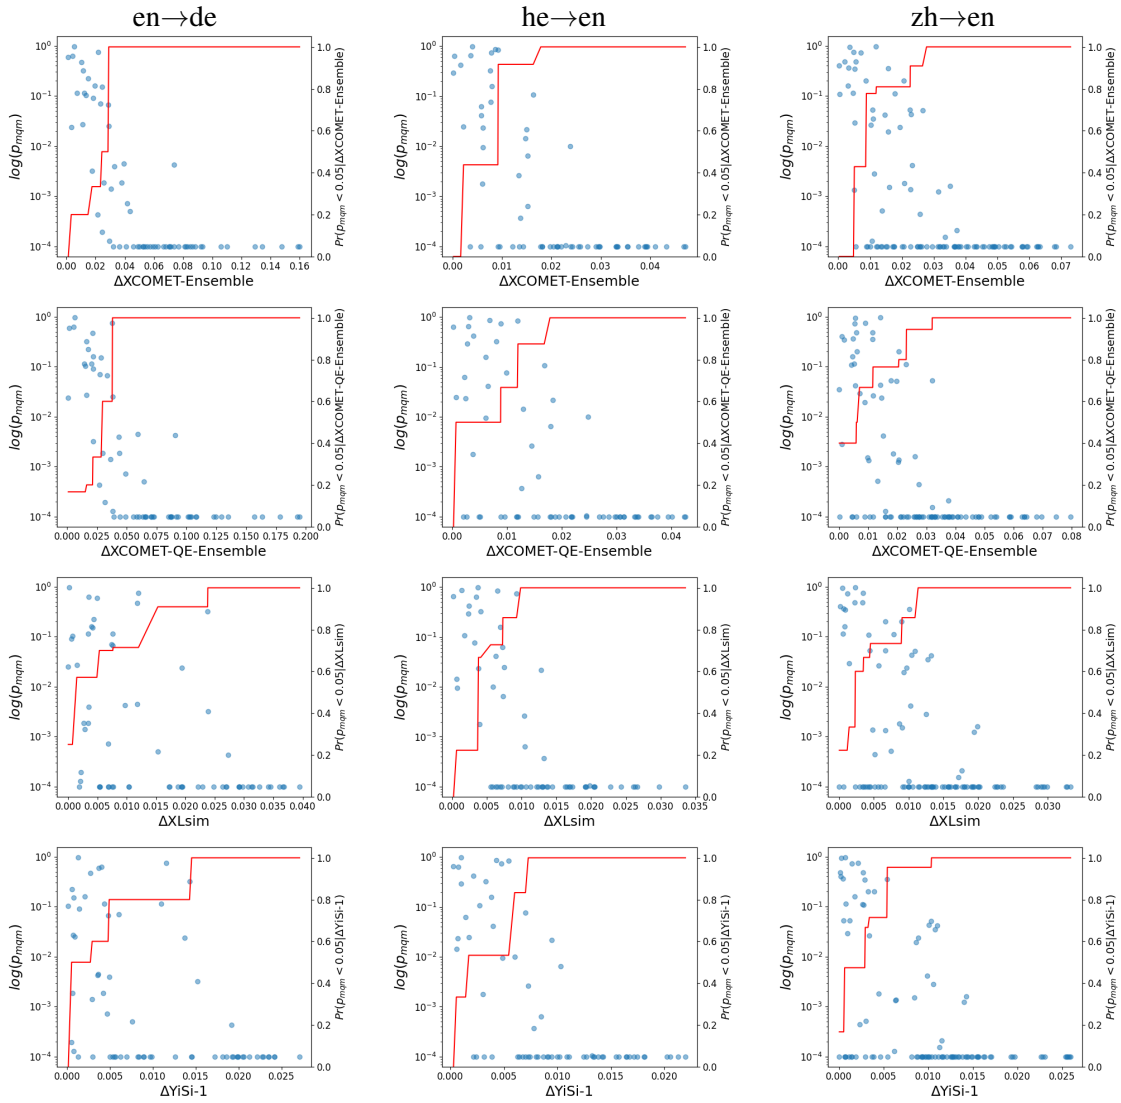

Figure 14: Log p-value of one-sided paired t-test on MQM scores (p_{mqm}) against the score difference of each metric (top to bottom: XCOMET-ENSEMBLE, XCOMET-QE-ENSEMBLE, XLSIM, YISI-1) for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

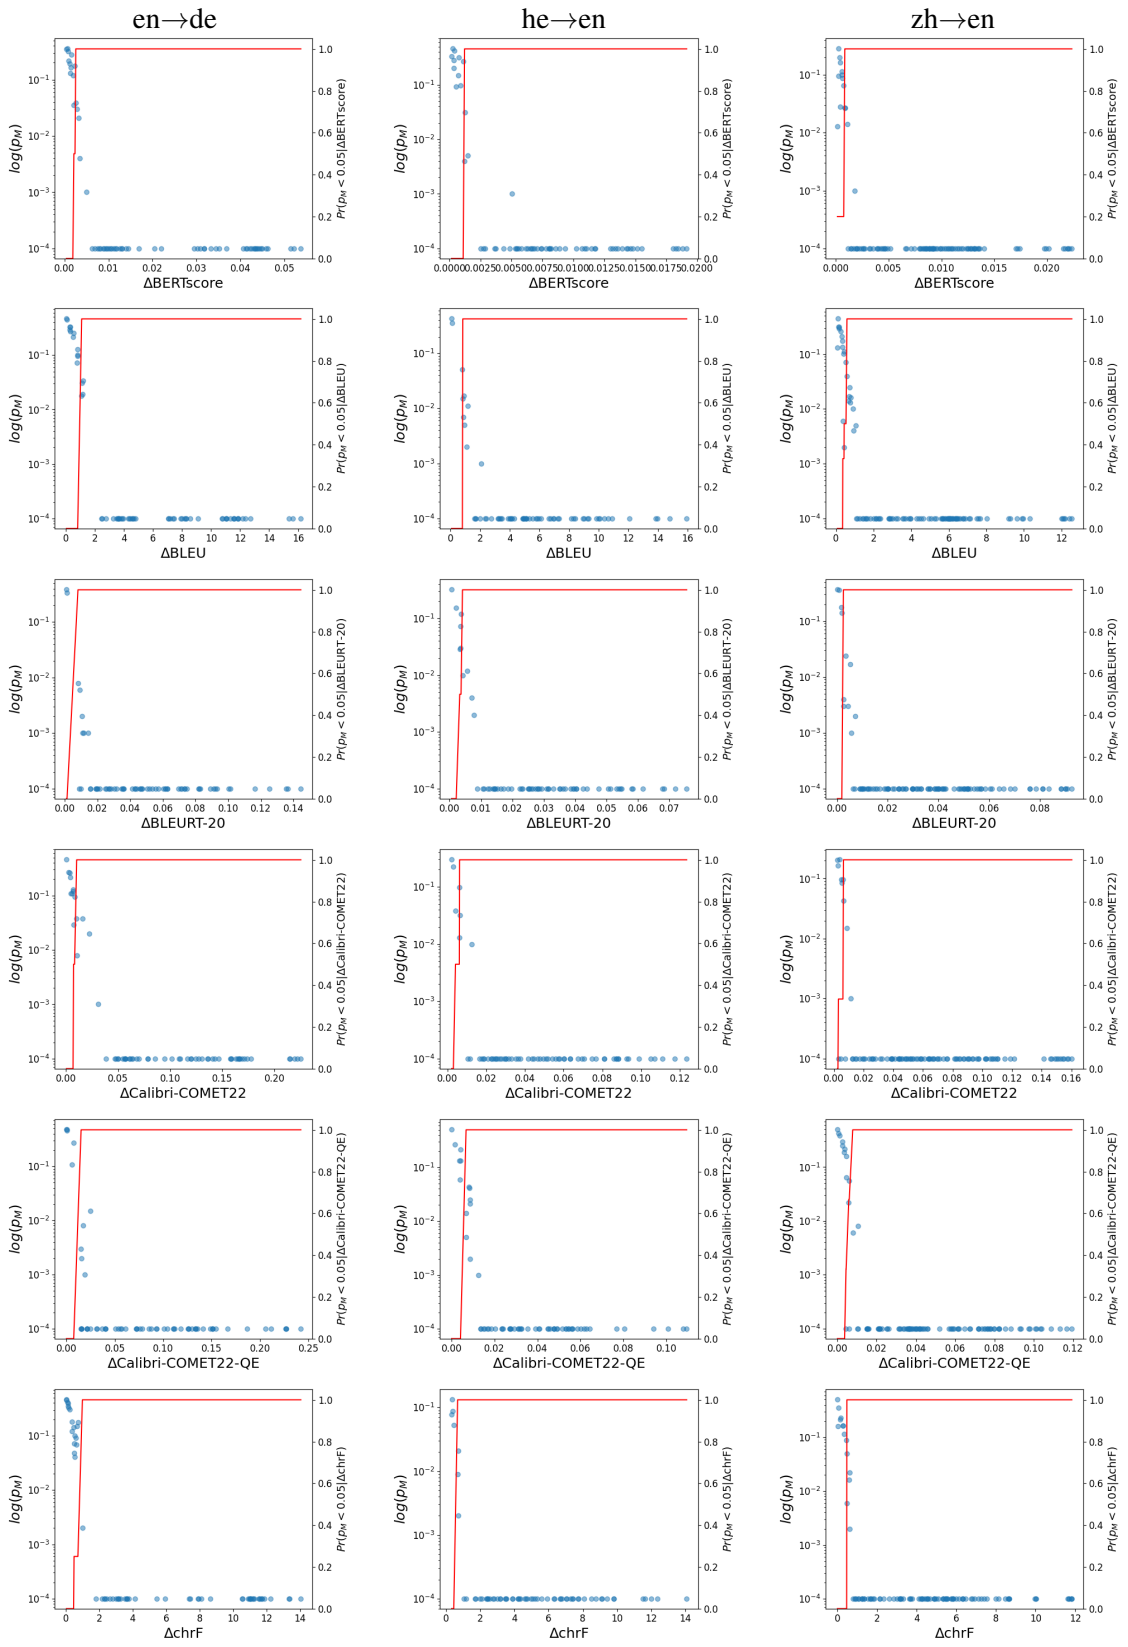

Figure 15: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: BERTSCORE, BLEU, BLEURT-20, CALIBRI-COMET22, CALIBRI-COMET22-QE, CHRF) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

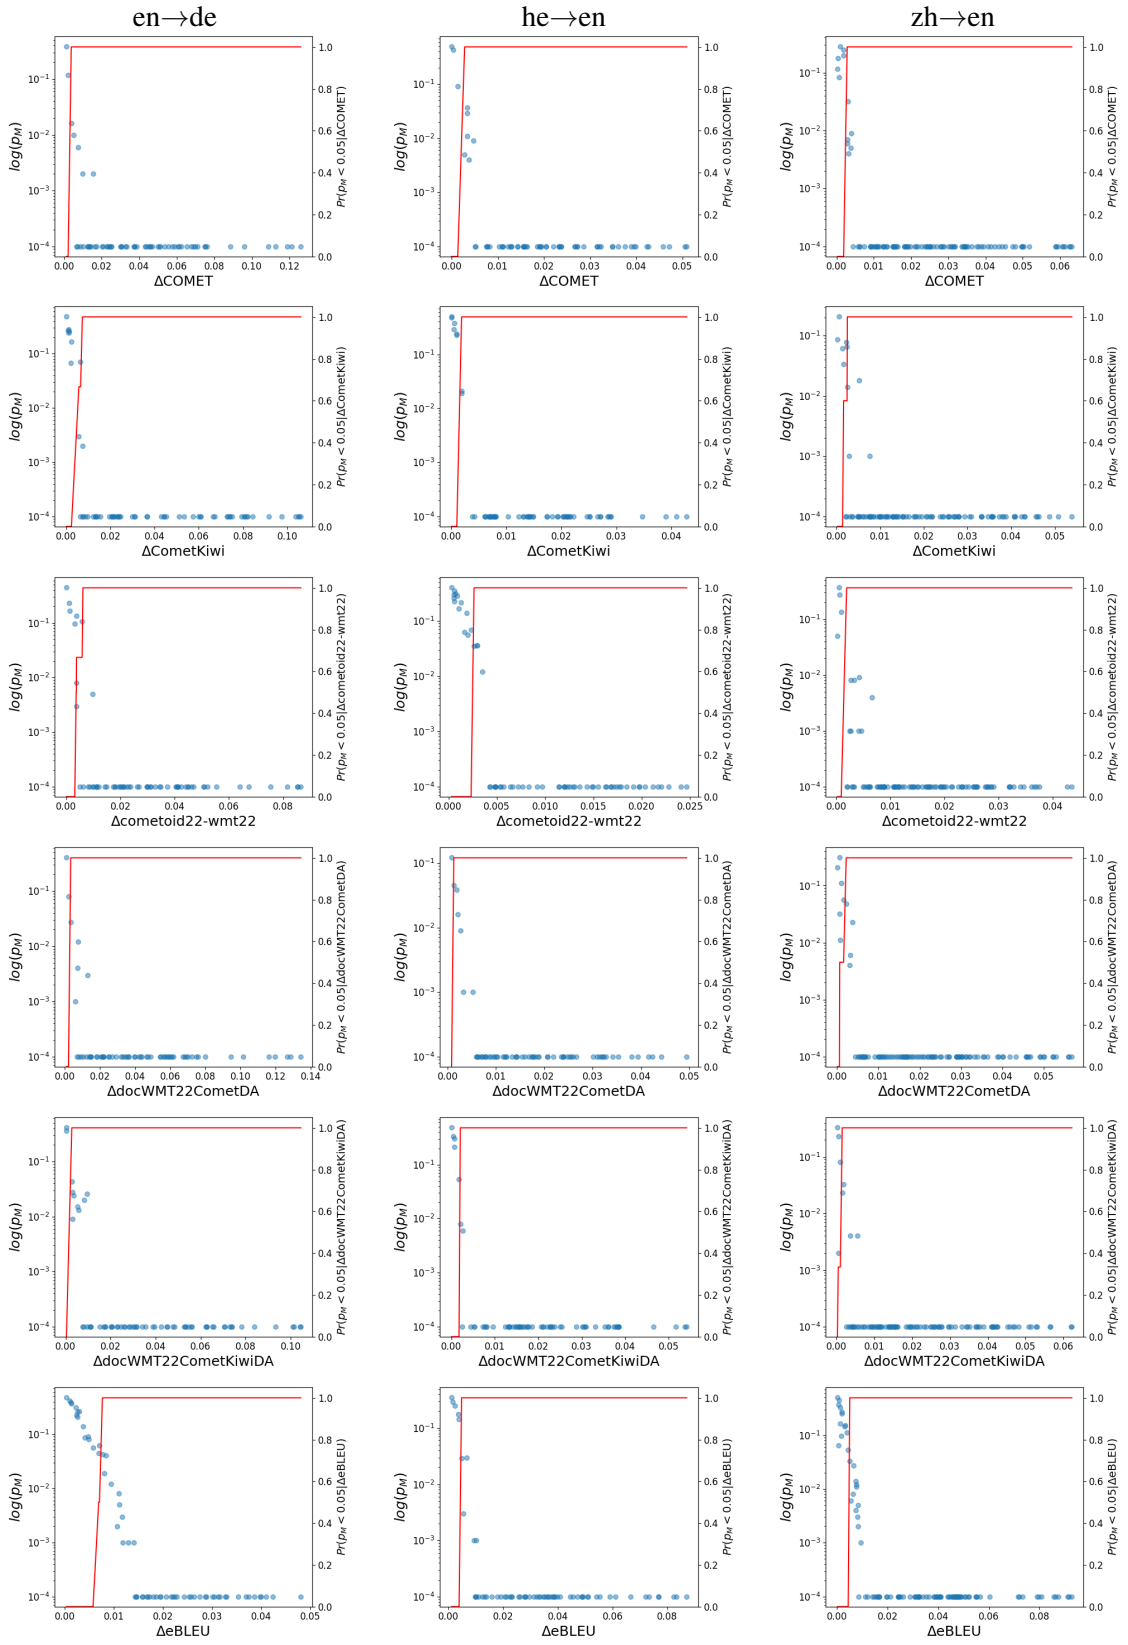

Figure 16: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: COMET, COMETKIWI, COMETOID22-WMT22, DOCWMT22COMETDA, DOCWMT22COMETKIWIDA, EBLEU) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

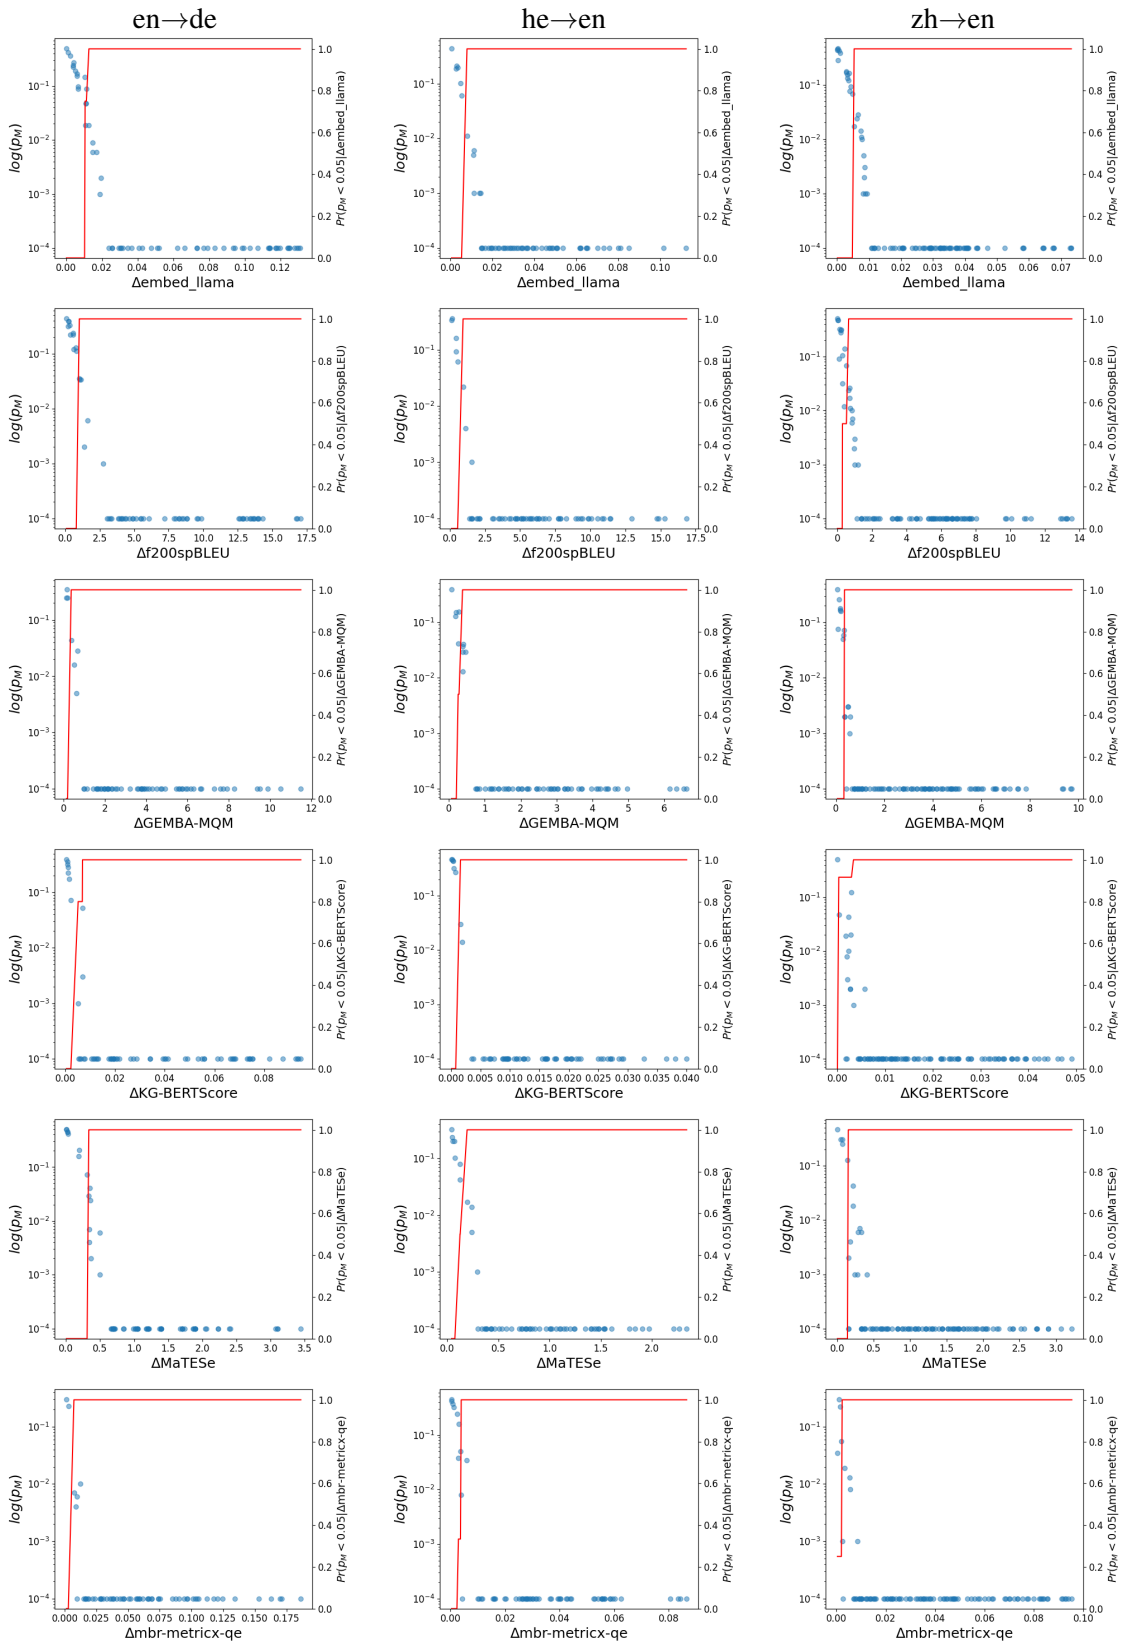

Figure 17: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: EMBED_LLAMA, F200SPBLEU, GEMBA-MQM, KG-BERTSCORE, MATESE, MBR-METRICX-QE) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

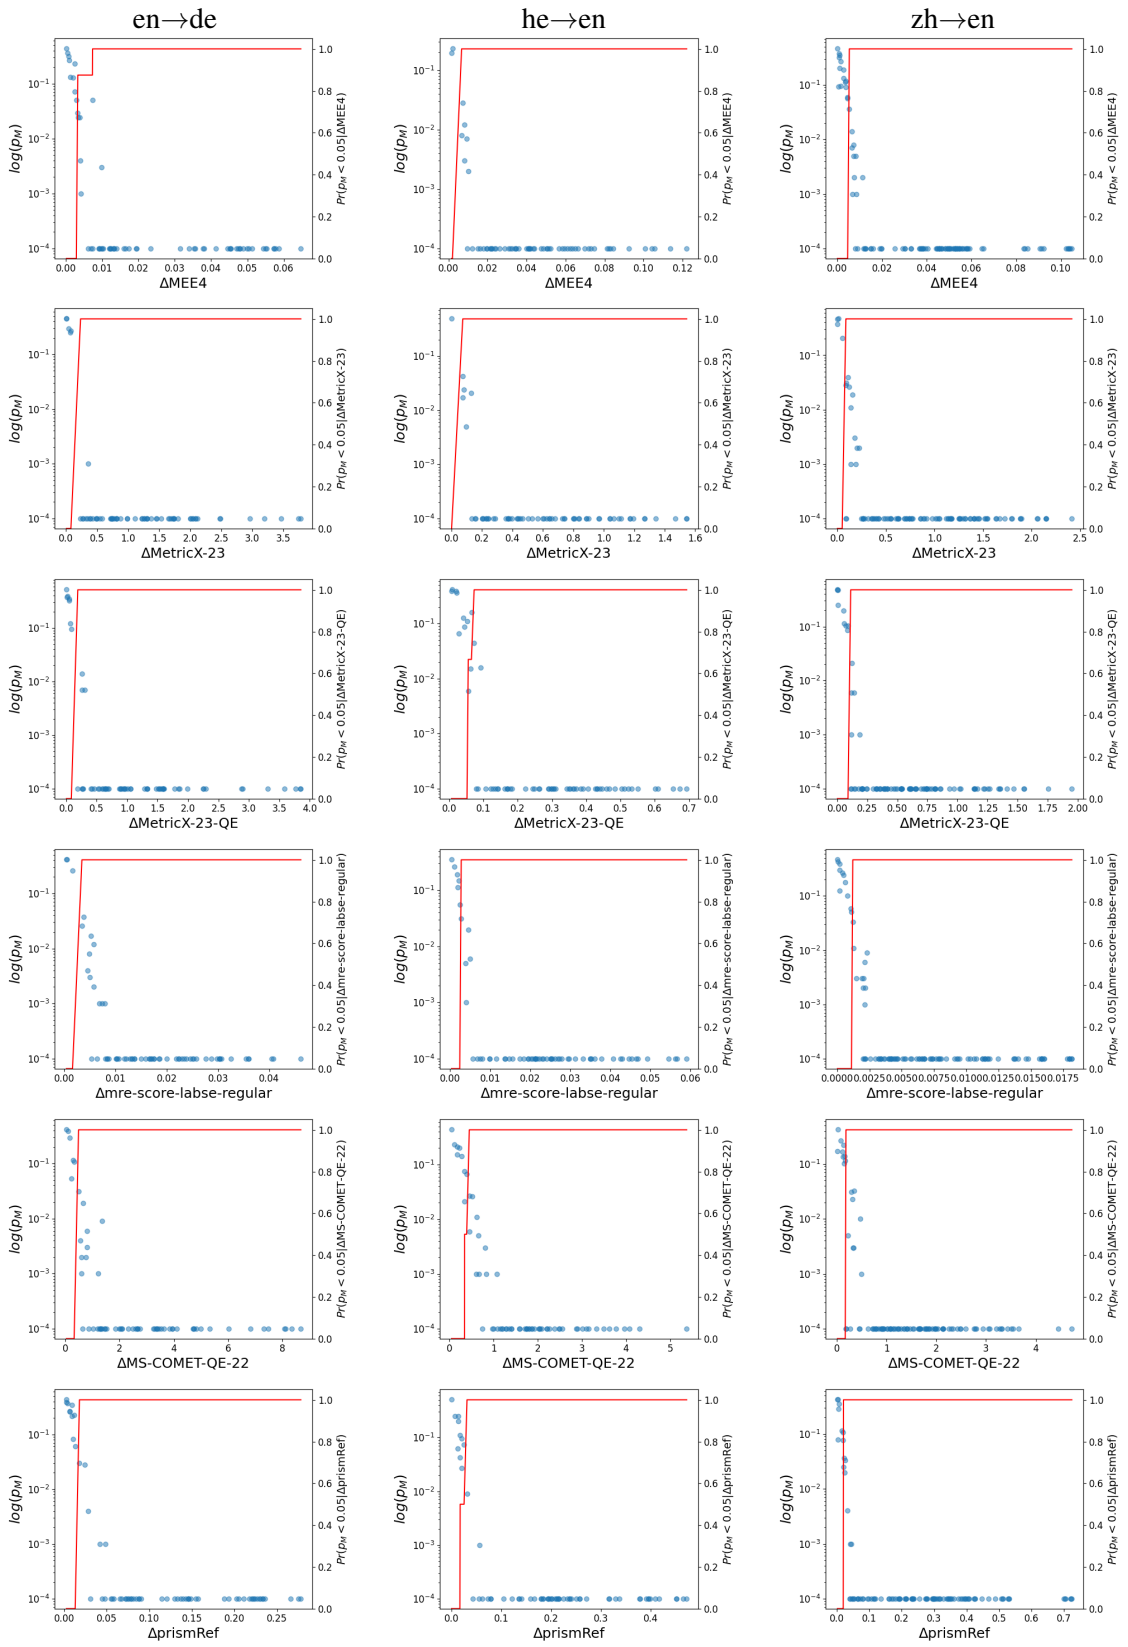

Figure 18: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: MEE4, METRICX-23, METRICX-23-QE, MRE-SCORE-LABSE-REGULAR, MS-COMET-QE-22, PRISMREF) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

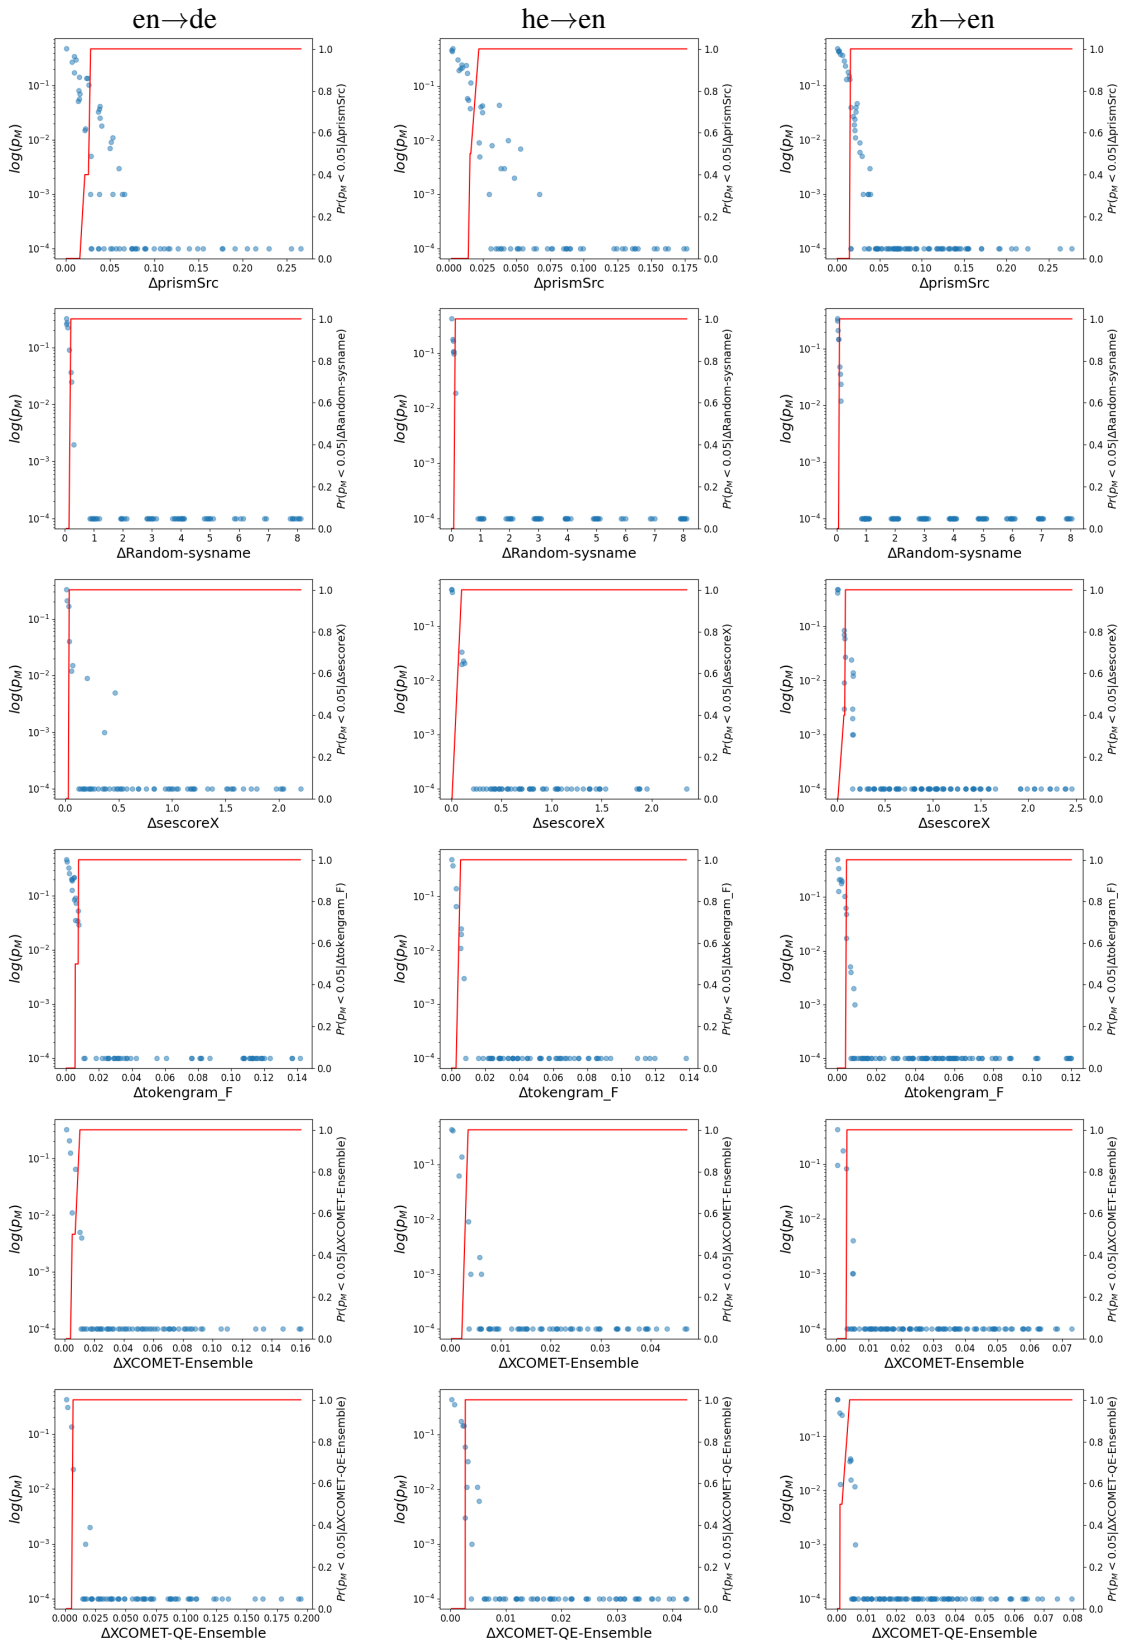

Figure 19: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: PRISMSRC, RANDOM-SYSNAME, SESCOREX, TOKENGRAM_F, XCOMET-ENSEMBLE, XCOMET-QE-ENSEMBLE) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

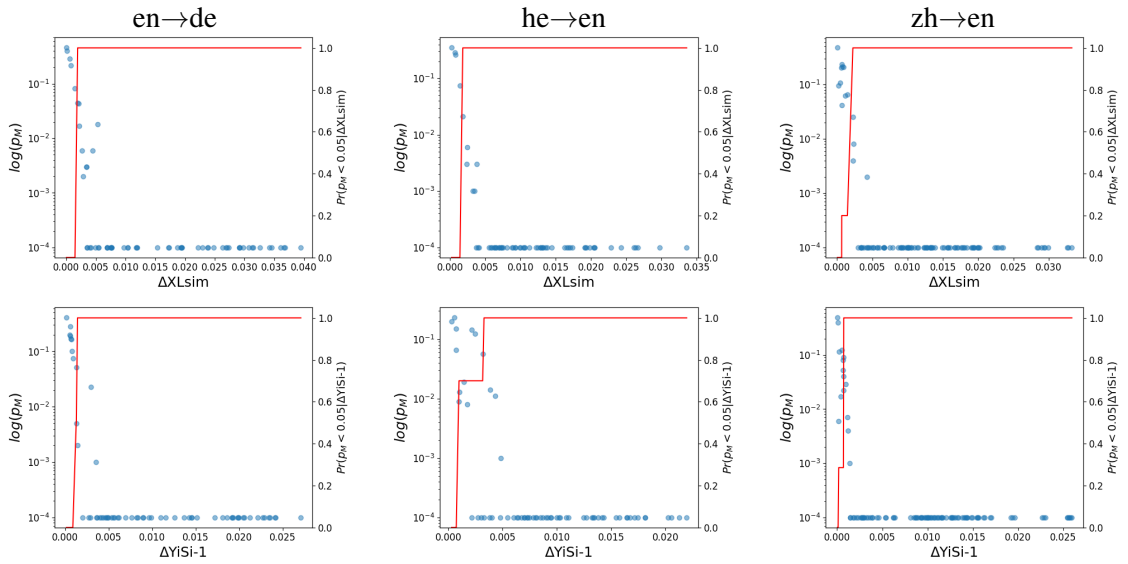

Figure 20: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (top to bottom: XLSIM, YISI-1) score difference for each system pair in each translation direction (left to right: en→de, he→en, zh→en). The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

Findings of the WMT 2023 Shared Task on Quality Estimation

Abstract

We report the results of the WMT 2023 shared task on Quality Estimation, in which the challenge is to predict the quality of the output of neural machine translation systems at the word and sentence levels, without access to reference translations. This edition introduces a few novel aspects and extensions that aim to enable more fine-grained, and explainable quality estimation approaches. We introduce an updated quality annotation scheme using Multidimensional Quality Metrics to obtain sentence- and word-level quality scores for three language pairs. We also extend the provided data to new language pairs: we specifically target low-resource languages and provide training, development and test data for English-Hindi, English-Tamil, English-Telegu and English-Gujarati as well as a zero-shot testset for English-Farsi. Further, we introduce a novel fine-grained error prediction task aspiring to motivate research towards more detailed quality predictions.

1 Introduction

This edition of the shared task on Quality Estimation (QE) aims to build on previous editions and findings to further benchmark methods for estimating the quality of neural machine translation (MT) output at run-time, without the use of reference translations. It includes (sub)tasks that consider the quality of machine translations at word- and sentence-level.

Over the past years, the QE field has been moving towards explainable, large, multilingual models that have been shown to achieve high performance, especially at sentence-level (Specia et al., 2021; Zerva et al., 2022). The recent proliferation of Large Language Model (LLM) technology and the consequential performance improvements in MT elevate the significance of advancing methodologies for quality estimation. In light of this, emphasis should be placed on multilingual quality estimation, in particular for low- and medium-resource languages, necessitating the development of more precise and interpretable quality assessment techniques. Additionally, it is important to address the challenge of robustness to hallucinations, prioritise sustainability, and optimise computational efficiency. These considerations collectively contribute to progress toward trustworthy and dependable QE systems that could facilitate real-time, reliable assessments of translation quality.

In this edition of the shared task, we further expand the provided resources, introducing new low-resource language pairs for Indian languages, namely Marathi, Tamil, Telugu, Gujarati and Hindi, as well as Farsi and Hebrew. Following the previous editions, we provide both annotations for direct assessments (DA), post-edits (PE) and Multidimensional Quality Metrics (MQM) (Lommel et al., 2014). We describe in detail the annotation process and provide statistics for the different language pairs in Section 2.

Overall, in addition to advancing the state-of-the-art at all prediction levels, our main goals are:

- to extend the languages covered in our datasets with low- and medium-resource languages;
- to investigate the potential of fine-grained quality estimation;
- to investigate new multilingual and language independent approaches esp. with regards to zero-shot approaches;
- to study the robustness of QE approaches to hallucinations; and
- to continue monitoring the computational efficiency of proposed approaches for sustainability purposes.

We thus designed two tasks this year:

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 629–653
December 6–7, 2023.

Task 1 The core QE task, which consists of separate sentence-level and word-level sub-tasks. For the sentence-level sub-tasks, the goal is to predict a quality score for each segment in a given test set, which can be a variant of DA (§2.1) or MQM (§2.2). For the word-level sub-task, participants had to predict translation errors in the form of binary quality tags (see §3.1.3).

Task 2 The fine-grained error prediction task, where participants were asked to detect error spans alongside error severities (§3.2).

The tasks make use of large datasets annotated by professional translators with either 0-100 DA scoring, post-editing or MQM annotations. We update the training and development datasets of previous editions and provide new test sets for Tasks 1 and 2. The datasets and models released are publicly available[1].

Apart from the data made available through the QE shared task, participants were also allowed to explore any additional data and resources deemed relevant, across tasks. In addition, LLMs could also be used both to extend resources and to complement predictions.

The shared task uses CodaLab as a submission platform, where each sub-task corresponds to a separate competition instance. Participants (Section 5) could submit up to a total of 10 submissions per sub-task. Results for all tasks evaluated according to standard metrics are given in Section 6. Baseline systems were trained by the task organisers and entered into the platform to provide a basis for comparison (Section 4). A discussion on the main goals and findings from this year's task is presented in Section 7.

2 Datasets

2.1 DA & Post-edit data:

For all language pairs, the data provided is selected from publicly available resources. Specifically for training, we used the language pairs from the MLQE-PE dataset (Fomicheva et al., 2022), as well as newly annotated data for languages spoken in India (Hindi, Tamil, Telugu and Gujarati). Overall, we provided training data for 15 language pairs with DA annotations, 12 with post edits, and 3 with MQM annotations, accounting for a mix of high, medium and low-resource languages. The statistics for the provided data are detailed in Table 1.

For the English-Marathi language pair included in the last edition, we provided a novel test set this year. To expand on language resources for the QE shared task, we chose Hindi (Hi) and Gujarati (Gu) as target languages from the Indo-Aryan language family, Tamil (Ta) and Telugu (Te) were chosen from the Dravidian language family. For En-Hi, En-Ta, En-Te, and En-Gu, dataset curation and annotation were performed with the help of professional translators who were native speakers of the target language. The annotators were provided with guidelines which discussed DA score ranges with various error types. Additionally, parallel segments were curated from the following parallel corpora: *i) Anuvaad* parallel corpus[2] (General, Healthcare and Legal domain; *ii*) IITB English-Hindi parallel corpus[3] (Kunchukuttan et al., 2018) (Culture/-Tourism domain), and parallel segments scraped from NPTEL[4]; and *iii*) SpokenTutorials[5] (Education domain). The curated segments were selected from the above-mentioned domains to ensure cross-domain impact and performance.

From the *Anuvaad* parallel corpus, we filtered source and parallel segments based on LaBSE (Feng et al., 2022) at high threshold values in the range [0.85, 0.99]. This helps us ensure the presence of good-quality reference translations from a noisy parallel corpus. We then selected source sentences for the dataset by varying token length in buckets of $0-10$, $10-20$, and $20-30$ tokens. This allows us to get annotations on various sentence lengths and helps manage the annotation cost to a certain extent. Moreover, translation models tend to generate erroneously over longer sequences (Varis and Bojar, 2021), and ensuring short and longer source sentences are a part of the data helps us presume a balanced DA distribution in the human annotation. We obtained the translation with the 1.3B parameter NLLB model (Costa-jussà et al., 2022) from HuggingFace[6]. The inference was performed with 5 beams, limiting the n-gram repetition to 2 and maximum length to 80 tokens, with early stopping enabled. The curation of source

segments from parallel corpora allowed us to compare the performance with IndicTrans (Ramesh et al., 2022) and 600M parameter NLLB model, in terms of TER and BLEU, helping us select the model and parameters above.

During the annotation, weekly validation of randomly selected instances was performed by an unbiased native speaker who provided feedback to further improve annotations during the data curation. After all three annotators performed the DA annotations, we separated the data into training, development, and test sets while filtering for a balanced distribution of DA scores across all sets.

For the En-Fa dataset, we used the post-edited data provided in Azadi et al. (2022) to get the word-level quality annotations. It contains 1K sentences derived from some English scientific articles in the domains of technology, computer science, and humanities. These sentences were firstly translated to Farsi, using an RNN-based commercial MT system named Faraazin[7]. Then, each sentence was given to a professional human translator to be post-edited and provide the correct translation with minimum edits. These post-edits were finally validated by another annotator to ensure their quality.

2.2 MQM Data

As **training data**, we used the annotations released for the Metrics and QE shared tasks in the previous years (Freitag et al., 2021a,b). Together, these annotations, cover 3 high-resource language pairs, namely: Chinese-English (Zh-En), English-German (En-De) and English-Russian (En-Ru), and span across two domains (News and Ted Talks).

As **test data**, we annotated new evaluation sets for three language directions. A low-resource language pair, Hebrew-English (He-En), and two high-resource language pairs, English-German and Chinese-English. The evaluation sets were annotated by professional translators following a MQM typology (Burchardt, 2013) and specific guidelines[8].

The documents used for the evaluation sets are shared with the General MT task in WMT and follow the same distribution of domains in that data. These documents were translated using the NLLB (Team et al., 2022) model of 1.3B parameters[9], the same model used in Section 2.1. We note that the En-De sources were originally organised in document-level, and we opted for converting them to smaller segments, so that we do not divert from the processing applied for the other LPs. Hence we first applied sentence splitting and then followed the same translation and annotation process described in this section.

All evaluation sets were annotated by professional translators and, for En-De and Zh-En the annotations were reviewed by a separate group of professional translators that amended any incoherences or disagreements from the first round of annotation. Regarding the domains of the data, for He-En, two different evaluation sets were annotated, one with newswire articles and another from product user reviews. For En-De, documents from four domains were annotated: transcriptions of meetings, newswire articles, social media posts, and product user reviews. For Zh-En, documents from three domains were used: manuals from information technology software or devices, newswire articles and product user reviews.

3 Quality Estimation tasks

In what follows, we briefly describe each sub-task, including the datasets provided for them.

3.1 Task 1: Predicting translation quality

The ability to accurately estimate the quality of translations on sentence- or word-level on-the-fly, i.e., without access to human-references is at the core of the QE shared task. Sentence and word-level estimates can provide complementary views of the quality of a sentence capturing different aspects (e.g. overall fluency versus specific mistranslations).

Following last edition, the data was produced in the following ways:

1. DA sentence level scores: The quality of each source-translation pair is annotated by at least 3 independent expert annotators, using DA on a scale 0-100.

2. MQM approach: Each source-translation pair is evaluated by at least 1 expert annotator, and errors identified in texts are highlighted and classified in terms of severity (minor, major, critical) and type (grammar correctness, omission, style, mistranslation, among others). We use this information for both word and sentence level quality scores.

[7] https://www.faraazin.ir/

[8] http://bit.ly/mqm-guidelines

[9] Model identifier FACEBOOK/NLLB-200-1.3B

3. Post-editing approach: The translation is post-edited to obtain the closest possible, fully correct translation of the source. By considering the alignment between the source, translation and post-edited sentence, we can propagate the errors from the source to the translated sentence and annotate the segments that were potentially mistranslated and/or not translated at all. We use this information to infer word-level quality scores.

The DA and MQM sentence level annotations were further processed to obtain normalised quality scores that have the same direction between high and low quality. We provide more details on the required pre-processing in §3.1.1 and §3.1.3.

3.1.1 Sentence-level quality prediction

This year we used a single competition instance both for DA and MQM-derived annotations aiming to motivate the submission of models that are robust to both annotation formats. To that end, we also aligned the scores by processing and normalising them as follows:

- For the **DA** scores we standardize the scores with respect to each annotator and then compute the mean average of standardized scores for each sentence.
- For the **MQM** scores we need to first compute the overall score from the individual errors. Hence for each annotator, we first compute the sentence-level score as

$$MQM^{sent}(hyp) = \frac{100 - \sum_{e \in hyp} severity(e)}{|hyp|}, \quad (1)$$

where hyp is a hypothesis sentence represented as a sequence of tokens, e is an error annotated in that sentence and the $severity$ is computed but adding:

  + 1 point for minor errors
  + 5 points for major errors
  + 10 points for critical errors

To align with DA annotations we subtract the summed penalties from 100 (perfect score) and we then divide by the sentence length (computed as number of words). We then normalise per annotator as in the DA case and compute the mean average in the case of multiple annotators.

Regarding evaluation, systems in this task (both for DA and MQM) are **evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient ρ as the primary metric**. This is what was used for ranking system submissions. Pearson's correlation coefficient, r, and Kendall τ were also computed as secondary metrics but not used for the final ranking of systems.

3.1.2 Hallucinations

Hallucinations are highly pathological translations that contain content that is detached from the source (Raunak et al., 2021). As such, they can have devastating impact when models are deployed *in the wild* for real-world applications. Quality estimation systems are an appealing and attractive strategy to identify and flag these translations before they reach end-users. However, recent research has found that QE models may not appropriately penalize hallucinations and other critical errors (Raunak et al., 2022; Guerreiro et al., 2023c). This concern is further amplified for low-resource languages, where this undesirable behavior may arise even more frequently (Dale et al., 2023b). As such, in this edition of the shared task, we created data to assess the capability of submitted QE models in detecting hallucinations.

The data was created through a three-step process: (i) we started by generating translations for all language pairs of this year's shared task with NMT models[10], using the FLORES `devtest` and `test` splits (Goyal et al., 2022), as well as WikiMatrix data available through OPUS (Schwenk et al., 2019); then (ii) we automatically detected hallucinations generated by the models; and finally (iii) manually verified the flagged translations in order to guarantee that they are hallucinations. To automatically detect the hallucinations, we followed the procedure from Guerreiro et al. (2023a), which directly draws from several relevant contributions from research works in the literature of hallucination detection (Ferrando et al., 2022; Dale et al., 2023a; Guerreiro et al., 2023c).

To evaluate the performance of the submissions, we created, for each language pair, an *evaluation* set that consists of: all the hallucinations for the language pair, and the samples whose gold score is above the 25th percentile. This is to ensure that the non-hallucinations in the evaluation set are not

[10]We used the massively multilingual models (175M and 615M parameters) released in Goyal et al. (2022).

highly pathological translations (they may however be incorrect translations). We report the Area Under the Receiver Operating Characteristic curve (AUROC) and Recall at k (R@k), where k is defined as the number of hallucinations in the evaluation set. A perfect QE detector would have 100 AUROC and 100% Recall at k. We report the statistics of the evaluation sets in Table 8.

3.1.3 Word-level quality prediction

This sub-task focuses on detecting word-level errors in the MT output. The goal is to automatically predict the quality of each token using a binary decision, i.e., using OK as a label for tokens translated correctly and BAD otherwise.

We follow the annotation conventions of the previous edition, i.e., we do not consider source-side annotations, and incorporate omission errors to the target token annotations. Specifically, to account for omission errors, we consider the following convention: the token on the right side of the omitted text in the translation is annotated as "BAD". An additional `<EOS>` token is appended at the end of every translation segment to account for omissions at the end of each sentence. This allows the provision of a unified framework for both the post-edit originated annotations and the MQM annotations.

We thus use the same source-translation pairs used for the sentence-level tasks and obtain the binary tags as follows:

- For post-edited data, we use the methodology to obtain *translation error distance* (TER) scores (Snover et al., 2006) to obtain alignments between translation and post-edit and annotate the misaligned tokens as BAD.
- For MQM data, the tokens that fall within the text-spans annotated as errors (or any severity or category) are annotated as BAD. If the whitespace between two words is annotated as an error, then this is considered an omission, and the next token is annotated as BAD.

For the word-level task, **submissions are ranked using the Matthews Correlation Coefficient (MCC, Matthews, 1975) as the primary metric**, while F1-scores are provided as complementary information.

3.2 Task 2: Fine-grained error detection

For this task we attempt to focus on finer-grained quality predictions, taking advantage of the detailed information provided in the MQM annotation schema. Specifically, the MQM schema allows the annotation of additional information for each identified error. Specifically, each error span is annotated with error severity (*minor*, *major*, *critical*)

as well as error type (see also Figure 1). Such information allows for a more detailed analysis of the errors of MT systems, an understanding of their failure points and can provide the basis towards more explainable quality estimation.

Ideally, a fine-grained QE system is expected to be able to predict both the error type and its corresponding severity. However, the cardinality of error categories, the complexity of disentangling between them and the scarcity of MQM annotations render such a classification task particularly challenging. Hence, in this first attempt, we chose to focus only on **error severity** and merged together the major and the critical labelled errors due to the scarcity of the latter (see Table 2). As a result, we aimed to classify error spans as either *minor* or *major*.

LP	minor	major	critical
En-De	652	595	81
Zh-En	633	1063	242
He-En	792	1837	3

Table 2: Error severities (original: before merging critical and major severities) for the 2023 MQM test set.

As such, the information used for this task consists of: *i*) start and end index positions for each error span; and *ii*) the simplified error severity. The error spans are identified as sequences of continuous characters within a target hypothesis, allowing for annotations of single white spaces and punctuation marks in order to account for omission and punctuation errors respectively. Aiming to mimic the human annotations and simplify the task, overlapping error spans were allowed. Figure 1 shows an example of annotations.

For the evaluation, the primary metric was **F1-score**, computed on the character level and weighted to allow for half points for correctly identified span but misclassified severity. Precision and recall were also provided as complementary metrics. The evaluation approach is inspired by (Fonseca et al., 2019) but does not consider document-level annotations. With respect to overlapping annotations, we allow for multiple character level annotations [11] and will consider the best matching annotation per character position. As such for each segment we compute recall for the characters in

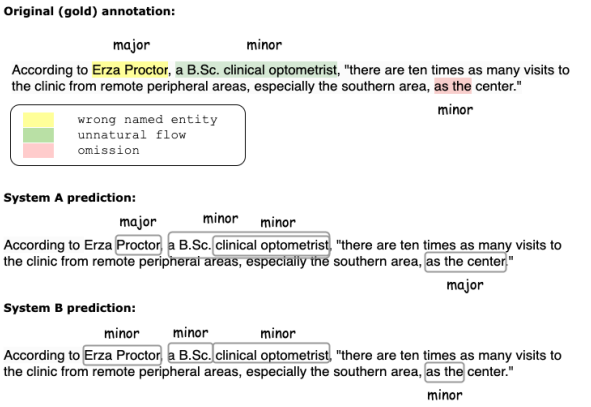

Figure 1: Example of gold annotations (MQM) for Task 2 (top) and respective prediction examples (bottom). Example taken from He-En test set.

gold annotation text spans, by computing the ratio between the overlap with system error spans and the gold error span length and weighting severity mismatches by 0.5. Respectively, we compute precision with respect to the system error span length and apply the same weighting convention (down-weighting by 0.5 for mismatched error severities). Figure 1 and Table 3 shows an example of the aforementioned process [12].

4 Baseline systems

4.1 Task 1: quality estimation

For the **sentence-level** sub-task, we opted for COMET-QE models (Rei et al., 2021) respectively pretrained on the DA and MQM QE data from WMT'21. Models are publicly available to download[13].

For the **word-level** sub-task, we trained a simplified architecture inspired by COMETKIWI (Rei et al., 2022a). More specifically, we used the multi-task architecture combining the sentence-level target and the binary word-level targets. However, we did not pretrain on HTER scores or Metrics data, and we skipped the few-shot language adaptation and language-specific tuning of task weights. The architecture of the baseline model is shown in Figure 2. The list of hyperparameters and their corresponding values can be found in appendix A.

[11] The gold data was processed to remove identical segments that correspond to the same span but have different error categories, but it preserved any partially overlapping segments that correspond to different error categories and/or severities.

[12] The link to evaluation scripts can be found at: https://github.com/WMT-QE-Task/qe-eval-scripts/blob/main/wmt23/

[13] https://wmt-qe-task.github.io/subtasks/task1/

Systems	Precision	Recall	F1-score
System A	$\frac{1*7+1*28+0.5*6}{7+28+13} = 0.79$	$\frac{1*7+1*28+0.5*6}{12+28+6} = 0.83$	0.81
System B	$\frac{0.5*12+1*28+0.5*6}{12+28+6} = 0.80$	$\frac{1*12+1*28+0.5*6}{12+28+6} = 0.80$	0.80

Table 3: Example of Precision and Recall computations for each annotation in the example of Figure 1.

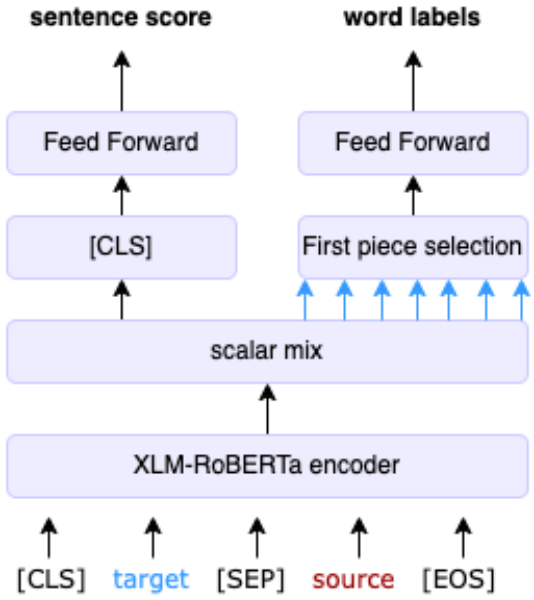

Figure 2: Baseline model for Task1 word level. Figure adapted from (Rei et al., 2022a)

4.2 Task 2: fine-grained error detection

For **Task 2** we constructed a simple baseline by using the same model used for Task 1 word-level, and post-process the predictions as follows:

- Detokenize the sentence
- Annotate continuous BAD tokens as a single text span
- Assume all errors are major

For all models, a large XLM-RoBERTa pre-trained encoder was used, without additional language tuning. The specific hyperparameters used are presented in Table 11.

5 Participants

Table 4 lists teams who officially took part to the QE shared task this year. In the remaining of this section, we report a brief system description gathered from each participant. For each team, we indicate the task(s) and sub-task(s) (*i.e.* language-pair(s)) they participated into.

Bering Lab (T1-SL; En-De, Zh-En): For each language pair, the team used an ensemble of the best three models from a pool of 10 models jointly trained for the word and sentence level tasks using a novel relative ranking loss function and Adversarial Weight Perturbation (AWP) to improve the robustness of the model. Using no additional pseudo-generated data, they pre-train the models using publicly available data from the previous WMT conferences that were augmented using the TER tool to generate binary word tags. They then fine-tuned 10 separate models on the labelled data from the WMT 2022 QE task randomly split into 10 folds. The models are fine-tuned in two steps. In the first step, the models are fine-tuned without AWP using the same objective as the pre-training step. Then, the best checkpoint from the first step is selected and tuned on the same objective, but with AWP. For the final submission they ensemble (average) the z-normalized scores from the top three models to get the final predictions.

(T1-WL; En-De, Zh-En): For each language pair, they use an ensemble of five models jointly trained for the word and sentence level tasks using a novel relative ranking loss function. Using no additional pseudo-generated data, they pre-train the models using publicly available data from the previous WMT conferences that were augmented using the TER tool to include word tags. They then split the labelled data from the WMT 2022 QE task into 20 folds and chose the best combination of five folds based on the minimum mean of the Kolmogorov-Smirnov goodness-of-fit scores between each validation set. Using these 5 folds, they fine-tune 5 final models using the same objective as the pre-training step. For the final prediction, the team chose the max score from each model for each token to get the final predictions.

NJUNLP (T1 & T2; En-De): Inspired by Direc-

tQE (Cui et al., 2021) and CLQE (Geng et al., 2023b), NJUNLP submission continues exploring pseudo data methods for QE. They generate pseudo MQM data using parallel data from the WMT translation task. Specifically, they replace the reference tokens with these tokens sampled from translation models. To simulate translation errors with different severities, they sample tokens with lower generation probabilities for worse errors. They pre-train the XLMR large model on pseudo MQM data, then fine-tune it on real QE data (including PE data). At both stages, they jointly learn sentence-level scores (MSE loss and margin ranking loss) and word-level tags (cross-entropy loss). For Task 1, the QE model outputs the sentence scores and the 'OK' probability of each token.

For Task 2, they set different thresholds for the 'OK' probability to predict fine-grained severity. They regard consecutive 'BAD' tokens as a whole span and take the worse severity of each token as the result. They train different models with different parallel data and ensemble their results as the final submission.

HW-TSC (T1-SL; En-De, Zh-En, En-Mr, En-Hi, En-Ta, En-Te, En-Gu): HW-TSC uses CrossQE, the same model as the one reported in (Tao et al., 2022), which consists of a multilingual base model and a task-specific downstream layer. The input is the concatenation of the source and the translated sentences. To enhance the performance, they finetuned and ensembled multiple base models using multilingual encoders such as XLM-RoBERTa, InfoXLM and RemBERT as well as a CometKiwi model. Moreover, they introduce a new corruption-based data augmentation method, which generates deletion, substitution and insertion errors in the original translation and uses a reference-based QE model to obtain pseudo scores.

(T2; all): For Task 2 they they convert the original word-level binary classification to a 3-way classification to adapt to Task 2 severities (no-error, minor, major). They then use a multitasking Comet model based on CometKiwi (Rei et al., 2023) which combines sentence scores and word-level tags using a weighted loss function. They set the weight of the sentence score sub-module to 0. They use InfoXLM-large and XLM-RoBERTa-large as the pre-trained encoders used during training and train on different data subsets for each LP. They finally use CometKiwi-da and continue to train a model based on CometKiwi-da. They finally combine the results over five checkpoints using the union of the predicted spans, which out-performed token-level majority voting.

KUNMT (T2; En-De, Zh-En): KUNMT proposes the use of different models to decompose tasks and post-editing with a large language model. In the process of error determination, span extraction, and severity assessment for each error span, distinct models were employed sequentially. The error determination model determines if an error exists in the sentence, and then the span assessment model explores the parts of the sentence where the error exists. For the spans where the error exists, the severity evaluation model evaluates whether the severity of the error is minor or major. All models were built upon XLM-RoBERTa-large, with some incorporating prompt-based learning. Results were subsequently calibrated using a large language model and tailored prompt engineering for the specific task.

Unbabel-IST (T1 & T2; all): the submission for Task 1 (word-level and sentence-level) follows their work from last year (Rei et al., 2022b). The major difference is the inclusion of the data from this year (e.g. sentence-level DA's for En-Te, En-Hi, En-Gu, En-Ta) and scaling the size of the pretrained encoder from InfoXLM to XLM-R XL and XXL (XXL was only used for sentence-level). They ensemble multiple checkpoints for the sentence-level subtask, using a weighted averaging of the predicted scores, optimised by LP.

For Task 2 they experimented with word-level models from Task 1 with GPT-4 prompts and with XCOMET (Guerreiro et al., 2023b). Their primary submission uses XCOMET which stands for eXplainable COMET. This model is trained with references to perform regression and error span identification. During inference the model can be used without refer-

ences, yet, for this task they found that using pseudo-references yields better performance if used with a simple heuristic where they first use a sentence-level QE system trained for Task 1 to evaluate the pseudo-reference. If the pseudo-reference is of high-quality, they give more weight to it otherwise, they give more weight to the source.

IOL Research (T1-SL; all): The IOL team experimented with several pretrained language models with extra modules to predict sentence level score and word tags including mBERT, XLM-RoBERTa-large, mDeberta, RemBert and InfoXLM. They first finetuned these models on DA and MQM scores data of QE and Metrics tasks in the previous years. Then, source text and its translation are fed into finetuned models added with extra modules for both sentence and word-level tasks. For sentence level, they separate embeddings of source text and translation of each layer in transformer models, and make a weighted sum among different layers for source and translation. Then the weighted embeddings of source and translation are concatenated and fed into a two-layer deep neural network to get score prediction with mean squared error (MSE) loss.

(T1-WL; all): For the word-level subtask, they use BiLSTM layer or one-layer DNN to do tag prediction on each token of translation with cross-entropy loss. The best checkpoint of each model is chosen by determining which checkpoint is best with respect to either Spearman correlation coefficient or MCC score, after training for three (3) epochs. The model of each language pair is tuned individually. The final result for each language pair is predicted by a weighted ensemble of different model checkpoints with LP-specific weights computed through weight searching using Optuna.

MMT (T1-SL; En-De, En-Mr, En-Hi, En-Ta, En-Te, En-Gu): For the studied language pairs, the MMT team enriched the training dataset through the application of eleven distinct data augmentation techniques, such as synonym substitution and back-translation, individually on the source sentence of each training instance. The results were generated using the best-performing model chosen from those trained on the corresponding augmented training datasets (in the case of English-German, the chosen model was trained on the augmented dataset created by applying the top four effective data augmentation techniques to each source sentence). The training methodology adheres to the COMET framework, with the foundational pre-trained model being XLM-RoBERTa-large.

SurreyAI (T1-SL; En-Mr, En-Hi, En-Ta, En-Te, En-Gu): The team proposes ensembleTQ as the main model, for which they train multiple multilingual QE models by fine-tuning pretrained language models (PTLMs) with autoencoder architecture. To that end they use the MonoTransQuest (Ranasinghe et al., 2020) architecture and report mean z-scores. The PTLMs that they combine in the ensemble are InfoXLM-large, XLMV-base and XLM-RoBERTa-large.

6 Results

In this section, we present and discuss the results of our shared task. Please note that for all the three sub-tasks we used statistical significance testing with $p = 0.05$.

6.1 Task 1

As we have seen in Task 1 description sentence-level submissions are evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient ρ along with the following secondary metrics: Pearson's correlation coefficient, r, and Kendall's τ. Nonetheless, the final ranking between systems is calculated using the primary metric only (Spearman's ρ). Statistical significance was computed using William's test.

For the word-level task, the submissions are ranked using the Matthews correlation coefficient (MCC). F1-scores are provided as complementary information only and statistical significance was computed using randomisation tests (Yeh, 2000) with Bonferroni correction (Abdi, 2007) for each language pair.

The results for Task 1 are described in Tables 5 and 6. Looking at the obtained scores, we can observe an overall improved performance for the sentence-level scores, compared to previous years. While it is hard to make direct comparisons since

the test-sets are new (and many language pairs are introduced for the first time), we can see that top performers obtain higher scores for En-Mr and Zh-En compared to the previous edition, and only for En-De we observe a relative drop (potentially justifiable by the introduction of more domains in the test set this year). Interestingly, for the word-level scores we observe higher correlations for the zero-shot tasks, as opposed to the ones where more training and development resources were made available.

We observe that especially for the sentence-level task all participants this year submitted ensembled predictions, with the ensemble size ranging from 3 to 12 models. We note that several teams combined models using different pre-trained encoders (HW-TSC, IOL Research, Surrey) and some participants focused their efforts on optimising the ensembled scores. Most notably, Bering Lab use a multi-step training where they select the best models on the first step, retrain with their proposed Adversarial Weight Perturbation method and then ensemble the top-3 models for the final submission. IOL research and Unbabel-IST also optimise the ensemble weights using optuna search.

We finally observe that following the trend of previous editions several participants experiment with training data augmentation techniques. Notably, most approaches this year focus on data augmentation that relates to the word-level or fine-grained annotations, either by computing TER-based word tags (Bering Lab), or by corrupting the target translations to generate pseudo-data with artificially generated error spans (NJUNLP, HW-TSC). For the latter, NJUNLP replace tokens and make use of the token distribution to approximate major versus minor errors (i.e, lower versus higher generation probabilities) and generate MQM-style annotations. Instead, HW-TSC propose to randomly corrupt the target (where corruption corresponds to insertion, deletion or replacement of a token) and use a heuristic score of the corrupted target to approximate a DA annotation style.

Best performers A total of seven teams participated in the **sentence-level sub-task**, yet only Unbabel-IST and IOL Research participated for all language pairs (including the zero-shot language pair, *He-En*), with Unbabel winning in the multilingual setting. However, for the individual language pairs, we observe different teams ranking at the top for different language pairs. Specifically, HW-TSC ranks at the top for all Indic language pairs, sharing the win with Unbabel-IST for En-Mr, En-Hi and En-Gu. On the MQM annotations, Unbabel-IST won the Zh-En and He-En language pairs, while IOL-Research and NJUNLP ranked top for En-De.

A total of four teams participated in the **word-level sub-task**, and similarly to the sentence-level only Unbabel-IST and IOL Research participated for all language pairs (including both zero-shot language pairs: *He-En* and *En-Fa*). NJUNLP won the task for the En-De language pair while Unbabel-IST ranked at the top for Zh-En, He-En, En-Mr and the multilingual task. IOL Research tied at the top for En-Fa.

We observe that while submissions consist of a mix of monolingual and multilingual submissions, and participants adopted a set of different strategies to design their architectures and tuning process, the top-ranking participants do share some common methodological choices. Specifically, all aforementioned participants tune their models in a multitasking setup, taking advantage of not only the sentence-level scores but also the word-level

quality tags. This inferred alignment between fine-grained quality annotations and overall quality at the segment level seems to be a promising direction for further improvements in quality estimation.

6.2 Task 2

For Task 2, the submissions are ranked using the F1-score, computed at character level for the annotated error spans, as described in Section 3.2. Precision and Recall scores are also provided as complementary information to help contextualise the performance observed. Statistical significance was computed using randomisation tests (Yeh, 2000) with Bonferroni correction (Abdi, 2007) for each language pair. The results for Task 2 are described in Table 7.

For this subtask we also had participants using pretrained large language models to enhance their submissions. Both KUNMT and Unbabel-IST (for the complementary submission of the latter) used GPT-4 with prompts tailored to fine-grained error span detection. KUNMT use an approach where they combine two prompts in a chain-of-thought manner, asking the model to act as an expert that either:

- Acts as an expert annotator that evaluates the translation and annotates error spans and severities (following the task instructions); or
- Acts as annotation validator and edits previous annotations or marks them as good.

We provide the full prompts in the Appendix E. In turn, Unbabel considers GPT4 both for the word level part of Task 1 and for Task 2, using prompts inspired by (Fernandes et al., 2023).

Aside from the use of LLMs, there are two main approaches in participating submissions: *i*) Participants who extended the word-level approach to obtain fine-grained error spans (HW-TSC, NJUNLP);

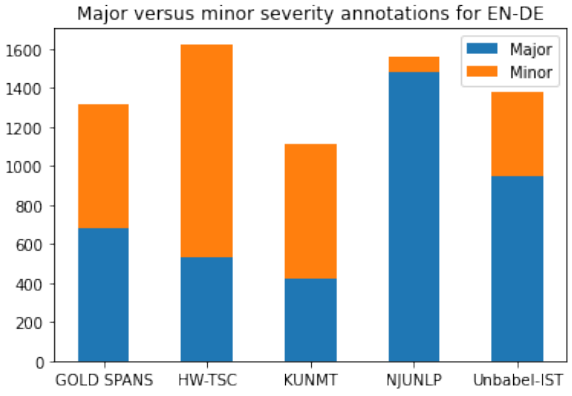

Figure 3: Balance between major and minor errors for each team and the original annotation (first bar).

and *ii*) participants who designed a methodology directly targeting error-spans (KUNMT, Unbabel-IST). To expand the word-level approach, NJUNLP maintain the binary OK/BAD labels and tune different thresholds to decide the severity of the BAD tags. They resolve severity inconsistencies over spans by taking the worst severity. Instead, HW-TSC convert the binary task to a 3-way classification ([OK, MINOR, MAJOR]) and tune on the Task 2 data. On the other hand, in their main approach, Unbabel-IST depart from the word-level approach and tune XCOMET directly on error span annotations, in a multitask setting (predicting both overall sentence score, and severities over spans).

Analysing the results, we can observe that with the exception of KUNMT, most submissions obtain higher *Recall* scores compared to *Precision*. Moreover, if we look at the distribution of identified error severities for e.g. En-De (see Figure 3) we can also observe a difference in the severity proportions as NJUNLP and Unbabel-IST identify mostly "major" errors and obtain better performance compared to KUNMT and HW-TSC that predict less skewed severities, with proportions closer to the gold data.

Best performers. Four teams participated in Task 2, IST-Unbabel, HW-TSC, KUNMT and NJUNLP, with only Unbabel-IST and HW-TSC participating in all tasks. NJUNLP ranked first for the En-De language pair while Unbabel-IST ranked first for the rest, including the multilingual track. We note that both top-ranking participants are using ensemble approaches as well as enhancing their approaches with pseudo-data (pseudo-references in the case of Unbabel-IST and pseudo-MQM scores in the case of NJUNLP).

7 Discussion

In what follows, we discuss the main findings of this year's shared task based on the goals we had previously identified for it.

Granularity of quality annotations We note that while performance for the sentence-level quality scores is better, the finer-grained annotations are also contributing towards these improvements. Indeed, while in comparison participants achieve lower performance for the fine-grained and word-level tasks, **most of the top-ranking submissions across tasks constitute multi-task approaches**, that combined information from the finer-grained annotations and the sentence level scores.

Moreover, comparing the F1-scores between the word-level Task 1 and Task 2, while F1-scores for Task 2 are somewhat lower, considering the additional complexity of considering error severities and multiple spans, the performance seems promising. To further encourage future participation and improved performance we aim to focus on extending MQM annotations for the next iterations, but also revising the error severity definition to potentially include '*critical*' errors.

Zero shot predictions We observe that performance for the zero-shot language pairs, He-En and En-Fa was not hampered by the lack of training and development resources. While fewer participants submitted predictions for these languages, their performance was on par with other language pairs. For for the word-level task, scores were actually higher than those observed for other language pairs. Looking closer at the approach adopted by the participants in these tasks, we can see that besides relying on multi-lingual encoders no additional data was used to train for these languages, across tasks. These findings are encouraging towards annotating a wider range of language pairs (maintaining the emphasis on low and medium source languages) to test on for the upcoming editions, even when training resources are scarce.

Hallucinations We report the hallucination detection results in Table 9. Overall, the results indicate that good-quality QE models are capable of detecting hallucinations very satisfactorily. Some submissions, in fact, obtain perfect or near-perfect results for some language pairs, which indicates that they are able to appropriately penalise the severity of hallucination errors. Not only that, but they can

Intelligente Pflege-Bett / Smart-**Oscillation: Bett-Bett-Bett-Bett-Bett-Bett-Bett** mit technischer Ausstattung einschließlich Sensoren und Notifizierungsfunktionen sind als "intelligente" oder "intelligente" Bett-Bett bekannt.

Table 10: Examples of hallucinations not flagged in the bottom k of the respective language pair by the best systems in Task 1 Sentence-level.

also distinguish the hallucinations from other translations whose quality may not necessarily be high. This is a property that was not observed in previous iterations of QE models (Amrhein and Sennrich, 2022; Raunak et al., 2022), in particular those that were based on dual encoding of the source and the translation (e.g., COMET-QE (Rei et al., 2020)).

Nevertheless, even the top-performing QE systems, including the winning submissions, may struggle with localised critical errors such as oscillations. We show two such examples in Table 10. In fact, although most pathological hallucinations are detected, some egregious examples have not been detected by both the IOL Research and Unbabel-IST systems (e.g., a he-en translation that contains 70 hallucinated <unk> tokens, and a zh-en translation that contains the oscillation "Tropical and Sub-Tropical Plains and Plains, Tropical and Sub-Tropical Plains and Plains, Tropical and Sub-Tropical High Plains, Sub-Tropical Plains and Sub-Tropical Plains, Sub-Tropical Plains and Sub-Tropical Plains").

One hypothesis for this undesirable behavior is that such samples are out-of-distribution for the QE systems. As such, augmenting the training sets with examples of such hallucinations (e.g., as done in XCOMET (Guerreiro et al., 2023b)) may be a straightforward yet effective approach for correcting this behavior.

8 Conclusions

This year's edition of the QE Shared Task introduced a number of new elements: new low-resource language pairs (including two zero-shot ones), new test sets, and new fine-grained error detection task that we aspire to continue in future editions. It also introduced a mix of hallucinated data together with the original translations, allowing us to assess the robustness of submissions and detect failure patterns that will hopefully help develop more robust QE systems in the future.

The tasks attracted a steady number of participating teams and we believe the overall results are a great reflection of the evolution of the QE field. We note that the gold labels and best submissions to all tasks are made available for those interested in further analysing the results. We aspire for the future editions to continue the efforts set in this and previous years and expand the resources and coverage of QE, while further exploring recent and more challenging subtasks such as fine-grained QE and explainable QE.

9 Ethical Considerations

MQM and DA annotations in this paper are done by professional translators. They are all paid at professional rates.

Organisers from Unbabel and University of Surrey have submitted to this task without using prior access to test sets nor using any insider information.

A Hyper-parameters of pre-trained baseline models for Task 1 Quality Estimation

Hyper-parameter	**T1 Sentence-level** COMET-QE	**T1 Word-level** COMETKIWI
Encoder Model	XLM-RoBERTa (large)	XLM-RoBERTa (large)
Optimizer	Adam (default parameters)	Adam (default parameters)
n frozen epochs	0.3	0.3
Keep embeddings frozen	True	True
Learning rate	3e-05 and 1e-05	1e-06 and 1e-05
Batch size	4	4
Loss function	MSE	MSE and CE ($\epsilon = 1.0$)
Dropout	0.15	0.1
FP precision	32	32
Feed-Forward hidden units	[2048, 1024]	[2048, 1024]
Word weights	–	[0.3, 0.7]
Feed-Forward activation	Tanh	–

Table 11: Hyper-parameters of both the COMET-QE and the CometKiwi models used as baselines for Task 1 Quality Estimation.

B Official Results of the WMT23 Quality Estimation Task 1 Sentence-level

Tables 12, 13, 14, 15, 16, 17, 18, 19 and 20 show the results for all language pairs and the multilingual variants, ranking participating systems best to worst using Spearman correlation as primary key for each of these cases.

Model	**Spearman**	Pearson	Kendall
Unbabel-IST •	0.594	0.580	0.438
IOL Research	0.556	0.513	0.407
BASELINE	0.372	0.308	0.265

Table 12: Official results of the WMT23 Quality Estimation Task 1 Sentence-level **Multilingual** (average over all language pairs). Teams marked with "•" are the winners, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey.

E GPT-4 prompts for Task 2

We add below the prompts used by KUNMT team with GPT4 for Task 2.

Expert annotator prompt:

You are an expert in the Fine-grained error span detection task. The goal of this task is to predict the word-level translation error spans. you will be asked to predict both the error span (start and end indices) as well as the error severity (major or minor) for each segment. There can be multiple error spans, and you must indicate the severity of the error for the spans that exist. If no errors exist in the translation, the error span is (-1,-1) and the error severity is no-error.

Expert validator prompt:

Review this result by checking the work done by the other workers. If the work was done correctly, mark it as "GOOD"; if there were any errors, re-annotate the Error Span and Error Severity. To avoid

inconsistencies, we expect the indices of the errors spans to correspond to characters in the target string before tokenisation, i.e., the target string that will be provided as test data.'

Findings of the Word-Level AutoCompletion Shared Task in WMT 2023*

Abstract

This paper presents the overview of the second Word-Level autocompletion (WLAC) shared task for computer-aided translation, which aims to automatically complete a target word given a translation context including a human typed character sequence. We largely adhere to the settings of the previous round of the shared task, but with two main differences: 1) The typed character sequence is obtained from the typing process of human translators to demonstrate system performance under real-world scenarios when preparing some type of testing examples; 2) We conduct a thorough analysis on the results of the submitted systems from three perspectives. From the experimental results, we observe that translation tasks are helpful to improve the performance of WLAC models. Additionally, our further analysis shows that the semantic error accounts for a significant portion of all errors, and thus it would be promising to take this type of errors into account in future.

1 Introduction

Computer-aided translation (CAT) helps human translators produce high-quality translations with the assistance of machine translation systems (Koehn et al., 2003; Vaswani et al., 2017), and it has witnessed a lot of attention during the past decades (Bowker, 2002; Koehn, 2009; Foster et al., 1997; Langlais et al., 2000; Barrachina et al., 2009; Alabau et al., 2014; Knowles and Koehn, 2016; Santy et al., 2019; Huang et al., 2021). Among all the tasks in CAT, Word-Level autocompletion (WLAC) is one of the most fundamental tasks and its goal is to autocomplete a word when a human translator types a sequence of characters (Huang et al., 2015; Li et al., 2021), in order to accelerate the editing process for human translators under CAT settings. To facilitate the research in WLAC, the first WLAC shared task was held in WMT 2022 (Casacuberta et al., 2022; Yang et al., 2022; Ángel Navarro et al., 2022; Moslem et al., 2022; Ailem et al., 2022). This year, we continue holding the second edition of WLAC shared task in WMT 2023.

In this paper, we summarize the overview of the WLAC shared task in WMT 2023, which is named by WLAC 2023 for brevity, including data preparation process, submitted systems and their evaluation results. Specifically, WLAC 2023 involves two language pairs, i.e. Chinese-English and German-English, and contains four directional sub-tasks in total, similar to WLAC 2022 shared task. For training data preparation, we follow the common practice of leveraging a bilingual corpus for simulation. For test data preparation, however, there is one important difference in this year to make the test data more similar to realistic scenarios: for some testing examples (see §2.2), their typed character sequences are obtained from the typing process of human translators.

We have received twenty-one submissions in total from four teams in WLAC 2023. We evaluate all these submissions and present their overall evaluation results. In particular, we conduct a thorough analysis of submitted systems to better understand the challenges and difficulties emerged in WLAC tasks. The analysis of these systems is investigated according to three perspectives which include the frequency of target words, the size of context, as well as the human defined error types. From all the perspectives, we observe some insights which might be useful for further improvement on WLAC in future. In summary, our main findings are highlighted as follows:

1. Through effective use of translation models, it is able to substantially benefit the WLAC models in terms of accuracy.

2. Among all type of errors, the semantic error

* The authors are listed alphabetically except the first author.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 654–662
December 6–7, 2023.

makes up the majority of error cases, where predicted words are semantically deviated from the ground-truth words.

3. It is possible to directly use large language models (LLMs) for WLAC tasks, but the results show that currently LLMs can not effectively handle WLAC without fine-tuning.

2 Task Description and Data Preparation

2.1 Task Definition

WLAC tasks aim to auto-complete a target word for the CAT process. The definition of WLAC is as follows: given a source sequence x, translation context $c = (c_l, c_r)$, where c_l and c_r are left and right side context respectively, and a character-level typed sequence s by human translators, WLAC aims to predict the target word w with s as its prefix, which should be the most appropriate to be placed between c_l and c_r (Huang et al., 2015; Li et al., 2021). Formally, we expect to model the relationship following the below equation:

$$w = f(x, s, c_l, c_r) \quad (1)$$

More generally, the right or left side context could be empty in real-world CAT systems. Consequently, there are four types of situations should be considered in WLAC tasks:

1. zero-context: both c_l and c_r are empty;
2. suffix: c_l is empty while c_r is non empty;
3. prefix: c_l is non empty while c_r is empty;
4. bi-context: both c_l and c_r are non empty.

	EN-DE	EN-ZH
Sentence Pairs	4,465,840	15,886,041
Words (src/tgt)	120M/114M	441M/395M

Table 1: The statistical description of the total number of sentence pairs and the scale of tokenized words on English ⇔ German and English ⇔ Chinese language pairs.

2.2 Data Preparation

We mainly follow the previous edition settings for data preparation, which includes two language pairs, i.e. English ⇔ Chinese and English ⇔ German. Both translation directions are considered in the evaluation, resulting in four directional tasks.

Training Data Following previous edition settings, we employ simulated training data $\langle x, s, c, w \rangle$ for this year WLAC. The construction of which follows the algorithm proposed by Li et al. (2021) [1]. The reason of such a simulation is to compensate for the limited size of manually annotated training data.

Specifically, for English ⇔ German language pair, we use the WMT14 EN-DE training dataset preprocessed by Stanford NLP Group [2], which is about 4.5 million sentence pairs; For English ⇔ Chinese pair, we leverage UN Parallel Corpus dataset [3] from WMT17, which consists of 15 million sentence pairs. Moses tokenizer [4] is applied to both English and German sentences while Jieba [5] is used to segment Chinese sentences. The detailed statistical description of the datasets is shown in Table 1.

For a fair comparison, only the above-mentioned corpus is allowed to be employed for bilingual training. However, there is no limitation for any monolingual data usage and even for pre-trained language models (Devlin et al., 2018) or large language models such as ChatGPT and Llama (Touvron et al., 2023).

Testing Data Similar to the data preparation in WLAC 2022, testing data in this year consists of two types of datasets as well. **Type I** is the conventional simulation on bilingual data which follows the same construction rules as the training data; **Type II** testing data is obtained from the real-world post-editing scenario. To alleviate any information leakage about the testing sets, the bilingual dataset and post-editing data are created by a third-party company [6] to guarantee that both data are not included in the training data.

In details, to create the testing examples for Type II testing set, we focus on the words that the translators had modified and then sample their context according to four types. [7] In particular, unlike WLAC 2022 where the typed sequence is randomly sam-

[1] The scripts for simulation is available at https://github.com/lemaoliu/WLAC.

[2] https://nlp.stanford.edu/projects/nmt/data

[3] https://conferences.unite.un.org/UNCorpus/Home/DownloadOverview

[4] https://github.com/moses-smt/mosesdecoder

[5] https://github.com/fxsjy/jieba

[6] We paid about 10,000 dollars to obtain the test data from the third-party company.

[7] Since the sentences from post-editing naturally belong to bi-context type, we need to obtain all types of examples via randomly sampling context.

Date Type	ZH⇒EN	EN⇒ZH	DE⇒EN	EN⇒DE
Sentence Pairs				
Type I	11341	11430	9653	9367
Type II	5044	5173	4910	5172
Overall	16385	16603	14539	14564
Averaged Length (src/tgt)				
Type I	28.88/4.71	31.88/4.46	28.73/4.47	29.18/4.43
Type II	32.29/5.71	35.66/5.42	32.93/5.46	33.61/5.24
Overall	29.16/4.85	32.22/4.58	29.19/4.59	29.72/4.53

Table 2: The total number of testing examples for both Type I and II cases over four language pair directions. A/B denotes that A is the averaged number of source words in the source sentences and B is the averaged number of target words in the context.

Data Type	ZH⇒EN	EN⇒ZH	DE⇒EN	EN⇒DE
Bi-context				
Type I	2489	2514	2081	2021
Type II	1107	1139	1060	1117
Overall	3596	3653	3141	3138
Prefix				
Type I	3884	3902	3416	3315
Type II	1729	1766	1739	1830
Overall	5613	5668	5155	5145
Suffix				
Type I	2499	2534	2098	2033
Type II	1113	1147	1066	1123
Overall	3612	3681	3164	3156
Zero-Context				
Type I	2466	2479	2058	1997
Type II	1098	1122	1046	1103
Overall	3564	3601	3104	3100

Table 3: The number of testing examples on four types of context cases for each sub-tasks.

pled according to target words, in WLAC 2023 the typed sequences for Type II dataset are obtained according to the typing process of human translators. This makes examples in Type II data more realistic than those in WLAC 2022.

Finally, when generating testing examples from the parallel sentences and post-edited sentences, we increase the proportion of *Prefix* type this year because the *Prefix* context type is more likely to match the popular left-to-right interactive translation systems. The statistics of sentence pairs are shown on Table 2 and the statistics of the different context types are shown on Table 3.

3 Experimental Setting

3.1 Evaluation Metric

According to the findings from WLAC 2022 (Casacuberta et al., 2022), the automatic evaluation result is highly consistent with the human evaluation result on the same dataset. Hence, in this year, we only employ the automatic evaluation for the submitted systems. Specifically, we use accuracy as the automatic evaluation metric (Li et al., 2021) to demonstrate the performance of all submitted systems:

$$acc = \frac{N_{\text{match}}}{N} \quad (2)$$

where N_{match} is the total number of correctly predicted words and N is the total number of all testing samples.

3.2 Submitted Systems

We received 21 submissions from 4 teams. We briefly summarize their approaches below.

SJTU-MTLAB The SJTU-MTLAB participates in all language directions. They submitted both word-level model and BPE-level model and their BPE-level model performs better (Chen and Wang, 2023). The BPE-level model is based on the Transformer architecture with encoder and decoder, where the encoder take the source sentence and all context as input and the decoder is responsible for generating the target word. They also introduce another decoder to generate the full target sentence, and jointly train the full model with WLAC task and machine translation task. The translation decoder is discarded during inference to maintain a reasonable inference cost. For more details about this system, it can be found in Chen et al. (2023).

Systems	ZH-EN	EN-ZH	EN-DE	DE-EN
Traditional Supervised Method				
SJTU-MTLAB	56.93	61.16	67.27	68.16
HW-TSC	56.40	57.80	66.42	68.10
PRHLT/sys1	-	-	37.05	39.98
PRHLT/sys2	-	-	37.38	43.56
Few-Shot Method				
KnowComp/0-shot	9.82	-	9.72	7.53
KnowComp/1-shot	21.43	-	14.96	15.34
KnowComp/5-shot	27.74	-	21.98	22.95

Table 4: Official evaluation results for all submitted systems. The score is reported in accuracy.

HW-TSC The Huawei Translation Services Center (HW-TSC) participates in all language directions. They model the WLAC task in the BPE level and iteratively generates a subword to compose the prediction word. [8] Specifically, they employ an encoder-decoder architecture, where the encoder encodes the source sentence and the decoder takes as input the target side context. They first train a machine translation task as a baseline and then they fine-tune the baseline with WLAC data and BERT-style MLM data to get the final model.

KnowComp KnowComp group proposes a large language model (LLM) based system for this year's WLAC task. They first randomly sample in-context examples as prompts to obtain the row ChatGPT outputs and extract the final prediction by post-processing (Wu et al., 2023). Specifically, they provide the source sentence x and target sentence with a special token `[mask]` as a placeholder for x (i.e., $(c_l, \texttt{[mask]}, c_r)$), and let LLMs predict the word that should fill in the mask position. Since more than one word may be generated, they search for the first word that starts with the pre-typed sequence s as the final prediction. They evaluate the submitted systems in Chinese ⇒ English, German ⇒ English, and English ⇒ German directions.

PRHLT PRHLT group participates in English ⇔ German and German ⇔ English categories. Their submitted system is developed on a segment-based interactive machine translation (IMT) system (Ángel Navarro et al., 2023). It predicts the results by word correction task based on a sequence of segmented contexts. Moreover, to further enhance the system performance under zero-context situations, they developed a dictionary-based translation module for zero-context word completion. Additionally, they made a second submission which fine-tunes an LLM (mT5) (Xue et al., 2020) to adapt it to the WLAC task. To perform this fine-tuning they created a new parallel dataset in which source sentences are the concatenation of the original source sentences + left context + right context + typed sequence, and the target sentences are the autocompletions.

[8] HW-TSC team does not submit the system report this year, but it is told that the system is very similar to that used in WLAC 2022 by personal communication with the team members.

4 Experimental Result and Analysis

4.1 Evaluation Results

Overall result The overall evaluation results of all submissions are reported on Table 4. The performance of HW-TSC and SJTU-MTLAB are comparable, and both systems perform the best among all the submissions. Both HW-TSC and SJTU-MTLAB make use of the knowledge from machine translation, and the large gains indicate the effectiveness to incorporate WLAC task with machine translation task according to the experiments in the system report of Chen and Wang (2023). Furthermore, we can see that fine-tuning the large mT5 model (PRHLT/sys2) delivers substantial improvements over PRHLT/sys1. It is worth noting that the KnowCamp system does not involve re-training for WLAC tasks, and thereby it is unfair to compare it with other systems which are trained with the large scale of the supervised training data. Anyway, its evaluation result still shows that the large language model can not handle the WLAC task well without fine-tuning on the training data.

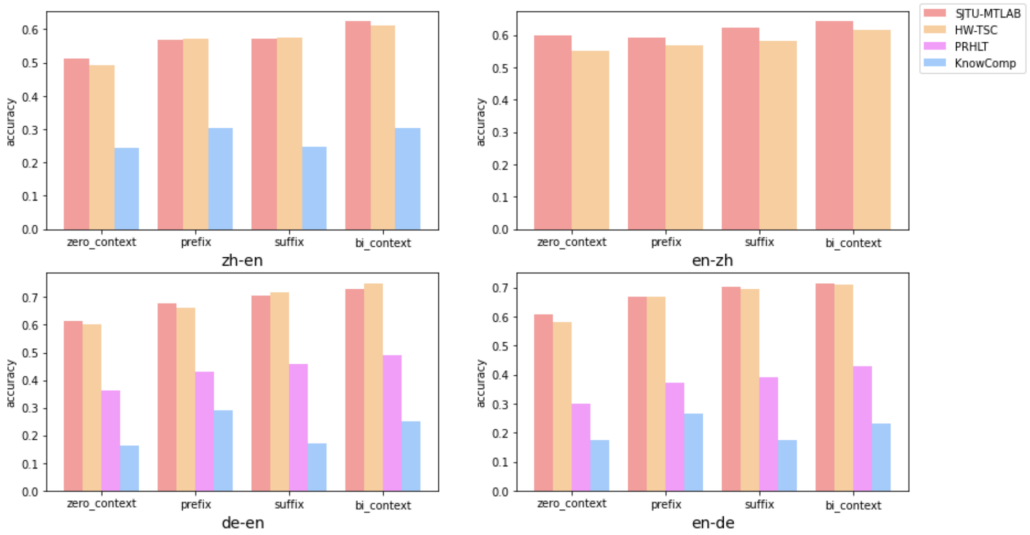

Figure 1: The accuracy of all language directions among different context types.

Result for context types In addition to the overall result, we also evaluate the submissions according to different context types of testing examples for all sub-tasks. The accuracy of four systems for four context types is illustrated in Figure 1, where only the best system from each team is evaluated. As we can see, for most systems, the accuracy increases from *zero_context* to *bi_context*. This indicates that more context can bring better performance. One exception is KnowComp, which does not perform well in *zero_context* and *suffix*. One of the possible reasons is that the large language models would find it difficult to make a correct prediction with little(*zero_context*) or unusual context type (the setting of *suffix* is contradictory with the left-to-right paradigm in large language models).

4.2 Analysis

In this subsection, we conduct a thorough analysis on the evaluation results from three perspectives. Since the analysis results are similar across different language directions, we conduct the following analysis on the de-en direction, because all the systems have submitted results on this direction.

Frequency The first perspective is to analyze the accuracy according to the word frequency. To this end, we divide testing examples into 16 bins according to the frequency of their ground-truth word: suppose an example is with a frequency of f ($f \geq 1$), then it is placed into the bin with id as the rounding number of $\min(16, \log f)$. Then we calculate the accuracy for each bin and the result is depicted in Figure 2. From the figure it is observed that it is very difficult to predict the rare words (i.e. their frequency is zero) in WLAC, which is in line with the task of neural machine translation (Luong et al., 2015). When the frequency is more than one, the accuracy is much higher than that for frequency of zero; however, the accuracy does not strictly increase as the frequency gets higher than one.

Context size The second perspective is to analyze the accuracy of each system according to the context size. The number of words in the left and right contexts indicate whether the context provides the sufficient information to predict the target word and thus the accuracy of each system might be influenced by the context size. Since different examples may have different length in the sentence, we group the examples into bins according to the relative context size defined by the ratio of the context size to the size of the source sentence. Then we measure the accuracy for each bin and the results for all systems are illustrated in Figure 3. As shown from this figure, for all the supervised systems the accuracy generally increases when the relative context size becomes larger. However, the KnowComp system seems to be insensitive to the context size. This fact may indicate that KnowComp does not make full use the context, which provides an explanation why KnowComp does not work well for WLAC.

Error Analysis In order to look deeper into the reason why the models make wrong prediction, we propose to manually analyze the errors made by each system, which is the third perspective. To this end, we first define three types of errors for each

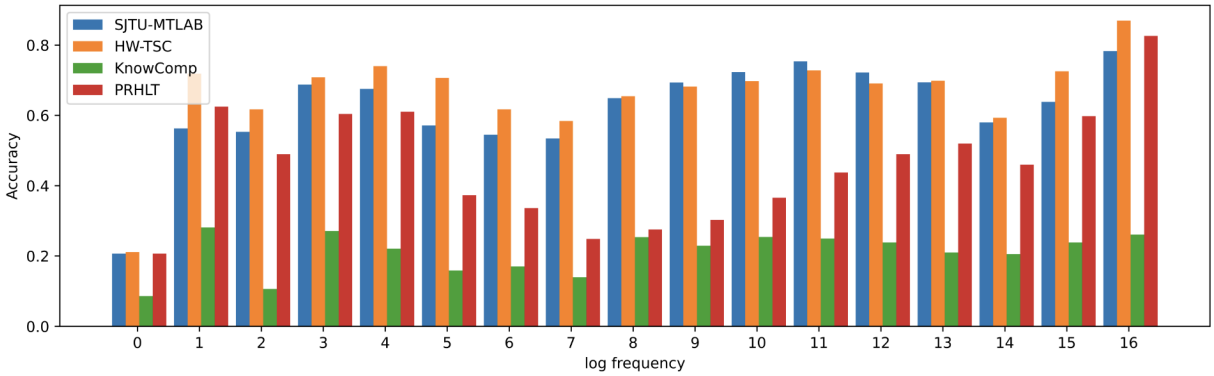

Figure 2: The accuracy of different bins organized according to the frequency of ground-truth target word. Each bin id corresponds to the rounding number of $\min(16, \log f)$ with f as the frequency of the target word.

incorret prediction. The first one is the *constraint error*, where the predicted word fails to meet the constraint of typed character sequence. There are two main reasons to this error: 1) the system does not use the hard constraint manner during inference; 2) the system uses the hard constraint during inferenct but still can not predict a word which satisfies the constraint due to some unusual typed character sequence. Another common type of errors is morphology error, where the prediction has similar semantics with ground truth but has different morphology. For example, the ground truth is *needs* while the prediction is *need*. We detect this type of error by *nltk.stem* [9] tool. The third error is called semantic error, where the predictions are completely deviated from the ground-truth words in semantic. To measure how much the prediction deviate from the ground truth, we use the fastText[10] tool to compute the semantic similarity of predictions and ground truths. We report the proportion of errors where the semantic similarity of prediction and label is less than 0.3.

The results for all systems are reported in Table 5. According to the constraint errors, the SJTU-MTLAB and HW-TSC can meet the constraint well, while the LLM based method, KnowComp, often fails to generate a proper word with given typed character sequence. After manually checking the results from all these systems, we find that both SJTU-MTLAB, PRHLT and KnowComp does not employ the hard constraint during inference and HW-TSC sometimes can not predict a word satisfying the constraint due to unusual typed sequences. In addition, according to the morphology error, as we can see from Table 5, there are still a non-negligible amount of predictions fall into this group, indicating the potential for further improvement. Finally, according to the semantic error, as reported in Table 5, most of the errors belongs to this group. This is the most critical error type, and we recommend reducing this part of the error is very promising to improve the overall performance.

4.3 Discussion on future direction

Through the overall results and analysis, we point out some possible direction of further improvement:

- Incorporating machine translation task. The SJTU-MTLAB and HW-TSC introduce machine translation into the WLAC task and show superior performance. This indicates the importance of adding translation knowledge into WLAC and we encourage more effective method to combine these two tasks.

- Improving large language models for WLAC. KnowComp employs the large language models through in-context learning for WLAC. Although its performance is not as good as other systems, it still exhibits potential because it does not leverage the large-scale supervised data for training. Indeed, simply fine-tuning the large mT5 model on the supervised data yields respectful results (see PRHLT/sys2). Therefore, it is promising to further improve LLMs by using of the supervised data.

- Alleviating the semantic error. The large amount of semantic error indicates that the current systems still fail to model the problem in many cases. We expect the development of more powerful models to push the SOTA forward by taking semantic error into account.

[9] https://www.nltk.org/api/nltk.stem.html
[10] https://fasttext.cc/

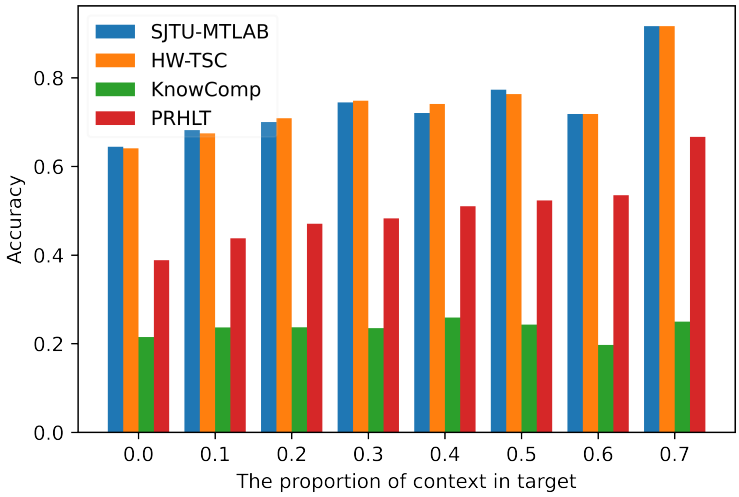

Figure 3: The accuracy of different bins organized according to the relative context size of each example. The relative context size is defined by the ratio of the size of left and right contexts to the size of the source side for each example.

Systems	Constraint	Morphology	Semantic
SJTU-MTLAB	4.12%	12.62%	57.69%
HW-TSC	1.89%	10.98%	56.28%
KnowComp	22.30%	6.77%	74.57%
PRHLT	7.18%	10.23%	59.85%

Table 5: The proportion of different types of error among constraint error, morphology error, and the semantic error respectively. The sum of each line does not equal to 1 because different types or error may share overlaps.

5 Conclusion

This paper presents the overview for the shared task of Word-level Auto-Completion, which is the key component of computer-aided translation. We describe the task definition, data preparation process, the submitted systems, evaluation metric and evaluation results of the systems. We have received twenty-one submissions from four participants this year. We report the evaluation results of all systems, conduct a thorough analysis on the prediction results of these systems and obtain some insightful findings. We hope that our findings can encourage the emerge of more powerful models and attract more researchers to participate the study of computer-aided translation.

Acknowledgements

We would like to appreciate the annotators for their creating test data on this shared task. In addition, we thank the participants for their contributions on this shared task.

Abstract

The WMT 2023 Terminology Shared Task investigates progress in machine translation of texts with specialized vocabulary. The participants were given the source text and segment-level terminology dictionaries for three language pairs: Chinese→English, English→Czech, and German→English. We evaluate 21 submissions from 7 teams on two main criteria: general translation quality and the effectiveness of translating specialized terminology. Systems took varied approaches — incorporating terminology at inference time or weakly supervised training that uses terminology access. While incorporating terminology dictionaries leads to improvement in the translation quality, incorporating an equal amount of information from the reference leads to similar results. This challenges the position of terminologies being the crux of meaning in translation, it can also be explained by inadequate metrics which are not terminology-centric.

1 Introduction

General-purpose machine translation models often show limitations when applied to specialized tasks, like translating specialized vocabulary. This gap is critical in medicine, science, and law, where language precision is paramount — medical inaccuracies, juridical misunderstandings, and technological malfunctions can lead to serious problems. The translation of technical terms is not a mere exercise in lexical fidelity — it supports effective communication in highly specialized fields. Terminology correctness and consistency has already been long in focus from the modelling (Dinu et al., 2019; Hasler et al., 2018), evaluation (Zouhar et al., 2020; ibn Alam et al., 2021; Semenov and Bojar, 2022) and translators' perspective (Cabré, 2010; Vargas-Sierra, 2011; Arcan et al., 2017).

We shed light into recent advancement in this area by assessing MT systems with segment-level terminology dictionaries. Alongside the general evaluation of translation quality, our shared task emphasizes the *effectiveness* terminology dictionaries. This task follows the latest efforts on evaluating progress in terminology-enhanced translation (Alam et al., 2021). While we are also concerned with the quality of the translation, we refocus on measuring the relative improvement of incorporating the terminology dictionary. Focusing on System A being overall better with terminologies than System B might obscure the fact that System A is already good without terminologies while the methods of System B improves. From research perspective, System B gives us more insight into how to more efficiently incorporate terminology dictionaries. Additionally, it disentangles the terminology-incorporation methods from the general MT methods.

(2023). **Base** is without any terminologies, **Proper** is real terminologies and **Random** are random but aligned phrases from source to the reference.

2 Task Description

We focus on how translation quality improves with the incorporation of segment-level terminology on German→English, English→Czech, and Chinese→English datasets. Participants are given source sentences along with a segment-level terminology dictionary (*Source* and *Hints* in Table 1). For the purposes of this study, we define terminology as low-frequency words or phrases that occur typically within a particular domain, such as computer science paper abstract. We scan the source and references for such phrases and provide this segment-level annotation, together with the source, to the participants in the form $X \rightarrow Y$ where X is a span from the source and Y is a span from the reference (*Proper* in Table 2).

Given that the participants are given a part of the reference, Y, this raises the following question: *Is the improvement in translation quality due to the information that a particular terminology X is translated as Y or merely because a part of the reference is leaked to the model?* To better attribute any performance gains, we therefore also test a different mode, where we give the participants "terminologies" where X' and Y' are still aligned spans and translations of each other, but sampled randomly. That is, they are treated as terminology but are, in fact, random phrases (*Random* in Table 2). For this reason, we ask the participants to carry out the translation in three distinct modes:

- **Base**: MT with no terminology dictionary.
- **Proper**: MT with a terminology dictionary. For example *"Sprachmodell" → "language model"*.
- **Random**: MT with randomly chosen, but correct, non-terminological translations. For example *"Hund" → "dog"*.

By comparing performance across these modes, we isolate the model's inherent translation ability and its ability to make use of the terminology.

3 Data

For MT training, the participants were restricted to only the parallel or monolingual datasets enumerated in the WMT general track (Kocmi et al., 2023).[2] The inclusion of pre-trained models was permitted, provided that such usage was explicitly declared. Any employment of terminology-specific datasets that were not part of the specified resources was expressly disallowed. For the terminology-targeted evaluation, we repurposed one dataset and created two new ones. From all of them, we provided 100 segments to the participants as a sanity-check development set. See examples for all language pairs in Table 2.

3.1 Chinese→English Test Data

Our Chinese→English translation test data is sourced from the BWB corpus (Jiang et al., 2023), which covers web novels annotated with, among others, terminologies. The BWB corpus comprises

[2] www2.statmt.org/wmt23/translation-task.html

X→Y	Count	X/Y Words	Terms
German→English	2963	22.2/22.6	3.8
English→Czech	3005	25.6/21.6	3.6
Chinese→English	2640	9.7/36.9	1.1

Table 3: Our test dataset size, average number of words per line and average number of terms per segment (equal between *Proper* and *Random*).

Term.	Prompt
Proper	Identify and annotate all terminology entities (consider only consecutive words) from source sentence and match them with the counterpart in the translated sentence.
Random	Identify and annotate as many as possible aligned words (consider only consecutive words) between source sentence and the translated sentence.

Prompt 1: The upper prompt formulation extracts proper terminology and the bottom extracts random terminology. See Prompt 2 (Appendix) for the full example with few-shot examples.

~3k sentences across six web novels. These annotations identify each named entity and concept in the sentences, highlighting their co-referred expressions. The average terminology count per line is 1.1 (Table 3). Examples of such terminology are in Table 2. Terminology often faces issues of mistranslation or contextually inconsistent translation. Additionally, MT quality declines when terminology is positioned as the subject due to the Chinese's subject-dropping nature.

3.2 English→Czech and German→English Test Data

For the next two language directions we created a new semi-automatically annotated corpus of terminologies. For English→Czech we used 3k sentence pairs from a dataset of NLP papers abstracts (Rosa and Zouhar, 2022). For German→English we used 3k sentence pairs from a dataset of medical paper abstracts (MuchMore Springer Bilingual Corpus). In both cases, the focus on academic texts was guided by the high occurrence of terminology in this domain (3.8 and 3.6, Table 3).

Automatic alignment tools usually have lower precision than linguists and linguists have lower recall and the collection is both time and budget consuming. Therefore, to extract the aligned terminology, we use human-machine collaboration. First, we use GPT-4 (OpenAI, 2023) to create aligned terminology pairs from source and references. We use two few-shot prompts to collect the raw alignments (Prompts 1 and 2). Then we ask linguists to validate these alignments and fix those that are incorrect (either missing terminology, wrong alignment or pairs that are not a terminology). For the Czech-English language pair, humans revised approximately 8% of GPT annotations. There is no modification to terminology in the German-English GPT annotations. Consultation with German linguist affirmed that no adjustments were necessary. Nonetheless, further examination is needed to fully assess GPT's proficiency in terminology alignment for German. This task was sponsored by Microsoft and we release both the pre- and post-alignment data for the further research of GPT capabilities.

4 Participants and System Descriptions

We received a total of 21 per-language submissions from 7 teams. We provide short descriptions of their systems, based on the submitted details.

AdaptTerm (Moslem et al., 2023b). The terminology-enriched MT system builds on Moslem et al. (2023a); Haque et al. (2020). It consists of:

1. using an LLM to generate bilingual synthetic data based on the provided terminology;
2. fine-tuning a generic model, OPUS, with a mix of the terminology-based synthetic data generated by #1 and a randomly sampled portion of the original generic data; and
3. generating translations with the fine-tuned model from #2, and then fixing translations that do not include the required terms with an LLM.

Lingua Custodia (Liu, 2023). This submission includes all three language directions. They use two strategies to extract synthetic terminology from the training data. The first one relies on the invariable n-grams between the source and the target sentence, while the second one extracts parallel sentences that appear inside another training sample as one terminology item. Then, they train a Transformer-based model with annotated data using the extracted terminology, identical to Alam et al. (2021). In addition, after the text annotation, they further apply several annotated data filters to reduce some bias introduced by the automatic annotation. The final trained model can be used directly to translate a text with any new terminology.

OPUSCAT (Nieminen, 2023). A standard Transformer system is finetuned with parallel data where parts of the source sentences have been annotated with their corresponding translations in the target sentences, causing the system to learn to copy the annotated target parts from the source sentence into the target sentence. The translations are generated using a series of models, with different fine-tuned terminology models acting as backoff models to the base transformer model, in cases where the base transformer output does not contain the specified terminology.

UEDIN (Bogoychev and Chen, 2023). Their primary system, *twoshot*, is 2-shot decoding where we enforce terminology constraints via terminology hints in the source and if this does not work we use alignment-based methods to identify the mistranslated terminology word on the target side and penalize it, giving the decoder a chance to generate the hinted word. System *Tag* is decoding with terminology hints while *LLM* is an unconstrained contrastive system.

BJTU-LB (no description paper). They train the in-context learning ability of the model, and then concatenate the term translation pairs in front of the sentence to be translated as the context. The model can generate different translation results according to different contexts.

VARCO-MT (Park et al., 2023). The *ForceGen* is a Transformer-based model that is tailored to ensure the appearance of given terminology in the generated output. By modifying the input format and decoding process, it incorporates a copy mechanism on the source side, allowing it to copy the target terminology from the provided terminology pairs. During the generation process, it uses a force decoding technique, which compels the model to actively generate the target terminology as needed. The *TSSNMT* is a novel Transformer-based NMT model that uses a shared encoder to process both input text and terminology. The model then employs cross-attention mechanisms between the two encoder hidden states and passes them through a gate, enabling the model to autonomously decide which pieces of information (input or terminology) to focus on during translation.

Huawei. Did not submit system description. The translations are also on a subset not used for final evaluation. We include the results in the analysis sections in gray (Huawei) for completeness but urge the readers not to draw any comparisons to other systems.

5 Evaluation

Our evaluation is focused on: (1) general translation quality, (2) quality of translation of specific terminologies, and (3) efficiency in using segment-level terminology dictionaries.

Standard Metrics. Following recent trends in MT evaluation (Kocmi et al., 2021), we use ChrF (Popović, 2015) and COMET (Rei et al., 2020) for the general translation quality evaluation.[3] While the latter one is generally touted as more robust and correlated more with human judgement, in this case we are also concerned in exact match of n-grams, which is captured by ChrF.

Term Success Rate. In the terminology success rate we compare the machine-translated terms with their dictionary equivalents. One would be tempted to check for the presence of the reference terminology translation in the output by the regular expression match. However, this is sensitive to minor orthographic variants. Therefore, we use fuzzy search with threshold of 90% to scan for terminology matches, yielding a number between 0 (no terminology translated correctly) to 1 (all terminology translated correctly).

Term Consistency. This metric looks at whether technical terms are translated uniformly across the entire text corpus. We aim for high consistency, measured by the low occurrence of multiple translations for the same term within the text. We use the approach suggested by Semenov and Bojar (2022). Given the source sentences, outputs, and source terms assigned to each sentence, we firstly make word alignment for the source sentences and outputs, and extract the aligned translated terms for each source term occurrence. Then, we automatically choose the "pseudo-reference" terminology translations, based on which translation of which source term occurred in the text first. In the last step, we compare two sets –the real outputs and the pseudo-references for each term occurrence– by means of F_1 score on a scale of 0 (no consistent terminology) to 1 (all terminology translated consistently).

[3] ChrF uses the defaults from sacreBLEU (Post, 2018) and COMET is `wmt22-comet-da`.

System	ChrF De→En	ChrF En→Cs	ChrF Zh→En

Table 4: Averages of ChrF and COMET scores with *Proper* terminology dictionaries. The ⋆ marks best within each column (language) and metric.

5.1 Main Results (Table 4)

We begin the comparison using two standard metrics of MT quality in the case where *Proper* terminology dictionaries were provided. The choice of the best-performing system diverges based on the two metrics: *Lingua Custodia* is selected as the best by ChrF in two language directions, it ranks the same system on Zh→En as the second lowest-performing one. In contrast, COMET ranks *UEDIN$_{LLM}$* as the best across all three language directions. Given that this metric better captures human judgement (Freitag et al., 2022), this ranking is likely more close to the true quality.

5.2 Terminology Quality (Table 6)

The results are even more different when focusing solely on the correctness of the terminology. Overall, most systems translate 60%-70% of terminologies correctly. For terminology consistency, the most immediate outlier is *VARCO-MT$_{TSSNMT}$*, yielding impressive score of 0.971 on Chinese→English. Table 5 illustrates how even in the same document the terminology can be translated differently, which is undesired.

Source	Die Krankheit entwickelt sich bei Kindern und jungen Erwachsenen und folgt dem Muster der Blaschko-Linie.
MT	The condition develops during childhood and adolescence and follows the pattern of the blaschko line.
	...
Source	Ungefähr 95% aller Personen, die M. leprae ausgesetzt sind, entwickeln die Krankheit nicht.

5.3 Terminology Utility (Tables 7 and 8)

Previous investigations into the general translation and terminology translation quality did not reveal many differences between the systems. We now focus on the usefulness of the additional information and show the difference between *Base* and either *Proper* or *Random* terminology dictionaries in Table 7. Notably *AdaptTerm* and *Lingua Custodia* improve the most from their *Base* version. With an exception of *OPUS-CAT*, both ChrF and COMET

System	ChrF +Proper	ChrF +Random	$COMET_{22}^{DA}$ +Proper	$COMET_{22}^{DA}$ +Random	T. Consistency +Proper	T. Consistency +Random	T. Success Rate +Proper	T. Success Rate +Random

Huawei	0.2	0.9	-0.004	0.010	-0.010	0.042	0.033	-0.012

Table 7: Average difference in each metric between the *Base* and added dictionary (*Proper* or *Random*). All numbers are averages across all languages except for † which is Chinese→English only.

improves across all metrics when given any of the two dictionaries. This challenges the notion that the additional information supplied to the MT system needs to be terminology while in fact it can be any information that leaks from the reference. Focusing on a particular language pair in Table 8, there seems to be weak effect of lower variance when terminology dictionaries are provided.

System	$COMET_{22}^{DA}$ Zh→En Base	Proper	Random

6 Related Work

Similar to the previously shared task on translation using terminologies (Alam et al., 2021), our terminology hints are mined semi-automatically. We also extend this line of work by contrasting random and proper terminologies. The focus on terminologies in translation is an important one. Both Zouhar et al. (2020) and Semenov and Bojar (2022) show that the ordering of the system diverges when comparing performance on terminologies versus general performance.

Constrained Decoding. A simple paradigm for improving terminology translation is constrained decoding. Anderson et al. (2017) track constraint satisfaction using a finite-state machine. Hokamp and Liu (2017) reduce the time complexity to linear and Post and Vilar (2018) further improve on this.

Other approaches. Other than constrained decoding, several works have approached the problem by guiding the text generation model, including those that modify the token-level distribution using an external model (Stahlberg et al., 2017; Gulcehre et al., 2017; Chatterjee et al., 2017; Pascual et al., 2021), and those that incorporate constraints into the training process through additional annotations (Dinu et al., 2019; Bergmanis and Pinnis, 2021; Niehues, 2021, *inter alia*).

7 Conclusion

This iteration of machine translation with terminologies focused on evaluating the efficiency of using segment-level terminology dictionaries. I.e. it is not enough that the system performs well but it should also perform better when given this additional information. Indeed, the improvement between *Base* and *Proper* terminology enriched translations ranged across systems between 0 and 10 ChrF points. This helps isolate which terminology-enhancement methods are the most useful.

Limitations

The evaluation datasets are based on publicly-available data, which might have been leaked to the training of submitted systems, skewing the results. We further acknowledge that the comparisons in this work were not done using statistical testing.

Ethical Consideration

The work of both linguist working on the validation of GPT alignment was well-paid of around a twice to three times the minimal hourly wage in their respective countries. The annotated texts did not contain any sensitive or explicit passages.

Abstract

We present the results from the 9^{th} round of the WMT shared task on MT Automatic Post-Editing, which consists of automatically correcting the output of a "black-box" machine translation system by learning from human corrections. Like last year, the task focused on English→Marathi, with data coming from multiple domains (healthcare, tourism, and general/news). Despite the consistent task framework, this year's data proved to be extremely challenging. As a matter of fact, none of the official submissions from the participating teams succeeded in improving the quality of the already high-level initial translations (with baseline TER and BLEU scores of 26.6 and 70.66, respectively). Only one run, accepted as a "late" submission, achieved automatic evaluation scores that exceeded the baseline.

1 Introduction

This paper presents the results of the 9^{th} round of the WMT task on MT Automatic Post-Editing (APE). The task involves the automatic correction of the output generated by a "black-box" machine translation system by learning from human-revised machine-translated output supplied as training material. The overall task formulation (see Section 2) remained consistent with that of all previous rounds. In this formulation, the challenge revolves around fixing errors in English documents that have been automatically translated by a state-of-the-art, non-domain-adapted neural MT (NMT) system unknown to the participants. In continuity with last year's round, the evaluation focused on English→Marathi,[1] with training/dev/test data selected from a mix of domains, namely- healthcare, tourism, and general/news (see Section 3).

Three teams participated in the task by submitting a total of four runs for the final evaluation (see Section 4).[2] However, while only two out of the three participants were able to submit their runs on time, the one remaining submission arrived with a two-month delay. This led us to categorize it as a late (therefore, unofficial) submission for the sake of fairness to the other participants.

For all the teams, the task posed significant challenges primarily due to the high average quality of the initial translations slated for post-editing (26.6 TER / 70.66 BLEU / 79.78 chrF). This challenge was compounded by the substantial imbalance in distribution between near-perfect translations (approximately 40% of the total) and those necessitating extensive revisions (approximately 20%). As a consequence, none of the official runs was able to improve over the baseline in terms of the task's automatic evaluation metrics (Section 5.1), with the best run achieving results (27.73 TER / 69.03 BLEU / 78.64 chrF) that highlight a slight quality degradation compared to the original, untouched NMT outputs that represent our baseline. For the sake of completeness, we report that the late submission achieved a slight improvement over the baseline, attested by TER, BLEU, and chrF scores of 25.74, 71.27, and 80.41, respectively. The results computed by means of automatic evaluation metrics were also confirmed by our human evaluation based on direct assessment (Section 5.2).

2 Task Description

MT Automatic Post-Editing (APE) is the task of automatically correcting errors in a machine-translated text. As pointed out by (Chatterjee et al., 2015), from the application point of view, the task is motivated by its possible uses to:

- Enhance MT output by harnessing information that is not available to the decoder or by conducting deeper text analysis, which may

[1] Marathi is an Indo-Aryan language predominantly spoken by Marathi people in the Indian state of Maharashtra.

[2] A fourth participant withdrew the submitted run, which was affected by major errors in the generated outputs.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 672–681
December 6–7, 2023.

be prohibitively expensive during the decoding phase.

- Address systematic errors stemming from an MT system whose decoding process is inaccessible for focused modifications.
- Provide professional translators with improved MT output quality, thereby reducing the need for subsequent human post-editing.
- Tailor the output of a general-purpose MT system to align with the lexicon and style requirements of a specific application domain.

This 9^{th} round of the WMT APE shared task kept the same overall evaluation setting of the previous eight rounds. Specifically, the participating systems had to automatically correct the output of an unknown "black-box" MT system (a generic NMT system not adapted to the target domain) by learning from training data containing human revisions of translations produced by the same system. For the second year in a row, the selected language pair was English-Marathi (with Marathi as the target language for post-editing). Training, development and test data were drawn from the following three domains: healthcare, tourism, and general/news.

3 Data, Metrics, Baseline

3.1 Data

In continuity with last year, the selected language pair is English-Marathi. Marathi is one of the most spoken Indian languages, with approximately 83 million native speakers and 16 million speakers as a second/third language.[3] Marathi is a known agglutinative language and presents various challenges to machine translation compared to its other Indian counterparts (Khatri et al., 2021; Banerjee et al., 2021). Moreover, the English-Marathi language pair is considered low-resource compared to English-Hindi/Bengali/Malayalam (Ramesh et al., 2022), despite having more native speakers worldwide.

The **training** and **development** datasets supplied to the participants remain consistent with those employed in the 2022 iteration of the task. These datasets consist of 18,000 and 1,000 (*source*, *target*, *human post-edit*) triplets, wherein:

- The source (SRC) is an English sentence;
- The target (TGT) is a Marathi translation of the source produced by a generic, black-box NMT system unknown to participants. This multilingual NMT system (Ramesh et al., 2022) is based on the Transformer architecture (Vaswani et al., 2017) and is trained on a total of 49 million sentence pairs where the En-Mr parallel corpus is 4.5 million sentence pairs. This parallel data is generic and covers many domains, including the three domains covered by the APE 2023 test set, namely-healthcare, tourism/culture and general/news.
- The human post-edit (PE) is a manually revised version of the target, which was produced by native Marathi speakers.

We provide the same corpus of artificially generated data as additional training material from the last round. It consists of 2 million triplets derived from the *Anuvaad* en-mr parallel corpus.[4] The *Anuvaad* parallel corpus consists of data for 12 en-X language pairs, where X comprises 12 Indian languages, including Marathi. The English-Marathi data consists of 2.5 million parallel sentences. Specifically, the *source*, *target*, *post-edit* instances of this synthetic corpus are respectively obtained by combining: *i)* the original English source sentence from the *Anuvaad* corpus, *ii)* its automatic translation into Marathi,[5] *iii)* the original Marathi target sentence from the *Anuvaad* corpus.

Test data consisted of 1,000 (*source*, *target*) pairs, similar in nature to the corresponding elements in the train/dev sets (*i.e.,* same domains, same NMT system). The human post-edits of the target elements were left apart to measure APE systems' performance both with automatic metrics (TER, BLEU, chrF) and via human evaluation.

3.2 Metrics

The participating systems were evaluated both by means of automatic metrics and manually. Automatic evaluation (Section 5.1) was carried out after tokenizing the data with *sacremoses*[6], by computing the distance between the automatic post-edits produced by each system for the target elements of

[3] Ethnologue-2022 - Ethnologue has been an active research project since 1951 which maintains online archives of recognized languages list, and their statistics.

[4] https://github.com/project-anuvaad/anuvaad-parallel-corpus

[5] from IndicTrans En-X Model (Ramesh et al., 2022)

[6] https://pypi.org/project/sacremoses/

the test set, and the human corrections of the same test items.

The official systems' ranking is based on the average (case-sensitive) TER (Snover et al., 2006) calculated on the test set by using the TERcom[7] software: lower average TER scores correspond to higher ranks. As additional performance indicators, BLEU (Papineni et al., 2002) and chrF (Popović, 2015) were computed[8]. The human evaluation (Section 5.2) was conducted via source-based direct human assessment (Graham et al., 2013a).

3.3 Baseline

The official baseline results were the TER/BLEU/chrF scores calculated by comparing the raw MT output with human post-edits. This corresponds to the score achieved by a "*do-nothing*" APE system that leaves all the test targets unmodified.

4 Submissions

As shown in Table 1, this year, we received submissions from three teams, one of which submitted their run with a two-month delay that motivates its categorization as a late submission[9]. The main characteristics of the participating systems are summarized below.

Korea Advanced Institute of Science and Technology (kaistai). This team participated with a system inspired by the recent surge of large language models (LLMs) that have been successfully applied to a variety of language generation tasks. Their goal was to verify whether LLMs could perform the APE task through prompting. To this aim, they used gpt-3.5-turbo with specific prompts designed to generate either (a) post-edits or (b) post-edits along with the rationales behind them. While the results of preliminary evaluations based on COMET suggested the viability of the approach for medium-/high-resource language pairs, they also highlighted that the often radical changes produced by LLMs can potentially be penalized by more strict reference-based evaluations based on BLEU, TER, or chrF.

Korea University (KU_UPs). The participation of this team was centred on data filtering techniques. With a focus on removing potentially harmful material from a model training perspective, the proposed method concentrates on eliminating the two extremes of the training data distribution: the (near-)perfect MT outputs on one side, and those that require complete rewriting on the other. According to preliminary experiments carried out on previous APE datasets (WMT2020/2021/2022), data selection driven by TER and COMET yields better performance when the outlier instances requiring excessive post-editing are removed from the training. On this basis, the submitted APE system was built by training the multilingual M2M100-418M model (Fan et al., 2021).

Huawei Translation Service Center and Xiamen University School of Informatics (HW_TSC). – late submission – This team participated with a Transformer-based system pre-trained on the provided synthetic APE data and then fine-tuned on the real APE data augmented via automatic translation (with Google Translate run on the post-edits in the training set) and by integrating En-Mr parallel sentences from FLORES-200 (NLLB Team et al., 2022). R-Drop (Liang et al., 2021), which regularizes the training inconsistency induced by dropout, is used to mitigate overfitting during the training phase. A sentence-level Quality Estimation system is also used to select the most appropriate output, choosing between the original translation and the corresponding APE-generated output.

5 Results

5.1 Automatic Evaluation

Automatic evaluation results are shown in Table 2. The submitted runs are ranked based on the average TER (case-sensitive) computed using human post-edits of the MT segments as a reference, which is the APE task's primary evaluation metric. To provide a broader view of systems' performance, BLEU and chrF results computed using the same references are also reported.

As can be seen from the table, the three rankings coherently show that the best official submission (by the KU_UPS team, which achieved scores of 27.73 TER, 69.03 BLEU, and 78.64 chrF) outperforms the others. None of them, however, was able to improve the quality of the original translations (*i.e.* the *do nothing* baseline), differently from

[7] http://www.cs.umd.edu/~snover/tercom/

[8] chrF was computed using SacreBLEU https://pypi.org/project/sacrebleu/(version 2.3.0)

[9] A fourth participating team retracted their submitted run due to errors in the generated outputs that significantly affected their final results.

Table 2: NEWResults for the WMT23 APE English-Marathi shared task – average TER (↓), BLEU (↑), chrF (↑). Gray† indicates a late submission, which was received after the conclusion of this year's human evaluation and, consequently, is not discussed in Section 5.2.

the slightly better outputs of the late submission by HW_TSC. This prompts further analyses to explore the underlying reasons for this unexpected outcome. We do this in two ways: 1) by giving a closer look at systems' behaviour (Section 5.1.1), in order to spot trends in their post-editing strategies; 2) by analysing the task's inherent level of difficulty (Section 5.1.2) in terms of the possibility to learn valuable correction patterns from the training data and effectively apply them to the supplied test set.

5.1.1 Analysis: Systems' Behaviour

Modified, improved and deteriorated sentences To gain a first insight into the behaviour of participating systems, Table 3 provides an overview of each submitted run, detailing the number of modified, improved, and deteriorated sentences, along with the systems' overall precision (*i.e.,* the ratio of improved sentences to the total count of modified instances where improvement or deterioration is observed). It's worth noting that each system has modified a much higher number of sentences than the combined total of improved and deteriorated ones. This discrepancy accounts for modified sentences in which the corrections do not result in any variations in TER. This "grey area", where the automatic assessment of quality improvement or degradation is not feasible, underscores the importance of including human evaluation for a comprehensive assessment of systems' performance (see Section 5.2). As can be seen from the table, and in line with the findings from previous rounds, conservative post-editing seems to yield better results compared to the adoption of aggressive strategies. The difference between the top-ranked system and the other submitted runs is indeed evident when we look at the proportion of modified test sentences (37.4%[10] vs $\geq 93.1\%$), indicating that limiting the applied edits to the strictly necessary ones remains the main challenge to achieve significant quality improvements. While this outcome may be influenced by the reference-based automatic evaluation framework employed (as it penalizes correct edit operations that deviate from those presented in the reference), it is noteworthy that the results of the manual evaluation, as detailed in Section 5.2, align with this observation.

Another observation is that precision is certainly the other key factor in achieving good APE results. Besides being much more conservative, the best submission stems, in fact, for a higher precision in selecting the edit operations to be applied (48.11[11] vs ≤ 21.00). Also, this finding aligns with the outcomes of previous rounds, in which the winning system consistently exhibited the highest precision. Notably, the precision of this year's official submissions (averaging 29.62) is significantly lower than the values observed in previous rounds (*e.g.,* 69.0, 53.96, 69.49 for the top-ranked system in 2020, 2021, and 2022, respectively).[12] This difference in precision may well explain why none of them were able to improve upon the baseline results.

Edit operations Further indications about the system's behaviour can be drawn from a more fine-

[10] Which drops to 24.4% for the late submission.

[11] Further increased to 51.89 for the late submission.

[12] This holds even if we include the late submission in the computation, with an average precision that slightly grows to 35.19.

Systems	Modified	Improved	Deteriorated	Prec.
HW-TSC_HW_1_PRIMARY.txt†	244 (24.4%)	110 (45.08%)	102 (41.8%)	51.89
KU_UPs-filtered4-PRIMARY.tsv	374 (37.4%)	153 (40.9%)	165 (44.11%)	48.11
kaistai_prompt-wo-cot_contrastive	931 (93.1%)	187 (20.08%)	709 (76.15%)	20.87
kaistai_prompt-w-cot_primary	989 (98.9%)	193 (19.51%)	777 (78.56%)	19.89
Average	76.46%	26.83%	66.27%	29.62

Table 3: Number (raw and proportion) of test sentences modified, improved and deteriorated by each run submitted to the APE 2023 English-Marathi subtask. The "Prec." column shows systems' precision as the ratio between the number of improved sentences and the total number of modified instances for which improvement or deterioration can be assessed in terms of TER variations. Average values considering only the three official submissions.

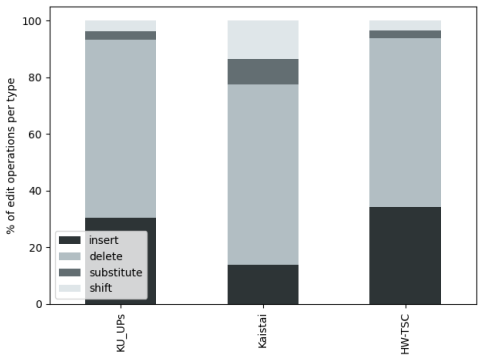

Figure 1: Distribution of edit operations (insertions, deletions, substitutions and shifts) performed by the three primary submissions to the WMT23 APE English-Marathi shared task.

grained analysis of the distribution of their edit operations (insertions, deletions, substitutions, and shifts). Such distribution is obtained by computing the TER between the original MT output and the output of each primary submission, taken as a reference. As shown in Figure 1, although the overall behaviour of the systems is similar, some differences are noticeable. Indeed, in line with previous rounds, they all exhibit a high percentage of deletions, followed by insertions, substitutions and shifts. However, for the best official submission,[13] the percentage of the latter two types of operations is minimal (2.9% substitutions and 3.67% shifts) and balanced by a less skewed distribution of insertions (30.52%) and deletions (62.91%). Especially the comparatively higher proportion of more "radical" (*i.e.,* structural) modifications applied by the worse system (13.43% shifts), which again suggests its lower conservativeness, can account for its lower automatic evaluation scores.

[13]Note, however, that the same consideration also applies for the late submission.

5.1.2 Analysis: Complexity Indicators

While systems' behaviour is influenced by implementation and architectural choices on the one hand, it also depends on the data used for training, development, and evaluation on the other. Therefore, looking at the intrinsic difficulty of the task from a data perspective is also crucial for interpreting the observed performance of the systems. To delve into this aspect, we concentrate on the possibility of learning useful correction patterns during training and successfully applying them at test time. We analyse such a possibility in terms of three indicators, namely: *i)* repetition rate, *ii)* MT quality, and *iii)* TER distribution in the test set. For the sake of comparison across the nine rounds of the APE task (2015–2023), Table 4 reports, for each dataset, information about the first two aspects. The third one, instead, will be discussed by referring to Figure 2.

Repetition Rate The repetition rate (RR), measures the repetitiveness inside a text by looking at the rate of non-singleton n-gram types (n=1...4) and combining them using the geometric mean. Higher RR values indicate greater text repetitiveness, which may imply an increased likelihood of learning correction patterns from the training set that are also applicable to the test set. As shown in the last row of Table 4, the RR values for the SRC, TGT, and PE elements (averaged across the training, development, and test sets) are relatively low. Furthermore, upon closer examination, Table 5 reveals a non-negligible difference between the RR values of the SRC, TGT, and PE elements in the training set compared to the corresponding values calculated on the test set. This difference is particularly pronounced for the PE sentences, where the RR is more than two times higher. Although the reported RR values can be considered indicative of a challenging task, it is important to

Table 4: Basic information about the APE shared task data released since 2015- languages, domain, type of MT technology, repetition rate and initial translation quality (TER/BLEU of TGT). The last column (δ TER) indicates, for each evaluation round, the difference in TER between the baseline (*i.e.,* the "*do-nothing*" system) and the top-ranked official submission.

Data	RR
Train_src	1.55
Train_mt	1.03
Train_pe	0.81
Dev_src	1.4
Dev_mt	0.8
Dev_pe	0.64
Test_src	2.6
Test_mt	1.9
Test_pe	1.91

Table 5: Repetition Rate (RR) values of source (src), target translation (mt) and post-edited translation (pe) elements in the APE 2023 training, development and test sets.

note that the top-ranked submissions in previous rounds (e.g. in 2022 and 2020) were able to achieve significant improvements over the baseline despite similar RR values (with δ TER values of -3.49 and -12.13, respectively). This variability reinforces the findings from previous rounds, emphasizing that RR alone is insufficient as a complexity indicator. Rather, it underscores the significance of examining its interaction with other indicators and its potential cumulative impact on them.

MT Quality As emphasized by the findings from all previous rounds of the task, a more reliable indicator of complexity is the quality of the machine-translated (TGT) texts that require correction. We assess this quality by computing TER (↓) and BLEU (↑) scores (shown in the Basel. TER/BLEU columns in Table 4), using the human post-edits as references.[14] In principle, higher-quality original translations leave less room for improvement to APE systems, which have at the same time fewer errors to learn from during training and fewer corrections to make at test time. On one side, indeed, training on good (or near-perfect) automatic translations can significantly reduce the number of learned correction patterns. On the other side, testing on similarly high-quality translations can have two effects: *i)* it reduces the number of corrections required and the applicability of learned patterns, and *ii)* it increases the risk of introducing errors, especially when post-editing near-perfect TGTs. This observation is supported by the strong correlation (>0.83) between the initial MT quality ("Basel. TER" in Table 4) and the TER difference between the baseline and the top-ranked submission ("δ TER" in Table 4) previously reported in the analysis of the 2015-2022 rounds by Bhattacharyya et al. (2022).

Looking at the baseline TER score, this year's test data look for a comparatively lower difficulty for APE systems compared to most of the previous rounds, which in only 2 cases (*i.e.,* for the two languages covered in 2020) appear to be less challenging. Interestingly, however, when looking at the baseline BLEU score, the difficulty appears to be higher, with up to 6 previous test sets featuring translations of lower quality (hence easier to handle) compared to this year. The reasons for such differences deserve further investigation, which might shed light on the fact that, contrary to expectations, MT quality is less indicative of this year's task difficulty compared to previous rounds[15].

[14] Scores for the newly introduced chrF metric are not included in the table, as they would not be comparable with values from previous rounds where chrF was not considered.

[15] Considering this year's data, in fact, the correlation between "Basel. TER" and "δ TER" in Table 4 drops from >0.83

TER distribution in the test set Complementary to repetition rate and MT quality, the TER distribution (computed against human references) for the translations present in the test provides valuable insights for interpreting the results of this year's round of the task. While TER distribution and MT quality may appear to be closely related, it's important to note that, even at similar overall quality levels, more or less skewed distributions can create distinct testing conditions. Indeed, as shown by previous analyses (Bojar et al., 2017; Chatterjee et al., 2018, 2019, 2020; Akhbardeh et al., 2021; Bhattacharyya et al., 2022), more challenging rounds of the task were typically characterized by TER distributions heavily skewed toward lower values (*i.e.,* a larger percentage of test items having a TER between 0 and 10).

On one side, a higher proportion of (near-)perfect test instances, requiring minimal or no corrections, increases the likelihood that APE systems will make unnecessary edits, which will be penalized by automatic evaluation metrics. Conversely, less skewed distributions may be easier to handle, as they provide automatic systems with more opportunities for improvement, with a larger number of test instances necessitating revision. In the lack of more focused analyses on this aspect, we can hypothesize that under ideal conditions from the APE standpoint, the peak of the distribution would correspond to "post-editable" translations containing enough errors that leave some margin for focused corrections but not too many errors to be so unintelligible to require a whole re-translation from scratch.[16] In light of the above observations, the APE 2023 test set can be considered as particularly challenging. As illustrated in Figure 2, the TER distribution exhibits a U-shaped (bimodal) pattern, characterized by two prominent peaks corresponding to the two most critical regions within the $0-100$ TER range. At one extreme, the first peak corresponds to the vast majority of test instances (about 45% of the total) that can be considered as perfect or near-perfect translations (*i.e.,* 0<TER<5), which implies a high chance of applying unnecessary corrections. At the other extreme, the second peak corresponds to a significant portion of test items (about 20%) that can be considered as too poor and unintelligible (*i.e.,* $95<TER<100$) to grant the safe application of any post-editing strategies. Although the remaining portion of the test set falls almost entirely in the range of "post-editable" outputs (*i.e.,* $10<TER<40$), its small size significantly reduces the potential for improvement through the APE process. Overall, this year's test set deviates significantly from all previous ones, where the TER distributions have never been characterized by such a pronounced bimodal pattern. In light of this, we can conclude that while, on the one hand, the repetition rate and machine translation quality do not provide sufficiently convincing insights to justify performance below the baseline for the official submissions, on the other hand, the TER distribution has posed a significant challenge for this year's participants.

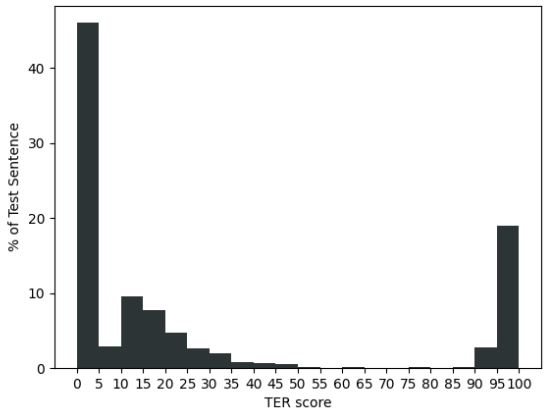

Figure 2: TER distribution in the APE 2023 English-Marathi test set.

5.2 Human Evaluation

We conducted a human evaluation of the primary system submissions to complement the automatic evaluations. However, this could be performed only for the official system submissions, as the late submission was received after the conclusion of the human assessments. This section discusses our evaluation procedure and the results obtained from it.

5.2.1 Evaluation Procedure

We provided annotation guidelines to professional translators who are native speakers of the target language. The same guidelines were also used to collect Indic language quality estimation shared task dataset (Zerva et al., 2022). The annotators provided a source-based direct assessment (DA) (Gra-

to 0.78.

[16]For instance, based on the empirical findings reported in (Turchi et al., 2013), TER=0.4 is the threshold that, for human post-editors, separates the "post-editable" translations from those that require complete rewriting from scratch.

	Avg DA	Avg z
test.pe	83.76	0.426
KU_UPs-filtered4-PRIMARY	66.56	−0.171
test.mt	65.86	−0.138
kaistai_prompt-w-cot_primary	64.79	−0.116

Table 6: Results for the human evaluation campaign for the En-Mr language pair. Systems ordered by DA score; systems within a cluster are considered tied; lines indicate clusters according to Wilcoxon rank-sum test p <0.05.

ham et al., 2013b; Cettolo et al., 2017; Bojar et al., 2018) score to each segment containing the source and the APE system output. We hired 4 translators to evaluate the two primary system submissions (KU_UP & KAISTAI), manually post-edited segments (*test.pe*), and the MT Output (*test.mt*). We chose to allocate an equal number of instances to each translator after shuffling, and only a single DA annotation was collected for each instance (Toral, 2020). Shuffling the instances before allocation helps prevent annotator bias towards a single system in the direct assessments.

The annotation guidelines provide a detailed description of potential adequacy and fluency-based errors based on which the translator could estimate the direct assessment score range. However, the translators were additionally instructed to prioritize adequacy errors and focus on assessing the semantic similarity between the source and the system output. The annotators manually entered the DA score between 0-100. The collected DA annotations were unshuffled based on the segment IDs, which were unknown to the translators. We expected the human post-editing to be of higher quality compared to APE system submissions and, consequently, better than the MT baseline.

5.2.2 Evaluation Results

We present the results obtained from the human evaluation campaign in Table 6. As expected, the human post-edited segments were rated the highest at 83.76 mean DA score. However, contrary to automatic evaluation, the submission by KU_UP was rated slightly better than the MT baseline (test.mt). But, the score difference in both cases-human and automatic evaluation, seems insignificant. Additionally, as per the Wilcoxon Rank-sum test, KU_UP and MT baseline score distributions seem to be in a cluster. In line with the automatic evaluation, the mean DA obtained by the submission from *kaistai* was rated the lowest at 64.79, lower than the MT baseline at 65.86. This submission utilizes LLMs to perform the APE task and raises a question on the viability of LLMs for APE when a low-resource language is concerned. LLMs are mostly fine-tuned and/or evaluated on task datasets in English (Hendrycks et al., 2020; Longpre et al., 2023), and there remain unanswered questions on their viability for complex and challenging multilingual tasks like APE. Owing to a challenging test set this year, our analysis highlights the difficulty posed by the task and implores us to consider a different setting in which the APE task can perhaps gain assistance through a translation quality signal. QE systems have been explored for assisting the APE task in a supervised multi-task scenario, which intuitively helps the model perform better at both tasks.

6 Conclusion

We presented the results from the 9^{th} shared task on Automatic Post-Editing at WMT. In continuity with the 2022 round, the task focused on the automatic correction of NMT outputs generated by a black-box English-Marathi system. The three participating systems were evaluated both automatically (with TER as the primary metric, BLEU, and ChrF) and manually. According to automatic evaluation results, only one (late) submission succeeded in outperforming the *do-nothing* baseline. The analysis of this year's data suggests that one of the main causes of difficulty might be the bimodal, U-shaped TER distribution of the test instances, which substantially differs from the test set distributions observed in all previous rounds (skewed but a pattern closer to normal). Our manual evaluation confirms the automatic evaluation outcomes and affirms the challenge posed by APE for the current approaches. We observe that one of the systems performs quite close to the MT baseline while the other performs well below the same. Additionally, the lack of multilingual datasets in LLM training/benchmarking raises a question on the viability of performing challenging multilingual tasks like APE. All in all, these findings advocate for further research on this challenging problem, which, far from being solved, this year revealed new nuances in terms of difficulty. Next year, we plan to introduce two new low-resource language pair datasets for the APE task. Future developments will also

likely include a re-definition of some aspects of the evaluation settings, which have remained relatively stable over the years. For instance, the set of automatic evaluation metrics will likely be reconsidered and expanded so as to include more semantics-oriented measures, with an eye on the advent of large language models increasingly adopted also for APE.

Acknowledgements

We would like to thank Zibanka Media Services Pvt. Ltd., and Techliebe, who worked with us to create the APE datasets for English-Marathi.

Abstract

This paper presents the results of the low-resource Indic language translation task organized alongside the Eighth Conference on Machine Translation (WMT) 2023. In this task, participants were asked to build machine translation systems for any of four language pairs, namely, English-Assamese, English-Mizo, English-Khasi, and English-Manipuri. For this task, the IndicNE-Corp1.0 dataset is released, which consists of parallel and monolingual corpora for northeastern Indic languages such as Assamese, Mizo, Khasi, and Manipuri. The evaluation will be carried out using automatic evaluation metrics (BLEU, TER, RIBES, COMET, ChrF) and human evaluation.

1 Introduction

Low-resource Indic languages refer to the vast array of languages spoken in India, which, unfortunately, possess limited linguistic resources available for their study and development. These languages typically suffer from a combination of factors that set them apart from the more prominent and widely supported languages spoken in the country. The challenges these languages face include having a smaller number of speakers, a relative lack of governmental support, inadequate documentation, and limited access to technological resources.

India is renowned for its linguistic diversity, with a rich tapestry of languages spoken across the subcontinent. The Eighth Schedule of the Indian Constitution officially recognizes 22 languages, which receive significant government backing and protection. However, beyond these major languages, numerous smaller languages and dialects are spoken by various indigenous and minority communities throughout the country.

These low-resource Indic languages face a series of interconnected challenges that make their preservation and promotion difficult: lack of written scripts, limited vocabulary resources, inadequate linguistic research, and insufficient digital content. The collective impact of these factors makes it challenging to preserve and promote low-resource Indic languages. As a consequence, they are at risk of falling into disuse, with their speakers shifting to more widely recognized languages. Efforts to document, revitalize, and support these languages are crucial not only for linguistic diversity but also for the preservation of cultural heritage and the rights of minority language communities in India.

Efforts are being made by various organizations, researchers, and language enthusiasts to address the issues faced by low-resource Indic languages (Pal et al., 2013a,b; Pal, 2018). These initiatives involve language documentation, the development of writing systems, the creation of linguistic resources such as parallel corpora (Ramesh et al., 2022), parallel fragment extraction from comparable corpora (Gupta et al., 2013; Pal et al., 2014), dictionaries and grammars, and the promotion of language use through educational programs and digital platforms.

Technology indeed plays a pivotal role in supporting low-resource Indic languages. In recent years, machine learning and natural language processing techniques have been harnessed to create innovative solutions for these languages, including speech recognition, machine translation, and text-to-speech systems. These technological advancements offer a transformative potential in addressing the linguistic challenges faced by these languages and can have a profound impact on their preservation and revitalization.

To work towards the goal of supporting low-resource Indic languages, we organized the "Indic MT Shared Task" focusing on several less-popular languages that belong to different language families. These languages include As-

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 682–694

samese (Indo-Aryan), Mizo (Sino-Tibetan), Khasi (Austroasiatic), and Manipuri (Sino-Tibetan). In this shared task, we present IndicNE-Corp1.0 in which parallel (English-Assamese (en–as), English–Mizo (en–lus), English–Khasi (en–kha), English–Manipuri (en–mni)) and monolingual (Assamese, Mizo, Khasi, Manipuri) corpora for northeastern Indic languages available.

2 Shared Task: Low-Resource Indic Language Translation

In recent years, there has been significant improvement in the performance of machine translation (MT) systems. This progress can be attributed to the development of new techniques, such as multilingual translation and transfer learning. As a result, the benefits of MT are no longer restricted to users of widely spoken languages. This advancement has led to a growing interest within the research community in expanding MT coverage to encompass a wider range of languages, each with its unique geographical presence, degree of diffusion, and level of digitalization.

However, despite the enthusiasm for extending MT to more languages and users, there remains a substantial challenge. The challenge stems from the fact that MT methods typically require large volumes of parallel data for training high-quality translation systems. This requirement has proven to be a major hurdle, particularly when dealing with low-resource languages where obtaining such extensive parallel data can be exceedingly difficult. Consequently, there is a pressing need to develop MT systems that can perform well even when trained on relatively small parallel datasets. The ability to achieve effective machine translation with limited resources is of paramount importance for increasing accessibility and usability across a wide spectrum of languages and linguistic communities. In this translation task, our focus was on the following language pairs (both directions for each):

- Subtask-1 : English ↔ Assamese
- Subtask-2 : English ↔ Mizo
- Subtask-3 : English ↔ Khasi
- Subtask-4 : English ↔ Manipuri

In this translation task, participants had the opportunity to submit up to 1 PRIMARY system for each language pair/translation direction, where no additional parallel data was permitted for training. Additionally, participants could submit up to 2 CONTRASTIVE systems for each language pair/translation direction. This structure allowed participants to showcase their translation systems under various conditions and constraints, including the absence of additional parallel data in the case of PRIMARY systems.

3 Dataset: IndicNE-Corp1.0

In the creation of IndicNE-Corp1.0, we compiled datasets from our prior research projects, including contributions from Laskar et al. (2020, 2022); Khenglawt et al. (2022); Laskar et al. (2021); Laitonjam and Ranbir Singh (2021). These datasets served as the foundation for constructing both parallel and monolingual corpora. In our earlier works, we undertook the development of English-Assamese (eng-asm) (Laskar et al., 2020, 2022), English-Mizo (eng-lus) (Khenglawt et al., 2022), English-khasi (eng-kha) (Laskar et al., 2021), English-Manipuri (eng-mni) (Laitonjam and Ranbir Singh, 2021) parallel and monolingual corpora for Assamese, Mizo, Khasi and Manipuri languages. The different online sources were explored that include Bible, multilingual online dictionary (Xobdo and Glosbe), multilingual question paper, PMIndia[1] (Haddow and Kirefu, 2020), web pages, blogs and online news papers. The collected data statistics for parallel (train, validation and test set) and monolingual corpora are presented in subsequent sections below. For primary investigation in this shared task, we have not included very complex sentences in the test set.

3.1 Assamese

Assamese exhibits a subject-object-verb (SOV) word order, in contrast to the subject-verb-object (SVO) word order found in English. Additionally, it is characterized as an agglutinative language, as discussed by Sarma et al. (2017) and Baruah et al. (2021), signifying its propensity to incorporate suffixes and prefixes into words to convey diverse grammatical meanings. This intricacy poses a notable challenge for machine translation systems, as they must accurately analyze and generate these intricate word forms.

Furthermore, Assamese boasts a complex verb conjugation system encompassing tense, aspect, mood, and agreement markers. These markers hold

[1] http://data.statmt.org/pmindia/v1/ parallel/

the power to significantly alter the meaning of a verb, making it a formidable task for translation systems to capture these subtleties with precision. The data statistics for the English-Assamese parallel data are presented in Table 1.

Type	Sentences	Tokens	
		eng	asm
Train	50,000	969,623	825,063
Validation	2,000	31,503	25,929
Test	2,000	32,466	27,483

Table 1: English-Assamese parallel data statistics for train, valid, and test set

3.2 Mizo

Mizo follows the object-subject-verb order when the object is considered. Mizo is a tonal language (Lalrempuii et al., 2021; Khenglawt et al., 2022), which means that differences in pitch or tone can represent different meanings. The vowels (a, aw, e, i, o, u) primarily indicate intonation. In the Mizo language, the main tones are rising, falling, high, and low. For example, depending on the tone, the word "ban" in Mizo can mean a pillar, the arm, to stretch, arrive at, sticky, or dismiss. A circumflex (ˆ) is frequently used to indicate long intonations (primarily to distinguish them from short intonations). Mizo is an agglutinative and highly inflected language with declension of nouns and pronouns. It also has many monosyllables and decomposable polysyllables, with meaning derived from each syllable. A sentence's tense can be changed by including particles such as "ang," "dawn," "mek," "tawh," and so on. The data statistics for the English-Mizo parallel data are presented in Table 2.

Type	Sentences	Tokens	
		eng	lus
Train	50,000	981,468	1,06,2414
Validation	1,500	38,525	40,983
Test	2,000	21,905	25,098

Table 2: English-Mizo parallel data statistics for train, valid and test set

3.3 Khasi

Khasi follows the subject-verb-object word order. It orthography has 23 alphabets and has six vowels, the vowels are "a e i ï o u". In Khasi orthography the alphabets "c f q v x z" are not present and instead the letters "ï ñ ng" are present which makes the orthography to be different from English or other orthographies (Warjri et al., 2021). Khasi is rich in subject agreement markers. Subject agreement is indicated by verbs, adjectives, and adverbs. Nouns have their own grammatical number and gender. In morphology, Khasi is mostly isolating; while some words are derived through specific morphological processing, others are found standing alone with no morphology indicated. As a result, (a) word categories such as Nouns, Verbs, Adjectives, and so on are invariant, and (b) words are mostly mono-morphemic in nature, so it is common to encounter only isolating words in a single long sentence or discourse. The data statistics for the English-Khasi parallel data are presented in Table 3.

Type	Sentences	Tokens	
		eng	kha
Train	24,000	7,29,930	8,75,545
Validation	1,000	24,609	37,407
Test	1,000	24,150	35,901

Table 3: English-Khasi parallel data statistics for train, valid and test set

3.4 Manipuri

Manipuri language uses Bengali script[2] and Meetei mayek[3] in written form. In this dataset, we use the Bengali script. Manipuri language also has an extensive suffix with limited prefixation and verb-final word order in a sentence, i.e., subject-object-verb order (Huidrom et al., 2021). Linguistic features of this language include agglutinative verb morphology, tone, the absence of grammatical person, number, gender, and a prevalence of aspect over tense. The data statistics for the English-Manipuri parallel data are presented in Table 4.

Type	Sentences	Tokens	
		eng	mni
Train	21,687	390,730	330,319
Validation	1,000	16,905	14,469
Test	1,000	14,886	12,775

Table 4: English-Manipuri parallel data statistics for train, valid, and test set

Table 5 presents the statistics for parallel data length differences among the four language pairs. In Figure 1, we illustrate the overlapping tokens between the test set and the training and validation sets for these same four language pairs. In addition to the parallel data, we have also made available monolingual corpora for Assamese, Mizo, Khasi,

[2]http://unicode.org/charts/PDF/U0980.pdf
[3]http://unicode.org/charts/PDF/UABC0.pdf

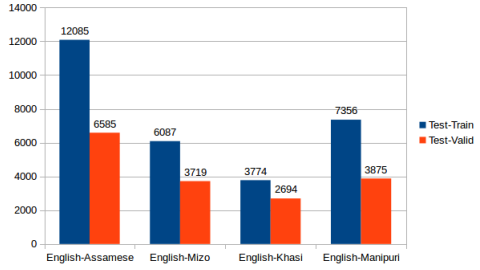

Figure 1: Overlapping tokens among test-train and test-validation data set of English-Assamese, English-Mizo, English-Khasi and English-Manipuri

and Manipuri. The monolingual data statistics per languages are presented in Table 6.

Language	Size (MB)	Sentences	Tokens
asm	805	2,624,715	49,232,154
lus	145	1,909,823	27,936,225
kha	104	182,737	22,140,361
mni	716	2,144,897	36,514,693

Table 6: Monolingual data statistics for Assamese, Mizo, Khasi and Manipuri languages

4 Participants and System Descriptions

In this shared task, a total of 31 teams registered and contributed, as indicated in Table 8, the released the dataset have been distributed among participants. In Table 7, we have compiled the system outputs submitted by participants, encompassing both primary and contrastive submission types.

Language Pair	Number of Participants
English-Assamese	13 (Primary), 11 (contrastive)
English-Mizo	10 (Primary), 8 (contrastive)
English-Khasi	11 (Primary), 8 (contrastive)
English-Manipuri	14 (Primary), 11 (contrastive)

Table 7: Number of participants in the low-resource Indic language translation task at WMT23

However, we have received system description papers from 9 teams and included concise system details for those teams where the authors provided such information.

CFILT-IITB (Gaikwad et al., 2023): The participant utilized phrase-pair injection (Sen et al., 2021), back-translation (Sennrich et al., 2016), and transfer learning with the help of large pre-trained multilingual IndicTrans2 model (Gala et al., 2023) to build NMT systems for the English-Assamese and English-Manipuri language pairs.

IOL Research (Zhang et al., 2023): The contributor used monolingual data to train two denoising language models similar to T5 (Raffel et al., 2020) and BART (Lewis et al., 2019), and then used parallel data to fine-tune the pre-trained language models to obtain two multilingual machine translation models. Besides, the multilingual machine translation models were used to translate English monolingual data into other multilingual data, forming multilingual parallel data as augmented data (Sennrich et al., 2016) to build NMT systems for English-Assamese, English-Mizo, English-Khasi, and English-Manipuri language pairs.

IACS-LRILT (Suman et al., 2023): The team IACS-LRILT used IndicBART (Dabre et al., 2022) pre-trained language model for fine-tuning the training data to build NMT systems for English-Assamese, and English-Manipuri language pairs.

GUIT-NLP (Ahmed et al., 2023): Team GUIT-NLP used back-translation (Sennrich et al., 2016) strategy and explored NMT systems by leveraging subword tokenization (Sennrich et al., 2015; Kudo and Richardson, 2018) and hyperparameters tuning for English-Assamese, English-Mizo, and English-Khasi language pairs.

NITS-CNLP (Singh et al., 2023): The NITS-CNLP team used the OpenNMT toolkit (Klein et al., 2017) and built a transformer-based (Vaswani et al., 2017) NMT model with hyperparameters tuning for the English-Manipuri language pair.

NICT-AI4B (Dabre et al., 2023): The group explored NMT systems by leveraging back-translation strategy (Sennrich et al., 2016) with denoising techniques (Lewis et al., 2020; Dabre et al., 2022) and fine-tuned IndicTrans2 model (Gala et al., 2023) for the English-Assamese, English-Mizo, English-Khasi, and English-Manipuri language pairs.

MUNI-NLP (Signoroni and Rychly, 2023): The participant explored transformer-based (Vaswani et al., 2017) NMT systems by investigating different hyperparameters tuning for English-Assamese, English-Mizo, English-Khasi, and English-Manipuri language pairs.

CUNI (Kvapilíková and Bojar, 2023): The CUNI team used back-translation (Sennrich et al., 2016) for data augmentation, denoising, leveraging multilingual masked language modelling, and

Data	Length	Number of Sentences

	21-30	18679	14316	7320	4764
	31-40	3245	8007	6656	1947
	41-50	149	473	3977	944

Table 5: Length-wise sentence group distribution for the test, train, and validation parallel data of English-Assamese, English-Mizo, English-Khasi, and English-Manipuri

built NMT systems for English-Assamese, English-Mizo, English-Khasi, and English-Manipuri language pairs.

ATULYA-NITS (Agrawal et al., 2023): This group used Google Colab, and trained the transformer model (Vaswani et al., 2017) using a T4 GPU for the English-Assamese, and English-Manipuri language pairs.

Organizer: The shared task organizer used the OpenNMT toolkit (Klein et al., 2017) and built biLSTM-based NMT systems with hyper-parameters tuning only on parallel data for the English-Assamese, English-Mizo, English-Khasi, and English-Manipuri language pairs.

5 Results and Discussion

We present results[4] for both directions of the four language pairs, namely, English-Assamese in Table 9, English-Mizo in Table 10, English-Khasi in Table 11, and English-Manipuri in Table 12. Here, we have reported the evaluation scores of those teams who submitted system output and their associated papers. To evaluate quantitative results, standard evaluation metrics (Papineni et al., 2002), namely, BLEU (bilingual evaluation under study), TER (translation error rate) (Snover et al., 2006), RIBES (rank-based intuitive bilingual evaluation score) (Isozaki et al., 2010), ChrF (character n-gram F-score) (Popović, 2015) and COMET (Rei et al., 2020). Moreover, we have hired linguistic experts who possess linguistic knowledge of the concerned language pair and randomly selected 20 sample sentences of primary submission type for manual evaluation (reported in Table 13 to 16). The human evaluator evaluates the candidate translations based on adequacy, fluency, and overall rating. Adequacy of translation measures the amount of meaning of reference translation, which is contained in a candidate translation. Furthermore, a translation is considered fluent if it is a well-formed sentence of the target language, irrespective of its correspondence with the reference translation. For example, given the reference translation to be "He wakes up early in the morning," the candidate translation "He is flying to Delhi" is inadequate, as it contains no content of the reference translation. However, the translation is fluent because the sentence has a proper meaning, and it is a well-formed sentence in the English language. The overall rating takes into account adequacy as well as fluency of candidate translation. An adequate and fluent translation is considered excellent and assigned a high overall rating. The human evaluation parameters have been rated on a scale of 0–5, with larger values signifying the better. Final adequacy, fluency, and overall rating scores are the average scores of individual test sentences.

Table 8: Registered participants in the low-resource Indic language translation task at WMT23 and dataset released to them. Not all the teams participated in all language pairs. **Bold marks** are those who submitted system outputs and system description papers

Discussion:

- For both directions of English-Assamese, Team: IACS-LRILT attains the best BLEU score (as shown in Table 9). They utilized the IndicBART language model in fine-tuning the training model. Also, Assamese-to-English translation attains higher scores than English-to-Assamese translation. It is due to the fact that Assamese is a highly inflectional, morphologically rich, and agglutinative language.
- For both directions of English-Mizo, Team: NICT-AI4B attains the best BLEU score (as shown in Table 10). They utilized IndicTrans2 model in fine-tuning the training model. It is observed that encountering tonal words for English-to-Mizo translation is a challenging task.
- For both directions of English-Khasi, Team: IOL Research attains the best BLEU score (as shown in Table 11). They used denoising language models (T5 / BART) and data augmentation techniques.
- For English-to-Manipuri translation, Team: CUNI attains the best BLEU score (as shown in Table 12). They used data augmentation, denoising, leveraging multilingual, and masked language modelling techniques. And, Manipuri-to-English translation, Team: IACS-LRILT attains the best BLEU score (as shown in Table 12) by utilizing the IndicBART language model in fine-tuning the training model. Also, it is observed that Manipuri-to-English translation attains higher scores than English-to-Manipuri translation. This is due to the fact that Manipuri is a morphologically rich and highly agglutinative language.
- In human evaluation, it is noticed that fluency scores are better than adequacy scores for all language pairs submission. The reason behind this is that NMT systems are well known for producing fluent translations (Koehn and Knowles, 2017).

6 Conclusion

We presented the results of the participating teams in the four language pairs translation task in terms of automatic and human evaluation metrics. We released a dataset, namely, IndicNE-Corp1.0 in the shared task on low-resource Indic language translation at the eighth conference on machine translation (WMT) 2023. The dataset comprises four low-resource languages, namely, Assamese, Mizo, Khasi, and Manipuri which belong to the northeastern region of India. In the future, we will include more northeastern Indic language datasets in addition to increasing the existing dataset size.

Comments

A few teams, namely, TRANSSION MT (TRANNSION, China), HW-TSC (Huawei Translate Center, China), ANVITA (Centre for AI and Robotics (CAIR), India), COGNITIVE LAB-IIITM (Indian Institute of Information Technology, Manipur, India) and NITR (NIT Rourkela, India) submitted system results but unfortunately did not submit the associated system description paper. Therefore, we have not reported their results in this paper.

Acknowledgements

We would like to thank all the participants for their active participation in this shared task. Also, thankful to the organizers and reviewers of the Eighth Conference on Machine Translation (WMT) 2023.

Abstract

We benchmark the performance of segment-level metrics submitted to WMT 2023 using the ACES Challenge Set (Amrhein et al., 2022). The challenge set consists of 36K examples representing challenges from 68 phenomena and covering 146 language pairs. The phenomena range from simple perturbations at the word/character level to more complex errors based on discourse and real-world knowledge. For each metric, we provide a detailed profile of performance over a range of error categories as well as an overall *ACES*-Score for quick comparison. We also measure the incremental performance of the metrics submitted to both WMT 2023 and 2022. We find that 1) there is no clear *winner* among the metrics submitted to WMT 2023, and 2) performance change between the 2023 and 2022 versions of the metrics is highly variable. Our recommendations are similar to those from WMT 2022. Metric developers should focus on: building ensembles of metrics from different design families, developing metrics that pay more attention to the source and rely less on surface-level overlap, and carefully determining the influence of multilingual embeddings on MT evaluation.

1 Introduction

Challenge sets are a useful tool in measuring the performance of systems or metrics on one or more specific phenomena of interest. They may be used to compare the performance of a range of *different* systems or to identify performance improvement/degradation between successive iterations of the *same* system.

Challenge sets exist for a range of natural language processing (NLP) tasks including Sentiment Analysis (Li et al., 2017; Mahler et al., 2017; Staliūnaitė and Bonfil, 2017), Natural Language Inference (McCoy and Linzen, 2019; Rocchietti et al., 2021), Question Answering (Ravichander et al., 2021), Machine Reading Comprehension (Khashabi et al., 2018), Machine Translation (MT) (King and Falkedal, 1990; Isabelle et al., 2017), and the more specific task of pronoun translation in MT (Guillou and Hardmeier, 2016).

The WMT 2021 Metrics shared task (Freitag et al., 2021) introduced the task of constructing contrastive challenge sets for the evaluation of MT metrics. Contrastive challenge sets aim to assess how well a given metric is able to discriminate between a *good* and *incorrect* translation of the *source* text. The provision of a *reference* translation allows for flexibility: it may be included for the assessment of reference-based (i.e. MT) metrics, or excluded for the assessment of reference-free (i.e. Quality Estimation (QE)) metrics.

We re-submitted ACES[1] (Amrhein et al., 2022), originally developed for the WMT 2022 challenge sets shared task (Freitag et al., 2022), to the corresponding shared task at WMT 2023. ACES largely focuses on translation accuracy errors and consists of 68 phenomena ranging from simple perturbations at the word/character level to more complex errors based on discourse and real-world knowledge. We report on both the performance of metrics submitted to WMT 2023, and on the incremental performance of those metrics that were submitted to both WMT 2022 and WMT 2023. We also repeat the analyses in Amrhein et al. (2022) for the WMT 2023 metrics to confirm whether the findings from WMT 2022 still hold.

Overall, we find similar trends to those observed last year. Again, we do not find one clear winner and whilst neural metrics tend to perform better than their non-neural counterparts, different categories of metrics exhibit different strengths and weaknesses. The major challenges identified in Amrhein et al. (2022) still hold: (i) reference-based metrics are still overly reliant on the reference

*Equal contribution by all authors.

December 6–7, 2023.

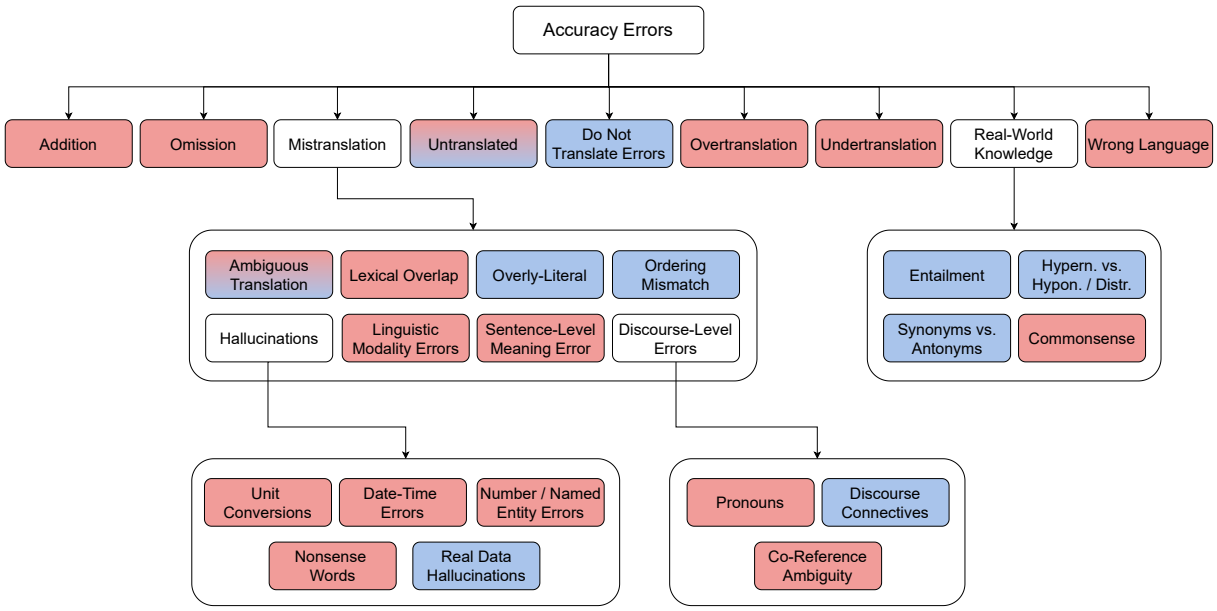

Figure 1: Diagram of the error categories on which our collection of challenge sets is based. Red means challenge sets are created automatically, and blue means challenge sets are created manually.

and do not pay enough attention to the source, (ii) reference-based metrics still rely on surface-level overlap, and (iii) the over-reliance on multilingual embeddings still persists – evidence from our analyses suggests that language agnostic representations present in the multilingual space may harm performance. Accordingly, our recommendations are also similar to those of last year. Metric developers should focus on: constructing ensembles of metrics with different design principles, developing metrics that also focus on information in the source, reducing dependence on surface-level overlap with the reference, and reassessing the impact of multilingual embeddings on MT evaluation.

With respect to incremental performance changes between metrics submitted to both 2022 and 2023, we observe mixed results. Whilst improvements are observed for some metrics, there is a degradation in performance for other metrics. However, even for those metrics for which an overall improvement was observed, this improvement was inconsistent across the top-level categories in ACES. Further, the performance even degraded for some categories.

2 ACES Overview

The Translation **A**ccuracy **C**hallen**E** Set (ACES) consists of 36,476 examples covering 146 language pairs and representing challenges from 68 linguistic phenomena. These phenomena are grouped into ten top-level categories: addition, omission, mistranslation, untranslated, do not translate errors, overtranslation, undertranslation, real-world knowledge, wrong language, and punctuation [2]. The mistranslation and real-world knowledge categories are further sub-categorised to include additional fine-grained categories. We illustrate the broad accuracy error categories in Fig 1 and give examples for each of the top-level categories in Appendix A.

The focus of ACES is on translation accuracy errors, reflecting the need to evaluate contemporary MT systems that are capable of producing fluent but potentially error-prone output. The selection of the top-level categories in the ACES error hierarchy is based on the *Accuracy* class in the Multidimensional Quality Metrics (MQM) ontology (Lommel et al., 2014), and extended to include translations defying *real-world knowledge* and translations in the *wrong language*. ACES includes a wide range of phenomena ranging from simple perturbations that involve the omission/addition of characters or tokens, to more complex scenarios involving mistranslations e.g. ambiguity or hallucinations in translation, untranslated elements of a sentence, discourse-level phenomena, and real-world knowledge.

Each ACES example consists of a *source* sentence, a *reference* translation, a *phenomenon label* indicating the error type, and two translation

[2]Note that although the focus of ACES is on *accuracy* errors, we also include a small set of *fluency* errors for the punctuation category.

	Mistranslation - Overly literal (Idioms)
SRC (de):	Er hat versucht, mir die Spielregeln zu erklären, aber **ich verstand nur Bahnhof**.
REF (en):	He tried to explain the rules of the game to me, but **I did not understand them**.
✓:	He tried to explain the rules of the game to me, but **it was all Greek to me**.
✗:	He tried to explain the rules of the game to me, but **I only understood train station**.
	Real-world Knowledge - Commonsense
SRC (en):	Die Luft im Haus war kühler als in der Wohnung.
REF (de):	The air in the house was cooler than in the apartment.
✓:	The air in the house was cooler than in the apartment because **the apartment** had a broken air conditioner.
✗:	The air in the house was cooler than in the apartment because **the house** had a broken air conditioner.

Table 1: Examples from the Mistranslation and Real-world Knowledge categories in ACES. An example consists of a source sentence (SRC), reference (REF), good (✓) and incorrect (✗) translations, and a phenomenon label indicating the error type. en: English, de: German. Top: the German idiom "ich verstand nur Bahnhof" has been translated in an overly-literal way in the incorrect translation. Bottom: the incorrect translation contains an error in commonsense reasoning as to why the air in the house was cooler than in the apartment.

hypotheses: an *incorrect* translation containing an error relating to the phenomenon of interest, and a *good* translation. Several examples from ACES are presented in Table 1. In the top example, from the *Mistranslation* error category, the incorrect translation contains an *overly literally* translation of the German *idiom* "ich verstand nur Bahnhof" (corresponding to the English expression "it was all Greek to me"). In the bottom example, from the *Real-world Knowledge* error category, both the good and incorrect translations contain additional information not present in the source sentence, however, the incorrect translation contains an error in *commonsense* reasoning as to why the air in the house was cooler than the apartment.

ACES examples were constructed from pre-existing datasets, using a range of automatic, semi-automatic, and manual methods. A detailed description of each of the phenomena in ACES can be found in Amrhein et al. (2022).

3 Related Work

Challenge sets have been used for several tasks (Li et al. (2017); McCoy and Linzen (2019); Ravichander et al. (2021), *inter alia*) to investigate the behaviour of these tasks under a specific phenomenon rather than the standard test distribution (Popović and Castilho, 2019). Lately, with the success of neural metrics, the development of challenge sets for MT evaluation has promoted great interest in studying the strengths and weaknesses of these metrics. We summarise here recent work on challenge sets for MT metric evaluation.

DEMETR (Karpinska et al., 2022), which comprises 31K English examples translated from ten languages, was developed for evaluating MT metric sensitivity to a range of 35 different types of linguistic perturbations, belonging to semantic, syntactic, and morphological error categories. These were divided into minor, major, and critical errors according to the type of perturbation, similar to the grading of error categories to compute the weighted ACES-Score. As in ACES, example generation was carefully designed to form minimal pairs such that the perturbed translation only differs from the actual translation in one aspect. The application of DEMETR in evaluating a suite of baseline metrics revealed a similar pattern to the analyses in Amrhein et al. (2022) - that metric performance varies considerably across the different error categories, often with no clear *winner*. It is worth noting that DEMETR and ACES each have their respective advantages: all examples in DEMETR have been verified by human annotators; ACES provides broader coverage in terms of both languages and linguistic phenomena.

In addition to ACES, three other datasets were submitted to the WMT 2022 challenge sets shared task (Freitag et al., 2022): SMAUG (Alves et al., 2022), the HWTSC challenge set (Chen et al., 2022), and the DFKI challenge set (Avramidis and Macketanz, 2022). These datasets differ from ACES in terms of their size, and the languages and phenomena/categories they cover (see Table 2).

Both SMAUG and HWTSC contained five different phenomena each pertaining to a single category of critical error for meaning change. In comparison, the DFKI challenge set has over 100 linguistically motivated phenomena, organised into 14 categories. Whereas the aim of ACES was to provide a broad coverage of language pairs, the other datasets provide an in-depth focus on specific lan-

	Ex.	Lang. pairs	Phenomena	Categories
SMAUG	632	2	5	5
HWTSC	721	1	5	5
DFKI	19,347	1	>100	14
ACES	36,476	146	68	10

Table 2: Comparison of challenge sets for MT metric evaluation in terms of: **Ex**amples, **Lang**uage**-pairs**, Phenomena, and Categories.

guage pairs: SMAUG (pt↔en and es→en), DFKI (de↔en), and HWTSC (zh↔en). Whilst there is a clear overlap between the ACES phenomena and those in SMAUG and HWTSC, many of the phenomena in the DFKI dataset are complementary such that in the case of evaluating metrics for the German-English pair, metric developers might consider benchmarking on both datasets.

4 Metrics

We list below the metrics that participated in the 2023 challenge set shared task and the baselines provided by the organisers.

4.1 Baseline Metrics

BERTScore (Zhang et al., 2020) uses contextual embeddings from pre-trained language models to compute the cosine similarity between the tokens in the hypothesis and the reference translation. The resulting similarity matrix is used to compute precision, recall, and F1-scores.

BLEURT-20 (Sellam et al., 2020) is a BERT-based (Devlin et al., 2019) regression model, which is first trained on scores produced by automatic metrics/similarity of pairs of reference sentences and their corrupted counterparts. It is then fine-tuned on WMT human evaluation data to provide a score for a hypothesis given a reference translation.

BLEU (Papineni et al., 2002) compares the token-level n-grams in the hypothesis with those in the reference translation. It then computes a precision score weighted by a brevity penalty.

chrF (Popović, 2017) provides a character n-gram F-score by computing overlaps between the hypothesis and reference translation.

COMET-22 (Rei et al., 2022) is an ensemble between a vanilla COMET model (Rei et al., 2020) trained with Direct Assessment (DA) scores and a multitask model that is trained on regression (MQM regression) and sequence tagging (OK/BAD word identification from MQM span annotations). These models are ensembled together using a hyperparameter search that weights different features extracted from these two evaluation models and combines them into a single score. The vanilla COMET model is trained with DAs ranging from 2017 to 2020 while the Multitask model is trained using DAs ranging from 2017 to 2020 plus MQM annotations from 2020 (except for en-ru which uses TedTalk annotations from 2021).

COMET-Kiwi (Rei et al., 2022) ensembles two QE models similarly to COMET-22. The first model follows the classic Predictor-Estimator QE architecture where MT and source are encoded together. This model is trained on DAs ranging from 2017 to 2019 and then fine-tuned on DAs from MLQE-PE (the official DA from the QE shared task). The second model is the same multitask model used in the COMET-22 submission but without access to a reference translation. This means that this model is a multitask model trained on regression and sequence tagging. Both models are ensembled together using a hyperparameter search that weights different features extracted from these two QE models and combines them into a single score.

f200spBLEU (Goyal et al., 2022) computes BLEU over text tokenised with a single language-agnostic SentencePiece subword model. For the f200spBLEU version of spBLEU used in this year's shared task, the SentencePiece tokeniser (Kudo and Richardson, 2018) was trained using data from the FLORES-200 languages.

MS-COMET-22 (Kocmi et al., 2022) is built on top of the COMET (Rei et al., 2020) architecture. It is trained on a set of human judgments several times larger – covering 113 languages and 15 domains. Furthermore, the authors propose filtering out those human judgements with potentially low quality. MS-COMET-22 is a reference-based metric that receives the source, the MT hypothesis and the human reference as input.

Random-sysname is a random baseline. The metric takes the name of the system as the only parameter. It uses a discrete score. Segment-level scores follow a Gaussian distribution around mean value X (in the range 0-9) and a standard deviation of 2. The mean X is calculated from the name of the system as: $X = sha256(sysname)[0]\%10$

The idea behind this baseline is two-fold. Firstly, having a baseline showing how a random metric would perform could help to put scores into context (in particular, pairwise accuracy can create a perception of great performance while 50% is just a toss of a coin). Secondly, it could help to detect errors in metric meta-evaluations.

YiSi-1 (Lo, 2019) measures the semantic similarity between the hypothesis and the reference translation by using cosine similarity scores of multilingual representations at the lexical level. It optionally uses a semantic role labeller to obtain structural similarity. Finally, a weighted F-score based on structural and lexical similarity is used for scoring the hypothesis against the reference translation.

4.2 Metrics Submitted to WMT 2023

We list the descriptions of the metrics submitted to WMT 2023 by the metric developers and refer the reader to the relevant system description papers for further details.

Embed_Llama relies on pretrained Llama 2 embeddings, without any finetuning, to transform sentences into a vector space that establishes connections between geometric and semantic proximities. This metric draws inspiration from Word2vec and utilizes cosine distance for the purpose of estimating similarity or dissimilarity between sentences.

MetricX-23 and MetricX-23-QE are learned reference-based and reference-free (respectively) regression metrics based on the mT5 encoder-decoder language model. They further finetune the mT5-XXL checkpoint on direct assessment data from 2015-2020 and MQM data from 2020 to 2021 as well as synthetic data.

Tokengram_F is an F-score-based evaluation metric that is heavily inspired by chrF++. By replacing word-grams with token-grams obtained from contemporary tokenization algorithms, tokengram_F captures similarities between words sharing the same semantic roots and thus obtains more accurate ratings.

Partokengram_F we did not receive a description of this metric.

XCOMET is a new COMET-base model that is trained to identify errors in sentences along with a final quality score and thus leads to an explainable neural metric. The metric is optimised towards regression and error span detection simultaneously. The same model may be used both with references (XCOMET) and without references (XCOMET-QE). The models are built using XLM-R XL and XXL, thus XCOMET-XL has 3.5B parameters and XCOMET-XXL has 10.7B parameters. The metric is trained in stages where it first sees DAs and then is fine-tuned with MQM. XCOMET-ENSEMBLE is an ensemble between 1 XL and 2 XXL checkpoints that result from these training stages.

XLsim is a supervised reference-based metric that regresses on human scores provided by WMT (2017-2022). Using a cross-lingual language model (XLM-RoBERTa (Conneau et al., 2020)), a supervised model is trained using a Siamese network architecture with CosineSimilarityLoss. **XLSIMQE** is the reference-free variant of this metric.

Cometoid22 is a reference-free metric created using knowledge distillation from reference-based metrics. First, using COMET-22 as a teacher metric, the MT outputs submitted to the WMT News/General Translation task since 2009 are scored. Next, a student metric, called Cometoid22, is trained to mimic the teacher scores without using reference translation. The student metric has the same architecture as COMET-QE, and is initialised with pre-trained weights from the multilingual language model InfoXLM. Three variants were submitted: cometoid22-wmt21,22,23, where the suffix indicates the training data cut-off year.

COMETKiwi-XL and COMETKiwi-XXL use the same COMETKiwi model architecture from WMT 2022 but replace InfoXLM with XLM-R XL and XXL (for COMETKIWI-XL and COMETKIWI-XXL respectively).

KG-BERTScore incorporates a multilingual knowledge graph into BERTScore and generates the final evaluation score by linearly combining the results of KGScore and BERTScore. In contrast to last year, COMET-QE is used to calculate BERTScore.

GEMBA-MQM is an LLM-enabled metric for error quality span marking. It uses three-shot prompting with a GPT-4 model. In contrast to EAPrompt (Lu et al., 2023), it does not require language-specific examples and requires only a single prompt.

5 Results

5.1 Phenomena-level Results

As in Amrhein et al. (2022) we begin by providing a broad overview of metric performance on the different phenomena categories, before conducting more detailed analyses (see Section 5.3). We restrict the overview to the metrics which provide a) segment-level scores and b) scores for all language pairs and directions in ACES. Out of the metrics that participated, 33 fulfil these criteria: 10 baselines, 11 reference-based, and 12 reference-free metrics.

We first compute the Kendall's tau-like correlation scores[3] (Freitag et al., 2021, 2022) for all of the ACES examples. This metric measures the number of times a metric scores the good translation above the incorrect translation (concordant) and equal to or lower than the incorrect translation (discordant):

$$\tau = \frac{concordant - discordant}{concordant + discordant}$$

We then report the average score over all examples belonging to each of the nine top-level accuracy categories in ACES, plus the fluency category *punctuation* (see Table 3). In addition, we compute the ACES-Score, a weighted combination of the top-level categories, which allows us to identify high-level performance trends of the metrics (see Equation 1). Note that the ACES-Score ranges from -29.1 (all phenomena have a correlation of -1) to 29.1 (all phenomena have a correlation of +1).

$$\text{ACES} = sum \left\{ \begin{array}{r} 5 * \tau_{\text{addition}} \\ 5 * \tau_{\text{omission}} \\ 5 * \tau_{\text{mistranslation}} \\ 1 * \tau_{\text{untranslated}} \\ 1 * \tau_{\text{do not translate}} \\ 5 * \tau_{\text{overtranslation}} \\ 5 * \tau_{\text{undertranslation}} \\ 1 * \tau_{\text{real-world knowledge}} \\ 1 * \tau_{\text{wrong language}} \\ 0.1 * \tau_{\text{punctuation}} \end{array} \right\} \quad (1)$$

Overall, the best-performing metrics submitted to this year's shared task, according to the ACES-Score, are COMETKIWI (a reference-free baseline metric), and KG-BERTSCORE (a reference-free metric). BLEU remains one of the worst-performing metrics, with only the random baseline, RANDOM-SYSNAME, achieving a lower ACES-Score. XCOMET-ENSEMBLE is the top ranking among the reference-based metrics. We caution that we developed ACES to investigate strengths and weaknesses of metrics on a phenomena level – hence, we advise the reader not to draw any conclusions based solely on the ACES-Score.

As observed in Amrhein et al. (2022) the performance of the metrics is highly variable, with no clear *winner* in terms of performance across all of the top-level ACES categories. We also observe similar trends in terms of the most challenging categories (*addition*, *undertranslation*, *real-world knowledge*, and *wrong language*). We find that, unlike last year, some metrics perform similarly to or worse than the baseline metrics. In particular, EMBED_LLAMA and GEMBA-MQM which are designed using Large Language Models (LLMs), struggle with this challenge set. This suggests that we need better design strategies in using the rich representations from LLMs for MT evaluation. In general, we find that reference-free metrics perform on par or better than reference-based metrics.

In terms of performance across the top-level categories, we also observe variation in the performance of metrics belonging to the baseline, reference-based, and reference-free groups. The reference-free group exhibits overall stronger performance compared with the other groups, but in particular for the *mistranslation*, *overtranslation*, *undertranslation*, and *real-world knowledge* categories.

[3]Evaluation scripts are available here: https://github.com/EdinburghNLP/ACES

Table 3: Average Kendall's tau-like correlation results for the ACES top-level categories and ACES-Scores (final column). Metrics are grouped into baseline (top), and participating reference-based (middle) and reference-free (bottom) metrics. Note that *Average* is an average over averages. Best results are highlighted in green.

5.2 Mistranslation Results

Next, we drill down to the fine-grained categories of the largest ACES category: *mistranslation*. We present metric performance for the sub-level categories (*discourse*, *hallucination*, and *other*) in Table 4. The *discourse* sub-category includes errors involving the mistranslation of discourse-level phenomena such as pronouns and discourse connectives. *Hallucination* includes errors at the word level that could occur due to hallucination by an MT model, for example, the use of wrong units, dates, times, numbers or named entities, as well as hallucinations at the subword level that result in nonsensical words. The *other* cub-category covers all other categories of mistranslation errors including overly-literal translations (see example in Table 1) and the introduction of ambiguities in the translation output. Again, as in 2022, we find that performance on the different sub-categories is highly variable, with no clear *winner* among the metrics. We also make similar observations to those in Amrhein et al. (2022), that the hallucination phenomena are generally more challenging than discourse-level phenomena; performance on the hallucination sub-category is poor overall.

5.3 Analysis

We repeat the analyses we performed in Amrhein et al. (2022) for the metrics submitted to WMT 2023 to confirm whether our findings from WMT 2022 still hold. We highlight similar observations to those from WMT 2022 and summarise our insights below.

5.3.1 How sensitive are metrics to the source?

Finding: Reference-based metrics tend to ignore the source.

In the ACES *Mistranslation - Ambiguous Translations* category, examples were designed in such a way that given an ambiguous reference the correct translation candidate can only be identified through the source sentence (See an example in Table 9). We leverage this property to present an analysis aimed at discovering how important the source is for different metrics. We exclude from the analysis all metrics that a) do not take the source and b) do not cover all language pairs. This leaves us with 22 metrics: seven reference-based metrics, fourteen reference-free metrics, and the RANDOM-SYSNAME baseline. In Table 5 we present results for the *Ambiguity - Discourse Connectives* (for the ambiguous English discourse connective "since" which can have either causal or temporal meaning), and *Ambiguity - Occupation Names Gender* (male and female) challenge sets.

Table 4: Average Kendall's tau-like correlation results for the sub-level categories in mistranslation: **disco**urse-level, **halluci**nation, and **other** errors. Metrics are grouped into baseline (top), and participating reference-based (middle) and reference-free (bottom) metrics. Note that *Average* is an average over averages. Best results are highlighted in green.

In addition, we measure the correlation gain when metrics receive access to disambiguation information via the source – for this we use the *Real-world Knowledge - Commonsense* challenge set i.e. a scenario in which the source contains disambiguation information (See an example in Table 1). In Table 6 we observe that the correlation gain is lower for the majority of the reference-based metric correlation scores compared with the reference-free metric correlation scores, when access to the subordinate clause is provided via the source.

Table 5: Results on the challenge sets where the good translation can only be identified through the source sentence. Upper block: reference-based metrics, lower block: reference-free metrics. Best results for each phenomenon and each group of models is marked in bold and green and the average over all can be seen in the last column.

In line with last year's findings, we report that reference-based metrics still lag behind reference-free metrics in terms of their correlation on challenge sets that can only be disambiguated by looking at the source. This indicates that reference-based metrics still rely too much on the reference translation. We conclude that our initial finding from 2022 still holds: that reference-based metrics tend to ignore relevant information in the source. One exception is XCOMET-ENSEMBLE, a reference-based metric that reaches similar correlations and correlation gains as some of the mid-performing reference-free metrics. We suspect that by training the same model to exhibit reference-based and reference-free behaviour, the model learns to utilise the information from the source in addition to the reference, when provided.

5.3.2 How much do metrics rely on surface overlap with the reference?

Finding: Reference-based metrics still rely on reference overlap.

Surface-level metrics are often too reliant on overlap with the reference. We aim to discover whether neural reference-based metrics submitted to the 2023 shared task are able to avoid this problem. Using the *Hallucination - Numbers and Named Entities* challenge set we compared how well reference-based and reference-free metrics[4] on average can identify *number* and *named entity* mismatches. In these challenge sets, we perform both word-level and character-level edits (i.e. substitutions) to simulate the hallucination behaviour. In order to thoroughly understand the behaviour of

Largest gains are bolded.

metrics under such hallucination errors, we introduced three levels. The first, easiest level follows Freitag et al. (2021) and applies a change to an alternative translation to form an incorrect translation. The second level uses an alternative translation that is lexically very similar to the reference as the good translation and applies a change to the reference to form an incorrect translation. The third, and hardest level, uses an alternative translation that is lexically very different from the reference as the good translation and applies a change to the reference to form an incorrect translation. In this way, our challenge set tests whether number and named entity differences can still be detected as the surface similarity between the two translation candidates decreases and the surface similarity between the incorrect translation and the reference increases. See an example of the different levels below as taken from the dataset paper -

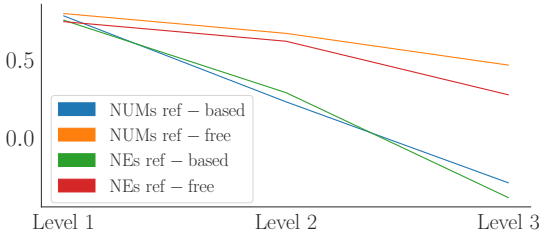

Figure 2: Decrease in correlation for reference-based and reference-free metrics on the named entity and number hallucination challenge sets.

SRC (es): Sin embargo, Michael Jackson, Prince y **Madonna** fueron influencias para el álbum.
REF (en): Michael Jackson, Prince and **Madonna** were, however, influences on the album.

Level-1 ✓: However, Michael Jackson, Prince, and **Madonna** were influences on the album.

Level-2 ✗: Michael Jackson, Prince and **Garza** were, however, influences on the album.

Level-3 ✓: The record was influenced by **Madonna**, Prince, and Michael Jackson though.
Level-3 ✗: Michael Jackson, Prince and **Garza** were, however, influences on the album.

We take the average correlation for all reference-based and reference-free metrics that cover all languages. We then plot the decrease in correlation with increasing surface-level similarity of the incorrect translation to the reference (Figure 2). As in the corresponding analysis of the WMT 2022 metrics, we observe that, on average, reference-based metrics have a much steeper decrease in correlation than the reference-free metrics as the two translation candidates become more and more lexically diverse and the surface overlap between the incorrect translation and the reference increases. This indicates that reference-based metrics may prefer a) an incorrect translation in cases where it is lexically similar to the reference but contains a severe error over b) a good translation that shares little overlap with the reference.

We also observe a clear effect of surface-level overlap between the reference and the hypothesis

	reference-based	reference-free
hallucination	-0.32 ± 0.15	+0.06 ± 0.06
overly-literal	-0.22 ± 0.14	0.00 ± 0.03
untranslated	-0.44 ± 0.11	-0.03 ± 0.06

Table 7: Average correlation difference and standard deviation between the challenge sets with reference-copied good translations and the challenge sets with the synonymous good translations.

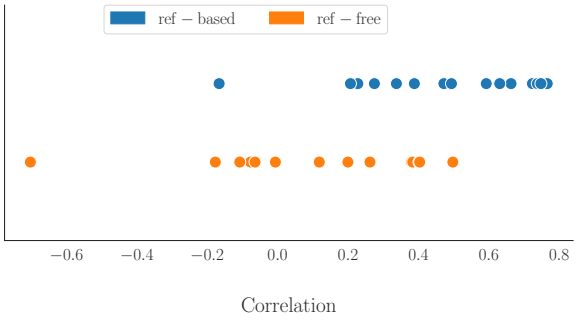

Figure 3: Correlation of reference-based metrics (blue) and reference-free metrics (orange) on the sentence-level untranslated test challenge set.

on three challenge sets for which we have different versions of the good translation, where the error was corrected with: a) the corresponding *correct token* from the reference and b) *a synonym for the correct token* from the reference. In Table 7, we can see a much larger difference in correlation between the challenge sets with reference-copied good translations and the challenge sets with the synonymous good translations, for the reference-based metrics as compared to the reference-free metrics. That is, it is much easier for reference-based metrics to identify mistranslations when the good translation matches a term in the reference compared with when a synonym is used. Furthermore, when the incorrect translation *shares a high degree of lexical overlap with the reference but does not have the same meaning* (as in the *Mistranslation - Lexical Overlap* challenge set based on adversarial paraphrase from PAWS-X (Yang et al., 2019)), the reference-based metrics only reach a correlation of 0.05 ± 0.16 on average. In contrast, the reference-free metrics reach a correlation of 0.27 ± 0.16.

We again conclude that although state-of-the-art reference-based MT evaluation metrics are no longer solely reliant on surface-level overlap, it still has a considerable influence on their predictions.

5.3.3 Do multilingual embeddings help design better metrics?

Finding: Multilingual embeddings can be harmful with poor design.

We are interested in the extent to which the representations in neural MT evaluation metrics, which are trained on multilingual models, are language-dependent. For this analysis, we investigated the effect of alignment of multilingual embeddings (including LLMs) on the evaluation task through the *wrong-language* and *untranslated - full sentences* phenomena for those metrics that provided scores for examples in all language pairs. In the *wrong-language* phenomenon, the incorrect translation contains a high-quality translation of the source in a similar language to the target language while the good translation is the machine translation output of the source sentence in the target language. In the challenge set for *untranslated - full sentences*, the incorrect translation is a copy of the source sentence and the good translation is machine translation output in the target language. Multilingual embeddings learn cross-lingual representations by reducing the language-specific properties during pretraining (Wu and Dredze, 2019). We hypothesised that making representations language agnostic may harm MT evaluation in cases where translations are extremely poor, such that they remain untranslated or hallucinate from a similar language.

In Figure 3 we plot the correlations for all reference-based and reference-free metrics. Overall, we observe that several metrics from 2023 have much better correlation scores than 2022 indicating that newer models have developed strategies to avoid learning language-agnostic representations. In particular, we find that many of the reference-free metrics submitted to the 2023 shared task have improved on the *untranslated - full sentences* category (though a few reference-free metrics from 2022 had performance closer to 1, which is not the case with the 2023 metrics). This is a welcome change as we expect these metrics to perform a more faithful evaluation when many of the words remain untranslated in the hypothesis, especially in the lower resource setting. Whilst some reference-free metrics struggle considerably on this challenge set and almost always prefer the copied source to the real translation, reference-based metrics generally exhibit good correlation i.e. they can identify the copied source quite easily. As reference-based metrics tend to ignore the source, the scores are likely based on the similarity between the reference and the MT output. This is evident from their poor

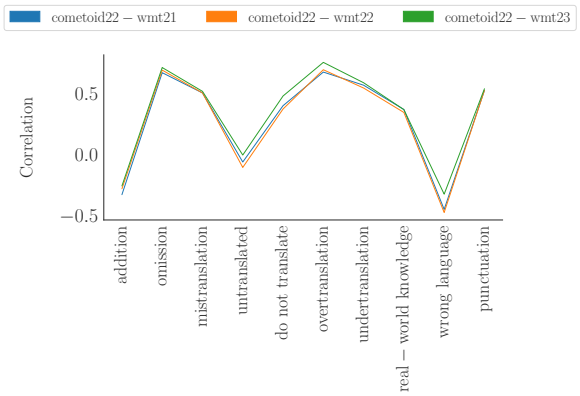

Figure 4: Correlations for different top-level phenomena categories with different models trained on successively more data.

performance on the *wrong - language* category (see Table 3). This suggests that language-agnostic representations present in the multilingual space may harm performance.

5.4 Training data size effects

One submission this year, namely COMETOID22, submitted three different reference-free metric versions, each trained on successively more data. This allows us to investigate the effects of the metric training data size[5] on the performance on ACES. (Note that we cannot draw any conclusions about the training data size of the pretraining models that are used.) In Figure 4 we can see the effect of training data size on the performance on the top-level phenomena categories. COMETOID22-WMT23, the model that has seen the most data, outperforms the other two metrics on almost all top-level categories. The correlation gain is especially pronounced for the *untranslated*, *do not translate* (content in the source is erroneously translated into the target language), *overtranslation* (the target translation contains more specific information than the source) and *wrong language* categories (see Table 9 for examples for each of the phenomena). For clearer insights as to where the performance gain comes from, we would need to analyse the training data in depth. However, it is evident from these results that more training data is beneficial for metric development. In the next section, we look at metric score changes over metric implementation cycles - where likely more than just the training data changed.

[5]Note that for COMETOID22 this is not human judgement labelled data but rather pseudo labelled data where labels come from the reference-based COMET-22 model.

5.5 Changes over one year

We compare the results of metrics submitted by the same teams last year and this year in Table 8.

We report changes in performance in terms of deltas, computed by subtracting the 2022 score from the 2023 score. We do this for the following pairs of metrics: KG-BERTSCORE (2022) and KG-BERTSCORE (2023); COMETKIWI (2022) paired with COMETKIWI-XL (2023) and COMETKIWI-XXL (2023); COMET-22 (2022) paired with XCOMET-ENSEMBLE (2023), XCOMET-XL (2023) and XCOMET-XXL (2023).

We observe that KG-BERTSCORE has improved over its performance of last year. From the description provided by the metric developers, the main difference is that the 2023 version of KG-BERTSCORE metric uses COMET-QE instead of BERTScore (Zhang et al., 2020) to compute the similarity between the source and the hypothesis. Whilst we might therefore attribute the increase in performance to this change, a more systematic comparison of the two metric versions would be required to confirm whether this is the only contributing factor.

The metrics in the COMETKIWI family exhibit: a slight drop in performance (COMETKIWI-XL) and a similar performance to that of last year (COMETKIWI-XXL). The difference can be attributed to changing the underlying encoder, XLM-R XL and XLM-R XXL (Goyal et al., 2021) respectively, and the use of additional fine-tuning data made available this year. We have seen that the addition of more training data helps in Section 5.4. Considering that there is no improvement in the performance, we question if an increase in the underlying model capacity of the encoder alone is useful for obtaining better MT evaluation.

Performance change for the XCOMET family is variable: there is a performance increase for XCOMET-ENSEMBLE (compared to COMET-22), for XCOMET-XL the increase is smaller, and the performance of XCOMET-XXL is degraded. The XCOMET family is designed to provide both a quality score and an error span. Considering that the metric also provides an explanation of the scores without hurting the performance, this is indeed a positive change. Finally, it is worth noting that for *all* metrics in Table 8 a change in performance is observed for almost all ACES categories, for all metrics.

	COMETKiwi		KG-BERTScore	XCOMET

Table 8: Comparison of average Kendall's tau-like correlation: delta calculated as 2023 score minus 2022 score.

Whilst it is not possible to draw conclusions or make predictions about the future of metric development based solely on the observations from two consecutive metrics shared tasks, we highlight several high-level changes. Firstly, we note the participation of many more COMET-based metrics in 2023, compared with 2022. This is presumably based on the success of COMET at previous shared tasks and its adoption within the MT community. We find that three metrics from 2022 are now used as baseline metrics namely COMET-22, COMETKIWI, and MS-COMET-QE-22. In contrast to the submissions in 2022, we find some new metrics that use lexical overlap through text matching or embeddings (TOKENGRAM_F, PARTOKENGRAM_F, and EBLEU). However, their performance trend is similar to other surface overlap metrics. This year has also seen submissions based on large language models (EMBED_LLAMA and GEMBA-MQM). As seen in Section 2, their moderate performance indicates the need for more effective approaches. Additionally, we note an overall increase between 2022 and 2023 in the number of metrics submitted to WMT that a) provide segment-level scores and b) provide scores for all language pairs and directions in ACES. There were 37 segment-level metrics at WMT 2022, 24 of which covered the language pairs and directions in ACES, compared with 47 and 33, respectively in 2023. This suggests that the interest in metric development remains high, and could be increasing.

From our analyses in Section 5.3, we also draw similar conclusions to Amrhein et al. (2022) with the exception of reference-free metrics improving at the *Untranslated - Full Sentences* task. Despite the success of LLMs across various tasks (Brown et al., 2020), leveraging them to evaluate translated outputs still requires some improved design strategies. All these observations suggest that evaluating MT outputs is indeed a hard problem (Neubig, 2022). While we do have a good suite of metrics to provide a proxy for evaluation, there are indeed several interesting challenges that need to be tackled before we find an ideal evaluation regime. And even then, we need to continuously monitor this to ensure that we do not optimise towards metric weaknesses that we have not yet discovered.

5.6 Recommendations

We provide the same recommendations as last year:

No metric to rule them all. There is no consistent winning metric across all categories (see Table 3). We recommend developing evaluation methods that combine different design strategies for robust evaluation. We also recommend innovation in the ensemble building as simple strategies like majority voting do not lead to significant improvement (Moghe et al., 2023). We find that some submissions in this year's shared task already contain ensembles (XCOMET-ENSEMBLE, XCOMET-QE-ENSEMBLE) which suggests that our recommendations are in line with the efforts of the community.

The source matters. The trend where reference-based metrics tend to disregard information in the source is also persistent, as seen in Section 5.3. We also observe that reference-free metrics are highly competitive with reference-based metrics as seen in Table 3 and also in Freitag et al. (2022); Zerva et al. (2022), *inter alia*. Furthermore, as references are often not perfect themselves (Freitag et al., 2020), it is ideal to develop evaluation regimens that focus more on the information in the source sentence than

the references.

Surface overlap still prevails. Neural metrics were introduced to overcome surface-level overlap present in the string-based metrics. However, the results in Section 5.3.2 suggest that neural metrics tend to focus more on lexical overlap than semantic content. We thus recommend including paraphrases in the training regime as well as designing loss functions that explicitly discourage surface-level overlap.
Lastly, simple strategies to model language-specific information in the metrics could also improve the robustness of the metrics to language pair attacks.

6 Conclusion

We re-submitted the ACES Challenge Set to WMT2023 to identify the strengths and weaknesses of the metrics submitted to this year's shared task. Overall, we find similar trends to that of last year. While neural metrics tend to be better, different categories of metrics have different strengths, and we do not find one clear winner. With respect to the metrics that were resubmitted with some design changes, we find that these design changes have variable outcomes with a performance drop in some cases. The major challenges of (i) metrics not paying enough attention to the source, (ii) reference-based metrics still relying on surface-level overlap, and (iii) over-reliance on multilingual embeddings still persist. Hence, our recommendations are also similar to that of last year: build ensembles of different design families, encourage development that better utilises information in the source, include diverse training examples to reduce the influence of surface-level overlap, and carefully determine the influence of multilingual embeddings/LLMs on MT evaluation.

Limitations

When comparing the results of the baseline metrics common to the 2022 and 2023 metrics shared tasks, we observed differences in the scores returned for a small subset (2,659; approx 7%) of the ACES examples. A subsequent investigation suggested that differences in the pre-processing steps by the shared task organisers in 2022 and 2023 may have led to the differences; we further conjecture that differences in handling the double quotes present in some of the ACES examples may be one of the main causes. Regardless of the source of the differences, we highlight that care should be taken when pre-processing the ACES dataset prior to benchmarking metric performance, especially when the aim is to draw comparisons with results reported in previous work. However, we note that this issue is not specific to ACES, but may potentially affect any text-based dataset. With the exception of the comparison of results from 2022 and 2023 in Section 5.5, for which we used the subset of 33,817 examples which were unaffected by pre-processing differences, all other results reported in this paper use the full set of 36,476 ACES examples. We also note that ideally, incorrect processing of double quotes by a metric should not lead to a difference in scores especially when dealing with semantic errors.

As we re-submitted the same version of the ACES dataset to WMT 2023, the same biases described in Amrhein et al. (2022) remain: 1) there is greater coverage in terms of phenomena and number of examples for some language pairs (particularly en-de and en-fr), 2) more examples are provided for categories for which examples may be generated automatically, compared to those that required manual construction/filtering, 3) errors present in the datasets used to construct the examples may have propagated through into ACES, 4) the focus of the ACES is on accuracy errors; the inclusion and evaluation of fluency errors remains a direction for future work.

ACES consists of examples that target a range of linguistic phenomena, which are then arranged in a hierarchy of error categories. In order to provide metric profiles over this range of error categories we require segment-level scores. We therefore report only results for those metrics submitted to WMT 2023 that provide segment-level scores; metrics that provide only system-level outputs are excluded. Further, we excluded those metrics that did not provide scores for all of the language pairs in ACES from the results and analyses in this paper.

The 2023 WMT metric shared task evaluated metrics at the paragraph level for English-German. Currently, ACES is not able to capture document-level metric performance. We hope such challenge sets will become available in the near future to be able to track metric improvements beyond the sentence level.

Ethics Statement

As described in Amrhein et al. (2022) some examples within the ACES challenge set exhibit biases.

However, this is necessary in order to expose the limitations of existing metrics. The challenge set is already publicly available.

Acknowledgements

We thank the organisers of the WMT 2023 Metrics task for organising the Challenge Sets shared task, and the shared task participants for scoring our challenge sets with their systems. We thank Nikolay Bogoychev and the anonymous reviewers for their insightful comments and suggestions. This work was supported in part by the UKRI Centre for Doctoral Training in Natural Language Processing, funded by the UKRI (grant EP/S022481/1) and the University of Edinburgh (Moghe), and by the Swiss National Science Foundation (project MUTAMUR; no. 176727) (Amrhein). We also thank Huawei (Moghe) and the RISE Center for Applied AI (Guillou) for their support.

Challenging the state-of-the-art Machine Translation Metrics from a Linguistic Perspective

Eleftherios Avramidis, Shushana Manakhimova, Vivien Macketanz and Sebastian Möller
German Research Center for Artificial Intelligence (DFKI),
Speech and Language Technology, Berlin, Germany
firstname.lastname@dfki.de

Abstract

We employ a linguistically motivated challenge set in order to evaluate the state-of-the-art machine translation metrics submitted to the Metrics Shared Task of the 8th Conference for Machine Translation. The challenge set includes about 21,000 items extracted from 155 machine translation systems for three language directions (German⇔English, English→Russian), covering more than 100 linguistically-motivated phenomena organized in 14 categories. The metrics that have the best performance with regard to our linguistically motivated analysis are the COMETOID22-WMT23 (a trained metric based on distillation) for German-English and METRICX-23-C (based on a fine-tuned mT5 encoder-decoder language model) for English-German and English-Russian. Some of the most difficult phenomena are *passive voice* for German-English, *named entities, terminology* and *measurement units* for English-German and *focus particles, adverbial clause* and *stripping* for English-Russian.

1 Introduction

Most NLP evaluation has relied for years on testing the system performance on randomly picked test sets and producing a single generic score. Yet, machine learned systems learn to make abstractions and due to these, phenomena who are on the long tail of the training and test data may be overlooked hidden behind a very high generic score. Additionally, generic scores are often helpful to show relative improvement and reflect overall quality, but cannot explain the performance in a comprehensive way.

For example, old-style machine translation (MT) metrics measuring lexical overlap would equally penalize the omission of an article and the omission of the particle forming the negation in a sentence, although negation is more crucial for its meaning. While the evaluation of so obvious errors has been addressed by the trained MT metrics, their evaluation relies on correlations with human judgments on randomly picked test-sets. In this case, a single correlation score may not be able to explain the strengths and weaknesses of the metrics with regard to the functioning of language.

Motivated by these considerations, we employ a multifold test set with linguistically-motivated challenges that will allow us to understand the metric performance from a linguistic perspective. These challenges are organized in smaller sets, one set per phenomenon, whereas the phenomena are organized in broader categories. By measuring the ability of the metrics to detect the errors in these challenge sets, we can get scores that indicate different aspects of linguistic performance.

This paper describes the application of such a challenge set on the evaluation of the MT metrics submitted at the relevant shared task of the 8th Conference of Machine Translation (Freitag et al., 2023). The rest of the paper is structured as following: Section 2 describes related work, and section 3 describes the way the challenges were selected. In Section 4 the results are presented and described, first from the perspective of metric comparison and then focusing on the performance for particular linguistically-motivated categories and phenomena per language direction. Some conclusions are given in Section 5.

2 Related work

There has been a growing interest for more fine-grained evaluation of Natural Language Processing (NLP) tools, as shown by the increasing number of publications many of whom have received distinctions (Ribeiro et al., 2020; Avelino et al., 2022; Campolungo et al., 2022). Concerning machine translation (MT), initial efforts were made in the 1990s with the introduction of test suites (King and Falkedal, 1990), and these efforts have been revitalized in light of recent advancements in the

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 713–729
December 6–7, 2023.

field (Guillou and Hardmeier, 2016). To the best of our knowledge, the first endeavours related to the use of challenge sets in a meta-level in order to evaluate MT metrics were applied to Quality Estimation metrics (Avramidis et al., 2018), based on the first version of our linguistically-motivated test suite (Macketanz et al., 2018). The analysis was broadened to cover a broader range of MT metrics, including reference-based ones, as appeared in the Findings paper of the Metrics shared task of the 6th Conference on Machine Translation (Freitag et al., 2021), which was based on a later version of our test suite on German-English (Avramidis et al., 2019, 2020; Macketanz et al., 2021, 2022a), a resource also employed in this paper.

With the occasion of the first challenge set subtask for the metrics shared task of the 7th Conference on Machine Translation (Freitag et al., 2022), a few more challenge sets emerged. ACES (Amrhein et al., 2022) for example, focuses on 68 accuracy errors. Similarly, Alves et al. (2022) evaluate the robustness of MT metrics by generating translations with critical errors. In a more linguistic direction, Chen et al. (2022) examine the capability of the metrics to correlate synonyms in different areas and to discern catastrophic errors at both word- and sentence-levels.

Our submission at that sub-task (Avramidis and Macketanz, 2022) augmented the preliminary analysis appearing at Freitag et al. (2021) by adding the language direction of English-German and presenting a more fine-grained analysis, not only in the category level but also on the phenomenon level. This year's submission, explained on our paper, includes that same challenge set as last year, whereas English-Russian has been added as an additional language direction.

3 Method

3.1 Test suite for MT systems

Here, we are going to explain how we created the pool of MT sentences that were used for the challenge set. The selection was based on a linguistically-motivated test suite (Macketanz et al., 2022a)[1]. The test suite contains a set of source sentences focusing on particular phenomena, each of them accompanied by some rules or regular expressions that can detect which translations would be accepted for these source sentences. This allows a semi-automatic evaluation when new translations are provided, whereas a human annotator resolves cases not covered by the rules.

For this experiment, we employed the test suite on three language directions: German-English (Avramidis et al., 2020), English-German (Macketanz et al., 2021) and English-Russian (Macketanz et al., 2022b). The German-English side consists of 5,539 German test sentences covering 107 linguistically motivated phenomena, the English-German side consists of 4,782 English test sentences covering 126 phenomena, and the English-Russian side consists of 1,225 English test sentences covering 64 phenomena. All language directions are organized in 14 categories, which nevertheless differ among the directions.

The above described test suite has been used to evaluate the outputs of 116 German-English, 29 English-German systems and 10 English-Russian systems submitted at the translation task of the Conference of Machine Translation (WMT). German-English outputs were collected from systems submitted in the years 2018-2021, English-German outputs in the years 2020-2021 and English-Russian in 2022.

3.2 Challenge set for MT metrics

The sentences selected with the help of the test suite are consequently used to create the challenge set. The source sentences and the system outputs have to be organized in contrastive pairs of correct/incorrect translations and a reference. In order to achieve this, for every source sentence from the test suite selection we create a challenge item including:

- one correct translation to be used as a reference translation,
- another correct translation to be used as the first translation candidate
- one incorrect translation to be used as the contrastive translation candidate

The two candidate translations and the reference consist one challenge item. Since source and translations were collected as a result of testing for a particular phenomenon, the same phenomenon will be what the challenge item will test.

Given that we may have many correct and wrong translations for the same source, the reference and the translations of the challenge items result from random combinations of correct and wrong translations from the collected WMT outputs. Therefore,

[1] https://github.com/DFKI-NLP/mt-testsuite

the same source sentence may appear many times.

As a result, we get a challenge set with 10,402 items for German-English, 8,945 items for English-German and 1,727 items for English-Russian.

3.3 Evaluation of metrics

For each challenge item, the two machine translation (MT) outputs, are provided to the metrics as separate MT hypotheses. Which output is correct, and which is incorrect, is hidden from the metrics. These hypotheses are then evaluated against the previously mentioned reference and/or the source. An item is deemed correctly scored when the metric assigns a higher score to the correct MT output compared to the incorrect one. Following this, the statistics below are computed:

i) **Accuracy per Phenomenon**: the ratio of all correctly-scored challenge items per phenomenon to the total number of challenge items for that particular phenomenon.

ii) **Accuracy per Category**: the ratio of all correctly-scored challenge items per category to the total number of challenge items for that category, after consolidating the underlying phenomena of that category into a single set.

Significance tests are performed to compare the highest metric accuracy for each phenomenon with all other metric accuracies for the same phenomenon. This is a one-tailed Z-test, conducted with a significance level of $\alpha = 0.95$. Metrics with accuracies that are not significantly worse than the highest accuracy are considered to share the top position for that phenomenon. A similar approach is used to identify the best accuracies per category, after aggregating the challenge items from the underlying phenomena within each category.

Metric categories We conduct this significance testing in two stages: first, for all metrics involved in the shared task, and then separately for each of the three metric categories (baseline, Quality Estimation (QE) as a metric, reference-based). Systems that are significantly superior per phenomenon across all metrics are highlighted with a gray background, while those that are significantly superior per metric category are denoted in boldface.

Averaging Lastly, we provide three types of averaging scores:

i) **Micro-average:** This approach considers all items equally, aggregating all test items to compute the average percentages.

ii) **Category macro-average:** Here, all categories are treated equally, with the percentages being computed independently for each category and then averaged.

iii) **Phenomenon macro-average:** This average treats all phenomena equally, with the percentages being computed independently for each phenomenon and then averaged.

4 Results

The results are displayed in detail in Tables 1, 2 and 3 for the category level and in Tables 4, 5 and 6 for the phenomenon level, for the three language directions respectively.

4.1 Metric performance analysis

Here we are observing the statistics with a focus on comparing the performance of various metrics on the challenge set.

German-English The accuracies of the metrics, as measured for several categories in German-English, can be seen in Table 1. The best performing metric for German-English is COMETOID22-WMT23 (Gowda et al., 2023), which, wins significantly based on both the micro-average (83%) and the macro-average (87%). This metric is a distilled QE model that has been trained on COMET (Rei et al., 2020) scores of WMT outputs, including the ones of WMT23. For this reason, we include it into the reference-aware metrics. We notice that its performance among the other metrics is impressive. It is the first metric in 6 categories and among them the only one who wins at *Verb tense/aspect/mood* and *function words*, achieving 93% and 91% accuracy respectively.

Another two reference-based baseline metrics, COMET and PRISMREF (Thompson and Post, 2020a,b) share the first position when the category macro-average is considered (82%). None of the other reference-aware metrics submitted this year managed to compete with the metrics with the highest accuracy mentioned above.

The lowest performing metric is the reference-less random baseline RANDOM-SYSNAME, provided by the organizers (44%), followed by XL-SIMQE (55-58%; Mukherjee and Shrivastava,

2023) and MATESE (57-58%; Perrella et al., 2022).

When considering the metric performance with regard to particular categories, one can see, again this year, that different metrics win in different combinations of categories. Here, only COMETOID22-WMT23 as mentioned above, wins 6 metrics, followed by PRISMREF and METRIC-23-C, which win 4 categories. 17 metrics do not win any category, ranging in accuracies around 75%.

English-German The accuracies of the metrics, as measured for several categories in English-German, can be seen in Table 2. The best performing metric in English-German is METRICX-23-C, which is in the first significance cluster based on both the micro-average (81%) and the category macro-average (84%). This metric uses the mT5 encoder-decoder language model, which is fine-tuned using direct assessment data, MQM (Lommel et al., 2014) data and synthetic data. The categories to which its success may be mostly attributed are the *multi-word expressions* (MWE; with 92%) and the non-verbal agreement (95%).

Another three metrics share the first position, when the micro average is considered, namely the QE version of the latter, *MetricX-23-QE-c* and also *mbr-metricx-qe* (Naskar et al., 2023) and XCOMET-Ensemble. It is impressive that QE methods manage to reach high accuracy without access to reference content.

When looking at the worse-performing metrics, MATESE here performs worse than the baseline (36-38%), followed by PARTOKENGRAM_F (55-56%; Dreano et al., 2023b).

In English-German it is even harder to say which metrics perform well in multiple categories, as only one of them, XCOMET-QE-ENSEMBLE, achieves the highest performance in 3 categories (*function words, non-verbal agreement and subordination*). The rest of the metrics show a good performance in 2 categories or fewer.

English-Russian The accuracies of the metrics, as measured for several categories in English-German, can be seen in Table 3. For this language pair, variants of the MetricX achieve significantly higher accuracies than all the other metrics. In particular, METRICX-23-C achieves the highest accuracy based on both micro-average and category macro-average, whereas METRICX-23-B and METRICX-23-QE-C achieve a slightly lower macro-average, which is nevertheless not significantly worse than the one of the former. MATESE is again by far the lowest performing metric (32/34%), lower than the random baseline. We may assume that this metric has not been optimized for this language direction.

4.2 Linguistically motivated analysis

In this section, we are focusing on the results for particular phenomena or categories.

4.2.1 German-English

Category-level The overall average accuracy of all metrics with regard to the linguistically motivated categories is at 76% for German-English, which is two percentage points lower than last year's average. It is still a fact, that the metrics in average fail to predict properly the scores for one out of four challenge items that we provided. Luckily, there has been noticeable accuracy for some categories, for example METRICX reference-based variants achieved an accuracy of 96% for *false friends*, whereas *negation* errors have been scored correctly with a 98.5

The worse performing category is *Verb valency*, where the best metrics achieved only 66% accuracy, and the rest of the metrics averaged to a mere 56%. In this category one can observe the lowest accuracy, given by an LLM-based metric, EMBED_LLAMA (Dreano et al., 2023a) with 41%.

Phenomenon-level The best accuracy for this language pair (Table 4) is achieved this year at several variations of verb tenses, i.e. *Transitive - future II, Modal negated - present, Reflexive - preterite subjunctive II* and *Intransitive - pluperfect* which get more than 85% in average.

The lowest accuracy of all metrics in average is given for *passive voice*, where the highest accuracy achieved by several metrics is only 54.5%. Errors related to *commas, domain-specific terms* and *locations* have also been scored with a less than 65% accuracy.

4.2.2 English-German

Category-level The overall average accuracy of all metrics with regard to the linguistically motivated categories is at 71-73% for English-German. The category where all metrics perform better in average is *negation* (83%), where 11 of the metrics achieve more than 90% accuracy. Negation is closely followed by *function words Non-verbal agreement* (80%).

The worse performing category in average is *named entities and terminology* (58,8%), where most metrics' accuracies are close to 50%, except for BLEURT (Yan et al., 2023) (80.3%). The rest of the categories lie in rather mediocre accuracies, between 58.8% and 80%.

Phenomenon-level The English-German phenomena, where metrics perform best in average (Table 5) are the *transitive conditional II simple, gerunds, contact clause* and the *intransitive present perfect simple*, achieving more than 85% of accuracy. The phenomena which incur the lowest average accuracies are the *transitive present progressive, measuring units*, *modals* and *intransitive - future II progressive* with less than 50% accuracy. The former and the latter were observed as the most difficult phenomena to score also last year.

4.3 English-Russian

This analysis for English-Russian occurs for the first time this year, based on the MT outputs collected at last year's shared task. For this purpose the test instances are much fewer than the other language pairs and therefore the numbers are not very conclusive. Therefore, categories and phenomena that have only a handful of samples will not be included in our analysis, although they appear in the tables.

Category-level Here, the average accuracy over all metrics is much lower than the other language directions, reaching only 66%, only 20% above the random baseline. The best performing category is *ambiguity* (86,3%), more than 13% better than the following categories. The worst performing categories are *function words* and *punctuation*, with less than 55%. The rest of the categories range in accuracies between 53 and 73%.

Phenomenon-level The good performance of the *ambiguity* category is also confirmed in the table on the phenomenon level (Table 6), as in Russian this is the only phenomenon of this category, as opposed to other language pairs where we also have examples of structural ambiguity. The most difficult phenomena to score appear to be the *focus particles, adverbial clause* and *stripping* with less than 50% average accuracy, in many cases lower than the random baseline.

5 Conclusion

In this paper we analysed the performance of several state-of-the-art metrics with regard to particular linguistically-motivated phenomena for three language pairs, German-English, English-German and for the first time, English Russian. The analysis gave a multitude of observations, regarding both the performance of the metrics and the corresponding linguistic observations.

The metrics demonstrating the best performance in average are COMETOID22-WMT23 for the German-English language pair, and METRICX-23-C for both the English-German and English-Russian language pairs. Quality estimation methods have impressively good performance in several phenomena. Some metrics that report usage of LLMs (EMBED_LLAMA) have not scored very high in overall, indicating that more work is required in this direction.

Among the various linguistic phenomena, we could identify some of the particularly challenging ones. In German-English, metrics have difficulties scoring the *passive voice* properly. In English-German *named entities and terminology* as well as specific *measurement units* pose the most difficulties. In English-Russian translation, translations with *focus particles*, *adverbial clause*, and *stripping* phenomena emerge as particularly complex challenges.

Acknowledgements

This research was supported by the German Research Foundation (Deutsche Forschungsgemeinschaft; DFG) through the project TextQ and by the German Federal Ministry of Education (BMBF) through the project SocialWear (grant num. d01IW20002). We would like to thank Hans Uszkoreit, Aljoscha Burchardt, Ursula Strohriegel, Renlong Ai, He Wang, Ekaterina Lapshinova-Koltunski and Sergei Bagdasarov for their prior contributions for the creation of the test suite.

Abstract

The tokengram_F metric presented in this paper is a novel approach to evaluating machine translation that has been submitted as part of the WMT23 challenge. It offers a new perspective on evaluating machine translation that takes advantage of modern tokenization algorithms to provide a more natural representation of the language in comparison to word *n*-grams.

Tokengram_F is an F-score-based evaluation metric for Machine Translation that is heavily inspired by chrF++ and can act as a more accurate replacement. By replacing word *n*-grams with *n*-grams obtained from tokenization algorithms, tokengram_F captures similarities between words sharing the same semantic roots.

While requiring minimal training based on an open corpus of monolingual datasets, the tokengram_F metric proposed still retains excellent performance that is comparable to more computationally expensive metrics. The tokengram_F metric demonstrates its versatility by showing satisfactory results, even when a tokenizer for a specific language is not available. In such cases, the tokenizer of a related language can be used instead, highlighting the adaptability of the tokengram_F metric to less commonly-used languages.

1 Introduction

Machine Translation (MT) is a subdomain of Neural Language Processing (NLP) that is focused on the translation of one natural language to another, with the aim of producing natural-sounding sentences. To evaluate the quality of algorithm-generated translations, evaluation metrics provide quantitative scores to objectively assess the accuracy of the model. Machine-generated translations are compared to human-generated translations in different ways depending on the evaluation metric. In recent years, machine translation has seen a great deal of progress in terms of accuracy and fluency. However, there is still a need for more robust evaluation metrics that can effectively measure the quality of machine-generated translations.

Popular metrics in MT include BLEU (Papineni et al., 2002), which measures the overlap between sequences of words in the reference and generated texts; chrF (Popović, 2015), which is an F1 score at the character-level; chrF++ (Popović, 2017), which extends chrF with word *n*-grams; TER (Snover et al., 2006), which counts the erroneously-aligned words between the reference and the generation, and METEOR (Banerjee and Lavie, 2005), which takes into account synonyms and stems.

More recent metrics rely on neural network architectures, such as COMET (Rei et al., 2020) and MS-COMET (Kocmi et al., 2022). By using the similarity of vector representations of the generated translation and the reference translation, they provide state-of-the-art machine evaluation of translations at the cost of being expensive to train and compute.

Since its third instance in 2006, the Workshop on Statistical Machine Translation (WMT) has released an evaluation task to compare metrics each year. Generated translations are usually ranked by humans, and the correlation coefficient between the human-performed ranking and the evaluation metric-performed ranking determines the quality of the metric.

2 Tokengram_F

2.1 Tokenization

As text cannot be directly processed by machine learning algorithms, it first has to be converted into a numerical representation. Tokenization splits the text into smaller character sequences, including but not limited to phonemes, syllables, letters, words or base pairs, collectively named tokens. The tokenization process also often consists of adding special tokens, such as the unknown <unk> token to represent never-seen characters or the padding

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 730–737
December 6–7, 2023.

<pad> token to pad the sentence to a fixed length. Each token can be converted to and from a unique identifier, which is usually an integer between 0 and the maximum vocabulary size minus one.

2.2 chrF++

An n-gram refers to a consecutive series of n tokens that are extracted from a given corpus of text or speech, with these units of text being defined based on the particular context of the application. A character-gram, or unigram, is a token that contains exactly one character, while a word-gram contains an entire word. chrF++ is an F-score using both word-grams and character-grams to compare the generated translation to the reference translation. The general formula is

$$ngrF\beta = (1 + \beta^2)\frac{(ngrP \times ngrF)}{(\beta^2 \times ngrP + ngrR)}$$

where β determines the weight of the recall as discussed in Section 3.4.3.

2.3 Modern tokenization algorithms

Subword-based tokenization divides words depending on their number of occurrences in the training data. Subwords can be combined to represent less frequent words or even words that were not present in the training data. For instance, in cases where a word such as "decaying" is absent from the vocabulary, an English tokenizer may represent it by combining the "decay" and "ing" tokens.

Byte Pair Encoding (BPE) (Sennrich et al., 2016), had been used for data compression long before it was ever applied in NLP-related tasks. After first counting the frequency of each unique word in the training data, BPE merges frequent occurrences of subword pairs until it reaches the desired vocabulary size.

Instead of starting from a small vocabulary representing the set of unique words, and growing in size from there (as in BPE), Unigram (Kudo, 2018) initialises its base vocabulary to a large number of symbols and then trims it down to the desired size. It is analogous to factor analysis, as at each step it calculates the loss of information that would be induced by removing each token, and then erases the less important ones from its vocabulary.

The sentence "The kingly sovereign governs" becomes:

```
words: "The" "kingly" "sovereign" "governs"
tokens: "The" "king" "ly" "sovereign" "govern" "s"
```

2.4 Replacing word-grams

When using word-grams for scoring, each word is compared regardless of its proximity to other words. For example, the words "say" and "saying" share a common root but this link would be lost when using word-grams.

In this work, the authors claim that modern tokenization algorithms can be used instead of word-grams to split the text in a more natural manner that reflects the structure of each language. Tokengram_F is an evaluation metric derived from chrF++ that replaces the use of word-grams by tokens learned either by Unigram or by BPE.

3 Methodology

3.1 Framework

SentencePiece (Kudo and Richardson, 2018) is a fast data-driven text tokenizer and detokenizer implementing the Unigram algorithm. The vocabulary size (number of individual tokens) needs to be provided before training. The minimum vocabulary size would consist of the number of special tokens and individual characters of the alphabet for each language. A large vocabulary size might lead to overfitting and a reduction in the effectiveness of the model, given that some parameters will be dedicated to rare words.

3.2 Training

The tokengram_F score uses the same 3-letter ISO-639-2 language code as the Tatoeba dataset, while the WMT tasks rely on the 2-letter ISO-639-1 language code. The website of the Library of Congress (Library of Congress, 2017) was used for conversions between the two norms.

The Tatoeba Translation Challenge (Tiedemann, 2020) is an initiative that aims to evaluate the effectiveness of MT systems on a large, diverse, and high-quality parallel corpus. While the main training data relies on OPUS (Tiedemann, 2012), which provides open-source sentence-aligned text corpora to support data-driven NLP, Tatoeba also provides monolingual datasets extracted from CirrusSearch Wikimedia dumps (Foundation, 2023).

Out of the 279 different languages available, 240 had a sufficiently large corpus to be included in the work described in this paper.

3.3 Exceptions

As the tokengram_F metric is dependent on the utilization of the Tatoeba monolingual datasets for tokenizer training, adaptations were necessary to accommodate languages that are not represented within this dataset.

3.3.1 Livonian:

While there is no dataset in the Tatoeba Translation Challenge to train a Livonian tokenizer, the Latvian tokenizer produced satisfactory results and was utilised as a substitute, highlighting the versatility of the tokengram_F metric and its ability to accommodate languages that are less frequently used.

3.3.2 Serbian and Indonesian:

The Tatoeba challenge does not offer monolingual datasets for neither Serbian nor Indonesian. Nevertheless, the Tatoeba Wikimedia data, which are appropriate for tokenizer training and available for both the Serbian and Indonesian languages, were employed as a substitute.

3.4 Tokengram_F parameters

3.4.1 Tokenization algorithm:

While Tokengram_F can be used with any tokenization algorithm, this study examined both BPE and Unigram.

3.4.2 *n*-gram length:

This parameter determines the number of items in the reference that will be compared with each item in the source sentence, to assess the degree of correspondence of the two sentences.

Previous work (Popović, 2015, 2017) has indicated that for chrF++ there is no necessity to set the maximum word *n*-gram length beyond N=6.

3.4.3 Beta:

In this metric, the relative importance of precision and recall in the evaluation metric is determined by the β parameter. When beta is equal to 1.0, precision and recall have equal importance, while when beta is equal to 3.0, recall is three times more significant than precision. Previous research (Popović, 2015) has evaluated two beta values, 1.0 and 3.0, with the latter being considered "the most promising variant" due to the higher correlations it obtained.

3.4.4 Vocabulary size:

The goal of the present study is to mitigate the effect of infrequent words on the accuracy of the tokengram_F metric. To investigate the influence of vocabulary size on the performance of the metric, three tokenizers were trained for each language using vocabulary sizes of 16,000, 32,000, and 50,000 tokens. As the average vocabulary size tends to decrease from one year to the next (Libovický, 2021), wider vocabularies have not been examined.

3.5 Optimal parameters

3.5.1 Finetuning

The optimal parameters were determined based on achieving the highest average correlation among segments or systems across three datasets: WMT20 (Mathur et al., 2020), WMT21 (Freitag et al., 2021), and WMT22 (Freitag et al., 2022).

Initially, the *n*-gram length was assessed at values of 3, 6, and 9, while maintaining a vocabulary size of 50,000. Consistent with the findings of the original paper, a *n*-gram length of 6 demonstrated the strongest correlation as shown in Table 1, and thus it was chosen for subsequent evaluations.

Subsequently, the beta values of 2, 3, and 4 were examined specifically for an *n*-gram length N of 6. The best overall correlation is obtained with Unigram and β=3.0.

Table 3 presents the results obtained with a vocabulary size of 32,000. As with the previous vocabulary size, the choice of the tokenization algorithm only slightly affects the results. A β of 3.0 or 4.0 seems to give the best results.

As shown in Table 2, the vocabulary size of 16,000, which was the smallest size examined, exhibits generally weaker correlations compared to larger sizes, thus precluding the exploration of smaller sizes.

3.5.2 Results

Despite the marginal disparity, when the results are not rounded, the optimal parameters for tokengram_F are found to be a vocabulary size of 50,000, unigram tokenization, an *n*-gram length N=6, and a β value of 3.0.

3.6 Source code

The source code of tokengram_F is available at https://github.com/SorenDreano/tokengram_F.

4 Conclusion

Instead of using word *n*-grams as a basis for comparing a generated translation with a reference translation, tokengram_F utilises contemporary tokenization algorithms to accomplish this task. As a result, words that share common roots are deemed similar, regardless of whether they are exact matches or not.

The results obtained from evaluating the tokengram_F metric on the WMT20, WMT21, and WMT22 datasets indicate that the use of tokens generated through the SentencePiece framework leads to improved performance compared to the use of traditional word-grams in the chrF++ metric. Full results are displayed in Appendix A. The tokengram_F metric is a simple and efficient method for obtaining a reasonable correlation with human rankings, with the added benefit of requiring minimal training time to be applied to new languages.

In the segment-level task of the WMT22 edition, tokengram_F managed to obtain better overall correlations than any other metric that could provide results for all language pairs, including ones that require extensive neural networks to operate. With the exception of two tasks, tokengram_F outperformed both chrF and chrF++ metrics.

In conclusion, the tokengram_F metric is presented as a promising alternative for evaluating the quality of machine translations, as it offers a simple and efficient solution with above-average performance compared to other models. The findings of this study provide strong evidence of the potential of the tokengram_F metric as a valuable evaluation tool for machine translation. Its combination of simplicity, efficiency, and adaptability make it an attractive alternative to existing metrics and a promising direction for future research in the field.

5 Further work

The optimal number of tokens in a tokenizer may vary depending on the language. Subsequent research could concentrate on determining the most suitable vocabulary size per language.

The majority of the tokenizers were trained using the MonoLinguage Datasets from the Tatoeba Challenge, which are based on data from the Wikimedia Foundation. It remains possible that alternate data sources may produce varying results.

Abstract

Embed_llama is an assessment metric for language translation that hinges upon the utilization of the recently introduced Llama 2 Large Language Model (LLM), specifically focusing on its embedding layer, to transform sentences into a vector space that establishes connections between geometric and semantic proximities.

Investigations utilizing previous WMT datasets have revealed that within the Llama 2 architecture, relying solely on the initial embedding layer does not result in the highest degree of correlation when assessing machine translations. The incorporation of additional layers, however, holds the potential to augment the contextual understanding of sentences.

As a contribution to the WMT23 challenge, this study delves into the advantages derived from employing a pre-trained LLM that has not undergone fine-tuning specifically for translation evaluation tasks, to provide a metric conducive to operation on readily accessible consumer-grade hardware. This research digs into the observation that deeper layers within the model do not result in a linear increase in the spatial proximity between sentences within the vector space.

1 Introduction

The assessment of algorithm-generated translations entails the utilization of evaluation metrics that furnish quantitative scores to objectively gauge the precision of the model's output. Various methodologies are employed to juxtapose machine-generated translations with their human-generated counterparts, contingent upon the specific evaluation metric employed. In recent years, the realm of machine translation (MT) has witnessed notable advancements in terms of both translation accuracy and linguistic fluency.

Over time, there has been a significant enhancement in the correlation coefficient between human assessments and the automated evaluation of sentences generated by machines. Earlier metrics, such as BLEU (Papineni et al., 2002) or chrF++ (Popović, 2017), predominantly relied on the textual overlap between reference translations and the machine-generated counterparts. In contrast, contemporary approaches, exemplified by COMET (Rei et al., 2020), harness recent breakthroughs in Natural Language Processing(NLP) and transformer models, enabling them to consider not only individual words, but also to leverage contextual semantics for a more comprehensive evaluation.

In the domain of Machine Learning (ML) applied to NLP, the embedding layer assumes a pivotal role within neural network architectures, particularly in tasks centered on textual data. Its central objective lies in the transformation of discrete tokens, encompassing entities like words or characters into continuous vector representations. These vector representations, which maintain continuity, are amenable to acquisition and manipulation by neural networks and are commonly referred to as *word embeddings*.

2 Embed_Llama

The initial component in a Natural Language Processing (NLP) model is typically an embedding layer, which serves the purpose of converting the distinct identifiers of tokens within the input sentence into a vectorized representation. In this context, it is essential to emphasize that sentences conveying similar semantic content should exhibit proximity in the vector space, irrespective of the presence of word-level overlap, in contrast to sentences chosen randomly.

Embed_Llama draws inspiration from Word2vec (Mikolov et al., 2013) using Llama 2 (Touvron et al., 2023), a contemporary open-source pre-trained model. Rather than needing to train an extra NLP model for the purpose of assessing translation quality, a viable alternative approach involves uti-

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 738–745
December 6–7, 2023.

lizing a pre-trained, extensive neural network like Llama 2, which has been originally trained for next-token prediction. This approach allows for the investigation of how closely related sentences evolve across the model's various layers, all without incurring the supplementary expenses associated with fine-tuning or training anew.

2.1 Word2vec

Word2vec is a methodology that utilizes a neural network model to extract word associations from comprehensive textual corpora. Post training, this model possesses the capability to identify synonymous terms and offer word suggestions for unfinished sentences. As the terminology implies, Word2vec symbolizes individual words by employing distinct numerical vectors, systematically engineered to encapsulate both the semantic and syntactic characteristics inherent to the words.

Embed_Llama leverages vectorial space to estimate similarity or dissimilarity. This estimation is accomplished by computing the cosine distance between two sentences.

2.2 Vocabulary size

The lexical repertoire of Llama 2 encompasses 32,000 unique tokens, a figure lower than that of both GPT-2 (Radford et al., 2019) and GPT-NeoX (Black et al., 2022), which both employ 50,000 unique tokens. Regrettably, the specific vocabulary sizes pertaining to GPT-3 (Brown et al., 2020) and GPT-4 (OpenAI, 2023) remain undisclosed.

2.3 Embeddings

The dimensionality of the embedding space represents a hyperparameter subject to adjustment. Embeddings of higher dimensions have the capacity to capture more intricate relationships; however, it is noteworthy that such higher-dimensional embeddings may necessitate increased quantities of data and computational resources for their effective utilization.

2.4 Cosine distance

The cosine similarity metric quantifies the similarity between two n-dimensional vectors by computing the cosine of the angle between them. This scoring measure finds common application in the domain of text mining (Singhal, 2001). The general formula for two vectors A and B is:

$$\cos\theta = \frac{\mathbf{A}\cdot\mathbf{B}}{\|\mathbf{A}\|\|\mathbf{B}\|}$$

To enable efficient computation on consumer-grade hardware, the two sentences slated for comparison are padded to match the maximum token count of the longer sentence in the pair. Consequently, a sentence initially shaped as [length] transforms into the shape [length ×4,096] following its processing through the embedding layer.

3 Hyperparameter

As the objective of this current study revolves around the utilization of a pre-trained network, our sphere of influence is limited to a sole hyperparameter, namely, the number of blocks to retain before computing the cosine distance.

3.1 Block architecture

As shown in Figure 1, each block, denoted as the *LlamaDecoderLayer*, is structured with several components, including an attention layer, two normalization layers, and a multi-layer perceptron. The multi-layer perceptron, in turn, consists of three linear layers along with an associated activation function, while the attention layer also includes a rotary embedding layer.

The Llama 2 model, comprising 7 billion parameters, encompasses an embedding layer, 32 blocks, and a projection layer. To determine the optimal number of blocks, datasets extracted from the WMT challenge editions of 2020, 2021, and 2022 were employed. Due to the limited GPU memory allocation in the current project, it was only feasible to investigate the Llama 2 model up to a depth of 22 blocks, whereas the model has a total of 32 available blocks.

)
```

Figure 1: Architecture of the Llama2 model as displayed in the Huggingface library

3.2 Exploring the depth

It was initially hypothesized that increasing the number of blocks would improve the contextual

representation of sentence meaning. Figure 2 reveals that, in contrast to our initial hypotheses, the augmentation of block quantities does not significantly modify the correlation between the systems and the ground truth, whether by augmentation or reduction. Furthermore, it is noteworthy that this correlation exhibits variability across different datasets. Specifically, the Pearson correlation between the number of layers and algorithm accuracy is 0.34 for the WMT20 dataset, but it decreases to -0.79 for the WMT22 dataset.

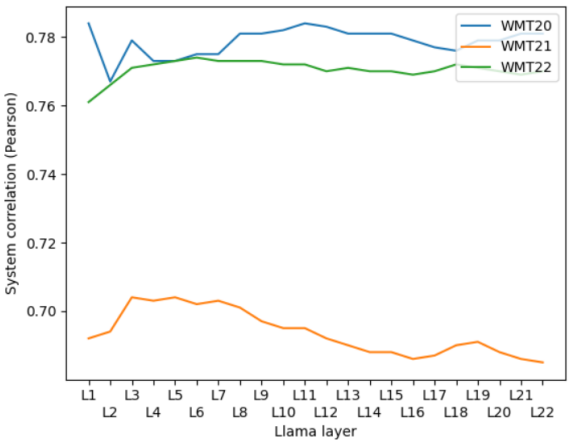

Figure 2: System correlations depending on the Llama layer

As shown in Figure 3, these observations hold with respect to segment correlation as well. The quantity of blocks employed in the Embed_Llama does not consistently enhance the metric's quality, whether for individual segments or entire systems.

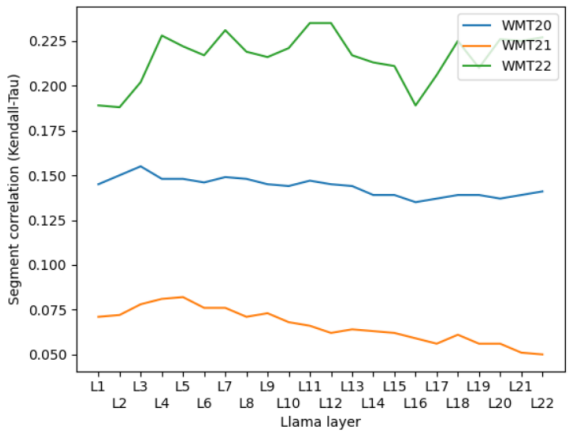

Figure 3: Segment correlations depending on the Llama layer

The highest levels of correlation between human rankings and Embed_Llama rankings were achieved by utilizing a mere two blocks following the embedding layer, resulting in optimal overall performance across the WMT20, WMT21, and WMT22 datasets. This not only expedited the computational process, but also decreased the GPU memory demands for metric computation.

3.3 Inter-languages variations

As depicted in Figure 4, the associations between metric quality and language pairs exhibit large variations. For instance, when considering the Hungarian-to-English language pair, the Pearson coefficient registers at 0.83, whereas it falls to -0.85 for the Czech-to-Ukrainian pair.

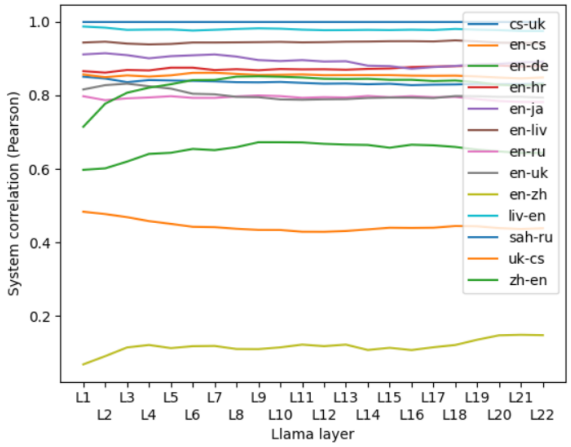

Figure 4: System correlations for each language pair in the WMT2022 dataset depending on the Llama layer

3.4 Intra-languages variations

Considerable variability is observed even within the same language pair across various datasets. For instance, the English-to-Chinese language pair is encompassed within the WMT2020, WMT2021, and WMT2022 datasets. However, as illustrated in Figure 5, no discernible correlations emerge between the number of utilized blocks and the quality of Embed_Llama scores. This is evident in the transformation of the Pearson coefficient, which shifts from -0.28 in the WMT2021 to 0.73 in the WMT2022 dataset.

3.5 Inter-datasets variations

Table 1 presents the average mean values and their corresponding standard deviations, showcasing the relationship between metric accuracy and the number of utilized blocks for language pairs common to all three datasets. It is notable that, apart for the English-to-Japanese pair, there exists a significant degree of variability in the performance of the

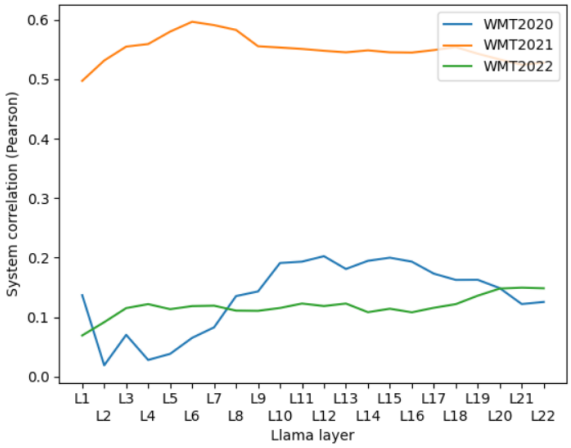

Figure 5: System correlations of the English-to-Chinese language pair depending on the Llama layer and the dataset

Language pair	Mean	Standard deviation
en-cs	-0.34	0.22
en-de	-0.02	0.4
en-ja	-0.89	0.04
en-ru	-0.02	0.54
en-zh	0.35	0.45
zh-en	-0.17	0.46

Table 1: Means and standard deviations of the system correlations depending on the Llama layer when WMT2020, WMT2021 and WMT2022 are merged

same language pairs across different datasets. This variability is underscored by the substantial standard deviations in relation to the absolute values of the means. Given the limited usage of just three datasets, it is essential to acknowledge that the relatively small sample size may hinder the ability to draw conclusive inferences regarding inter-dataset variability.

3.6 Full results

Tables 2, 4 and 6, correspondingly, present the Pearson correlation coefficients for datasets WMT2020, WMT2021 and WMT2021, illustrating the association between the algorithm-assigned scores and the actual rankings of the evaluated systems for individual language pairs.

With regard to segment-level correlations, they are presented in Tables 3, 5 and 7 for WMT2020, WMT2021, and WMT2022, respectively. It is noteworthy that, in contrast to system correlations, these are represented by Kendall coefficients, which are utilized as a measure of ordinal association.

It is noteworthy that the observed variations in these correlations are predominantly influenced by the specific language pairs, rather than the depth of the final block employed prior to cosine similarity computation, aligning with our anticipated outcome.

3.7 Source code

The source code of Embed_Llama is available at https://github.com/SorenDreano/embed_llama.

4 Conclusion

Although the authors initially anticipated that Embed_Llama would exhibit suboptimal performance for a majority of language pairs, except for those involving English, due to the apparent constraints posed by a limited vocabulary size and the nature of the dataset Llama 2 was trained on, the actual performance did not exhibit a significant underperformance.

The results from previous iterations of the WMT metrics shared task, presented in Appendix A, indicate that this approach may not meet the contemporary state-of-the-art standards exemplified by METRICX_XXL (unpublished) and COMET-22 (Rei et al., 2022).

The methodology involving the utilization of a non-finetuned, pre-trained Large Language Model (LLM) to assess translation quality through vector space similarity comparisons remains a prospective avenue of inquiry. This prospect gains relevance in light of forthcoming open-source models characterized by expansive vocabularies and training data encompassing diverse languages.

5 Further work

Given the recent proliferation of open-source LLMs, it is likely that another model, either presently or in the near future, may surpass the performance of Llama 2 for translation evaluation without necessitating any fine-tuning.

In the current investigation, the exploration has been confined to the 7 billion parameters model. It remains conceivable that employing a more extensive model with increased parameters may yield a more precise metric, albeit at the trade-off of heightened computational resource demands.

In the present evaluation, an exploration was limited to the initial 22 blocks. Subsequent endeavors

may consider augmenting this number, as doing so could potentially result in further benefits.

Moreover, it is worth noting that the optimal selection of the number of blocks to employ may be contingent upon the specific target language. Consequently, adjusting this hyperparameter based on the language in question could potentially yield enhanced correlation results.

In the scope of the current academic study, solely the cosine distance served as the chosen similarity measure for tensors. Future research endeavors may wish to investigate alternative distance metrics, such as the Euclidean distance or the Manhattan distance, for potential exploration.

eBLEU: Unexpectedly Good Machine Translation Evaluation Using Simple Word Embeddings

Abstract

We propose eBLEU, a metric inspired by BLEU metric that uses embedding similarities instead of string matches. We introduce *meaning diffusion vectors* to enable matching n-grams of semantically similar words in a BLEU-like algorithm, using efficient, non-contextual word embeddings like fastText. On WMT23 data, eBLEU beats BLEU and ChrF by around 3.8% system-level score, approaching BERTScore at -0.9% absolute difference. In WMT22 scenarios, eBLEU outperforms f101spBLEU and ChrF in MQM by $2.2\%-3.6\%$. Curiously, on MTurk evaluations, eBLEU surpasses past methods by $3.9\%-8.2\%$ (f200spBLEU, COMET-22). eBLEU presents an interesting middle-ground between traditional metrics and pretrained metrics.

1 Introduction

The machine translation field has improved significantly, with various metrics developed to measure translation quality. Translation quality in human eyes is usually a delicate balance to convey meaning, style, tone, and other dimensions of text from one language into another with different idioms and concept ontologies. After all, translation is not only about translating words from one language to another literally, but ensuring that the core meaning behind is also accurately conveyed.

Traditional metrics, like the **BLEU** score (Papineni et al., 2002) or ChrF (Popović, 2015), have proven effective over last 20 year. However, there has been growing evidence that they have not kept pace with the performance of recent NMT and LLM MT systems (Kocmi et al., 2021; Freitag et al., 2022). BLEU essentially computes a score based on string n-grams matches. One clear limitation of this approach is that it fails to recognize semantically similar words. For instance, in the eyes of BLEU, the words (*cat*, *kitty*) are as different as (*cat*, *book*) or (*fire*, *water*).

Recent neural metrics, on the other hand, have explored the potential of leveraging pretrained language models for encoding entire sentences. These models either compare encoded sentences in a shared embedding space or employ a trained classifier to predict human scores, as demonstrated by Rei et al. (2020); Zhang et al. (2020); Freitag et al. (2022). These methods are more capable of capturing semantic nuances.

In this paper, we introduce **eBLEU**, a metric designed to address the mentioned limitation of the BLEU score while keeping the calculation as close to BLEU as possible by using the word embedding similarities instead of string matching. By doing so, eBLEU enhances the metric by recognizing semantically similar n-grams. Our method relies on the *meaning diffusion map* to approximate n-gram matching in a BLEU-like algorithm. The core implementation leverages efficient, non-contextual word embeddings, such as fastText embeddings.

2 Related work

In machine translation, measuring quality is a balance of many potentially competing factors. The most prominent are language quality (fluency) and accuracy of meaning conveyed (adequacy). Other factors may be critical in special scenarios. Consider the conveyance of tone or cultural register in translated dialog (see for example registers in East-Asian languages). Or the conveyance of flow in a translated play (see some examples of translations of the Greek epic Iliad in Mendelsohn, 2011).

Traditional automatic quality assessment methods, like BLEU and METEOR (Banerjee and Lavie, 2005), rely on string matching against a reference. The more matches, the more a candidate captures of the intended meaning in the reference, as proxy for adequacy. While features like n-gram matching in BLEU and explicit ordering penalties in METEOR act as proxy for fluency.

Such metrics suffer from limitations inherent to

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 746–750
December 6–7, 2023.

their literal string matching core, which some try to mitigate (e.g. via lemmatization or synonym dictionaries). These limitations are clearer in light of the more complex and semantically rich language produced by recent Neural MT systems and Large Language Model MT systems.

BERTScore (Zhang et al., 2020) utilizes a similar idea to ours, matching contextual encodings of words in candidate/reference pairs. While it uses unigrams only, eBLEU uses n-grams as well, and calculates token matches differently. Other systems, like COMET (Rei et al., 2020), are finetuned on human judgement scores for machine translation evaluation specifically.

3 Preliminaries

3.1 BLEU

The BLEU formula applied to a single candidate/reference sentence pair X, Y is:

$$\underset{N}{\texttt{BLEU}}(X,Y) = \texttt{bp}(X,Y) \prod_{n \in 1..N} \texttt{pr}_n(X,Y)^{w_n} \tag{1}$$

where $\texttt{bp}(X,Y)$ is the brevity penalty. This score ranges between $[0,1]$ for lowest and highest match.

The n-gram precision $\texttt{pr}_n(X,Y)$ is:

$$\frac{\sum_{s \in [X]^n} \min(C(s,X), C(s,Y))}{\sum_{s \in [X]^n} C(s,X)} \tag{2}$$

Set of n-gram substrings in candidate

Count of s in candidate

3.2 Embeddings

At the core, our method utilizes simple word embeddings that can be generated from sub-word information or memorized for full words as appropriate. We do not require tokenization of words into sub-words. Here we use the fastText word embeddings (Bojanowski et al., 2017). Other simple word embeddings should be appropriate as-is but were not tested. FastText is trained for every language separately and we require a trained fastText model for the target language in any translation pair.

3.3 String Matching

Strings under strict equality are literal representations of unique identities: the string *abc* is equal only to *abc* itself. This works for BLEU. Now we want to match based on the closeness of meaning instead, where (*cat*, *cats*) would be closer together than (*cat*, *book*).

4 eBLEU description

We propose the following formulation for an embedding-based matching in the style of BLEU precision from eq. (2).

Let X refer to the candidate sentence, and Y refer to the reference sentence. Now, given an asymmetric similarity function $\texttt{mdSim}(a \mid b)$ from a with reference to b, we can define the following analogous values for "precision" and "recall":

$$\text{precision: } \texttt{pr}(X,Y) = \texttt{mdSim}(Y \mid X) \tag{3}$$

$$\text{recall: } \texttt{re}(X,Y) = \texttt{mdSim}(X \mid Y) \tag{4}$$

$\overline{m}_n$ is the n-gram score of the pair, defined as the geometric mean of the n-gram precision and recall from eq. (3, 4):

$$\overline{m}_n = \left(\texttt{pr}_n(X,Y) \cdot \texttt{re}_n(X,Y)\right)^{\frac{1}{2}} \tag{5}$$

The final score is a weighted geometric average of the n-gram-based scores $\overline{m}_n$ between candidate and reference, for $N = 4$ and $w_n = N - n$.

$$\underset{N}{\texttt{eBLEU}}(X,Y) = \texttt{lp}(X,Y) \prod_{n \in 1..N} \overline{m}_n^{\,w_n/N} \tag{6}$$

where $\texttt{lp}$ is a modified length penalty which penalizes longer candidates as well.

(e)BLEU This shows the analogous structure of eBLEU compared to BLEU, given an appropriate definition for $\texttt{mdSim}$ as used in eq. (3, 4).

4.1 Aggregating Similarity Values

Similar to $\texttt{pr}_n(X,Y)$, we want $\texttt{mdSim}(Y \mid X)$ to be a single value for a candidate/reference sentence pair, as if aggregating the meaning diffusion values m_x for $x \in X$:

$$\texttt{mdSim}(Y \mid X) = \frac{\sum_x \min(\mathbf{m}_X, \mathbf{m}_{X|Y})}{\sum_x \mathbf{m}_X} \tag{7}$$

Index over words in cand.

MD vector of words in cand.

Compare Equation (7) for eBLEU with Equation (2) for BLEU.

4.2 Meaning Diffusion

Meaning Diffusion (MD) is a value for each word in a sentence indicating *the ratio of similar words*

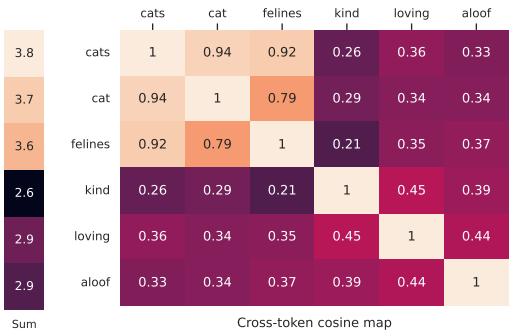

Figure 1: *(Right)* Meaning Diffusion Map between some words for illustration. Notice the similarity of *cats, cat, felines* and the relative similarity of *kind, loving* but not *aloof*. *(Left)* Meaning Diffusion Vector is the sum of a word's similarity to all words in the sentence.

in the same sentence. This allows claims such as "*there exists* $2/7$ `eats` " in:

The cat `eats` *, no,* `devours` *the food.*

That is: $m_{\text{eats}} \approx 2/7$. See also Figure 1 *(Left)*.

MD Map $\hat{\mathbf{S}}_{y,y'}$ is a weighted sum over the candidate side (x) with `softmax`-normalized weights. It approximates the similarity matrix of the reference Y against itself (see Figure 1 *(Right)*), as seen *through* the candidate X. The **L1** variant replaces `softmax` with a simple division by the sum of values: $\mathbf{S}_{y,x} / \sum_x \mathbf{S}_{y,x}$.

MD Vectors $\mathbf{m}_*$ represent each word's total closeness to all other words in the same sentence ($\mathbf{m}_Y$) or through a candidate sentence ($\mathbf{m}_{Y|X}$).

$$\hat{\mathbf{S}}_{y,y'} = \underset{x}{\texttt{softmax}}(\mathbf{S}_{y,x}) \cdot \mathbf{S}_{x,y} \tag{8}$$

$$\mathbf{m}_{Y|X} = \sum_{y'} \hat{\mathbf{S}}_{y,y'} \tag{9}$$

$$\mathbf{m}_Y = \sum_{y} \mathbf{S}_{y,y} \tag{10}$$

Vector Similarity For the candidate/reference X, Y, let $\mathbf{X}, \mathbf{Y}$ be the embedding matrices shaped as *token* $\times$ *embedding*. $\mathbf{S}_{x,y}$ is Cosine vector similarity clipped within $[0, 1]$, defined as:

$$\mathbf{S}_{x,y} = \texttt{clip}_{[0,1]} \cos_{\textit{embedding}}(\mathbf{X}, \mathbf{Y}^\top) \tag{11}$$

4.3 N-gram Scores

For each $n \in 1..N$, we calculate the n-gram score of a sentence pair using $\mathbf{S}^n_{x,y}$: the geometric mean of the cosine scores of adjacent words in each sentence, such that the n-gram-aware $\mathbf{S}^n_{x,y}$ is of shape $|X| - n + 1 \times |Y| - n + 1$.

4.4 Length Penalty

The length penalty penalizes length mismatch between candidate and reference, as used in eq. (6):

$$\texttt{lp}(X, Y) = \begin{cases} 1.0 & \texttt{ratio} \leq 0.5 \\ e^{0.5 - \texttt{ratio}} & \text{else} \end{cases} \tag{12}$$

$$\texttt{ratio} = \frac{\texttt{abs}(|X| - |Y|)}{|Y|} \tag{13}$$

5 Evaluation and Results

In this section, we describe the evaluation of the metric and the results

5.1 Meta-evaluation

We use the WMT Metrics 2022 test set (Freitag et al., 2021) which contains human judgments based on three different protocols: MQM, DA+SQM and MTurk DA. The translation systems are mainly from participants of the WMT22 General MT shared task (Kocmi et al., 2022). The source segments and human reference translations for each language pair contain around 2,000 sentences from four different texts domains: news, social, conversational, and e-commerce.

Human labels are produced via three methods:

- MQM - annotated by professionals who mark individual errors in each translation, as described in (Freitag et al., 2021)
- DA+SQM - professional annotators are asked to rate each translation on a scale 0-100 (Kocmi et al., 2022)
- MTurk DA - low paid crowd of MTurk annotators is asked to rate each translation on a scale 0-100, for how much it resembles human reference (Kocmi et al., 2022)

To determine the correlation of automatic metrics with humans, we measure system-level, pairwise accuracy (Kocmi et al., 2021), which is defined as the number of system pairs ranked correctly by the metric with respect to the human ranking divided by the total number of system pair comparisons. Formally:

$$\text{Accuracy} = \frac{|\text{sign}(\text{metric}\Delta) == \text{sign}(\text{human}\Delta)|}{|\text{all system pairs}|}$$

We reproduced scores reported in the WMT22 Metrics shared task findings paper with the official

System	MQM	DA-SQM	MTurk
COMET-22	**83.94%**	**84.19%**	62.61%

f200spBLEU	11	**86.8%**
BLEU	12	85.9%
ChrF	12	85.2%
eBLEU-FastText		
↪ Softmax	9	**89.3%**

Table 2: WMT23 System-level ranking clusters and correlations on en-de, he-en, zh-en language pairs.[2]

WMT22 script.[1] Scores match Table 8 (DA+SQM and DA) and Table 11 for MQM of the WMT22 Metrics findings paper (Freitag et al., 2022).

5.2 Results

On **WMT23** scenarios (Table 2), eBLEU scores $\mathbf{89.3}\%$, improving noticeably on ChrF, BLEU, and f200spBLEU, beating the latter by $\mathbf{2.5}\%$ points. Its ranking cluster (**9**) puts it much closer to more sophisticated embedding-based metrics (like BERTScore) than string metrics like BLEU. Notably, this was achieved by the Softmax variant, which scored below the L1 variant on the more accurate human MQM and DA-SQM scenarios.

On **WMT22** scenarios (Table 1), eBLEU outperforms both f101spBLEU and ChrF in MQM by $2.2\% - 3.6\%$ in system-level accuracy.

eBLEU shows SOTA correlation with MTurk evaluations at $\mathbf{70.82}\%$, beating existing methods by $3.9\% - 8.2\%$ (f200spBLEU, COMET-22). Although Freitag et al. (2022) shows them to be of sub-optimal quality, this is interesting as MTurk evaluations often involve manual n-gram matching—a nice result given the intuition behind our method.

6 Conclusion

6.1 eBLEU: Between Strings and Neural Eval

In this paper, we introduced eBLEU, a novel metric that adapts the BLEU algorithm by adding embedding-based semantic understanding. By incorporating word embedding similarities and leveraging *meaning diffusion vectors*, eBLEU bridges the gap between literal and semantic matching.

We show that eBLEU can outperform widely adopted metrics like (sp)BLEU and ChrF, and approaches some pretrained contextual embedding-based metrics, like BERTScore, using simpler, cheaper-to-compute embeddings like fastText.

On WMT23, eBLEU scores 89.3%, placing almost halfway between BLEU, and COMET, an especially finetuned model for MT evaluation.

Although eBLEU lags behind the latest pretrained metrics, it presents an interesting approach for a simple semantically informed metric.

6.2 Limitations

However, it is important to recognize the limitations. Fundamentally, eBLEU does not attempt to improve the BLEU formula as a proxy for adequacy and fluency. Thus predictably, it lags far behind the latest pretrained metrics such as COMET or BLEURT. As language models, the core of these systems holds the advantages of large pre-training data, contextual understanding of input candidates and references, and potentially task-specific fine-tuning for the translation domain. Their more general nature allows for much improved measurement of adequacy and fluency among the range of possible translations that humans may produce and judge acceptable.

In summary, eBLEU offers a semantically-aware machine translation evaluation metric extending standardized BLEU algorithm. There may exist other such methods that bridge the gap further while improving inference time, efficiency, or interpretability where needed.

Abstract

This paper describes our submissions to the 2023 Conference on Machine Translation (WMT23) Metrics shared task. Knowledge distillation is commonly used to create smaller student models that mimic a larger teacher model while reducing the model size and hence inference cost in production. In this work, we apply knowledge distillation to machine translation evaluation metrics and distill existing reference-based teacher metrics into reference-free (quality estimation; QE) student metrics. We mainly focus on students of Unbabel's `COMET22` reference-based metric. When evaluating on the official WMT22 Metrics evaluation task, our distilled `Cometoid` QE metrics outperform all other QE metrics on that set while matching or out-performing the reference-based teacher metric. Our metrics never see the human ground-truth scores directly – only the teacher metric was trained on human scores by its original creators. We also distill `ChrF` sentence-level scores into a neural QE metric and find that our reference-free (and fully human-score-free) student metric `ChrFoid` outperforms its teacher metric by over 7% pairwise accuracy on the same WMT22 task, rivaling other existing QE metrics.[1]

1 Introduction

The Conference on Machine Translation (WMT) organizes an annual shared task for meta-evaluation of machine translation (MT) evaluation metrics (Freitag et al., 2022), where numerous MT evaluation metrics are proposed and revised each year. The MT metrics are broadly categorized as: (i) reference-based metrics, which score MT hypothesis against one or more reference translations from humans, and (ii) reference-free metrics, which do not require references and instead score hypothesis directly against the source sentence. Reference-free metrics, also known as quality estimation (QE) metrics, are an attractive choice in scenarios where reference translations are either unavailable or unreliable. However, currently, QE metrics lag behind the reference-based metrics by a considerable margin according to metrics meta-evaluation results (Freitag et al., 2022).

Knowledge distillation (KD) (Liang et al., 2008; Hinton et al., 2015) is commonly used to create smaller student models that mimic larger teacher models (Kim and Rush, 2016) which reduces computational cost when deploying models in production (Kim et al., 2019). Other use cases of KD in MT include distillation from auto-regressive teacher translation models to non-autoregressive students (Zhou et al., 2020) where the students "suffer" from an information bottleneck (here: no access to their own previous output in a time sequence) which impedes their performance when trained on original data. The simplified and probably smoothed output distribution of the teacher is easier to "digest" and often results in improved performance for the student.

In this work, we treat existing reference-based metrics as teachers and by applying knowledge distillation, we create reference-free student metrics that completely eliminate the need for references in evaluation. This is achieved by introducing a hard information bottleneck: just dropping the reference during training while keeping the original reference-based teacher score.

2 Experiments

2.1 Data Preparation

Our training set combines public and internal data sets. The public data is composed of all the MT systems submitted to WMT News (or General) Translation task between years 2009 and 2023. Our internal data set is prepared by translating parallel data using four MT systems: Moses SMT (Koehn et al., 2007), readily available bilingual NMT (Tiede-

[1] Metrics and usage instructions are available at: https://github.com/marian-nmt/wmt23-metrics

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 751–755
December 6–7, 2023.

mann and Thottingal, 2020), multilingual transformer NMT (Gowda et al., 2021), and Microsoft Translator service. The number of examples in our training data is reported in Table 1.

For each training example i, let s_i, r_i and h_i, be source, reference and MT hypothesis segments, respectively. Each example is initially scored using teacher metrics that use reference translations and later references are dropped while training the student metrics. In this work, we use `COMET22` (Rei et al., 2022a) and `ChrF` (Popović, 2015) as teacher metrics. Teacher metrics that need source, reference and hypotheses as inputs – e.g. `COMET22` – produce training data in the form of $(s_i, r_i, h_i) \rightarrow \mathbb{R}$. The reference-only teachers such as `ChrF` produce $(r_i, h_i) \rightarrow \mathbb{R}$. All teacher sentence-level scores are normalized to the $[0, 1]$ range. For `COMET22` this required no change; for `ChrF`, computed by SacreBLEU (Post, 2018), we divide scores by 100.

Distilled students are trained on source-hypothesis pairs $(s_i, h_i) \rightarrow \mathbb{R}$ where the score is from the respective original reference-based teacher. Neither the references nor the human scores are directly seen by the student. However, indirectly, human scores may have been used by the teacher metric, which is the case for `COMET22`, but not for `ChrF`.

Dataset	Number of Examples
WMT09-21 systems	4.0M
WMT22 systems	0.5M
WMT23 systems	0.5M
Internal dataset	6.8M

Table 1: Training dataset size.

2.2 Model

Our distilled models have a similar architecture to `COMET-QE` models (Rei et al., 2020a),[2] and are implemented in MarianNMT (Junczys-Dowmunt et al., 2018), a fast NMT toolkit.[3] We slightly simplify the architecture by removing the encoder layer mixing and the batch-normalization present in the original implementation (neither seemed to contribute to any improvements), but we keep the general architecture of the added FFN regressor and the way how the encoder embeddings of source and hypothesis are combined into a single vector. Final output scores are squashed to the $[0, 1]$ range via a sigmoid function.

Similar to `COMET22`, we initialize our student models with the pretrained weights from InfoXLM (Chi et al., 2021),[4] specifically `infoxlm-large` that has 24 transformer layers (Vaswani et al., 2017).

We create the following four student models:

- `Cometoid22-wmt21`: student model distilled from `COMET22` and trained on scored data from the WMT News Translation task from 2009 - 2021 and similarly sized private data.
- `Cometoid22-wmt22`: Same as above, except we include system outputs submitted to WMT22. This is our *primary* submission to WMT23 Metrics shared task.
- `Cometoid22-wmt23`: Same as the above, except we include the system outputs submitted to WMT23.
- `ChrFoid-wmt23`: Same as the above, but we use segment-level `ChrF` as the teacher. This is an experimental model trained after the WMT23 Metrics shared-task deadline and has not been submitted to the shared task.

We evaluate our models on the WMT22 shared task while including WMT22 shared-task system outputs (MT systems and their reference-based scores) in the training data. This may seem suspicious at first, but note that our models do not use any human scores (the actual ground-truth of the task) in the training process, neither did the reference-based teachers which were trained before the WMT22 shared task. For the part of the evaluation where system submissions are available, this can be seen as part of an involved scoring process where the teacher remains blind to WMT22/WMT23 outputs, but the student does see them during distillation.

However, we are aware that this view may be disputable, hence we have submitted our `Cometoid22-wmt22` (blind to WMT23 outputs) as the primary submission to the WMT23 shared task instead of `Cometoid22-wmt23` that has seen scored WMT23 outputs (but not the actual ground-truth). We also provide results for `Cometoid22-wmt21` which is fully blind in regard to both – WMT22 and WMT23 outputs.

2.3 Training

We ensure that scores from teacher metrics are in $[0, 1]$ range and optimize student metrics using cross-entropy loss.[5] Rei et al. (2020b) found that freezing InfoXLM layers for a number of epochs and training only the added parameters is beneficial, however, we were unable to confirm this with our metrics; we have fine-tuned all parameters till convergence according to perplexity on a small heldout subset of the data. For the final primary submission, we added the heldout data back to the training data and trained for the same number of iterations. We see minor improvements from Mix-up regularization (Pinto et al., 2022) which we use for all student trainings.

3 Results and Analysis

We report system level pairwise accuracy obtained using `mt-metrics-eval`,[6] the official meta-evaluation pipeline used in WMT22 Metrics task. Table 2 shows that our COMETOID metrics are the top-performing QE metrics on the WMT22 Metrics data set. Interestingly, COMETOID student models also outperform the `COMET22` reference-based teacher model on DA+SQM data (we do fare worse on the smaller MQM data set only). Last but not least, `ChrFoid` – our student metric distilled from the `ChrF` (Popović, 2015) string-based metric – does surprisingly well and out-performs the teacher metric by a considerable margin despite now being reference-free.

[5] Our preliminary experiments with mean absolute error loss performed inferior to cross-entropy.

4 Related Work

Reference-free (QE) metrics: Comet20-QE (Rei et al., 2020b) and CometKiwi22 (Rei et al., 2022c) are popular QE metrics. UniTE (Wan et al., 2022) supports inference in reference-free mode, in addition to reference-based mode. These metrics rely on scores from human evaluators during training and are limited by availability of high quality human ratings. Our metrics are trained with scores from teacher models and are trained on larger training data than what has been rated by human evaluators.

Distillation: Pu et al. (2021) and Rei et al. (2022b) apply knowledge distillation to the reference-based metrics, however, their distillation is aimed at reducing the model size for the sake of reducing computational cost during inference. Our work differs from theirs, as we distill with the aim of removing the need for human references at inference time.

5 Conclusion

We believe this work describes a perhaps simpler avenue towards more powerful QE metrics than proposed so far: *build strong reference-based first, next distill into even stronger QE metrics*. It further seems that performance improves with adding fully synthetic data (via adding larger amounts of inputs and automatically scored outputs). This effect seems also applicable to "dumb" metrics like `ChrF`: we have arrived at CHRFOID, a QE metric that has seen no human scores at all, and yet rivals the performance of the best previously available QE metrics. Knowledge distillation combined with a strong information bottleneck (reference-based to reference-free) seems to be the key in this new approach.

Limitations

Using available system outputs of the *same* shared task for training the metric may be a disputable approach even if the ground-truth was not used. Training time and model size of our distilled metrics are similar to the other popular metrics, and may be a limitation.

Ethics Statement

Knowledge distillation of existing models is always close to "model-stealing". The information provided here should be used responsibly and with publicly available models or according to terms of service.

Abstract

This report details the MetricX-23 submission to the WMT23 Metrics Shared Task and provides an overview of the experiments that informed which metrics were submitted. Our 3 submissions—each with a quality estimation (or reference-free) version—are all learned regression-based metrics that vary in the data used for training and which pretrained language model was used for initialization. We report results related to understanding (1) which supervised training data to use, (2) the impact of how the training labels are normalized, (3) the amount of synthetic training data to use, (4) how metric performance is related to model size, and (5) the effect of initializing the metrics with different pretrained language models. The most successful training recipe for MetricX employs two-stage fine-tuning on DA and MQM ratings, and includes synthetic training data. Finally, one important takeaway from our extensive experiments is that optimizing for both segment- and system-level performance at the same time is a challenging task.[1]

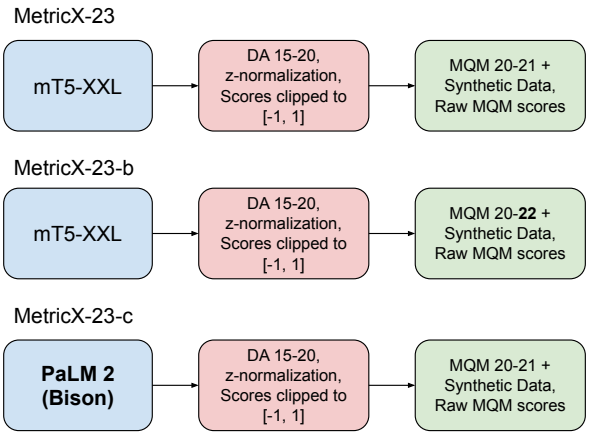

Figure 1: A high-level summary of the 3 different submissions to the WMT'23 Metrics Shared Task. MetricX-23-b and MetricX-23-c differ from the primary submission in that the "b" version is finetuned on MQM 2022 data in addition to 2020 and 2021, and the "c" version uses PaLM 2 as its pretrained language model (differences in bold). Each of the submission also includes a QE variant that follows the same training procedure.

1 Introduction

Automatic evaluation metrics are critical to the development of machine translation (MT) systems. They are the most frequently used method for comparing two MT systems and deciding which generates higher quality translations. Each year, the Conference on Machine Translation (WMT) runs a Metrics Shared Task to benchmark the quality of state-of-the-art evaluation metrics (Freitag et al., 2022). Meta-evaluating metrics by measuring how well they correlate to human ratings of translation quality is critical for understanding the extent to which automatic evaluations of MT systems are trustworthy.

This report details the MetricX-23 submission to the Metrics Shared Task. MetricX is a learned regression-based metric that is trained to predict a floating point score that represents the quality of a candidate translation. This year, we made 3 different submissions to the shared task that vary in the training data that is used for finetuning and which pretrained language model is used for initialization. Our primary submission, denoted MetricX-23, is based on the mT5 encoder-decoder language model (Xue et al., 2021), which is further finetuned on direct assessment (DA) ratings, MQM data (Lommel et al., 2014; Freitag et al., 2021), and synthetic data. Our contrasting submission, MetricX-23-b, includes additional MQM data, and MetricX-23-c finetunes the PaLM 2 language model (Anil et al., 2023) instead of mT5. Each of the 3 submissions has a reference-based and quality estimation (QE, or reference-free) version.

Figure 1 contains a high-level overview of the training recipe that we used for our submissions. In

[1]Our code and mT5-based models can be found at https://github.com/google-research/metricx.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 756–767
December 6–7, 2023.

order to arrive at the metrics that were ultimately submitted to the shared task, we ran various experiments that are detailed in this report. The key takeaways from those experiments include:

1. Training on z-normalized DA scores instead of the raw scores tends to be a trade-off between segment- and system-level performance;
2. Training on raw MQM ratings is better than z-normalized ratings;
3. Training on DA data followed by MQM data yields a better metric than on either type of data individually;
4. Synthetic data is necessary for the metric to learn to score the reference against itself higher than a machine translation against the reference;
5. Metric performance improves significantly as the size of the pretrained language model increases.

2 Metric Descriptions

The MetricX-23 metrics that were submitted to the Metrics Shared Task are all learned regression-based metrics that are trained to predict a floating point number that represents the quality of a given translation.

The input to the reference-based metrics is the candidate translation (hypothesis) and reference segments—each with a corresponding prefix ("candidate:" and "reference:", respectively)—concatenated together. The combined input is encoded by the model, and then the metric uses the encoding to predict a score. This stands in contrast to COMET-style metrics in which the hypothesis and reference are encoded separately, then combined in order to predict a score (Rei et al., 2020). The QE variants use the source segment instead of the reference, with the prefix changed to "source:".

We use two different network architectures for different versions of the metric. The choice of architecture depends on which pretrained language model is used to initialize the model.

The first architecture is based on the encoder-decoder mT5 language model (Xue et al., 2021). The input is encoded by the encoder, then the output logit from an arbitrary token in the vocabulary distribution from the first step of decoding is selected to represent the score for the hypothesis and trained accordingly.[2] In practice, we found that this method for using the pretrained weights for both the encoder and decoder worked better than using a regression head on top of the encoder and discarding the decoder.

The second architecture is the prefix language model based on Transformer (Vaswani et al., 2017) used by the PaLM 2 model (Anil et al., 2023). We augment the architecture by adding a feedforward regression layer on top of the input encoding. The output from the feedforward layer is trained to predict the translation quality score.

Both types of model are trained with a mean squared error (MSE) loss function. Further implementation details related to checkpoint selection, optimization, etc., can be found in §3.3. Information related to training data, label normalization, etc., can be found in §4.

3 Experimental Setup

3.1 Training and Evaluation Data

The two data sources that are primarily used to train and meta-evaluate MT metrics are the direct assessment (DA) data and Multi-dimensional Quality Metrics (MQM; Lommel et al., 2014; Freitag et al., 2021) that have been collected by WMT over the years, and both of which are publicly available. We use the DA data for training and the MQM data for both training and evaluation.

The DA judgments come from non-expert annotators that score the quality of a translation on a scale from 0 to 100. Often, the scores are z-normalized per rater in order to better compare across raters, since each rater may have a different rating strategy despite using the same scale. We experiment with using different subsets of the DA data from 2015 to 2021, as well as using the raw rating or z-normalized rating as the ground-truth quality score.

In contrast, the MQM ratings are done by professional raters. Each rater marks specific spans of text within a translation that contain an error, and label that error with a severity level and category. Each error receives a weight based on its severity and category. A segment's MQM score is the sum of the error weights in the segment. Our experiments use the MQM data collected by WMT

[2]The specific token to use can be chosen arbitrarily from the vocabulary, but the same token is then used throughout the training and inference. In our case, we opted for one of the `<extra_id_**>` tokens reserved in mT5's vocabulary.

from 2020 to 2022. The 2022 ratings are our primary evaluation dataset, and all correlations that we report are calculated on this dataset.

Our experiments additionally leverage a metrics challenge set, DEMETR (Karpinska et al., 2022), for metric meta-evaluation. DEMETR is a collection of paired translations that probe a metric's ability to correctly model different phenomena. The pairs of translations differ by some linguistic phenomena, with one translation assumed to be higher-quality than the other, and the metric is evaluated on how often it correctly ranks the two translations. We use DEMETR to evaluate how frequently the reference translations evaluated against itself receives a higher score than a machine translation evaluated against the same reference.

3.2 Meta-Evaluation

In our experiments, we calculate the metrics' agreements with human judgments of translation quality using four different correlations. At the system-level, we use both Pearson's r and pairwise accuracy (Kocmi et al., 2021). System-level Pearson's r captures how strong the linear relationship is between the metric and human scores for MT systems. Pairwise accuracy evaluates a metric's ranking of MT systems by calculating the proportion of all possible pairs of MT systems that are ranked the same by the metric and human scores.

At the segment-level, we use the no-grouping Pearson's r and the group-by-item pairwise accuracy with tie calibration as described by Deutsch et al. (2023).[3] The no-grouping Pearson's r quantifies the linear relationship between the metric and human scores across all possible translations from every system and document. The group-by-item pairwise accuracy calculates the proportion of all possible pairs of translations for the same input segment that are ranked the same or predicted to be a tie by the metric and human, then averages the accuracies over all possible input segments. Since regression-based metrics rarely predict ties and the segment-level pairwise accuracy rewards correct tie predictions, Deutsch et al. (2023) uses a procedure called tie calibration that automatically introduces ties into metric scores by introducing an ϵ such that any two translations with a difference in metric score less than ϵ are considered to be tied.

[3]We chose this pairwise accuracy over Kendall's τ, which has typically been used in WMT Metrics evaluation, for its superior handling of ties in metric scores.

3.3 Implementation Details

Our metrics are implemented with TensorFlow (Abadi et al., 2015) and the T5X library (Roberts et al., 2022). Each training run uses 64 TPUs and trains for a maximum of 10K steps with a batch size of 512 on the DA data, or 3K steps with a batch size of 256 on the much smaller MQM dataset. Adafactor is used for optimization (Shazeer and Stern, 2018). Checkpoint selection is done by selecting the model that has the highest segment-level pairwise accuracy after tie calibration on the en-de and zh-en language pairs.

We are publicly releasing our mT5-based submissions, converted from TensorFlow to PyTorch (Paszke et al., 2019) checkpoints, along with corresponding code to use them to predict translation quality scores.

4 Experimental Results

We made three different submissions to the shared task, each with a reference-based and QE variant:

1. **MetricX-23(-QE):** An mT5-XXL model that was finetuned on a combination of DA data from 2015–2020, MQM data from 2020–2021, and synthetic data.
2. **MetricX-23(-QE)-b:** The same as MetricX-23(-QE) except we additionally included MQM data from 2022.
3. **MetricX-23(-QE)-c:** The same as MetricX-23(-QE) except it is a finetuned PaLM-2 Bison model.

An overview of these submissions is shown in Figure 1. In the rest of this section, we describe the experimental results that led us to these submissions.

The experiments in the process of determining the best training recipe were performed with mT5-XL (3.7B parameters), but our final submissions then use the XXL variant with 13B parameters. All results are reported as the mean of 3 independent runs, along with the standard deviation across the runs, unless stated otherwise.

4.1 Training Data

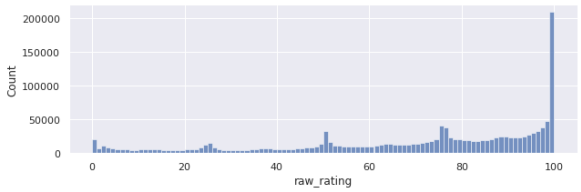
We start by determining which of the data available from previous WMT Metrics Shared Tasks is useful for training our metric, and whether it is beneficial to perform any transformations of the ratings before using them for training.

4.1.1 DA Ratings

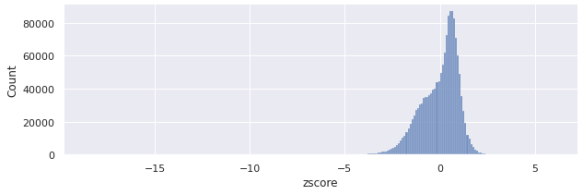
DA ratings have been used for scoring candidate translations in the shared task since 2015. To obtain DA ratings, human annotators were asked to provide an integer score on a scale of 0 to 100 for a translation produced by an MT system, given a reference translation produced by an expert translator.[4] There are over 2M raw DA ratings available from the years between 2015 and 2021, spanning 40 different language pairs. The total number of ratings drops to ca. 1M when ratings for the same segment (from different raters) are aggregated, which we do in order to avoid providing the model with different signals for the same translation.

Since the DA ratings come from hundreds of different raters, the WMT Metrics Shared Task organizers typically z-normalize them per rater before using them as the ground truth for metric evaluation. This is to make the ratings more comparable across different raters, considering some of them can be very strict, others lenient, and some can use the whole rating scale, while others just a narrow range of it. Hence a DA rating of, say, 50 can end up being used for translations of widely varying quality. The normalization ensures that the mean of each rater's ratings is 0 and the standard deviation is 1. These official normalized DA ratings, which we refer to as z-scores, are available along with the *raw* DA ratings in the data from the shared tasks.

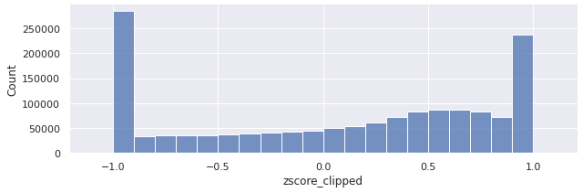
Score Normalization. In our first experiment, we compare the performance of our metric finetuned on the raw DA ratings and on the z-scores on different subsets of the DA data. As the first two rows of Table 1 show, using z-scores results in an overall weaker performance, but a drastic improvement on segment-level Pearson's r (42.93 vs. 38.83 for zh-en). Thus, picking between using raw ratings or z-scores for training the metric comes down to the preference between high *system*-level or high *segment*-level performance. Given the models' performance on the system-level metrics is already relatively high (between 80 and 99), we choose to use z-normalized DA ratings over their raw counterparts for our submissions. Nevertheless, as we show in Section 4.2, adding synthetic data during finetuning can restore some of the system-level performance. Moreover, our later experiments in Section 4.3 demonstrate that further finetuning on MQM ratings is more effective using a model first finetuned on DA z-scores than raw DA ratings.



(a) Raw DA ratings.



(b) DA z-scores.



(c) Clipped DA z-scores.

Figure 2: WMT15-20 DA rating distributions after z-normalization and after clipping to $[-1.0, 1.0]$, compared to the raw rating distribution.

Score Clipping. Normalized and raw ratings follow very different distributions, as depicted in Figure 2. The raw rating distribution is relatively flat across the whole range with a large spike at the maximum value, i.e., 100. In contrast, the z-score distribution ranges roughly from -17 to 5, with the majority of the mass between -1 and 1, a sharp peak around 0.65, and a long tail on the negative side. In order to prevent the model from putting too much weight on the outliers during training, and not learning to differentiate well between translations scored around zero, we propose clipping the scores to be in the $[-1.0, 1.0]$ range.[5] This creates a spike on the right end, similar to that observed on the raw rating distribution, but also a spike on the left end, similar in magnitude to the other spike (see Figure 2c). Finetuning a model on the clipped z-scores results in segment-level performance gains compared to the unmodi-

[4] Technically, some of the translation data is "target-original", meaning that the reference (target) is the text originally to be translated, and the source is the translation. This is the case for some language pairs in the DA data from earlier years.

[5] MSE loss magnifies errors in predictions greater than 1 and shrinks errors smaller than 1 relative to the absolute difference.

Table 1: Performance of MetricX that is initialized with mT5-XL, finetuned on DA ratings in different ways. "15-20" indicates that ratings from the years 2015 through 2020 were used, "z" indicates z-normalized scores, and "clipped" denotes experiments with the scores clipped to the $[-1.0, 1.0]$ range. Note that the data from 2015 is a small set of 2,500 z-normalized ratings only, so there is technically no data from 2015 in the "15-20 raw" setting.

fied z-scores, though further sacrifices some of the system-level performance (compare rows 2 and 3 in Table 1). Compared to finetuning on raw ratings (row 1 vs. row 3), there is up to 16% increase on the segment level (Pearson on zh-en), at the cost of an up to 9% drop in system-level performance (Pearson on en-de).

Data Selection. The DA ratings we used in our experiments thus far were from 2015 to 2020. Saving the WMT22 data for the validation set, we have the option of adding the WMT21 DA ratings to the training set. Doing this leads to moderate gains in system-level en-de performance, yet an equal, if not bigger, performance drop in zh-en across all metrics (compare the last two rows in Table 1). We also tried excluding earlier years of DA ratings, such as 2015–2017 or 2015–2018, since up until 2018 a half of the translations in the data were target-original (Barrault et al., 2019), and all DA annotations were reference-based (Ma et al., 2019), as opposed to source-based, such as is the case with a good part of the DA annotations from 2019 onward, and all of the MQM ratings. We hypothesized that the older data might thus be providing some low-quality signals to the model during training, negatively affecting the performance. Nevertheless, the model seems to prefer additional training data, even if of a mixed quality, as we consistently observed a slight drop in performance after excluding the earlier years, especially on system level. Therefore, the rest of the experiments uses DA data from 2015 to 2020.

4.1.2 MQM Ratings

MQM ratings have been collected in the context of the WMT Metrics Shared Task only since 2020. Due to the MQM annotation being significantly more labor-intensive, there is significantly less data collected per year than using the DA methodology. In fact, MQM ratings are only available for three language pairs, namely en-de, zh-en and en-ru. Since we reserve the ratings from 2022 for validation, we are left with only two years worth of MQM data to use for training, which amounts to approximately 114K ratings. For both training and evaluation we negate the MQM scores, changing thus the range to $[-25, 0]$, so that the score corresponding to no errors in the translation would be the highest value, as opposed to the lowest value, in the range. In the following paragraphs, we discuss our experiments with finetuning a model on MQM ratings only, in order to see if the model learns anything different than what it learns from the DA ratings.

Data Selection. We start this set of experiments with finetuning our model on the combination of '20 and '21 MQM ratings, and confirming that there is an added benefit to it over finetuning on just one of the years. As demonstrated by the first two rows in Table 2, finetuning on the '20 and '21 data individually leads to very different performance across the set of metrics. Using just the '20 MQM data by itself, our model achieves better segment-level performance than using all of the DA data, however, it is the opposite case on system level. As for training on '21 data only, the performance is significantly worse overall despite a slightly better segment-wise pairwise accuracy on en-de. Although this may suggest that the '21 MQM data is of a lower quality, it may also simply be the consequence of the '21 data having only a little over a third of the number

	SEG pairwise acc.		SEG Pearson		SYS pairwise acc.		SYS Pearson

Table 2: Performance of MetricX initialized with mT5-XL on the WMT22 MQM dataset, finetuned on different subsets of MQM ratings. "z" indicates z-normalized scores.

of ratings in the '20 data.[6] Finetuning on both the '20 and the '21 data combined, however, outperforms both of the individual years on segment-level metrics, while it lands somewhere in between according to system-level metrics (see row 3 in the table). Hence, we use the MQM ratings from both years in all of our subsequent experiments.

Score Normalization. We observed on the DA data that z-normalization has certain benefits, so we experiment with it even on the MQM data. We perform the z-normalization ourselves in the same way the shared task organizers normally do for the DA ratings, and compare a model finetuned on these z-scores to one finetuned on the raw MQM ratings. It is clear from the comparison of rows 3 and 4 in Table 2 that z-normalization drags the performance down, especially on the segment level.[7] One possible explanation could be that the normalization has a negative effect here because of the raters having annotated different sets of documents each, and the set of raters being very small at the same time. It could also be that z-normalization is actually not a very practical transformation of training labels for this task, yet it helps in case of DA ratings, which are of a much lower quality.[8] The metrics are evaluated against raw MQM ratings, so z-normalization during training could negatively impact its Pearson correlation at test time. At any rate, based on this result, we opt for the raw MQM ratings when finetuning our models henceforth.

[6] In the '20 MQM data, candidate translations have multiple ratings, so we also experimented with averaging them, but that, somewhat surprisingly, resulted in a consistently lower performance across the board.

[7] We verified that this is the case both with and without aggregating the ratings of the same translations by multiple raters in the '20 data.

[8] For instance, z-normalization discounts the ratings of raters who gave the same score, e.g., 100, to most of the translations they rated.

4.2 Adding Synthetic Data

Using the DEMETR challenge set, we discovered that training MetricX on either the DA or the MQM dataset does not teach it to reliably score a translation that exactly matches the reference higher than or equal to a machine translation, which should be a basic sanity check for an evaluation metric. In order to fix this behavior, we create simple synthetic examples where the reference is copied as the candidate translation and the label is set to the maximum score. Depending on the training set these synthetic examples are used along with, the labels may need to be rescaled to ensure they correspond to the maximum score, e.g., 100 when used with raw DA ratings or 0 with MQM ratings. Since z-scores do not have a maximum value, per se, there is no straightforward way of incorporating this synthetic data into such a training set. Clipped z-scores make this trivial though, which is another argument for training MetricX on clipped DA z-scores instead of the full range of z-scores. We use all of the references across all language pairs in the DA data between 2015 and 2022 to construct this synthetic dataset, which amounts to a little over 180K unique examples.

We also prepare a second synthetic dataset with the opposite type of examples, that is, ones that have no candidate translation and therefore a label corresponding to the minimum score (i.e., 0 for DA, and -25 for MQM). It is created using the same data as the other synthetic dataset, only instead of copying the reference, we set all of the translations to an empty string, resulting in the same number of synthetic examples.

Next, we perform experiments to determine what the minimum ratio of synthetic examples to regular training examples is with which a high accuracy on

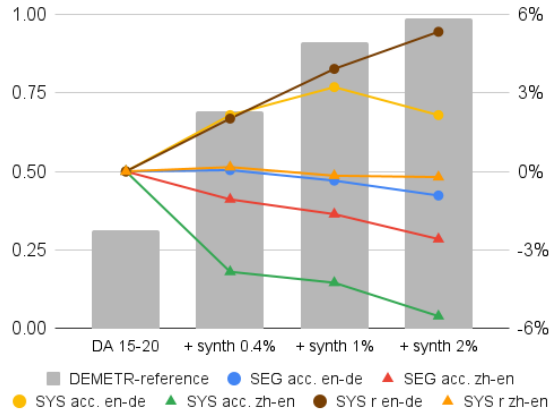

Figure 3: Effects of adding different proportions of synthetic data to the DA 15-20 training set (using clipped z-scores). The gray bars indicate the DEMETR-reference score (with the scale on the left y-axis), while the lines show the relative increase or decrease of the correlation metrics w.r.t. using no synthetic data (with the scale on the right y-axis). "Acc." stands for pairwise accuracy, and "r" denotes Pearson's r. Segment-level Pearson's r followed similar trends to segment-level accuracy, and was therefore omitted for better readability.

the DEMETR-reference metric can be achieved.[9] Figure 3 illustrates the effects of adding the synthetic data to the "DA 15-20 z clipped" training set in the following proportions: 0.4%, 1%, and 2% of the DA examples.[10] As we can see by looking at the gray bars, the synthetic data has the desired effect of bringing the accuracy of correctly scoring a reference higher than a machine translation from a mere 31% to almost 100%. However, this comes at a cost. With the increasing amount of synthetic data, the segment-level performance slowly degrades for both language pairs (see the blue and red lines in the plot). On the system level side, we see mixed results: a big improvement for en-de (see the yellow and brown lines) and a comparable drop in performance for zh-en, though only according to pairwise accuracy (see the orange and green lines). As such, we find adding 1% of synthetic examples to the DA data a good compromise between achieving relatively high DEMETR scores and maintaining good performance on the segment- and system-level correlation metrics. For the actual scores, we refer the reader to row 1 in Table 3.

We carried out a similar study with the MQM 20-21 training data, landing on 2% of synthetic examples as the best proportion.[11] Note that, with a model finetuned on raw MQM ratings, the accuracy on DEMETR was relatively high to begin with, typically between 80% and 90%. The 2% of synthetic data brought it up to nearly 99% though. Interestingly, training on the combination of MQM and synthetic data did not have a negative impact on the correlation metrics, as was the case with DA data. On the contrary, the performance received a consistent boost across all metrics, with an up to 1% increase in system-level scores and 5% in segment-level scores (see row 2 in Table 3).

4.3 Two-Stage Finetuning

In the previous two sections, we identified the best subset and format of the DA/MQM ratings, and we found the right balance between the DA/MQM examples and the synthetic examples for training a MetricX model. Here, we take it one step further and perform two-stage finetuning experiments, wherein we first finetune the model on the DA 15-20 training set, and then further finetune it on MQM 20-21 data with a smaller learning rate. The reason for finetuning on the two datasets in this order is 3-fold: (1) MQM is substantially smaller and has a limited language coverage, (2) MQM is a higher-quality dataset, and (3) the metric's performance is ultimately evaluated on MQM ratings (whether it be our validation set, or the shared task's test set).

Of all the four combinations of raw and z-normalized DA and MQM ratings, we found, somewhat surprisingly, that using DA z-scores (aggregated) in the first stage followed by raw MQM ratings in the second stage leads to the best results. Intuitively, using raw ratings in both stages, or z-scores in both stages, should provide a smoother learning process for the model, as it does not need to relearn the label scales.[12] Nevertheless, it appears that the neural model is not negatively affected by the shift, and instead it prefers learning from the DA and MQM data in their respective most effective format.

Before diving into the two-stage experiment results, let us recap that, so far, MetricX achieved the best segment-level performance when finetuned on the MQM 20-21 dataset, and the best system-level performance on the DA 15-20 dataset (in fact, substantially better than on the MQM dataset). The top two rows in Table 3 show the performance of models finetuned on these datasets individually,

[9] When included in the training data, both of the synthetic datasets are added in the same proportion.

[10] 1% corresponds to ca. 10K synthetic examples.

[11] Since the MQM dataset is much smaller, 2% here corresponds to only ca. 2K synthetic examples.

[12] In the experiments with raw ratings in both stages, we rescaled the DA ratings to the $[-25, 0]$ range, so as to match the MQM scale used then in the second stage.

	SEG pairwise acc.		SEG Pearson		SYS pairwise acc.		SYS Pearson		DEMETR

Table 3: Performance of MetricX initialized with mT5-XL, finetuned first on DA 15-20 clipped z-scores, and subsequently on MQM 20-21 raw ratings, with synthetic data added at different stages. DA_{syn} denotes the DA dataset with 1% of synthetic examples, and MQM_{syn} is the MQM dataset with 2% of synthetic examples. For comparison, the first two rows show the performance of models finetuned on DA_{syn} and MQM_{syn} individually. The last two rows correspond to models finetuned in the first stage on the DA dataset with the '21 ratings added but with all into-English language pairs excluded. Standard deviations are omitted in this table for better readability.

with synthetic data included, serving thus as baselines for the following experiments. Now, the third row shows the scores for a model finetuned in the two-stage fashion without any synthetic data. Comparing these results with those of a model finetuned on the MQM dataset only (see row 3 in Table 2), we see a dramatic improvement in performance across the board. For example, the segment-wise accuracy for zh-en increases from 52.72 to 54.09, and Pearson's r for en-de from 47.59 to 52.30. In system-level metrics we see similar gains, such as the accuracy going up from 83.52 to 86.45, and Pearson's r from 72.70 to 75.46 for zh-en. Similarly, rows 2 and 4 in Table 3 can be compared to see a similar difference, only this time for models trained with synthetic data too. This demonstrates a clear benefit of training our MetricX model on both the DA and the MQM data over training it on either of them individually. That being said, the system-level performance still lags significantly behind models finetuned on DA data only, so there appears to be a trade-off between segment- and system-level performance.

Next, we examine whether there is a difference between including synthetic data in the first stage or the second stage of finetuning. Rows 4 and 5 in Table 3 correspond to these two experiments. The scores show that using synthetic examples in the second stage not only ensures a higher DEMETR accuracy (91.93 vs. 82.03), but also higher correlations with the human scores according to virtually all of the other metrics. Moreover, compared to not using synthetic data at all (see row 3 in the table), combining it with the MQM data in the second stage does not generally sacrifice the overall performance, not to mention it almost doubles the DEMETR accuracy.

Finally, we also tried including synthetic data in both finetuning stages, but not until after the shared task's submission window has passed, hence, we did not use this method in our final MetricX version. The gains over using the synthetic data in the second stage only are rather inconsistent, nevertheless the DEMETR score further increases to 97.53 (see row 6).

4.4 Additional Experiments

Although in Section 4.1 we concluded that adding DA ratings from WMT21 to the training set dragged the performance down, we noted that that was the case for the zh-en language pair only. Revisiting this experiment after the submission, we found that excluding the into-English DA data from WMT21 and including the synthetic data as described in Section 4.2 is, in fact, a potentially better training set than the same with the WMT21 ratings omitted altogether. As we can see in Table 3, the model performs consistently better across most of the metrics when finetuned with the WMT21 out-of-English language pairs included (compare rows 7–8 with rows 5–6). So, while this seems to be the best training recipe, it is not the one we followed for the shared task submissions. Instead, we used DA 15-20 (without synthetic data) in the first stage, corresponding to row 4 in the table.

4.5 Scaling Analysis

Having arrived at our final MetricX training recipe using mT5-XL (3.7B parameters) as the pretrained model, we now briefly compare its performance

	SEG pairwise acc.		SEG Pearson		SYS pairwise acc.		SYS Pearson	
	en-de	zh-en	en-de	zh-en	en-de	zh-en	en-de	zh-en
mT5-L	59.63 ±0.34	53.98 ±0.06	50.82 ±2.16	55.91 ±0.53	76.07 ±0.74	**87.55** ±0.63	79.92 ±1.20	**93.63** ±2.48
mT5-XL	61.61 ±0.12	54.05 ±0.29	51.55 ±1.06	58.81 ±0.12	75.21 ±0.74	85.71 ±1.10	76.65 ±1.44	89.89 ±0.23
mT5-XXL	**61.92** ±0.19	**54.76** ±0.13	**54.57** ±0.36	**60.06** ±0.50	**82.48** ±0.74	86.81 ±1.10	**84.49** ±0.30	90.85 ±0.31

Table 4: Performance of MetricX with different variants of mT5 as the initialization model, trained using our final recipe, which involves first finetuning on DA 15-20 ratings and then on MQM 20-21 ratings with synthetic data.

with two other variants of mT5: one smaller (mT5-Large with 1.2B parameters) and one larger (mT5-XXL with 13B parameters). From Table 4 it is clear that MetricX can benefit from a bigger pretrained model for initialization, as mT5-XXL has a good margin on mT5-XL across all metrics. The XXL variant thus becomes our choice for all of our mT5-based submissions to the shared task.

Interestingly, mT5-Large outperforms the two bigger variants in system-level metrics on the zh-en language pair, and that not by a negligible margin. Combined with the results in the earlier sections and our observation that the system-level performance of MetricX is typically highest right at the beginning of training, and quickly declines as the model gradually improves on segment-level metrics, it appears it may be challenging to come up with a single MT evaluation metric that excels at both the segment and the system level. This phenomenon can also be observed among several of the top metrics in the WMT22 Metrics Shared Task (Freitag et al., 2022), as well as in recent large language model-based approaches to automatic MT evaluation (Kocmi and Federmann, 2023).

4.6 Submission Summary

Throughout the whole of Section 4 thus far, we were reporting results averaged across three independent runs, so as to more reliably develop the best training recipe for the reference-based version of MetricX. Here, we present the performance of our individual final submissions to the WMT23 Metrics Shared Task, described at the beginning of this section, including our QE (or reference-free) metric submissions. All of our submissions follow the same recipe—i.e., are first finetuned on the DA 15-20 aggregated and clipped z-scores, and then further finetuned on MQM 20-21 ratings combined with synthetic examples—but differ in (1) the pretrained model used for initialization, (2) whether they use reference or source segments in the input (the latter being used for the QE submissions), and (3) whether the second-stage training set includes the '22 MQM ratings or not. For the QE variants, we followed the same training recipe as the reference-based version; we did not do a significant amount of analysis into whether the design choices we made for the reference-based metric were also the correct decisions for the QE version. For the models that do use the '22 data for finetuning (which we otherwise use as the validation set), we do not report any scores. For these two submissions, we picked the model checkpoint based on the equivalent training runs without the '22 ratings.

Our remaining four submissions have their scores summarized in Table 5. Between the two reference-based variants (rows 1–2), the mT5-based MetricX is dominant in segment-level scores, whereas the PaLM-2-based one has a strong lead on the system level. The story is similar for the two QE variants (rows 3–4), only the segment-level score differences are less pronounced. Overall, on the WMT22 MQM validation set, the QE variants are not very far behind their reference-based counterparts in performance.

5 Related Work

For many years, lexical-based metrics like BLEU (Papineni et al., 2002) and ChrF (Popović, 2015) were the standard method for automatically evaluating MT output. However, as it was demonstrated that learned evaluation metrics correlate to human ratings significantly higher than lexical-based metrics (Freitag et al., 2022), the vast majority of recent research on MT evaluation has used learned metrics.

Learned MT metrics, such as BLEURT (Sellam et al., 2020; Pu et al., 2021) and COMET

Table 5: Meta-evaluation scores of our four MetricX submissions that did not include the '22 MQM data in the training set. Note that these scores correspond to single runs, as opposed to all the previous results that were averaged across 3 runs.

(Rei et al., 2020, 2022a), differ largely in their network architecture and the specific tasks they are trained to do. Our metric is most closely related to BLEURT. Like BLEURT, the MetricX network architecture creates a joint encoding of both the hypothesis and reference translations together, in contrast to COMET-style metrics that encode them independently. Our network is trained only to do either reference-based or reference-free (QE) judgments of sentence-level translation quality, whereas some metrics like UniTE (Wan et al., 2022) are trained to both tasks at the same time or CometKiwi (Rei et al., 2022b), which learns to predict both word-level quality scores in addition to an overall sentence-level score. Other learned metrics, such as MaTESe (Perrella et al., 2022), take an alternative approach to regression-based metrics and derive a sentence-level quality score by identifying error spans in translations, like is done in the human evaluations of MQM.

More recent approaches to MT evaluation leverage large language models (LLMs) to do zero-shot scoring by either directly predicting scalar quality scores or phrase-level error tagging (Kocmi and Federmann, 2023; Fernandes et al., 2023). These approaches typically leverage models that are orders of magnitude larger than metrics that are trained specifically for MT evaluation.

In comparison to the MetricX submission to the WMT22 Metrics Shared Task, this year's submission shares the same architecture, but we performed a significantly larger number of experiments to arrive at the final models, which are detailed in this report. We also explore how metric performance changes as a function of the number of parameters, experiment with initializing with different pretrained language models, and include a QE submission.

6 Conclusion

In this report, we presented in detail our approach to training MetricX-23, a regression-based MT evaluation metric. We submitted six versions of MetricX-23 to the WMT23 Metrics Shared Task, including both reference-based and QE variants. Some of our findings are that (1) training on direct assessment (DA) ratings and subsequently on MQM ratings leads to a significantly better performance than training on either of the two datasets alone, (2) z-normalization of DA ratings helps achieve better segment-level performance, but is not useful for high-quality MQM ratings, and (3) adding a small amount of synthetic data to the training set, targeting a challenge set, can also boost the metric's overall performance.

Throughout our experiments, we observed an undesirable tension between segment- and system-level performance, making it challenging to improve our metric in both aspects at the same time. Nevertheless, increasing the size of the model used to pre-initialize the metric appears to be one reliable way to increase the overall performance, at least to a certain point. Future work may benefit from a better understanding of the trade-off between segment- and system-level performance, and whether it would be better to focus on separate metrics for these two types of MT evaluation.

GEMBA-MQM: Detecting Translation Quality Error Spans with GPT-4

Tom Kocmi and **Christian Federmann**
Microsoft, One Microsoft Way, Redmond, WA-98052, USA
{tomkocmi,chrife}@microsoft.com

Abstract

This paper introduces GEMBA-MQM, a GPT-based evaluation metric designed to detect translation quality errors, specifically for the quality estimation setting without the need for human reference translations. Based on the power of large language models (LLM), GEMBA-MQM employs a fixed three-shot prompting technique, querying the GPT-4 model to mark error quality spans. Compared to previous works, our method has language-agnostic prompts, thus avoiding the need for manual prompt preparation for new languages.

While preliminary results indicate that GEMBA-MQM achieves state-of-the-art accuracy for system ranking, we advise caution when using it in academic works to demonstrate improvements over other methods due to its dependence on the proprietary, black-box GPT model.

Table 1: Preliminary results of the WMT 2023 Metric Shared task. The first column shows the system-level accuracy, and the second column is the Metrics 2023 meta evaluation. Metrics with gray background need human references. The table does not contain the worst-performing, non-standard metrics due to space reasons.

1 Introduction

GEMBA-MQM builds on the recent finding that large language models (LLMs) can be prompted to assess the quality of machine translation (Kocmi and Federmann, 2023a). We release the scoring script.[1]

The earlier work Kocmi and Federmann (2023a) (GEMBA-DA) adopted a straightforward methodology of assessing single score values for each segment without specifying the scale in detail. Employing a zero-shot approach, their technique showed an unparalleled accuracy in assessment, surpassing all other non-LLM metrics on the WMT22 metrics test set (Freitag et al., 2022).

Next, Lu et al. (2023) (EAPrompt) investigated prompting LLMs to assess individual error classes from a multidimensional quality metrics (MQM) framework (Freitag et al., 2021), where each error can be classified into various error classes (such as accuracy, fluency, style, terminology, etc.), subclasses (accuracy > mistranslation), and is marked with its severity (critical, major, minor). Segment scores are computed by aggregating errors, each weighted by its respective severity coefficient (25, 5, 1). While their approach employed a few-shot prompting with a chain-of-thought strategy (Wei et al., 2022), our GEMBA-MQM approach differs in two aspects: 1) We streamline the process using only single-step prompting, and 2) our prompts are universally applicable across languages, avoiding the need for manual prompt preparation for each language pair.

Another notable effort by Fernandes et al. (2023) paralleled the EAPrompt approach, also marking MQM error spans. In contrast, their approach used a PaLM-2 model, pooling MQM annotations to sample a few shot examples for the prompt. Their

```
(System) You are an annotator for the quality of machine translation. Your task is to identify
errors and assess the quality of the translation.

(user) {source_language} source:\n
```{source_segment}```\n
{target_language} translation:\n
```{target_segment}```\n
\n
Based on the source segment and machine translation surrounded with triple backticks, identify
error types in the translation and classify them. The categories of errors are: accuracy
(addition, mistranslation, omission, untranslated text), fluency (character encoding, grammar,
inconsistency, punctuation, register, spelling),
 locale convention (currency, date, name, telephone, or time format)
style (awkward), terminology (inappropriate  for context, inconsistent use), non-translation,
other, or no-error.\n
Each error is classified as one of three categories: critical, major, and minor.
Critical errors inhibit comprehension of the text. Major errors disrupt the flow, but what
the text is trying to say is still understandable. Minor errors are technically errors,
but do not disrupt the flow or hinder comprehension.

(assistant) {observed error classes}
```

Figure 1: The general prompt for GEMBA-MQM omits the gray part which performed subpar on internal data (we include it in GEMBA-locale-MQM). The "(user)" and "(assistant)" section is repeated for each few-shot example.

fine-tuning experiments did not improve system-level performance for the top-tier models.

2 Description

Our technique adopts few-shot learning with the GPT-4 model (OpenAI, 2023), prompting the model to mark quality error spans using the MQM framework. The underlying prompt template is modeled on guidelines for human annotators and shown in Figure 1.

In contrast to other methods, we use three predetermined examples (see Appendix A), allowing the method to be used with any language pair, avoiding the need to create language pair specific MQM few-shot examples. This was the original limitation that prevented Fernandes et al. (2023) from evaluating AutoMQM beyond two language pairs. Our decision was not driven by a desire to enhance performance — since domain and language-specific prompts typically boost it (Moslem et al., 2023) — but rather to ensure our method can be evaluated across any language pairs.

3 Experiments

To measure the performance of the GEMBA-MQM metric, we follow the methodology and use test data provided by the WMT22 Metrics shared task (Freitag et al., 2022) which hosts an annual evaluation of automatic metrics, benchmarking them against human gold labels.

We compare our method against the best-performing reference-based metrics of WMT22: MetrixX_XXL (non-public metric), COMET-22 (Rei et al., 2022), UNITE (Wan et al., 2022b), BLEURT-20 (Pu et al., 2021), and COMET-20 (Rei et al., 2020). In addition, we also compare against "classic" string-based metrics BLEU (Papineni et al., 2002) and ChrF (Popović, 2015). Lastly, we compare against reference-less metrics of WMT22: CometKIWI (Rei et al., 2022), Unite-src (Wan et al., 2022a), Comet-QE (Rei et al., 2021), MS-COMET-QE-22 (Kocmi et al., 2022b).

We contrast our work with other LLM-based evaluation methods such as GEMBA-DA (Kocmi and Federmann, 2023b) and EAPrompt (Lu et al., 2023), conducting experiments using two GPT models: GPT-3.5-Turbo and the more powerful GPT-4 (OpenAI, 2023).

3.1 Test set

The main evaluation of our work has been done on the MQM22 (Freitag et al., 2022) and internal Microsoft data. Furthermore, a few days before the camera-ready deadline, organizers of Metrics 2023 (Freitag et al., 2023) released results on the blind test set, showing performance on unseen data.

The MQM22 test set contains human judgments for three translation directions: English into German, English into Russian, and Chinese into English. The test set contains a total of 54 machine translation system outputs or human translations. It

contains a total of 106k segments. Translation systems are mainly from participants of the WMT22 General MT shared task (Kocmi et al., 2022a). The source segments and human reference translations for each language pair contain around 2,000 sentences from four different text domains: news, social, conversational, and e-commerce. The gold standard for scoring translation quality is based on human MQM ratings, annotated by professionals who mark individual errors in each translation, as described in Freitag et al. (2021).

The MQM23 test set is the blind set for this year's WMT Metrics shared task prepared in the same way as MQM22, but with unseen data for all participants, making it the most reliable evaluation as neither participants nor LLM could overfit to those data. The main difference from last year's iteration is the replacement of English into Russian with Hebrew into English. Also, some domains have been updated; see Kocmi et al. (2023).

Additionally, we evaluated GEMBA-MQM on a large internal test set, an extended version of the data set described by Kocmi et al. (2021). This test set contains human scores collected with source-based Direct Assessment (DA, Graham et al., 2013) and its variant DA+SQM (Kocmi et al., 2022a). This test set contains 15 high-resource languages paired with English. Specifically, these are: Arabic, Czech, Dutch, French, German, Hindi, Italian, Japanese, Korean, Polish, Portuguese, Russian, Simplified Chinese, Spanish, and Turkish.

3.2 Evaluation methods

The main use case of automatic metrics is system ranking, either when comparing a baseline to a new model, when claiming state-of-the-art results, when comparing different model architectures in ablation studies, or when deciding if to deploy a new model to production. Therefore, we focus on a method that specifically measures this target: system-level pairwise accuracy (Kocmi et al., 2021).

The pairwise accuracy is defined as the number of system pairs ranked correctly by the metric with respect to the human ranking divided by the total number of system pair comparisons.

Formally:

$$\text{Accuracy} = \frac{|\text{sign}(\text{metric}\Delta) == \text{sign}(\text{human}\Delta)|}{|\text{all system pairs}|}$$

We reproduced all scores reported in the WMT22 Metrics shared task findings paper using the official WMT22 script.[2] Reported scores match Table 11 of the WMT22 metrics findings paper (Freitag et al., 2022).

Furthermore, organizers of Metrics shared task 2023 defined a new meta-evaluation metric based on four different scenarios, each contributing to the final score with a weight of 0.25:

- system-level pairwise accuracy;
- system-level Pearson correlation;
- segment-level Accuracy-t (Deutsch et al., 2023); and
- segment-level Pearson correlation.

The motivation is to measure metrics in the most general usage scenarios (for example, for segment-level filtering) and not just for system ranking. However, we question the decision behind the use of Pearson correlation, especially on the system level. As Mathur et al. (2020) showed, Pearson used for metric evaluation is sensitive when applied to small sample sizes (in MQM23, the sample size is as little as 12 systems); it is heavily affected by outliers (Osborne and Overbay, 2004; Ma et al., 2019), which need to be removed before running the evaluation; and it measures linear correlation with the gold MQM data, which are not necessarily linear to start with (especially the discrete segment-level scores, with error weights of 0.1, 1, 5, 25).

Although it is desirable to have an automatic metric that correlates highly with human annotation behaviour and which is useful for segment-level evaluation, more research is needed regarding the proper way of testing these properties.

4 Results

In this section, we discuss the results observed on three different test sets: 1) MQM test data from WMT, 2) internal test data from Microsoft, and 3) a subset of the internal test data to measure the impact of the MQM locale convention.

4.1 Results on MQM Test Data from WMT

The results of the blind set MQM23 in Table 1 show that GEMBA-MQM outperforms all other techniques on the three languages evaluated in the system ranking scenario. Furthermore, when evaluated in the meta-evaluation scenario it achieves the third cluster rank.

In addition to the official results, we also test on MQM22 test data and show results in Table 2. The

Source	Vstupné do památky činí 16,50 Eur.
Hypothesis	Admission to the monument is 16.50 Euros.
GPT annot.	locale convention/currency: "euros"

Table 4: An example of a wrong error class "locale convention" as marked by GEMBA-locale-MQM. The translation is correct, however, we assume that the GPT model might not have liked the use of Euros in a Czech text because Euros are not used in the Czech Republic.

main conclusion is that all GEMBA-MQM variants outperform traditional metrics (such as COMET or Metric XXL). When focusing on the quality estimation task, we can see that the GEMBA-locale-MQM-Turbo method slightly outperforms EAPrompt, which is the closest similar technique.

However, we can see that our final technique GEMBA-MQM is performing significantly worse than the GEMBA-locale-MQM metric, while the only difference is the removal of the locale convention error class. We believe this to be caused by the test set. We discuss our decision to remove the locale convention error class in Section 4.3.

4.2 Results on Internal Test Data

Table 3 shows that GEMBA-MQM-Turbo outperforms almost all other metrics, losing only to COMETKIWI-22. This shows some limitations of GPT-based evaluation on blind test sets. Due to access limitations, we do not have results for GPT-4, which we assume should outperform the GPT-3.5 Turbo model. We leave this experiment for future work.

4.3 Removal of Locale Convention

When investigating the performance of GEMBA-locale-MQM on a subset of internal data (Czech and German), we observed a critical error in this prompt regarding the "locale convention" error class. GPT assigned this class for errors not related to translations. It flagged Czech sentences as a locale convention error when the currency Euro was mentioned, even when the translation was fine, see example in Table 4. We assume that it was using this error class to mark parts not standard for a given language but more investigation would be needed to draw any deeper conclusions.

The evaluation on internal test data in Table 4 showed gains of 1.7% accuracy. However, when evaluating over 15 languages, we observed a small degradation of 0.2%. For MQM22 in Table 2, the degradation is even bigger.

When we look at the distribution of the error classes over the fifteen highest resource languages in Table 5, we observe that 32% of all errors for GEMBA-locale-MQM are marked as a locale convention suggesting a misuse of GPT for this error class. Therefore, instead of explaining this class in the prompt, we removed it. This resulted in about half of the original locale errors being reassigned to other error classes, while the other half was not marked.

In conclusion, we decided to remove this class as it is not aligned with what we expected to measure and how GPT appears to be using the classes. Thus, we force GPT to classify those errors using other error categories. Given the different behaviour for internal and external test data, this deserves more

Error class	GEMBA-locale-MQM	GEMBA-MQM
accuracy	960,838 (39%)	1,072,515 (51%)
locale con.	808,702 (32%)	(0%)
fluency	674,228 (27%)	699,037 (33%)
style	23,943 (1%)	41,188 (2%)
terminology	17,379 (1%)	290,490 (14%)
Other errors	4,126 (0%)	10615 (1%)
Total	2,489,216	2,113,845

Table 5: Distribution of errors for both types of prompts over all segments of the internal test set for the Turbo model.

investigation in future work.

5 Caution with "Black Box" LLMs

Although GEMBA-MQM is the state-of-the-art technique for system ranking, we would like to discuss in this section the inherent limitations of using "black box" LLMs (such as GPT-4) when conducting academic research.

Firstly, we would like to point out that GPT-4 is a proprietary model, which leads to several problems. One of them is that we do not know which training data it was trained on, therefore any published test data should be considered as part of their training data (and is, therefore, possibly tainted). Secondly, we cannot guarantee that the model will be available in the future, or that it won't be updated in the future, meaning any results from such a model are relevant only for the specific sampling time. As Chen et al. (2023) showed, the model's performance fluctuated and decreased over the span of 2023.

As this impacts all proprietary LLMs, we advocate for increased research using publicly available models, like LLama 2 (Touvron et al., 2023). This approach ensures future findings can be compared both to "black box" LLMs while also allowing comparison to "open" models.[3]

6 Conclusion

In this paper, we have introduced and evaluated the GEMBA-MQM metric, a GPT-based metric for translation quality error marking. This technique takes advantage of the GPT-4 model with a fixed three-shot prompting strategy. Preliminary results show that GEMBA-MQM achieves a new state of the art when used as a metric for system ranking, outperforming established metrics such as COMET and BLEURT-20.

We would like to acknowledge the inherent limitations tied to using a proprietary model like GPT. Our recommendation to the academic community is to be cautious with employing GEMBA-MQM on top of GPT models. For future research, we want to explore how our approach performs with other, more open LLMs such as LLama 2 (Touvron et al., 2023). Confirming superior behaviour on publicly distributed models (at least their binaries) could open the path for broader usage of the technique in the academic environment.

Limitations

While our findings and techniques with GEMBA-MQM bring promising advancements in translation quality error marking, it is essential to highlight the limitations encountered in this study.

- Reliance on Proprietary GPT Models: GEMBA-MQM depends on the GPT-4 model, which remains proprietary in nature. We do not know what data the model was trained on or if the same model is still deployed and therefore the results are comparable. As Chen et al. (2023) showed, the model's performance fluctuated throughout 2023;

- High-Resource Languages Only: As WMT evaluations primarily focus on high-resource languages, we cannot conclude if the method will perform well on low-resource languages.

Acknowledgements

We are grateful to our anonymous reviewers for their insightful comments and patience that have helped improve the paper. We would like to thank our colleagues on the Microsoft Translator research team for their valuable feedback.

Metric Score Landscape Challenge (MSLC23): Understanding Metrics' Performance on a Wider Landscape of Translation Quality

Chi-kiu Lo 羅致翹 **Samuel Larkin** **Rebecca Knowles**

{chikiu.lo,samuel.larkin,rebecca.knowles}@nrc-cnrc.gc.ca

Abstract

The Metric Score Landscape Challenge (MSLC23) dataset aims to gain insight into metric scores on a broader/wider landscape of machine translation (MT) quality. It provides a collection of low- to medium-quality MT output on the WMT23 general task test set. Together with the high quality systems submitted to the general task, this will enable better interpretation of metric scores across a range of different levels of translation quality. With this wider range of MT quality, we also visualize and analyze metric characteristics beyond just correlation.

1 Introduction

Under time and human resource constraints, automatic metrics are often used as a proxy of manual evaluation for machine translation (MT) quality. The WMT Metrics shared task evaluates how well a variety of automatic metrics correspond to human judgments of MT quality, as evaluated on the WMT General (formerly News) shared task data. Those MT systems being evaluated are typically high-performing systems, especially for high-resource language pairs. However, in practice, the lessons learned are applied to a broader range of systems in development, including low-resource and low-quality output.

This challenge set[1] aims to gain insight into metric scores across a broader MT quality landscape. It provides a collection of low- to medium-quality MT output on the WMT23 general task test set. This serves several purposes. Together with the high quality systems submitted to the general task, this will enable more thorough understanding of metric scores across a range of different levels of translation quality: useful knowledge for researchers considering applying these metrics to lower-resource language pairs or lower-performing domains. This challenge set also allows us to explore metric characteristics beyond just correlation, which has been a main focus of past work. By expanding the range of MT quality analyzed, we shed light on some unexpected or under-explored properties of metrics, such as metrics that can distinguish between high quality systems but are not able to differentiate different levels of MT quality on the lower end of the quality scale (or vice versa) and metrics that use their space of scores in very different ways (e.g., discretized, or with specific score ranges with particularly large numbers of ties).

We focus on four language pairs: Chinese→English (ZH→EN), Hebrew↔English (HE↔EN), and English→German (EN→DE). Three of these correspond to the focus languages of the WMT 2023 Metrics shared task (EN→DE, HE→EN, ZH→EN), and they also cover several language families and aspects of translation evaluation (i.e., the paragraph-level evaluation of EN→DE), as well as including a sentence-level out-of-English direction (EN→HE). We combine source and reference data from the news portion of the WMT 2023 General MT task test sets with our challenge set, the low- and medium-quality MT output that we generated to cover a range of MT quality.

We begin by describing the training data (Section 3.1) and models (Section 3.2) used in for constructing our challenge set (Section 3.3). We also briefly describe the additional data (Section 4) and metrics (Section 5) analyzed. In Section 6 we analyze the distribution of different metrics over the challenge set. We find that some metrics exhibit strikingly different characteristics on the low-quality systems as compared to the systems submitted to WMT, while others exhibit unexpected characteristics (e.g., large numbers of tied scores) that would not have been apparent from standard correlational analysis or from high-quality WMT submitted systems alone. We conclude by arguing

[1] Available at https://github.com/nrc-cnrc/MSLC23

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 776–799
December 6–7, 2023.

that examining metric characteristics and performance over a wider landscape of MT quality—or indicating clearly when a metric has only been tested on high-quality MT—is an important factor for researchers to consider when building, presenting, and applying new metrics (especially if those metrics will be applied to lower-quality outputs).

2 Related Work

Przybocki et al. (2009) outlined four objectives in the search for new and improved automatic MT evaluation metrics: 1) "high correlation with human assessments of translation quality"; 2) "applicable to multiple target languages"; 3) "ability to differentiate between systems of varying quality" and finally, 4) "intuitive interpretation". Over the years, the WMT Metrics shared tasks (Callison-Burch et al., 2007; Bojar et al., 2017b; Freitag et al., 2021, 2022, i.a.) focused mainly on evaluating MT evaluation metrics on the first two objectives.

Many other research efforts on meta-evaluation of metrics also focused on their ability to correlate with human judgment. Graham and Baldwin (2014) introduced Williams' significance tests for understanding the confidence of the correlation analysis. Mathur et al. (2020) pointed out that Pearson's correlation is sensitive to outliers and proposed to remove outliers in Pearson's correlation analysis at system level. Kocmi et al. (2021) proposed to use pairwise accuracy to evaluate metrics based on whether the metric's pairwise rankings of two systems agrees with human pairwise rankings. Deutsch et al. (2023) introduced a tie calibration procedure enabling fair comparison between metrics that do and do not predict ties for pairwise accuracy analysis at the segment level. Marie (2022) and Lo et al. (2023) studied the relationship of metrics' score differences and statistical significance of ranking decision. Notably, these works are mostly based on the data released by WMT Metrics shared task. That means the translation output scored by the metrics in these work were generated by the participants of the WMT News/General Translation shared task, typically consisting of high-quality MT output.

There is growing interest in understanding metric performance beyond correlation. Moghe et al. (2023) note that neural metrics are not interpretable at the segment level across different language pairs. The WMT Metrics shared task introduced the challenge sets subtask (Freitag et al., 2021, 2022) to challenge metrics on particular translation errors, including negation and polarity, word/sentence addition/omission, tokenization, punctuation, numeric expression, casing number swapping, spelling, etc., in order to shed light on metric strengths and weaknesses. The challenge sets created by Macketanz et al. (2018); Avramidis et al. (2020); Avramidis and Macketanz (2022) were more linguistically motivated and covers more than 100 phenomena, including tenses, relative clauses, idioms, focus particles, etc. The ACES challenge set (Amrhein et al., 2022) covers 146 translation directions and 68 types of errors, ranging from simple perturbations to more complex errors based on discourse and real-world knowledge. The SMAUG challenge set (Alves et al., 2022) and the HWTSC challenge set (Chen et al., 2022) focused on the robustness of metrics on translation errors involving named entities, numeric/date/time entities, etc.

We note that even as MT evaluation metrics become better at correlating with human judgment on translation quality for high-quality MT systems, metric performance may be untested on low- to medium-quality MT output. Hence, we design the MSLC23 challenge set to gain insights of metric behavior on a more complete landscape.

3 Challenge Set

The challenge set consists of data translated by MT systems of varying quality. We describe the training data used to build these systems as well as the MT models.

3.1 Training Data

To build the lower-quality MT systems that we analyze in this work, we use standard WMT datasets from WMT 2023 (Kocmi et al., 2023) for EN→DE and HE↔EN and from WMT 2017 (Bojar et al., 2017a) for ZH→EN. For EN→DE and ZH→EN, we used the *newstest2020* data as our validation set. For HE↔EN, we used a random sample of 2000 lines, ensuring no overlap between sentence pairs in the training and validation set. For full details of training data, see Appendix A. Appendix B describes the preprocessing and subword segmentation performed.

3.2 MT Models

We build two main types of systems: baselines and pseudo-low-resource systems. All systems were

built using Sockeye-3.1.31 (Hieber et al., 2022), commit 13c63be5, with PyTorch-1.12.1 (Paszke et al., 2019). For more details on parameters and training, see Appendix C.

The baselines are standard Transformer models trained over the available data, but without any additional components (e.g., backtranslation, factors, tagging, etc.). The pseudo-low-resource systems are produced using subsets of the training data, to simulate lower-resource settings (see Appendix D for details). We checkpoint all systems frequently so that we can use output at various levels of training as representative of different levels of quality.

We note that the EN→DE 2023 shared task is performed at the paragraph level. In our work we do not perform paragraph-level MT; instead we use as a baseline sentence segmentation, translation of the individual sentences, and concatenation back into paragraphs of the resulting translation output.

3.3 Translation Output

We use the news data portions of each of the 2023 General MT task test sets for these language pairs. This consists of 139 paragraphs for EN→DE (translated by 12 different systems), 516 lines for EN→HE (translated by 6 different systems), 1558 lines for HE→EN (translated by 6 different systems), and 763 lines for ZH→EN (translated by 6 different systems).

We use checkpoints from each of the systems we built to produce the low- and medium-quality MT output. For ZH→EN and HE↔EN, all checkpoints were selected from the baseline systems; for EN→DE, they were selected from the baseline system as well as the 50k, 200k, and 400k pseudo-low-resource systems. These checkpoints were selected to cover a range of BLEU scores from less than 1 to between 20 and 30 (shown in Appendix E, Tables 11 and 12; we assign the selected systems the letters A through F, or through L in the case of EN→DE, with A being the lowest quality system in all cases),[2] and were then spot-checked manually to confirm that they did generally appear to represent incremental (but noticeable) improvements in quality. We note that we did not perform a full or extensive manual evaluation, and as such cannot make claims of statistically significant human judgment differences between the checkpoints. Another potential limitation of this choice to select checkpoints is that they may be more similar to one another than separately-trained systems would be (cf. the benefits of ensembling diverse sets of systems or the potential minor drawbacks of ensembling checkpoints rather than separately trained models in Farajian et al. (2016); Sennrich et al. (2016), i.a.). Nevertheless, we expect this should provide some coverage of low- to mid-quality MT for scoring by various metrics.

[2]Computed with sacreBLEU (Post, 2018) with signature: nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.3.1 For HE↔EN, the systems were selected based on BLEU scores computed with refA as the reference, as refB had not yet been released. The range of BLEU scores remains similar, and we present all other HE↔EN results based on scores with refB.

4 General MT Submissions

Our challenge set has aimed to cover the range of low-quality MT systems, but to obtain a fuller picture, we also include the metric scores assigned to the systems submitted to the WMT2023 General MT Task (Kocmi et al., 2023) in our analysis. For these systems, we have human annotation scores in the form of multidimensional quality metrics (MQM; Burchardt, 2013) scores for EN→DE, HE→EN, and ZH→EN.

5 Metrics

There are dozens of metrics submitted by the task organizers and participants in WMT23 Metrics shared task. Under the time and space limitations, we only examine the baseline metrics submitted by the task organizers and the primary metrics submitted by the participants. Due to the random shuffling of items in the challenge sets before their delivery to the scorers, we can only examine metrics that produce scores at the segment level, as the system-level scores returned do not correspond to the underlying systems in our datasets. We describe the metrics included in this work in Appendix F.

6 Analysis

We are interested in metric performance and characteristics at both the segment level and the system level. In the case of EN→DE, the segments are paragraphs, while in all other cases they are typically sentences. For metrics that use the reference, HE↔EN are scored against refB (a higher-quality reference translation than refA), while EN→DE and ZH→EN are scored against refA.

For EN→DE, HE→EN, and ZH→EN, we have access to human scores for all submitted WMT MT systems (but not for the challenge set systems).

These take the form of MQM scores over a consistent subset of the test set. For the remainder of this work unless otherwise noted, in order to make appropriate comparisons between metric scores on the challenge set, metric scores on the submitted WMT MT systems, and the human annotations, we restrict our analysis to only those segments that are in the news domain and that correspond to the set for which we have human annotations (104 paragraphs for EN→DE, 619 segments we use all 516 segments of the test set data that are in the news domain because we do not have any human annotations).

6.1 Segment Level

Since we only have human annotations for the WMT MT submissions and not our challenge set, we must be cautious in the conclusions that we draw about metric *performance* from the scores they assign to segments. However, we can observe that different metrics exhibit different *characteristics*, even as they score an identical set of segments over an identical set of systems.

6.1.1 Distributions of Scores

As we see in the histograms along the diagonal of Figure 1, showing a subset of the baseline and submitted metrics, different metrics exhibit very different score distributions. This can also be seen in Figures 3, 4, 5, and 6 in Appendix G. Some show a somewhat bimodal distribution of scores, some are closer to normally distributed, and there are a number of metrics whose score distributions do not fall into either of those patterns. Additionally, they differ in whether they exhibit a strong separation between the segments produced by the low-quality systems from our challenge set and the segments produced by the WMT submissions or whether they assign a range of low to high scores to most systems (i.e., having clear overlap in score range across all systems). While we cannot conclude that any of these metrics is more *accurate*, we can note that their varied characteristics suggest that they may be measuring different things and/or that different metrics may have different strengths and weaknesses across the translation quality landscape.

There are also metrics that use an approximation of a discrete score space, such as GEMBA-MQM. This particular metric also scores nearly all segments produced by our low-quality systems as the lowest available score, particularly for EN→DE, meaning it would not be a suitable metric to distinguish between low-to-mid quality (e.g., low-resource) translation systems. XCOMET-Ensemble assigns a wider range of scores to the low-quality segments, but the range and distribution of those scores is fairly consistent across the low-quality systems in our challenge set, meaning that it also struggles to distinguish between system quality levels at the lower end, albeit for a different reason. We can also see this when we examine system-level scores.

6.1.2 Universal Translations and Universal Scores

In Yan et al. (2023), the authors observe what they term "universal translations": target language output that receives high scores regardless of the reference to which they are compared. Here, we observe what one might consider to be "universal scores" instead. Some metrics, like Calibri-COMET22, use a wide range of scores in general, but have a very small subset of scores that appear a very large number of times. For the set of annotated news segments across all challenge set and WMT MT systems for EN→DE, 1673 unique scores are assigned to segments. The vast majority occur only once, but there are two non-minimum/maximum scores that occur 210 and 206 times, respectively (the score zero, i.e. the maximum score for perfect translation in this case, also appears 206 times). In contrast, COMET assigns 2446 unique scores over the same subset of segments, with the most frequent of those scores occurring 7 times. We note that Calibri-COMET22 (and Calibri-COMET22-QE) exhibit this frequently-appearing-score characteristic across the different language pairs, though the number and exact value of the extremely frequent scores differs across language pairs. Importantly, this is not explainable by the data itself: other metrics assign a wide variety of scores to the same segments that receive these particularly common scores, which makes the common scores visible in the Calibri-COMET22 column as the apparent vertical lines (most visible in comparison to COMET). As is evident from both the histogram and the scatterplots, these common scores are most frequently assigned to the segments in our challenge set, to the extent that this unexpected characteristic is not clearly visible when the plot is restricted to only the WMT MT submissions rather than including the challenge set (see Figure 10). This highlights the importance of performing evaluation over a wide

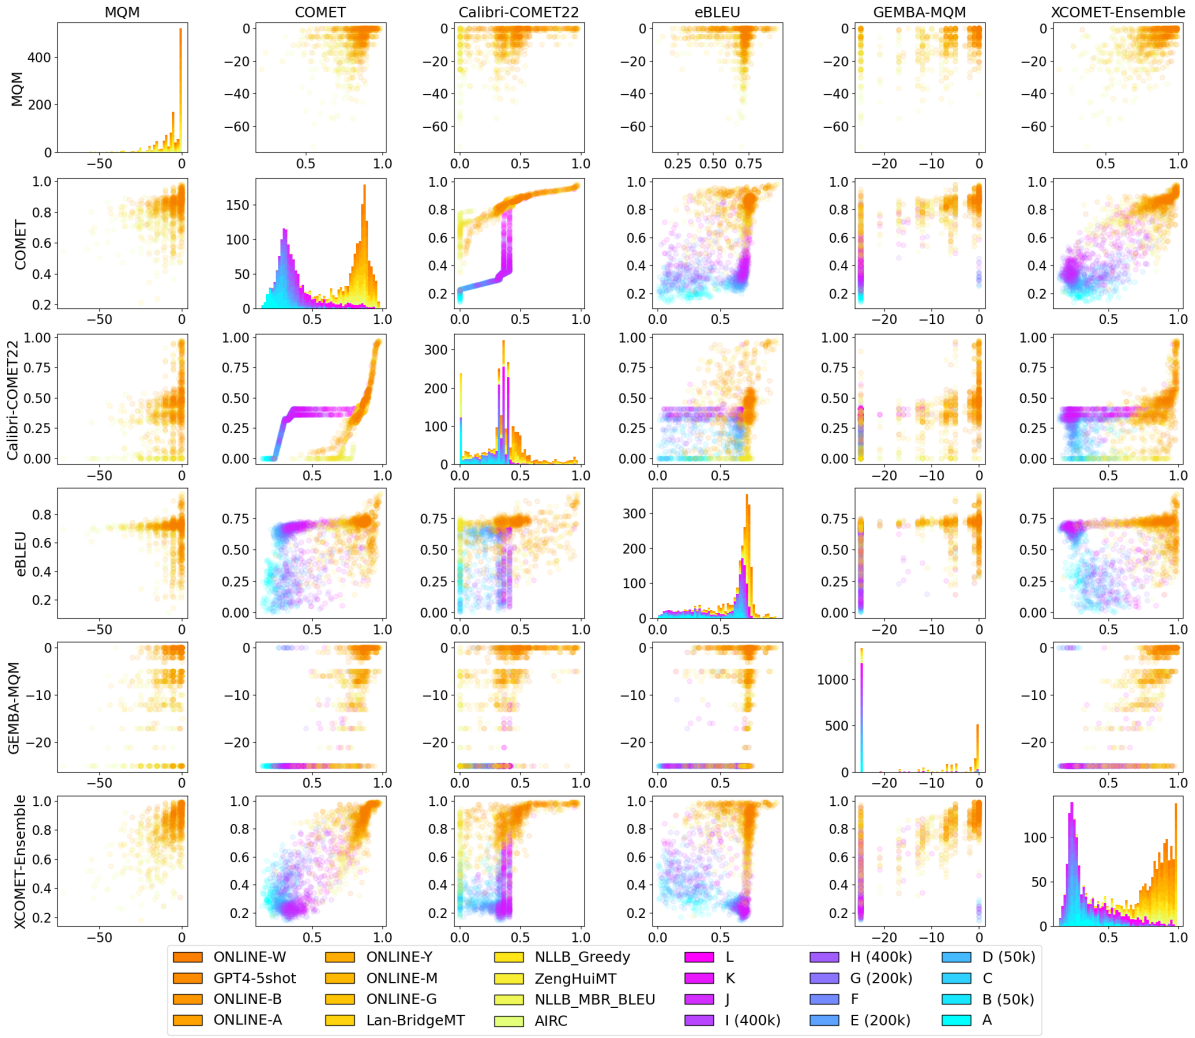

Figure 1: A subset of the metrics (and MQM scores) for EN→DE. The diagonal entries show stacked histograms of segment scores across the challenge set (cool colours/bottom) and submitted WMT systems (warm colours/top). The off-diagonal entries are scatterplots where each point is a single segment positioned according to the score assigned to it by row and column metrics; each point is coloured according to the MT system that produced it.

range of MT quality, in order to discover unexpected issues like this prior to applying the metrics to low-resource or otherwise low-quality MT.

The eBLEU metric exhibits a slightly more dispersed version of this, where a large number of segments receive scores in a fairly narrow band relative to the metric's overall score distributions. However, in the case of eBLEU, this is not specific to the challenge set data, but is also observed in the WMT MT data.

6.2 System Level

To analyze system-level scores, we produce them as an average over all of the segment-level scores in the restricted test set (news domain segments in the set of segments for which WMT MT systems were human-annotated) for a given MT system.[3] These system-level scores can also be used in order to gain a better understanding of the overall range of a metric's scores, as well as what kind of scores are assigned to very low quality machine translation (e.g., the A and B systems from the challenge set).

In Figure 2 (as well as Figures 7, 8, and 9 in Appendix G), we observe that metrics show different patterns of scores at the system level. We observe that some metrics exhibit unexpected characteristics on the low-quality data, such as MaTESe, which ranks some of the low-quality systems in reverse order.[4]

We do not have MQM scores for any of the data in the challenge set, which means that we do not know how much of a gap in quality there is between our best low-quality system and the lowest-performing MT systems submitted to WMT. However, we can observe that metrics differ widely in their estimates of the gap; embed_llama, for example, shows error bar overlap between the highest performing system from our challenge set and the lowest-scored system from the submissions, while GEMBA-MQM shows a very large gap between the two groups of systems,[5] with many of the other metrics falling between these extremes.

Similarly, again examining characteristics without making claims about metric performance, we notice variety amongst the metrics in terms of the range of scores they assigned to each group of systems, as seen in the slope of the system scores. In some cases, there are quite similar slopes (e.g., embed_llama), while in other cases there is a steep slope for the challenge set as compared to the WMT MT systems (e.g., BERTScore or COMET) meaning that the challenge set covers a wide range of (lower) scores while the WMT MT set covers a smaller range of higher scores, and finally some systems where the slopes are similar but both less steep (e.g., Calibri-COMET22-QE and GEMBA-MQM) and each set of systems covers a small range of scores with a gap in between. Without MQM scores for the challenge set, we do not know whether one of these patterns is indicative of a metric that more closely resembles human annotations or not (i.e., we do not know whether the challenge set covers a wider range of quality than the WMT MT systems, which would support metrics having a steeper slope/wider range in the scores assigned to it).

We also note some variety across language pairs. The reversal of scores seen in MaTESe is less obvious in the EN→DE data, though that may be related to greater overlap in the EN→DE challenge set data quality.

In future work, obtaining MQM scores for one or more of the systems in our challenge set would permit us to draw conclusions about metric performance in these areas (i.e., about whether there is indeed quality overlap between the two sets, and what appropriate ranges of scores might be for each of the sets).

All of these observations about variation in metric characteristics raise an important issue in the evaluation and adoption of new metrics: since their correlation with human rankings is often demonstrated on the high-quality MT output being scored at WMT, it is not necessarily appropriate to use them for the evaluation of low-resource or lower-quality MT output without additional study.

6.3 Additional Discussion

We briefly mention two other items of note from our exploration of the data.

Outside of the set of data for which there are human annotations (i.e., not appearing in our figures), for HE→EN there are 14 news domain segments for which the ZengHuiMT system output an empty string. Different metrics handle this in

[3] This includes the baseline BLEU.

[4] Though we do not have extensive human evaluation, we are confident that, e.g., system E should not be ranked below system A.

[5] For EN→DE, in Figure 7, the Calibri-COMET22 metrics both find several of the highest performing systems from our challenge set to be better than several of the submitted systems, while most other metrics rank the challenge set systems below the submitted systems.

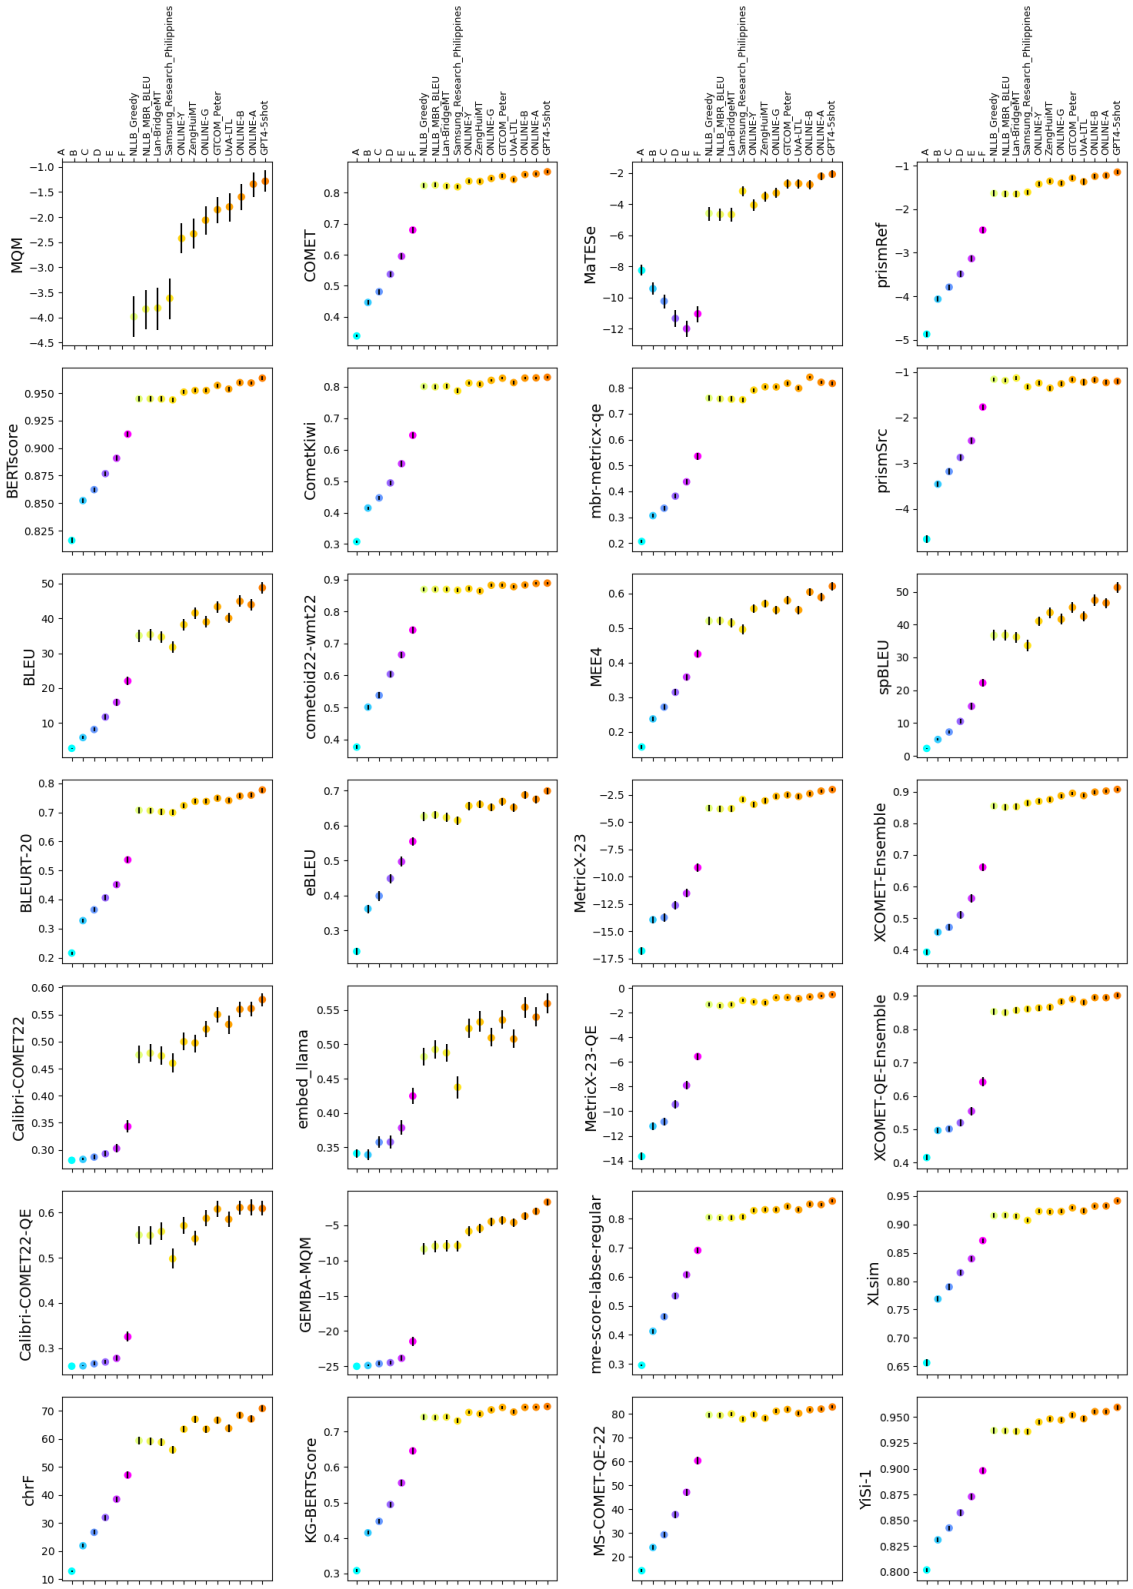

Figure 2: System average scores (with error bars computed via bootstrap resampling 1000 times for $p < 0.05$) for HE→EN across the challenge set (cool colours/left) and submitted WMT systems (warm colours/right). Our challenge set systems are ordered from left to right with BLEU scores, while the submitted WMT systems are ordered by MQM score on the news domain.

Metric	Score	Range
BERTscore	0.000	(0.000, 1.000)

Table 1: Average metric scores assigned to empty strings in the HE→EN news data, shown with the full range of metric scores assigned to the news data. Metrics with asterisks by their name did not assign the same scores to all the empty strings, though the differences were quite small.

different ways; some assign a score of 0 (or the metric's lower bound score), while others assigned relatively high scores due to the fact that the source and reference were very short (each source and reference consisted only of a single period). Table 1 shows the scores assigned by metrics to these empty strings as well as the range of scores over the full HE→EN news data (including segments that were not human-annotated, as the empty strings were also not included for human annotation).

We also observe two examples of systems that receive noticeably lower scores from a number of metrics than would be expected based on their human ranking: NLLB_Greedy (EN→DE, Figure 3) and Samsung_Research_Philippines (HE→EN, Figure 5). We leave this as an area for future investigation.

7 Conclusions

This challenge set expands the range of system quality scored by metrics at the shared task. This expanded range of MT quality reveals interesting characteristics and limitations of some new metrics when applied to a broader range of systems. The smaller variations in segment-level scores given by some metrics at the low end of quality could indicate that these metrics struggle to discriminate low-quality MT systems. This is further shown by the observation that some metrics rank the low-quality systems in reverse order at the system level. We have discovered a "universal score" phenomenon for some metrics, where a small subset of non-minimum/maximum distinct scores are assigned to a variety of translation output. This characteristic was not visible in the high-quality MT output alone, highlighting the importance of this type of testing. We also observe diverse behaviors from different metrics on empty string translation.

Our challenge set serves as a complement to the standard correlation-based analyses and also provides useful information to researchers who are considering using these metrics in low-resource or low-quality domains. We recommend that metric researchers check their metrics' performance on a wider landscape of translation quality or be clear about the limitations of their metrics' testing.

Limitations

A major limitation of this work is our choice to select low-quality systems on the basis of BLEU scores, which was done for reasons of time and cost. We attempted to mitigate this by spot-checking to confirm that we saw noticeable differences between various pairs of low-quality systems, but a more thorough human annotation would be beneficial. We are also limited in the set of languages we have explored, using only four language pairs, as well as the limited news domain.

Acknowledgements

We thank Adam Poliak for comments and feedback on a sample of the English–Hebrew dataset. We thank our colleagues and the anonymous reviewers for feedback and suggestions as well as the WMT Metrics Task and General Task organizers for providing data and annotations.

A Corpora Sizes

Corpora are from WMT23 (Kocmi et al., 2023) and WMT17 (Bojar et al., 2017a).

A.1 EN→DE

From the download table at EMNLP 2023: General Machine Translation, we retrieved all **EN→DE** corpora. The *train* corpus is composed of *airbaltic*, *czechtourism*, *ecb2017*, *EESC2017*, *EMA2016*, *rapid2016*, *europarl-v10*, *news-commentary-v18*, *WikiMatrix.v1.de-en.langid* and *wikititles-v3*. We chose *newstest2020* as our *validation*. Corpora statistics are described in Table 2.

Name	# lines	# de words	# en words
train	14,227,278	234,635,104	246,351,534
validation	1418	45,855	44,018

Table 2: Corpora sizes for EN→DE, computed on raw text (not tokenized) using `wc`.

A.2 HE↔EN

From the instructions of EMNLP 2023: General Machine Translation, we retrieved all **HE→EN** corpora.[6] Then, using *wmt23-heen/train.{heb,eng}* and *WikiMatrix.en-he*, we sampled sentence pairs for the *validation* and *test* sets and the remaining pairs were used for *train* making sure that all three are mutually exclusive. Corpora statistics are described in Table 3.

Name	# lines	# en words	# he words
train	2,227,830	38,307,579	30,943,929
validation	2000	20,459	16,620

Table 3: Corpora sizes for EN→HE, computed on raw text (not tokenized) using `wc`.

A.3 ZH→EN

We used corpora from WMT2017.[7] *train* is composed of all 20 *Books*, *casia2015*, *casict2015*, *casict-A*, *casict-B*, *datum*, *NEU*, *news-commentary-v18.en-zh*, *WikiMatrix.v1.en-zh.langid* and *wikititles-v3*. We chose *newstest2020* as our *validation*. Corpora statistics are described in Table 4.

Name	# lines	# en words	# zh words
train	12,995,613	218,659,998	43,676,661
validation	2000	65,561	3716

Table 4: Corpora sizes for ZH→EN, computed on raw text (not tokenized) using `wc`.

B Subword Segmentation

After some light normalization consisting of converting non-breaking hyphen, normalizing spaces, replacing control characters with spaces and collapsing multiple spaces,[8] we trained a 32k tokens, bilingual sentencepiece unigram subtokenizer using HuggingFace's tokenizers (Moi and Patry, 2022) for each language pair. The corpora used for training the subword model were:

- **EN→HE** uses all of *wmt23-heen/train.{eng,eng}*
- **EN→DE** uses our concatenated *train*
- **ZH→EN** uses our concatenated *train*

C System Descriptions

For all systems, we used Sockeye-3.1.31 (Hieber et al., 2022), commit `13c63be5` with PyTorch-1.12.1 (Paszke et al., 2019). Training was performed on 4 Tesla V100-SXM2-32GB GPUs for **EN→DE** and **ZH→EN** and 4 Tesla V100-SXM2-16GB GPUs for **EN→HE** and **HE→EN**. Training times are shown in Table 5.

Name	Time (h)
ende	6 - 35
enhe	10.3
heen	6.5
zhen	83.5

Table 5: Training times in hours.

Table 6 describes the differences with Sockeye's default parameters. Note that we kept all intermediate checkpoints (from which we later select the outputs used for the challenge set) and used the entire validation during checkpoint evaluation.

[6] `mtdata get-recipe -ri wmt23-heen -o wmt23-heen`

[7] https://www.statmt.org/wmt17/translation-task.html

[8] https://github.com/nrc-cnrc/PortageTextProcessing/blob/main/bin/clean-utf8-text.pl

Name	Value
amp	*True*
grading clipping type	*abs*
max sequence length	*200:200*
batch type	*max-word*
checkpoint interval	*10*
initial learning rate	*0.06325*
learning rate scheduler type	*inv-sqrt-decay*
learning rate warmup	*4000*
max checkpoints	*110*
max epochs	*1000*
max num checkpoint not improved	*32*
optimizer	*Adam*
optimizer Betas	*0.9, 0.98*
optimized metric	*BLEU*
update interval	*10*
attention heads	*16:16*
shared vocabulary	*True*
transformer FFN	*4096:4096*
transformer model size	*1024:1024*
weight tying	*True*

Table 6: Differences from Sockeye's default parameters.

On top of the changes from Table 6, for **EN→HE** and **HE→EN**, we lowered the **batch size** to *6144* and changed **max checkpoints** to *330*.

For all language pairs, we have trained a baseline system using the entire *train* corpus. Additionally, for **EN→DE**, we also trained systems that use a uniformly random subsample of *train* namely, 50k, 200k and 400k (the pseudo-low-resource systems).

D Pseudo-Low-Resource Corpora

Due to human error in the sampling code, the pseudo-low-resource training data used for the EN→DE systems trained on 50k, 200k, and 400k—intended to be a random sample from the full training data—instead primarily consists of data from the first four corpora shown in Table 7. Table 8 shows the small number of differences between these subsampled corpora and simply selecting the first n lines of the full training corpus. The main consequence of this is that these systems may be skewed towards particular domains.

E Checkpoints in Challenge Set

In Table 9 we see the checkpoint IDs for systems included in the challenge set for HE↔EN and ZH→EN. Table 10 shows the same for EN→DE. The corresponding BLEU scores are shown in Tables 11 and 12, respectively.

Corpus Name	# Sentences
airbaltic	839
czechtourism	6758
ecb2017	4147
EESC2017	2,857,850
EMA2016	347,631
rapid2016	1,030,808
europarl-v10	828,473
news-commentary-v18	203,744
WikiMatrix.v1	2,579,106
wikititles	1,474,203
total	14,227,278

Table 7: (EN→DE) Sub-corpora sizes in the order they were merged to create the final sampled *train*.

Sample Size	# Differences	# lines *EESC2017*
50k	282	38,256
200k	70	188,256
400k	34	388,256

Table 8: EN→DE; Number of sentences that are different from the original train's head and how many sentences from *EESC2017* that were used.

System	EN→HE	HE→EN	ZH→EN
A	68	58	61
B	98	87	91

F Metrics

Table 13 shows a summary of the human annotations and metrics included in this work and the translation directions they participated in. In the following, we briefly describe the key characteristic of each metric.

F.1 Baseline Metrics

BLEU (Papineni et al., 2002) is the (clipped) precision of word n-grams between the MT output and its reference weighted by a brevity penalty.

spBLEU (Team et al., 2022) is BLEU computed with subword tokenization done by the Flores-200 Sentencepiece Model (Kudo and Richardson, 2018).

chrF (Popović, 2015) uses character n-grams to compare the MT output with the reference and it is a balance of precision and recall.

BERTScore (Zhang et al., 2020) uses cosine similarity of contextual embeddings from pre-trained transformers to compute F-scores of sentence level similarity.

BLEURT-20 (Sellam et al., 2020) is fine-tuning RemBERT to predict direct assessment (DA; Graham et al., 2013, 2014, 2016) scores for a MT-reference pair.

COMET (COMET-22) (Rei et al., 2022) is an ensemble of two models: COMET-20 and a multitask model jointly predicting sentence-level multidimensional quality metrics (MQM) and word-level translation quality annotation, where COMET-20 is fine-tuning XLM-R to predict DA scores for a MT-source-reference tuple. **CometKiwi** is a quality estimation metric that is similar to COMET, except it scores the MT output against the source, instead of the reference translation.

MS-COMET-QE-22 (Kocmi et al., 2022) is a COMET-QE-20 based quality estimation metric trained on a larger and filtered set of human judgements, covering 113 languages and 15 domains.

prismRef (Thompson and Post, 2020) uses a neural paraphrase model to score the MT output against the reference translation. **prismSrc** is the quality estimation version, which scores the MT output against the source, instead of the reference translation.

YiSi-1 (Lo, 2019) measures the semantic similarity between the MT output and reference by the IDF-weighted cosine similarity of contextual embeddings extracted from pretrained language models, e.g. RoBERTa, CamemBERT, XLM-R, etc., depending on the target language in evaluation.

F.2 Primary submissions

Calibri-COMET22 uses isotonic regression on the COMET-22 output scores to predict the fraction of translations with no error produced by the MT system. **Calibri-COMET22-QE** is a quality estimation metric that is similar to Calibri-COMET22, where it uses COMETKiwi as base model.

cometoid22-wmt22 (Gowda et al., 2023) is a quality estimation metric that uses COMET-22 as a teacher metric and trains a student model to predict the teacher scores without using reference translation.

eBLEU (ElNokrashy and Kocmi, 2023) uses non-contextual word embeddings and relative meaning diffusion tensors to approximate the token similarity in the MT output and reference and computes translation quality scores similar to BLEU.

embed_llama (DREANO et al., 2023) is the

Table 13: Human annotation and metrics included in this work, with their coverage of language pairs. Metrics that are not marked as reference-based are reference-free (a.k.a quality estimation) metrics.

cosine similarity of the MT output and reference based on Llama 2 sentence embeddings.

GEMBA-MQM (Kocmi and Federmann, 2023) uses three-shot prompting on the GPT-4 model with a single prompt and no language specific example.

KG-BERTScore (Wu et al., 2023) is the linear combination of KGScore and COMET-QE based BERTScore, where KGScore is incorporating multilingual knowledge graph into BERTScore.

MaTESe (Perrella et al., 2022) trains Deberta (for English) and InfoXLM (for German and Russian) encoders to identify MQM error spans and severity using WMT22 Metrics shared task MQM data.

mbr-metricx-qe (Naskar et al., 2023) uses the underlying technique of minimum bayes risks (MBR) decoding to develop a quality estimation metric. It uses an evaluator machine translation system and a reference-based utility metric (specifically BLEURT and MetricX) to calculate a quality estimation score of a model.

MEE4 (Mukherjee and Shrivastava, 2023) is an unsupervised, reference-based metric that is a weighted combination of syntactic similarity based on a modified BLEU score, lexical, morphological and semantic similarity using unigram matching and contextual similarity with sentence similarity scores from multilingual BERT.

MetricX-23 (Juraska et al., 2023) is a regression metric that finetunes the mT5-XXL checkpoint using direct assessment data from 2015-2020 and MQM data from 2020 to 2021 as well as synthetic data. **MetricX-23-QE** is the quality estimation variant that uses the source, instead of the reference, for scoring.

mre-labse-regular (Viskov et al., 2023) is a trained metric that is based on the encoder part of mT0-large model and contextual embeddings from LaBSE. It concatenates the source, reference and MT output as input.

XCOMET-Ensemble (Guerreiro et al., 2023) is an ensemble of a XCOMET-XL and two XCOMET-XXL checkpoints that result from the different training stages. XCOMET is similar to COMET but is trained for both regression and sequence tagging for identifying MQM error spans, where the intent is to make it a more interpretable learnt metric. **XCOMET-QE-Ensemble** is the quality estimation version.

XLsim (Mukherjee and Shrivastava, 2023) is a supervised reference-based metric that regresses on human scores provided by WMT (2017-2022) based on XLM-RoBERTa using a Siamese network architecture with CosineSimilarityLoss.

G Additional Figures

Here we show additional figures, including the full set of histograms for EN→DE (Figure 3), EN→HE (Figure 4), HE→EN (Figure 5) and ZH→EN (Figure 6) as well as the system scores for EN→DE (Figure 7), EN→HE (Figure 8), and ZH→EN (Figure 9).

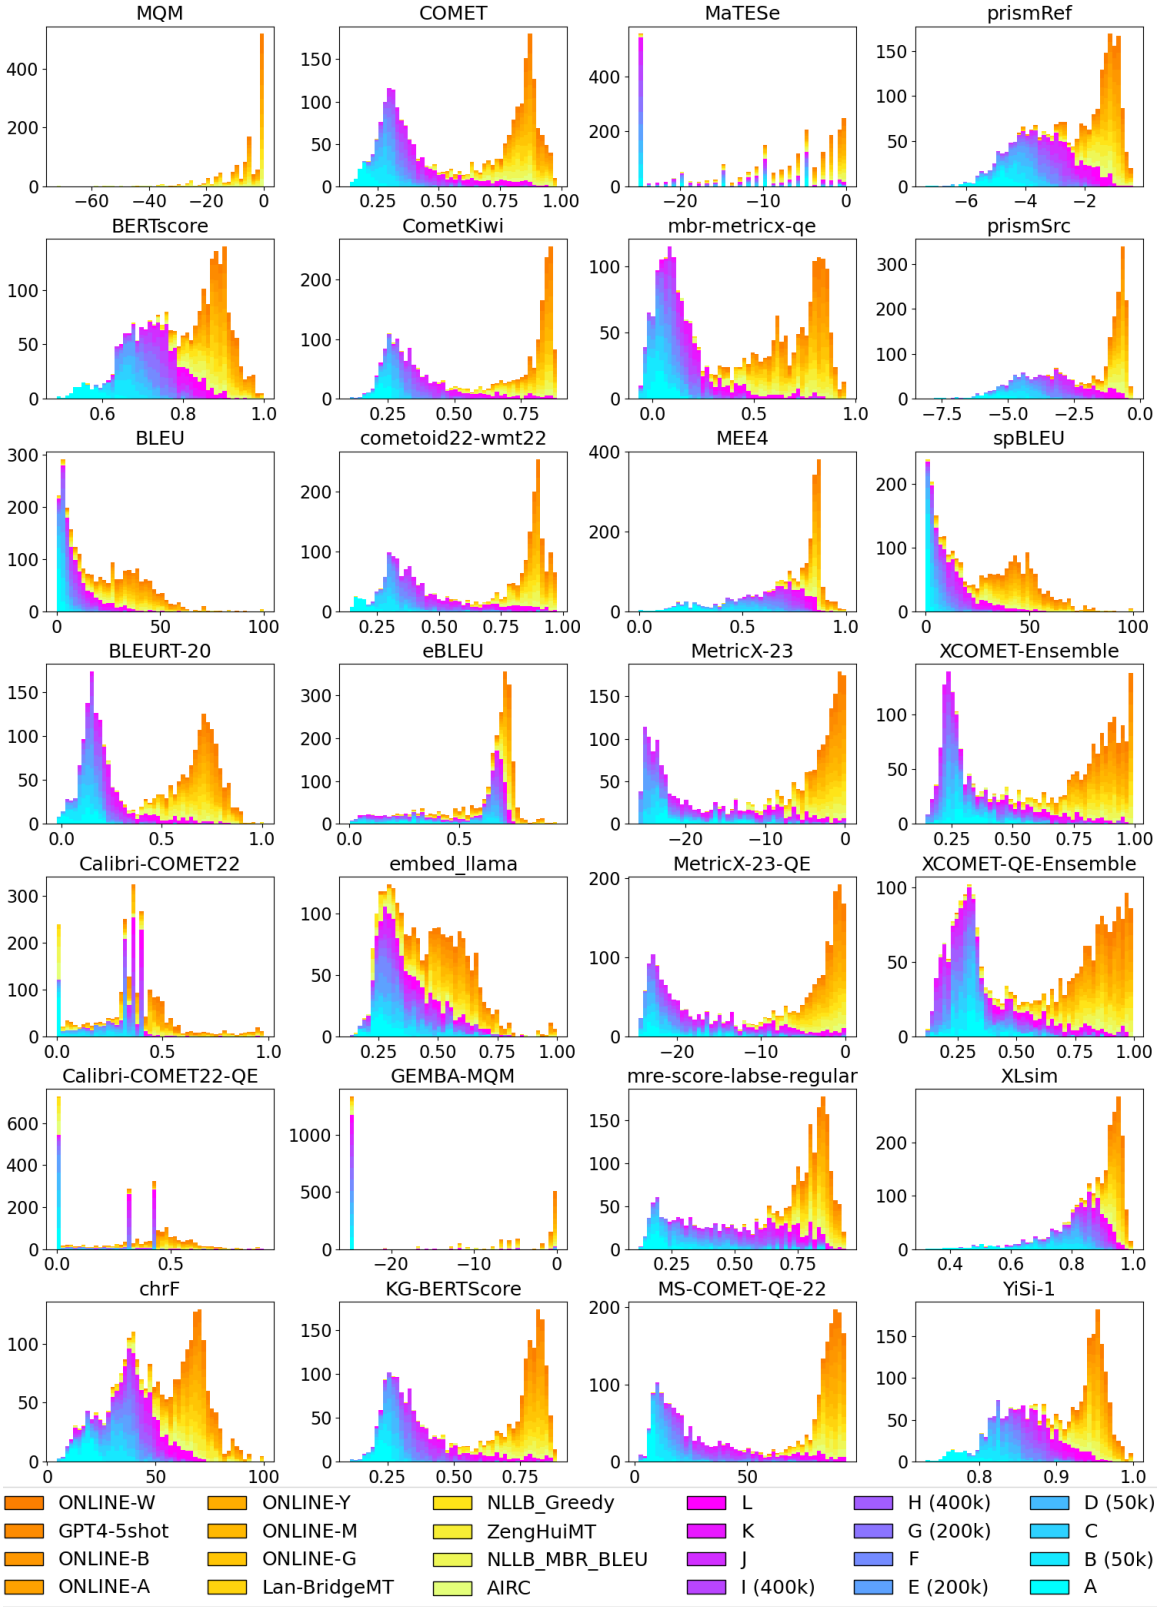

Figure 3: Stacked histograms (one subplot per metric) of segment scores for EN→DE across the challenge set (cool colours/bottom of the stacked histograms) and submitted WMT systems (warm colours/top of the stacked histograms).

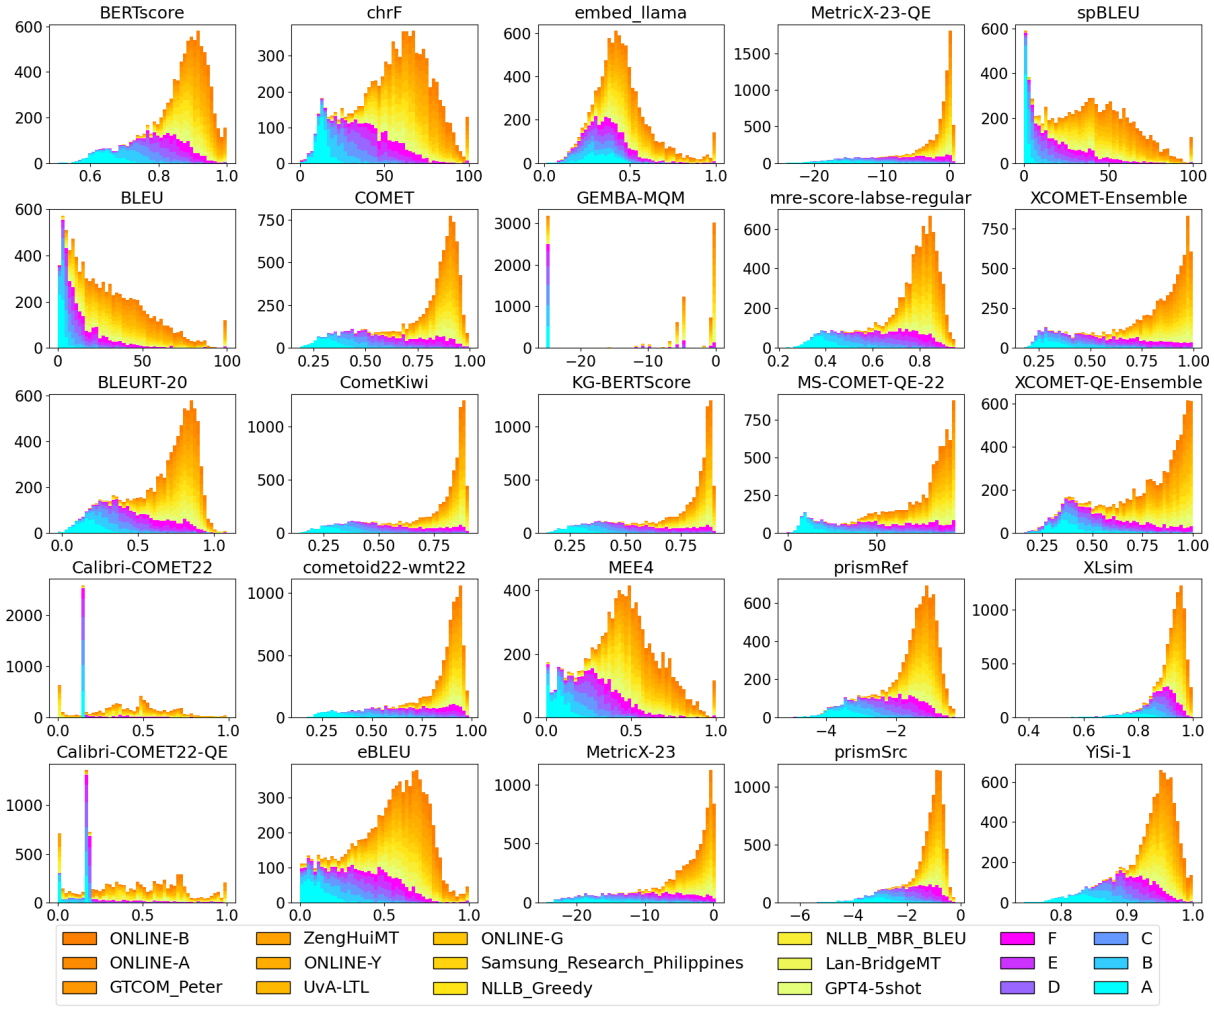

Figure 4: Stacked histograms of segment scores for EN→HE across the challenge set (cool colours/bottom) and submitted WMT systems (warm colours/top).

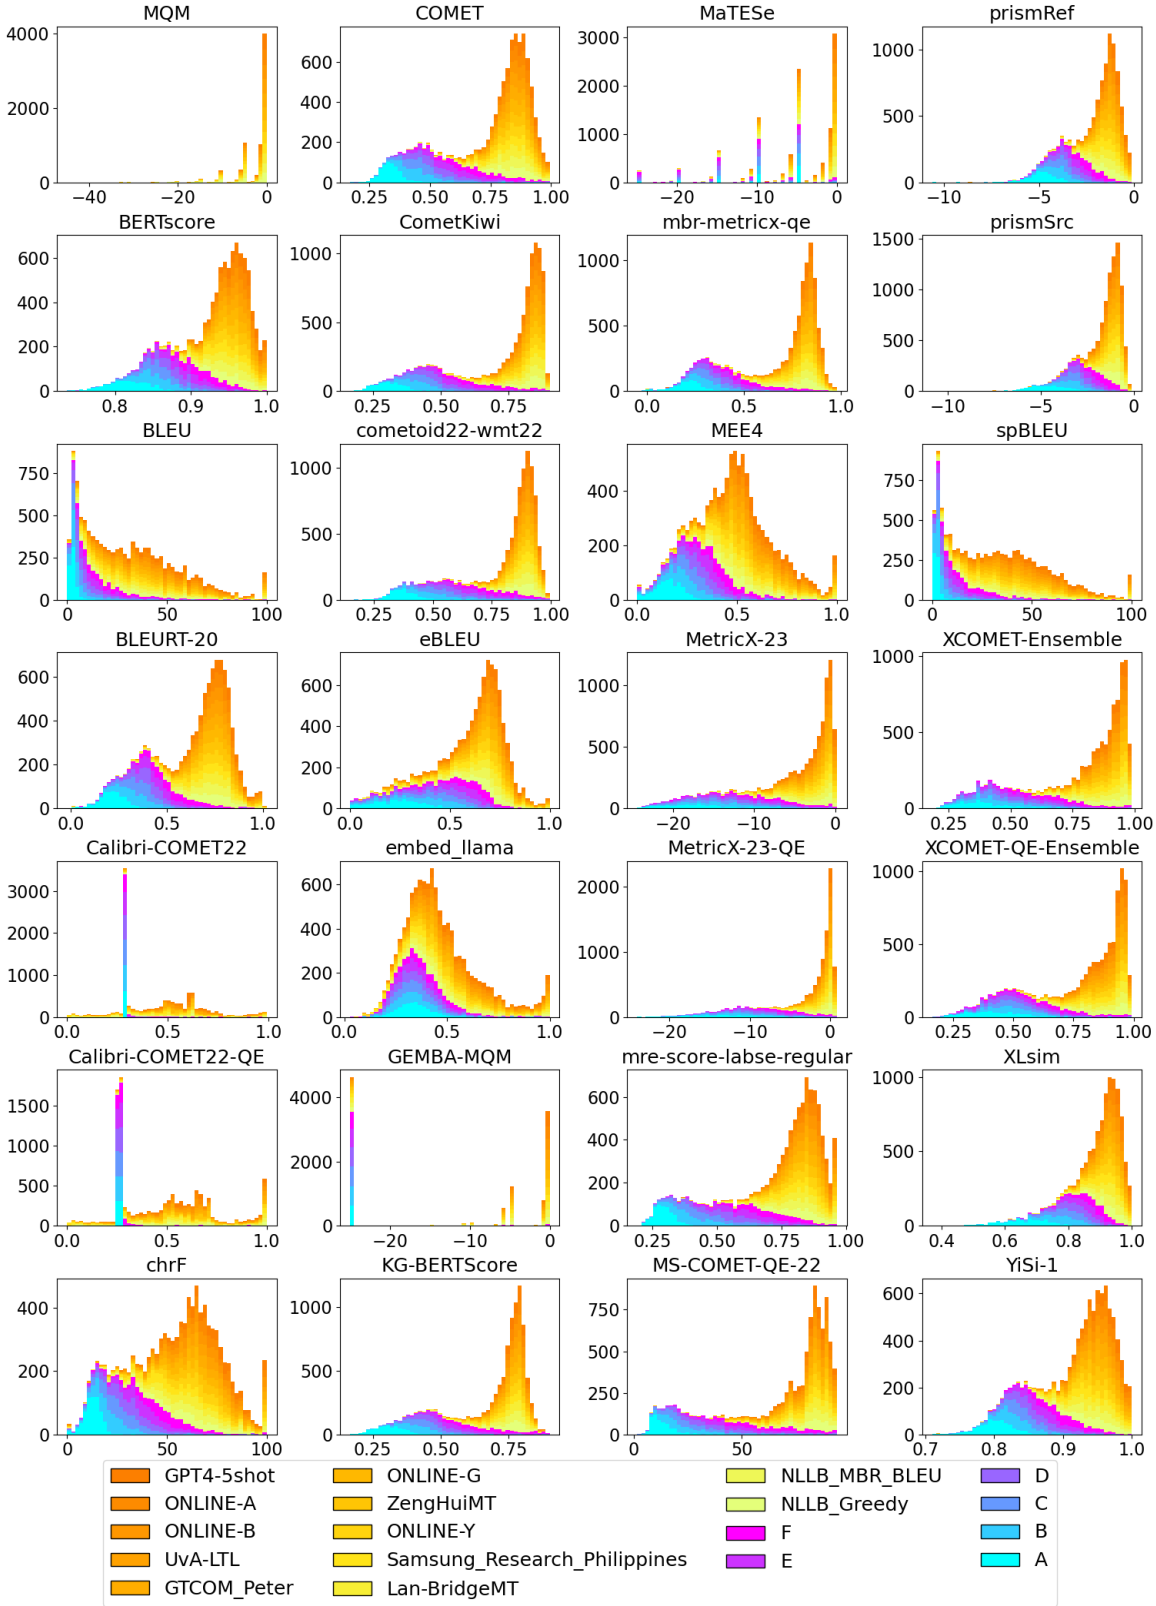

Figure 5: Stacked histograms of segment scores for HE→EN across the challenge set (cool colours/bottom) and submitted WMT systems (warm colours/top).

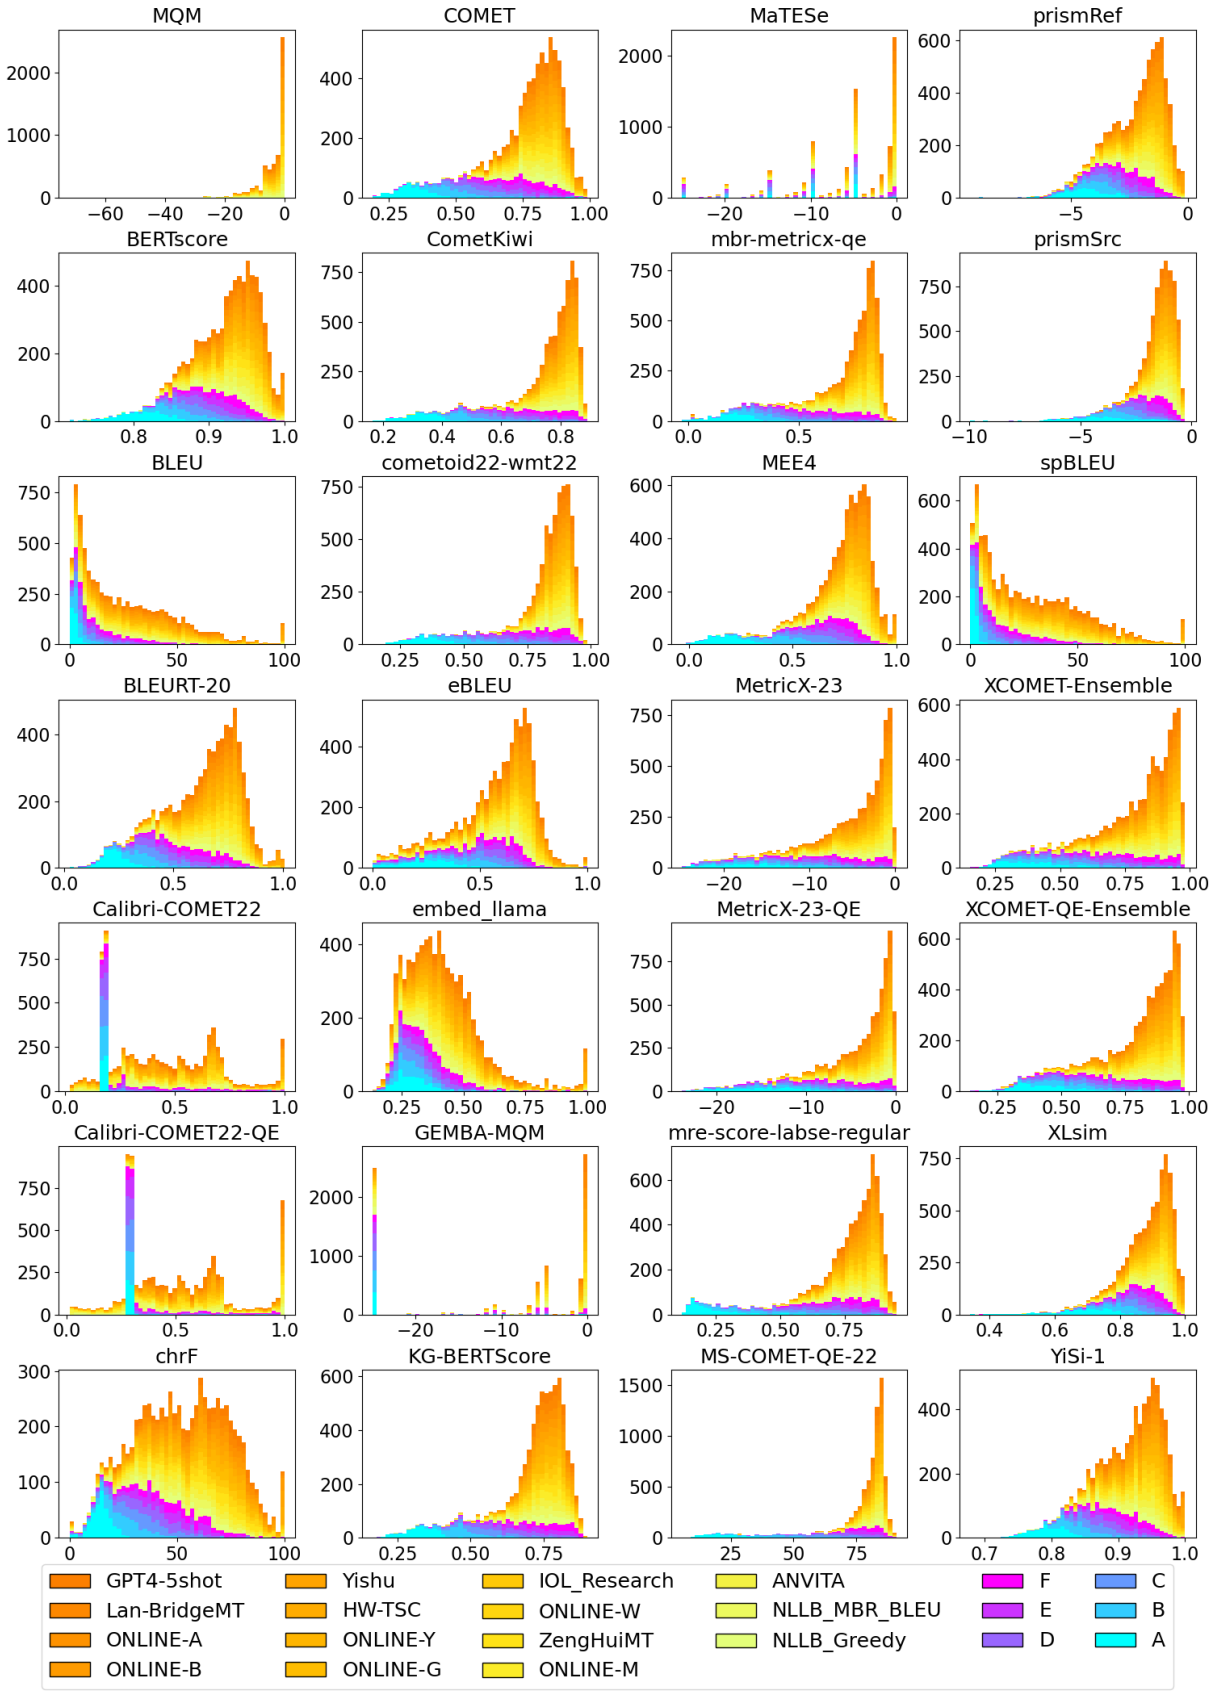

Figure 6: Stacked histograms of segment scores for ZH→EN across the challenge set (cool colours/bottom) and submitted WMT systems (warm colours/top).

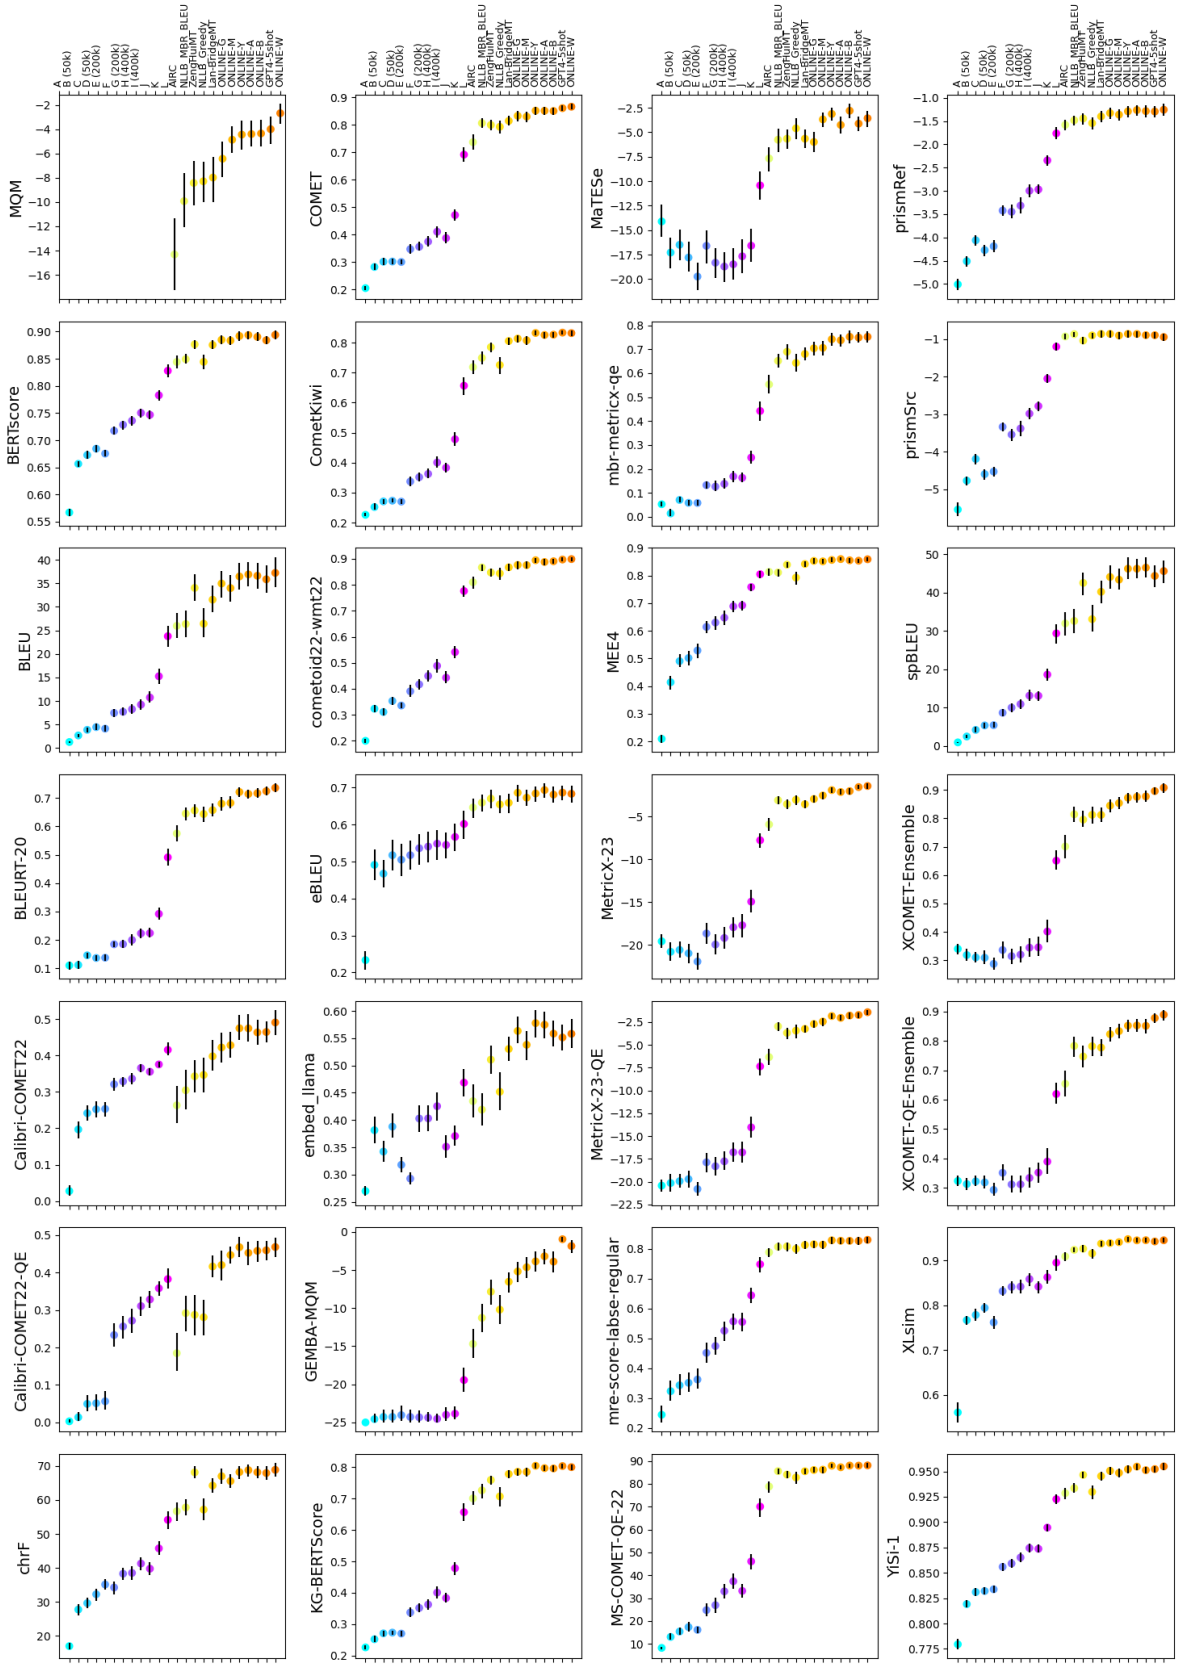

Figure 7: System average scores (with error bars computed via bootstrap resampling 1000 times for $p < 0.05$) for EN→DE across the challenge set (cool colours/left) and submitted WMT systems (warm colours/right). Our challenge set systems are ordered from left to right with BLEU scores, while the submitted WMT systems are ordered by MQM score on the news domain.

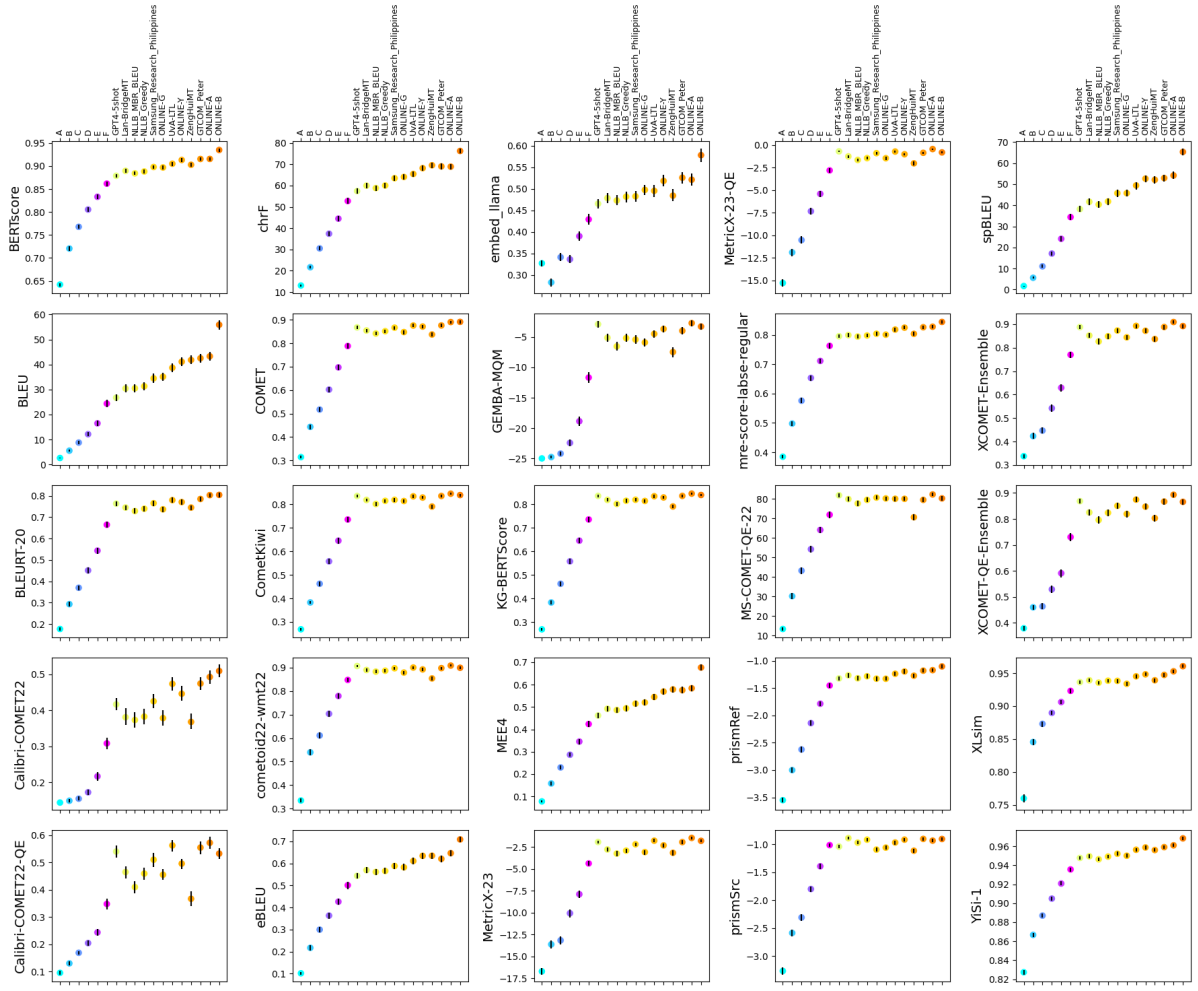

Figure 8: System average scores (with error bars computed via bootstrap resampling 1000 times for $p < 0.05$) for EN→HE across the challenge set (cool colours/left) and submitted WMT systems (warm colours/right). All systems are ordered from left to right by BLEU scores (as direct assessment scores were not yet available for EN→HE).

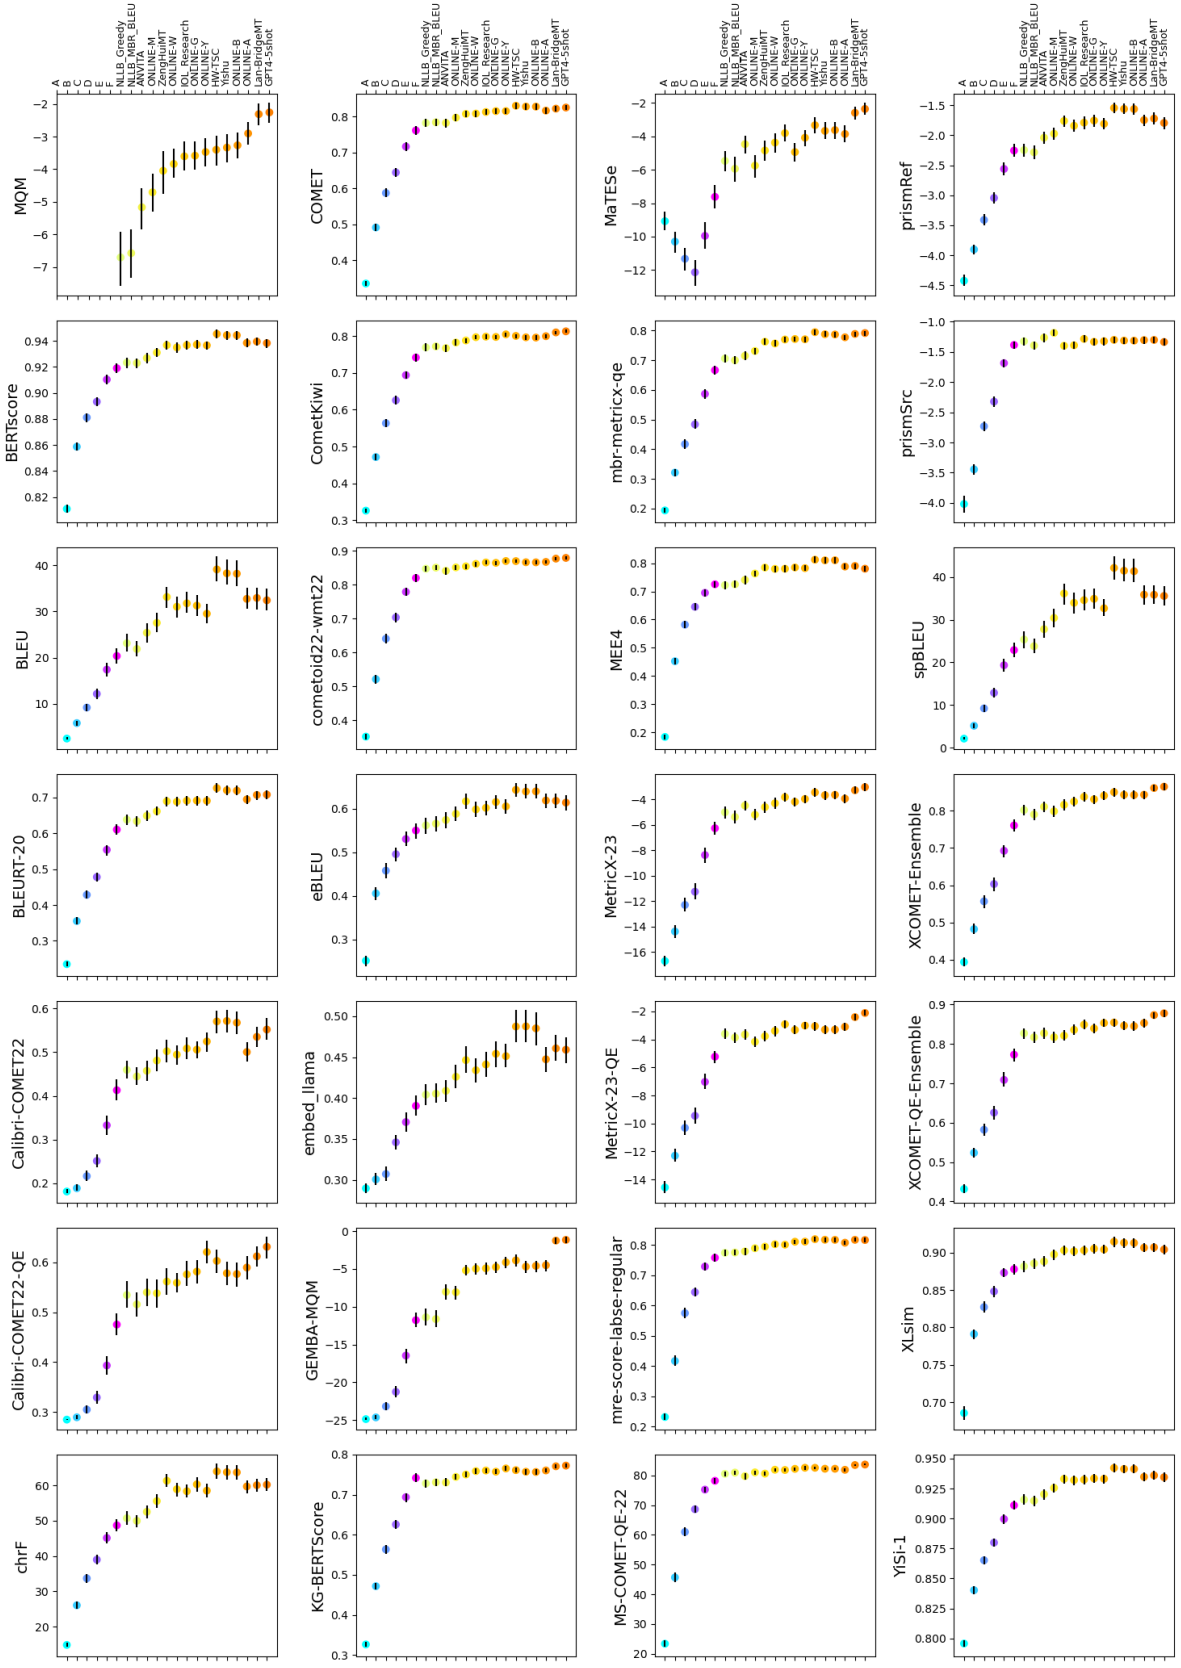

Figure 9: System average scores (with error bars computed via bootstrap resampling 1000 times for $p < 0.05$) for ZH→EN across the challenge set (cool colours/left) and submitted WMT systems (warm colours/right). Our challenge set systems are ordered from left to right with BLEU scores, while the submitted WMT systems are ordered by MQM score on the news domain.

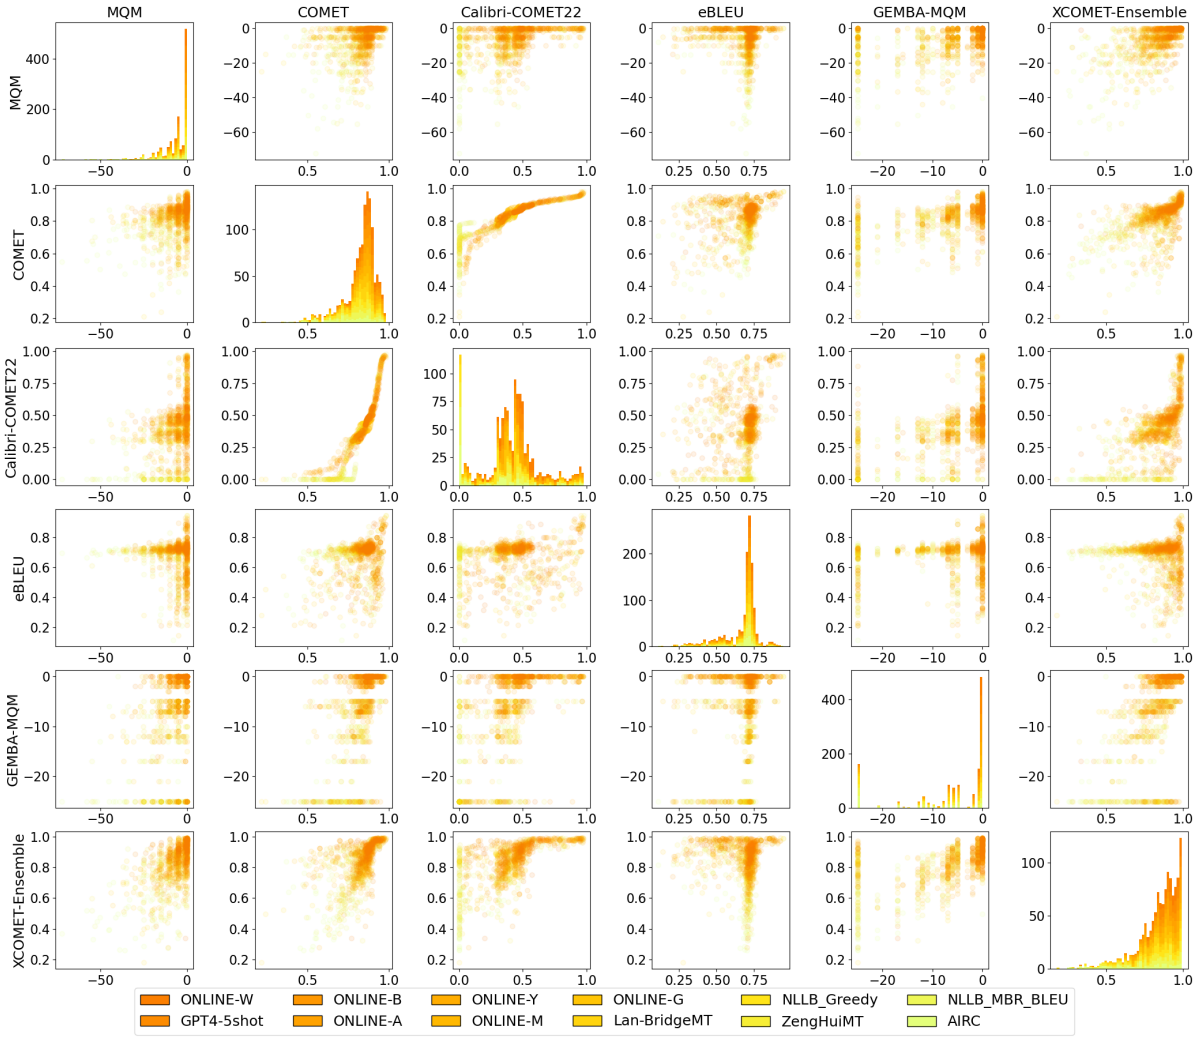

Figure 10: A subset of the metrics (and MQM scores) for EN→DE, showing only the high-quality WMT MT system submissions. The diagonal entries show stacked histograms of segment scores. The off-diagonal entries are scatterplots where each point is a single segment positioned according to the score assigned to it by row and column metrics; each point is coloured according to the MT system that produced it.

MEE4 and XLsim : IIIT HYD's Submissions' for WMT23 Metrics Shared Task

Abstract

This paper presents our contributions to the WMT2023 shared metrics task, consisting of two distinct evaluation approaches: a) **Unsupervised Metric** (MEE4) and b) **Supervised Metric** (XLSim). MEE4 represents an unsupervised, reference-based assessment metric that quantifies linguistic features, encompassing lexical, syntactic, semantic, morphological, and contextual similarities, leveraging embeddings. In contrast, XLsim is a supervised reference-based evaluation metric, employing a Siamese Architecture, which regresses on Direct Assessments (DA) from previous WMT News Translation shared tasks from 2017-2022. XLsim is trained using XLM-RoBERTa (base) on English-German reference and mt pairs with human scores. Here are the links for MEE4 [1] and XLsim[2] metrics.

1 Introduction

In recent times, there has been a growing interest in Neural Machine Translation (NMT) systems, leading to significant improvements in machine translation (MT) quality. Over the past few years, the field of MT evaluation has seen substantial advancements. Each year, the WMT conference hosts a metrics-shared task, where new evaluation metrics are introduced and those demonstrating a strong correlation with human judgments are highlighted from the array of newly devised metrics. In the last three years of the WMT Metrics Task (Freitag et al., 2022, 2021; Mathur et al., 2020), neural-based metrics have predominantly taken the lead. Nevertheless, n-gram-based and lexical-based metrics (Papineni et al., 2002; Popović, 2015) continue to be favored as automatic MT evaluation tools due to their flexibility and efficiency.

As a result, this year we participated in the metrics shared task, evaluating machine translation outputs using two types of metrics: an unsupervised metric and a supervised metric.

Unsupervised Metric: Our unsupervised metric, MEE4 (Mukherjee and Shrivastava, 2022), relies on a combination of lexical and embedding similarity measures. Notably, MEE4 demonstrated strong performance in the previous year's shared task (Freitag et al., 2022), surpassing several baseline metrics such as BERTscore (Zhang* et al., 2020), BLEU (Papineni et al., 2002), F101SPBLEU (Goyal et al., 2022) , and CHRf (Popović, 2015). In our efforts to improve its performance further this year, we conducted experiments with two different sentence embedding models: LaBSE (Feng et al., 2022) and the stsb-xlm-r-multilingual [3]. Interestingly, our findings indicated that MEE4, when equipped with LaBSE as the sentence embedding model, exhibited superior performance compared to the alternatives.

Supervised Metric: Unlike the existing neural models which are huge in size, our goal was to build a more compact supervised training model (XLsim) that offers improved performance. To achieve this, we created a SentenceTransformer model by combining a pre-trained transformer model with a pooling layer. This hybrid approach enables the generation of sentence embeddings, which can be compared using cosine similarity to assess similarity between sentences.

2 MEE4

MEE4 is an improved version of MEE focusing on computing contextual and syntactic equivalences, along with lexical, morphological, and semantic similarity. The goal is to comprehensively evaluate the fluency and adequacy of MT outputs while also considering the surrounding context. Fluency is determined by analyzing syntactic correlations, while context is evaluated by comparing sentence

December 6–7, 2023.

similarities using sentence embeddings. The ultimate score is derived from a weighted amalgamation of three distinct similarity measures: a) Syntactic similarity, which is established using a modified BLEU score. b) Lexical, morphological, and semantic similarity, quantified through explicit unigram matching. c) Contextual similarity, gauged by sentence similarity scores obtained from the Language-Agnostic BERT model (Feng et al., 2022).

In our experiments this year, we made adjustments to MEE4 while maintaining the same underlying architecture. Specifically, we computed the evaluation scores using a different sentence embedding model.

In addition to our previous choice, we utilized the stsb-xlm-r-multilingual model. This particular sentence-transformers model is designed to map sentences and paragraphs into a 768-dimensional dense vector space, making it suitable for various tasks such as clustering and semantic search. It's worth highlighting that the version of XLM-R (Conneau et al., 2020) we employed is considered a state-of-the-art model for multilingual Semantic Textual Similarity (STS) (Reimers and Gurevych, 2020).

2.1 Multilingual Sentence Encoders

Numerous multilingual sentence encoders, including mBERT (Devlin et al., 2018), consist of single self-attention networks. These models are pretrained on monolingual corpora in over 100 languages and are optimized for masked language modeling. Here, the model is tasked with predicting randomly selected tokens in the original text that have been replaced by a placeholder.

However, these pretrained multilingual sentence encoders often exhibit limited sensitivity to cross-language semantic similarity. To address this issue, Reimers and Gurevych employed human Semantic Textual Similarity (STS) annotations to enhance a pretrained multilingual sentence encoder, specifically BERT resulting in *stsb-xlm-r-multilingual* model .

In contrast, LaBSE differs slightly as it has been trained not only for masked language modeling but also for translation language modeling.

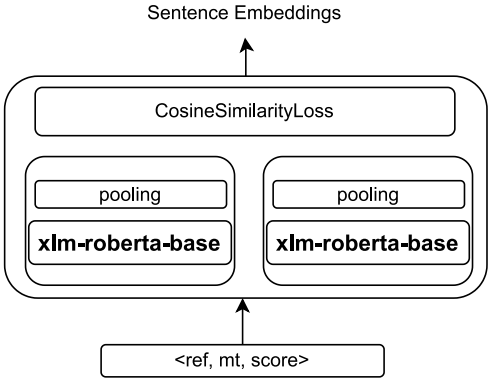

Figure 1: Illustration of our methodology using siamese network architecture
En: English IL- Indian Langauge

3 XLSim: MT Evaluation Metric based on Siamese Architecture

XLsim is a supervised reference-based metric that regresses on human scores provided by WMT (2017-2022). Using a cross-lingual language model XLM-RoBERTa-base[4] (Conneau et al., 2020), we train a supervised model using a Siamese network architecture with CosineSimilarityLoss.

3.1 Training Data

The WMT DA human evaluation data[5] (WMT17-WMT22) (Kocmi et al., 2022; Akhbardeh et al., 2021; Barrault et al., 2020, 2019; Bojar et al., 2018, 2017) contains raw score and z-score; we considered z-score for our training purpose by normalizing it to a range of 0-1.

3.2 Siamese Network Architecture

Similar to SBERT, we train the network with a Siamese Network Architecture (Reimers and Gurevych, 2019). In this siamese network, for each sentence pair, we pass *reference translation (ref)* and *hypothesis translation (mt)* through our network which yields the embeddings u und v. The similarity of these embeddings is computed using cosine similarity and the result is compared to the gold similarity score *(score)*. This allows our network to be fine-tuned and recognize sentence similarity. Figure 1 illustrates our XLsim training architecture.

While training, we used **CosineSimilarityLoss**, which automatically ensures training in a siamese network structure.

ref	I believe that financially, automakers are doing very well now, maintaining high sales margins.
mt	I believe car manufacturers are feeling very good financially right now, maintaining high sales margins.
score	0.77

Table 1: Input Example

3.3 CosineSimilarityLoss

CosineSimilarityLoss expects that the input consist of two texts and a float label. Refer Table 1.

It computes the vectors $u = model(input[0])$ and $v = model(input[1])$ and measures the cosine-similarity between the two. By default, it minimizes mean squared error loss.

3.4 Training Details

In our experiment, we focused on the en-de[6] language pair and utilized specific columns from the wmt-da-human-evaluation dataset, which included translation (mt), reference translation (ref), and z-score (score). Among the total 125,992 en-de samples available, we partitioned them as follows: 105,992 samples were used for training, 10,000 for validation, and another 10,000 for testing.

We employed a SentenceTransformer architecture to train our model, leveraging a multilingual pre-trained transformer model, XLM-RoBERTA base model. XLM-RoBERTa (Conneau et al., 2020) model is pre-trained on 2.5TB of filtered CommonCrawl data containing 100 languages.

We utilized the CosineSimilarityLoss function for a total of 4 training epochs. Our training setup involved a batch size 16, employing the Adam optimizer with a learning rate 2e-5 and a linear learning rate warm-up strategy over 10% of the training data. The entire training process was carried out on NVIDIA GPUs, specifically T4 x2.

3.5 Inference

To assess translation quality based on reference, our trained model generates embeddings for reference and translation sentences and subsequently calculates the cosine similarity between these embeddings. This similarity measure serves as a metric for evaluating the quality and similarity between the translation and reference text (refer figure 2).

[6]we chose the language-pair having a more significant number of samples than other language-pairs.

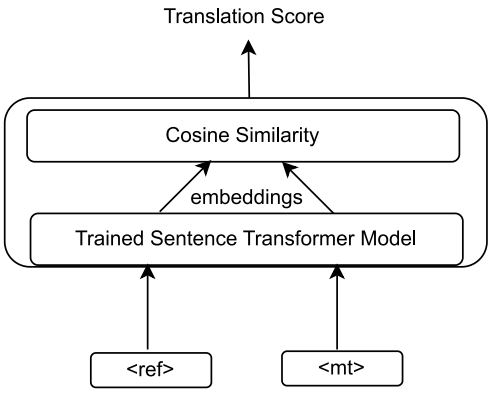

Figure 2: XLsim architecture at inference (to compute segment-level scores)

Model	COMET	XLsim
Size	2.32 GB	1.1 GB
Training Samples#	1,027,155	105,992
Pearson correlation	0.68	0.52

Table 2: Comparison with the SOTA neural metric based on Pearson Correlation with human scores.

Table 2 reports the comparison of our trained metric with the existing state-of-the-art metric, COMET (Rei et al., 2022) in terms of model size, total training samples and pearson correlation on the 10000 en-de samples (test samples see 3.4). It is worth noticing that the difference in correlation is 0.16 which is minute and model is 50% lesser in size.

4 WMT23 Metric Shared Task Submission

4.1 Segment Level Evaluation

For Segment-level task, we submitted the sentence-level scores obtained by our reference-based unsupervised metrics namely MEE4 (primary metric) and MEE4_stsb_xlm.

For the same Segment-level task, we also submitted the sentence-level scores obtained by our reference-based supervised evaluation metric (XLsim).

4.2 System Level Evaluation

To calculate the system-level score for each system, we take the average of the segment-level scores that we've derived. We employ a similar approach when computing system-level scores based on segment-level human annotations, such as DA's and MQM.

testset	lp	#sentences	XLsim	MEE4	MEE4_stsb_xlm
generaltest2023	en-de	6684	**0.67**	0.64	0.47
	zh-en	29640	0.68	**0.74**	0.59
	he-en	22920	0.76	**0.78**	0.62
challengeset	en-de	33470	**0.73**	0.71	0.64
	zh-en	6996	0.86	**0.91**	0.89
	he-en	9466	0.80	**0.86**	0.85

Table 3: Pearson correlation of evaluated scores on WMT23 submissions with COMET metric.

This suggests that a metric with a strong correlation at the segment level should also exhibit a robust correlation at the system level.

4.3 Results

Table 3 provides the details of the WMT23 Metric Shared Task test-set for the language pairs we investigated. However, it's important to note that the final and most comprehensive analysis will rely on the official results, where metric submissions are thoroughly compared to human judgments.

In our preliminary assessment, we have reported Pearson correlation scores for the submitted metrics when compared to COMET at the segment-level. This analysis helps us gauge the performance of the three metrics in relation to the state-of-the-art metric. In case of Unsupervised metrics, it appears that MEE4, which utilizes LaBSE, outperforms MEE4_stsb_xlm, which employs stsb-xlm-r-multilingual as its sentence embedding model. This difference in performance may be attributed to the training techniques applied to LaBSE, which involve both masked language modeling and translation language modeling, making it more effective for the task. Indeed, it's evident that XLsim exhibits a relatively strong correlation with COMET, almost exceeding 0.7. However, when compared to MEE4, there is a mild decrease in performance, particularly in the zh-en (Chinese to English) and he-en (Hebrew to English) language pairs, where the correlation drops by approximately 0.06.

This slight decline in performance for XLsim in certain language pairs could be attributed to the fact that even though XLsim utilizes the pre-trained multilingual XLM-Roberta model, the training data (ref, mt) was primarily in the German (de) language.

5 Conclusion and Future Work

In this paper, we describe our submissions to the WMT23 Metrics Shared Task. Our submission includes segment-level and system-level translation evaluation scores for sentences of three language pairs English-German (en-de), Chinese-English (zh-en) and Hebrew to English (he-en). We evaluate this year's test set using: a)two unsupervised metrics, *MEE4 and MEE4_stsb_xlm*. These metrics are based on lexical and embedding similarity match that evaluates the translation on various linguistic features (syntax,lexical, morphology, semantics and context) ; b) a supervised metric, XLsim that learns on en-de WMT DA human evaluation data from 2017-2022. It is observed that all the three metrics displayed a positive correlation (>0.5) with the baseline metric COMET.

Certainly, there are promising research directions to explore, especially in the realm of metric enhancement. In our future work, we intend to delve deeper into these areas:

MEE4 Metric Improvement: One of our primary objectives is to refine and enhance MEE4, seeking more efficient approaches that can better estimate translation quality while achieving higher agreement with human judgments. This might involve exploring novel techniques in sentence embedding, fine-tuning, or leveraging additional linguistic information.

XLsim Enhancement: For XLsim, we plan to boost its performance by optimizing the training data. This involves ensuring that it is trained on a more diverse set of languages and data to improve its cross-lingual capabilities. Simultaneously, we aim to maintain its compactness and ensure it remains trainable with fewer computational requirements.

These future research directions hold the potential to contribute significantly to the field of machine translation evaluation, ultimately leading to more robust and accurate metrics that align closely with human assessments.

Quality Estimation using Minimum Bayes Risk

Subhajit Naskar, Daniel Deutsch, and Markus Freitag
Google
{snaskar,dandeutsch,freitag}@google.com

Abstract

This report describes the Minimum Bayes Risk Quality Estimation (MBR-QE) submission to the Workshop on Machine Translation's 2023 Metrics Shared Task. MBR decoding with neural utility metrics like BLEURT is known to be effective in generating high quality machine translations. We use the underlying technique of MBR decoding and develop an MBR based reference-free (quality estimation) metric. Our method uses an evaluator machine translation system and a reference-based utility metric (specifically BLEURT and MetricX) to calculate a quality estimation score of a model's output. We report results related to comparing different MBR configurations and utility metrics.

1 Introduction

The task of quality estimation (QE) is to assign a sentence- or word-level quality score to a machine translation (MT) output without the use of a reference translation. In this paper, we describe the methodology used in our sentence-level QE metric submission to the 2023 Workshop on Machine Translation's Metrics Shared Task.

Minimum Bayes Risk (MBR) decoding has been widely used in machine translation to address the limitation of MAP decoding (Kumar and Byrne, 2004; Eikema and Aziz, 2020; Müller and Sennrich, 2021). Freitag et al. (2021b) showed applying MBR decoding using BLEURT (Sellam et al., 2020) as a utility function can out-perform beam search decoding.

MBR decoding can be viewed as a method for reranking candidate outputs from an MT system. It first samples a set of hypothesis translations from the model, scores each hypothesis against a set of pseudo-references (generally, the same set of sample hypotheses) with a utility metric, then selects the hypothesis with the highest average score to be the final translation.

Central to MBR is assigning a quality score to a hypothesis translation without the use of a reference. Because this decoding procedure has been successful in improving the quality of translations from an MT system, in this work, we explore how MBR could be repurposed as a QE metric.

Our proposed metric uses an MT system in conjunction with a utility metric to assign a quality score to a translation without using a reference. The metric assigns a score to a hypothesis translation by using the utility metric to evaluate the hypothesis against a set of pseudo-references that are sampled from the MT model.

In this work, we experiment with creating a metric that uses different MT systems, utility functions, and different pseudo-reference pool sizes. Our experiments demonstrate that (1) a better utility function results in better MBR-QE scores, (2) the choice of MT system can have significant impact on QE metric performance, and (3) the size of the pseudo-reference pool does not have a significant impact on overall metric quality.

Based on our experiments, we chose our primary MBR-QE submission to be an in-house encoder-decoder model with MetricX (Freitag et al., 2022) as the utility function with a pseudo-reference pool size of 256.

2 Metric Descriptions

MBR decoding has two components: an MT system and a utility function. The MT model $P_{model}(y|x)$ estimates the probability of target segments y given a source segment x. The utility function estimates the quality of a translation h given a reference translation r. The best hypothesis is selected using the expected utility with respect to a finite sample generated by the model. The underlying assumption is that the model provides good approximation for the true distribution of human translations.

We adopt that assumption to develop an MBR-

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 806–811
December 6–7, 2023.

based quality estimation metric. The MBR-QE metric uses an MT system P to generate the set of pseudo-references, denoted $\hat{R}$. Then, the utility function defines the quality of a translation h given $\hat{R}$ as the average score over all of $\hat{R}$:

$$\text{MBR-QE}(h) = \frac{1}{|\hat{R}|} \sum_{\hat{r} \epsilon \hat{R}} u(h, \hat{r}) \quad (1)$$

This methodology has multiple potential pitfalls. First, because the distribution P is used to substitute for the distribution of human translations, any significant divergence between these two distributions will lead to the QE score becoming inconsistent because the pool of pseudo-references will not resemble human references. This can be mitigated by using a high quality MT system. Arguably, the MT system should have better performance compared to the MT models that are being evaluated.

Second, our QE metric is dependent on the quality of the utility function. If it has limitations or biases, they will affect the predicted quality scores and introduce inconsistencies between the QE score and ground-truth human quality scores.

We next discuss the experimental setup for analyzing our proposed QE metric.

3 Experimental Setup

3.1 Pseudo-Reference Generation

Our MBR-QE metric relies on the assumption that if the MT system that generates the pseudo-references can be used as an approximation for the distribution of human translations, then the aggregated utility metric score can be used a quality estimate for hypothesis. Therefore, the MT model and method for generating pseudo-references is critical for the effectiveness of this metric.

MT Systems. The MT system used for our shared task submission is an in-house encoder-decoder translation model that is similar to the Google Translate production model. In this report, we also experiment with generating pseudo-references from the PaLM 2 (Bison) large language model (Anil et al., 2023) using 5-shot prompting.

Sampling Method. We generate pseudo-references from the MT system using epsilon sampling (Hewitt et al., 2022; Freitag et al., 2023) with $p = 0.02$ and sampling temperature 1.0. We experiment with using a different number of pseudo-references.

3.2 Utility Functions

Freitag et al. (2021b) showed that MBR decoding works well with neural evaluation metrics. We experiment with 2 neural metrics as the utility function in MBR-QE.

BLEURT v0.2 (Sellam et al., 2020; Pu et al., 2021): BLEURT v0.2 is a learned regression-based metric that is trained to predict the quality of a translation given a reference. It is pre-initialized with RemBERT (Chung et al., 2020) and finetuned using a combination of WMT human evaluation data from 2015-2019 and synthetic data.

MetricX (Freitag et al., 2022): MetricX is a learned regression-based metric that is based on mT5 (Xue et al., 2021). It is trained on a combination of direct assessment and MQM (Lommel et al., 2014; Freitag et al., 2021a) data that was collected by WMT. We use the reference-based version that uses mT5-XXL.

3.3 Meta-Evaluation

We use four different correlations to calculate the metrics' agreements with human judgments. At the system-level, we use pairwise accuracy (Kocmi et al., 2021) and Pearson's r. System-level Pearson's r captures how strong the linear relationship is between the metric and human scores for MT systems. Pairwise accuracy evaluates a metric's ranking of MT systems by calculating the proportion of all possible pairs of MT systems that are ranked the same by the metric and human scores.

At the segment-level, we use group-by-item pairwise accuracy with tie calibration (Deutsch et al., 2023) and no-grouping Pearson's r. The no-grouping Pearson's r calculates the linear relationship between the metric and human scores across translations from every system and document. The group-by-item pairwise accuracy calculates the proportion of all possible pairs of translations for the same input segment that are ranked the same or tied by the metric and human. Then the accuracy scores are averaged over all possible input segments. We use tie calibration (Deutsch et al., 2023) that automatically introduces ties into metric scores based on a threshold. This tie calibration is required as regression-based metrics rarely predict ties.

Our experiments are performed using the WMT'22 English-to-German (en-de) and Chinese-to-English (zh-en) MQM ratings (Freitag et al., 2022). These datasets are commonly used for meta-

evaluation and are the latest available from the Metrics Shared Task. We did not evaluate using en-ru since it is not included as a language pair in the WMT'23 evaluation.

4 Experimental Results

The main experimental results are shown in Tables 1 and 2. Table 1 compares the two utility functions with various pseudo-reference pool sizes when using the in-house MT system, and Table 2 does the same but for the PaLM 2-based system.

Comparing Utility Functions. For both MT systems and all pseudo-reference pool sizes, the MBR-QE metric that uses MetricX as a utility function in general has higher correlations than when BLEURT is used. This result is expected since MetricX was the best performing metric in the WMT'22 evaluation. This is evidence that the quality of the utility function is important for the quality of the MBR-QE score.

Comparing MT Systems. When comparing whether the encoder-decoder MT system or PaLM 2 is used to generate the pool of pseudo-references, there is no clear winner between the two. The MBR-QE score has a higher correlation at the segment-level with the encoder-decoder model, but the correlations are higher at the system-level with PaLM 2. It is not clear why this is the case.

Pseudo-Reference Pool Size. Overall, the correlations are surprisingly stable for each of the different numbers of pseudo-references. Most of the differences comes between pairwise accuracy at the system-level, but this correlation can be sensitive; there are not many system pairs, so if one or two system rankings change, it can have a large impact on the overall accuracy. In the future, we could explore decreasing the pseudo-reference pool size even further to understand its impact on the overall MBR-QE metric quality.

Comparing to Other Metrics. Table 3 shows the comparion between our submission, denoted MBR-QE, to other QE metrics that were the top-performing QE metrics in the WMT'22 Metrics Shared Task, CometKiwi (Kepler et al., 2019; Rei et al., 2022b) and UniTE-src (Wan et al., 2022). The table additionally contains results for the best reference-based metrics MetricX and COMET-22 (Rei et al., 2022a).

Compared to the QE metrics, MBR-QE in general has the best-performance across most evaluation settings, demonstrating that it is a state-of-the-art QE metric. In some cases, it even out-performs the reference-based metrics, namely in the system-level Pearson correlation.

MBR-QE leverages MetricX as the utility function. MBR-QE still under-performs with respect to MetricX, demonstrating that the human references are still valuable and that the pseudo-references do not perfectly match the distribution of human translations, which is expected given that the MT system is not perfect. However, the gap in performance between the two metrics is relatively small in some settings.

4.1 Submission Summary

Both of our submissions to the Metrics Shared task use the in-house MT system to generate 256 pseudo-references with epsilon sampling ($p = 0.02$ and temperature 1.0). Our primary submission uses MetricX as the utility function, and the contrastive submission uses BLEURT.

5 Related Work

Incorporating evaluation metrics into reranking the outputs from MT systems has been very successful. For example, the Freitag et al. (2021b) showed that reranking translations with BLEURT as part of MBR produced higher-quality translations. This work served as the inspiration for our QE metric submission.

Research on quality estimation focuses on predicting word- and sentence-level quality scores (Zerva et al., 2022). The most successful approaches to predicting sentence-level scores are learned regression-based metrics that are trained to predict ground-truth quality scores, like CometKiwi (Kepler et al., 2019; Rei et al., 2022b) or UniTE-src (Wan et al., 2022). Our metric is quite different from these approaches in that it is not directly trained to predict quality scores, but rather it leverages a reference-based metric combined with an MT system to score a translation. To the best of our knowledge, ours is the first metric that uses MBR to build a QE metric.

6 Conclusion

In this report, we proposed a new QE metric called MBR-QE that repurposes an MT system in combination with MBR to score a translation without ac-

The SLIDE metric submission to the WMT 2023 metrics task

Vikas Raunak and **Tom Kocmi** and **Matt Post**
Microsoft
Redmond, Washington, USA
{viraunak,tom.kocmi,mattpost}@microsoft.com

Abstract

We describe our submission of a new metric, SLIDE (Raunak et al., 2023), to the WMT 2023 metrics task. SLIDE is a reference-free quality-estimation metric that works by constructing a fixed sentence-length window over the documents in a test set, concatenating chunks and then sending them for scoring as a single unit by COMET (Rei et al., 2022a). We find that SLIDE improves dramatically over its context-less counterpart on the two WMT22 evaluation campaigns (MQM and DA+SQM).

1 Introduction

Reference-based metrics such as COMET typically perform far above their source-based quality estimation (QE) counterparts. One explanation is that the human reference provides an answer or grounding to many types of translation ambiguities, such as pronoun selection, that may be impossible to predict from just a single input sentence alone. A handful of approaches have looked at extending metrics with source- and target-side context (Vernikos et al., 2022; Deutsch et al., 2023; Raunak et al., 2023) in hopes of providing stronger correlation with human judgments. We base our submission on SLIDE (Raunak et al., 2023), which explicitly postulates and provides evidence for the claim that source-side context may work to provide the same information as human references.

2 Metric settings

SLIDE is parameterized by (w, s), a window and a stride. The window, w, is a fixed-size sentence window that is moved across each document in a test set. The sentences in the window are concatenated on the source and system systems with a space, and then sent directly to the underlying QE model, COMETKiwi (Rei et al., 2022b) in our submission, for evaluation as a single chunk. The window is then incremented by s sentences, and a new value computed. These values are treated independently, summed and averaged over a test set in typical fashion. Documents that are shorter than the window size, and the "remainder" portions of documents that cannot be perfectly tiled by the window and stride, are skipped.

In practice, we used a (w, s) value of $(6, 6)$ for all languages except EN-DE and DE-EN. For those languages, the data was provided at the paragraph level. We therefore simply took the provided segmentations one-by-one, without providing a window or stride. We chose this value because it had some of the best reported results in Raunak et al. (2023, Figure 1). Table 1 repeats Table 2 from

Metric	MQM	DA+SQM

Table 1: Pairwise system accuracy against the WMT22-MQM and DA+SQM annotations. Metrics that use a reference are marked with ®. We mark our entries in bold. **COMETKiwi (public)** uses no context. Our entry to the WMT23 task, SLIDE (6,6), improves over it in both settings.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 812–814
December 6–7, 2023.

their paper, depicting results on the WMT22 tasks with the pairwise accuracy (Kocmi et al., 2021). Our entries are marked in bold. SLIDE improves dramatically over its context-less counterpart. We also call attention to COMETKiwi (WMT-22); this is the number from the official submission to the task, which performs much better than the publicly available model.

3 Results

The WMT23 test set (Freitag et al., 2023; Kocmi et al., 2023) for each language pair comprises a set of documents containing between 1 and 173 lines, with a mean of 9.7 and a median of 7 across 14 language pairs.

At the time of publication, official results were not available, so we cannot comment on how well the strong results from Raunak et al. (2023) generalized to the new settings in WMT23.

We note also that we discovered after the submission that a bug in our code resulted in debugging output appearing in the data to be scored by COMET. This unfortunately affects the scores and means that SLIDE's placement in the official rankings are incorrect.

4 Conclusion

In this system description, we presented our submission to the WMT 2023 metrics task. SLIDE is designed as a reference-free quality-estimation metric which leverages the strength of contextual information by constructing a fixed sentence-length window over documents in a test set. The initial findings from Raunak et al. (2023) showcased the potential of SLIDE to deliver enhanced performance over context-less metrics, particularly in the WMT22 evaluation campaigns.

While we anticipate the official results from the WMT23 metrics task, bug in our code might have affected SLIDE's standing in the rankings.

We believe that SLIDE is a step forward in our collective endeavor to create metrics that align more closely with human judgments. Future works may explore optimizing window and stride configurations or integrating advanced algorithms to further exploit the potential of context in quality estimation tasks.

Abstract

Machine translation is a natural language generation (NLG) problem that involves translating source text from one language to another. Like every task in the machine learning domain, it requires an evaluation metric. The most obvious one is human evaluation; however, it is expensive, time-consuming, and not easily reproducible automatically. In recent years, with the introduction of pretrained transformer architectures and large language models (LLMs), state-of-the-art results in automatic machine translation evaluation have significantly improved in terms of correlation with expert assessments. We introduce MRE-Score, which stands for seMantically-informed Regression Encoder Score. It is an approach that constructs an automatic machine translation evaluation system based on a regression encoder and contrastive pretraining for the downstream problem.

1 Introduction

WMT Metrics Shared Task (Freitag et al., 2022) is a machine learning competition where participants have to construct an automatic evaluation system for machine translation for several language pairs. For WMT23 Metrics Shared Task[1], three language pairs are considered: English-German (en-de), Chinese-English (zh-en), and Hebrew-English (he-en). For each source sentence, there is a corresponding target machine-translated text and a reference human translation. The main goals of this competition are:

1. To achieve the strongest correlation with human judgment of translation quality over a diverse set of machine translation systems.

2. To illustrate the suitability of an automatic evaluation metric as a surrogate for human evaluation.

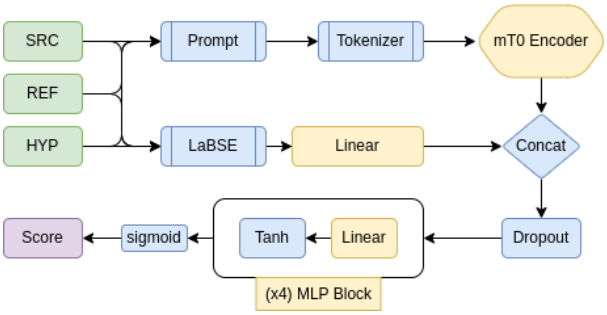

Figure 1: Final model architecture. Blocks in blue represents static components that were not trained. Blocks in yellow represent trained parts of the model.

3. To test the robustness of metrics when evaluating domains other than news data.

4. To create high-quality datasets for developing and evaluating metrics.

Within the WMT23 Metrics competition, our investigation focuses on the approach of constructing evaluation models to solve the regression problem based on expert degrees. Specifically, we construct regression models using a pretrained transformer encoder from the mT0 model family (Muennighoff et al., 2022), both vanilla models and with additional contrastive representation tuning. mT0 is finetuned version of mT5 (Xue et al., 2020), multilingual transformer model, which demonstrated capabilities of crosslingual generalization to unseen tasks and languages. Similar approaches demonstrated the best results in WMT21 (Freitag et al., 2021) and WMT22 (Freitag et al., 2022) Shared Tasks.

We release our code and pre-trained models openly to foster further research.[2]

December 6–7, 2023.

construction: (1) classical lexical overlap models, on the one hand, and LLM-based approaches based on (2) unsupervised matching, (3) regression, and (4) zero-shot prompting, on the other hand. Classical lexical overlap methods measure overlap between source, reference, and target sentence n-grams (Papineni et al., 2002; Lin, 2004; Banerjee and Lavie, 2005). Modern unsupervised matching-based approaches use large language model (LLM)-based encoders such as BERT to compute the semantic similarity between reference and hypothesis texts (Zhang et al., 2019; Zhao et al., 2019) or between source and hypothesis texts (Zhao et al., 2020). In modern regression approaches, models are fine-tuned to predict human evaluation scores. Generally, they consist of a transformer encoder model and a regression head. As input, they can use late binding with source, reference, and target texts or different concatenation combinations (Sellam et al., 2020; Rei et al., 2020). LLM-based zero-shot approaches use prompt engineering for LLMs with the expectation of a score in the generation output (Kocmi and Federmann, 2023). In some research, attempts are made to predict evaluation scores as a weighted sum of digit tokens, where the weights are token probabilities from a Markov chain probability model (Liu et al., 2023).

The previous winner of the WMT Metrics Shared Task competition was the proprietary MetricX(Freitag et al., 2022) model, which used a regression approach. One of the state-of-the-art models in machine translation is GPT-4 with zero-shot scoring. However, due to the time consumption of its inference and the closeness of regression approaches with relatively small backbones (e.g., COMET used the base version of XLM-RoBERTa (Conneau et al., 2019) with 2.5B parameters), task-specific NLG evaluation with sophisticated tricks with vector representation and training datasets may provide better results.

Contrastive Learning Contrastive learning for NLP problems is a popular pretraining approach for improving results in downstream tasks. For example, the recent E5 model (Wang et al., 2022) is pretrained in a contrastive manner using a curated large-scale text pair dataset to solve various tasks that require a single-vector representation of texts, both after finetuning and in a zero- or few-shot manner. Another work that investigated contrastive learning for extrapolating vector representations for different tasks is InstructOR (Su et al., 2022). This model incorporates instructions in contrastive learning and achieved good results for tasks that were unseen during pretraining. The idea of knowledge transfer in the latent space may provide improvements with clean datasets and an appropriate fitting process.

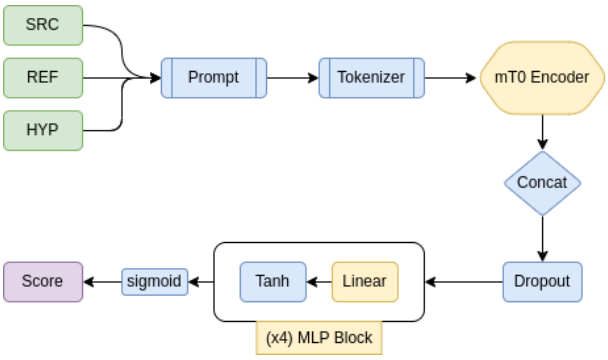

Figure 2: Architecture of the base model.

3 Method

3.1 Architecture

The main essence of our approach is to use vector representations from the encoder of the Big Science mT0 (Muennighoff et al., 2022) model as input for the Feed-Forward layer. This idea has already been proven successful in other approaches, such as COMET (Rei et al., 2020) and BLEURT (Sellam et al., 2020), and we have attempted to further improve upon it in various ways.

All our experiments use the same basic structure, as illustrated in Figure 2. First, the source text is presented as a prompt and is tokenized using the mT0 tokenizer. The resulting tokens are then processed by the mT0 encoder to obtain vector representations. Subsequently, mean pooling is applied to these vectors, and the resulting representations are passed through a Multilayer Perceptron (MLP). Prompting is necessary to present the data (source, reference, hypothesis) in a convenient format. In our approach, the prompt consists of concatenating the source, reference, and hypothesis with a separator token [sep]. It is worth noting that the mT0 tokenizer does not have a specific separator token, so another token can be selected for this purpose. Mean pooling is used to obtain sentence embeddings from the mT0 encoder representations, which are then suitable for further processing by a fully connected layer.

During the process, we tested various configurations of Multilayer Perceptron (MLP). We experi-

mented with the number of linear layers, activation functions between layers and at the end, as well as with dropouts. Insufficient linear layers resulted in a deterioration of metrics as they were unable to extract all the necessary information from the embeddings. On the other hand, adding too many layers did not have any significant impact on the results. Hence, we settled on using 4 layers. We tested Tanh and ReLU as activation functions between layers, and found that Tanh yielded slightly better results. This observation is likely due to the fact that Tanh is commonly used in neural networks for working with text embeddings. For the activation function at the end, we compared two options: sigmoid and a simple threshold approach (rounding to 100 if the result is >100 and to 0 if < 0). The use of sigmoid resulted in significantly better outcomes. In addition, we experimented with the inclusion of dropouts and found that it made sense to add only one dropout before the first linear layer after mean pooling. Otherwise, too much useful information was deleted and the MLP did not have sufficient time to extract it.

We also explored the possibility of incorporating an external «hint» in addition to the embeddings of the mT0 encoder. This approach is illustrated in scheme 1. For obtaining additional representations, we chose LaBSE (Feng et al., 2020), a state-of-the-art model in the bitext mining task, which serves as a proxy task for machine translation. In our architecture, we included an additional component responsible for preprocessing LaBSE embeddings. After obtaining these representations, they were passed through a linear layer, and the resulting vectors were concatenated with the outputs from mT0 passed through Mean Pooling. The inclusion of the linear layer after LaBSE serves as an additional degree of freedom and helps reduce the dimensionality of the vectors.

In the end, we selected a configuration that utilized a pre-trained approach combining contrastive learning mT0 and LaBSE to submit our results. This configuration demonstrated the best metrics on our test data.

3.2 Contrastive pretraining

To enhance the vector representation and address the specific characteristics of the Hebrew language, which is not as widely studied as English or German, we experimented with tuning encoder embeddings using contrastive learning. For each source text, we created two contrastive loss components: one for the reference translation and one for the machine translation. To implement this approach, we needed to specify negative examples that we wanted to be dissimilar to the source text in terms of vector representations. We used the Sentence-T5 model (Ni et al., 2021) to embed each source text and its two translations. Additionally, we constructed two ANN (Approximate Nearest Neighbor) indexes (Johnson et al., 2019): one for human references and another for machine translations. These indexes allowed us to find the K furthest points from the source texts based on the dot product. Note that for normalized vectors:

$$\|x-y\|_2^2 = 2 - 2x^T y \;\rightarrow$$
$$\min_x \left(x^T y\right) = \max_x \left((-x)^T y\right) = \min_x \left(\|(-x)-y\|_2^2\right) \tag{1}$$

The loss function is defined as the negative log likelihood with an arbitrary similarity function $\mathrm{sim}(x,y)$ (we used $\mathrm{sim}(x,y) =< x,y >$) and a temperature parameter τ. Our goal is to incorporate scaled target values of three types: SQM, DA, and MQM, with different prioritization weights in the loss function. For a given source text s, its reference translation r, and machine translation t, we have an expert degree $a^c_{s,t} \in [0,1]$ of type c with a prioritization weight γ_c. Each source text s is embedded as e_s, the reference translation r is embedded as e^+_r, and the machine translation t is embedded as e^+_t. In the case of reference translations, we denote the K furthest points from s as $\left\{e^-_{r,k}\right\}_{k=1}^K$. Similarly, in the case of machine translations, we denote the K furthest points from s as $\left\{e^-_{t,k}\right\}_{k=1}^K$.

The component for human reference:

$$\mathbf{L}\left(e_s, e^+_r, \left\{e^-_{r,k}\right\}_{k=1}^K\right) = -\log p_{s,r} \tag{2}$$

$$p_{s,r} = \frac{\exp\left(\frac{\mathrm{sim}(e_s,e^+_r)}{\tau_r}\right)}{\exp\left(\frac{\mathrm{sim}(e_s,e^+_r)}{\tau_r}\right) + \sum_{k=1}^K \exp\left(\frac{\mathrm{sim}(e_s,e^-_{r,k})}{\tau_r}\right)} \tag{3}$$

This formula is general negative log-likelihood (NLL) with temperature for self-supervised learning (Wang and Isola, 2022).

The component for machine translation:

$$\mathbf{L}\left(e_s, e_t^+, \left\{e_{t,k}^-\right\}_{k=1}^K\right) = -\log p_{s,t,c} \tag{4}$$

$$p_{s,t,c} = \frac{\exp\left(\alpha_t \frac{\text{sim}(e_s, e_t^+)}{\tau_t}\right)}{\exp\left(\alpha_t \frac{\text{sim}(e_s, e_t^+)}{\tau_t}\right) + \sum_{k=1}^K \exp\left(\frac{\text{sim}(e_s, e_{t,k}^-)}{\tau_t}\right)} \tag{5}$$

$$\alpha_t = \gamma_c a_{s,t}^c \tag{6}$$

Here we have a modified version of previous loss where we use target scores and their prior weights as temperature, but only for positive object.

Consider the derivative of the temperatured NLL loss w.r.t. to source text dot product as similarity function:

$$\frac{\left(1 - \frac{\exp\left(e_s^T e^+/\tau\right)}{Z(e_s)}\right)}{e^+\tau} - \sum_{e^-} \frac{\frac{\exp\left(e_s^T e^-/\tau\right)}{Z(e_s)}}{e^-\tau}$$

We have two separate additives with actually independent temperature coefficients. Increasing them removes the gradient changing effect and provides a pipeline for reducing the gradient step for bad and noisy translations. We can model such effect with human degrees with prioritizing ones over others.

Having a batch of quadruplets $\left\{\left(s, r, t, a_{s,t}^c\right)_n\right\}_{n=1}^N$ and using formulas above, the total loss can be written as:

$$\mathbf{L}\left(\left\{\left(s, r, t, a_{s,t}^c\right)_n\right\}_{n=1}^N\right) = \frac{1}{N}\sum_n \mathbf{L}\left(\left(s, r, t, a_{s,t}^c\right)_n\right) \tag{7}$$

$$\mathbf{L}\left(\left(s, r, t, a_{s,t}^c\right)_n\right) = \\ = \mathbf{L}\left(e_{s_n}, e_{r_n}^+, \left\{e_{r_n,k}^-\right\}_{k=1}^K\right) + \mathbf{L}\left(e_{s_n}, e_{t_n}^+, \left\{e_{t_n,k}^-\right\}_{k=1}^K\right) \tag{8}$$

Here we have an empirical risk over the batch, for each point we have two additive components for human reference and machine translation correspondingly.

3.3 Synthetic data

In this year's WMT Metrics Shared Tasks, the organizers presented us with a novel language pair: Hebrew-English. This language pair is not included in any of the available training data for MT evaluation metrics. Consequently, we believe that it was intended to test the ability of novel metrics for zero-shot transfer. To address this challenge, we made the decision to create a synthetic dataset for the Hebrew-English language pair, following the approach proposed by Rei et al. (2022b).

First, we selected a subset of English-Hebrew translations from the publicly available OPUS dataset (Tiedemann, 2012). From a total of approximately 1 million translations, we randomly chose 60,000 translations (Hebrew texts) and translated them back from Hebrew to English. To ensure a diverse range of translation quality, we selected three translation models of different sizes from the NLLB project (Costa-jussà et al., 2022): models with 600M and 1.3B parameters, which were distilled from 54B Mixture-of-Experts teacher models, as well as a 3.3B model that was trained from scratch. Each model was used to generate translations for an equally-sized portion of the dataset. Synthetic quality scores for these translations were computed as the average of scores calculated by the COMET-22 (Rei et al., 2022a) and BLEURT-20 (Sellam et al., 2020) metrics.

4 Experiments

4.1 Data

For our experiments, we utilize datasets from the previous year's WMT Metrics Shared Tasks as both training and evaluation data. These datasets provide three types of scores:

- MQM - Multidimensional Quality Metrics (Burchardt, 2013): This metric encompasses a wide range of issues that occur with translation.
- SQM - Scalar Quality Measure: This metric provides segment-level scalar ratings with document context.
- DA - Direct Assessment: This metric measures the quality of a translation on a scale from 0 to 100, based on the adequacy and fluency of the sentence.

We utilize all the available data and apply min-max scaling to rescale the score values, ensuring

they fall within the range of 0 to 1. For DA and SQM scores, we used dataset-level statistics for scaling. However, for MQM scores, we adapted the scaling to accommodate different score ranges. Specifically, the English-German and Chinese-English pairs had a range of −25 to 0, while the English-Russian pair had a range of $-\infty$ to 100.

The resulting composition of the training dataset for our experiments is as follows:

- MQM scores for WMT competitions from the years 2020 and 2021, covering 3 language pairs (en-ru, zh-en, en-de).
- SQM scores for the year 2022, covering 12 language pairs.
- DA scores for the years 2017-2022, covering 41 language pairs.

For the test set, we selected the MQM scores for the year 2022 to ensure comparability with existing metrics.

Furthermore, we included synthetic data for the Hebrew-English language pair, as described in Section 3.3. Out of the total 60,000 examples, we randomly chose 50,000 examples for the training set and the remaining 10,000 examples for the test set. Since the scores for the synthetic data were computed using existing metric models, they naturally fell within the range of 0 to 1, and no additional re-scaling was required. In total, we had 1,527,567 examples in the training set and 77,575 in the test set.

4.2 Experimental settings

All experiments were conducted with a fixed random seed. For the base of the generic model, we chose the encoder part of the mT0-large model introduced in Muennighoff et al. (2022). An MLP on top of the encoder consists of three layers with hidden sizes of 384, 96, and 1, using the hyperbolic tangent activation function. We also apply dropout with a rate of $p = 0.1$. For models that utilize embeddings, we include a resizing dense layer that projects the concatenated embeddings vector into vectors with a size of 512.

For contrastive pretraining, we once again utilize the encoder part of the mT0-large model. Contrastive examples are collected into a total batch size of 128 examples. Furthermore, we accumulate batches across four iterations, resulting in an effective batch size of 512 for each training process.

Pipeline	en-de	zh-en	en-ru	he-en
Comet-22	0.281	0.395	0.330	NA
CometKiwi	0.266	0.343	0.297	NA
Base	0.276	0.179	0.350	0.796
Base + Emb.	0.255	0.173	0.331	0.785
CL Base	0.223	0.101	0.307	0.786
CL Base + Emb.	0.222	0.105	0.315	0.792

Table 1: Experimental results on WMT22 Test Set along with our synthetic test set for He-En. **Base** model represents model that only consits of mT0-large encoder and MLP head. **CL Base** represents model that was pretrained with contrastive loss before fine-tunning.

The first two models, which are based on the original mT0-large encoder, were trained for 3 epochs with an aggressive learning rate of 2×10^{-4}. The other two models, which utilize a contrastively-pretrained encoder, were trained for 1 epoch with a learning rate of 5×10^{-5}. In both cases, the batch size was set to 8 due to the substantially larger sequence sizes.

All our experiments were conducted in a distributed data-parallel setting across 4 GPUs. The learning rate was scaled accordingly based on the number of processes.

4.3 Hardware, Computational Budget and Environmental Impact

For our experiments, we utilized the CITEC computational cluster hosted at Bielefeld University. Each node in the cluster consists of 4xA40 GPUs with 48GB of VRAM, 1xAMD EPYC 7713 64-Core CPU, and 512GB of RAM.

The total computational budget for our experiments is 175 GPU-hours (~43.75 hours per node × 4 GPUs). Considering that the A40 GPU has a power draw of 300W under full load, and the current carbon intensity of the German power grid is 510gCO2eq/kWh [3], our estimated total carbon footprint is approximately 26.775 kgCO2eq. It is important to note that this number should be considered a lower bound, as we have not accounted for the power draw of other components of the computing node, such as the CPU and cooling.

5 Results and Discussion

We trained and tested each configuration on our test data using the Kendall-τ correlation metric. The results in Table 1 show that the base configuration has the best performance in most language pairs. However, adding external semantically-informed embeddings improves the quality for the model version with the contrastive loss. We didn't manage to get better results relatively to the base model, even for the rare language pair. We think that it's due to choice of negative sampling strategy, lack of theoretical approach analysis and hyperparameter tuning. Temperature is sensitive parameter, the wrong choice of it could lead to permanent overfitting and noisy results. We need to test more natural approach with adding scaled human degrees as general temperature for all softmax components. Also we should test other approaches with metric learning, e.g. Multi-Class N-pair loss (Sohn, 2016).

6 Conclusion

This paper presents our experiments with semantically informed architectures with a regression head. This led us to conclude that the additional awareness of the encoder and extra pretraining may positively affect the model quality in these conditions. In the future, it would be possible to explore other ways to inform the model and conduct experiments with larger versions of our implemented architectures.

Limitations

While we examine a novel approach to NLG evaluation, it is important to note limitations in our research.

Firstly, due to time and computational resource constraints, we have not conducted hyperparameter search. This opens up a possibility of finding better results for reported model configurations. Additionally, we have only made one experiment with one fixed random seed for each configuration. Increasing the number of runs would improve result stability.

Abstract

This paper presents the submission of Huawei Translation Service Center (HW-TSC) to the WMT23 metrics shared task, in which we submit two metrics: KG-BERTScore and HWTSC-EE-Metric. Among them, KG-BERTScore is our primary submission for the reference-free metric, which can provide both segment-level and system-level scoring. While HWTSC-EE-Metric is our primary submission for the reference-based metric, which can only provide system-level scoring. Overall, our metrics show relatively high correlations with MQM scores on the metrics tasks of previous years. Especially on system-level scoring tasks, our metrics achieve new state-of-the-art in many language pairs.

1 Introduction

Due to the expensive cost of human evaluation, automatic metrics (Freitag et al., 2022) for machine translation (MT) (Wei et al., 2021, 2022a) is critically important for MT research and development. While human evaluation is still very important, automatic metrics allow the rapid evaluation and comparison of MT systems on large collections of text and facilitate expansion to low resource languages (Li et al., 2022) and domains (Yang et al., 2021; Wu et al., 2022a). Depending on whether the references are required or not, automatic metrics are categorized into two categories: (1) reference-based metrics like BLEU (Papineni et al., 2002), METEOR (Lavie and Agarwal, 2007), BERTScore (Zhang et al., 2020) and BLEURT (Sellam et al., 2020), which evaluate the hypothesis by referring to the references; (2) reference-free metrics like YiSi-2 (Lo, 2019) and COMET-QE (Rei et al., 2020, 2021), which are also referred to as quality estimation (QE). These metrics estimate the quality of hypothesis based solely on the sources, without relying on the references.

The WMT23 metrics shared task invites submissions of reference-free metrics and reference-based metrics to find automatic metric scores for translations at the segment-level and system-level. This paper presents the contribution of HW-TSC to the WMT23 metrics shared task. Slightly different from our participation last year (Liu et al., 2022a), we only submit two metrics this year. Details of our metrics (KG-BERTScore and HWTSC-EE-Metric) are illustrated in Table 1.

Metric	Category	Segment-level	System-level
KG-BERTScore	reference-free	✓	✓
HWTSC-EE-BERTScore	reference-based	✗	✓

Table 1: Details of our metrics

KG-BERTScore (Wu et al., 2022b) incorporates multilingual knowledge graph (Chen et al., 2017) into BERTScore (Zhang et al., 2019) and generates the final evaluation score by linearly combining the results of KGScore and BERTScore. Our efforts this year build on findings and observations from our participation in the WMT22 metrics shared task (Liu et al., 2022a) to further improve the accuracy of KGScore and BERTScore. The choice of a named entity (NE) annotator (Marrero et al., 2013) is critical to KGScore. With the emergence of large language models (LLMs) (Wei et al., 2022b; Kasneci et al., 2023) such as ChatGPT (Ding et al., 2022), the NE annotator seems to have one more option. Therefore, we try to use ChatGPT[1] for NE annotation and find that LLM-assisted NE annotation can empower the metric. At the same time, the selection of a QE model is crucial for BERTScore. Since COMET-QE (Rei et al., 2022) has proven to be the state-of-the-art QE model, we use it to calculate BERTScore this year.

The HWTSC-EE-Metric (Liu et al., 2022b) is developed using existing metrics with the goal of creating a more balanced scoring system at the sys-

*These authors contributed equally to this work.

December 6–7, 2023.

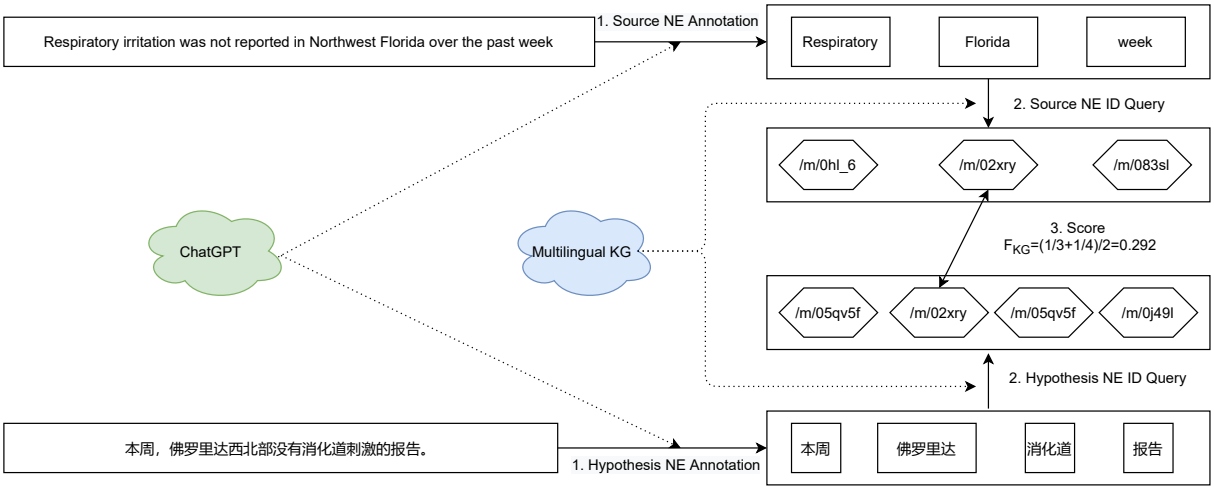

Figure 1: A Calculation Example of KGScore on English-Chinese Language Pair

tem level. This is achieved by assigning weights to segment-level scores obtained from backbone metrics. The weights are determined based on the difficulty of each segment, which is determined by the entropy of a hypothesis-reference pair. Segments with higher entropy values, indicating higher difficulty, receive larger weights in the aggregation of system-level scores by HWTSC-EE-Metric.

2 Metrics

This section introduces our metrics for WMT23 metrics shared task, including KG-BERTScore and HWTSC-EE-Metric.

2.1 KG-BERTScore

KG-BERTScore (Wu et al., 2022b) is a reference-free metric we proposed last year, which generates the final evaluation score by linearly combining the results of KGScore and BERTScore. For a given KGScore F_{KG} and BERTScore F_{BERT}, KG-BERTScore $F_{KG-BERT}$ is defined as:

$$F_{KG-BERT} = \alpha \cdot F_{KG} + (1-\alpha) \cdot F_{BERT}, \quad (1)$$

where α is an adjustable weight parameter.

We have made some improvements to the implementation details of KGScore and BERTScore, which will be described in detail below.

2.1.1 KGScore

KGScore refers to scoring based on the matching rate of NE. Figure 1 is a calculation example of KGScore on English-Chinese language pairs. The calculation process includes three steps:

Firstly, we utilize a NE Annotator to annotate NEs in the source and hypothesis sentences. Last year we used spacy[2] (Algamdi et al., 2022) as the NE annotator, but it didn't work very well. This year we try to use ChatGPT to annotate NE, and find that its effect is better than spacy, which means that LLM-assisted NE annotation is feasible.

Secondly, we match cross-lingual NE pairs by querying multilingual knowledge graphs. Google Knowledge Graph[3] (Google KG) is a general-purpose multilingual knowledge graph that we have chosen to use as always for querying NE IDs. Since same-meaning NEs in different languages share the same NE ID in Google KG, we can match cross-lingual NE pairs by NE ID. One more thing to be noted is that an NE without an ID is considered invalid and will not participate in the subsequent calculation of KGScore.

Finally, we explore using NE's matching rate to score. For a given test set with n sentence pairs, assuming that S_i is the NE numbers in the i-th source sentence, H_i is the NE numbers in the i-th hypothesis sentence, and SH_i is the number of matched cross-lingual NE pairs. The segment-level NE matching rates of the i-th source sentence and hypothesis sentence are respectively defined as:

$$F_{KGS_i} = \frac{SH_i}{S_i} \quad if\ S_i \neq 0\ else\ 1 \quad (2)$$

$$F_{KGH_i} = \frac{SH_i}{H_i} \quad if\ M_i \neq 0\ else\ 1 \quad (3)$$

[2] https://spacy.io/models

[3] https://developers.google.com/knowledge-graph

Then the segment-level calculation formula of KGScore is defined as:

$$F_{KG_i} = \frac{F_{KGS_i} + F_{KGH_i}}{2} \tag{4}$$

For the system-level KGScore, we first calculate the system-level NE matching rates of source sentences and hypothesis sentences are respectively defined as:

$$F_{KGS} = \frac{\sum_{i=1}^{n} SH_i}{\sum_{i=1}^{n} S_i} \tag{5}$$

$$F_{KGH} = \frac{\sum_{i=1}^{n} SH_i}{\sum_{i=1}^{n} H_i} \tag{6}$$

Then the system-level calculation formula of KGScore is defined as:

$$F_{KG} = \frac{F_{KGS} + F_{KGH}}{2} \tag{7}$$

2.1.2 BERTScore

BERTScore (Zhang et al., 2020) refers to scoring based on semantic similarity. We initially use Sentence-BERT (Reimers and Gurevych, 2019) to calculate the semantic similarity score between the source and hypothesis. Last year we used a reference-free HWTSC-teacher-Sim metric (Zhang et al., 2022) as BERTScore to make the score more relevant to MQM score (Lommel et al., 2014). As COMET-QE has been proven to be the state-of-the-art reference-free metric on WMT22 metrics shared task, we use the COMET-QE model[4] to score and serve as BERTScore this year.

2.2 HWTSC-EE-Metric

The HWTSC-EE-Metric, also known as the entropy-enhanced (EE) Metrics (Liu et al., 2022b), was employed in system-level shared tasks this year. Unlike traditional methods of acquiring system-level scores, EE metrics deviate from the normal approach of obtaining system-level scores via arithmetic average. EE metrics assign higher weights to difficult samples present in the evaluation set, as opposed to treating all source-reference pairs equally, as human scorers tend to do in MT evaluation. It is worth noting that simple samples can be easily translated, leading to similar human scores for different hypotheses. Conversely, challenging samples within the evaluation set play a crucial role in differentiating top candidates from inferior systems. Consequently, MT evaluation metrics should encourage systems that excel in translating difficult samples. Contrary to concerns about incorrect scoring, the use of challenging segments to evaluate MT systems has actually shown potential for improving metric performance. EE metrics, in particular, place a strong emphasis on the translation quality of difficult hypotheses and allocate higher weights to them in system-level scores.

2.2.1 Working Process of EE Metrics

EE metrics use the average qualities of hypotheses to determine the difficulty of a segment. One key measure used in this process is chunk entropy (Yu et al., 2015), which quantifies the quality of translation between the reference and the hypothesis. Higher chunk entropy indicates higher uncertainty in translation, while lower entropy suggests good confidence in the hypothesis. By calculating the entropy, easy and difficult samples can be classified accordingly through a threshold value h. In the process of aggregating scores, hypotheses are assigned weights based on their group, whether they belong to the easy or difficult category. Easy samples receive a lower weight denoted as w/N_e, while difficult samples receive a higher weight $(1-w)/N_d$. The reason for such a weight discrepancy lies in the larger number of easy hypotheses compared to difficult ones. The balance coefficient w may vary depending on the language pairs and evaluation datasets utilized. This weight assignment strategy ensures that the weights of easy samples remain significantly lower than those of difficult samples, considering the different samples in each category.

2.2.2 Enhancements to HWTSC-EE-Metric

The earlier version of EE metrics incorporates two adjustable hyperparameters, h and w, which are responsible for selecting difficult samples and assigning weights to each group, respectively. However, the presence of these hyperparameters hampers the practical application of EE metrics. Furthermore, these hyperparameters often vary across different language pairs and evaluation datasets, as evidenced by our preliminary experiment that involved up to 10 different parameters using the WMT19 evaluation set. Consequently, it becomes challenging to identify a suitable combination of hyperparameters for real-world scenarios. To address this issue, in last year's WMT metrics shared tasks (Liu et al., 2022a), we simplified the com-

[4] https://huggingface.co/Unbabel/wmt22-cometkiwi-da

putation of the system-level score by employing a normal distribution fitting approach to determine the threshold h for each translation direction. This year, we further simplified the estimation of w by using a fixed value of 0.8, as opposed to the three different configurations of w used last year. Based on the results of WMT22, we observed that the value 0.8 corresponds to an appropriate balance of weights between difficult and easy groups, as it exhibits a high correlation with human MQM scores on recent WMT test sets. Another modification in this year's HWTSC-EE-Metric is the replacement of our backbone metric from BERTScore (Zhang et al., 2019) to COMET score (Rei et al., 2022). Specifically, we adopted the model *wmt22-comet-da*[5], which is known for its robust segment-level MT evaluation capabilities, as the segment-level backbone metric for HWTSC-EE-Metric this year.

3 Experiments

This section introduces the experimental results of KG-BERTScore and HWTSC-EE-Metric on previous metrics shared tasks.

3.1 Experiment of KG-BERTScore

In order to verify the feasibility of the improved KG-BERTScore, we conduct experiments on the WMT22 metrics shared task data. Since it is time-consuming and expensive to query ChatGPT and Google Knowledge Graph API, we only verify the effect of KG-BERTScore on Chinese-English language pair. In the experiment, we first calculate F_{KGS} and F_{KGH} through NE annotation and NE pair matching, and then calculate KGScore. Next, we use COMETKiwi-22 as BERTScore to calculate the final KG-BERTScore.

We calculate the correlation of the scores of each stage (including F_{KGS}, F_{KGH}, KGscore and KG-BERTScore) with the MQM scores without considering human translation. To facilitate comparison with the official results of the WMT22 metrics shared task, the segment-level correlation adopts Kendall correlation, and the system-level correlation adopts Pearson correlation.

3.1.1 Segment-level Correlation

Table 2 shows Kendall Tau correlation of reference-free metrics with segment-level MQM scores for the WMT22 Chinese-English language pair, which is calculated without human translation. We find that KGScore has a relatively low segment-level correlation with MQM scores, while COMETKiwi-22 has a relatively high segment-level correlation with MQM scores. Therefore, when calculating KG-BERTScore, we set α to a smaller value (i.e., 0.1). Overall, the segment-level correlation between KG-BERTScore and MQM scores is only slightly higher than that of COMETKiwi-22.

Metric	Correlation
KG-BERTScore-22	0.219
COMETKiwi-22	0.364
F_{KGS}	0.017
F_{KGH}	0.055
KGScore	0.061
KG-BERTScore (α=0.1)	**0.365**

Table 2: Kendall Tau correlation of reference-free metrics with segment-level MQM scores for the WMT22 Chinese-English language pair, which is calculated without human translation.

3.1.2 System-level Correlation

Table 3 shows Pearson correlation of reference-free metrics with system-level MQM scores for the WMT22 Chinese-English language pair, which is calculated without human translation. The system-level correlation between KGScore and MQM scores is relatively close to that of COMETKiwi-22, so we set α to a larger value (i.e., 0.9). Surprisingly, the system-level correlation between KG-BERTScore and MQM scores is significantly higher than that of COMTKiwi-22.

In addition, the segment-level and system-level correlations of KGScore with MQM scores are higher than those of F_{KGS} and F_{KGH}, which indicates that both source and hypothesis NE pair matching rates should be considered when calculating KGScore.

Metric	Correlation
KG-BERTScore-22	0.743
COMETKiwi-22	0.866
F_{KGS}	0.660
F_{KGH}	0.376
KGScore	0.697
KG-BERTScore (α=0.9)	**0.947**

Table 3: Pearson correlation of reference-free metrics with system-level MQM scores for the WMT22 Chinese-English language pair, which is calculated without human translation.

Table 4: Correlations with system-level human MQM scores on datasets of WMT21 news and WMT21 tedtalks. EE-BERTScore-$*$ represents our last year's submission in WMT22. HWTSC-EE-Metric represents our submission in WMT23. **With Human** indicates evaluation on MT systems and human translations, and **w/o Human** indicates MT systems only. Best correlations are marked in bold.

3.1.3 Effect of Different Weights

KG-BERTScore generates the final evaluation score by linearly combining the results of KGScore and BERTScore. α is an adjustable weight parameter in the linear combination formula, which affects the correlation between KG-BERTScore and MQM scores. To analyze the effect of α value, we calculate the segment-level and system-level correlations of KG-BERTScore and MQM scores under different α values for the WMT22 Chinese-English language pair. The result is shown in Figure 2. The segment-level correlation between KG-BERTScore and MQM scores is highest when the α value is 0.1, and the system-level correlation between KG-BERTScore and MQM scores is the highest when the α value is 0.9. That is to say, when the correlation between KGScore and MQM scores is relatively low, α should take a smaller value, otherwise, α should set a larger value.

On the WMT23 metrics shared task, we cannot know the MQM score in advance. Therefore, we refer to the above experimental settings, and set α to 0.1 and 0.9 on the segment-level and system-level metrics shared tasks, respectively. In addition, we do not calculate KG-Score and set α to 0 on non-MQM language pairs due to the slow speed of accessing ChatGPT.

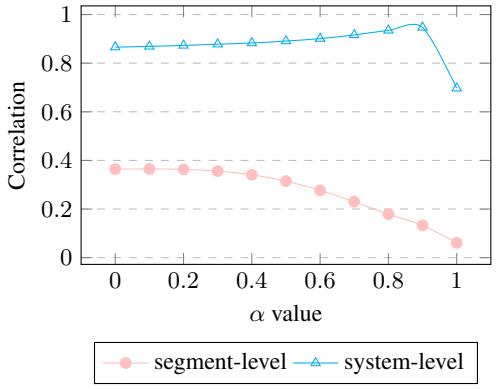

Figure 2: The segment-level and system-level correlations between KG-BERTScore and MQM scores under different α values for the WMT22 Chinese-English.

3.2 Experiment of HWTSC-EE-Metric

To evaluate the performance of the HWTSC-EE-Metric, a series of experiments were conducted primarily on the WMT21 test sets using the MQM scores as the human scoring standard. To investigate the impact of using human translations as part of the system, the results obtained from two sets of systems for each language pair are compared. The evaluation was based on three coefficients: Pearson's correlation coefficient (r), Kendall's τ, and Spearman's ρ, which are used to assess the system-level correlations with human evaluations.

Table 4 presents a performance comparison between the HWTSC-EE-Metric (our submission in WMT23), EE-BERTScore (our submission in WMT22), and two standard metrics (BERTScore and COMET). The HWTSC-EE-Metric demonstrates higher overall correlations with human MQM evaluations compared to its backbone, the standard COMET score. Furthermore, out of the 36 comparison terms, the HWTSC-EE-Metric achieves the best performance in 20 cases. This strong performance indicates the effectiveness of our entropy-based enhancing strategy and parameter estimation approach.

As EE metrics evaluate a system based not only on the individual system itself but also on other participating systems, the inclusion of human trans-

lations may influence the performance of EE metrics. As shown in Table 4, most metrics exhibit a decline in performance when human translations are included. The improvements of the HWTSC-EE-Metric in correlations with MQM are not consistently steady, which aligns with the findings of (Freitag et al., 2021) that most metrics struggle to accurately score translations that differ from MT systems. However, we observed that the HWTSC-EE-Metric mitigates the performance reduction of COMET in some cases (*e.g.*, En→ De in WMT21 datasets), but there are also instances where the HWTSC-EE-Metric does not improve COMET in terms of correlations (*e.g.*, En→ Ru in WMT21 TED talks). Overall, when human translations are included as additional outputs, EE metrics tend to be less robust and provide a less significant improvement over standard metrics.

4 Conclusion

This paper presents HW-TSC's submission to the WMT23 metrics shared task, in which we summit a reference-free metric (KG-BERTScore) and a reference-based metric (HWTSC-EE-Metric). We have made some improvements to these two metrics compared to last year's submission. One of the most critical improvements is on KG-BERTScore, we empower the metric with LLM-assisted NE annotations, significantly improving its correlation with MQM scores. The experimental results on previous WMT metrics tasks show great effectiveness of our research direction and the superiority of our metrics.

Abstract

We introduce the submissions of the NJUNLP team to the WMT 2023 Quality Estimation (QE) shared task. Our team submitted predictions for the English-German language pair on all two sub-tasks: (i) sentence- and word-level quality prediction; and (ii) fine-grained error span detection. This year, we further explore pseudo data methods for QE based on NJUQE framework[1]. We generate pseudo MQM data using parallel data from the WMT translation task. We pre-train the XLMR large model on pseudo QE data, then fine-tune it on real QE data. At both stages, we jointly learn sentence-level scores and word-level tags. Empirically, we conduct experiments to find the key hyper-parameters that improve the performance. Technically, we propose a simple method that covert the word-level outputs to fine-grained error span results. Overall, our models achieved the best results in English-German for both word-level and fine-grained error span detection sub-tasks by a considerable margin.

1 Introduction

Quality Estimation (QE) of Machine Translation (MT) is a task to estimate the quality of translations at run-time without access to reference translations (Specia et al., 2018). There are two sub-tasks in WMT 2023 QE shared task[2]: (i) sentence- and word-level quality prediction; and (ii) fine-grained error span detection. We participated in all two sub-tasks for the English-German (EN-DE) language pair. The annotation of EN-DE is multi-dimensional quality metrics (MQM) [3], aligned with the WMT 2023 Metrics shared task. The MQM annotation provides error spans with fine-grained categories and severities by human translators.

Inspired by DirectQE (Cui et al., 2021) and CLQE (Geng et al., 2023), we further explore pseudo data methods for QE based on the NJUQE framework. We generate pseudo MQM data using parallel data from the WMT translation task. Specifically, we replace the reference tokens with these tokens sampled from translation models. To simulate translation errors with different severities, we sample tokens with lower generation probabilities for worse errors (Geng et al., 2022). We pre-train the XLMR (Conneau et al., 2020) large model on pseudo MQM data, then fine-tune it on real QE data. At both stages, we jointly learn sentence-level scores (MSE loss and margin ranking loss) and word-level tags (cross-entropy loss).

For task (i), the QE model outputs the sentence scores and the "OK" probability of each token. For task (ii), we set different thresholds for the "OK" probability to predict fine-grained severities. We regard consecutive "BAD" tokens as a whole span and take the worse severity of each token as the result. We train different models with different parallel data and ensemble their results as the final submission.

Overall, we summarize our contribution as follows:

- Empirically, we conduct experiments to find the key hyper-parameters that improve the performance.
- Technically, we propose a simple method that converts the word-level outputs to fine-grained error span results.

Our system obtains the best results in English-German for both word-level and fine-grained error span detection sub-tasks with an MCC of 29.7 (+4.1 than the second best system) and F1 score of 28.4 (+1.1) respectively. We rank 2nd place on sentence-level sub-tasks with a Spearman score of 47.9 (-0.4 than the best system).

Span 2	55:70	Minor

Table 1: An example from the WMT2023 English-German MQM dataset. We mark the error span with red color. The translation back is generated by Google Translate.

2 Background

Given a source language sentence X and a target language translation $\hat{Y} = \{y_1, y_2, \ldots, y_n\}$ with n tokens, the MQM annotation provides error spans with fine-grained categories and severities (minor, major, and critical) by human translators. The MQM score sums penalties for each error severity and then normalizes the result by translation length:

$$\text{MQM} = 1 - \frac{n_{\text{minor}} + 5n_{\text{major}} + 10n_{\text{critical}}}{n}, \quad (1)$$

where n_{severity} denotes the number of each error severity and n denotes the translation length.

As shown in table 1, participating systems are required to predict tags $G = \{g_1, g_2, \ldots, g_n\}$ of each word and MQM score m for sub-task (i), where the binary label $g_j \in \{\text{OK}, \text{BAD}\}$ is the quality label for the word translation y_j. For sub-task (ii), we need to predict both the character-level start and end indices of every error span as well as the corresponding error severity. The primary metrics of sentence-level, word-level, and span detection subtasks are Spearman's rank correlation coefficient, Matthews correlation coefficient (MCC)[4], and F1-score respectively[5].

3 Methodology

Generally, we unite the sub-tasks (i) and (ii) as follows:

- We generate pseudo MQM data for sub-task (i) using parallel data and translation models as shown in the left of figure 1.
- We pre-train the QE model with pseudo data and fine-tune it with real QE data for sub-task (i) as shown in the right of figure 1.
- We ensemble the results of models trained with different parallel data for sub-task (i).
- We convert word-level probabilities for sub-task (i) to error span and fine-grained severities for sub-task (ii).

3.1 Pseudo MQM Data

We adopt the pseudo MQM data method described in (Geng et al., 2022).

3.1.1 Corrupting

Given a parallel pair (X, Y), we corrupt the reference Y as shown in figure 2:

- We sample the number of spans t according to the distribution of WMT2022 QE EN-DE valid set (Zerva et al., 2022a).
- According to the distribution of WMT2022 QE EN-DE valid set, we sample the length of each span n_i one by one to ensure that the total length is less than reference length n.
- We randomly sample the start indices for i-th span in $[\text{EOL}_i, n - \sum_{j=i}^{t} n_j]$ to ensure each span lie in the sentence, where EOL_i is the end indices of last span ($\text{EOL}_0 = 0$).
- We sample the severity of each span according to the distribution of a WMT2022 QE EN-DE valid set.
- We randomly insert or remove some tokens in each span to simulate over- and under-translations.

[5] https://github.com/WMT-QE-Task/wmt-qe-2023-data/blob/main/task_2/evaluation

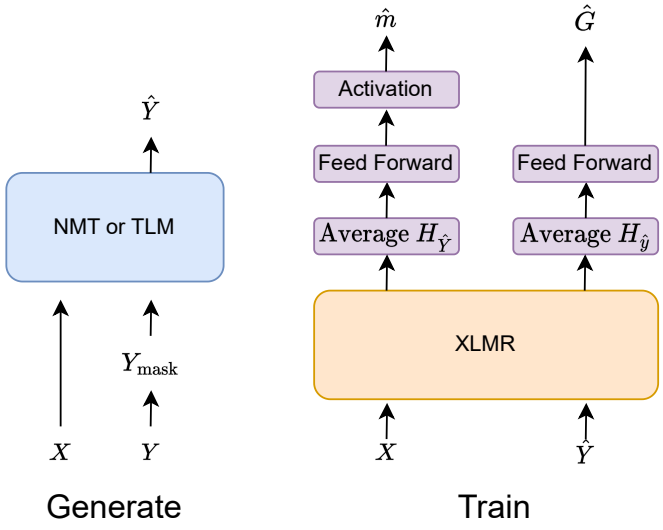

Figure 1: Illustration of the whole procedure.

- We tag tokens on the right of the omission errors and tokens that are not aligned with reference tokens as "BAD". The rest tokens are tagged as "OK". We calculate the MQM score using Eq. 1 based on the sampled severities.

3.1.2 Fixing

To generate pseudo translations, we replaced these error tokens with the "mask" symbol and sampled these tokens with neural machine translation (NMT) model (Vaswani et al., 2017) or translation language model (TLM) (Conneau and Lample, 2019). For the NMT model, we generate these error tokens from left to right with teacher forcing, while the TLM model generates these tokens parallel. To simulate errors of different severities, we sample tokens with lower generation probabilities for graver pseudo errors. To generate diverse pseudo translations, we random sample one of the tokens with the top k generation probability as the error token. In practical, we use $k = 2, 10, 100$ for minor, major, and critical errors, respectively.

3.2 Pre-training and Fine-tuning

3.2.1 QE Model

Since the pre-train models significantly improve MT evaluation performance (Rei et al., 2022; Zerva et al., 2022b), we use the XLMR large model (f) as the model backbone. To obtain the features conditioned on source sentences, we input the concatenation of source sentences and translations:

$$H_X, H_{\hat{Y}} = f(X, \hat{Y}). \tag{2}$$

Then, we average the representations $H_{\hat{Y}}$ of all target tokens as the sentence score representation H_{sent}.

$$H_{\text{sent}} = \text{Average}(H_{\hat{Y}}) \tag{3}$$

The sentence score representation passes through one linear layer and an optional activation function σ to output the score prediction $\hat{m}$.

$$\hat{m} = \sigma(\text{FFN}(H_{\text{sent}})), \tag{4}$$

where we set σ as the Sigmoid function or null. We average sub-tokens' representations as the representation of the whole word. We input the word representations H_{word} to one linear layer and softmax function to predict binary labels:

$$\hat{G} = \text{softmax}(\text{FFN}(H_{\text{word}})). \tag{5}$$

3.2.2 QE Loss

Following the multi-task learning framework for QE (Zerva et al., 2021), we joint learn the sentence- and word-level tasks. We use two loss functions for the sentence-level task: the margin ranking loss and the mean square error (MSE) loss. The margin ranking loss is defined as follows:

$$L_{\text{Rank}} = \max(0, -r(\hat{m}^i - \hat{m}^j) + \epsilon), \tag{6}$$

where $\hat{m}^i$ and $\hat{m}^j$ denote the output scores of i-th and j-th translations from current batch; r denotes the rank label, $r = 1$ if $m^i > m^j$, $r = -1$ if $m^i < m^j$; ϵ denotes the margin, we set $\epsilon = 0.03$ for all experiments. As shown in (Geng et al.,

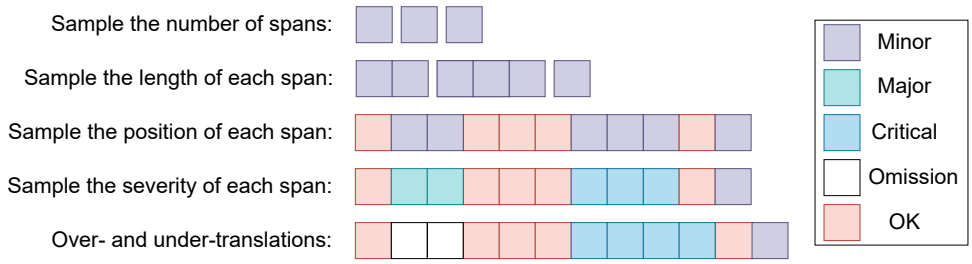

Figure 2: Illustration of the pseudo MQM data method (Geng et al., 2022). The word-level tags of this pseudo translation are annotated as "OK BAD OK OK BAD BAD BAD BAD OK BAD" and the MQM score is -0.6.

2022), the ranking loss is critical to achieving good performance. And the MSE loss is defined as:

$$L_{\text{MSE}} = \text{MSE}(m, \hat{m}). \tag{7}$$

We use cross-entropy (CE) loss for the word-level task:

$$L_{\text{CE}} = \sum_{i=1}^{n} \text{CE}(g_i, \hat{g}_i), \tag{8}$$

where $\hat{g}_i$ denotes the tag predicted for i-th word. The final QE loss function is the weighted sum of previous loss functions:

$$L_{\text{QE}} = L_{\text{CE}} + \alpha L_{\text{MSE}} + \beta L_{\text{Rank}}, \tag{9}$$

where α and β denote the weights for different loss functions. We use the Eq. 9 for both pre-training and fine-tuning.

3.3 Ensemble

We generate one pseudo MQM data for each parallel pair. We train different QE models with different pseudo MQM data and ensemble their results as the final submission. For the sentence-level task, we calculate the z-scores of each output and the average of these z-scores as the predictions. For the word-level task, we use QE models to output "OK" probabilities $P = \{p_1, p_2, \ldots, p_n\}$, where p_i denotes the "OK" probability for i-the word in the translation. Then, we average "OK" probabilities and set a threshold ϵ_{BAD} to decide whether the word is "BAD":

$$\hat{g}_i = \begin{cases} \text{OK} & \text{if } p_i > \epsilon_{\text{BAD}} \\ \text{BAD} & \text{if } p_i \leq \epsilon_{\text{BAD}} \end{cases} \tag{10}$$

3.4 Sub-task (ii)

To unite the word-level sub-task and fine-grained error span detection sub-task, we propose a simple method that covert the word-level outputs to fine-grained error span results. Based on the ensemble "OK" probabilities, we set two thresholds ϵ_{major} and ϵ_{minor}. Then, we can output the fine-grained error tags $S = \{s_1, s_2, \ldots, s_n\}$, where p_i as follows:

$$\hat{s}_i = \begin{cases} \text{OK} & \text{if } p_i > \epsilon_{\text{minor}} \\ \text{Minor} & \text{if } \epsilon_{\text{Major}} < p_i \leq \epsilon_{\text{Minor}} \\ \text{Major} & \text{if } p_i \leq \epsilon_{\text{Major}} \end{cases} \tag{11}$$

Finally, we regard consecutive error tokens as a whole span and take the worst severity of error tokens as the span severity. As recommended by the reviewer, we also try to take the majority category as the span severity. However, we found that only one prediction changed from"major" to "minor". That may be because the task is imbalanced and there are more "major" errors. As a result, this strategy achieves the same F1-score as the previous one.

4 Experiments

4.1 Implementation Details

We use parallel data from the WMT translation task to generate the pseudo MQM data. We use the WMT2022 QE EN-DE dataset and the WMT2022 Metric EN-DE dataset for fine-tuning. We also incorporate the post-editing annotation EN-DE datasets (WMT17, 19, and 20) to warm up the QE model.

We implement our system based on the NJUQE framework, which is built on the Fairseq(-py) (Ott et al., 2019) toolkit. We use NVIDIA V100 GPUs to conduct our experiments. To search the hyper-parameters, we utilize the grid search method. All experiments set the random seed as 1. We set $\alpha = 1$ and $\beta = 1000$ for both pre-training and fine-tuning. When pre-training, we use four GPUs. We set the learning rate to 1e-5, the maximum number of

σ	Spearman
w/o σ	50.02
sigmoid	52.41

Table 2: Results on the validation set of WMT2022 QE EN-DE task with different normalize function σ.

tokens in a batch to 1400 and update the parameters every four batches. We evaluate the model every 600 updates and perform early stopping if the validation performance does not improve for the last ten runs. When fine-tuning, we use one GPU. we set the learning rate to 1e-6, the maximum number of sentences in a batch to 20. We evaluate the model every 300 updates and perform early stopping if the validation performance does not improve for the last ten runs.

4.2 Results

We achieve the best results on EN-DE for both word-level and fine-grained error span detection sub-tasks with an MCC of 29.7 (+4.1 than the second best system) and F1 score of 28.4 (+1.1) respectively. We rank 2nd place on sentence-level sub-tasks with a Spearman score of 47.9 (-0.4 than the best system).

5 Analysis

In this section, we show some key hyper-parameters that improve the performance.

5.1 The normalize function σ

Although the MSE loss improves sentence-level performance, we need to avoid the over-fitting of score predictions. We set the normalize function σ as the sigmoid function to provide smooth gradients. As shown in table 2, we achieve better sentence-level performance by using the sigmoid function.

5.2 Dropout Rate of the Output Layers

We also use the dropout method (Gal and Ghahramani, 2016) on the output layers to avoid over-fitting. Table 3 shows that the QE model obtains better performance when we set the dropout rate as 0.2.

Dropout Rate	Spearman
0	52.41
0.1	52.93
0.2	53.11
0.3	52.15

Table 3: Results on the validation set of WMT2022 QE EN-DE task with different dropout rate.

6 Conclusion

We present NJUNLP's work to the WMT 2023 Shared Task on Quality Estimation. In this work, we generate pseudo MQM data using parallel data. We pre-train the XLMR large model on pseudo MQM data, then fine-tune it on real QE data. At both stages, we jointly learn sentence-level scores and word-level tags. Empirically, we conduct experiments to find the key hyper-parameters that improve the performance. Technically, we propose a simple method that covert the word-level outputs to fine-grained error span results. Overall, our models achieved the best results in English-German for both word-level and fine-grained error span detection sub-tasks by a considerable margin.

Abstract

Quality estimation (QE) is an essential technique to assess machine translation quality without reference translations. In this paper, we focus on Huawei Translation Services Center's (HW-TSC's) submission to the sentence-level QE shared task, named Ensemble-CrossQE. Our system uses CrossQE, the same model architecture as our last year's submission, which consists of a multilingual base model and a task-specific downstream layer. The input is the concatenation of the source and the translated sentences. To enhance the performance, we finetuned and ensembled multiple base models such as XLM-R, InfoXLM, RemBERT and CometKiwi. Moreover, we introduce a new corruption-based data augmentation method, which generates deletion, substitution and insertion errors in the original translation and uses a reference-based QE model to obtain pseudo scores. Results show that our system achieves impressive performance on sentence-level QE test sets and ranked the first place for three language pairs: English-Hindi, English-Tamil and English-Telegu [1]. In addition, we participated in the error span detection task. The submitted model outperforms the baseline on Chinese-English and Hebrew-English language pairs.

1 Introduction

Quality estimation (QE) involves automatically scoring machine translation outputs without depending on reference translations (Specia et al., 2018). In the WMT 2023 QE shared task, there are two subtasks — quality estimation and fine-grained error span detection and each task involves several language pairs. Our team — Huawei Translation Services Center (HW-TSC) — participated in the sentence-level quality prediction and the fine-grained error span detection tasks over all language pairs except the zero-shot language pair. Fine-tuning pre-trained language models, which offers abundant semantic information, has become the paradigm for QE tasks (Rei et al., 2020). In this paper, we describe Ensemble-CrossQE, HW-TSC's system for sentence-level QE task, which leverages multiple pre-trained language models and data augmentation technique. Our system designs can be summarized as follow:

- **Model**: We employed our previous year's architecture, CrossQE (Tao et al., 2022), as the foundation. For every language pair, models were individually fine-tuned. Additionally, we used CometKiwi (Rei et al., 2022), a multilingual QE model and fine-tuned it for single language pairs.
- **Data augmentation**: The original training dataset was augmented with a novel corruption-based approach. A reference-based QE model was used to generate pseudo scores for corrupted translations by taking the original translation as reference and a corrupted translation as the new translation.
- **Ensemble**: For each language pair, 12 checkpoints were considered for the final ensemble. These checkpoints originated from four base models: XLM-R (Conneau et al., 2020), InfoXLM (Chi et al., 2021), RemBERT (Chung et al., 2020), and CometKiwi (Rei et al., 2022), and three training dataset configurations: original dataset, augmented dataset, and augmented dataset followed by the original dataset. The ensemble weight for each checkpoint was optimized with Optuna (Akiba et al., 2019). On average, eight checkpoints were used per language pair after optimization.

Our system achieves remarkable results and outperforms the baseline given by the competition organizer by a large margin. Additionally, we provide

[1] http://www2.statmt.org/wmt23/quality-estimation-task_results.html

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 835–840
December 6–7, 2023.

detailed results of each model with and without data augmentation in Table 1. To analyze the importance of each model in the ensemble, we present the ensemble weights in Figure 1 and 2. It is worth noting that the models fine-tuned with the proposed data augmentation technique were assigned higher weights in the ensemble.

2 Background

2.1 Task Description [2]

Sentence-level QE with direct assessment (DA) anotations: The goal is to predict the quality score for each source-target sentence pair. The golden-truth quality scores were obtained from human translators who rated each translation from 0 to 100. The scores from three or four translators were normalized and averaged to get the final score. This year's QE shared task has five language pairs with DA quality scores: English-Marathi (en-mr), English-Hindi (en-hi), English-Tamil (en-ta), English-Telegu (en-te) and English-Gujarati (en-gu). Only en-mr has 26,000 training samples, while the other languages have just 7,000 training samples each.

Sentence-level QE with multi-dimensional quality metrics (MQM) anotations: The goal is to predict the quality score for each source-target sentence pair. MQM can be used to identify quality issues in translation products, classify them against a shared, open and standardized error typology, and generate quality measures that can be used to gauge how well the translation product meets quality requirements. Calculating different scores by error type, the summing penalties for each MQM error category are +1 point for minor errors +5 points for major errors, and +10 points for critical errors. This year's QE shared task has two language pairs with MQM quality scores: English-German(en-de) and Chinese-English(zh-en). The en-de has 28900 training samples and zh-en has 35300 training samples.

Fine-grained error span detection: Participants of this task need to identify the error span (start and end indices) and the error severity (major or minor).

2.2 Base Models

- **XLM-R** (Conneau et al., 2020): A transformer-based masked language model trained on a massive multilingual corpus with more than two terabytes of data.
- **InfoXLM** (Chi et al., 2021): A cross-lingual pre-trained model that leverages multilingual masked language modeling, translation language modeling and cross-lingual contrast learning.
- **RemBERT** (Chung et al., 2020): A rebalanced mBERT model with factorization of the embedding layers. The input embeddings are smaller and kept for fine-tuning, while the output embeddings are larger and discarded after pre-training.
- **CometKiwi** (Rei et al., 2022): A multilingual reference-free QE model that uses a regression approach and is built on top of InfoXLM. It has been trained on direct assessments from WMT17 to WMT20 and the MLQE-PE corpus.

3 Method

3.1 Model Architecture

3.1.1 Task1: Sentence-level QE with direct assessment (DA) and multi-dimensional quality metrics (MQM) anotations

As shown in Equation 1 and 2, the embeddings of source sentence $\mathbf{s}$ and translated sentence $\mathbf{t}$ are concatenated in both orders $[\mathbf{s}, \mathbf{t}]$ and $[\mathbf{t}, \mathbf{s}]$ to form the input of pre-trained model f_{base}. The output token-level embedding sequences are processed by an average pooling layer to obtain vector reprsentations $\mathbf{h}_{s1}$ and $\mathbf{h}_{t1}$ for source and translation respectively. These feature vectors are enhanced by taking their absolute difference and element-wise multiplication, as shown in Equation 3 and 4. Finally, all feature vectors are concatenated and fed into a regression head that predicts the final score y (Equation 5). This architecture enables information exchange between source and translated sentences at an early stage of the network and has proven to be significantly more effective than combining cross-lingual information after the pre-trained model.

$$\mathbf{h}_{s1}, \mathbf{h}_{t1} = f_{base}([\mathbf{s}, \mathbf{t}]) \quad (1)$$

$$\mathbf{h}_{t2}, \mathbf{h}_{s2} = f_{base}([\mathbf{t}, \mathbf{s}]) \quad (2)$$

$$\mathbf{f}_1 = [\mathbf{h}_{s1}, \mathbf{h}_{t1}, |\mathbf{h}_{s1} - \mathbf{h}_{t1}|, \mathbf{h}_{s1} \odot \mathbf{h}_{t1}] \quad (3)$$

$$\mathbf{f}_2 = [\mathbf{h}_{s2}, \mathbf{h}_{t2}, |\mathbf{h}_{s2} - \mathbf{h}_{t2}|, \mathbf{h}_{s2} \odot \mathbf{h}_{t2}] \quad (4)$$

$$y = f_{score}([\mathbf{f}_1, \mathbf{f}_2]) \quad (5)$$

[2] https://wmt-qe-task.github.io/

3.1.2 Task2: Error span detection

Our model was adapted from CometKiwi (Rei et al., 2022). The original binary classification was changed to three-way classification with the following labels: major error, minor error, no error. We disabled the sentence-level prediction head by setting the weight of the original sentence module to 0.

3.2 Corruption-based Data Augmentation

Algorithm 1 Corruption-based data augmentation

Require: source s, translation t, DA $score$
Ensure: $score > 70$

$n \leftarrow min(randint(0, 5), len(t))$
$i \leftarrow 0$
$\hat{t} \leftarrow t$
while $i < n$ **do**
  $\hat{t} \leftarrow corrupt(\hat{t})$
  $i \leftarrow i + 1$
end while
$score_{new} \leftarrow score \times \frac{f_{QE}(s,\hat{t},t)}{f_{QE}(s,t,t)}$
return $s, \hat{t}, score_{new}$

This year's QE shared task primarily focuses on low-resource languages. The scarcity of training data poses a challenge of overfitting. We tried to overcome this problem by augmenting the dataset with various types of noise, including deletion, insertion and substitution errors. Our approach is described in Algorithm 1. We first selected source-translation pairs (s and t) that had a score above 70. We did not use low quality translations for augmentation, as our approach was designed to generate translation with lower scores compared to the original translation. Then, we randomly sampled the number of corruptions and iteratively incorporated these corruptions into the translation, resulting in a new translation ($\hat{t}$). The corruption types are listed as follows:

- **Deletion**: A random word in the translation was deleted.
- **Insertion**: A random word in the translation was selected and inserted in a random position.
- **Substitution**: A random word was replaced with another word in the translation.

To generate a pseudo score for each new translation, we employed a reference-based QE model [3] f_{QE}. The key idea is to use the original translation as the reference and the corrupted translation as the new translation. Since the output of the QE model is in the range between 0 and 1, we can use this value to scale the original score to obtain the pseudo score. However, we observed that even when the reference and translation are the same, the model will not generate a score close to 1, which is inconsistent with the assumption that if there is no corruption, the score should be unchanged. Therefore, we constructed the scaling factor as the ratio between the corrupted translation score and the uncorrupted translation score ($\frac{f_{QE}(s,\hat{t},t)}{f_{QE}(s,t,t)}$). This data augmentation method can be viewed as distilling knowledge from a pre-trained reference-based QE model and it has the potential to increase model generalisability and provide diverse checkpoints for ensemble.

4 Experiments

4.1 Experimental setups

4.1.1 Task1

Our system is built on top of the COMET package [4]. We fine-tuned four pre-trained models, namely XLM-R, InfoXLM, RemBERT and CometKiWi [5], on a single Nvidia Tesla V100 GPU with a batch size of 4, gradient accumulation of 8 and mean square error loss function. We stopped the training when there was no improvement in terms of Spearman correlation on the dev set for five test runs. For each language pair, the augmented dataset, which contains more than ten times data than the original dataset, was pre-generated instead of generated on-the-fly to improve training efficiency. We considered three schedules: training the model with the original dataset; training it with the augmented dataset (only DA training set); and first training it with the augmented dataset and then finetuning it on the original dataset. The training step took around 3 hours and 10 hours with the original and the augmented dataset respectively.

With four base models and three schedules, we obtained twelve checkpoints for each language pair. We ensembled these checkpoints by taking the

weighted-average of predicted scores. The weights were optimized using Optuna, an automatic hyperparameter search framework. We used the Spearman correlation as the objective, set the step to 0.05, and ran 1000 trials on the dev set.

4.1.2 Task2

We fine-tuned two pre-trained models, XLM-R and CometKiwi, for 10 epochs with batch size of 32. We created two training subsets using the annotated data from 2020 to 2022. Consequently, four checkpoints were obtained for each language pair. We combined the results of these checkpoints by using the union of the predicted spans, which outperformed token-level majority voting.

4.2 Results

4.2.1 Task1

Results of sentence-level QE in terms of Spearman correlation are shown in Table 1. Without data augmentation, CometKiwi has the best average correlation of 0.597, while XLM-R, InfoXLM and RemBERT are close behind with around 0.585. Figure 1 reveals the importance of each model in the ensemble. CometKiwi has the highest weight for four language pairs, meaning it contributes most to the final prediction. Other base models perform similarly, with XLM-R being most important for en-hi language pair.

The corruption-based data augmentation approach has the most notable benefits for the en-mr language pair. The performance of models based on XLM-R, InfoXLM and CometKiwi are improved significantly. It is worth noting that these models do not need to be fine-tuned on the original training set to achieve comparable or better results than no augmentation, even when more than 90% of the targets are pseudo labels. For other language pairs, data augmentation has limited benefits when used with a single base model. One possible reason is that the reference-based model did not produce high-quality pseudo labels for language pairs with limited resources. However, we did observe that models with data augmentation played important roles in the ensemble. As shown in Figure 2, on average, models without data augmentation were assigned a weight of only 20%, whereas models that were trained purely on augmented data or pretrained on augmented data had a total weight of 80%, indicating that data augmentation can improve the performance of the ensemble and prevent overfitting.

Our final ensemble consists of 12 checkpoints, but some of them have zero weight after optimization. Therefore, the average number of models in the ensemble for each language pair is eight. The ensemble outperforms any single model on the dev set by a noticeable margin. On the test set, the ensemble achieves outstanding results, with Spearman scores higher than 0.69 for three language pairs (en-mr, en-ta, en-gu) and the Spearman of en-ta even reached 0.775. Our submissions are much better than the organizer's baseline. The assessment results of MQM are shown in Table 2. With the model ensemble methods, the assessment results have been significantly improved.

4.2.2 Task2

The results for error span detection are displayed in Table 3. Our system achieved an F1 score of 0.235 on the zh-en language pair, which is significantly higher than the baseline. Moreover, for the language pair without supervised data (he-en), our system achieved a relative improvement of 33% over the baseline.

5 Conclusion

This paper mainly presents HW-TSC's sentence-level QE system called Ensemble-CrossQE. Using our previous year's model CrossQE as the foundation, we carried out comprehensive experiments with different pre-trained models. To further improve the robustness for low-resource language pairs and provide various checkpoints for model ensemble, we introduced a corruption-based data augmentation method. For sentence-level QE task, our system delivers a good performance on all language-pairs with DA annotations. In the future, we will investigate distillation method to transfer the knowledge of the ensemble to a single model to improve efficiency and we plan to leverage external parallel data and translation models for data enhancement. Additionally, in this paper, we only present brief investigations of the error span detection task. Therefore, we plan to further explore word-level QE tasks, which can improve the interpretability of QE.

Abstract

We present the joint contribution of Unbabel and Instituto Superior Técnico to the WMT 2023 Shared Task on Quality Estimation (QE). Our team participated on all tasks: sentence- and word-level quality prediction (task 1) and fine-grained error span detection (task 2). For all tasks, we build on the CometKiwi-22 model (Rei et al., 2022b). Our multilingual approaches are ranked first for all tasks, reaching state-of-the-art performance for quality estimation at word-, span- and sentence-level granularity. Compared to the previous state-of-the-art, CometKiwi-22, we show large improvements in correlation with human judgements (up to 10 Spearman points). Moreover, we surpass the second-best multilingual submission to the shared-task with up to 3.8 absolute points.

1 Introduction

Quality Estimation (QE) is the task of automatically assigning a quality score to a machine translation output without depending on reference translations (Specia et al., 2018). This paper details the collaborative effort of Unbabel and Instituto Superior Técnico (IST) in the WMT23 Quality Estimation shared task, which encompassed two primary tasks: (i) sentence- and word-level quality prediction and (ii) fine-grained error span detection.

As of last year, some language pairs in the test set were absent from the training data. To address this, following a similar approach to the previous year, our systems were developed to achieve good multilingual generalization and to accommodate previously unseen languages. To achieve this, we start by leveraging the direct assessments (DA) labeled data obtained from the WMT Metrics shared task from 2017 to 2020, the MLQE-PE dataset (Fomicheva et al., 2022), and the training data (DA) specifically annotated for Indian languages in the 2023 shared task edition. In total, these datasets encompass close to 1M annotations covering 38 language pairs. We start by constructing generic models using this corpus. These generic QE models were subsequently fine-tuned for this year's subtasks.

For Task 1 – sentence-level, we fine-tuned our generic models exclusively with this year's DA data. The architecture of these models remains consistent with our submission from the previous year, but we employ XLM-R XL and XXL as pretrained encoders (Conneau et al., 2020). For the word-level quality prediction task, we follow the successful approach of combining the sentence- and word-level signals into one loss during the finetuning step, which has yielded positive results in previous iterations (Rei et al., 2022b). For fine-grained error span detection, we conducted experiments exploring various approaches that build upon our word-level and sentence-level strategies. In terms of contrasting systems, we explored UnbabelQi[1] and GPT-4 (OpenAI, 2023). For GPT-4, we used a prompt designed to predict both the location and severity of errors in each translation, akin to the approach used in AutoMQM (Fernandes et al., 2023).

Overall, our main contributions are: (i) we introduce approaches for multilingual machine translation quality estimation that are consistently first-ranked at word-, span-, and sentence-level granularity; (ii) we explore different approaches to predict the span of problematic translations along with their error severities (OK, Minor, Major); (iii) we publicly release two of our best models for research purposes (CometKiwi -XL[2] and -XXL[3]). To the best of our knowledge, these are the largest open-source QE models publicly released.

Our submitted systems attain the top multilingual results in all tasks: For Task 1 sentence-

level prediction, our multilingual system achieves 59.4 Spearman correlation points, surpassing the second-best system by nearly 4 absolute points. For word-level, our system achieves a 31.7 MCC score, outperforming the second-best system by almost 2 absolute MCC points. For error span prediction, our multilingual system achieves a 22 F1.0 score, beating the second-best system by more than 5 F_1 points.

2 Overview of the shared-task

QE systems are designed according to the granularity in which predictions are made (e.g., sentence- or word-level QE). In sentence-level QE, the goal is to predict a single quality score $\hat{y} \in \mathbb{R}$ given the whole source and its translation as input. Word-level QE works at a lower granularity level, with the goal of predicting binary quality labels $\hat{y}_i \in \{\text{OK}, \text{BAD}\}$ for all $1 \leq i \leq n$ *machine-translated words*, indicating whether that word is a translation error. In fine-grained error span detection, systems are tasked with flagging which parts of the segment, i.e., sequences of consecutive characters, contain errors. If an error span is found, the system has to point out its severity; in this shared task, an error span's severity can be classified as MINOR or MAJOR. We sometimes refer to the parts of the segment that do not belong to an error span as being labelled as OK. We participated on all tasks of this year's shared-task. We specify the language pairs and the released data below:

Task 1 – Sentence-level quality prediction: Submissions for this task were evaluated based on their correlation with Direct Assessment (DA) annotations for five language pairs: English→Marathi (*en-mr*), English→Hindi (*en-hi*), English→Tamil (*en-ta*), English→Telugu (*en-te*), and English→Gujarati (*en-gu*). Furthermore, they were evaluated using Multidimensional Quality Metrics (MQM) annotations for three language pairs: English→German (*en-de*), Chinese→English (*zh-en*), and English→Hebrew (*he-en*). Training data was made available for all language directions except for *he-en*.

Task 1 – Word-level quality prediction: Submissions for this task underwent evaluation based on tags inferred from post-editions for English→Farsi (*en-fa*) and English→Marathi (*en-mr*). Additionally, they were assessed using MQM annotations for *en-de*, *zh-en*, and *he-en*. No additional training or development data with word-level tags were made available. To the best of our knowledge, no word-level data is available for *en-fa* and *he-en*.

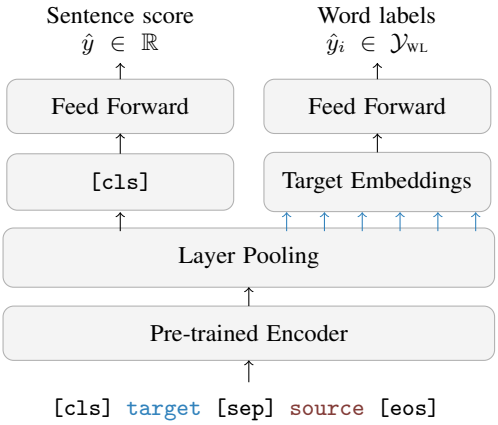

Figure 1: Our model follows COMETKIWI for sentence-level (left part) and word-level QE (right part). We represent the output space of the word-level head by $\mathcal{Y}_{\text{WL}}$.

Task 2 – Fine-grained error span detection: submissions were evaluated on error spans obtained via MQM annotations for 3 language pairs (*en-de*, *zh-en* and *he-en*). No training nor development data is available for *he-en*.

3 Implemented Systems

We largely follow the architecture of COMETKIWI (Rei et al., 2022b) – see Figure 1 for an illustration. We concatenate the machine translated sentence $\boldsymbol{t} = \langle t_1, ..., t_n \rangle$ and its source sentence counterpart $\boldsymbol{s} = \langle s_1, ..., s_m \rangle$ to serve as input to the encoder. This encoder then produces hidden state matrices $\boldsymbol{H}_0, ..., \boldsymbol{H}_L$ for each layer $0 \leq \ell \leq L$, where $\boldsymbol{H}_\ell \in \mathbb{R}^{(n+m)\times d}$, where $\ell = 0$ corresponds to the embedding layer and d is the hidden size. Following this, all hidden states are fed to a scalar mix module (Peters et al., 2018) that learns a weighted sum of the hidden states of each layer of the encoder, producing a sequence of aggregated hidden states $\boldsymbol{H}_{\text{mix}}$ as follows:

$$\boldsymbol{H}_{\text{mix}} = \lambda \sum_{\ell=0}^{L} \beta_\ell \boldsymbol{H}_\ell. \quad (1)$$

Here λ is a scalar trainable parameter, $\boldsymbol{\beta} \in \triangle^L$ is given by $\boldsymbol{\beta} = \mathsf{sparsemax}(\boldsymbol{\phi})$ using a sparse transformation (Martins and Astudillo, 2016), with $\boldsymbol{\phi} \in \mathbb{R}^L$ as learnable parameters, and where we

denote by $\triangle^L := \{\boldsymbol{\beta} \in \mathbb{R}^L : \mathbf{1}^\top \boldsymbol{\beta} = 1, \boldsymbol{\beta} \geq 0\}$ the probability simplex.[4]

For sentence-level models, we use the hidden state of the `<cls>` token as the sentence representation, which, in turn, is passed to a 2-layered feed-forward module in order to get a sentence score prediction $\hat{y} \in \mathbb{R}$. For word-level and error span detection models, we first retrieve the hidden state vectors associated with each each token in $\boldsymbol{t}$, and then pass them to a linear projection to get word-level predictions $\hat{y}_i \in \mathcal{Y}_{\text{WL}}$, $\forall_{1 \leq i \leq n}$. The output space of the word-level predictions is different depending on whether the models are constructed for word-level quality prediction ($\mathcal{Y}_{\text{WL}} = \{\text{OK}, \text{BAD}\}$), or error span detection ($\mathcal{Y}_{\text{WL}} = \{\text{OK}, \text{MINOR}, \text{MAJOR}\}$).

Pretrained multilingual encoders. Similarly to (Rei et al., 2022b), we employ InfoXLM L (Chi et al., 2021).[5] Additionally, we experiment with scaled-up multilingual encoders, including XLM-R XL,[6] and XLM-R XXL.[7] InfoXLM L comprises 24 encoder blocks with 16 attention heads each, totaling 550M parameters. XLM-R XL and XLM-R XXL have 32 attention heads for each encoder block, 36 and 48 encoder blocks and a total of 3.5B and 10.7B parameters, respectively.

Generic models for all tasks. We create, for each model size, a generic model that will then be further adapted to each separate task. To train these models, we use the collective corpora from 2017 to 2019 DA annotations of the WMT Translation shared task, and the MLQE-PE corpus (Fomicheva et al., 2022). We include the human annotations respective to the language pairs of this year's shared task for 7 different language pairs: DA annotations for *en-mr*, *en-hi*, *en-ta*, *en-te*, *en-gu*, and MQM annotations for *en-de* and *zh-en*. Overall, the generic models are trained on sentence-level quality prediction with over 940k samples with source, translation and quality score on 38 different language pairs. When presented with multiple DA scores for the same sentence pair, we used the z-score of the DAs for training but we first normalize the DAs between 0 and 1, where 1 represents a perfect translation and 0 a random one.

Task adaptation. After having obtained the generic models, we will train models for each separate stream of the shared-task, i.e., sentence-level, word-level or error span prediction. To do so, we consider the multi-task optimization from Rei et al. (2022b) wherein sentence scores can be used alongside supervision from word-level tags. Formally,

$$\mathcal{L}_{\text{SL}}(\theta) = \frac{1}{2}(y - \hat{y}(\theta))^2 \tag{2}$$

$$\mathcal{L}_{\text{WL}}(\theta) = -\frac{1}{n}\sum_{i=1}^{n} w_{y_i} \log p_\theta(y_i) \tag{3}$$

$$\mathcal{L}(\theta) = \lambda_{\text{SL}}\mathcal{L}_{\text{SL}}(\theta) + \lambda_{\text{WL}}\mathcal{L}_{\text{WL}}(\theta), \tag{4}$$

where $w \in \mathbb{R}^{|\mathcal{Y}_{\text{WL}}|}$ represents the class weights given for the word-level tags,[8] and $\lambda_{\text{SL}}, \lambda_{\text{WL}} \in \mathbb{R}_+$ are used to weigh the sentence and word-level losses, respectively. Note that $\lambda_{\text{SL}} = 1$ and $\lambda_{\text{WL}} = 0$ yields a fully sentence-level model, whereas $\lambda_{\text{SL}} = 0$ and $\lambda_{\text{WL}} = 1$ yields a word-level model.

Using unconstrained models. For error span detection, we evaluate UnbabelQi, an Unbabel demo QE system, alongside GPT4 (OpenAI, 2023). We prompt GPT4 to produce an MQM annotation for each source-target pair, based on five-shot examples which vary across language pairs but are consistent within segments of the same language pair. We also apply this system in Task 1, deriving a sentence-level score from error spans, in alignment with the MQM framework. This approach bears similarity to AutoMQM (Fernandes et al., 2023).

3.1 Task 1: Quality prediction

After the pretraining phase, we *further* **separately** adapt the generic models to the released DA and MQM data for this year's shared task.

3.1.1 Sentence-level quality prediction

Adaptation for Sentence-level. In order to tailor our models to the language pairs featured in this year's shared task, we conducted full fine-tuning until convergence on the released validation set. This fine-tuning exclusively leveraged the recently released Direct Assessment (DA) annotations for this year's task. This approach yields additional improvements for those languages. In the case of the MQM language pairs, our preliminary experiments revealed that attempting significant performance

[4] As it has been shown in (Rei et al., 2022a) not all layers are relevant and thus, using `sparsemax` we learn to ignore layers that do not help in the task at hands.

[5] https://huggingface.co/microsoft/infoxlm-large

[6] https://huggingface.co/facebook/xlm-roberta-xl

[7] https://huggingface.co/facebook/xlm-roberta-xxl

[8] These parameters help control how much we penalize the different granularities of word-level errors.

improvements on the MQM data led to noteworthy drops in correlations for the other language pairs using DAs. Consequently, for the MQM language pairs, we opted to employ the generic models as they are.

Ensembling models. Similarly to Rei et al. (2022b), we use Optuna (Akiba et al., 2019) to assemble four models – two XL and two XXL – into a single system. We do so by finding the optimal weights for each language pair among these four multilingual models, and combining their predictions according to those weights. Notably, the XXL models are generic models, whereas the two XL checkpoints were further optimized with this year's shared task data. As expected, the XL models carry more weight for Indian languages, while the XXL generic models were deemed more crucial for MQM languages.

3.1.2 Word-level quality prediction

For the word-level QE tasks, we experimented with both the multi-task setting and word-labels only.

Training word-level models. This year, no training or development data with word-level tags were made available. As such, the training data for our models consists of the training data used in Rei et al. (2022b), combined with the development sets from the 2022 WMT Shared Task. As the word-level task was going to be tested in a zero-shot scenario for two out of five language pairs (*en-fa*, *he-en*), contrary to Rei et al. (2022b), we do not prepend a language prefix to the beginning of the source and target segments during training. Moreover, for the post-edit (PE) models, we removed samples from two language pairs (*ps-en* and *en-cs*) from the training data. We did so to assess, during validation, the models' capability to generalise in a zero-shot scenario. For the MQM models, we used all available annotations, including those in *en-ru*.

Ensembling models. For word-level we followed a similar ensembling technique used for sentence-level. Specifically, we combined multiple systems trained with different hyperparameters, encoder size and pre-training setups. In the case of word-level predictions, we aggregate multiple predictions into OK/BAD tags by following the *ensemble-tags* procedure from Rei et al. (2022b). In this approach, we combine the predicted tags of each model: for every input segment, we get a combined tag, $\alpha \sum_{i \in \mathcal{M}} w_i c_i$, where c_i is the tag predicted by the model and α is the weight for the BAD tag. We use Optuna to determine the optimal weights w_i for each model and the optimal BAD weight α for each LP. In the final submission, we combine six models (five PE models and one MQM model). Five of these models use InfoXLM as the encoder model, and one PE model uses XLM-R XL.[9] Refer to Table 2 for the test set results.

3.2 Task 2: Fine-grained error span detection

In this task, we investigated three distinct approaches. The first approach extends word-level models by modifying their output predictions. More precisely, it involves transforming consecutively predicted BAD tags into character-level error spans, rather than categorizing individual words based on the first subword. To determine the error severities of these spans, we considered two options: labeling all the subwords within the span as either MINOR or MAJOR. Our best results were achieved with the latter approach.

The second approach leverages XCOMET (Guerreiro et al., 2023) in conjunction with a pseudo-reference obtained from DeepL or Google Translate.[10] Similar to our models from Task 1 word-level, XCOMET is trained with a multitask objective. Additionally, XCOMET is simultaneously optimized for both reference-free and reference-based evaluation, following UNITE (Wan et al., 2022). During inference, XCOMET can leverage a reference translation to enhance error identification. Since we employ a pseudo-reference that may contain translation errors, we initially assess the quality of the pseudo-reference using a generic QE system from Task 1 (reference_score). For all pseudo-references with a score below 0.5, we run XCOMET with QE-only input. For pseudo-references scoring above 0.5, the input weights for XCOMET are determined as follows:

$$\begin{aligned} \text{diff} &= 1 - \text{reference\_score} \\ \text{src\_weight} &= 2 \cdot \text{diff} \\ \text{ref\_weight} &= (1 - \text{src\_weight}) \cdot 0.4 \\ \text{uni\_weight} &= (1 - \text{src\_weight}) \cdot 0.6 \end{aligned}$$

Here, `src_weight` represents the weight assigned to the source-only input, `ref_weight` de-

[9] We found it hard to obtain performance boosts by scaling up to XLM-R XL on the word-level task. As such, we did not experiment with XLM-R XXL.

[10] We choose the best translation using the generic XXL model from task 1.

notes the typical metric input (reference-only input), and `uni_weight` represents a unified input where the model receives all three sentences (translation, source, and reference). Notably, for pseudo-references with a QE score of 1, we rely solely on a reference-only input and the unified input. We refer to this approach as XCOMET-PS-REF.

We also contrast the aforementioned approaches with two unconstrained QE systems: UnbabelQi and GPT-4, as mentioned in Section 3. We refer to these approaches as UNBABELQI and GPT4-QE, respectively.

4 Experimental Results

We present the results on the official test set for each of the tasks for multiple model/data configurations. Sentence-level submissions were evaluated using the Spearman rank correlation. Pearson and Kendall correlation were also used as secondary metrics, but here we report only Spearman since it was the primary metric used to rank systems. word-level submission were evaluated using MCC, F_1-OK, and F_1-BAD, but we report only MCC as it was considered the main metric. Error span detection was evaluated using F_1 score in which the positive labels are all the characters belonging to erroneous spans. Furthermore, each true positive is downweighted to half if the system failed to classify the error span's severity (e.g., MINOR instead of MAJOR). The submitted systems were independently evaluated on in-domain and zero-shot LPs for direct assessments and MQM.

4.1 Quality Estimation

Sentence-level. Results for sentence-level are presented in Table 1. Results indicate that retraining the system from the previous year, specifically COMETKIWI with InfoXLM, using data that encompasses this year's DA, leads to significant improvements. Remarkably, this improvement in correlations is achieved while maintaining the same level of correlations for *en-de* (a high-resource language pair for which both models share the same data) and *he-en*, a language pair that both models had not seen during training. Surprisingly, there was a drop in correlations for *zh-en* even though both models saw the same *zh-en* data. Nevertheless, the overall performance of the newly retrained version improved by 4.4 Spearman points.

As anticipated, among the three backbone transformers, the XXL model is the top performer, with significant improvements across all language pairs when compared to InfoXLM. Moreover, additional finetuning on this year's training data results in further improvements for the Indian languages. Notably, concerning the MQM data, this supplementary finetuning step not only preserves performance but sometimes even increases it. Similar to last year, the ensemble of high-performing models once again makes up our best submission.

Finally, despite performing well in Task 2, GPT4-QE shows poor correlations at sentence-level prediction with the exception of the *en-de* for which GPT4-QE, although lagging behind the ensemble approach, surpasses our individual models.

Method	Post-edit		MQM			
	en-fa†	en-mr	en-de	zh-en	he-en†	avg.

Table 2: Results for word-level QE in terms of MCC for the post-edit and MQM LPs. The ensemble is composed by multiple post-edit and MQM models. We represent zero-shot LPs with †.

Word-level. We report the best individual systems Table 2. Our best individual systems were trained on top of the InfoXLM L generic model. For PE models, we used multi-task objective in Eq. 4, as we found that combining the sentence-level and word-level loss was beneficial. However, for MQM models, we trained word-level only models, by setting $\lambda_{\text{SL}} = 0.0$ and $\lambda_{\text{WL}} = 1.0$.

Interestingly, we found that PE models are very competitive on MQM language pairs. For example, the best overall performance for *he-en* was actually obtained with a PE word-level model. This is also reflected on the Optuna weights obtained for our final ensemble, wherein the weights of the PE models are significantly higher than those of the MQM models for all language pairs but *en-de*. In fact, our final ensemble for *en-zh* and *en-he* consists solely of PE models trained with different learning rates, λ_{SL}, λ_{WL} and w. Further investigation on two different vectors may lead to improved word-level models: (i) balancing DA and MQM word-level annotations, and (ii) appropriately leveraging the larger capacity of scaled up encoder models.

Fine-grained error span detection. Results for fine-grained error span detection are shown in Table 3. Using a word-level model to obtain error span predictions leads to reasonable performance, comparable to our unconstrained submission, UNBABELQI, a model directly tasked with error span detection. That said, XCOMET-PS-REF, an error span detection model, surpassed both of the previous approaches. We attribute the improved performance to this system being an ensemble of two significantly larger models, and to the usage of a pseudo-reference. We found the latter to be particularly beneficial on *he-en*, a language pair for which we had no training data.

Method	en-de	zh-en	he-en†	avg.
2nd place (Li et al., 2023)				0.165
Baseline	0.167	0.219	0.083	0.156
WORD-LEVEL	0.235	**0.272**	0.105	0.204
XCOMET-PS-REF	0.259	0.270	**0.125**	0.218
UNBABELQI	0.249	0.227	0.111	0.196
GPT4-QE	**0.273**	0.265	0.121	**0.220**

Table 3: Results for fine-grained error span detection (Task 2). Evaluation metric is F_1 score. We represent zero-shot LPs with †. The first two systems are constrained while the other two are unconstrained submissions.

The best approach in terms of average F_1 was GPT4-QE, mostly due to the improved performance on *en-de*. While this is a promising finding for LLM-based quality estimation systems, there are limitations. First, obtaining a sentence-level score from the error spans (as per the MQM framework) leads to poor correlations with human judgements derived from DA (see Table 1) and with low-resource language-pairs like *he-en*. Second, despite being useful in practice and leading to gains in F_1, it is hard to control GPT's precision and recall. We found that the number of examples included in the prompt, their ordering, and the number of errors within each example led to noticeable changes in the system's propensity to flag errors. Thirdly, running QE with a system such as GPT-4 is expensive and slow even for a shared task exercise.

5 Final Remarks

We describe Unbabel and IST joint submission to WMT23 QE shared task. Our approaches correlate well with human judgements for all the three granularities of translation quality prediction, ranking first in all multilingual tasks and surpassing the pre-

vious state-of-the-art model, COMETKIWI-22, by up to 10 Spearman correlation points. Overall, our models follow the same architecture of last year's participation, COMETKIWI. However, this year we leverage more data and larger encoder models. Our best final systems are ensembles of different models trained on DA, post-edits or MQM scores that complement each other. Interestingly, our best systems surpass GPT-4 by a large margin for sentence-level translation quality prediction, and they are comparable to GPT-4 at error span detection.

Abstract

Quality Estimation (QE) systems are important in situations where it is necessary to assess the quality of translations, but there is no reference available. This paper describes the approach adopted by the SurreyAI team for addressing the Sentence-Level Direct Assessment shared task in WMT23. The proposed approach builds upon the TransQuest framework, exploring various autoencoder pre-trained language models within the MonoTransQuest architecture using single and ensemble settings. The autoencoder pre-trained language models employed in the proposed systems are XLMV, InfoXLM-large, and XLMR-large. The evaluation utilizes Spearman and Pearson correlation coefficients, assessing the relationship between machine-predicted quality scores and human judgments for 5 language pairs (English-Gujarati, English-Hindi, English-Marathi, English-Tamil and English-Telugu). The MonoTQ-InfoXLM-large approach emerges as a robust strategy, surpassing all other individual models proposed in this study by significantly improving over the baseline for the majority of the language pairs.

1 Introduction

The primary objective of quality estimation (QE) systems is to assess the quality of a translation without relying on a reference translation. This make QE valuable within translation processes, as it enables the determination of whether an automatically generated translation is sufficiently accurate for a specific purpose. This aids in deciding whether the translation can be used as is, requires human intervention for full translation, or necessitates post-editing by a human translator (Kepler et al., 2019b). Quality estimation can be conducted across various levels: word/phrase level, sentence level and document level. This paper considers only the sentence-level QE and presents our participation in the WMT23 Sentence-level direct assessment (DA) shared task. In the context of this task, participating systems are required to predict the DA score for a given (source, target) pair. This score serves as a measure of the translation quality.

Building upon the ideas presented in TransQuest by Ranasinghe et al. (2020b), our investigation explores the use of various pre-trained models within the MonoTransQuest architecture for the sentence-level quality estimation shared task. The architecture employs autoencoder pre-trained language models to fine-tune the QE data to predict a score which indicates the quality of translation. Using the MonoTransQuest architecture as the base we employ the pre-trained transformers separately to implement the systems MonoTQ-XLMV, MonoTQ-InfoXLM-large and MonoTQ-XLMR-large. In addition, we propose ensembleTQ which combines the output of MonoTransQuest when using different pre-trained models. All the proposed systems achieve a significantly higher Spearman correlation score compared to the baseline.

The paper is structured as follows. Section 2 briefly presents related work on quality estimation. Section 3 provides a concise overview of the dataset used in the sentence-level QE shared task. Moving on to Section 4, we introduce the autoencoder pre-trained language models and proposed systems and detail the training methodology. Section 5 is dedicated to the evaluation and Section 6 comprises the result and discussion. The paper concludes by summarizing findings, highlighting conclusions, and suggesting potential avenues for future research in the final section.

2 Related work

Quality estimation in machine translation has evolved significantly throughout the years. Initially, it relied on feature engineering and conventional machine learning techniques like SVM and basic

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 849–855

neural networks (Specia et al., 2015; Scarton and Specia, 2014). However, Neural Networks has since become central to quality estimation, where there is no more need of feature engineering, and the models can be trained directly on the data (Kepler et al., 2019b,a; Specia et al., 2018). Recently, Transformer-based architectures have arisen as robust solutions for machine translation and quality estimation. Notably, there are two widely recognized frameworks that leverage this transformative approach for QE tasks: TransQuest (Ranasinghe et al., 2020a) and CometKIWI (Rei et al., 2022).

Ensemble methods have also been explored extensively in Quality Estimation tasks (Bao et al., 2022; Geng et al., 2022; Kepler et al., 2019b; Ranasinghe et al., 2020b; Rei et al., 2022). The ensemble approach from Lim and Park (2022) using K-folds consistently outperformed the standard method, underscoring the prevalent belief that ensemble strategies enhance performance outcomes. However, some of the research studies (Ranasinghe et al., 2020b; Bao et al., 2022; Rei et al., 2022) show that combining multi-lingual models through ensembling yields better results than the traditional k-fold ensemble technique. Geng et al. (2022) suggest an alternative ensemble method that merges the results from models trained using various sentence-level metrics.

Our study delves into the performance of cutting-edge pre-trained transformer-based approaches when applied to sentence-level Quality Estimation tasks.

3 Dataset

We focus on Sentence-Level Direct Assessment tasks which comprise datasets for 5 language pairs which has English on the source side and Indian languages on the target side: English-Gujarati (En-Gu), English-Hindi (En-Hi), English-Marathi (En-Mr), English-Tamil (En-Ta) and English-Telugu (En-Te). Among these language pairs, En-Hi language pair is considered mid-resourced and all the other language pairs are low-resourced. Each language pair includes around 7,000 sentence pairs in the training set, as well as around 1,000 sentence pairs in both the development and testing sets. Each translation was evaluated by three professional translators who assigned a score between 0 and 100. These Direct Assessment (DA) scores were normalized using the z-score. The final score for the sentence-level task requires predicting the mean DA z-scores for the test sentence pairs. More details on this can be found in Zerva et al. (2022).

4 Methodology

This section outlines the approach taken to formulate our quality estimation techniques. We begin by detailing the autoencoder pre-trained language models employed in our architecture. Then we explain the architecture and the strategy employed to train these network architectures in detail.

4.1 Pre-trained models for fine-tuning

1. XLMR-large

   XLM-Roberta (Conneau et al., 2020) is a pre-trained transformer-based language model which is a part of the Cross-lingual Language Model (XLM). This model employs large-scale cross-lingual pre-training to capture contextual information and representations across 100 languages. The model is trained on 2.5TB of filtered CommonCrawl data from multiple languages, allowing it to effectively learn cross-lingual and language-specific patterns. The XLM-R architecture takes sequences as input, with a maximum token limit of 512, and generates contextualized embeddings for each token, enabling it to perform well on various natural language processing tasks across different languages (Ranasinghe et al., 2020b, 2021).

2. XLMV

   XLMV is a multilingual language model with a one million token vocabulary trained on 2.5TB of data from Common Crawl (same as XLM-R) (Liang et al., 2023). In the context of large multilingual language models, a common practice involves employing a single vocabulary shared across a diverse set of languages. Even with the expansion in model complexity, including parameter count and depth, the vocabulary size has remained relatively static. This constraint in vocabulary hampers the potential of multilingual models such as XLM-R to capture nuanced representations effectively (Wang et al., 2019).

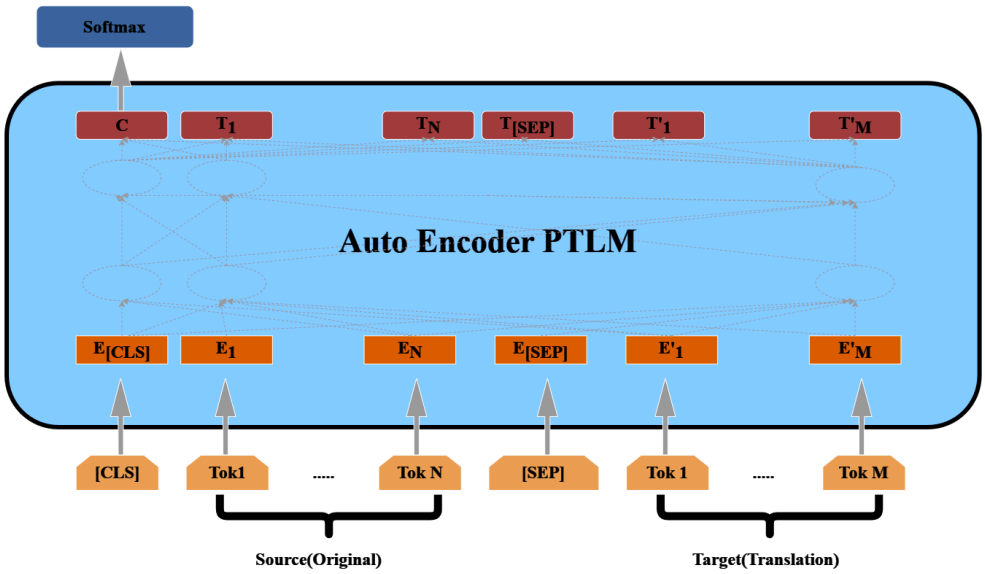

Figure 1: Architecture diagram of the proposed approaches

XLMV introduced an innovative strategy addressing this issue by achieving scalability to extensive multilingual vocabularies. XLMV involves prioritizing vocabulary allocation based on language-specific lexical overlap, ensuring sufficient coverage for each language. The outcome is tokenizations that hold enhanced semantic significance and are generally more concise compared to those generated by XLM-R.

3. InfoXLM-large

   InfoXLM-large (Chi et al., 2021), is an information-theoretic framework for cross-lingual language model pre-training. It extends the XLM-R architecture by formulating cross-lingual pre-training to maximize mutual information between multilingual texts at different granularities. This approach enhances the model's capability to learn effective cross-lingual representations by capturing shared information across languages. InfoXLM-large introduces a novel pre-training task based on contrastive learning, treating bilingual sentence pairs as views of the same meaning. By jointly training on monolingual and parallel corpora, the model improves the transferability of its representations for various downstream cross-lingual tasks (Rei et al., 2022; Bao et al., 2022).

4.2 Architecture

The proposed architecture of MonoTransQuest employs a pre-trained language model as shown in Figure 1. The MonoTransQuest architecture in TransQuest (Ranasinghe et al., 2020b) considers only the XLMR transformer model. In our proposed system, we train multiple multilingual QE models by fine-tuning autoencoder pre-trained language models (PTLMs) and report mean z-scores. The PTLMs are namely XLMV, InfoXLM-large, and XLMR-large which we have explained in section 4.1. The model's input consists of the original sentence (source) and its translation (target) concatenated, with a [SEP] token. This token marks the separation of the original sentence and the translated sentence. The pre-trained auto-encoder accepts input sequences with a token limit of 512 and produces a sequence representation as output. The initial token of the sequence is [CLS] token, encompassing a distinctive embedding to signify the entire sequence. Subsequently, embeddings are assigned to each word in the sequence. Ranasinghe et al. (2020b) highlights the superiority of the CLS-strategy over the MEAN-strategy (calculating the mean of all output vectors corresponding to the input words) and MAX-strategy (determining the maximum value across the output vectors of input words) for pooling within the MonoTransQuest framework. We have used the CLS-strategy (using the output of the [CLS] token) to extract the output from the transformer model. Consequently, we employed

Table 1: Spearman (ρ) and Pearson (r) correlation between the proposed approach predictions and human DA judgments. The best Spearman score obtained for each language pair (any method) is marked in bold. Rows II, III, and IV indicate the single-configuration settings of MonoTransQuest architecture with different pre-trained transformer models as explained in Section 5.1, and ensembleTQ in row V is explained in Section 5.2. The baseline results are in Row I.

the [CLS] token's embedding as input for a softmax layer. The softmax layer predicts the translation's quality score. The mean-squared-error loss function was used as the objective function for training.

4.3 Training and Implementation Details

We started the training with MonoTQ-XLMV which incorporates the XLMV-base model with MonoTransQuest for all 5 language pairs. We had the batch size as 8. We have used Adam Optimizer (Kingma and Ba, 2014) with a learning rate of 2e-5. The model is trained using 3 epochs. The training process exclusively utilized the training data. Early stopping was enforced if the evaluation loss failed to show improvements over ten consecutive evaluation rounds. We continued the training with the same set of configurations for MonoTQ-InfoXLM-large and MonoTQ-XLMR-large separately. MonoTQ-XLMV and MonoTQ-InfoXLM-large required twice the training time compared to MonoTQ-XLMR-large which required approximately 40 minutes of training on a GPU with 48GB of memory.

The proposed systems are built upon the most up-to-date version of `TransQuest`[1] framework and executed using Python 3.9 and PyTorch 2.0.1. The integration of pre-trained encoders (`XLMV`[2], `XLMR-large`[3] and `InfoXLM-large`[4]) into the MonoTransQuest architecture was facilitated through the application of HuggingFace's Transformers library.

5 Evaluation

In this section, we outline the evaluation outcomes of our models. We assess the performance of the proposed models under two circumstances: single model configuration and ensembleTQ.

The primary evaluation criterion employed was Spearman's rank correlation coefficient (Sedgwick, 2014), which is a statistical measure used to evaluate the strength and direction of association between two variables. Also, we have calculated the Pearson correlation coefficient (Cohen et al., 2009) as a secondary metric for the evaluation. In the context of Quality Estimation (QE) for machine translation, it is used to evaluate the correlation between the machine-predicted quality scores and the gold standard labels provided by human annotators in the test dataset. Spearman's rank correlation coefficient assesses the monotonic relationship between the two variables, unlike the Pearson correlation (Cohen et al., 2009), which measures the linear relationship between two variables. It is calculated by first ranking the values of both variables in ascending or descending order and then computing the Pearson correlation coefficient between the two sets of ranks. Spearman's rank correlation coefficient is often preferred because it is less sensitive to outliers and non-linear relationships between the predicted scores and human scores.

Table 2: Spearman (ρ) and Pearson (r) correlation between the predictions from the participated systems in WMT23 sentence-level QE shared task and human DA judgments. The best Spearman and Pearson score obtained for each language pair is marked in bold. Even though we have experimented with the single model configurations, we only submitted our ensembled approach (SurreyAI-ensembleTQ) for the shared task competition.

5.1 Single model configurations

Initially, our evaluation focused on the single model configurations of the proposed framework. This involved training a quality estimation model using a single autoencoder pre-trained language model on the training data for each language pair separately. Subsequently, we assessed each model's performance (MonoTQ-XLMV, MonoTQ-InfoXLM-large, MonoTQ-XLMR-large) on the corresponding test set for each language pair. The outcomes of this evaluation for the single model configuration are presented in Table 1.

5.2 EnsembleTQ

Recently, ensemble techniques have demonstrated their efficacy in enhancing transformer-based models' performance (Xu et al., 2020). Following this approach, we employed an ensemble strategy to experiment further to see whether it enhance the performance. For every input within the test set, we aggregate the output scores from various distinct pre-trained models integrated into the MonoTransQuest architecture. Subsequently, we calculate the average of the cumulative score, divided by the number of pre-trained models, resulting in the ensembleTQ score. Finally, we compute the Spearman and Pearson correlation scores for the ensembleTQ score, providing a comprehensive evaluation of our ensemble approach.

6 Result and Discussion

The research is divided into two distinct settings, as outlined in Sections 5.1 and 5.2. The primary evaluation metric employed in this study is the Spearman correlation coefficient.

As shown in Table 1, is notable that the baseline model does not surpass our proposed approaches in terms of Spearman correlation scores in most cases. This outcome underscores the specific strengths and limitations associated with different model architectures. Complementing the Spearman correlation analysis, the examination of Pearson correlation scores further enriches the assessment. The MonoTQ-InfoXLM-large model consistently exhibits superior Pearson correlation scores across a majority of the language pairs, accentuating its robust performance characteristics.

From our experiment results, as shown in Table 1, it's notable that the single-model configuration of MonoTQ-InfoXLM-large and MonoTQ-XLMV outperform ensemble-TQ for the majority of the language pairs. Observing the results outlined in both Table 1 and Table 2, it becomes evident that MonoTQ-InfoXLM-large and MonoTQ-XLMV not only outperform other systems among our own proposed approaches, they also exhibit a competitive performance with the best-performing system in the WMT23 sentence-level shared-task. MonoTQ-InfoXLM-large shows a very close Spearman correlation score with the winning system of the WMT23 sentence-level task for the En-Gu, En-Hi and En-Ta language pairs. Also, MonoTQ-XLMV shows the highest Spearman

Table 3: Rows 1-5 display the disk footprint of ensemble model submissions related to the sentence-level task for WMT23. Meanwhile, Rows 6-8 present the disk footprint of our TQ models with single model configuration.

correlation score for the En-Te language pair. This observation raises the question that do the practice of ensembling always guarantees performance enhancement. Table 3 presents the memory requirements of both ensemble approaches and single-model configurations. Interestingly, in most cases ensemble models demand significantly more memory space than single-model setups, despite only offering a marginal boost in performance. This observation prompts us to reconsider the efficiency of employing ensemble models.

The conducted experiments across mid-resourced and low-resourced language pairs unravel intricate performance dynamics among various models.

7 Conclusion

This paper comprehensively evaluates the proposed architecture within the context of sentence-level direct quality assessment, employing diverse encoder-based pre-trained models. Our investigation notably highlights the enhanced performance attributed to the MonoTQ-InfoXLM-large, which surpasses the other configuration approaches, namely MonoTQ-XLMV, ensembleTQ strategy and MonoTQ-XLMR-large. While our outcomes in the WMT23 sentence-level Direct Assessment task did not attain peak performance, they nevertheless exhibited a marked improvement over the baseline and showed notable performance scores close to the winning systems.

Looking ahead, our research trajectory anticipates a continued exploration of quality estimation employing large language models. This involves further experimentation encompassing a broader spectrum of low-resourced language pairs. These forthcoming endeavours aspire to deepen our insights into the intricacies of direct quality assessment and contribute to advancing the frontiers of natural language processing. Also, we are focused on continuing the experimentation of pre-trained language models incorporated into different QE frameworks.

Abstract

This paper presents our submission to the WMT 2023 Quality Estimation (QE) shared task 1 (sentence-level subtask). We propose a straightforward training data augmentation approach aimed at improving the correlation between QE model predictions and human quality assessments. Utilising eleven data augmentation approaches and six distinct language pairs, we systematically create augmented training sets by individually applying each method to the original training set of each respective language pair. By evaluating the performance gap between the model before and after training on the augmented dataset, as measured on the development set, we assess the effectiveness of each augmentation method. Experimental results reveal that synonym replacement via the Paraphrase Database (PPDB) yields the most substantial performance boost for language pairs English-German, English-Marathi and English-Gujarati, while for the remaining language pairs, methods such as contextual word embeddings-based words insertion, back translation, and direct paraphrasing prove to be more effective. Training the model on a more diverse and larger set of samples does confer further performance improvements for certain language pairs, albeit to a marginal extent, and this phenomenon is not universally applicable. At the time of submission, we select the model trained on the augmented dataset constructed using the respective most effective method to generate predictions for the test set in each language pair, except for the English-German. Despite not being highly competitive, our system consistently surpasses the baseline performance on most language pairs and secures a third-place ranking in the English-Marathi[1].

1 Introduction

Quality Estimation (QE) strives to assess the output of Machine Translation (MT) systems without the availability of a reference translation of known high quality (Blatz et al., 2004; Specia et al., 2009, 2013; Kanojia et al., 2021). This capability serves as a valuable asset for expediting and cost-effectively facilitating the evaluation phases throughout the development cycle of MT systems.

In this paper, we describe our contribution to the QE shared task at the Eighth Conference on Machine Translation (WMT23). We participate in the Task 1 of the shared task and we specifically focus on the sentence-level subtask, which centers on predicting the quality score of neural MT outputs at the sentence level without access to reference translations. Our study encompasses six language pairs: *English-German (En-De)*, *English-Marathi (En-Mr)*, *English-Hindi (En-Hi)*, *English-Tamil (En-Ta)*, *English-Telegu (En-Te)*, *English-Gujarati (En-Gu)*, with annotations derived in two different ways: multi-dimensional quality metrics (MQM) (Freitag et al., 2021) and direct assessments (DA) (Fomicheva et al., 2022). Participating systems are assigned the task of predicting the quality score (MQM or DA) for each source-target sentence pair, and their performance is evaluated using Spearman's rank correlation coefficient as the primary metric, supplemented by the Kendall and Pearson coefficients as secondary metrics for assessment.

Our approach investigates the potential to enhance the performance of QE models by exposing them to a diverse range of training examples. To this end, we identify eleven different data augmentation methods and apply each of them individually to augment the training set for each language pair. Our results reveal that, for most language pairs, these methods result in varying degrees of performance improvement, with the most effective methods being synonym substitution using the PPDB, words insertion guided by contextual word embeddings, back-translation, and direct paraphrasing. We also show that for some language pairs, it

[1]Our code and data are available at https://github.com/Yulong-W/DataAug-QE.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 856–862
December 6–7, 2023.

is feasible to further enhance the model's performance by training it on an augmented set formed through the amalgamation of part or all of the said augmentation methods; however, the extent of improvement remains constrained. For each language pair except English-German, we generate predictions utilising the model trained on the augmented dataset constructed through the respective most effective method. Although our submission may not be considered highly competitive, they consistently achieve significantly improved performance compared to the organisers' baseline for the majority of language pairs. Notably, for the English-Marathi pair, our submission ranks third place with the Spearman score of 0.650. This observation indicates that the training data augmentation approach may hold particular promise and offer advantages when applied to the English-Marathi language pair.

2 Methodology

As mentioned above, we identified a total of eleven distinct data augmentation methods, as detailed in Table 1. For all the given source sentences and their corresponding MT hypothesis in the training dataset for each language pair, each method is independently applied only to the source sentences, leading to the creation of the respective transformed source-target sentence pairs. Our hypothesis posits that training the QE model on the augmented training set, which incorporates these transformed instances, holds the potential to bolster its performance. For each original instance, we generated one augmented sample per method and assigned to the augmented data the same quality score as the original translation hypothesis. However, it is noteworthy that certain methods, such as AS and RD, possess the potential to alter the meaning of the source-side sentence (Kanojia et al., 2021), consequently inducing changes in MT output and, by extension, the assigned quality label. In such instances, there is a likelihood of introducing noises to the augmented training dataset. A systematic exploration of the meaning-preserving capacity of these perturbation methods and the impact of those introduced noises at training time on the performance of the model necessitates further investigation.

3 Experiments

In this section, we describe our experimental settings, present the results achieved on the development and test sets, and perform analysis derived from our experimental findings. We additionally offer insights into the influence of the quantity of augmented training examples on the performance of the QE model.

3.1 Experimental Settings

Language Pairs (LPs). We conducted experiments on six language pairs. The training, development, and test datasets for each language pair utilised in our study are accessible via the shared task website[2], and we present the dataset statistics in Table 2. We applied each data augmentation method on the source sentences in the training set of each language pair.

Models. Our training methodology adheres to the PyTorch-based COMET framework (Rei et al., 2020), with the foundational pre-trained model be-

[2] https://wmt-qe-task.github.io/subtasks/task1/

LPs	Training	Development	Test
		MQM	
En-De	28909	1005	1897
		DA	
En-Mr	26000	1000	1086
En-Hi	7000	1000	1074

En-Te	7000	1000	1075
En-Gu	7000	1000	1075

Table 2: Number of examples in the training, development and test set, respectively, for each language pair.

ing XLM-RoBERTa-large (Conneau et al., 2020). We fine-tuned the pre-trained XLM-RoBERTa-large model on the original and the augmented training sets for each language pair, respectively and evaluated them on the development set. The best-performing model was chosen from those trained on the corresponding augmented training datasets (in the case of English-German, the chosen model was trained on the augmented dataset created by applying the top four[3] effective data augmentation techniques to each source sentence) to generate the predictions on the test set. All experiments were conducted using 2 16GB Nvidia v100 GPUs.

Data Augmentation Methods. Methods WSS to BT: We utilised the NLPAug library (Ma, 2019) to perform the augmentation. In method PSS, we used the small size English PPDB (Pavlick et al., 2015). In the absence of any synonymous expressions documented for all the words within a source-side sentence in methods WSS and PSS, the augmented sample will persist unaltered in comparison to its original version. For methods WSS to CWS, the percentage of word will be augmented is set to the default value of 0.3, as in the implementation of the NLPAug library (Ma, 2019). In method BT, a sentence is translated from English to German, then back to English to obtain its paraphrased version (Ng et al., 2019). Method DP: Direct paraphrasing was performed by soliciting a Generative Pre-trained Transformer (GPT) (Brown et al., 2020) series model, specifically GPT-3.5-turbo, to generate responses for the prompt: *Generate a similar paraphrase for this sentence: [source sentence]*, using the OpenAI ChatGPT API.

[3]At the time of results submission, this number (i.e., 4) was randomly set. However, as illustrated in Figure 1, augmenting the training dataset for the English-German language pair using the best two methods yielded the most optimal performance.

3.2 Evaluation Results and Discussion

Table 3 illustrates the performance gap of the QE model on the development set before and after training on each augmented dataset created through the respective data augmentation method for each examined language pair. As can be seen from Table 3, in the majority of instances, the training data augmentation approaches demonstrated their effectiveness in enhancing the performance of the QE model. In the following, we discuss the observations for all the studied language pairs.

English-German. Method PSS exhibited the most significant performance improvement across all three evaluation metrics. Augmenting the training set with method CWI yielded the same improvements in terms of Spearman and Kendall correlations compared to augmenting it with PSS, albeit resulted a lower Pearson score. However, it was observed that presenting the model with modified training examples generated using method WSS and RS did not contribute to the enhancement of Spearman correlation. In fact, it even had an adverse effect, causing a slight reduction (0.3%) in the Kendall score.

English-{Marathi, Gujarati}. Training the model on the augmented set incorporating examples generated by substituting words with synonyms from PPDB (method PSS) proved to be the most effective approach in enhancing the correlation between the predictions of the model and human judgments of quality, with Spearman correlation increased by 6.8% and 7.1%, respectively. Other types of approaches also resulted in varying degrees of performance improvement.

English-{Hindi, Tamil}. For the English-Hindi language pair, augmenting the training set with both CWI and DP has been observed to yield identical improvements in terms of Spearman and Kendall correlations, emerging as the most effective approach. In the case of English-Tamil, the most notable enhancement was achieved by paraphrasing the source sentences in the original training dataset using the GPT-3.5-turbo model (method DP), as measured by Spearman and Kendall correlations. However, concerning the Pearson metric, method BT (back-translation) led to the most substantial improvements for both language pairs, amounting to 12.6% and 10.8%, respectively.

Table 3: The performance (%) of the QE model trained on the original, and the augmented training sets generated through applying the data augmentation methods, when evaluated on the development set for the examined language pairs. Values shown in the shaded areas are changes (%) relative to the original performance of the model, with the rightmost column shows their averages in terms of Spearman correlation. We highlight the values that denote the most substantial performance improvements across the Spearman, Kendall, and Pearson metrics.

English-Telegu. Our experimental training data augmentation approach was found to be notably ineffective when applied to the language pair English-Telegu. As shown in Table 3, in regard to Spearman and Kendall correlations, only method CWI yielded slight performance improvements, while the other approaches predominantly resulted in a decrease in the performance of the model. Indeed, these alternative approaches led to varying degrees of performance decline, with the most significant decrease being 4.2% in Spearman and 3.6% in Kendall, respectively. This may be attributed to the heightened sensitivity of English to Telegu translation concerning modifications applied to the source sentences. Consequently, noises might be introduced during the process of augmenting the training set, thereby contributing to a decline in the performance of the QE model.

Overall, our investigation revealed that, for the examined language pairs, method PSS yielded a relative performance increase of 3.8% on average, establishing itself as the most effective, with the second-best being CWI (3.5%). Interestingly, both method BT and method DP, designed for paraphrasing purposes, exhibited an identical average performance improvement of 2.8%. Conversely, the average increase was only 1.0% for method WSS, despite sharing the same objective of synonym substitution with method PSS. This suggests that employing synonym substitution via the English PPDB confers greater benefits to enhancing the performance of the QE model compared to performing it via WordNet. Furthermore, potential meaning alternation methods, such as AS and RD (Kanojia et al., 2021), yielded a lower average enhancement compared to some meaning-preservation methods like BT and DP. However, additional experimental confirmation is requisite.

3.3 Official Test Results

Based on the insights derived from Table 3, we systematically selected the most efficacious approach to augment the training set for each language pair and trained the respective model. Subsequently, we utilised each resulting model to generate predictions on the corresponding test dataset. For English-German language pair, it was observed that the performance of the QE model (0.303 Spearman),

when trained on the augmented dataset generated by applying PSS, was inferior to the baseline score determined during our initial test phase. Therefore, we took the initiative to curate a new training set wherein four augmented examples were generated for each original sample, employing the top four data augmentation methods identified as correspondingly effective. We then employed the re-trained model to generate quality predictions for English-German pair. The performance of our submitted models is presented in Table 4[4].

LPs	Spearman	Kendall	Pearson
	MQM		
En-De	0.316	0.237	0.221
	DA		
En-Mr	0.650	0.466	0.663
En-Hi	0.494	0.345	0.570
En-Ta	0.547	0.384	0.531
En-Te	0.337	0.228	0.281
En-Gu	0.540	0.386	0.581

Table 4: Official results of our submission to the WMT sentence-level QE shared task 2023.

Our most promising results were observed in language pair English-Marathi, where our submission ranked third among the six participating teams. This highlights the effectiveness of the training data augmentation approach in improving the capability of the QE model to precisely predict the quality score of English-Marathi translation pairs in the absence of a reference. However, when considering English-German, despite training the model on an augmented dataset with larger and more diverse samples, its performance still falls below the baseline score (0.340 Spearman). This discrepancy suggests that data augmentation approach may not be as efficient in enhancing the QE performance for this specific language pair. Nevertheless, we observed that this performance (0.316 Spearman) remains slightly superior to that achieved with the training set containing fewer augmented samples (0.303 Spearman), which indicates that increasing the number of augmented training examples might contribute to enhancing the performance of the model, and we provide further elaboration in Section 3.4 below. In contrast, for the remaining four language pairs we investigated, the performance of our submitted models consistently outperformed the baseline score. Specifically, our submission demonstrated a notable enhancement over the baseline score in Spearman correlation for English-Hindi (+0.213), English-Telugu (+0.144), and English-Gujarati (+0.203), while the improvement for English-Tamil was comparatively less pronounced. Despite the above-baseline performance achieved, our submission is presently ranked fifth in these language pairs, signifying the necessity for additional investigation and refinement of our approach to attain elevated performance levels.

[4]A comparison of our results with the organiser's baseline and submissions from other participating teams is available at http://www2.statmt.org/wmt23/quality-estimation-task_results.html.

3.4 Impact of Training Example Quantity

Thus far, a singular augmented example has been generated corresponding to each defined augmentation method for every original training sample in our studied language pairs, with the exception of English-German. To examine the impact of the number of augmented samples on the performance of the QE model and to explore potential complementarity among these augmentation techniques, we trained the models for each language pair on augmented training sets of varying sizes, generated by employing the respective top N effective augmentation methods (where N ranges from 1 to 11), and then assessed their performance, as shown in Figure 1.

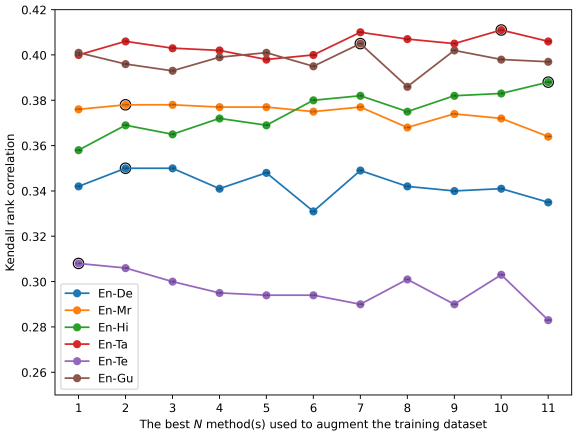

Figure 1: The performance of the QE models on the development set across six language pairs, trained on augmented datasets generated utilising the respective best N data augmentation methods. The optimal performance was denoted by encircling the respective data point with a black circle.

It can be seen from Figure 1 that for five lan-

guage pairs English-{Tamil, Gujarati, Marathi, Hindi, German}, increasing the number of augmented training samples can enhance the model's performance, although this phenomenon is not universal for certain language pairs, such as English-Tamil. However, we observed that there was a negligible degree of performance improvement across these five language pairs, with the most notable enhancement being merely 0.03 (from 0.358 to 0.388), as demonstrated in the case of English-Hindi. Even worse, for the language pair English-Telegu, exposing the model to a more diverse set of training examples resulted in a decline in performance. Notably, training the model on an augmented set comprising eleven augmented samples per original instance led to the nadir in performance, recording a value of 0.283. This underscores the constraints of current data augmentation methods in boosting the efficacy of the QE model, emphasizing the imperative to devise more effective approaches. Nonetheless, a positive insight has been discerned; the language pair English-Hindi appears to derive particular benefits from the augmentation of training examples. As the number of applied top N augmentation methods increased, the performance of the model consistently surpassed that of the model with only the best one applied, notwithstanding fluctuations in performance. Finally, based on the empirical findings depicted in Figure 1, definitive conclusion regarding the complementarity of specific data augmentation approaches cannot be drawn, as it is inherently specific to each language pair. For instance, the efficacy of combining the best two augmentation methods was observed in the English-{Marathi, German} pairs, whereas for English-{Tamil, Gujarati, Hindi}, optimal performance was attained through the amalgamation of the top 10, 7, and 11 training data augmentation methods, respectively.

4 Conclusion

In this paper, we proposed a training data augmentation approach to the WMT 2023 sentence-level QE shared task. We systematically identified eleven various data augmentation methods and applied each of them individually on the source-side sentences to generate augmented training samples for the six studied language pairs. The experimental results demonstrated that in most cases, these methods can enhance the correlation between the predictions of the QE model and human-provided quality scores to varying degrees, albeit not to a significant extent. In addition, we show that training the model on the augmented set, generated through the combination of these methods, contributed further to performance enhancement, although this phenomenon was not universally observed and the degree of improvement was at a negligible level. Our methodology yielded a third-ranking outcome for English-Marathi and a fifth-place ranking for other DA annotated language pairs, among the submissions from the six teams. In terms of future work, we intend to explore other more effective augmentation approaches and extend our study to encompass a more diverse array of language pairs and QE models.

Limitations

The work presented in this paper should be considered preliminary, given that we exclusively conducted experiments employing a training data augmentation approach and assessed its impact solely on the original development set. There is ample room for further exploration into the robustness of the QE model without any augmentation interventions on the studied perturbations and the impact of these proposed perturbations, when applied during training, on the capability of the QE systems to identify critical errors in translation resulting from modifications to the source sentences. Moreover, the extent to which the introduced perturbations may alter the meaning of the source-side sentences remains unclear, necessitating further investigation.

Acknowledgements

The authors would like to thank the University of Manchester Department of Computer Science Kilburn Scholarship, the Manchester-Melbourne-Toronto Research Fund 2022, and the Turing Scheme for supporting this work. We also express our sincere gratitude for the invaluable comments and suggestions provided by the anonymous reviewers and acknowledge the support of the Computational Shared Facility at The University of Manchester in facilitating the execution of our experiments.

Abstract

This paper presents the submissions of IOL Research in WMT 2023 quality estimation shared task. We participate in task 1 Quality Estimation on both sentence and word levels, which predicts sentence quality score and word quality tags. Our system is a cross-lingual and multitask model for both sentence and word levels. We utilize several multilingual Pretrained Language Models (PLMs) as backbones and build task modules on them to achieve better predictions. A regression module on PLM is used to predict sentence level score and word tagging layer is used to classify the tag of each word in the translation based on the encoded representations from PLM. Each PLM is pretrained on quality estimation and metrics data from the previous WMT tasks before finetuning on training data this year. Furthermore, we integrate predictions from different models for better performance while the weights of each model are automatically searched and optimized by performance on Dev set. Our method achieves competitive results.

1 Introduction

Quality Estimation (QE) is the task of predicting the quality of a target machine translation without using reference texts or human inputs (Specia et al., 2018). Since machine translation is in high demand nowadays, the development of QE system becomes crucial for the broad application of machine translation. In WMT 2023 Quality Estimation shared task, there are two tasks: quality estimation and fine-grained error span detection. This paper describes our submission to task 1 quality estimation in both sentence and word levels in detail.

Considering the powerful capability and widely used in previous QE tasks of pretrained language models (PLMs) (Zerva et al., 2022; Specia et al., 2021), our method utilizes different multilingual PLMs to encode *source-translation* sentence pairs and predict sentence-level scores or word-level tags. Such PLMs are pretrained on various languages which could show incredible ability when trained QE models are transferred to unseen language pairs. Meanwhile, extra task modules are added to PLMs to boost the interaction between source and translation sentences to make better predictions. Also, it is common that using other task data similar to QE can further improve the performance of QE. According to the results from previous years' QE tasks, we use the data from QE and Metrics tasks from previous years' WMT tasks, as well as Automatic Post-Editing (APE) data, to pretrain PLMs before training on data of this year.

Moreover, ensemble methods of different models are explored in sentence and word level tasks. For sentence level, we sum scores with weights from different models which are filtered by the performance on the Dev set. As for word level, we use voting or weighted sum of tag probabilities to get the final predicted tags. Taking zero-shot language pairs into account, we choose the best model evaluated on other language pairs to test if they can generalize to unseen language pairs.

2 Quality Estimation Task

2.1 Task description

WMT 2023 Quality Estimation task 1 contains two tasks. The sentence level task aims at predicting a quality score for *translation* and the word level task is to classify a quality tag for each word in *translation*. Both tasks have zero-shot language pairs to test the generalization ability of QE models and use the same *source-translation* pairs for each language pair.

Sentence level There are two types of quality scores. One is the Direct Assessments (DA) score which is given by human annotators for each *source-translation* pair. The other is the Multi-dimensional Quality Metrics (MQM) score which is defined and computed under MQM methodology.

Table 2: The statistics of dev and test data

A regression model is always employed to predict quality scores.

Word level The tags of words in *translation* are annotated by human annotators according to the MQM or DA annotations. This task requires predicting an OK or BAD for each word in *translation* given *source-translation* pairs. HTER (Specia and Farzindar, 2010)-like scores for translations can be collected by calculating the ratio of 'BAD' tags in tag sequence of *translations*. For example, given a tag sequence "OK OK BAD BAD OK", an HTER-like score is deduced by computing 2/5=0.4.

Data QE task provides official train and dev datasets gathered from competitions of previous years and the statistics are shown in Table 1 and Table 2. On account of the task similarity to QE, we also collect the MQM data (Freitag et al., 2021a,b) from previous WMT Metrics tasks[1] and APE data from QT21 (Specia et al., 2017) and APE-QUEST (Depraetere et al., 2020) to do further pretraining. We calculate HTER-like score for each *source-translation* pair in APE data for the purpose of merging with those of DA and MQM.

3 Method

3.1 Model architecture

We design distinct task modules on top of encoders for regression on sentence level and sequence tagging on word level. Source and translation texts are concatenated and input into the encoder and then task modules to get scores or tags. Our model architecture is illustrated in Fig.1.

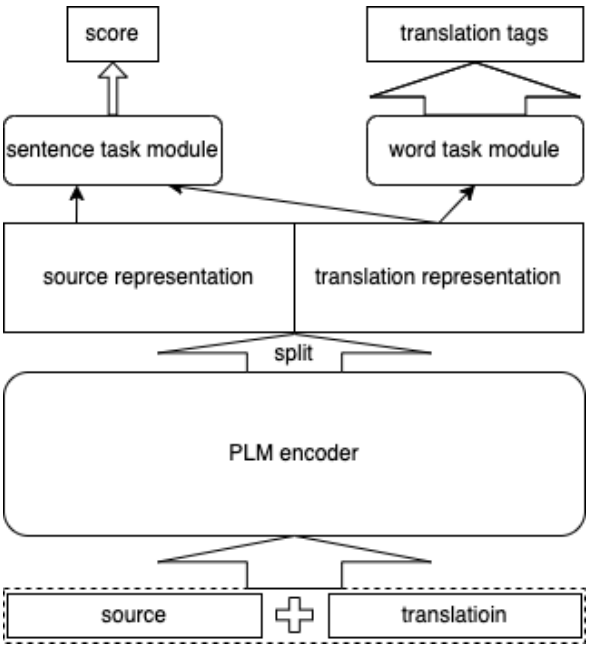

Figure 1: Model architecture with task modules for sentence-level scoring and word-level tagging

Sentence regression module Inspired by ESIM (Chen et al., 2017) and RE2 (Yang et al., 2019), the cross attention between *source* and *translation* reflects the similarity between words in different languages. Also considering that different layers in a transformer (Vaswani et al., 2017) based PLM catch different granularities of features of *source* and *translation* (Jawahar et al., 2019), we determine to combine these two kinds of methods to strengthen the representations of *source* and *translation*. In detail, for *source* s and *translation* t respectively, mixed layer-wise representations s_{mix} and t_{mix} from a PLM with L layers are computed in Eq. 1~Eq. 4.

$$s^l = mean\_pooling([s_1^l, s_2^l, ..., s_m^l]), \quad (1)$$

$$t^l = mean\_pooling([t_1^l, t_2^l, ..., t_n^l]), \quad (2)$$

$$s_{mix} = \sum_{l=1}^{L} w_s^l * s^l, \; where \sum_{l=1}^{L} w_s^l = 1 \quad (3)$$

$$t_{mix} = \sum_{l=1}^{L} w_t^l * t^l, \; where \sum_{l=1}^{L} w_t^l = 1 \quad (4)$$

Then cross attention outputs s_{ca} and t_{ca} from the last layer of PLM are calculated to get token level

[1] https://github.com/Unbabel/COMET

interactions between *source* and *translation* as shown in Eq. 5 ~Eq. 9.

$$e_{ij} = s_i^T t_j \tag{5}$$

$$s_i^{ca} = \sum_{j=1}^{n} \frac{exp(e_{ij})}{\sum_{k=1}^{n} exp(e_{ik})} t_j, \ \forall i \in [1, 2, ..., m] \tag{6}$$

$$t_j^{ca} = \sum_{i=1}^{m} \frac{exp(e_{ij})}{\sum_{k=1}^{m} exp(e_{kj})} s_i, \ \forall j \in [1, 2, ..., n] \tag{7}$$

$$s_{ca} = mean\_pooling([s_1^{ca}, s_2^{ca}, ..., s_m^{ca}]) \tag{8}$$

$$t_{ca} = mean\_pooling([t_1^{ca}, t_2^{ca}, ..., t_n^{ca}]) \tag{9}$$

Next, features of *source* and *translation* are fused separately to transform into a combined representation through feedforward network (FFN) layer by Eq. 10 and Eq. 11.

$$s_{comb} = FFN([s_{ca}; s_{mix}; |s_{ca} - s_{mix}|; s_{ca} * s_{mix}]) \tag{10}$$

$$t_{comb} = FFN([t_{ca}; t_{mix}; |t_{ca} - t_{mix}|; t_{ca} * t_{mix}]) \tag{11}$$

Finally, the sentence-level score is obtained by another FFN layer in Eq. 12.

$$score = FFN([s_{comb}; t_{comb}]) \tag{12}$$

Word tagging module We choose two distinct modules to generate tags for words after encoded by PLM. A Bidirectional-LSTM (Hochreiter and Schmidhuber, 1997) (BiLSTM) layer is added to enhance the interaction between the representations of *source* and *translation*, and a FFN layer on it to predict tags in *translation*. Another kind of module only adopts a FFN layer to generate tag predictions to avoid overfitting on training data.

Multitask combination In order to boost the individual performance of sentence level and word level models, we propose a multitask training approach. Both the regression module and tagging module are added to the encoder which predicts the sentence score like DA or MQM and word tags simultaneously. For language pairs that have no DA or MQM data but only word tags, we take HTER scores as sentence scores. We train word-level models by optimizing the prediction of HTER scores and word tags simultaneously. To not damage the potentiality of tagging module, some simple regression modules are used when doing multitask training, including

$$score = FFN(mean\_pooling(\mathbf{t}_{[1:n]})) \tag{13}$$

and

$$score = FFN([\bar{s}; \bar{t}; |\bar{s} - \bar{t}|; \bar{s} * \bar{t}]) \tag{14}$$

where $\mathbf{t}_{[1:n]}$ is the list of word representations of *translation* from tagging module, and $\bar{s}$ and $\bar{t}$ are the mean representations of words' representations of *source* and *translation* from the encoder.

Loss The losses for score regression, word tagging and multitask training are described as follows:

$$\mathcal{L}_{sent} = (score_{pred} - score_{true})^2 \tag{15}$$

$$\mathcal{L}_{word} = -\frac{1}{n} \sum_{i=1}^{n} \log p(y_i) \tag{16}$$

$$\mathcal{L}_{multitask} = \mathcal{L}_{sent} + \mathcal{L}_{word} \tag{17}$$

where $p(y_i)$ is the probability of OK/BAD tag from the model.

3.2 Score refinement

According to the similar definitions and score intervals of DA and MQM, we transform the score s out of [-1, 1] as close to [-1,1] as possible while keeping the Spearman correlation coefficient unchanged using Eq. 18 to lessen the need for predicting extreme values during training.

$$s' = \begin{cases} \text{(s+1)*0.1-1,} & \text{s} < -1 \\ \text{s,} & \text{-1} \leq \text{s} \leq 1 \\ \text{(s-1)*0.1+1,} & \text{s} > 1 \end{cases} \tag{18}$$

3.3 Encoder selection

QE requires texts from different languages as input, so we take multilingual PLMs as encoders which are pretrained on colossal multilingual corpus. The following PLMs are selected as encoders: XLM-Roberta-Large (Conneau et al., 2020)[2], RemBert (Chung et al., 2021)[3], InfoXLM-Large (Chi et al., 2021)[4] and mDeBERTa (He et al., 2021)[5]. Each PLM is combined with different task modules for training.

[4]https://huggingface.co/microsoft/infoxlm-large
[5]https://huggingface.co/microsoft/mdeberta-v3-base

3.4 Model Training

We first pretrain encoders with a simple regression head to do regression on WMT Metrics and HTER data while retaining the checkpoints of encoders with the best performance on Dev set. When using WMT Metrics data, we train two versions of models where one uses DA data only and the other uses a mix of DA and MQM data. Subsequently, we drop the regression head and then finetune the pretrained encoder with different task modules on multilingual QE data. In order to eliminate the possible side effect of position variation in *translation*, we swap the input order of *source* and *translation* as a comparison. We conduct single-task and multitask training for both sentence and word levels.

3.5 Ensemble methods

Sentence level For each language pair having training data, we randomly search weights for the weighted sum of the top 10 models in accordance with the Spearman correlation coefficient on Dev set. As for zero-shot language pairs, we pick the best two or three trained models from those language pairs having training data individually then predict and average the scores from them.

Word level We propose three strategies of tag prediction ensemble for each word. At first, for each language pair having training data, the top 10 models with the best Matthews Correlation Coefficient on Dev set are picked out. Therefore each word in *translation* has 10 predicted tags or 10 probability pairs of (OK, BAD) from different models. The final tag of one word is acquired in one of three ways:

1 if one of 10 tags is BAD, the final tag is BAD;

2 if one of 10 tags is OK, the final tag is OK;

3 if the weighted sum of probabilities of OK is larger than that of BAD, the final tag is OK, and vice versa.

When utilizing the third one, the weights of models are searched randomly as in sentence-level ensemble. As for zero-shot language pairs, we pick the best two trained models from those language pairs having training data individually and apply one of the above strategies to get final predictions.

4 Experiments

4.1 Settings

All our models are completed with PyTorch and transformers (Wolf et al., 2020)[6] and trained on NVIDIA GeForce RTX 3090 24G for the pretraining and finetuning described in 3.4. Models are trained with AdamW (Loshchilov and Hutter, 2017) with learning rate of 1e-5, max sequence length of 230, batch size of 16 and 3 epochs. Models with different task modules are optimized by selecting the checkpoint with the best Spearman correlation coefficient or Matthews Correlation Coefficient (MCC) on Dev set for each language pair separately. Three versions of PLM are pretrained as described in 3.4 for each combination of language pair and PLM, which are listed in the order of "DA-only, DA+MQM, HTER" in Table 4, Table 7 and Table 8 while Table 3 are only "DA-only, DA+MQM" for each language pair. Optuna (Akiba et al., 2019) is used to search the weights of model ensembles described in 3.5.

4.2 Results and Analysis

Sentence level For results in Table 3 of Dev set with MQM annotations, results based on mDeBERTa perform best in all settings. Models with PLMs pretrained on "DA-only" data achieve better results than those "DA+MQM" models which indicates that the difference in score range between DA and MQM has a great effect. For Table 7 of Dev set with DA annotations, models pretrained on "DA-only" data perform best among different combinations of PLMs and language pairs. Also, InfoXLM and XLM-Roberta-Large show higher correlations than other PLMs. Meanwhile, the score refinement defined in 3.2 has a positive impact in both Table 3 and Table 7 which suggests the necessity to unify the range of different scores. However, correlations of different PLMs vary a lot for each language pair which suggests we still have room for improvement. Also, when using multitask training, the Spearman correlation coefficient increases compared to only training on sentence-level data. The "DA+MQM" data improves the performance of En-De while becoming worse on Zh-En.

Word level The results in Table 4 indicate that pretraining data, PLM and task modules affect the model performance to varying degrees. Since HTER data is most related to word-level task, the

InfoXLM	0.5309	0.4599	0.3037	0.2863

Table 3: Spearman correlation on Dev of sentence level on combinations of training data and score refinement(optional)

results based on pretraining on HTER data are best. Besides, models with RemBert or InfoXLM on En-De give bad results while models with BiLSTM as task module on Zh-En overfit on Dev set when submitting to test. In addition, swapping the order of *source* and *translation* has no improvement. For En-De and En-Mr, training on word-level data only is better than multitask training.

Multitask As shown in Table 8, multitask training improves the correlation of sentence-level task on all language pairs while only MCC of Zh-En grows. The score refinement method raises the correlation of word-level task obviously compared to models without applying score refinement. Yet, it does not always have a positive effect on sentence-level task. The multitask training for Zh-En avoids overfitting on Dev set and using BiLSTM as task module surpasses using FFN. Different PLMs will perform better if combined with specific task modules, which needs further experiments.

Ensemble The official results of models ensemble on dev and test for sentence level and word level are shown in Table 5 and Table 6 respectively. The ensemble method outperforms single model performance by a large margin. Our models have competitive results on all language pairs.

5 Conclusion

This paper describes our work for WMT 2023 Quality Estimation Task 1 on both sentence level and word level. With the help of PLMs and extra data, we can train better representations of *source* text and its *translation* for quality estimation task. We also experiment with diverse combinations of PLMs, task modules, and pretraining datasets. We find that QE systems for certain language pairs need to adopt particular combinations to acquire improvement, which reveals that there are distinct characteristics between languages. Such features make it hard to build one model for all languages, especially those without labeled data. The multitask training approach shows obvious improvements and prevents models from overfitting. Besides, the score refinement trick does not always give us positive feedback which suggests the number range is not the only factor to train on DA and MQM data properly. As expected, the ensemble method makes the predictions have a higher correlation with the ground truth. For future work, we will explore more profitable pretraining techniques for quality estimation and efficient modules that work well for various language pairs.

Limitations

Although our method has shown competitive results on most language pairs, evaluation results on zero-shot language pairs suggest that the model is not so powerful in generalization and relies on manual adjustment to some extent like choosing the weights among different models in the ensemble. Such operations could affect the model performance when transferring to unseen language pairs. Furthermore, we only designed two kinds of modules to generate tags in word-level task with slight improvement over baselines. It will be a potential research area to design more efficient prediction modules that can predict more accurate tags and we leave it as future work.

Also, other training configurations like weight decay and layer-wise learning rate decay were not experimented with sufficiently. Due to the discrepancy between training loss and evaluation metric, the choice of loss was a critical factor in model performance which was unexplored. Lastly, the limited amount of data constrained the improvement of models and overfitting on Dev set still has a great effect on optimization. We hope these analyses can promote the research of quality estimation.

Abstract

Word-level auto-completion (WLAC) plays a crucial role in Computer-Assisted Translation. In this paper, we describe the SJTU-MTLAB's submission to the WMT23 WLAC task. We propose a joint method to incorporate the machine translation task to the WLAC task. The proposed approach is general and can be applied to various encoder-based architectures. Through extensive experiments, we demonstrate that our approach can greatly improve performance, while maintaining significantly small model sizes.

1 Introduction

In recent years, more and more researchers have studied computer-aided translation (CAT) that aims to assist human translators to translate the input text (Alabau et al., 2014; Knowles and Koehn, 2016; Hokamp and Liu, 2017; Santy et al., 2019; Huang et al., 2021; Weng et al., 2019). The word-level auto-completion (WLAC) task (Casacuberta et al., 2022) is the core function of CAT, which involves predicting the word being typed by the translator given the translation context, as illustrated in Figure 1. Effective auto-completion has the potential to reduce keystrokes by at least 60% during the translation process (Langlais et al., 2000). A user survey indicates that 90.2% of participants find the word-level auto-suggestion feature helpful (Moslem et al., 2022). Therefore, WLAC plays an important role in CAT.

There are many existing methods for modeling WLAC, and they mainly differ in model architectures (Li et al., 2021; Yang et al., 2022b; Moslem et al., 2022; Yang et al., 2022a; Ailem et al., 2022). For example, Li et al. (2021); Yang et al. (2022a) design a BERT-like architecture to directly predict the target word while Yang et al. (2022b) employ a model similar to the auto-regressive NMT to predict the BPE tokens of the target word.

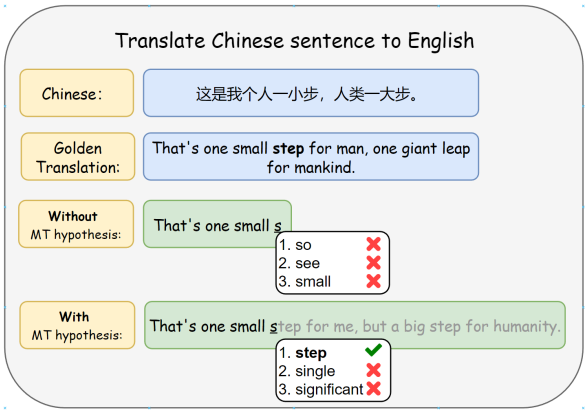

Figure 1: An example of word-level auto completion. Assume the human translator is going to input the *Golden Translation*. The auto-completion suggests the possible word candidates given the typed characters. It can be more accurate with the help of translation hypothesis from MT models.

The WLAC task comes from a real translation scenario: a human translator is translating a source sentence, who has already translated part of the sentence, and is typing a new word. The input contains three parts: the source sentence **s**, the partial translation **c**, and the typed sequence **t**. The WLAC task is to predict the word **w** that the translator is going to input (Li et al., 2021; Casacuberta et al., 2022). Rooted in the translation natural, we consider a fundamental question: what defines a correct word **w**? Theoretically, a good **w** should appear in the reference translation, as illustrated in Figure 1. Therefore, we attempt to incorporate knowledges from machine translation into the WLAC task. We presents two novel approach to enhance WLAC systems, called joint-inference and joint-training, to combine the MT task and the WLAC task during inference and training, respectively.

The effectiveness of our proposed method is validated through experiments conducted on the four language directions of the WLAC shared task

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 872–876
December 6–7, 2023.

in WMT2023 (§4). Remarkably, our approach achieves substantial improvements across two distinct backbone models.

2 Backbone Models for WLAC

In this section, we introduce two types of backbone models for the WLAC task. These backbone models serve as the foundation for our proposed techniques and experiments in subsequent sections.

Word-level Model The first backbone is called All-In-One Encoder (AIOE), which adopts a BERT-like(Devlin et al., 2019) Transformer Encoder architecture for word prediction similar to Li et al. (2021). The AIOE takes the concatenation of the source sentence, context, and typed sequence as its input. The input format is: $\boldsymbol{s}$ <*sep*> $\boldsymbol{c}_l$ <*tip*> $\boldsymbol{t}$ <*mask*> $\boldsymbol{c}_r$, where $\mathbf{c}_l$ is the left context to the input and $\mathbf{c}_r$ is the right context. Specifically, we append a <*mask*> token at the end of the typed sequence and leverage the final hidden state of the <*mask*> token for word prediction.

Despite its simplicity and efficiency, the AIOE model suffers from the out-of-vocabulary (OOV) problem, which can significantly hinder its performance. To this end, we introduce a variance of AIOE model that predicts word in sub-word level.

Sub-word-level Model Extending the word-level AIOE model to sub-word-level is straightforward: we consider the task of predicting a sequence of sub-words as a generation problem, and introduce a Transformer Decoder to the AIOE model to perform the generation. We use Byte-Pair Encoding (BPE) (Sennrich et al., 2016) for the sub-word tokenization, and call this model *AIOE-BPE*.

Due to the difficulty of labeling the WLAC data, we generate training data from parallel corpus for training the WLAC models, following the standard practice (Li et al., 2021; Casacuberta et al., 2022).

3 Enhancing WLAC by incorporating MT task

In this section, we propose two different approaches to improve the WLAC task.

3.1 Joint Inference with MT Model

This approach is to jointly consider the WLAC predictions and machine translation results during inference. We begin by generating the top-k predictions from the WLAC model. Next, we examine each word in the predictions and check if it is included in the translation. The first word in the top-k list that exists in the translation is selected as the final prediction. This strategy manually align the prediction with translation in a flexible way: the choice of WLAC model and translation model is arbitrary. The final performance is closely related to the choices of models.

However, this approach heavily relies on the quality of translation. A preliminary analysis show that for a naive MT model, only 44.6% of the WLAC labels exist in the translation. One possible solution is to enhance the input of MT model. We propose a *Context MT* model, which takes additional translation context and typed sequence as input, and generates full target sentence. The input of *Context MT* is the same as WLAC, so it's a better approximation of the golden translation model.

3.2 Joint Training with MT Task

One drawback of joint inference method is that the WLAC model isn't aware of the translation task during training, which means that the top-k predictions may deviate from the ground truth. To overcome this limitation, we propose a joint training approach, wherein the WLAC model and the MT model are trained together using a shared backbone encoder. Specifically, we extend the backbone model by introducing an MT decoder, transforming the whole model into an MT model. Here the MT model is the same as *Context MT* model described in §3.1. We define the training loss of the joint training model as the combination of the WLAC loss and the translation loss, represented as follows:

$$\mathcal{L} = \alpha \cdot L_{\text{WLAC}} + (1 - \alpha) \cdot L_{\text{MT}}, \qquad (1)$$

where α is a hyper-parameter controlling the balance between the two losses. To enhance the interaction between two tasks, we also share the final word prediction layer between the backbone model and the decoder. As described in section 4.1, the training data of WLAC is generated from parallel corpus, so there will be a full agreement between WLAC label and ground truth translation. This agreement enables the WLAC model to learn how to accurately predict words within the translations. Besides, the MT model can learn to generate translations based on the context provided by the WLAC predictions. By jointly training the two models, we enable them to mutually benefit from each other's knowledge and improve their respective tasks.

Model	#Parameters	zh-en	en-zh	en-de	de-en
AIOE	80M	46.71	54.82	51.75	50.64
AIOE-BPE	74M	50.79	53.48	57.23	61.96
AIOE+Joint Training	80M(105M)	51.40	58.70	56.22	54.57
AIOE-BPE+Joint Training	74M(100M)	**56.93**	**61.16**	**67.27**	**68.16**

Table 1: Experiment results on WMT23 WLAC test set. Results are reported as accuracy. The number of parameters in brackets means parameters in training stage.

The key advantage of joint training is that once the training is completed, we can only keep the backbone model and discard the MT decoder. Note that the backbone encoder can receive optimization signals from both the WLAC task and the translation task, so the backbone model has acquired the skill to agree with translation during training process. This enables us to maintain the agreement capabilities while preserving a small and efficient inference model.

4 Experiment

4.1 Datasets

We conduct evaluations of our model on two language pairs: English-Chinese and English-German. The zh-en dataset we used is the UN Parallel Corpus V1.0 from WMT17. For en-de, we use the training data from WMT14. We adopt the following strategy on parallel sentences to generate WLAC training data: firstly, we sample a target word **w** from the target language sentence, then we sample spans respectively from the left and right context of the target word, denoted as $\mathbf{c}_l$ and $\mathbf{c}_r$. Additionally, we sample a typed sequence from the target word. To sample typed sequence from Chinese words we use the pypinyin[1] tool. All models are trained on the generated training data, with data generated from the test set of WMT21 translation task serving as the validation set. For evaluation, we utilize the test set from the WMT22 WLAC shared task.

4.2 Experiment Details

For all AIOE model, we use a Transformer Encoder for 6 layers. The embedding size is 512, the dimension for feed-forward layer is 2048. Each layer has 8 attention heads. For AIOE-BPE model, we additionally add a Transformer Decoder with 6 layers. The MT decoder for joint training models are also 6 layers.

[1]https://github.com/mozillazg/python-pinyin

For AIOE model, we use a joint-vocabulary with the size of 120000. For AIOE-BPE model, the vocabulary size is 66630 for English-Chinese pair and 59918 for English-German pair.

The learning rate for training is 5e-4. We optimize the model for 200000 steps with a batch size of 32000 tokens. We average five checkpoints for better performance.

4.3 Comparison among Joint Methods

We firstly compare the performance of joint inference method and joint training method. For joint inference method, we use the word-level backbone AIOE model for the WLAC model, and consider two kinds of machine translation model: translation model trained on parallel corpus (MT) and translation model trained on WLAC input and translation output (*Context MT*). For the joint training method, we use AIOE-Joint model. All the experiments are conduct in zh-en direction. We conduct preliminary experiments on the WLAC22 test set and the result is reported in Table 2.

Method	Acc.
AIOE	53.87
AIOE+MT	54.20
AIOE+CMT	56.01
AIOE+JT	59.75

Table 2: Comparison of joint-methods. *Acc.* is the accuracy of WLAC22 task. AIOE+MT and AIOE+CMT is joint-inference method combined with different MT models. AIOE+JT is the joint training method.

It is observed that joint inference methods greatly outperform the baseline model, and the joint training method further improves the performance. The Context MT model is better than normal MT model for joint-inference, suggesting that more translation context is beneficial for the WLAC prediction. However, the overall performance of joint-inference is hindered by the quality of MT models, and the joint-training method can incorporate MT

Model	#Parameters	zh-en	en-zh	en-de	de-en
GWLAN(Li et al., 2021)	105M	51.11	48.90	40.69	53.87
HW-TSC(Yang et al., 2022b)	526M	59.40	-	63.82	62.06
AIOE+Joint Training	80M(105M)	59.75	56.59	44.67	62.77
AIOE-BPE+Joint Training	74M(100M)	**61.08**	**58.09**	**64.59**	**66.91**

Table 3: Experiment results on WMT22 WLAC test set. We implement the GWLAN model report the performance. The scores of HW-TSC model are copied from Yang et al. (2022b)

.

knowledge with WLAC more effectively. Based on these findings, we only focus on the joint training method for the subsequent experiments.

4.4 Main Results

The evaluation result on WLAC shared task is reported on Table 1. Our BPE-level methods have obtained better performance than word-level model except for en-zh, which indicates the word-level model may suffer from the OOV problem. No matter which backbone is used, our joint training method can greatly improve the backbone performance, indicating that our method is a general framework and has the potential to be applied to more encoder based models. Another obvious advantage of our model is its superior parameter efficiency. Our AIOE-BPE+Joint Training model achieves the best performance with only 100M training parameters and 74M parameters for inference.

4.5 Comparison with other models

We further compare our methods with existing systems. The experiment result on the WLAC22 test set is shown in Table 3. Compared to HW-TSC, our word-level methods have obtained better performance on zh-en and de-en. One exception is en-de, the word-level model performed badly because it suffers from OOV problem, where about 17% labels are OOV. After replacing the backbone with BPE-level model, our method show superior performance in all directions, while maintaining a much smaller size.

4.6 The impact of MT task

The influence of the hyper-parameter α on the model performance, as outlined in equation 1, directly reflects the impact of translation task. By setting α to 0, the model is essentially a translation model with additional context input. If $\alpha = 1$, the model corresponds to the AIOE model without joint training. In Figure 2, we present the accuracy achieved at varying values of α. Notably, as α increases from 0 to 0.75, the accuracy increases rapidly. This observation highlights the difference between the translation task and the WLAC task, emphasizing the necessity of optimizing the model specifically for the WLAC task to achieve better performance. Interestingly, even with α set to 0.99, the performance remains comparable to the best achieved performance. This finding is remarkable, as it suggests that even a small signal from the translation task can greatly enhance the WLAC task's performance when compared to the model with α set to 1. Consequently, our proposed joint training method effectively integrates the translation task into the WLAC task, resulting in substantial improvements.

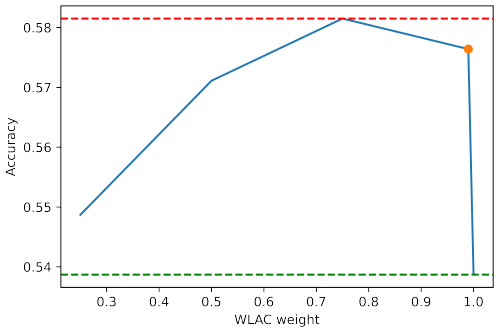

Figure 2: The impact of different α on the AIOE accuracy. Red dashed line is the best performance and the green represents the accuracy without joint training.

5 Conclusion

This paper proposes an effective approach to improve WLAC performance by combining the MT task and the WLAC task. We inject the translation knowledge into the WALC model by jointly train the two tasks. Extensive experiments show that the proposed approach surpasses several strong baselines with much smaller model size.

Abstract

This paper describes our submission to the *Word-Level AutoCompletion* shared task of WMT23. We participated in the English–German and German–English categories. We extended our last year segment-based interactive machine translation approach to address its weakness when no context is available. Additionally, we fine-tune the pre-trained mT5 large language model to be used for autocompletion.

1 Introduction

Despite its improvement in recent years with the emergence of neural machine translation (NMT), machine translation (MT) still cannot assure high-quality translations for all tasks (Toral, 2020). As a consequence, it is critical for professional translators to manually validate the translations generated by the NMT system for those scenarios with rigorous translation quality requirements. Computer-aided translation (CAT) tools emerged to improve the validation and editing process carried out by translators. With the aim of reducing the human effort of correcting the automatic translations, researchers approached CAT tools from many directions. Among CAT tools such as translation memory (Zetzche, 2007), augmented translation (Lommel, 2018) and terminology management (Verplaetse and Lambrechts, 2019); we can find autocompletion tools, which help professional translators by providing new partial translations according to the validated parts they have supplied to the system.

Word level autocompletion (WLAC) (Lin et al., 2021) was introduced as a shared task in WMT22 (Casacuberta et al., 2022). Its aim is to complete a target word given a source sentence, a sequence of characters typed by the human translator and a translation context. Four types of context are possible:

Zero-contex: no context is given.

Suffix: a sequence of translated words located after the word to autocomplete.

Prefix: a sequence of translated words located prior to the word to autocomplete.

Bi-contex: A combination of the *suffix* and the *prefix* type. That is, there is a sequence of translated words located after the word to autocomplete, and a sequence of translated words located prior to the word to autocomplete.

Note that, in all cases, the word to autocomplete is not necessarily consecutive to these contexts.

Approaches to WLAC include modeling the task as a structured prediction (generation) task (Yang et al., 2022b; Ailem et al., 2022), modeling it as a segment-based interactive machine translation (IMT) task (Navarro et al., 2022), using pre-trained NMT models and available libraries (Moslem et al., 2022), and using a generator-reranker framework (Yang et al., 2022a).

In this work, we extended the segment-based IMT approach from Navarro et al. (2022) by adding a module based on a statistical dictionary that tackles zero-context completions—which are the cases in which, not having any feedback, the IMT system performs at its worst. Additionally, since this year edition allowed the use of pre-trained large language model (LLM), we experimented using the mT5 model (Xue et al., 2021).

2 Segment-based interactive machine translation

Segment-based IMT establishes a framework in which a human translator works together with the MT system to produce the final translation. This collaboration starts with the system proposing an initial translation hypothesis y_1^I of length I. Then, the user reviews this hypothesis and validates those sequence of words which they consider

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 877–881
December 6–7, 2023.

to be correct ($\tilde{\mathbf{f}}_1, \ldots, \tilde{\mathbf{f}}_N$; where N is the number of non-overlapping validated segments). After that, they are able to merge two consecutive segments $\tilde{\mathbf{f}}_i$, $\tilde{\mathbf{f}}_{i+1}$ into a new one. Finally, they correct a word—which introduces a new one-word validated segment, $\tilde{\mathbf{f}}_i$, which is inserted in $\tilde{\mathbf{f}}_1^N$. This correction can also consist in a partially typed word $\tilde{\mathbf{f}}'_i$, in which case the system would complete it as part of its prediction.

The system's reacts to this user feedback by generating a sequence of new translation segments $\widehat{\mathbf{g}}_1^N = \widehat{\mathbf{g}}_1, \ldots, \widehat{\mathbf{g}}_N$; where each $\widehat{\mathbf{g}}_n$ is a subsequence of words in the target language. This sequence complements the user's feedback to conform the new hypothesis:

$$\begin{cases} \hat{y}_1^I = \tilde{\mathbf{f}}_1, \widehat{\mathbf{g}}_1, \ldots, \tilde{\mathbf{f}}'_i \widehat{\mathbf{g}}_i, \ldots, \tilde{\mathbf{f}}_N, \widehat{\mathbf{g}}_N \text{ if } \tilde{\mathbf{f}}'_i \in \tilde{\mathbf{f}}_1^N \\ \hat{y}_1^I = \tilde{\mathbf{f}}_1, \widehat{\mathbf{g}}_1, \ldots, \tilde{\mathbf{f}}_N, \widehat{\mathbf{g}}_N \text{ otherwise} \end{cases} \tag{1}$$

The word probability expression for the words belonging to a validated segment $\tilde{\mathbf{f}}_n$ was formalized by Peris et al. (2017) as:

$$p(y_{i_n+i'} \mid y_1^{i_n+i'-1}, x_1^J, f_1^N; \Theta) = \mathbf{y}_{i_n+i'}^\top \mathbf{p}_{i_n+i'}, \quad 1 \leq i' \leq \hat{l}_n \tag{2}$$

where l_n is the size of the non-validated segment generated by the system, which is computed as follows:

$$\hat{l}_n = \arg\max_{0 \leq l_n \leq L} \frac{1}{l_N + 1} \sum_{i'=i_n+1}^{i_n+l_n+1} \log p(y_{i'} \mid y_1^{i'-1}, x_1^J; \Theta) \tag{3}$$

3 Approaches

In this work, we extended Navarro et al. (2022)'s segment-based IMT approach by adding a new module that handles zero-context completions, which are harder for the IMT system to deal with (since there is no user feedback).

Additionally, we designed a new approach based on the mT5 LLM (Xue et al., 2021).

3.1 Segment-based IMT

Given a source sentence x_1^J, a sequence of typed characters $s_1^K = s_1, \ldots, s_K$ and a context $\mathbf{c} = \{\mathbf{c}_\text{l}, \mathbf{c}_\text{r}\}$, where $\mathbf{c}_\text{l} = c_{\text{l}1}, \ldots, c_{\text{l}S}$ and $\mathbf{c}_\text{r} = c_{\text{r}1}, \ldots, c_{\text{r}R}$; WLAC aims to autocomplete s_1^K to conform the word $w_1^W = s_1, \ldots, s_K, w_{K+1}, \ldots, w_W$. If we consider the context as the sequence of segments validated by the user ($\tilde{\mathbf{f}}_1^N = \mathbf{c}_\text{l}, \mathbf{c}_\text{r}$) and the sequence s_1^K as the partially-typed word correction (which would be inserted in $\tilde{\mathbf{f}}_1^N$ as a new one-word validated segment; leading to $\tilde{\mathbf{f}}_1^N = \mathbf{c}_\text{l}, s_1^K, \mathbf{c}_\text{r}$), we can view WLAC as a simplification of segment-based IMT. With that in mind, we can rewrite Eq. (1) as:

$$\hat{y}_1^I = \mathbf{c}_\text{l}, \widehat{\mathbf{g}}_1, s_1^K \widehat{\mathbf{g}}_2, \mathbf{c}_\text{r}, \widehat{\mathbf{g}}_3 \tag{4}$$

which, knowing that the prediction of the partially-typed correction corresponds to the first word of $\widehat{\mathbf{g}}_2$, can be rewritten as:

$$\hat{y}_1^I = \mathbf{c}_\text{l}, \widehat{\mathbf{g}}_1, s_1^K w_{K+1}^W, \widehat{\mathbf{g}}'_2, \mathbf{c}_\text{r}, \widehat{\mathbf{g}}_3 \tag{5}$$

Therefore, we can obtain the autocompleted word ($w_1^W = s_1^K w_{K+1}^W$) by performing a single step of the segment-based IMT protocol, discarding the rest of the translation prediction.

Zero-context

Since the core idea of IMT is reacting to a user feedback, not having any context results in the segment-based IMT approach performing at its worst. Thus, in this work we decided to create a special module dedicated to perform this kind of completion, using a variation of a statistical dictionary.

To that end, we computed *IBM's model 1* (Och and Ney, 2003) to obtain word alignments from source and target of the training set. Then, for each source word x_j, we compute the most probable translation t_a that starts with the sequence to complete s_1^K ($t_a = s_1, \ldots, s_K, t_{K+1}, \ldots, t_T$):

$$\hat{t}_j = \arg\max_{t_a} p(t_a | x_j) \tag{6}$$

where t_a belongs to the set of target words aligned with x_j that starts with s_1^K; and $p(t_a|x_j)$ is the alignment probability given by *IBM's model 1*.

Finally, we obtain the autocompleted word w_1^W as the most probable translation:

$$w_1^W = \arg\max_{t_1^J} p(t_1^J | x_1^J) \tag{7}$$

3.2 mT5

mT5 (Xue et al., 2021) is a multilingual variant of T5 (Raffel et al., 2020), pre-trained on a new Common Crawl-based dataset covering 101 languages. We choose to use this LLM since it has been pre-trained without any supervised training and, thus,

Figure 1: Example of adapting a training sentence for fine-tuning mT5.

can be easily adapted to any downstream task by simply fine-tuning the model.

Therefore, this approach consists in fine-tuning mT5 for WLAC. To do so, we created a new parallel dataset in which source sentences are the concatenation of the original source sentence, the left context, the right context and the typed sequence (using a special token as a delimiter); and target sentences are the autocompletion. Fig. 1 shows an example.

4 Experimental setup

In this section, we present the details of our experimental session.

4.1 Evaluation

The WLAC 23 shared task selected accuracy as the automatic metric with which to report the evaluation of the different systems. This metric is computed as the total number of correctly predicted words normalized by the total number of words to complete:

$$\text{Acc} = N_{\text{match}}/N_{\text{all}} \tag{8}$$

where N_{match} is the number of predicted words that are identical to the human desired word, and N_{all} is the total number of testing words.

4.2 Corpora

We conducted our experiments using the English–German corpus provided by the organizers, which is a version of the WMT14's dataset, preprocessed by Stanford NLP Group.

Table 1: Statistics of the WLAC 2023 corpus. *Run.* stands for running, K for thousands and M for millions.

Partition	Characteristic	De	En
Training	Sentences	$4M$	
	Run. Words	$110M$	$116M$
	Vocabulary	$1.6M$	$800K$
Validation	Sentences	2000	
	Run. Words	$53K$	$53K$
	Vocabulary	$10.5K$	$7.5K$

For fine-tuning mT5 (see Section 3.2), we processed the training data using the provided script[1] in order to create the simulated data. We repeated this process multiple times to increase the number of samples. Table 2 presents the data statistics.

Table 2: Statistics of the synthetic corpus generated for fine-tuning the mT5 model. *Run.* stands for running, K for thousands and M for millions.

Approach	Language	Overall	Prefix	Suffix	Bi-context	Zero-context
Segment-base IMT	De–En	0.400	0.453	0.151	0.395	0.570
	En-De	0.371	0.433	0.144	0.377	0.491
mT5	De–En	0.436	0.432	0.458	0.490	0.363
	En–De	0.374	0.373	0.389	0.431	0.301

4.3 Systems

The MT systems from our segment-based IMT approach were trained using *OpenNMT-py* (Klein et al., 2017). We selected a Transformer (Vaswani et al., 2017) architecture, with a word embedding size of 512. The hidden and output layers were set to 2048 and 512, respectively. Each multi-head attention layer has eight heads, and we stacked six encoder and decoder layers. We used Adam as the learning algorithm, with a learning rate of 2.0, b_1 of 0.9 and b_2 of 0.998. We set the batch size to 4096 tokens.

Additionally, we made use of the byte pair encoding (BPE) (Sennrich et al., 2016) algorithm, which was jointly trained on both languages of the dataset, applying a maximum number of 10.000 merges. Finally, we used our own implementation (based on *OpenNMT-py*) of segment-based IMT, which we adapted for WLAC. This implementation is openly available[2] for the benefit of the community.

For the mT5 approach, we made use of *HuggingFace's Transformer* (Wolf et al., 2019). Due to computing constrains, we selected *Google's mT5-base* model[3].

5 Results

Table 3 presents the official results of our approaches. We can see how both approaches yielded similar results. The main advantage of the segment-base IMT approach is that we can leverage an MT model for autocompletion by simply performing minor changes at the decoding step. However, looking at the results, while our zero-context proposal has successfully solved the problem of having no feedback, the system's performance significantly drops when the only available context is a suffix. In future works we shall address this behavior.

Regarding the mT5 approach, its main advantage is that we can adapt an already pre-trained mT5 model by simply performing fine-tuning with a WLAC dataset. With the exception of having no context, its behavior is constant for all kind of context. Additionally, it is worth remembering that we used *Google's mT5-base* model due to computing constrains. In a future work, we shall test how "bigger" mT5 models behave for this task.

6 Conclusions

In this work, we have presented our submission to WLAC shared task from WMT23. Our first proposal extended Navarro et al. (2022)'s segment-based IMT approach by adding a zero-context—based on a statistical dictionary—that handles separately the cases in which no context is given. This approach yielded satisfactory results for all cases except when the given context consists in a suffix.

Our second proposal consisted in leverage the pre-trained LLM model mT5 by performing a simple fine-tuning that enables the model to be used for WLAC, achieving satisfactory results for all type of contexts.

As a future work, we would like to study the behavior of the segment-based IMT approach when dealing with suffixes. Additionally we would like to consider the use of other LLM, as well as different versions of the mT5 model.

Abstract

The NLP community has recently witnessed the success of Large Language Models (LLMs) across various Natural Language Processing (NLP) tasks. However, the potential of LLMs for word-level auto-completion in a multilingual context has not been thoroughly explored yet. To address this gap and benchmark the performance of LLMs, we propose an LLM-based system for the WMT23 Word-Level Auto-Completion (WLAC) task. Our system utilizes ChatGPT to represent LLMs and evaluates its performance in three translation directions: Chinese-English, German-English, and English-German. We also study the task under zero-shot and few-shot settings to assess the potential benefits of incorporating exemplars from the training set in guiding the LLM to perform the task. The results of our experiments show that, on average, our system attains a 29.8% accuracy on the test set. Further analyses reveal that LLMs struggle with WLAC in the zero-shot setting, but performance significantly improves with the help of additional exemplars, though some common errors still appear frequently. These findings have important implications for incorporating LLMs into computer-aided translation systems, as they can potentially enhance the quality of translations. Our codes for evaluation are available at https://github.com/ethanyiwu/WLAC.

1 Introduction

Recent advancements in machine translation, especially due to the development of transformers and pre-trained language models, have been significant (Kong and Fan, 2021; Sun et al., 2023; Mohammadshahi et al., 2022). These methods have yielded impressive results in traditional sentence-level translation tasks (Bahdanau et al., 2015). However, challenges still exist that hinder the further progress of Computer-Aided Translation (CAT) (Esplà-Gomis et al., 2022) systems. Among various components that constitute CAT, Word-level AutoCompletion (WLAC) stands out as a core function (Li et al., 2021; Casacuberta et al., 2022). As shown in Figure 1, WLAC aims to suggest the correct word translation in the target language based on a sequence of human-typed characters and bidirectional context.

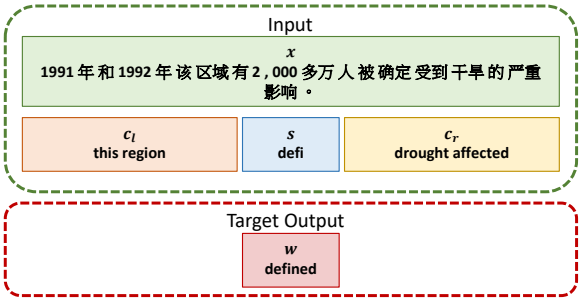

Figure 1: Illustration of the WLAC task for translating from Chinese to English, including various components involved in the translation process. The inputs consist of the source sentence x, the left context in the target sentence c_l, the right context in the target sentence c_r, and the pre-typed character sequence of the word to be predicted s. The task aims to predict the target output word w accurately.

While this task might seem straightforward for seasoned human translators, existing deep-learning approaches struggle to handle it effectively. This can be attributed to the fact that performant translation methods, which rely on pre-trained language models, cannot effectively interpret the typed sequence of characters as they are pre-trained at the token level. Other related studies have either only considered the source contextualization (Huang et al., 2015) or have been unable to handle multilingual translations effectively (Huang et al., 2018). Previous works have demonstrated that transformer-based frameworks, when trained with carefully designed masking or context transformation strategies, can efficiently tackle this task (Yang et al., 2022a,b; Navarro et al., 2022). Yet, these frameworks require extensive training, and their

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 882–889
December 6–7, 2023.

ability to transfer across different languages remains questionable.

With the recent progress made by Large Language Models (LLMs), such as ChatGPT (OpenAI, 2022), researchers have conducted extensive studies regarding their performances on various NLP tasks (Laskar et al., 2023; Liu et al., 2023; Li et al., 2023a; Yu et al., 2023). These LLMs possess advantages, such as ease of deployment and robust multilingual reasoning ability, making them particularly suitable for tasks like WLAC. However, a detailed study of LLMs' application in this context is lacking, and the systematic use of LLMs to assist CAT, especially in performing WLAC, remains unexplored.

This paper addresses these gaps by introducing a system that employs LLMs, specifically ChatGPT, for the WLAC task. ChatGPT has been chosen for its exceptional performance in general natural language tasks, negating the need for deploying or fine-tuning other models. Our approach uses a prompt-engineering-based method to convert all WLAC task inputs into comprehensible natural language sentences. Following this, we synthesize exemplars from the existing training set to facilitate in-context learning with ChatGPT (Wei et al., 2022b). The generations are subsequently parsed using carefully crafted rules to yield the final "predictions" from ChatGPT (Section 3). We then conduct comprehensive experiments using our system, covering scenarios from zero-shot to five-shots. Our experimental results indicate that our system achieves an average accuracy of 29.8% on the testing set. Through error analysis and case studies, we found that LLMs face challenges with WLAC in the zero-shot setting and identified four common types of mistakes that can be particularly addressed in the future. However, ChatGPT's performance significantly improves when provided with additional exemplars, highlighting the crucial role of in-context learning in tackling WLAC for LLMs (Section 4). We will make all codes publicly available upon acceptance of this paper.

2 Preliminaries

2.1 Task Definition

Formally, the objective of the WLAC task (Li et al., 2021) is to predict the target word w using three parts of inputs, which are denoted as the source sequence x, the human-typed characters s, and the translation context c, where $c = (c_l, c_r)$. The translation context consists of left context c_l and right context c_r, where c_l is a sub-sequence of the translated context on the left side of s, and c_r is a sub-sequence of the translated context on the right side of s. A running example is shown in Figure 1.

	Training	Validation	Test
zh-en	39,473	29,051	16,386
de-en	40,000	29,596	14,564
en-de	40,000	29,895	14,539

Table 1: Statistics regarding the number of data across three translation languages in each split.

Specifically, a notable challenge in training a masked language model for the WLAC task is the incomplete nature of the left and right contexts. These contexts may not necessarily constitute complete sentences; they can consist of partial words or even be empty. As a result, the context c and the typed sequence s do not necessarily provide a fully translated result of the source sequence. Moreover, the training data for this task does not include the complete translated result as a reference. This lack of complete supervision further complicates the establishment of robust training signals for masked language modeling (Li et al., 2023b), especially when compared to traditional translation tasks (Navarro et al., 2022).

2.2 Large Language Models

The emergence of large language models (LLMs) has recently gained the spotlight in the NLP community. GPT3.5 (Brown et al., 2020; Ouyang et al., 2022), ChatGPT (OpenAI, 2022), and LLaMA (Touvron et al., 2023) are some of the notable LLMs that have been well-developed, each boasting an exceptionally vast number of parameters. These LLMs are trained on massive corpora using advanced techniques, such as instruction tuning (Wei et al., 2022a) and reinforcement learning from human feedback (Christiano et al., 2017), on large computational infrastructures. As a result, recent studies have shown that LLMs excel at various downstream tasks, including causal reasoning and grounding (Chan et al., 2023; Wang et al., 2023c; Ou et al., 2023), commonsense reasoning (Fang et al., 2023, 2021b,a; Bian et al., 2023; Wang et al., 2023b), question-answering (Wang et al., 2023a; Qin et al., 2023), translation (Peng et al., 2023; Lu et al., 2023), and data mining tasks (Jin et al., 2023a,b,c). Since the WLAC task demands substantial reasoning and generation capabilities that

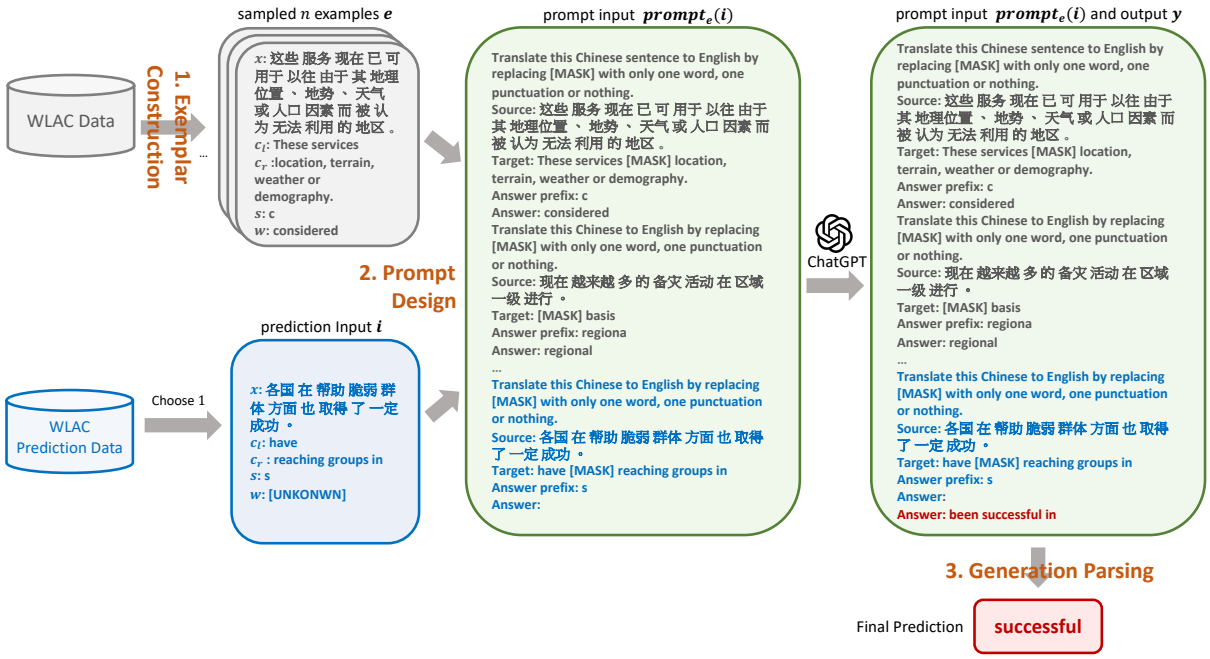

Figure 2: An overview of our framework when dealing with WLAC in translating from Chinese to English (zh-en). The input sentences (marked in blue) are concatenated with pre-constructed exemplars (marked in gray) to form a unified prompt. A large language model (ChatGPT) is then deployed to generate the response (marked in red), which is subsequently parsed to obtain the final prediction y.

rely on bidirectional contexts to accurately predict the target word, LLMs make for an ideal choice to perform WLAC due to their exceptional natural language understanding abilities and ease of deployment.

2.3 Dataset

We use the dataset provided by (Casacuberta et al., 2022) as our primary evaluation benchmark. We select three translation language pairs from the dataset: Chinese to English (zh-en), German to English (de-en), and English to German (en-de). To maintain consistency, we follow the *trn/dev/test* split released in the original dataset. Detailed statistics on the number of data are shown in Table 1.

3 Method

Figure 2 shows an overview of our framework, which consists of three steps: exemplar sampling, prompt design, and generation parsing.

3.1 Exemplar Sampling and Construction

To generate the input prompt for the LLM, we begin by employing random sampling to choose k data instances from the training split of the dataset. These selected instances serve as in-context learning exemplars. In our experiments, we explore different values of $k \in \{0, 1, 5\}$ to evaluate the performance of the LLM in both zero-shot and few-shot scenarios. The aim is to improve the model's familiarity with the task and its capacity to deliver precise answers by incorporating the provided exemplars into its learning process.

3.2 Prompt Design

We then design a natural language prompt to systematically combine both sampled exemplars and every testing data entry from the testing split, which serves as the input for the LLM. To assist the LLM in distinguishing different components of the input and the desired output, we introduce instructive tokens such as "Source" (the source sentence to be translated), "Target" (the target sentence with context c_l and c_r provided), "Answer prefix" (the pre-typed sequence s indicating the target word to be predicted at `[MASK]`), and "Answer" (representing the target prediction word w). For each testing data entry, we construct such a prompted sentence with the "Answer" for the testing entry left blank, awaiting completion. Combining all these prompted sentences creates a comprehensive paragraph of sentence input, as illustrated in Figure 2. This transforms the task into a blank-filling exercise, wherein the model fills in the missing word, the last word in our case.

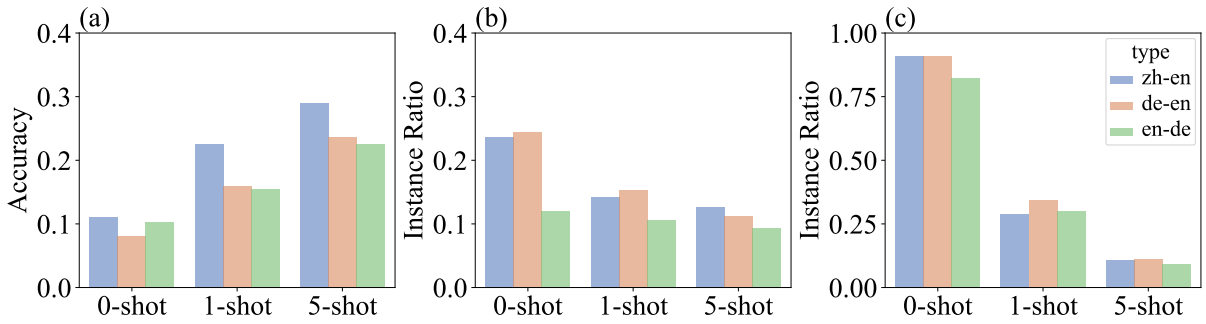

Figure 3: The fault rate and accuracy under different settings. (a) refers to the accuracy. (b) refers to the proportion of instances that don't start with the typed sequence s. (c) refers to the ratio of the generations which contain a sequence of words.

3.3 Generation Parsing

Since the generated content is in free-text form, it requires parsing to identify the predicted word as the final output of the WLAC task. The first step is to remove the cue word, such as "Answer," and separate the remaining sequence of tokens into individual words by splitting at blank spaces. To ensure that the selected word satisfies the constraint of the pre-typed sequence, we search for the first word that starts with the pre-typed sequence s as the final prediction. If such a word does not exist, the first word in the sequence is chosen as the final prediction. For example, if the generated content is "Answer: Hello World" and the pre-typed sequence is "Wo," the word "World" is the final prediction after parsing.

4 Experiments

4.1 Setup

We utilize the official ChatGPT API[1] to access the large language model for sentence completion. The model code employed is `gpt-3.5-turbo`, and the access date is July 2023. The temperature is set to 0.7 when generating to ensure consistent generation, while other control parameters are set to their default values.

4.2 Results

Our experimental results are presented in Table 2. We observe that five-shot prompting yielded the best performance, while not incorporating any training exemplar led to the worst performance. This outcome is reasonable, considering the model may not clearly understand the task objective and reasoning process. Importantly, incorporating just one additional exemplar had a significantly positive impact. This suggests that ChatGPT can quickly learn from provided exemplars and develop a sufficient understanding of the task. The accuracy improvement trends across the three translation directions are consistent, leading us to conclude that ChatGPT can achieve acceptable performance on the WLAC task with the help of training exemplars and in-context learning. However, even with five-shot prompting, the performance is only around 25% in terms of accuracy, leaving a large space for future improvements. Therefore, leveraging more advanced or meticulously designed prompts should be considered further to enhance ChatGPT's performance on the WLAC task.

Task	Shot #		
	0-shot	1-shot	5-shot
Zh - En	11.15	22.66	29.21
En - De	10.26	15.45	22.51
De - En	8.12	15.99	23.66

Table 2: Evaluation results (Accuracy %) on the testing sets of three translation directions.

4.3 Error Analysis

Upon further analysis of the results, we identify two common types of mistakes where the generated output deviates from the targeted answer. The first type of mistake occurs when the generated output fails to begin with the specified sequence s, while the second type of mistake involves the presence of multiple words in the generated output after removing the cue word. As depicted in Figure 3, the overall performance improves significantly as the number of shots increases. Nevertheless, there is a remarkably high rate of faults in generating

Table 3: Case studies of generations from ChatGPT. We select generation results from the 5-shot scenario.

word sequences that violate the instruction of using only a single word in the zero-shot approach. The transition from zero-shot to one-shot learning results in a considerable reduction in both fault rates. This indicates that the language model adheres to instructions more accurately by adding a single example. Moreover, the fault rate also further decreases in the five-shot setting.

4.4 Case Studies

To further demonstrate the difficulty of the task and the performance of ChatGPT, we select some generation results in the Chinese-English translation split, as shown in Table 3. Among these cases, we observe four types of tricky but common mistakes. Firstly, although the generated output and the target share the same semantic meaning, the generation is syntactically incorrect. We exemplify two generations that contain grammatical mistakes. Secondly, our approach may generate semantically accurate output that deviates from the target, particularly in cases where the input lacks detailed context. Moreover, the model may generate the content immediately after the context instead of following instructions to find a semantically correct word that matches the typed sequence. Finally, the model does not always comply with the instructions that require it to generate only one word. It may give a phrase or part of a sentence to combine the context into a complete sentence.

4.5 Discussions

While our system achieves acceptable performance, it falls significantly short of the performance achieved by systems last year (Casacuberta et al., 2022). This suggests that additional efforts are required to enhance ChatGPT's performance on the WLAC task, which might include: (a) Incorporating more training exemplars. For instance, increasing the number of training shots to ten or even more could be beneficial. (b) Reframing the exemplar selection problem as a subset selection problem. This approach involves selecting training exemplars based on their similarity to the testing entry or their diversity in relation to other exemplars, as proposed by Ye et al. (2023). (c) Improving the prompt to better leverage both left and right contexts. Additionally, advanced prompting techniques like chain-of-thought (Wei et al., 2022b) could be explored. (d) Incorporating external knowledge for reasoning, such as complex knowledge (Bai et al., 2023), conceptualization (He et al., 2022), and graph reasoning (Liu and Song, 2022; Liu et al., 2022, 2020).

5 Conclusions

In conclusion, this paper presents a novel LLM-prompting system to address the WLAC task. Our findings demonstrate that LLMs are highly capable

problem solvers and adept at learning in context for this particular task, albeit with performance that falls short of previous supervised learning systems. A detailed analysis uncovers several error types that contribute to the limited performance of ChatGPT. Therefore, we urge researchers to devote additional attention to the WLAC task using LLMs.

Terminology-Aware Translation with Constrained Decoding and Large Language Model Prompting

Nikolay Bogoychev* **Pinzhen Chen***
School of Informatics, University of Edinburgh
n.bogoych@ed.ac.uk, pinzhen.chen@ed.ac.uk

Abstract

Terminology correctness is important in the downstream application of machine translation, and a prevalent way to ensure this is to inject terminology constraints into a translation system. In our submission to the WMT 2023 terminology translation task, we adopt a translate-then-refine approach which can be domain-independent and requires minimal manual efforts. We annotate random source words with pseudo-terminology translations obtained from word alignment to first train a terminology-aware model. Further, we explore two post-processing methods. First, we use an alignment process to discover whether a terminology constraint has been violated, and if so, we re-decode with the violating word negatively constrained. Alternatively, we leverage a large language model to refine a hypothesis by providing it with terminology constraints. Results show that our terminology-aware model learns to incorporate terminologies effectively, and the large language model refinement process can further improve terminology recall.

1 Introduction

One of the major obstacles encountered by neural machine translation (NMT) systems pertains to the utilization of suitable domain-related words when translating specialized content not present in the training data. An illustrative instance of this challenge arises when translating "transformer" from English into another language, where the accurate translation depends on the context or the preference of the audience (Figure 1). A straightforward literal translation approach often leads to suboptimal outcomes, prompting human translators unfamiliar with domain-specific knowledge to resort to reference materials for terminology precision. This issue is prevalent in the translation industry, with many commercial translation service providers offering paid solutions to address it. Furthermore, it

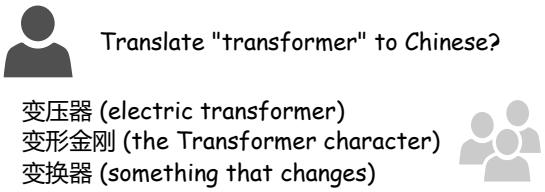

Figure 1: Terminology hints can help disambiguate polysemantic words when translating with limited context.

is a popular area in machine translation research, indicated by efforts such as WMT shared tasks organization and participation focusing on terminology and domain-specific translations (Alam et al., 2021; Bawden et al., 2019, 2020, inter alia).

This year's WMT terminology translation task features three language directions: German-to-English, Chinese-to-English, and English-to-Czech. In addition to reading in a source sentence, participating systems need to employ a provided dictionary, which contains source-target terminology word mappings, to incorporate into the target translation. For each source sentence in the test set, there are three modes of applying terminology constraints:

1. *Terminology* constraint: Dictionaries of real terminology words are provided, to be incorporated in the translations.

2. *Random* constraint: Random (but presumably correct) word mappings are obtained using a word alignment tool and provided as a pseudo-terminology dictionary.

3. *No* constraint: Source sentences can be freely translated without external information.

We interpret that the no-constraint setting allows us to measure the competing systems' quality and understand to what degree the systems effectively utilize the provided random and terminology dictionaries. Our baseline approach is to train

*Equal contribution.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 890–896
December 6–7, 2023.

a terminology-aware translation (TAT) system inspired by Dinu et al. (2019), where, in the training data, source words are tagged with desired translations inline on the source side. Then we propose two separate refinement strategies on top of it to aggressively encourage the appearance of terminologies:

1. We use a neural word aligner to identify terminology constraints missed by the baseline system, and use the same system to re-decode the source by negatively constraining (disallowing) previously incorrectly translated tokens.

2. We also investigate the capability of a large language model to simultaneously paraphrase an existing translation to include the desired terminology constraints via curated prompts.

Our proposed techniques can incorporate target terminology words with around 80% recall, using automatic and soft constraints in a two-step refinement process. We observe that for German-English, our terminology-aware training and negatively constrained decoding perform better, whereas, for Chinese-English and English-Czech, LLM-based refinement achieves higher scores. In terms of overall translation accuracy, we find that negatively constrained decoding could lead to a tiny drop and LLMs are able to maintain or improve quality according to a reference-free neural metric.

2 Related Work

Previous research on terminology translation could be divided into two categories: *soft* constraint and *hard* constraint, depending on whether the resulting translation system will enforce the appearance of desired target translations. In the soft constraint setting, the convention is to train a model that is able to ingest the target terminology words inline, directly placing them after the corresponding source words in the source input (Dinu et al., 2019). Many later implementations stem from this to include new elements such as additional lemmatization (Bergmanis and Pinnis, 2021) or grammatical error correction (Pham et al., 2021) as a post-processing step in order to achieve a more fluent output. Instead of placing the target constraint words inline, some other works train a system that takes the terminology constraint as either a prefix or a suffix (Jon et al., 2021; Turcan et al., 2022).

Most hard constraint work involves post-processing a translation with desired terminologies. Post et al. (2019) inserted untranslatable tokens (also known as placeholders) into the source, which will remain unchanged through the translation process. Then the placeholders are replaced with terminology words in the target language. This is entirely performed as a post-processing step. Such terminology replacement could also be done by keeping and replacing the source word at inference time, and it is also feasible to run target word replacement as post-processing (Molchanov et al., 2021). A hard constraint method guarantees that the chosen terminology token will appear, but often results in less fluent output, especially for morphologically rich languages because the context is not taken into consideration during replacement. It also mandates more complicated post-processing than the soft constraint approaches.

Our first post-processing proposal relies on constrained decoding, which refers to either allowing certain tokens or blocking specific tokens during inference time (Hokamp and Liu, 2017). It has been applied to terminology injection, paraphrasing, parallel sentence mining, etc (Hasler et al., 2018; Kajiwara, 2019; Chen et al., 2020). We opt for negatively constraining the tokens that violated the given terminology alignments by preventing them from entering the hypothesis beam in the refinement stage. These alignments are computed using word alignment tools (Dyer et al., 2013; Dou and Neubig, 2021).

Another post-processing method in our study prompts an LLM to refine a translation and incorporate terminology terms simultaneously. Whilst previous studies have explored the translation capability of LLMs (Vilar et al., 2023; Zhang et al., 2023), the works closely relevant to us are from Moslem et al. (2023) and Ghazvininejad et al. (2023). We adopt the paradigm from the latter, which re-words a constraint dictionary as a natural text and affixes it into a translation prompt. While they focused on rare words without directly benchmarking on terminology translation, our post-processing step can be seen as an extension of word-level controlled prompting to terminology translation with large language models. Both of our post-processing methods should be categorized as soft constraint approaches since there is no guarantee that negatively constrained decoding or an LLM will necessarily incorporate the constraints in a re-generation.

3 Terminology-Aware Training

The goal of our system implementation is to create a general-purpose terminology-aware translation system that is unsupervised and domain-agnostic, and requires the minimum effort of pre- and post-processing.

3.1 Terminology creation

Inspired by Dinu et al. (2019), we applied terminology constraints during training, but a key difference is that, unlike their approach, we assume that we have no access to downstream domain or terminology constraints during training, in order to build a general-purpose domain-agnostic system. Consequently, we have no curated terminology data to use. Therefore, we generate (pseudo-)terminology information using word alignments. Our workflow can be detailed as:

1. We compute the word alignment information for the entire training set using `fast_align` (Dyer et al., 2013).

2. For each sentence, we select all bijective source-target mappings as our terminology candidates. We also filter out trivial mappings where the source and target tokens are the same (e.g. numbers, names), because those mappings are simple and hence likely to be correctly translated by a translation system even without any terminology awareness.

3. In the training data, we replace $\texttt{srcword}_\text{i}$ in the source sentence with:
   $\texttt{srcword}_\text{i}$ `__target__` $\texttt{trgword}_\text{j}$ `__done__`
   where the $srcword_\text{i}$ is the i-th source word inside the sentence, and $trgword_\text{j}$ is the word inside the target sentence, corresponding to srcword_i according to word alignment information. This replacement occurs with around 10% probability for each candidate source-target pair. For a sentence that does not have an associated terminology constraint, the data is the same as normal NMT.

4. At inference time, we process the test data similarly to above, except that the source-target word mapping comes from a supplied terminology dictionary.

In practice, our translation system is trained with a mix of normal translation data and terminology-injected data. The advantage of this strategy is that the trained models are general-purpose, so they can translate normal texts without terminology injection. Further, they have been exposed to a wide variety of constraints during training, making them robust to potentially unseen domain constraints.

Overall, our method is very similar to Bergmanis and Pinnis (2021)'s work, except that we use whole words but not lemmas to ease pre-processing. We presume that the language model will be able to adjust the terminologies accordingly, especially for morphologically rich languages on the target side. This enables our method to be trivially transferable across languages.

Finally, our systems could easily be turned into hard-constrained by replacing the source word with the desired target terminology word. This could be feasible because our terminology-aware training installs the copying behaviour in the neural translation model, although in this mode the model would produce markedly less fluent output.

3.2 Model architecture

We trained Transformer-style machine translation models (Vaswani et al., 2017) using the Marian NMT toolkit (Junczys-Dowmunt et al., 2018). We used the `Transformer-Big` preset which is a 6 encoder, 6 decoder architecture with 1024 hidden size, and 4096 feedforward size.[1]

3.3 Data

The terminology task uses the same data as the constrained condition in the WMT23 general translation task. We carefully cleaned, filtered, and deduplicated the available WMT training sets provided by the organisers, as well as the available back-translation data. After preprocessing we were left with the following:

- German-to-English (`de-en`): 199M lines of parallel data and 29.5M lines of back-translated data.

- Chinese-to-English (`zh-en`): 21.8M lines of parallel data and 15.6M lines of back-translated data.

- Czech-to-English (`cs-en`): 61.8M lines of parallel data and 57M lines of back-translated data.

Refinement	`Source: ${source}`
	`Translation: ${translation}`
	`Please give me a better ${lang} translation without any explanation.`
	`"${srcword$_0$}" should be translated as "${trgword$_0$}";`
	`"${srcword$_1$}" should be translated as "${trgword$_1$}";`
	`...`
	`"${srcword$_k$}" should be translated as "${trgword$_k$}".` *(with k >= 0)*

Table 1: Large language model prompt templates for unconstrained and constrained translation.

3.4 General quality

The quality of our models without terminology translation is shown in Table 2, where we report BLEU (Papineni et al., 2002) and COMET_{DA}[2] (Rei et al., 2020) scores on test sets from the WMT22 general translation task. We note that terminology augmentation during training could result in a slight quality drop.

	BLEU	COMET_{DA}

en-cs	39.5	0.8715
zh-en	20.3	0.7559

Table 2: Performance of our terminology-aware translation systems in the WMT22 general translation task.

4 Post-Translation Terminology Injection

Despite training our model with terminology awareness, there is no mechanism to ensure that the desired terminology constraint will appear on the target side. The neural network decoding behaviour is not entirely predictable, especially given the assumption of no additional domain adaptation. Below, we present two distinct strategies to try *harder* to promote the terminology constraints, via automatic post-editing through constrained beam search and large language models.

4.1 Negatively constrained decoding

While it is easy enough to notice when a target terminology term is not generated as per a given constraint, it is not trivial to understand which word has been produced in place of the desired term. In order to do this, we make use of *awesome-align*, a neural multilingual word aligner (Dou and Neubig, 2021), with the following procedure:

1. For each source-translation pair, we check if all required terminology terms appear on the target side. If they do, then we stop processing more rules.

2. Then, we use *awesome-align* to compute word alignments and detect the word(s) that have been generated in place of the desired terms according to the provided terminology constraints.

3. We decode the source sentence again, penalising the words that violated the terminology constraint, by forbidding the decoder from generating them at each generation step, unless they carry more than 95% of the probability mass at a certain step.

In practice, this procedure can be repeated infinitely, until all terminology constraints are fulfilled, but we decided to limit it to only one iteration, to keep this a realistic production scenario in terms of computational budget.

4.2 Large language models

Recent years saw the rise of large language models (LLMs), which have a strong capability in various NLP tasks. In this paper, we investigate the effectiveness of using a large language model to generate terminology terms during translation by adding constraints to Chen et al. (2023)'s translation refinement prompts. We use two distinct prompts: free translation and translation refinement queries. The translation query sends a source sentence and

†Recall computed against terminology constraints.

‡Recall computed against random constraints.

Table 3: Terminology recall and translation quality measured by COMET_{QE} of our systems on the *blind test* set. TAT: terminology-aware translation; NCD: negatively constrained decoding; LLM: large language model.

requests a translation in the target language without any other information. On the other hand, the refinement query feeds back an unconstrained translation together with terminology constraints to request a new translation. This essentially forms an LLM version of the constrained beam search discussed in Section 4.1. The constraints are enforced through natural language instructions in the prompts, under the situation where the softmax distribution from an LLM is not accessible by users.

The LLM we use is OpenAI's GPT-3.5.[3] It is a closed-source commercial system, where the model weights and the inference states are not available to users. The model has a context window of 4096 which is sufficient to cover an instruction, a source sentence, several terminology constraints, as well as the target translation. It is public to all users at a relatively cheap cost. In our settings, each translation is carried out in a new query session.

In Table 1 we outline the two prompt templates we used. During querying, the placeholder variables are substituted with corresponding string values. For the refinement query, when a terminology dictionary is supplied, the source and target words are fed to the LLM via the prompt (Ghazvininejad et al., 2023); if there is no terminology dictionary, the query simply asks for a refined translation. The two-step experiment with LLMs can be summarized as follows:

1. We obtain an initial unconstrained translation, which may or may not fulfil all the terminology constraints. It can come from either the LLM itself or the terminology-aware translation model built in Section 3.1.

2. We query the LLM with the constrained translation prompt to obtain a refined translation with terminology incorporated in the prompt.

5 Results and Discussions

We present our *blind test* results in Table 3, which include both terminology recall and COMET_{QE} scores computed by us.[4] We used COMET_{QE} in particular because it does not require references

[3] `gpt-3.5-turbo-0613`, a snapshot of the GPT-3.5 model on 13 June 2023

[4] `wmt21-comet-da-qe`

which are not accessible to us. We assess the effectiveness of our methods by comparing the terminology recall of our systems with and without applying terminology constraints, in both *random* and *real terminology* scenarios.

5.1 Translation quality

In terms of translation quality reflected in COMET_{QE}, we observe that the LLM rows attain superior results, which is not surprising considering that we use an unconstrained commercial model GPT-3.5. By comparing TAT with TAT+NCD, or comparing LLM with LLM+LLM under a constrained scenario, we conclude that applying terminology constraints usually lead to a sacrifice in translation quality regardless of the language direction or the systems involved. Nonetheless, as a contrasting experiment with no constraint, LLM+LLM achieves a slightly better COMET_{QE} score than using an LLM to translate without refinement.

Our model performed poorly on the `zh-en` task in terms of COMET_{QE} scores. We suspect that this is because of the domain mismatch between the translation data from the general domain and the Chinese terminology test set. Upon manual inspection, we found that the latter includes web novels and literal writing which are likely to be under-represented in the generic training data.

5.2 Terminology recall

Focusing on terminology generation, compared with TAT or LLM in unconstrained settings, TAT marks 30-40 higher recall of terminology terms in the constrained *terminology* and *random* settings. This indicates that our terminology-aware training is effective in teaching translation models to follow customized source-target word alignments.

Next, as a post-processing step, negatively constrained decoding seems to be disappointing in practice. TAT+NCD often produces worse results than TAT alone in terms of both quality and terminology recall, except for `zh-en` with *random* constraints. We hypothesize that this could be due to two problems: (1) word alignment errors could propagate into this process, and (2) by applying NCD, we might capture a missed terminology term but at the cost of mis-translating other words. Our constraining procedure might be improved by performing shortlisting, namely positively constrained decoding, as opposed to negatively limiting the beam search in an iterative approach.

We find the results promising when using LLMs for terminology injection. Looking at LLM+LLM versus LLM alone in various constrained conditions, terminology recall improves significantly with very little drop in overall quality. Also by comparing TAT+LLM with TAT alone, we observe that TAT and LLMs each have their own merits depending on the language direction. In terms of recall, TAT wins in `de-en`, TAT+LLM wins in `zh-en`, and they are close in `en-cs`. However, TAT+LLM is way ahead if measured by COMET_{QE}. However, we must note that an LLM costs significantly more resources than a dedicated translation model at both training and inference time.

6 Conclusion and Future Work

We participated in all tracks of the WMT 2023 terminology shared task with a terminology-aware translation baseline, and two distinct refinement procedures using negatively constrained beam search and large language models separately. The results we produced gave us insights into the pros and cons of our systems. In future work, we could explicitly enforce the generation of the terminology token by identifying the appropriate time step and manipulating the probability distribution after softmax computation, even in an open-source large language model. This is not entirely trivial due to the presence of subwords but could be achievable.

Abstract

This paper presents Lingua Custodia's submission to the WMT23 shared task on Terminology shared task. Ensuring precise translation of technical terms plays a pivotal role in gauging the final quality of machine translation results. Our goal is to follow the terminology constraint while applying the machine translation system. Inspired by the recent work of terminology control, we propose to annotate the machine learning training data by leveraging a synthetic dictionary extracted in a fully non supervised way from the give parallel corpora. The model learned with this training data can then be then used to translate text with a given terminology in a flexible manner. In addition, we introduce a careful annotated data re-sampling step in order to guide the model to see different terminology types enough times. In this task we consider all the three language directions: Chinese to English, English to Czech and German to English. Our automatic evaluation metrics with the submitted systems show the effectiveness of the proposed method.

1 Introduction

It is well proven that modern Neural Machine Translation (NMT) systems (Sutskever et al., 2014; Bahdanau et al., 2014; Luong et al., 2015; Vaswani et al., 2017) achieve generally satisfying translation results. Nonetheless, the performance of translation with terminology control remains to be improved. This paper describes our submission to the WMT23 Terminology translation task in Chinese to English, English to Czech and German to English direction. The task aims to develop and evaluate machine translation systems which can translate domain specific terms in an accurate and consistent way with some extra terminology information. Note that the terminology is provided only in the inference phase, for the training there's no existing resources about the terminology.

Previous works on machine translation with terminology control can be grouped into two categories according to whether the method needs training the model with terminology information. One group incorporates the constraint during the inference time(Hokamp and Liu, 2017; Post and Vilar, 2018; Susanto et al., 2020). These methods can typically satisfy most of the constraints but suffer from high computational cost and sometimes low translation quality because it always tries to strictly apply the terminology constraint regardless of the correctness of the whole sentence. The other group integrates lexical constraints during training (Dinu et al., 2019; Crego et al., 2016; Song et al., 2019) by annotating the data with special tags in order to guide the model to learn the enforcement of the translation constraints. The main disadvantage of these methods is the lack of guarantee of all constraints in the translations. Another limitation of these works is that they usually requires a term dictionary to augment the data, such extra resource is not always trivial to obtain for some domains in some languages.

Our work follows the second line of methods which incorporate terminology in the training by inserting special tags. Upon the recent works of (Dinu et al., 2019; Ailem et al., 2021), our system has made several improvements:

1. a terminology extracted from the given training corpus in a full non supervised manner rather than from a supervised approach or a given dictionary like in (Ailem et al., 2021).
2. only use special tags without source factors(Dinu et al., 2019) to annotate source and target terms in parallel sentences.
3. use a careful tag sentence re-sampling process to represent various constraint scenarios.

We evaluate our work on all the WMT23 terminology task including the blind test. Since the

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 897–901
December 6–7, 2023.

reference is not released by the time of writing this paper, we evaluate our system by a simple naive strict match with respect to the target constraint. Our results show the effectiveness of the proposed method.

2 Method

In this section we present out system for the terminology task. Our approach is inspired by Ailem et al. (2021) and is further developed and adapted to this task.

2.1 Non supervised bilingual dictionary extraction

Approaches incorporating the constraints during the training time require some pre-built terminologies or dictionaries such as in the terminology task of *WMT2021*. The idea is to create training samples to guide the model to integrate the constraints when generating the output. However, in this year's shared task, terminology is not provided. Previous approaches such as Hazem and Morin (2016) and Liu et al. (2018) require heavy computation. Artetxe et al. (2016) can only learn single word bilingual lexicon. In this work, since our goal is to annotate the training data, having some noise in the extracted dictionary is affordable but the the number of the dictionary entries should be high enough to cover as much as possible different terminology constraint scenarios. Thereby we propose a simple yet efficient non supervised bilingual dictionary extraction approach which yields a large amount of aligned single and multi word items.

Our approach consists in extracting entries from two aspects: first we extract exact matching ngrams which contains more than 50% of non stop word or punctuation tokens from the two language texts, to prevent this process from being unnecessarily long, we limit the ngrams to five; the second aspect consists in extracting a whole sequence which is entirely included in another sequence of the corpus. The final dictionary contains both invariable and long sequence entries.

2.2 Data annotation

Following the work of Dinu et al. (2019) and Ailem et al. (2021), sentences matching source and target contraint terms are annotated with some special tags as illustrated in Figure 1.

Note that we also use mask tokens for the source term since this this provides a more general pattern

Source	His critics state that this will just increase the **budgetary deficit** .
Constraint	**budgetary deficit** → **Haushaltsdefizit**
term annotation	His critics state that this will just increase the <S> **budgetary deficit** <C> **Haushaltsdefizit** </C> .
+MASK	His critics state that this will just increase the <S> **MASK MASK** <C> **Haushaltsdefizit** </C> .

Figure 1: Training data annotation.

for the model to learn to perform the copy operation every time it encounters the tag **<S>** followed by the **MASK** token. Moreover, this makes the model more apt to support conflicting constraints, i.e., constraints sharing the same source part but which have different target parts. This may be useful if some tokens must be translated into different targets for some specific documents and contexts at test time. Our preliminary experiments have shown the effectiveness of adding masks after data annotation.

2.3 Annotated data resampling

After the automatic data annotation, several filters are applied to construct a final tagged data set which equals to 20% of the original data. The goal is to cover different constraint contexts so that the model can learn all possible cases. The criterions of the filters are as follows:

Constraint length. Oversample constraints with more composing tokens.

Constraint occurrence. Oversample constraints with low occurrence.

Constraint number. Oversample sentences with different constraint numbers.

Constraint position. Make sure that constraints at the beginning, middle and end of a sentence follow a distribution of 10%, 80% and 10%.

For all the oversampling, we apply a modified version of the temperature sampling with a temperature equal to 5:

$$P_t s(t) = \frac{P(t)^{1/T}}{\sum_i P(t_i^{1/T})}$$

where $P_t st$ is the temperature sampling probability for term t. T is the hyper-parameter temperature. $P(t)$ is the probability of term t, we assume it can be calculated by the following:

$$P_(t) = \frac{N(t)}{\sum_i N(t_i)}$$

where $N(t)$ is the frequency of term t in the training corpus. So $\sum_i N(t_i)$ represents actually the sum frequency of all terms. Finally the oversample size for term t, $N_{oversample}(t)$ will be the rounded up value of:

$$N_{oversample}(t) = P_ts(t) * \frac{N(t_{max})}{P_ts(t_{max})}$$

where t_{max} is the term having the highest frequency.

3 Experiments

3.1 Data

We participate in all three language pairs: Chinese to English (noted as zh2en), English to Czech (noted as en2cs) and German to English (noted as de2en). We use the corresponding parallel data provided by the general translation task and the development data of the terminology task. Since the given development set has only 100 sentences, we first oversample these 100 sentences by 10 times, then we randomly take 4000 sentences from given general data and add them to the oversampled data. This results in a final development set of 5000 sentences.

Regarding the training data annotation dictionaries, we extract invariable ngrams from one million random sentences. In addition, we follow what we have described in 2.1: sentences which are included in other longer sequences are added to the dictionary. An overview of the data is shown in 1.

Data	**size(sentence/item)**
zh2en train	33 892 215
zh2en dictionary	445 727
en2cs train	130 023 715
en2cs dictionary	559 063
de2en train	288 591 578
de2en dictionary	769 915

Table 1: Data used in the task

3.2 Settings

For all our translation models, we use a Transformer (Vaswani et al., 2017) with 6 stacked encoders/decoders and 8 attention heads as a building block for our systems. We also tie the source and target embeddings with the softmax layer with a shared source and target vocabulary. The model size is 512 for the source and target embeddings, 2048 for the inner layers of the fully connected feed-forward network and a dropout rate of 0.15.

Training batch size is set to 4000 tokens per iteration and we evaluate the model on the development set for every 5 000 iterations. The model is trained with an initial learning rate of 10^{-5} and 10 000 warm up steps. Training stop condition is 15 consecutive checkpoints without improvement. We use a length penalty of 0.65 and a beam size of 5 during inference for all models. All models are trained on two NVIDIA Geforce 2080Ti.

Before annotating the training data, we apply Moses tokenizer (Koehn et al., 2007)and we train a truecaser for each language and then truecase each language pair data. We also use *subword nmt*[1] to train a BPE (Sennrich et al., 2016) model of 50k merges.

3.3 Results

We evaluate our systems on the translation constraint success rate by a simple strict match because by the time of our naive evaluation, the reference was not available. We report our results on the test set in Table 2 with two settings: with and without terminology control.

	Accuracy% †	Accuracy% ‡
German to English	92.59	69.29
English to Czech	94.15	47.43
Chinese to English	83.77	22.21

†: with terminology, ‡: without terminology applied

Table 2: Term strict match accuracy (%) on the WMT23 testset with and without using extra terminology.

As shown in Table 2, our system achieves more than 90% accuracy on German to English and English to Czech test set. While the accuracy is obviously lower (roughly 10 points lower) on the Chinese to English test set, we think this might be related to the higher difficulty of the Chinese to English test set. In the test set, there are some

[1]https://github.com/rsennrich/subword-nmt

constraints which are basically named entity transcribed in *Pinyin*[2] script. For example, 段凌天 ⟶ *Duan Ling Tian* (Person), 武宗学府 ⟶ *the martial arts training institute* (Association). The model needs to somehow learn the transcription from Chinese character to *Pinyin* or a specific alignment on which there aren't much train data in the provided parallel corpus. As a whole, our system shows satisfying results when the terminology is provided. To study whether the high accuracy results are obtained by our terminology control system or not, we also evaluate our system but without giving any terminology during the inference. We should expect a big gap between the two settings (with and without terminology during the inference). The results confirm our assumption: an average of 40+ points of difference for the three directions.

For the blind test, we present our strict match accuracy in Table 3. The data in the blind test is provided in three different modes: the first one corresponds to general machine translation and the second one has the terminology dictionary added. The data is provided in three different modes. The last one has random, though correct, translations of words, which are not terminologies. The idea is to see if we obtain improvement between the different modes, in which case it means that the model is good at terminology control not because that it has learned the specific way of translating those terms but has learned how to make good use of terminology information.

	Accuracy% †	Accuracy% §	Accuracy% ‡
German to English	97.35	98.18	36.16
English to Czech	94.76	94.50	45.06
Chinese to English	93.26	74.20	48.45

†: with correct terminology; §: with random terminology; ‡: without terminology applied

Table 3: Term strict match accuracy (%) on the WMT23 blind testset with correct and random term, and without using extra terminology.

On all the language directions, our system achieve more than 90% accuracy when the terminology information is provided. When a random constraint is given, we consider the given random constraint term as the reference translation. In this case, we observe that our system can still obtain a high accuracy score. This means that the model is able to generalize the behavior of outputting any constraint. Finally, in the general translation setting, we see a sharp decreasing of the accuracy, 40+ points lower compared to the terminology setting. This phenomenon shows that the model is not just good on its own but can make good use of the terminology.

[2]en.wikipedia.org/wiki/Pinyin

4 conclusion

This paper describes our submission to the terminology shared task. We participate in three language directions, German to English, English to Czech and Chinese to English. We extract a bilingual dictionary for the three language directions in a fully non supervised way and train a neural machine translation model with augmented data for each direction. Our term strict match evaluation shows the effectiveness our proposed system for all the three directions.

5 Limitations

Since we pursue the line of works which incorporate terminology control by adding special tags during the training. This system has also the limit of not being able to guarantee the constraints to be present in the output because of the soft nature. This is mainly concertized by two cases:

- **No constraint**. The constraint is not presented at all in the translation.
- **Variant constraint**. The exact format of the constraint is not presented but a variant is proposed in the output.

We observe that for most of the time when the model fails to generate the target constraint, the scenario belongs to the second case which proposes a variant of the constraint. This translation is acceptable in a human evaluation context from time to time.

To address this main limit, we would like to exploit assembling our method with other techniques such as a post processing step to force the constraint if the constraint is not presented in the output.

Abstract

This paper discusses the methods that we used for our submissions to the WMT 2023 Terminology Shared Task for German-to-English (DE-EN), English-to-Czech (EN-CS), and Chinese-to-English (ZH-EN) language pairs. The task aims to advance machine translation (MT) by challenging participants to develop systems that accurately translate technical terms, ultimately enhancing communication and understanding in specialised domains. To this end, we conduct experiments that utilise large language models (LLMs) for two purposes: generating synthetic bilingual terminology-based data, and post-editing translations generated by an MT model through incorporating pre-approved terms. Our system employs a four-step process: (i) using an LLM to generate bilingual synthetic data based on the provided terminology, (ii) fine-tuning a generic encoder-decoder MT model, with a mix of the terminology-based synthetic data generated in the first step and a randomly sampled portion of the original generic training data, (iii) generating translations with the fine-tuned MT model, and (iv) finally, leveraging an LLM for terminology-constrained automatic post-editing of the translations that do not include the required terms. The results demonstrate the effectiveness of our proposed approach in improving the integration of pre-approved terms into translations. The number of terms incorporated into the translations of the blind dataset increases from an average of 36.67% with the generic model to an average of 72.88% by the end of the process. In other words, successful utilisation of terms nearly doubles across the three language pairs.

1 Introduction

The primary goal of the WMT 2023 Terminology Shared Task is to evaluate the ability of MT systems to accurately translate technical terminology. The task aims to assess the extent to which MT models can utilise additional information regarding the translation of terminology. The shared task requires the participants to provide three translations, one without terms and the others with two individual sets of terms.

There have been several advancements in the area of MT domain adaptation, where an MT model is expected to follow the style and terminology of a certain domain or client (Chu et al., 2017; Kobus et al., 2017). Moreover, some researchers give special focus to terminology while training and fine-tuning MT systems (Dinu et al., 2019; Hu et al., 2019b; Haque et al., 2020; Michon et al., 2020; Nayak et al., 2023). However, forcing an MT model to adhere to certain terminology at inference time is among the most challenging aspects of MT. Hence, several researchers have investigated approaches to terminology-constrained decoding at translation time (Hokamp and Liu, 2017; Hasler et al., 2018; Post and Vilar, 2018; Hu et al., 2019a; Exel et al., 2020). The goal is to ensure that the MT system can accommodate unseen terminology while retaining translation accuracy and fluency.

Recently, since the emergence of advanced LLMs such as GPT-3 (Brown et al., 2020), BLOOM (Le Scao et al., 2022), PaLM (Chowdhery et al., 2022), Falcon (Penedo et al., 2023), Llama 2 (Touvron et al., 2023), and Jais (Sengupta et al., 2023) to mention just a few, researchers have been exploring the capabilities of these models for a number of tasks including MT (Bawden and Yvon, 2023; Hendy et al., 2023; Jiao et al., 2023; Moslem et al., 2023; Vilar et al., 2023). Some work investigates whether it is possible to utilise LLMs for terminology-constrained MT using a pre-defined glossary (Moslem et al., 2023) or even a dictionary (Ghazvininejad et al., 2023). They found the approach is generally effective in increasing the number of terms used in the translation, even for low-resource languages.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 902–911
December 6–7, 2023.

We highlight our key contributions with the systems that we submitted for the WMT 2023 Terminology Shared Task as follows:

- **LLMs for domain-specific data augmentation:** In our previous work (Moslem et al., 2022), we employed LLMs, namely GPT-J (Wang and Komatsuzaki, 2021) and mGPT (Shliazhko et al., 2022), to generate domain-specific datasets based on the target sentences in a small authentic dataset, then generated the source sentences with back-translation (Sennrich et al., 2016; Poncelas et al., 2019), and finally fine-tuned an encoder-decoder MT model on this data. In this work, we take a couple of steps forward by instructing an LLM, namely ChatGPT (Brown et al., 2020; Ouyang et al., 2022), to generate terminology-based bilingual synthetic data. In other words, the LLM will generate both the source and target sides of translation pairs, making sure the pre-approved target terms provided by the organisers are used in the translations.

- **LLMs for terminology-constrained MT and MT post-editing:** In our previous work, we utilised an LLM for translation and provided it with a list of terms to support in-context learning, which improved adherence to the required terminology at inference time (Moslem et al., 2023). We also investigated whether we could use an LLM for post-editing MT generated by other systems. In this work, we prompt ChatGPT to insert missing terms into translations generated by an encoder-decoder MT system. In other words, if some of the translations generated by a fine-tuned MT model still do not include the terms provided by the organisers, we feed these translations into an LLM, namely ChatGPT, instructing it to incorporate these terms while using the same translation.

2 Method

In our submissions to the WMT 2023 Terminology Shared Task, we followed these steps:

(i) Generate bilingual synthetic data based on the pre-approved terms, using an LLM, namely ChatGPT.

(ii) Fine-tune a generic model, OPUS (Tiedemann and Thottingal, 2020), on a mix of the terminology-based synthetic data generated in (i) and a randomly sampled portion of the original generic training data.

(iii) Generate translations of the dev, test, and blind datasets provided by the organisers with the fine-tuned model from (ii).

(iv) Apply terminology-constrained automatic post-editing using ChatGPT to incorporate missing terms into translations that do not yet include the required terminology.

2.1 Synthetic Data Generation

We used ChatGPT "gpt-3.5-turbo"[2] to generate bilingual sentence pairs, using the terms provided by the organisers. So, given a target term, the model was asked to generate multiple translation pairs, including both the source (e.g. German) and the target (e.g. English). For parameters of ChatGPT's API, we used *top_p* 1 and *temperature* values 0 and 0.3 to generate diverse outputs.

Example prompt: Terminology-based generation

Please use the "Federal Ministry of Science" to generate just 20 numbered sentences in German-English in one Python dictionary format.

To filter the generated data, we first removed duplicate sentences from the whole dataset, based on both the source and target. Then, we applied language detection of both sides of the data using *fastText*[3] and *pycld2*[4] libraries to ensure that the generated sentences were in our desired languages. We excluded any sentences whose scores were below a certain threshold, namely 0.9 for *fastText* and 90 for *pycld2*.

The filtering step removed less than 1% of the generated data. However, due to computational resource and time limitations, we could not use all the generated data. Table 1 reports the number of generated, filtered, and used translation pairs.

Initially, we only had the development and test datasets, so we used them for the German-to-English language pair. Later, when the organisers released the blind dataset, we used the development, test and blind datasets for the Chinese-to-English and English-to-Czech language pairs.

[2]The model "gpt-3.5-turbo" is a relatively efficient and cost-effective option, so we wanted to understand the quality we can achieve with it.

Lang	Raw	Filtered	Used
DE-EN	124,215	104,318	68,265
EN-CS	187,471	103,797	64,218
ZH-EN	90,538	72,695	49,001

Table 1: Terminology-based bilingual data generated by ChatGPT for fine-tuning the OPUS model

To assess the quality of the bilingual data generated by ChatGPT, we computed cross-entropy scores (Moore and Lewis, 2010) of the synthetic translation pairs based on the strong encoder-decoder MT model, NLLB-200 3.3B (Costa-jussà et al., 2022). For scoring, we used CTranslate2[5] (Klein et al., 2020) *score_batch()* method with the parameters *batch_type* "tokens" and *max_batch_size* 2024. We scored each synthetic translation pair generated by ChatGPT, and then calculated the average score for the whole dataset. Computing dual cross-entropy scores according to two inverse translation models trained on clean data is an effective method to evaluate data quality (Junczys-Dowmunt, 2018). Hence, we computed the scores of both directions of each language pair according to the multilingual MT model NLLB-200 3.3B because both directions are generated by ChatGPT. To produce a baseline for translation quality, we generated the translations of the same datasets using NLLB-200 3.3B for each language direction with *beam_size* 4, and then scored these translations with the same model. As the scores are in the form of negative log probabilities, we converted them to their exponential equivalents for readability, which are reported in Table 2. It is normal that the model NLLB-200 generates higher scores for its own translations; however, we wanted to know to what extent such scores are comparable to those of ChatGPT's synthetic translation pairs. According to the scores, the German↔English language pair had the most comparable quality, followed by Czech↔English, and Chinese ↔English language pairs.

Among the approaches that can be employed for assessing the quality of synthetic bilingual data is semantic similarity between the two sides of each translation pair (e.g. with mUSE (Yang et al., 2020)). However, the scoring approach that we previously described and used achieves a similar goal while comparing the quality of the synthetic bilingual data to the translation quality of a strong MT baseline model, namely NLLB-200 3.3B.

2.2 Fine-tuning

Using the term-based synthetic bilingual data generated in the previous step, we fine-tuned encoder-decoder Transformer-based MT models (Vaswani et al., 2017). In particular, we fine-tuned OPUS MT models, with Hugging Face Transformers.[6] We applied mixed fine-tuning (Chu et al., 2017); in other words, we fine-tuned the baseline model with a mix of the terminology-based synthetic data generated from the previous step (cf. Section 2.1) and a randomly sampled portion of the original generic data used to train the OPUS baseline model. The numbers of segments taken from the OPUS generic data are as follows: CS: 372,928, DE: 419,881, ZH: 462,780. We over-sampled the synthetic terminology-based data to make it the same size as the used portion of generic data. The fine-tuning parameters are as follows: *train* = 0.9, *val* = 0.1, *batch_size* = 32, *learning_rate* = 2e-5, *accumulate_gradient* = 4, *weight_decay* = 0.01, *num_train_epochs* = 1, *max_input_length* = 256, *max_target_length* = 256. Finally, we used the fine-tuned model to generate translations for the development, test, and blind sets.

At first glance, the fine-tuning step might look redundant if the LLM can achieve the same translation quality directly, either via zero-shot translation or few-shot in-context learning (Moslem et al., 2023). However, domain-specific or terminology-based knowledge distillation (Treviso et al., 2023) from a massive LLM to a compact task-oriented MT model can help boost efficiency at inference time while enhancing domain adaptation and terminology adherence. Obviously, when authentic in-domain data is available, it can be used for fine-tuning instead of synthetic data for domain adaptation of the MT model. In production workflows,

[6] https://github.com/huggingface/transformers

only segments that do not meet specific quality criteria are passed to either human or automatic post-editing. Hence, deployment of a model fine-tuned on in-domain data can reduce the number of translations that need post-editing.

2.3 Terminology-constrained Automatic Post-Editing

For the shared task, the organisers provided two term sets for each source sentence in the test and blind datasets, and expected the participants to generate two translations that use one term set each. In this step of terminology-constrained automatic post-editing, we aim to refine the translations generated by an MT system by inserting the required terminology. To this end, we checked the translations generated by the fine-tuned model from the previous step (cf. Section 2.2). For each term set provided for the sentence, if the translation does not include all the terms, we ran this step of terminology insertion into the translation.

This step involves instructing ChatGPT to post-edit the translation by making sure it includes all the terms without changing the rest of the translation. For the API's parameters, we used *top_p* 1 and *temperature* values 0 and 0.2, and then chose the generation that fixed more terms.

Example prompt: Terminology-constrained post-editing

In the following <tgt_lang> translation, use the <tgt_term> to translate the <src_lang> term <src_term>, and the...[7] Leave everything else the same.\n\n

<src_lang>: <src_segment>\n
<tgt_lang>: <tgt_segment>

3 Evaluation

To assess the effectiveness of our process, we conducted two types of evaluation: (i) term-level evaluation in order to measure the level of adherence to the required terminology, and (ii) sentence-level evaluation in order to see whether the process affected the quality of the overall translation.

3.1 Term-level Evaluation

In Tables 3 and 4, we report the number of terms used in the translations of the test and blind datasets, respectively, in respect to the two term sets provided by the organisers. The results show the effectiveness of our proposed process, increasing the integration of the required terms in the final translations of the blind dataset from an average of 36.67% with the baseline generic model to an average of 72.88% after the LLM-based post-editing, across the three language pairs. Interestingly, prompting an LLM to integrate the required terms into the translations generated by a fine-tuned encoder-decoder MT model was more effective than solely using the fine-tuned model.

Lang	System	Total [1]	Used [1]	Total [2]	Used [2]	Avg %
DE-EN	Baseline	432	291	317	168	60.18
	Fine-tuned	432	302	317	165	60.98

	Fine-tuned	2892	1422	2908	970	41.26
	Term APE	2892	**2471**	2908	**2322**	**82.65**
Avg. %	Baseline					36.67
	Fine-tuned					38.98
	Term APE					**72.88**

Table 4: For the blind dataset, the number of terms used in the translations from the first term set [1] and the second term set [2]. According to the results, terminology-based automatic post-editing ("Term APE") using ChatGPT achieved the best adoption of the required terminology.

3.2 Sentence-level Evaluation

After the end of the submission phase, the organisers released the references for the participants to conduct automatic evaluation. The main purpose of this sentence-based evaluation process is to determine whether terminology integration affected the overall quality of translation. In general, as demonstrated in Table 4 and Table 5, this terminology-constrained automatic post-editing step significantly increased the inclusion of the necessary

[7] We can add more terms, if needed.

terms into the final translation while improving translation quality across the three language pairs.

For the automatic evaluation of each MT system, we used the BLEU (Papineni et al., 2002), chrF++ (Popović, 2017), and COMET (Rei et al., 2020) metrics. Since many of the Chinese-to-English segments in the blind dataset did not have two term sets, we evaluated only those that had two term sets (1629 segments out of 2640 segments). We observe that the evaluation scores of the Chinese-to-English translation task are much lower than those of the two other language pairs. This can be due to the literary nature of the blind dataset extracted from Chinese novels, which might be difficult for both the MT model and automatic evaluation metrics.

Lang	Count	System	BLEU	chrF++	COMET
DE-EN	2963	Baseline	19.81	48.04	21.81
		Fine-tuned	19.27	47.75	21.51
		Term APE [1]	32.36	60.84	40.25
		Term APE [2]	27.84	56.84	33.20
		Term APE Avg.	**30.10**	**58.84**	**36.73**
EN-CS	3005	Baseline	29.13	53.11	50.90
		Fine-tuned	24.54	49.14	33.78
		Term APE [1]	45.65	67.36	79.84
		Term APE [2]	37.88	61.19	63.64
		Term APE Avg.	**41.77**	**64.28**	**71.74**
ZH-EN	1629	Baseline	6.95	27.95	-50.90
		Fine-tuned	7.76	29.26	-38.83
		Term APE [1]	9.56	32.80	-18.96
		Term APE [2]	11.93	35.30	-13.51
		Term APE Avg.	**10.75**	**34.05**	**-16.24**

Table 5: Automatic evaluation of the overall translation quality across the three language pairs based on the blind dataset. The "Baseline" refers to the OPUS model without fine-tuning, while "Fine-tuned" refers to the model after domain adaptation with the bilingual terminology-based synthetic data generated by an LLM. Finally, the three last rows for each language pair refer to using ChatGPT for terminology-constrained automatic post-editing ("Term APE") of the MT output generated by the fine-tuned model. In other words, "Term APE [1]" indicates the results when the first term set was used to prompt ChatGPT to integrate terms of this set into the translation generated by the fine-tuned model, while "Term APE [2]" refers to using the second term set. Finally, "Term APE Avg." is the average of "Term APE [1]" and "Term APE [2]" for each language pair. Terminology-constrained automatic post-editing with ChatGPT achieves the best results across the three language pairs in terms of the overall translation quality. As reported in Table 4, the number of terms integrated after the automatic post-editing step also increased.

Moreover, it is worth noting that we used the English term while generating bilingual synthetic data (cf. Section 2.1) for the three language pairs. However, English is the target language for both Chinese-to-English and German-to-English language directions, while it is the source language for the English-to-Czech language direction. This can explain the performance degradation after the fine-tuning step in the English-to-Czech language direction (cf. Tables 4 and 5). In other words, it is recommended in the step of bilingual synthetic data generation to either use the target term or both the source and target terms while prompting the LLM to generate translation pairs.

As explained in Section 2.3, our final step of terminology-constrained automatic post-editing involves instructing an LLM to insert terms that were missing from the output of the fine-tuned model. This significantly increased term usage across all the Chinese-to-English, English-to-Czech, and German-to-English language pairs (cf. Table 4). Furthermore, as demonstrated in Table 5, this step had no detrimental effects on translation quality. In fact, integrating the necessary terms into the translation using ChatGPT improved translation quality according to our automatic evaluation.

4 Conclusion and Future Work

In this work, we showed that applying a multistep process of mixed fine-tuning on terminology-based synthetic bilingual data and then terminology-constrained automatic post-editing with an LLM can increase the adherence to the pre-approved terms in the generated translations. By the end of the process, the use of the required terms has increased in the translations of the blind dataset across the three language pairs from an average of 36.67% with the baseline generic model to an average of 72.88% after instructing an LLM to integrate the required terms into the translations.

Due to the task restrictions, we had to fine-tune OPUS models only. We would like to experiment with fine-tuning NLLB models, and probably the new SeamlessM4T (Barrault et al., 2023), Mistral (Jiang et al., 2023), and MADLAD-400 models (Kudugunta et al., 2023), on the same data and compare the output quality. In our experiments, we employed ChatGPT "gpt-3.5-turbo" for both terminology-based synthetic data generation and terminology-constrained automatic post-editing, as it is a relatively efficient and cost-effective option. In the future, we would like to repeat the same experiments with GPT-4 in order to assess the benefit of using a stronger language model on overall performance. We observe that BLOOM can be used as an alternative LLM for data generation; however, one-shot generation might work better than zero-shot generation. In this case, the prompt can consist of a term, a bilingual sentence pair,

and then another term. Interestingly, the model will predict a new translation pair including the second term. While certain open-source models such as Llama 2 and Falcon might be employed for the terminology-constrained automatic post-editing step for certain languages, we suspect that they will need fine-tuning before being reliably usable for most languages.

In future work, we will carry out a deeper analysis of the generated synthetic data together with the outputs of the fine-tuned models in order to understand how the properties of the synthetic data affect the fine-tuning results. It is important also to test the same approach for other languages, especially low-resource language pairs.

Moreover, it would be interesting to exclude the fine-tuning step and assess the overall translation quality after LLM-based post-editing. It is possible that domain adaptation through fine-tuning the baseline MT model either on authentic or synthetic data would still be beneficial. It can lead to domain-specific improvements in the overall translation quality that may not be achievable by the baseline model or the terminology-constrained post-editing step. Again, deploying a model fine-tuned on in-domain data into production can enhance terminology adherence in initial translations. As there is no need to send the translations that already include the pre-approved terms to the LLM for terminology-constrained post-editing, this can reduce the number of translations that require post-editing. Such an efficient workflow can allow us to save resources, and minimise latency at inference time. Similarly, there are potential advantages of employing an LLM for post-editing rather than for direct translation. Instead of solely relying on the translation quality of the LLM, quality estimation can be performed to select the best MT model in general or for the current source text segment. Ultimately, only segments that do not meet quality criteria are then passed to the LLM for post-editing.

OPUS-CAT Terminology Systems for the WMT23 Terminology Shared Task

Tommi Nieminen
University of Helsinki
tommi.nieminen@helsinki.fi

Abstract

This paper describes the submission of the OPUS-CAT project to the WMT 2023 terminology shared task. We trained systems for all three language pairs included in the task. All systems were trained using the same training pipeline with identical methods. Support for terminology was implemented by using the currently popular method of annotating source language terms in the training data with the corresponding target language terms.

1 Introduction

OPUS-CAT (Nieminen, 2021) is a collection of open source software consisting of a local neural machine translation (NMT) engine and plugins for computer-assisted translation (CAT) tools, such as Trados, memoQ and OmegaT. OPUS-CAT enables the use of NMT models trained in the OPUS-MT project (Tiedemann and Thottingal, 2020) in professional translation. As OPUS-CAT is aimed at professional translators, it is designed to be integrated into normal translation workflows. Multilingual term bases are one part of those workflows, so we have decided to implement a functionality for utilizing term bases in OPUS-CAT. This paper describes the methods used in OPUS-CAT for enforcing the use of terminology in machine translation output and the results of applying these methods to the data provided in the shared task. We trained new models for all three language pairs in the shared task. The shared task results were not available at the time of the submission of this paper.

2 Related work

Most published methods of constraining an NMT model to generate terminologically correct translations fall into three categories.

2.1 Constrained decoding

Hokamp and Liu (2017); Hasler et al. (2018): The beam search algorithm is modified to enforce the generation of target terms for each source term identified in the source sentence. The main advantage of constrained decoding is that it can be used with any model. The main disadvantages are slower decoding speed, and quality degradation due to the unconditional prioritizing of target terms, even in inappropriate contexts (such as generating the target term multiple times in the translation).

2.2 Pass-through term placeholders

Michon et al. (2020): Source terms identified in the source sentence are replaced by placeholders, which the NMT model passes through to the translation. The placeholders generated in the translation are then replaced by corresponding target terms. In order for the model to learn the correct pass-through behaviour, the model has to be trained with data that has been augmented with sentence pairs containing aligned placeholders on source and target sides. The main advantage of this approach is that the target terms are usually generated in correct positions. The disadvantage is that the information in the source term is discarded, which may degrade the quality of the overall translation. Generating morphological features for the target term may also be difficult.

2.3 Injecting target terms as soft constraints

Dinu et al. (2019): Source terms identified in the source sentence are annotated with target term information, and the NMT model uses these target term annotations to generate the term translations. Similar to the pass-through placeholder method, the training data of the model needs to be augmented with sentence pairs, where the source sentence has been annotated with target term information that also occurs in the target sentence. This will induce the model to generate translations that conform to the target term information present in the source text. While the constrained decoding and pass-through placeholder methods unconditionally

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 912–918
December 6–7, 2023.

ally enforce the use of the specified terminology in the generated translation (they place hard constraints on the output), in this method terms are soft constraints on the output: contextual factors may cause the model to not use the specified term in the translation. This is the desired behaviour, since terms are often polysemous, and the specified term translation is usually only appropriate for one sense of the term. For instance, a terminology might specify a translation for the word *file*, but the translation would only be relevant for the sense of *file* meaning an individual file in a computer file system, instead of e.g. a physical file, a wood file, or the imperative of the verb *to file*.

The terminology support in OPUS-CAT is based on the soft constraint method as it is the simplest to implement and has performed best in previous evaluations (Alam et al., 2021b).

3 Model training

The models were trained using a modified version of Mozilla's *firefox-translations-training*[1], an end-to-end pipeline for building NMT models, based on the Snakemake workflow management system (Mölder et al., 2021). The pipeline loads, preprocesses, cleans and filters the training data, and trains and evaluates the NMT models. For this shared task, a terminology annotation workflow has been added to the pipeline[2].

3.1 Data

The models were trained using the data provided for the constrained track of WMT23. Since sufficient parallel data was available for each language pair, we did not include any back-translated monolingual data in the training corpus. This simplifies and speeds up training, and from the point of view of terminological correctness there does not appear to be any obvious benefit to using back-translated data, even though it would almost certainly increase general output quality.

3.2 Data cleaning

The data was cleaned and filtered using the standard *firefox-translations-training* workflow, which consists of monolingual cleaning of source and target corpora, followed by the filtering of parallel sentences with Bicleaner or Bicleaner-AI. Data for **en-cs** and **de-en** were filtered with Bicleaner-AI, while no parallel cleaning was performed for **zh-en**, as no Bicleaner-AI model for **zh-en** was available to the pipeline.

3.3 Terminology annotation

A part of the cleaned and filtered data was annotated with artificial term information (the annotation script is available from https://github.com/TommiNieminen/soft-term-constraints). First, artificial term data is generated from the parallel data:

1. **POS tagging and dependency parsing:** Stanza (Qi et al., 2020) was used to identify the parts-of-speech (POS) and dependency relations of the tokens in the source and target sentences.

2. **Chunking:** The POS and dependency data from step 1 was used to identify noun and verb phrase chunks in the source and target sentences.

3. **Word alignment:** The filtered parallel corpus was aligned on word-level using FastAlign (Dyer et al., 2013).

4. **Chunk alignment:** Source chunks that were aligned with target chunks were identified based on the word alignment from step 3.

The above method is identical to the one in Bergmanis and Pinnis (2021) except for the addition of chunking.

As analyzing sentences with Stanza is quite slow, only a small portion of the parallel data was analyzed (approximately one in ten sentences). The noun and verb phrase chunks identified on the basis of the analysis were saved and used to annotate the data using two different annotation methods (see table 2 for examples):

1. **Append**: The target language chunk was appended to the aligned source language chunk, with the source and target chunks separated with a special separator tag. A start tag was also added before the start of the source chunk, and an end tag was added after the end of the target chunk.

2. **Replace**: The source language chunk was replaced with the aligned target language chunk. The target chunk in the source sentence was tagged with start and end tags.

Language pair	Raw	Cleaned	Annotated
Chinese to English	35,452,884	28,840,867	2,884,058
German to English	294,331,299	182,977,635	18,297,581
English to Czech	56,288,239	35,046,151	2,704,588

Table 1: Amount of parallel sentences available for each language pair. Base model is trained with cleaned data, and the terminology models are fine-tuned with a combination of clean and annotated data or just annotated data (**-omit** models).

Source	`This product is no longer available`
Append	`This <term_start> product <term_end> produkt <trans_end> is no longer available.`
Replace	`This <term_start> produkt <term_end> is no longer available.`

Table 2: Examples of **append** and **replace** annotation methods

These methods are identical to the ones in Dinu et al. (2019) except for the use of tags instead of factors to identify terms (similar to Ailem et al. (2021).

Since a source sentence can potentially have any number of source terms, the training data needs to contain source sentences with different amounts of annotated terms. The annotation algorithm keeps track of how many sentences with n terms have been annotated so far, and tries to ensure that the sentence counts approximate a geometric series, where the amount of sentences gets halved for every extra term. For instance, the annotated corpus for en-cs contains 1,353,810 sentences with one term, 676,895 sentences with two terms, 338,414 sentences with three terms and so forth. The justification for the ratio is that most sentences will contain only few terms, so the lower counts should be emphasized in training.

4 Observations on the shared task

This year's terminology task differs in from real-world use of terminology in machine translation in two important aspects:

1. Source terms have been unambiguously identified.

2. Target terms are specified in an already inflected form. This inflected form has been extracted from a reference translation, and therefore has a high probability of being a correct form to use in a translation.

In actual use cases, the NMT system would have to identify the source terms based on a lemma form provided in a term base, and only the lemma form of the target term would be available. The probability of the lemma term occurring as such in a correct translation is much lower than for the inflected term from a reference translation. The shared task is therefore much easier than the real-world task of translating with a term base.

Due to the use of inflected terms, the shared task also favours soft constraint models where the model is trained on surface forms of terms instead of lemma forms. Because of this, the models we have submitted for the shared task all use surface forms of the terms. However, this will induce the models to learn a simple copy behaviour (Dinu et al., 2019), instead of the more desirable copy-and-inflect behaviour (Bergmanis and Pinnis, 2021). In our OPUS-CAT production models, we intend to use lemma-based constraints, since we expect them to perform better in real-world scenarios, especially with morphologically complex target languages.

5 Models

Five different models were trained for each language pair. All of the models were trained with Marian (Junczys-Dowmunt et al., 2018) using the **transformer-big** model architecture (Vaswani et al., 2017). For each language pair, a combined SentencePiece (Kudo and Richardson, 2018) vocabulary (32,000 symbols, out of which ten symbols were reserved as potential term tags by using the user-defined symbol functionality of SentencePiece) was trained and used for both source and target languages. As transformer-big models are costly to train, a single base model was trained for each language pair using just the filtered corpus, and the base model was then fine-tuned with data

that had been augmented with the terminological annotations. Another motivation for using fine-tuning is the reuse of models: OPUS-CAT uses the OPUS-MT model collection that contains thousands of pre-trained models, and fine-tuning those models to support the use of terminology instead of training terminology models from scratch saves time and resources.

Yet another advantage of fine-tuning is that it makes it possible to quickly test the performance of different term annotation schemes. As mentioned, we experimented with the **append** and **replace** methods. For both methods, two models were trained, one where the annotated sentences were combined with the unannotated sentences when fine-tuning (**add**), and one where the unannotated sentences were omitted (**omit**). The expectation is that the **omit** model will specialize better to term translation, while the **add** model will retain better generic translation capabilities. In production use it may be best to use a specialized term model when terms are detected in the source sentence, and revert back to a generic model when no terms are detected.

The **zh-en** base model was trained until convergence (chrF validation metric did not improve for 20 consecutive validation steps). For the **en-cs** and **de-en** base models the training did not have time to converge before the deadline for shared task submission, but both models were trained sufficiently long to obtain competitive evaluation scores (on par with scores published for existing OPUS-MT models). The terminology models were trained by fine-tuning the base model with annotated data for one epoch.

When translating with a terminology model and a term base, a script is used to identify terms in the source text and to annotate the terms in the source sentence before translation, using the same annotation scheme as in the training data. Since the target side of the training data was not modified, the translation does not need to be post-processed.

5.1 Model n-best combination and reranking

For the submission to the shared task, we combine the outputs of the different types of models using a simple n-best reranking method (this is referred to as the **mixture** model in the tables):

1. An n-best list of size 8 is generated for each source sentence by each model.
2. Term occurrences are counted for each translation in the n-best lists.
3. The translation containing the most terms in all n-best lists is chosen as the final translation.
4. If translations from different models have the same amount of terms, the final translation is picked based on the following model hierarchy: **base**, **append**, **replace**, **append-omit**, **replace-omit** (the assumption is that the quality is best for the base model and worst for the omit models).
5. If there are multiple translations with the same amount of terms in a model's n-best list, translations higher in the n-best list are preferred.

The motivation for using this reranking method is that since the models use different approaches to generate translations, their combined n-best lists will be diverse, which increases the probability of finding a translation with correct terms. Also, in general it makes sense to rerank n-best lists in terminology translation, since the criteria for reranking is so clear (the highest amount of term occurrences).

6 Evaluation

6.1 Evaluation methods

General model performance was evaluated with BLEU and chrF metrics using sacreBLEU (Post, 2018).

Terminological correctness was evaluated by simply counting what percentage of the specified terms actually occur in the translation in the surface form in which they are defined. This naive method ignores two important issues: the correct placement of the term within the translation, and the matching of all other inflected forms of the term. Alam et al. (2021a) introduces more sophisticated term accuracy metrics to alleviate these issues, but we decided against applying them. Since we use evaluation mainly for sanity checking soft constraint models, which generally place terms correctly (and do not place terms at all if no plausible position is found for them), evaluating the correct placement is not crucial. Likewise, matching all inflected forms is not crucial in the context of this shared task, since the terminology is provided in an already inflected form, and our models have been trained with surface term annotations, and will likely have learned to copy the single inflected form provided to them.

Table 4: Term translation accuracy with the shared task dev set (sentence count is in parentheses under the language pair). In this scenario, the terms have been annotated to the input of the term models, and the term models perform better than the base model, as is to be expected.

6.2 Evaluation data

Models were evaluated against a selection of test sets allowed for the constrained track of WMT23 (see table 3 for results). Terminological correctness was evaluated using the development sets provided in the shared task (see table 4 for results). As the shared task development sets were quite small, we also created artificial terminology test sets for each language pair from the constrained track test sets, using the same annotation script that was used to annotate the training data (we did not use pre-existing terminologically annotated corpora due to the constrained track restrictions). Aligned noun and verb phrase chunks were identified in the test set sentences, and converted into sentence-level dictionaries similar to those in the shared task development sets (see table 5 for results).

Most NMT models trained on parallel data will exhibit some degree of copy behaviour, since source texts often contain target language words (this is especially common when the target language is English, due to its dominant position as a world language). Therefore it is plausible that the base models are already capable of copying target terms injected into the source sentence to the

Table 5: Term translation accuracy with the artificial term test set (test set sentence count is in parentheses under the language pair). Note that **mixture** will always have the best term accuracy, since it combines the output of other models based on term accuracy. Target terms have been added to the input for all models expect **base**. **base-term** is a **base** model translating input where source terms have been replaced with target terms.

translation. To determine the extent of this innate copying ability of the base model and the actual improvement brought by fine-tuning, a separate **base-term** test set was created from the artificial term test set by replacing the source terms in the source sentences with corresponding target terms.

6.3 Interpretation of the evaluation results

Results of the evaluation mostly conform to expectations. All soft constraint models outperform the base model in term translation, with the **append** and **replace** models performing best. This is somewhat surprising, since the **append-omit** and **replace-omit** models were expected to specialize better to term translation.

It is also surprising that the general translation quality of the soft constraint models is comparable to that of the base models. Strangely, the **zh-en** soft constraint models clearly outperform the base model even in general translation. This may be due to the **zh-en** base model converging early, after only 6 epochs of training. Still, it is counter-intuitive that fine-tuning with the small **omit** data sets consisting only of annotated sentences should noticeably improve general translation quality.

The results also confirm that the base models are quite capable of copying exact terms from the input sentence into the translation, especially the **de-en** model. However, injecting terms directly into the base model input seems to noticeably lower the overall translation quality.

7 Conclusion

Our submission for the shared task confirms that soft terminology constraint methods work with a variety of language pairs. We also demonstrate that soft constraint models can be created by fine-tuning base transformer models, which speeds up training and the investigation of different soft constraint methods and parameters. The results also indicate that fine-tuned soft constraint models have acceptable general translation quality, and do not require a back-off base model in production use.

Limitations

The soft constraint methods discussed assume terms are inflected, which is not usually the case when actually working with term bases. This limits the usability of the methods, especially with morphologically complex target languages. However, the annotation script also supports the use of lemma forms of terms. The reranking method used to produce the best term accuracy is computationally heavy, as it requires decoding with five separate **transformer-big** models.

Abstract

A lack of consistency in terminology translation undermines quality of translation from even the best performing neural machine translation (NMT) models, especially in narrow domains like literature, medicine, and video game jargon. Dictionaries containing terminologies and their translations are often used to improve consistency but are difficult to construct and incorporate. We accompany our submissions to the WMT '23 Terminology Shared Task with a description of our experimental setup and procedure where we propose a framework of terminology-aware machine translation. Our framework comprises of an automatic terminology extraction process that constructs machine translation datasets with terminology dictionaries in low-supervision settings and two model architectures with terminology constraints. Our models outperform baseline models by 21.51%p and 19.36%p in terminology recall respectively on the Chinese to English WMT'23 Terminology Shared Task test data.

1 Introduction

The WMT'23 Terminology Shared Task aims to assess machine translation models' abilities to leverage additional information. A terminology dictionary is provided with each line of source text. This is particularly useful for terminology consistency. The WMT'23 Terminology Shared task includes the language pairs Chinese-English, English-Czech, and German-English. We focus our submission on the Chinese-English pair. The task consists of three modes, as shown in Table 1.

Mode 1 assesses translation quality without additional terminology information. Mode 2 assesses translation quality with additional terminology information. Mode 3 assesses translation quality with a glossary containing random non-terminology.

In this paper, we describe our model building process for terminology translation from data preprocessing to model evaluation. We present two Transformer-based encoder-decoder models: Terminology Self-selection Neural Machine Translation (TSSNMT) and ForceGen Transformer (ForceGen-T). TSSNMT uses a shared encoder with a gating mechanism (Bapna and Firat, 2019), allowing the model to determine the weights of the source sentence and terminologies to use during generation. ForceGen-T enforces a decoder to generate the terminologies via force decoding (Reheman et al., 2023) and copy mechanism (Song et al., 2019), which enables the model to attend to terminologies during generation. Both models significantly outperform the baseline model.

2 Related works

Previous work on enhancing machine translation with pre-defined terminology encompasses three primary approaches.

First, a data-driven approach where terminologies are appended to input sentences (Dinu et al., 2019; Song et al., 2019). Song et al. (2019) suggest using copy mechanism to instruct the model to replicate the target terminology during the generation process.

Second, an alternative approach focuses on manipulating the model architecture. Bapna and Firat (2019) have used input sentences and their corresponding retrieved translation pairs to encode conditional source target memory. This approach uses a gated multi-source attention mechanism, which takes the encoded representation and the hidden state of the source as input, thereby steering the model toward the generation of the intended translation.

Third, efforts have been directed at tailoring the decoding process to incorporate terminologies. Hokamp and Liu (2017) and Post and Vilar (2018) have introduced constrained decoding techniques that reinforce the translated output's pre-specified terminologies.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 919–925

Table 1: Different Mode Scenarios

3 Data Process

The WMT'23 Terminology Shared Task is a constrained track, following the same rules of data usage as the WMT'23 General MT Task, forbidding the use of external data. However, unlike the WMT'21 Terminology Task, the provided training data lacks terminology information, and need to be artificially constructed.

3.1 Data Filtering

We first filter noisy data. We referenced the data cleaning methods described in the WMT'21 Terminology submissions (Molchanov et al., 2021; Wang et al., 2021).

1. Remove pairs that contain sentences that:
   (a) are empty, too short, too long.
   (b) are contain only symbols.
   (c) are at least 3 times longer than their counterpart.
2. Delete text pairs identified to be the wrong language. We used a combination of our in-house language detector for short texts and LangID (Lui and Baldwin, 2012) for long texts.
3. Remove pairs outside of a selected cosine similarity scope of latent vectors constructed by the LaBSE model (Feng et al., 2022).

See Appendix A for the amount of data filtered and the resulting performance comparison.

3.2 Word Alignment

After filtering data, we tokenize and word-align the text to extract desired terminology pairs for Modes 2 and 3. The overall process is described in Figure 1. We use our in-house tokenizer, referring to the tagging schema from Luo et al. (2019) for Chinese and the Moses (Koehn et al., 2007) tokenizer for English. Next, the tokenized parallel data is fed into a LaBSE (Feng et al., 2022) based word aligner, AccAlign (Wang et al., 2022). AccAlign generates pairs of indices for words from the source and target text, which are then utilized in extracting terminology pairs.

3.3 Terminology Extraction: Mode 2

The terminology extracted for Mode 2 are named entities, excluding time and number expressions. We use `SpaCy`'s (Honnibal and Montani, 2017) `zh_core_web_lg` as the Chinese NER model and `en_core_web_md` as the English NER model. Furthermore, we consider Chinese four-character idioms extracted by our in-house tokenizer. The idioms are added as additional Mode 2 candidates. Next, we reference our word alignment results from Section 3.2 to map candidates to their corresponding targets.

AccAlign occasionally fails to align multi-word terminology completely, which poses an issue for Chinese idioms. To account for this, we implement a soft matching strategy to interpret AccAlign's output indices, where we extract the entire phrase if the aligner maps the beginning and end indices, even when alignment is not complete in the middle of the phrase. We use strict matching for named entities, which only extracts words that appear in the alignment results.

To guarantee that our extracted terminology is accurate and exhaustive, we repurpose the provided training data source WikiTitles as an additional resource for terminology pairs. For each pair in WikiTitles, we check whether a term and its translation were present on both sides of the parallel text and add the relevant term pairs into the Mode 2 glossary.

3.4 Terminology Extraction: Mode 3

The terminology extracted for Mode 3 is intended to be relatively random yet accurate pairs from the parallel text. For simplicity, we exclusively

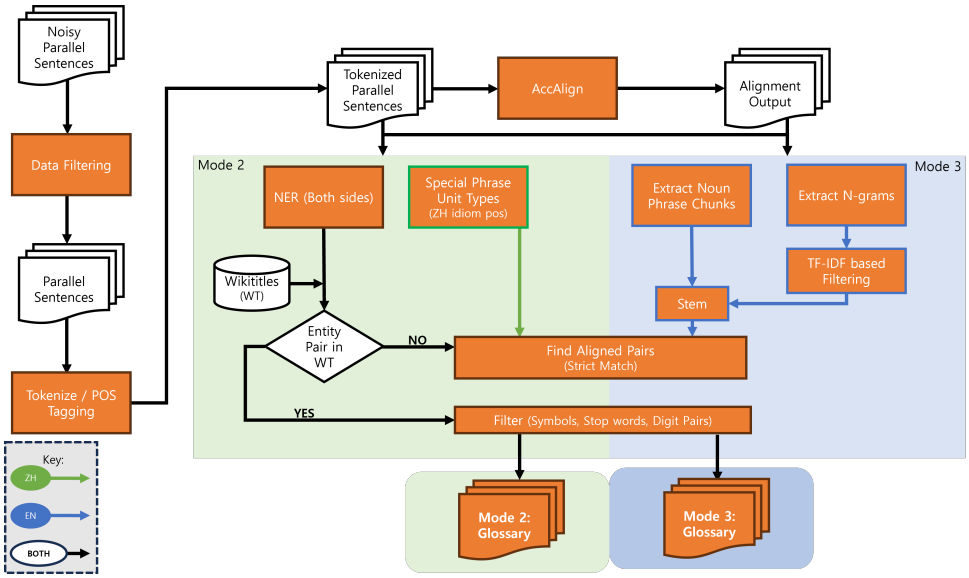

Figure 1: Data Construction Process

processed from the English side when generating Mode 3 candidates. We extracted n-grams ($1 \leq n \leq 4$) with high TF-IDF scores (Sparck Jones, 1988), as well as noun phrases (Loria, 2018), as the Mode 3 candidates. We take all Mode 3 candidate pairs that contain an appropriately aligned terminology, stem the English terms using `nltk` (Bird et al., 2009), and then randomly select of a maximum of ten term pairs for the Mode 3 glossary.

3.5 Development Data

The official Chinese-English development data is relatively small, thus we supplement it with a subset of the allowed data. We construct a supplemental development data with a random proportional sample from each provided training data source, which consists of 1,000 identical sentences throughout the three modes. Furthermore, we construct terminology for the different modes according to the above mentioned process. Additionally, we filter stop words and terms in neither the source nor target texts.

4 Models

This section presents two distinct models designed to incorporate terminologies into NMT models. The first model, Terminology Self-selection Neural Machine Translation (TSSNMT), employs a shared encoder architecture featuring a gating mechanism. This mechanism empowers the model to make decisions regarding the proportion of the source sentence and the terminologies to be processed during generation. The second model, ForceGen Transformer (ForceGen-T), takes a more straightforward approach, utilizing a standard Transformer model with force decoding (Reheman et al., 2023) and copy mechanism (Song et al., 2019). This approach enforces the model to initially generate the predefined terminologies before generating the remainder of the sentence. Copy mechanism is applied to replicate source-side target terminologies in the output.

4.1 TSSNMT

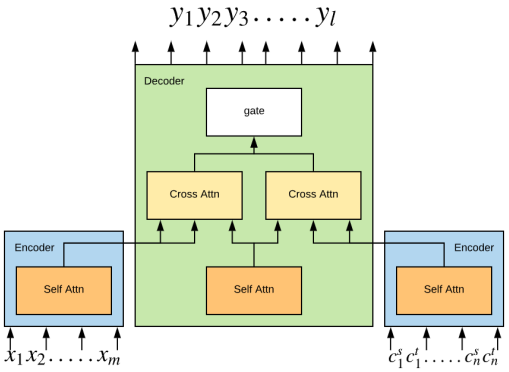

Figure 2: TSSNMT Model Structure. x, y, and c denote source, target and corresponding terminology respectively.

We have implemented the TSSNMT model with minor changes to the transformer architecture. The model has two encoders, as shown in Figure 2. Each encoder receives input in source sentences and source-target pair terminologies. These two en-

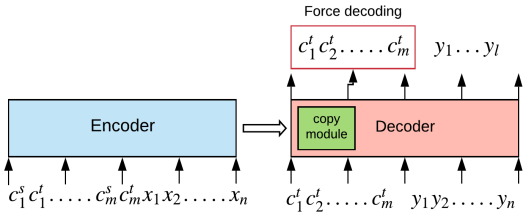

Figure 3: ForceGen model structure. x, y, and c denote source, target and corresponding terminology respectively.

coders share parameters and encode both the source sentences and the terminologies. The decoder calculates cross-attentions with these two encoder hidden states separately and then projects them to a gating mechanism (Bapna and Firat, 2019). Sharing parameters allows the model to decide weight distribution across the source and the terminology during generation.

4.2 ForceGen Transformer

We tailor a Transformer-based model to ensure the appearance of given terminologies in the generated output. Modifying the input format and decoding process incorporates copy mechanism on the source side, allowing it to copy the target terminology from the provided terminology pairs. Table 2 refers to the input sentence for this purpose.

During decoding, the model is reinforced to generate the given terminologies in a teacher-forcing manner. This approach aligns with findings by Reheman et al. (2023), who force a model to generate Translation Memory (TM) to enhance model performance. Instead, we provide the model with the terminologies, expecting it to consider them attentively during the decoding process. Once the terminologies are successfully generated, the model decodes the remainder of the input text. Copy mechanism enforces the source-side target constraints into the output. This approach is inline with that of Song et al. (2019), where copy mechanism significantly improves the ratio of terminology occurrences in the output.

We conduct preliminary experiments by training our models using the IWSLT17 (Cettolo et al., 2017) Chinese-English data and MUSE dictionary (Conneau et al., 2017) to assess the impact of the copy mechanism and force decoding. The primary objective is to determine whether the copy mechanism and the force decoding technique could complement each other. The outcomes, as presented in Table 3, reveal that the model yields the most favorable results when both the copy mechanism and force decoding are concurrently applied. This finding underscores the benefit of replicating source-side target terminology during the generation process, as it significantly aids in generating pre-specified terminologies during the force decoding phase. Consequently, when generating output after force decoding, the model effectively focuses on the target terminologies generated during decoding, facilitating successful incorporation of these terminologies into the final production. We apply both methods to our model, ForceGen-T.

5 Experiments

5.1 Evaluation setting

5.1.1 Pseudo test data

Both the provided WMT Terminology test data and blind data for the Chinese-English language pair contain only Chinese source lines and no target, so to evaluate the model, we constructed artificial target answers using ChatGPT (Ouyang et al., 2022) and reviewed the produced data manually. We then use this data as the test data to evaluate the model.

5.1.2 Evaluation metrics

The evaluation criteria for this translation task include overall terminology translation, terminology usage, and translation quality. We chose SacreBLEU (Post, 2018) , COMET (Rei et al., 2020), chrF (Popović, 2015) and Copy Success Rate (CSR). SacreBLEU and COMET scores are commonly used metrics in machine translation quality. For terminology translation and usage, we utilize CSR, which we define as the appearance rate of the desired terminology in the inferred text.

5.2 Experimental details

We use sentencepiece (Kudo and Richardson, 2018) to learn a joint byte pair encoding with a vocabulary size of 32K. Our preprocessing strategy involves pre-tokenizing Chinese data through an in-house Chinese tokenizer, while English data is exclusively tokenized using the Sentencepiece model. Please note that the training data tokenization process slightly differs from the data construction described in Section 3.

For all the experiments, we build upon the scale of the Transformer Big model (Vaswani et al.,

2017) architecture implemented using our proprietary toolkit. This model consists of 12 encoder layers and 6 decoder layers, providing a strong foundation for effectively integrating specified terminologies into the output. The specific configuration of each approach varies according to the respective model specifications. We list detailed configurations in Appendix B.

6 Results

Table 4 shows the Chinese-English translation results on the WMT'23 Terminology Task. We compare two approaches - TSSNMT and ForceGen-T against the baseline Transformer Big model. Both TSSNMT and ForceGen-T significantly outperform the baseline model in all automatic evaluation metrics. Highly elevated CSR scores underscore the successful integration of provided terminologies into the translated output. In contrast, higher scores in various syntactic and semantic metrics (COMET, SacreBLEU, and chrF) indicate the fluency and adequacy of the generated translations. Within the test data, both TSSNMT and ForceGen-T exhibit similar performance levels. However, when evaluating based on the CSR score, TSSNMT surpasses ForceGen-T by approximately 2%p. In contrast, within the blind data, ForceGen-T consistently demonstrates superior scores compared to TSSNMT, with particularly notable advantages in CSR scores.

7 Conclusion

This paper presents the comprehensive procedure of our submissions for the WMT'23 Terminology Shared Task. Our approach involves meticulous refinement and pre-processing of the provided data, subsequently used to train our models. We investigate and implement two strategies for effectively integrating the given terminologies into the output, demonstrating their superior performance compared to the baseline. The result shows that our approach can significantly improve translation accuracy by increasing the recall of terminologies. As a future endeavor, we aim to extend the validation of our approach to other languages.

8 Limitations

In this paper, we propose two successful terminology integration approaches in NMT. We confirm that our models achieve significant performance gains over the baseline model. Still, it is essential to note that these observed improvements are specific to a particular language pair, Chinese to English. Therefore, further experiments on a wide range of language pairs, including those with morphologically complex structures, are needed to validate the broader efficacy of our approaches.

It is worth noting that the inference speed of ForceGen-T linearly correlates with the number of terminologies that need to be generated. ForceGen-T is forced to generate the given terminologies first in decoding, inevitably requiring additional inference time. Consequently, the inference speed of ForceGen-T is slower than that of the baseline Transformer model.

Abstract

The paper presents the submission by HW-TSC in the WMT 2023 Automatic Post Editing (APE) shared task for the English-Marathi (En-Mr) language pair. Our method encompasses several key steps. First, we pre-train an APE model by utilizing synthetic APE data provided by the official task organizers. Then, we fine-tune the model by employing real APE data. For data augmentation, we incorporate candidate translations obtained from an external Machine Translation (MT) system. Furthermore, we integrate the En-Mr parallel corpus from the FLORES-200 dataset into our training data. To address the overfitting issue, we employ R-Drop during the training phase. Given that APE systems tend to exhibit a tendency of 'over-correction', we employ a sentence-level Quality Estimation (QE) system to select the final output, deciding between the original translation and the corresponding output generated by the APE model. Our experiments demonstrate that pre-trained APE models are effective when being fine-tuned with the APE corpus of a limited size, and the performance can be further improved with external MT augmentation. Our approach improves the TER and BLEU scores on the development set by -2.42 and +3.76 points, respectively.

1 Introduction

Automatic Post-Editing (APE) is a post-processing task in a Machine Translation (MT) workflow, aiming to automatically identify and correct errors in MT outputs (Chatterjee et al., 2020a). WMT has been holding APE task competitions in different languages and fields since 2015. Similar to WMT 2022, WMT 2023's APE task still focuses on the En-Mr language pair. Participants are provided with a training set comprising 18,000 instances, a development set, and a test set, with each containing 1,000 instances. Each dataset consists of triplets — the source (*src*) sentences, the corresponding machine-translation (*mt*) outputs, and the human post-edited versions (*pe*) of the translations. In this task, the source sentences have been translated into the target language by using a state-of-the-art neural MT system to get the machine-translation data. The provided data encompasses diverse domains, such as healthcare, tourism, and general/news. In addition, the synthetic training data is offered to participants, which is created by taking a parallel corpus, where the source data is translated using an MT system, and the references are considered as post-edits. Furthermore, participants are permitted to utilize any additional data for systems training.

Typically, training an APE model requires large amount of training data. However, obtaining *pe* is an expensive task in terms of time and money. As a result, there exists a scarcity of large-scale APE datasets.

To address this challenge, numerous data augmentation techniques have been proposed (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018; Lee et al., 2020; Wei et al., 2020; Zhang et al., 2023). Wei et al. (2020) augment the APE training data with translations generated using a different MT system. Huang et al. (2022) train an external MT to obtain more datasets consistent with APE tasks. They also use Google translation to back translate the post-edits in the training set. Deoghare and Bhattacharyya (2022) augment the APE data by generating phrase-level APE triplets using SMT phrase tables. To ensure the quality of the synthetic data, they employe the LaBSE technique (Feng et al., 2022) to filter low-quality triplets.

In our method, we use Google translation to back translate the post-edits in the training set. Subsequently, our dataset is structured as follows: the concatenation of source sentence, back translation and machine translation as the input, while the

*Work done during internship at Huawei

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 926–930
December 6–7, 2023.

post-edits serve as the reference output. Additionally, we incorporate En-Mr parallel sentences from FLORES-200 (Costa-jussà et al., 2022) dev and test data to our training set. Given that we have an En-Mr parallel corpus only and lack machine translation data, we directly utilize English sentences as the source input and Marathi sentences as the post-edits. Furthermore, we use R-Drop (Liang et al., 2021), which regularizes the training inconsistency induced by dropout and has been proven beneficial for different kinds of models.

Chatterjee et al. (2020b) have proven that APE systems often make unnecessary edits to translation output. To mitigate this issue of over-correction, we employ a sentence-level QE system to determine the final output, selecting between the APE system's output and the original machine-translated (*mt*) version.

When being evaluated on the development set, our approach improves the TER (Snover et al., 2006) by -2.42 points and the BLEU score (Papineni et al., 2002) by +3.76 points.

The contributions of our work are as follows:

- We employ two approaches for data augmentation: (1) We utilize Google translation to back translate the post-edits to get *src'*. (2) We add English and Marathi data from the FLORES-200 dataset to our training set.
- We utilize R-Drop to address over-fitting concerns and enhance the generalization capabilities of our model.
- We employ a sentence-level QE system to select the most appropriate output, choosing between the APE-generated output and the original translation.

2 Related Work

Last year's WMT22 APE shared task mainly focuses on transfer learning and data augmentation. Huang et al. (2022) employ the existing data to train an En-Mr translation model as a data augmentation method. Additionally, they utilize an external MT system to generate back-translations, which can be used to add a set of parallel corpora for the model to learn the rules of post-edits. Adapters are also incorporated into the APE model, allowing the training data to be steered to different adapters based on the output of a trained classifier. This facilitates the model in learning post-editing rules specific to different translations.

Deoghare and Bhattacharyya (2022) use two separate encoders to generate representations for src and mt. They also employ a pre-trained language model to initialize the weights for both our encoders. For data augmentation, they leverage external MT candidates and generate phrase-level APE triplets using SMT phrase tables. Furthermore, they filter low-quality APE triplets from the synthetic data using LaBSE-based filtering. They also use a sentence-level QE system to select the final output between the APE-generated output and the original translation.

With experience in previous competitions, we also utilize an external MT system to generate back-translations. Additionally, we adopt a sentence-level QE system for selecting the final output.

3 Dataset

3.1 Data source

We use the WMT22 official En-Mr APE dataset, which consists of a training set and a development set. The training set consists of 18,000 APE triplets across domains, such as healthcare, tourism, and general/news. We first use synthetic data with 2.57M instances to pre-train our model, which was prepared as a part of the 2022 APE shared task. Furthermore, we enrich our training set by incorporating 2,000 En-Mr parallel sentences from the FLORES-200 dataset. FLORES-200 is a high quality, many-to-many benchmark dataset, which contains about 204 languages. In our approach, we specifically extract the English and Marathi parallel corpus from this dataset for training purposes.

4 Model

Figure 1 shows the architecture of our APE model. In this section, we provide the details of our approach.

4.1 Fine-tuned Transformer

We basically treat the APE task as an NMT-like problem, which takes *src* and *mt* as input and generates *pe* autoregressively. Following previous works, we use a special token <*s*> to concatenate src and mt to generate the input sentence: [*src,* <*s*>*, mt*], while the target sentence is *pe*. Initially, we pre-train the APE model using the standard Transformer (Vaswani et al., 2017) structure on 2.57M synthetic training data. However, since there is a mismatch between the synthetic data and the real data in our task, we further fine-tune the APE

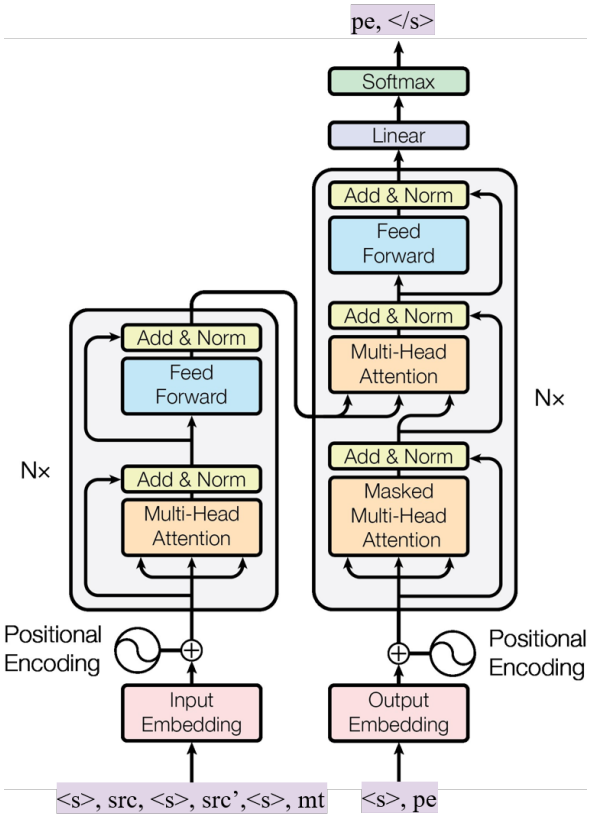

Figure 1: This figure shows the architecture of our model, where mt and augmented src' are concatenated with src before being input into the encoder, and post-edits are generated with the decoder.

model using the APE dataset. To further solve the problem of data scarcity, following (Huang et al., 2022), we use the Google translation system to create the *src'* from the provided *pe* text. We simply concatenate the *src'* with the original *src* and *mt* to form the new input: [*src, <s>, src', <s>, mt*]. Then, we use it in the same way as before, aiming to have the model learn complementary information from *src* and *src'*. During inference, the same input [*src, <s>, src', <s>, mt*] is employed to generate the output, thereby enabling the utilization of the external information derived from *src'*.

We also employ R-Drop during the fine-tuning stage to mitigate overfitting and enhance the generalization capabilities of our model.

4.2 Sentence-Level Quality Estimation

We use wmt22-cometkiwi-da (Rei et al., 2022) as our sentence-level QE model, which is a COMET quality estimation model. This model can be used for reference-free MT evaluation. It receives a source sentence and the respective translation and returns a single score between 0 and 1 that reflects the quality of the translation, where 1 represents a perfect translation. We use this model to rate both the original machine translation and the output generated by our APE system. We then compare the ratings for both sequences and select the one with a higher rating as the final output.

5 Experiment

5.1 Settings

Our model is implemented with fairseq (Ott et al., 2019). Note that the vocabulary and encoder/decoder embeddings of our model are shared between two languages and contain 30K subtokens. All models are trained on a Nvidia Tesla V100 GPU with 32GB memory. We use the batch size of 30,720 tokens in the pre-training stage and 8,192 tokens in the fine-tuning stage. We leverage the FP16 (mixed precision) training technique to accelerate the training process. In all stages, we apply the Adam optimizer(Kingma and Ba, 2015) with β_1 = 0.9, β_2 = 0.98 to train the model, where the inverse square root schedule algorithm and warmup strategy are adopted for the learning rate. Concretely, We use a learning rate of 5e-4 with 20k warm-up steps in the pre-training stage and a learning rate of 5e-5 with 4k warm-up steps in the fine-tuning stage. Besides, we set the dropout to 0.1 in the pre-training stage, 0.3 in the fine-tuning stage, and the value of label smoothing to 0.1 in all stages. Early stopping is adopted with patience 10 and 30 epochs during pre-training and fine-tuning, respectively. During inference, we use beam search with a beam size of 10. Finally, we employ BLEU to evaluate the model performance. TER and newly added evaluation metric chrF (Popovic, 2015) are also used to evaluate the model output.

System	BLEU↑	TER↓
Baseline (Do nothing)	64.62	22.93
+APE Data Fine-tuning	66.20	22.82
+External MT	66.46	22.12
+Flores data	66.83	22.01
+R-Drop	67.76	21.12
+Sentence-level QE	**68.38**	**20.51**

Table 1: Results on the WMT23 APE development set. A situation with a higher BLEU score but lower TER indicates a better result.

5.2 Result

Table 1 shows the experimental results evaluated on the dev set, where the baseline result is produced by directly calculating scores between the provided MT and PE.

The first experiment is performed by fine-tuning all parameters of the pre-trained Transformer on the official training set, which obtains 2+ performance gains compared with the baseline. This demonstrates that fine-tuning the pre-trained NMT model on the limited dataset can be useful. The experiment of adding external MT for data augmentation shows significant improvements in performance. The third row in Table 1 shows the results of the experiment where we add FLORES-200 data. In the fourth row, we show the results when R-Drop is adopted in our training stage. Toward the end, we utilize a sentence-level QE system to rate both the original translation and the APE output. We then select one of them with a higher rating as the final output of our APE system. With the combination of the APE model and sentence-level QE system, we see that the TER decreases to 20.50, and the BLEU score increases to 68.38 points.

6 Conclusion

This paper presents our APE system submitted to the WMT 2023 APE English-Marathi shared task. In our approach, we initially employ the data augmentation method to build the [*src,* <*s*>*, src',* <*s*>*, mt*] additional training datasets. We augment our training data by incorporating the En-Mr parallel sentences from Flores-200 dataset. We mitigate overfitting by employing R-Drop during the training phase. Moreover, we explore the sentence-level QE system to discard low-quality APE outputs. Evaluation of our APE system shows that our approach achieves significant gains on the WMT-22 APE development sets.

Limitations

One limitation of our approach is that while we utilize a sentence-level QE system to assess the quality of the APE output and the original translation, the APE system itself does not directly benefit from this evaluation process. While the QE system helps us identify and discard poor-quality APE outputs, it does not contribute to the improvement of the APE system itself.

Acknowledgements

We would like to thank the anonymous reviewers. Their insightful comments helped us in improving the current version of the paper.

Abstract

The internet is a vast repository of valuable information available in English, but for many people who are more comfortable with their regional languages, accessing this knowledge can be a challenge. Manually translating this kind of text, is a laborious, expensive, and time-consuming operation. This makes machine translation an effective method for translating texts without the need for human intervention. One of the newest and most efficient translation methods among the current machine translation systems is neural machine translation (NMT). In this WMT23 shared task: low resource indic language translation challenge, our team named ATULYA-NITS used the NMT transformer model for the English to/from Assamese and English to/from Manipuri language translation. Our systems achieved the BLEU score of 15.02 for English to Manipuri, 18.7 for Manipuri to English, 5.47 for English to Assamese, and 8.5 for Assamese to English.

1 Introduction

In countries like India, linguistic diversity is a significant aspect, with a multitude of languages varying across different regions. India officially recognizes 23 languages (Das et al., 2020) (e.g., Hindi, Sanskrit, Assamese, Odia, etc.), and alongside these, there are several hundred unofficial local languages spoken by communities. Despite India's vast population of approximately 1.4 billion, only about 11% of the population is proficient in English (Azam et al., 2013).

This language barrier becomes crucial when considering the abundance of valuable resources available on the internet, mostly in English, as a significant proportion of people in India cannot fully comprehend this content. Consequently, there arises a pressing need to translate such valuable information into local languages to facilitate knowledge sharing among the population. Such knowledge dissemination is crucial not just for business purposes but also for enabling the exchange of feelings, opinions, and actions, thereby fostering better communication and understanding among people from diverse linguistic backgrounds.

Manual translation of such copious amounts of content would be extremely laborious and time-consuming, making automatic machine translation an indispensable solution. However, machine translation for Indian languages presents its own set of challenges (Singh et al., 2021). One key challenge is the scarcity of parallel corpora, as there are fewer resources available for Indian languages compared to more widely spoken foreign languages. Moreover, the structural differences between Indian languages and English, particularly in terms of morphological richness and word order, pose significant obstacles to accurate translation. For instance, English follows a Subject-Verb-Object (SVO) word order, whereas Indian languages like Assamese and Manipuri, follow a Subject-Object-Verb (SOV) word order (Bora, 2015). Furthermore, English is a fusional language, while Assamese and Manipuri are agglutinative languages (Singh and Singh, 2022; , leading to distinct syntactic and morphological complexities that further complicate the translation process.

We participated in the Low-Resource Indic Language Translation task on translating two language pairs i.e. English to/from Assamese, and English to/from Mizo. We did the preprocessing of the given dataset and applied a neural machine translation technique i.e. transformer model. The performance was evaluated using the widely used evaluation metric BLEU. The rest of the paper is organized as follows: Section 2 discusses the existing machine translation systems and techniques tailored to Indian languages. In Section 3, we present details about the dataset, preprocessing of the dataset, and transformer model. In section 4, we discussed about the result. Finally, in Section 5, we

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 931–934

conclude with a discussion of the future prospects.

2 Literature Survey

Over the past few decades, machine translation (MT) has been the subject of extensive research. Researchers have explored various approaches in this field, including rule-based MT (Das and Baruah, 2014; Forcada et al., 2011), corpus-based MT, also known as data-driven MT (Laskar et al., 2022; Laitonjam and Singh, 2021; Singh and Bandyopadhyay, 2010), and hybrid-based MT (Laitonjam and Singh, 2022). Each of these approaches has its own advantages and disadvantages.

In rule-based MT, systems analyze the source text to create an intermediate representation, and depending on this representation, it can be further categorized into transfer-based (TBA) and interlingua-based (IBA) approaches. The corpus-based approach, on the other hand, relies on large parallel corpora consisting of text and their translations to acquire translation knowledge and is sub-divided into two sub-types, i.e. statistical machine translation (SMT) and example-based machine translation (EBMT). SMT generates translations using statistical models that combine language models and translation models with decoding algorithms. In contrast, EBMT uses existing translation examples to generate new translations. Hybrid-based machine translation combines aspects of both rule-based and corpus-based approaches to address their respective limitations.

The machine translation performance for Indian language pairs (e.g., Hindi, Bengali, Tamil, Punjabi, Gujarati, and Urdu) into English achieves an average accuracy of only 10%, (Khan et al., 2017) highlighting the need for improved machine translation systems for these languages. Neural Machine Translation (NMT) has emerged as a novel and promising technique for various languages, exhibiting remarkable results (Devi and Purkayastha, 2023; Laskar et al., 2022, 2021). In this paper, we have applied the transformer model to the English-Assamese and English-Manipuri language pair (Laskar et al., 2021; Singh and Singh, 2022)

3 Methodology and Evaluation

3.1 Dataset Details

The English-Assamese parallel corpus (Pal et al., 2023) comprised a grand total of 53,000 sentence pairs, while the Assamese monolingual corpus contained nearly 2.6 million sentences. Moving over to the English–Manipuri parallel corpus (Pal et al., 2023), it included a substantial 24,300 aligned sentence pairs. As for the Manipuri monolingual dataset, it contained roughly 2.1 million sentences.

3.2 Data Preprocessing

The dataset may contain repetition of sentences with the same source and the same target translation, sentences with the same source but different translations, sentences with different source text but the same translation. To address these issues, a solution was implemented by selecting unique sentence pairs from all available sentences and removing the duplicates. Sentences repeated more than once were completely removed to avoid ambiguity in determining the correct translation for a given source and vice versa. This preprocessing step aimed to ensure that the training and test sets did not contain the same sentences, which could result in better predictions for the test set but incorrect predictions for new sentences. Some additional preprocessing steps were carried out, including removing sentences with a length greater than 50, removing noisy translations and unwanted punctuations, filtering out sentences in other languages by applying language identification, and filtering out sentences containing HTML tags, illegal characters, and invisible characters. Finally, the dataset was split into training, testing, and validation sets, following shuffling. The English-Assamese parallel corpus was segregated into 49,500 for training, 2,000 for validation, and 1,000 for testing. Similarly, the English-Manipuri parallel corpus was divided into 21,000 for training, 2,000 for validation, and 1000 for testing.

3.3 Transformer Model

The Transformer model(Vaswani et al., 2017) is a powerful architecture used in tasks like machine translation. It excels in natural language processing, employing a technique called "self-attention" to process sequential data effectively. Unlike traditional models, it considers the context of the entire sequence, using multiple self-attention mechanisms known as "attention heads" to capture different relationships between words. Positional encoding is added to understand the word order. In machine translation, it consists of an encoder and a decoder communicating through attention mechanisms.

For the task of the English-Assamese language pair, along with the provided parallel corpus (Pal et al., 2023), we also used the monolingual corpus to create the vocabulary for the English and Assamese languages. The vocabulary extracted from the monolingual corpus generated a total of 107483 unique tokens in the Assamese language. The vocabulary size of the English language was 35487.

We used the transformer model to train the data. For the whole process, we used Google Colab and trained the model using a T4 GPU provided by Colab. We trained the model for 2000 training steps and 250 validation steps. We set the word vector size to 512 and used 6 layers of 512 hidden nodes. We set the transformer feed-forward size to 2048 and used 8 attention heads. We set the learning rate to 1 while using Adam optimization(Kingma and Ba, 2014). We used a batch size of 2048 with a dropout probability of 0.1 and used a label smoothing regularization technique to prevent overconfidence. The whole training process took around 4 hours when we used the batch size of 2048.

The vocabulary extracted from the monolingual corpus generated a total of 84072 unique tokens in the Manipuri language. For the English-Manipuri language pair, we trained the model for 1500 training steps and 150 validation steps, and all the remaining were similar to English-Assamese. The whole training process took around 3 hours.

4 Evaluation

4.1 Evaluation Metric

The Bilingual Evaluation Understudy (BLEU) score is a useful tool for determining the differences between translations produced by machines and those created by human translators (Papineni et al., 2002). This assessment method compares and aligns the number of n-grams in the translated output with the number of n-grams in the source text. In this context, a bigram comparison entails analyzing every word pair, while a unigram comparison relates to each individual token. It's significant to notice that this evaluation ignores the comparison's precise wording. This methodology is an improved version of a simple precision-based evaluation strategy.

4.2 Result

BLEU, chrf2, RIBES, and TER evaluation metrics on both language pairs are shown in Table 1.

Language Pair	BLEU	Chrf2	RIBES	TER
English-Assamese	5.47	21.66	0.21	0.5
Assamese-English	8.5	24.26	0.25	0.47
English-Manipuri	15.02	35.96	0.28	0.43
Manipuri-English	18.7	38.49	0.32	0.41

Table 1: The experimental result of language pairs on different evaluation metrics

5 Conclusion

In this paper, we applied NMT to the two most difficult language pairs (English-Assamese and English-Manipuri). We showed that the transformer model performs better for Indian languages. We achieved a fairly good BLEU score for the English-Manipuri language pair. So, this model can be used for domains such as tourism and education. Moreover, this transformer model is useful for various English-Indian language pair translations.

sks001@gmail.com, kb.guwahati@gmail.com

Abstract

This paper describes the submission of the GUIT-NLP team in the "Shared Task: Low Resource Indic Language Translation" focusing on three low-resource language pairs: English-Mizo, English-Khasi, and English-Assamese. The initial phase involves an in-depth exploration of Neural Machine Translation (NMT) techniques tailored to the available data. Within this investigation, various Subword Tokenization approaches, model configurations (exploring differnt hyper-parameters etc.) of the general NMT pipeline are tested to identify the most effective method. Subsequently, we address the challenge of low-resource languages by leveraging monolingual data through an innovative and systematic application of the Back Translation technique for English-Mizo. During model training, the monolingual data is progressively integrated into the original bilingual dataset, with each iteration yielding higher-quality back translations. This iterative approach significantly enhances the model's performance, resulting in a notable increase of +3.65 in BLEU scores. Further improvements of +5.59 are achieved through fine-tuning using authentic parallel data.

1 Introduction

Work on Machine Translation (MT) involving indigenous languages is on the rise to provide such languages a global existence rather than limiting its scope to regional geographical boundaries. But such a work is quite challenging owing to its typical characteristic being limited (low) resourced as NMT models are data hungry which tend to degrade with limited data input. Established methods like Back Translation (Sennrich et al., 2015b), Transfer Learning (Kim et al., 2019; Zoph et al., 2016), Multilingual Neural Translation (MNT) (Lakew et al., 2018; Ngo et al., 2020), Dual Learning (He et al., 2016; Wang et al., 2018) and such do exist to tackle the low-resource challenge. With the monolingual and limited parallel data provided to the teams to work with, Back Translation (BT) seemed to be an appropriate choice. In BT, a target to source model translates the target side monolingual data to generate a substantial amount of synthetic parallel data which could be augmented with the limited authentic parallel data to increase the volume of training data. Previous experiments (Sennrich et al., 2015a; Edunov et al., 2018), (Poncelas et al., 2018; Wu et al., 2019) have shown improved results in such scenarios.

The general NMT pipeline comprises of various stages like tokenization, subword tokenization, NMT model training, inference and post-editing. It should be noted that several methods are available for every stage making it difficult for the researcher to select the one that would suit the data best as each method has its own influence on the model performance. We, therefore, perform an initial investigation on two popular subword tokenization methods to find the best choice. The rest of the paper is organized as follows: Section 2 describes the methods applied for the task, Section 3 presents the experimental setup and the results obtained for the three language pairs: English-Mizo, English-Khasi and English-Assamese. Section 4 concludes the paper.

2 Methodology

The following section describes the methodology used for the task for each of the language pairs.

2.1 Data Exploration

In this section, we delve into the data used for the task, which encompasses two primary categories:

1. *Parallel Data:* This data category consists of two distinct, non-overlapping sets, specifically the training and validation set.

2. *Monolingual Data:* This category encompasses an extensive corpus with monolingual

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 935–940
December 6–7, 2023.

Language Pair	Train Set	Dev. Set
English-Mizo	50,000	1,500
English-Khasi	24,000	1,000
English-Assamese	50,000	2,000

Table 1: Parallel Data Statistics.

Language	Sentences*(in millions)*
Mizo	1.9
Khasi	0.18
Assamese	2.6

Table 2: Monolingual Data Statistics.

sentences. It is imperative to underscore that all participating teams are expressly instructed to rely exclusively on the provided data, refraining from any utilization of external resources.

Upon conducting a preliminary manual analysis of the data, several noteworthy observations have come to light:

(i) Instances exist within the corpus wherein sentences commence with multiple spaces.

(ii) Instances within the corpus also manifest where multiple spaces occur between words.

(iii) The corpus exhibits a mixture of both tokenized and untokenized sentences.

After having these disparities removed from the data, the sets are tokenized with Moses (Koehn et al., 2007) tokenizer for English, Mizo and Khasi as they share the same Roman script while Assamese is tokenized with IndicNLP[1]. Prior to tokenization of the English, Mizo and Khasi text, all characters are normalized to lowercase for consistency. With no difference in case for Assamese, this step is not required for the language. Additionally, a fundamental filtering routine is applied as part of the data preprocessing process as described below:

(a) *Removal of Empty Lines:* (Source, target) pairs containing empty lines on either the source or target side are systematically eliminated from the dataset.

(b) *Elimination of Duplicate Lines:* (Source, target) pairs characterized by duplicate lines in both the source and target segments are systematically removed. Duplicate content can introduce redundancy and skew the training process, hence necessitating their exclusion.

(c) *Relative Length-Based Filtering:* To maintain a balanced and coherent dataset, pairs where the length of the target sentence significantly exceeds that of the source sentence (or vice versa), exceeding a predetermined threshold (typically set at twice the length), are judiciously omitted.

2.2 Subword Tokenization

In the context of developing NMT models for low-resource Indian languages, subword tokenization emerges as a critical technique as it addresses out-of-vocabulary (OOV) challenge, morphological richness, facilitates cross-lingual transfer of knowledge, reduces the vocabulary size substantially. Two popular schemes are explored namely:

1. *Byte Pair Encoding (BPE):* BPE (Sennrich et al., 2015c) is a data compression technique designed to systematically merge the most common pair of character sequences. Consequently, frequent substrings are unified into single symbols, while rare words are segmented into smaller constituents. BPE is experimented in two forms:
   (a) Independent Vocabulary: This involves creating separate and independent subword vocabularies for both the source and target languages.
   (b) Shared Vocabulary: When dealing with closely related languages a shared subword vocabulary is a popular choice as it aligns (sub)words from source and target sentences into the same embedding space so as to strengthen the semantic correlation between them.

2. *Sentencepiece* (Kudo and Richardson, 2018): Though Sentencepiece (SP) has the capability to directly train subword models from raw text, eliminating the need for prior tokenization, we pre-tokenize it as (Kudo and Richardson, 2018) has shown better results with tokenized input. Also, SP supports subword regularization, which dynamically enhances the training data with on-the-fly tokenization during NMT model training. This process

[1] https://anoopkunchukuttan.github.io/indic_nlp_library/

contributes to the construction of a robust and accurate model, and it is not tied to any specific architectural configuration. Our experimentation with SentencePiece, implemented with independent vocabularies for English and Mizo, involves two main approaches:

(a) *With subword regularization:* With this method the model encounters different variations of subword splitting of the same word which could in turn be beneficial in producing a robust model for agglutinative languages. We have set the number of nbest candidates to 16 and the smoothing parameter to 0.1.

(b) *Without subword regularization.*

2.3 Using Monolingual Data

A relatively large monolingual data have been provided which could be made to use in various ways like constructing embeddings or for data augmentation. Back translation (Sennrich et al., 2015a) is a popular data augmentation method that exploits the target side monolingual data to create synthetic parallel corpus. Back Translation uses a base target→source model (initially trained on the limited genuine bitext) to translate the target side monolingual data. The synthetic data thus generated can serve as supplementary resource and could be explored in various ways.

Re-training the model on the manifold synthetic data is expected to boost up the model producing better translations. Two obvious assumptions can be made on the performance of an NMT model for low-resource scenario:

1. Data augmentation could boost up the model.
2. Also, more error-free the training data is, better is its performance.

Based on these assumptions and inspired by the previous reports on back-translation with iterations such as (Cotterell and Kreutzer, 2018; Hoang et al., 2018), we use an innovative twist to improvise model by using back translated data iteratively rather than using all in one go. In every iteration, the model is trained with increased data back translated by the previous iterations's improved model along with the original bitext thereby producing better translations for the next iteration. As the synthetic data is prone to error which could in turn hamper model performance (Poncelas et al., 2018), we add the back translated data proportionate to the size of the genuine bitext. Also, the trained model is followed by finetuning on the genuine bitext for further improvement (Tonja et al., 2023). Our method could be summarized by the following algorithm:

Algorithm 1 An innovative usage of Back Translation

Require: Authentic parallel corpus(S_0, T_0), target monolingual corpus(M), number of splits (n)
$M_0 \leftarrow Train_{(Target \rightarrow Source)}(S_0, T_0)$
$C_1, C_2, ..., C_n \leftarrow Split(M, n)$
such that $|C_i| \propto |S_0|$
$i \leftarrow 1$
while $i \leq n$ **do**

$$(S_i, T_i) = (S_0, T_0) \bigcup (M_{i-1}(\sum_{1}^{i} C_i), \sum_{1}^{i} C_i)$$

$$M_i \leftarrow Train_{(Target \rightarrow Source)}(S_i, T_i)$$

$$M_i \leftarrow FinetuneM_i(S_0, T_0)$$

$i \leftarrow i + 1$
end while

2.4 Post-Editing

The predicted translations (for English, Mizo and Khasi) have been post-edited in the following ways:

1. *Truecasing:* A truecaser model has been trained on the training set with the Moses' truecaser script.
2. Capitalizing the first character of every prediction.
3. As the text in the test set is not completely detokenized with several punctuation markers space separated, adjustments have been made to replicate the reference translations.

3 Experiments and Results

Experimental Setup: All the experiments have been conducted on the opensource NMT toolkit, OpenNMT (Klein et al., 2017). Subword vocabulary size is kept at 8000. The Transformer (Vaswani et al., 2017) has been customized to work on the small-scale dataset by simplifying the standard model. After conducting experiments

Table 3: Experimentation setup for English-Assamese

Model	En/Dec Layers	Attention Heads	Dimensions	Batch Size
Model 1	6	8	512	512
Model 2	3	4	256	256
Model 3	6	4	256	256

En/Dec : Encoder/Decoder

Table 4: Experimentation setup for English-Khasi

Model	Batch Size	BPE Vocab Size	En/Dec Layer	Attention Heads
M_1	256	6000	3	4
M_2	512	6000	3	4

SP_{w_reg} : SentencePiece with Subword regularization

BPE_{sh} : Byte Pair Encoding with shared vocabulary

BPE_{ind} : Byte Pair Encoding with independent vocabulary

with various parameter sets (including encoder and decoder layers, heads, embedding size, and feed-forward nodes), we have determined that the optimal configuration for English-Mizo data consists of 3 encoder and 3 decoder layers, a word vector size of 512, and 2048 nodes in the feed-forward layer. For English Assamese pair, three models have been built with varying hyperparameters and training is performed in both the directions. For English Khasi, two models have been built and trained. The model descriptions for English-Assamese and English Khasi are shown in Table 3 and Table 4 respectively. All the models are trained using the Adam optimizer with an initial learning rate of 2, incorporating Noam decay and 8,000 warm-up steps. The training process continues for 200,000 steps, with validation performed every 10,000 steps. Additionally, checkpoints are saved at 10,000-step intervals, and early stopping is implemented with a patience of 4 based on validation perplexity and accuracy.

Checkpoint Selection: Throughout training, checkpoints are saved every 10,000 steps. Among all the checkpoints generated, the model with the best validation perplexity and validation accuracy is chosen as the model for testing purposes.

3.1 Results

In Table 5 we report our results on the initial experiments using various subword tokenization schemes for English-Mizo. Our results have been evaluated by four evaluation metrics as provided by the organizers. It is clear from the results that Byte Pair Encoding using independent vocabularies works best for this data. Hence, for all the future experiments, BPE with independent vocabularies is selected as the standard format. Also, it should be noted that we have reported the results obtained with BPE (shared vocabulary) as the primary results for both En → Mizo and Mizo → En directions.

Table 6 summarizes the result obtained by our method of using proportionate back translated data which is in turn generated by the model developed in the previous iteration. The baseline scores are obtained by using 1M back translated data (translated by SP_{w_reg} model) which acheives a BLEU of value of 16.77 for En → Mz. In the 1st iteration, equal size of back translated data is added to the genuine bitext and the model is trained from scratch. It is able to achieve a BLEU score of 20.42. This shows the negative impact of adding a large size synthetic data, which is not error-free, relative to the authentic parallel data. Also, a significant improvement is noticed after fine-tuning on the given authentic data. Similar results are also seen in the 2nd iteration. The successive improvement is a successful implementation of our novel usage of back translation method.

The English-Assamese and English-Khasi experiments have been conducted using various configuration of the Transformer model as shown in Table 3 and Table 4 respectively. This is done to find the optimal model configuration for the languages. Though English and Khasi share the same script, the morphologies are completely different

Table 6: English-Mizo BLEU scores with our *novel* usage of Back Translation (BT)

Method	BT Data Size	En->Mz	Mz ->En
Baseline	1M	16.77	14.40
1st Iter.	50K	20.42	16.20
	FineTuned	26.01	20.06
2nd Iter.	100K	22.04	18.19
	FineTuned	**26.63**	**20.81**

Table 9: Results for English Khasi pair.

English → Khasi				
Model	**BLEU**	**CHRF**	**RIBES**	**TER**
M_1	10.41	33.31	0.63	71.67
M_2	10.27	32.63	0.63	70.71
Khasi → English				
M_1	8.74	30.54	0.63	79.64

and as Table 5 clearly manifests, appropriate hyperparameter values can bring about significant impact in the performance. The results obtained for English → Assamese is shown in Table 7 and Assamese → English is shown in Table 8. From both the tables, we see that Model 1 has shown the best results in both English → Assamese and Assamese → English translation. We, therefore, select the results obtained for Model 1 as the primary score. For English-Khasi, the results for model (M_1) is submitted as the primary score.

Table 7: Results for English → Assamese

Model	BLEU	CHRF	TER	RIBES
Model 1	4.89	25.16	87.21	0.46
Model 2	4.27	24.59	90.13	0.43
Model 3	3.75	22.65	93.57	0.42

Table 8: Results for Assamese → English

Model	BLEU	CHRF	TER	RIBES
Model 1	5.5	25.81	80.1	0.56
Model 2	4.7	24.96	81.53	0.55
Model 3	4.14	23.73	83.41	0.53

4 Conclusion

In this study, we have provided a comprehensive overview of our Neural Machine Translation (NMT) system developed for three language pairs: English-Assamese, English-Khasi, and English-Mizo, encompassing both translation directions. Our research delved into the intricacies of model configurations (Transformer layers, heads, batch sizes, etc.) and subword tokenization schemes (Byte Pair Encoding and SentencePiece and its variants). Through rigorous experimentation, we identified and adopted the optimal configurations for each language pair.

Challenged by the inherent scarcity of data in these low-resourced language pairs, we innovatively leveraged monolingual data to augment our translation models. We have presented a novel variation of a well-established technique for addressing the challenges of low-resourced NMT systems: *Back Translation*. This adaptation yielded remarkable results, surpassing the performance of conventional Back Translation methods by a substantial margin.

5 Limitation

We use the standard tokenization implementation (Moses) for English, Mizo and Khasi. Though Moses seems to work fine for English, certain disparities (associated with language-specific characters) are observed for Mizo and Khasi, both morphologically rich languages. Similar observations are also noted for Assamese. Using a customized tokenizer for these languages is believed to enhance the results which needs further investigation.

The dataset given was too small for Neural Machine Translation trainingespecially for Khasi. Though Back Translation is a well known method for low-resource setting, merely translating and using it as a pseudo-parallel corpus may not help as the monolingual data quality also has an impact. We have not used any mechanism to judge the quality. With our method, we iteratively use incremented back translations which is observed to boost the model. But the translation data is proportional to the original parallel corpus size which hinders leveraging fully the large monolingual corpus. We would like to explore ways to fully exploit the large availability of monolingual corpus for data augmentation or linguistic embellishments. Monolingual data usage is not explored (due to time constraint as we joined late) for the English-Assamese and English-Khasi which we plan to investigate in future. Our overall system lags in producing correct translations for long sentences. Semi-automatic post editing is utilized which needs further investigations in automatising the process.

Abstract

In this paper, we (Team NICT-AI4B) describe the MT systems that we submit to the Indic MT task in WMT 2023. Our primary system consists of 3 stages: Joint denoising and MT training using officially approved monolingual and parallel corpora, backtranslation and, MT training on original and backtranslated parallel corpora. We observe that backtranslation leads to substantial improvements in translation quality up to 4 BLEU points. We also develop 2 contrastive systems on unconstrained settings, where the first system involves fine-tuning of IndicTrans2 Data Augmentation (DA) models on official parallel corpora and seed data used in Gala et al. (2023), and the second system involves a system combination of the primary and the aforementioned system. Overall, we manage to obtain high-quality translation systems for the 4 low-resource North-East Indian languages of focus.

1 Introduction

The increasing online presence[1] of the Indian population along with the economic growth[2] of India has necessitated the development of translation systems for Indian languages. There have been substantial efforts towards collecting monolingual and parallel corpora, as well as developing machine translation systems using them (Ramesh et al., 2022; Doddapaneni et al., 2023). Most recently, IndicTrans2 (Gala et al., 2023), an MT system, and its accompanying parallel corpus BPCC, were released. This corpus covers all 22 Indian languages covered in the 8th schedule[3] of the Constitution of India.

While IndicTrans2 has achieved comparable or better results compared to existing systems like NLLB (Costa-jussà et al., 2022), a major limitation is that there is no specific focus on language subgroups. One of such subgroups is the North-East Indian languages, which this shared task focuses on. The task focuses on translation to/from English and the following 4 North-East Indian languages: Assamese, Manipuri, Mizo and Khasi. We submit constrained as well as unconstrained MT systems for the 8 translation directions in this task. For further details on the shared task, kindly refer to (Pal et al., 2023).

We leveraged ideas such as joint multilingual denoising and MT training followed by backtranslation at scale. First, due to the small size of the official parallel corpora, we utilized available and permitted monolingual corpora for all languages involved and trained on a combination of text-infilling and MT objectives to train an initial MT system. We used this system to generate large back-translated corpora, which were combined with the official parallel corpora to train the final primary system. The back-translated corpora, due to their scale, led to improvements up to 4 BLEU as measured on the development set. We also submitted two contrastive systems: the first one was obtained via fine-tuning IndicTrans2 DA models (Gala et al., 2023) and the second one was a system combination of the primary and the aforementioned contrastive system. We observed that our first contrastive system outperformed the primary for some language pairs due to the utilization of a strong pretrained MT model as initialization and additional high-quality data being used to fine-tune them. As for our second contrastive system, we observed improvements for directions where there was a small performance gap between the primary and the first contrastive system.

training (Lewis et al., 2020; Dabre et al., 2022), backtranslation (Sennrich et al., 2016), transfer learning (Zoph et al., 2016) and system combination (Heafield and Lavie, 2010, 2011).

The North-East Indian languages of focus in this shared task are all low-resource languages, and transfer learning via multilingualism is a reliable solution in this case. Transfer learning can be achieved by fine-tuning a pre-trained model (Zoph et al., 2016) but this involves two stages. On the other hand, multilingual training (Johnson et al., 2017; Dabre et al., 2020) involves implicit transfer via joint training. We explore both strategies when developing our systems.

Backtranslation (Sennrich et al., 2016) involves taking intermediate translation systems and translating monolingual corpora into another language. The synthetic-source and original target parallel corpora, can typically be orders of magnitude larger than the parallel corpora used to train the intermediate systems and when used at scale, such backtranslated corpora are known to help improve translation quality (Edunov et al., 2018) and therefore we attempt to use as much monolingual corpora as possible for backtranslation. While there are iterative backtranslation (Hoang et al., 2018) strategies where the process of model training and backtranslation is performed repeatedly, their computational complexity makes them a less attractive solution to us.

An alternative to backtranslation is denoising pretraining using monolingual corpora (Lewis et al., 2020; Dabre et al., 2022) and when combined with MT training as a joint objective (Kamboj et al., 2022) is known to significantly improve MT quality. Since backtranslation and denoising pre-training are known to be orthogonal (Liu et al., 2020), we leverage the joint denoising and MT training approach only for intermediate models which are used for backtranslation.

3 Our Systems

We submit 3 systems, one primary (constrained) and two contrastive (unconstrained).

3.1 Primary System

To create our primary system, we do the following:

1. Augment official monolingual data with the external monolingual corpora for the 4 North-East Indian languages and English.
2. Train a many-to-many encoder-decoder Transformer (Vaswani et al., 2017) model with the joint text-infilling (denoising) (Lewis et al., 2020; Dabre et al., 2022) and the MT objectives, using the augmented monolingual and official parallel corpora, respectively. To prevent the model from over-adapting to the infilling objective, we oversample the parallel corpora.
3. Use the aforementioned model to backtranslate the monolingual corpora.
4. Combine the backtranslated and official parallel corpora while oversampling the latter, and then train a many-to-many MT model.

3.2 Contrastive System #1

For our contrastive system, we investigate the potential of leveraging strong pretrained IndicTrans2 DA En-Indic and Indic-En models (Gala et al., 2023) for adaptation to newer languages and domains. It is important to note that we utilize off-the-shelf IndicTrans2 DA models trained on large-scale general-purpose corpora comprising both original and augmented backtranslated data. We refrain from using final models that are already fine-tuned with the same seed data that we use in this study, making them redundant in this context.

A trivial solution would be to adapt IndicTrans2 DA models to target languages and domains. However, this solution can often lead to catastrophic forgetting of translation ability on existing languages and domains. As a result, we explore approaches that satisfy two-fold objectives: 1) maximize the performance on a specific set of target languages and domains in the context of WMT shared task and 2) retain the overall performance on existing languages supported by the IndicTrans2 DA models. Our experiments involve a comparison of either of the approaches for adaptation of IndicTrans2 DA models to a specific set of few known and few unseen languages. We explore the following approaches:

1. **A1**: Direct fine-tuning of IndicTrans2 DA models on a combination of official parallel corpora and seed data used in Gala et al. (2023) for a set of languages under consideration for WMT Indic MT shared task.
2. **A2**: Direct fine-tuning of IndicTrans2 DA models on a combination of official parallel corpora and seed data used in Gala et al.

Parallel		Monolingual		
lang pair	# lines	lang	# lines (Org)	# lines (Aug)
as-en	50K	as	2.6M	8.05M
mz-en	50K	mz	1.9M	8.8M
kha-en	24K	kha	0.18M	0.73M
mni-en	21.6K	mni	2.14M	2.20M
		en	0	20M

Table 1: Parallel and monolingual data statistics. For the primary system, we only use the organizers' provided parallel data. We use monolingual data provided by the organizers as well as from Gala et al. (2023) and indicate the organizers' (Org) and augmented (Aug) sizes.

(2023) for all the languages supported by the IndicTrans2 DA models and WMT Indic MT shared task.

3. **A3**: Two-stage fine-tuning of IndicTrans2 DA models on 1) a combination of official parallel corpora and seed data used in Gala et al. (2023) for a set of languages under consideration for WMT Indic MT shared task, followed by 2) on a combination of official parallel corpora and seed data used in Gala et al. (2023) for all the languages supported by the IndicTrans2 DA models and WMT Indic MT shared task.

3.3 Contrastive System #2

Our second contrastive system combines the primary and first contrastive systems using a system combination approach called Multi-Engine Machine Translation (MEMT) (Heafield and Lavie, 2010, 2011). MEMT involves aligning 1-best outputs from each system using the METEOR aligner (Denkowski and Lavie, 2011), identifying candidate combinations by forming left-to-right paths through the aligned system outputs, and scoring these candidates using a battery of features. MEMT does not leverage any neural networks. We refer the readers to Heafield and Lavie (2010, 2011) for additional details.

4 Experiments

In this section, we describe the datasets, implementation and evaluation settings.

4.1 Datasets

We use the official parallel corpora and monolingual corpora provided by the organizers. We augment the monolingual corpora with those used in Gala et al. (2023). Particularly, we sample 20M English sentences, since the organizers did not provide any English monolingual data. The parallel and augmented monolingual corpora statistics are described in Table 1. For our first contrastive system, we also use a combination of BPCC seed corpora (Gala et al., 2023) and NLLB-seed corpora (Costa-jussà et al., 2022; Maillard et al., 2023) which was used in Gala et al. (2023) along with the official parallel corpora provided by the organizers for adaptation / fine-tuning IndicTrans2. Table 2 reports the statistics of different subsets used for training contrastive #1 system. For the languages primarily under consideration for the WMT Indic MT shared task, namely Assamese, Manipuri (Bengali), Khasi and Mizo, we use a total of ~196K bitext pairs encompassing seed and official parallel data.

	# langs / script	# samples
†BPCC seed	23	654,806
NLLB seed	3	18,579
WMT	4	145,321
Total	27	818,706

Table 2: Statistics of the parallel corpora used for training contrastive #1 system. † indicates that the BPCC seed also includes transliterated Sindhi (Arabic) data as released by Gala et al. (2023).

4.2 Implementation

Our primary systems are trained using YANMTT (Dabre et al., 2023). We train a single sentencepiece (Kudo and Richardson, 2018) tokenizer of 64K subwords for the Indic languages and English. We use 1M sentences per language, taken from the parallel and monolingual corpora. The model hyperparameters and optimizer details are described in Table 3. We ensure that the ratio of the official parallel and monolingual/backtranslated corpora remains balanced via temperature sampling (T=5.0) (Arivazhagan et al., 2019). We train our models till convergence with early stopping criteria with a patience of 5 and save separate checkpoints for each direction that exhibit best results for that direction based on BLEU (Papineni et al., 2002) metric on the development set. We use a fixed beam size of 4 and a length penalty of 0.8 when doing backtranslation.

For our first contrastive system, we fine-tune IndicTrans2 DA models with the standard fine-

Hyperparameter	Value

mni-en	8	1.4	16	1.2
en-as	8	1.4	8	1.4
en-kha	16	1.4	8	1.4
en-mz	16	1.4	8	1.4
en-mni	16	1.2	8	0.8

Table 4: Optimal decoding hyperparameters settings (beam size and length penalty) obtained by performing grid search on the development set for both primary and contrastive #1 systems.

tuning hyperparameter settings following Gala et al. (2023). Our first contrastive system is based on fine-tuning of IndicTrans2 DA models (Gala et al., 2023) which uses the fairseq library[4] (Ott et al., 2019). We train our systems till convergence on the development set and use the BLEU metric for early checkpointing. Furthermore, the vocabulary of IndicTrans2 DA models (Gala et al., 2023) lacks coverage for Mizo and Khasi. To address this, we extend the vocabulary and randomly initialize the newly added tokens in the embedding matrix of the IndicTrans2 DA models to incorporate representation for these languages. The expanded models serve as the base for fine-tuning.

For our second contrastive system using MEMT, we train 5-gram language models using KenLM (Heafield, 2011) and use default settings for system combination. Instead of taking only the best beam search output of each system being combined, we take the top 2 best translations in the beam, which simulates a combination of 4 systems.

For local evaluation, we use BLEU score (Papineni et al., 2002) measured using sacrebleu (Post, 2018), however, organizers additionally report chrF2 (Popović, 2017), RIBES (Isozaki et al., 2010) and TER (Snover et al., 2006). Human evaluation is not performed, but the organizers release COMET (Rei et al., 2022) scores as an approximation. For test set decoding, we identify optimal decoding hyperparameters (beam size and length penalty) by grid searching on the development set and list said hyperparameters in Table 4 for our primary and first contrastive system.

5 Results

In this section, we describe the results we obtained on the test sets.

5.1 Primary

Main result. Table 5 shows the results of our primary many-to-many system. For the Indic-En direction, Manipuri and Mizo to English exhibit reasonably high translation quality, at BLEU/chrF2 scores of 39.40/64.70 and 32.47/51.33 respectively. Assamese to English translation is the next best at 27.02/50.71. However, Khasi to English has the lowest translation quality among all. A critical observation is that there is no particular correlation between the sizes of the corpora and the MT quality. For example, Manipuri-English has the smallest parallel corpus (21,687 lines) and the second-smallest monolingual corpus (2.2M lines) but still exhibits the best translation quality for Manipuri to English. This could mean that the evaluation set is either easier for this pair or that it is easier to translate the pair compared to others.

For the reverse direction, once again Mizo and Manipuri exhibit the best translation quality, followed by Khasi and Assamese. Despite Assamese having more than 8 million monolingual sentences that were used for backtranslation, its translation quality is at 17.03 and 45.31 (BLEU and chrF2) which is not particularly high. The same decorrela-

en-mni	20.35	23.72	**24.62**

Table 6: Greedy search BLEU scores on the development set for Indic-En and En-Indic direction for the various models we trained in the process of getting to our final model. The “WMT PC" model uses only the parallel corpus for training. The “Intermediate" model is trained using the joint text infilling and MT objective and the “Final" model is trained with the backtranslated and organizers’ parallel data. All models are many-to-many. Please note that we use the IndicNLP tokenizer (Kunchukuttan, 2020) instead of standard tokenizer provided in sacrebleu (Post, 2018) for computing scores locally.

tion between corpora sizes and translation quality that existed for translation into English holds for the reverse direction. In addition, we report the BLEU scores for NLLB 54B MoE model on test set in Table 8.

Ablations. Although we report test set results only using the final system, we also report the BLEU scores on the organizer’s official dev set of the intermediate and final models in Table 6. Additionally, we report the results of a model that is trained only using the organizers’ official parallel corpora. It is clear that the intermediate model using joint denoising and MT training leads to a vast improvement in translation quality, indicating that the monolingual corpus brings substantial benefits. This is especially the case for Indic-En direction since we use around 20M monolingual English sentences. We observe that the En-Indic direction also has some performance gains (around 3 BLEU) but not as much as compared to the gains in the Indic-En direction (around 6 BLEU). This implies that the scale of monolingual data is an important factor, however, we are limited by the scale of monolingual data available for the Indic languages.

Furthermore, the final model, which uses backtranslated data from the intermediate model further shows improvements of approximately 4 BLEU. This indicates that in low-resource settings similar to ours, leveraging monolingual corpora first via denoising followed by backtranslation leads to the best models. Iterative backtranslation (Hoang et al., 2018) would be the ideal next step, but we chose to not pursue it because of compute constraints.

5.2 Contrastive

Contrastive #1: Main Result. Table 5 shows the results of our contrastive #1 system. We observe superior performance for the languages that are already covered in the off-the-shelf IndicTrans2 models (Assamese, Manipuri (Bengali)) as compared to the primary system. For Indic-En direction, Assamese and Manipuri to English exhibit reasonably high translation quality, achieving BLEU scores of 37.28 and 46.06 respectively. Furthermore, we also find mixed results between both systems for newly introduced languages such as Mizo and Khasi. For Khasi, the contrastive #1 system outperforms the primary system on both directions, whereas for

Model variants	FLORES-200 (18 lang)		WMT (all langs)		WMT (new langs)	
	En-Indic	Indic-En	En-Indic	Indic-En	En-Indic	Indic-En
IT2-DA	19.03	37.25	-	-	-	-
A1	3.85	35.81	24.70	32.50	23.20	24.40
A2	19.46	37.62	20.90	24.60	18.95	13.00
A3	18.68	38.07	25.80	32.30	24.50	24.20

Table 7: BLEU scores of different ablations described in Section 3.2 explored under contrastive #1 system on FLORES-200 devtest set (covers 18 languages) and WMT dev set (4 languages). Please note that we use the IndicNLP tokenizer (Kunchukuttan, 2020) instead of standard tokenizer provided in sacrebleu (Post, 2018) for computing scores locally.

	Primary		Contrastive #1		Contrastive #2		NLLB 54B MoE	
	en-xx	xx-en	en-xx	xx-en	en-xx	xx-en	en-xx	xx-en

mni	27.36	39.40	24.17	**46.06**	**27.40**	43.35	14.90	31.50

Table 8: Comparison of BLEU scores of all our systems - Primary, Contrastive #1, Contrastive #2 with massively multilingual NLLB 54B MoE model (Costa-jussà et al., 2022).

Mizo, the primary system outperforms the contrastive #1 system across both directions.

Contrastive #1: Ablations. In order to identify the optimal configuration for training the Contrastive #1 system, a series of ablations were conducted, involving a comparative analysis of three distinct approaches for fine-tuning the IndicTrans2 model (Gala et al., 2023), as detailed in Section 3.2. The baseline approach, denoted as A1, focuses solely on optimizing performance across 4 languages under consideration for WMT languages. However, this approach exhibits catastrophic forgetting on the existing supported languages. This is evident in the significant drop in average BLEU scores on the FLORES-200 test set (Goyal et al., 2022; Costa-jussà et al., 2022). Specifically, when fine-tuning IndicTrans2 DA model (Gala et al., 2023) to obtain A1 for the En-Indic language direction, the average BLEU score significantly dropped from 19.03 to 3.85. However, for the Indic-En direction, the drop is relatively modest, shifting from 37.25 to 35.81, although this drop can be made even lower.

To prevent catastrophic forgetting on existing supported languages, an alternative approach, labeled as A2, was experimented. This approach involves a joint fine-tuning on a combined set involving all the existing supported languages along with the newly introduced ones. Notably, this approach averts the issue of catastrophic forgetting. On the FLORES-200 benchmark (Goyal et al., 2022; Costa-jussà et al., 2022), the models resulting from this joint fine-tuning slightly surpass the performance of the IndicTrans2 DA models in both translation directions, showing an improvement of approximately 0.4 points. However, despite this improvement, the performance on the newly added languages such as Khasi and Mizo is suboptimal, significantly trailing behind the scores obtained using the A1 approach. We observe respective drops of 3.8 and 7.9 points in the En-Indic and Indic-En directions over A1.

Although approach A2 successfully resolved the issue of catastrophic forgetting, it did not fully meet our objective of optimizing for the newly introduced languages. As a result, we explored approach A3 which involves a two-stage fine-tuning procedure, wherein A1 is initially employed, followed by A2. As previously discussed, A1 resulted in a sharp decline in performance across the existing languages, but optimized to the newly introduced languages. However, we observe that this performance drop can be rectified by introducing an additional stage of fine-tuning involving a combined set of all languages, as seen in approach A2. A3 results in a fair retention of performance in terms of BLEU scores across the existing languages for both translation directions, Indic-En (with scores of 37.24 for IndicTrans2 DA and 36.68

for A3) and En-Indic (with scores of 19.03 for IndicTrans2 DA and 18.68 for A3). Moreover, on the newly introduced languages, models trained using the A3 approach demonstrate an improvement of nearly 8 points in the Indic-En direction and 4.9 points in the En-Indic direction on average, when compared to A2, as observed on the WMT 2023 IndicMT dev set. Notably, A3 achieves performance on par with A1 (optimized for four languages) in the Indic-En direction and even outperforms A1 by a margin of +1.1 in the En-Indic direction. Therefore, A3 achieves both the outcomes: performance retention on existing languages as well as optimization in performance for newer languages.

Contrastive #2: Main Result. Having obtained the best primary and contrastive systems, we combine them via MEMT. Table 5 contains the result of the system combination on the test set. For Indic-En direction, only Mizo to English benefits from system combination, where the best BLEU score improves from 32.47 to 33.30. For the En-Indic direction, we see improvements for all directions. Most notable is the improvement for English to Assamese, whose best BLEU score improves from 18.09 to 21.07. For other directions, the improvements are relatively smaller. One important observation is that when the performance gaps between the primary and contrastive #1 system is larger, the gains are smaller or are negative. Overall, it is important to note that such word level system combination still works despite the idea being over a decade old, however, the use of n-gram based LMs might be a limitation and replacing said LMs with neural LLMs might bring large benefits. We leave this for future work.

5.3 Lessons Learned

- In low-resource settings, leverage monolingual data first via denoising and then via backtranslation.
- A two-stage fine-tuning approach (introducing new languages first, followed by a combination of new and existing languages) is an effective approach when considering extending a pre-trained translation model to newer languages without catastrophic forgetting.
- System combination is still effective despite working at a word level.

6 Conclusion

In this paper, we have described our systems submitted to the WMT 2023 Indic translation task. We leveraged ideas ranging from joint denoising and MT training, backtranslation, fine-tuning pretrained models, and system combination. We reported our results, which show the benefits of the various ideas we explored. Finally, we recommend best practices.

7 Limitations

We identify the following limitations of our submissions:

- We did not perform ensembling or checkpoint averaging, which could boost our results by another 1-2 BLEU.
- Iterative backtranslation (Hoang et al., 2018) was not adopted due to compute constraints and can potentially boost quality even further.
- Although we reached the monolingual corpora limit for the Indic languages of focus, we could have used much larger English monolingual corpora but opted not to, once again, due to compute constraints. This would also require us to increase model sizes which was also not feasible.
- We have not leveraged any LLMs for our experiments, mainly because we are not sure if they have been trained on any of the test data, a common concern in recent times.
- MEMT is an old idea and does not use any neural language models, especially LLMs, which could enhance its performance.

Acknowledgement

We graciously thank Varun Gumma (SCAI Fellow, Microsoft Research) for his kind review of this draft, which helped us improve its readability and quality.

Abstract

Machine translation for low-resource Indian languages has long been a challenge due to the scarcity of high-quality parallel corpora, demanding the development of effective translation models. The WMT23 Low-Resource Indic Language Translation task encourages us to utilize creative techniques to address this issue and enhance the performance of machine translation systems for these languages. We focused on the translation of two low-resource Indic languages: Assamese and Manipuri, enabling bidirectional translation between English and these languages. This paper presents CFILT-IITB's submission to WMT23, highlighting our exploration of transfer learning-based methodologies. Our experiments produced notable results of **47.54 BLEU** on MNI→EN, **18.15 BLEU** on EN→ASM and **35.24 BLEU** on ASM→EN, **26.36 BLEU** on EN→MNI test sets. These results not only demonstrate the effectiveness of transfer learning-based techniques but also contribute to advancing machine translation capabilities for low-resource Indian languages, addressing a critical need in bridging language barriers and facilitating cross-cultural communication.

1 Introduction

In the realm of machine translation, the WMT23 IndicMT shared task emerges as an arena where the boundaries of translation technology are stretched to their limits. Our efforts revolve around the translation of the 'En-X' pair in both directions, where 'En' signifies English and 'X' encompasses Assamese, a member of the Indo-Aryan language family, and Manipuri, a representative of the Tibeto-Burman family. As the task focused on English to and from low-resource Indian languages, we were provided with a small parallel corpus for each 'En-X' pair. Furthermore, participants had access to a substantial amount of monolingual data for Assamese and Manipuri, creating an ideal setting for trying out new and creative approaches.

In the realm of Machine Translation, the Neural Machine Translation paradigm has emerged as a dominant force, as evidenced by seminal works such as (Bahdanau et al., 2014) and the comprehensive survey by (Dabre et al., 2020). However, Neural Machine Translation models are notoriously data-hungry, leading to performance degradation when confronted with low-resource languages, as highlighted by (Dewangan et al., 2021). To tackle this challenge, we turn to the promising technique of transfer learning, a well-established approach in machine learning where knowledge gained from one task is leveraged to enhance performance in a related task. In our pursuit of improving translation capabilities for low-resource languages, we harness the multilingual IndicTrans2 model, as introduced by (AI4Bharat et al., 2023). Our methodology involves fine-tuning this model using the 'En-X' parallel data provided for the task. By adopting this approach, we aim to capitalize on the acquired knowledge during training to significantly bolster the performance of the model in the specific translation task at hand.

IndicTrans2 is rooted in the transformer-based encoder-decoder architecture pioneered by (Vaswani et al., 2017). It was trained on the extensive Bharat Parallel Corpus Collection (BPCC), a publicly accessible repository encompassing both pre-existing and freshly curated data for all 22 scheduled Indian languages, this model boasts a comprehensive understanding of the linguistic diversity within the Indian subcontinent. To enhance its linguistic prowess, IndicTrans2 has undergone auxiliary training utilizing the rich resource of back-translated monolingual data. The model was then trained on human-annotated data to achieve further improvements. We used this model and fine-tuned it on the training data provided by WMT23.

The fine-tuned IndicTrans2 achieves good scores; hence we are using it for our final submission. We hypothesize that its stellar performance

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 950–953
December 6–7, 2023.

can be attributed to the amalgamation of language knowledge acquired during its initial training, coupled with the domain-specific expertise gleaned from the fine-tuning process, facilitated by the training data made available through WMT23.

2 Data

We use the IndicTrans2 model and fine-tune it on the WMT23. The original IndicTrans2 was trained on the Bharat Parallel Corpus Collection (BPCC) corpus. They have used FLORES-200 as their validation set for Assamese and extended FLORES-200 (Team et al., 2022) for Manipuri. For auxiliary training which includes back-translated monolingual sentences, they have used IndicCorp v2 (Kakwani et al., 2020) and one side of NLLB data as monolingual corpus. They have used standard test sets like FLORES-200, but they have also created a new benchmark called the IN22 test set which is an n-way parallel corpus for all 22 Indian scheduled languages.

We have fine-tuned the model using the WMT23 parallel corpus. The 'English-Assamese' pair has 50K parallel sentences, and the 'English-Manipuri' pair has around 21.6K sentences. The validation set consisted of the WMT23 validation set. The size of the validation set for the 'English-Assamese' is 2K sentences; for the 'English-Manipuri' pair, it was 1k sentences. The test set for both pairs was the WMT23 test set.

3 System Overview

In the pursuit of enhancing machine translation for low-resource languages, various approaches have emerged, such as Phrase-Pair injection and Back-translation, aimed at enhancing performance. Our system, on the other hand, takes a distinct path and relies on the knowledge gained from the multilingual training of IndicTrans2 and applies it to different low-resource languages.

Phrase-Pair Injection (PTI) (Sen et al., 2021), (Dewangan et al., 2021) and (Banerjee et al., 2021) utilized a technique to combine both Statistical Machine Translation (SMT) and Neural Machine Translation (NMT). The utilization of the phrase table during training is pivotal in Statistical Machine Translation (SMT) as it probabilistically maps phrases from the source to the target language. By incorporating these phrase mappings from the table into the existing parallel corpora, the training dataset for the Neural Machine Translation (NMT) model is significantly enriched. Consequently, this enrichment empowers the NMT model to excel in its translation performance.

Back-translation Back-translation (Sennrich et al., 2016; Conneau et al., 2020) is a technique that is used to improve the performance of low-resource translation systems using monolingual data. In this technique, a reverse model is employed to generate a parallel corpus from a monolingual corpus. This is a clever way to use the monolingual corpus to improve the translation performance of the NMT models. We do not include Back-translated sentences for training since we could not see any significant performance improvement.

Transfer Learning Transfer learning is a machine learning technique where a model trained on one task is adapted for a second related task. Instead of starting the training of a new model from scratch, transfer learning leverages the knowledge learned from the first task to improve learning on the second task. We have used IndicTrans2 (AI4Bharat et al., 2023), a powerful model that performs well for English-to-Indic and Indic-to-English translation for 22 scheduled Indian languages. This knowledge can be used to translate other Indian languages to and from English. Our approach entailed the fine-tuning of this model, leveraging the parallel corpus provided by the WMT23 for the IndicMT task. This fine-tuning process equipped the model with the expertise required to proficiently translate Assamese and Manipuri to and from English, ultimately yielding the most outstanding results. We do not inject phrase pairs since for such a low resource setting, it is difficult to see performance improvements even with phrase pair injections due to the inability of NMT models to capture the low resource language.

4 Experiments

4.1 Settings

All the experiments are conducted using two NVIDIA A100 GPUs each having 80GB of memory. Our models apply Adam (Kingma and Ba, 2015) as optimizer to update the parameters with $\beta_1 = 0.9$ and $\beta_2 = 0.98$. We employ a warm-up learning rate of 10^{-7} for 2000 update steps and a learning rate of $3 * 10^{-5}$. For normalization, we use a dropout value of 0.2 and normalize the proba-

Models	ASM→EN		EN→ASM		MNI→EN		EN→MNI	
	BLEU	**ChrF2**	**BLEU**	**ChrF2**	**BLEU**	**ChrF2**	**BLEU**	**ChrF2**
Baseline-1 (val)	2.32	-	1.64	-	3.12	-	2.67	-
IndicTrans2 (val)	25.60	47.20	14.70	41.40	33.40	58.50	11.90	43.50
FT IndicTrans2 (val)	34.60	52.40	**24.00**	46.00	47.00	67.30	**34.10**	62.20
FT IndicTrans2 (test)	**35.24**	**57.73**	18.15	**50.16**	**47.54**	**70.41**	26.36	**63.48**

Table 1: Comparison of results of Fined-tuned IndicTrans2 (AI4Bharat et al., 2023) on the test and val set. We compare val and test set results because we see that the EN-Indic model has overfitted for both languages and therefore we see a decrease in BLEU for EN-Indic models. We recommend readers to decrease the number of updates for better scores when the source is English.

bilities using smoothed label cross-entropy. We use GeLU activations (Hendrycks and Gimpel, 2016) for better learning. We train separate models for each language pair to avoid data imbalance and learn better low-resource representations.

We use the scareBLEU library[1] to calculate our BLEU (Papineni et al., 2002) and ChrF (Popović, 2015) scores with a word order of 2. We choose the checkpoint with the highest validation BLEU score.

4.2 Results

Table 1 shows that the highest translation quality achieved is via the use of large monolingual and parallel corpora. Since IndicTrans2 is trained in many Indian languages, it enhances the translation quality via the power of multilingualism. With only some minor tuning of the model over the training and validation set, IndicTrans2 achieves remarkable performance on Indic-En translations. Our baseline-1 system is a WMT-14 En-De fairseq model trained that utilizes only the parallel data and shows substandard BLEU scores over all the language pairs. With our experiments, we see that with even the monolingual corpora and back translation, the translation models only see minor improvements. We realized the power of multilingualism and switched to pre-trained models which have been trained on a substantial amount of data like IndicTrans2 (AI4Bharat et al., 2023) and NLLB (Team et al., 2022). We analyze their vocabulary and merge it with a new vocabulary learned over the monolingual corpora provided in the task. Even for languages that are not seen by the model like Mizo and Khasi in the *latin* script, the IndicTrans2 model with its pre-trained English vocabulary gives a BLEU score of an average of 7.2 on the val set over these language pairs. We see that when we fine-tune the pre-trained model, we see large gains over both the *val* and the *test* set. Finally, after many experiments, we submit a fine-tuned version of a very powerful multilingual model for the shared task.

5 Conclusion

In this paper, we present how CFILT-IITB utilized the power of multilingual models for the WMT23 IndicMT Low-Resource Machine Translation of Indian Languages Shared Task. Since, the data for low-resource languages is scarce, utilizing pre-trained multilingual translation models is very crucial. But to have reasonable to good performance over these models, it is helpful to have a model that is trained on similar languages. For this task, Indian languages like *Assamese* and *Manipuri* share similar structure and vocabulary with many Indian languages like *Bengali* which can be considered a high resource language for India. Training models over similar language does boost performance although to cover a wide variety of low-resource languages, one must face the curse of multilingualism. Our most proficient system attains an average BLEU score of 41.39 for Indic-English translation and 22.25 for English-Indic language pairs, specifically Assamese and Manipuri.

Limitations

Limitations of such powerful multilingual models are data extraction, enormous computing, and good data filtration techniques. Overcoming these obstacles is an open research problem.

Abstract

We present the submission of the CUNI team to the WMT23 shared task in translation between English and Assamese, Khasi, Mizo, and Manipuri. All our systems were pretrained on the task of multilingual masked language modelling and denoising auto-encoding. Our primary systems for translation into English were further pretrained for multilingual MT in all four language directions and fine-tuned on the limited parallel data available for each language pair separately. We used online back-translation for data augmentation. The same systems were submitted as contrastive for translation out of English where the multilingual MT pretraining step seemed to harm the translation performance. Other contrastive systems used additional pseudo-parallel data mined from monolingual corpora.

1 Introduction

We present our submission to the Indic MT shared task of the WMT23 workshop. We trained constrained systems in all evaluated language directions: English-Assamese (en-as), English-Manipuri (en-mni), English-Mizo (en-mz) and English-Khasi (en-kha).

A majority of languages in the world have a very limited amounts of translation resources to be used for training machine translation (MT) systems. Unsupervised learning techniques have been proposed to leverage monolingual texts in MT training, either in the pretraining phase (Liu et al., 2020; Conneau and Lample, 2019) or during fine-tuning by means of back-translation (Sennrich et al., 2016). This shared task is proposed as a realistic scenario where for each Indic language, the participants have access to several thousand parallel sentences paired with English and up to 2.6M additional unaligned sentences in each language. The texts are mixed from the religious domain and the general domain. In addition to the provided data, participants were allowed to use any monolingual texts and any pretrained models trained on monolingual texts.

In our other research, we focus primarily on unsupervised MT and we participated in this shared task to measure the impact of adding at least a small number of parallel sentences into the training. Therefore, we also evaluated our fully unsupervised systems in the conditions of Indic MT, where the languages are linguistically very different from English and some also have a different script.

A major obstacle, especially for our unsupervised models, is the domain mismatch in our training data. While monolingual English data we used come from NewsCrawl, the Indic training data includes texts from the religious domain. The issue is especially pronounced when we struggle with finding equivalent sentences in the monolingual corpora section 2.5, but it is problematic for the entire unsupervised training as the domain mismatch interferes with the underlying assumption of isomorphism of embedding spaces.

In this paper, we first introduce our training methodology (section 2), describe the data (section 3.1) and comment on the results (sections 4 and 5)

2 Methodology

2.1 Model Architecture

The architecture of all our NMT models is a 6-layer Transformer with 6 attention heads, GELU activations, and 0.1 dropout. In addition to token embeddings and trained positional embeddings, the model features language embeddings to pass the information which language direction is being used. Both input token embeddings and the final softmax layer have tied weights.

2.2 Pretraining on Monolingual Texts

We pretrain a Transformer encoder on the task of masked language modelling (MLM) on all available corpora in all languages. The details of

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 954–958

	as	kha	mni	mz	en
train (mono)	2.6M	183k	2.1M	1.9M	33M
train (para)	50k	24k	22k	50k	-
train (pseudo-para)	81k	95k	150k	66k	-
dev	2k	1k	1k	1.5k	-
test	2k	1k	1k	2k	-

Table 1: The number of sentences in the training, dev and test sets. Monolingual (mono) and parallel (para) data were provided by the organizers, pseudo-parallel data was created as described in Section 2.3.

the MLM task are given in Conneau and Lample (2019). We copy its weights into both the encoder and the decoder of the Transformer model and we continue the pretraining phase by training a multilingual denoising autoencoder (DAE). The noise function applied to the input sentence has the following components: word deletion with probability $p_{del} = 0.1$, word masking with probability $p_{mask} = 0.1$ and word shuffling within the window of length $l_{shuf} = 4$.

All our systems are pretrained on both MLM and DAE.

2.3 Pretraining on Multilingual Parallel Texts

In the second pretraining stage, we train a multilingual neural machine translation model (MNMT) on all available parallel data. In each training step, the model sees a mini-batch of parallel sentences for all language pairs. It uses language embeddings to detect the right translation direction.

2.4 Fine-tuning for Machine Translation

In the fine-tuning stage, we train a bidirectional model for each language pair in a semi-supervised fashion, using a cross-entropy loss on a small authentic parallel corpus. We augment the data with online back-translation (OBT) (Lample et al., 2018; Artetxe et al., 2018) to avoid over-fitting. In every OBT training step, the model is switched into an inference mode to create a mini-batch of training data by translating a portion of monolingual sentences. This operation is performed in both translation directions and the resulting mini-batch (with the synthetic sentences placed on the source side) is directly used for training.

2.5 Data Augmentation with Pseudo-Parallel Texts

We also measure whether we can earn some benefits by incorporating pseudo-parallel (PP) sentences into the MT training. We use the methodology of Kvapilíková et al. (2020) and search for parallel sentences in the training corpora. We search for the nearest neighbors in the multilingual sentence embedding space created by a multilingual sentence encoder. The encoder is the modified XLM-100 (Conneau and Lample, 2019) pretrained model fine-tuned on the MLM task for Assamese, Khasi, Mizo, Manipuri and English. The search metric is the modified cosine similarity $xsim$ (Artetxe and Schwenk, 2019) between the sentence embeddings which is required to be higher than 1:

	en-as	**en-kha**	**en-mni**	**en-mz**
Precision	35.03	9.67	7.92	22.54
Recall	18.55	10.50	5.70	18.00
F1 Score	24.26	10.07	6.63	20.01
Threshold	1.022	1.027	1.022	1.022

Table 2: Precision, Recall and F1 score on the Parallel Sentence Matching Task.

$$\text{xsim}(x, y) = \frac{\cos(x, y)}{\text{avgcos}(x) + \text{avgcos}(y)} > 1 \quad (1)$$

where

$$\text{avgcos}(\cdot) = \sum_{z \in \text{NN}_k(\cdot)} \frac{\cos(\cdot, z)}{2k} \quad (2)$$

where $\text{NN}_k(x)$ is the set of k nearest neighbors of x. We augment the existing authentic parallel corpora with the pseudo-parallel sentence pairs and train on the resulting corpus. The number of retrieved pseudo-parallel sentence pairs is indicated in table 1. The performance of the sentence encoder at the task of parallel corpus mining for the languages in question was measured by an auxiliary task where it was asked to find 1-2k parallel sentences (dev set) among 200k monolingual sentences from the train set in both languages. The results are summarized in section 2.4 where we see that the precision of correctly matched parallel sentences for Khasi and Manipuri is very low.

	en-as	en-kha	en-mni	en-mz	as-en	kha-en	mni-en	mz-en
MT+OBT	**14.1**	**16.6**	29.5	31.2	17.6	12.8	33.9	28.3

Table 3: BLEU score of our MT systems on the WMT23 test set.

In our experiments we evaluate the impact of MNMT and PP pretraining on the final translation quality.

3 Experiments

We train several models for each language pair. All models are pre-trained as described in 2.2. For our shared task submission, we train three kinds of semi-supervised models using all available parallel data:

- MNMT+MT+OBT models were trained for multilingual MT and fine-tuned for each language pair separately on a combination of authentic parallel data and synthetic parallel data created by OBT;
- MT+OBT models skip the multilingual MT pre-training step;
- PP+MT+OBT models are trained on pseudo-paralle data in addition to authentic and synthetic data. The pseudo-parallel corpus is removed after 5 epochs of training.

We compare the results of the semi-supervised models to unsupervised models trained without the authentic parallel data to measure the effect of limited amounts of parallel data. We experiment with gradually adding parallel sentences into the training and evaluate the performance of a model trained on 1k, 2k, 5k, 10k and 25k parallel sentences.

3.1 Data

In addition to the data provided by the organizers (Pal et al., 2023), we used 33M English sentences from NewsCrawl2022. The summary of the data is in table 1. We trained a BPE model on the concatenation of all Indic corpora and a downsampled Englih corpus. The BPE vocabulary size is 52k. During pre-processing, we first tokenized the texts using the Moses tokenizer which created a problem with the Assamese script as it decomposed several compound Unicode characters which had impact on the segmentation of texts with Assamese script (as, mni). The decomposed accents form a separate BPE unit which lead to a high segmentation of the Assamese and Manipuri texts. During post-processing we managed to compose the segmented text by running a special substitution on top of the standard detokenization. The unnecessary step of Moses tokenization likely cost us some final translation performance due to the sub-optimal BPE segmentation.

3.2 Training Details

We use the XLM[1] toolkit for training. For language model pretraining, we use mini-batches of 64 text streams (256 tokens per stream) per GPU and Adam (Kingma and Ba, 2015) optimization with `lr=0.0001`. For denoising and MT fine-tuning, we use mini-batches of 3,400 tokens per GPU and Adam optimization with a linear warm-up `(beta1=0.9,beta2=0.98,lr=0.0001)`. The models are trained on 8 GPUs.

4 Shared Task Results

For our shared task submission, we compared the performance of our experiments on the dev set and concluded that the fine-tuned multilingual NMT system (MNMT+MT+OBT) performs better than individual systems (MT+OBT) when translating into English and on par with individual systems when translating from English. Therefore, for our PRIMARY submission, we submitted the output of the multilingual model when translating into English and the output of the individual models when translating from English. The opposite results were submitted as CONTRASTIVE-1. The PP+MT+OBT systems were submitted as CONTRASTIVE-2. The final test set results are summarized in table 3.

The winning system for all language directions was a system called TRANSSION-MT which outperformed other systems with almost double the

[1] https://github.com/facebookresearch/XLM

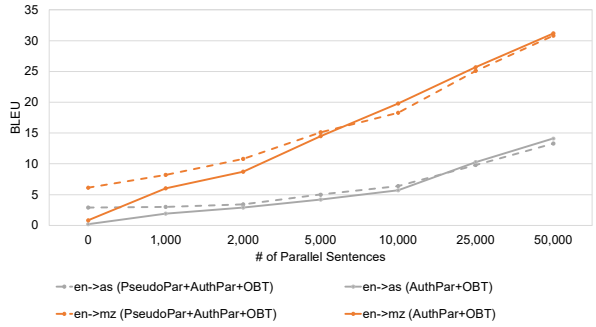

Figure 1: Relationship between the translation quality and the number of parallel sentences used for training.

BLEU score of the second best candidate (Pal et al., 2023). In general, our systems performed relatively better in translation from English which suggests that the translation to English may have been harmed by the bidirectional nature of our systems. Our en→mni system ranked second after TRANSSION-MT out of 14 participants. Our en→mz system ranked fourth out of 11 participants. The the remaining systems finished on the 5th-7th places.

5 Discussion

Asides from the shared task submission, we were interested in the following phenomena which we measured in our experiments:

- The gap between unsupervised and semi-supervised translation systems;
- The impact of pseudo-parallel data augmentation on the final translation quality;
- The development of translation quality in relation to the number of parallel sentences used during training.

Outside of the scope of the shared task, we trained unsupervised MT systems for Mizo and Assamese. For each of the two language pairs, we trained two systems, with and without pseudo-parallel sentences. table 3 shows that the unsupervised systems reach between 3 and 6 BLEU which is not a sufficient quality for practical use of the systems. The poor unsupervised results are most likely the consequence of the domain mismatch between English and Indic data as well as a mismatch between the English train set and the test sets. Our conclusions support the claims of other researchers (Marchisio et al., 2020; Vulić et al., 2019) that unsupervised MT models often fail in truly low-resource scenarios where it is not possible to obtain enough clean and domain-balanced monolingual training data and the underlying assumption of language isomorphism is challenged.

Data augmentation with pseudo-parallel sentences has zero or even a negative impact on the performance of our semi-supervised systems. For the unsupervised systems, on the other hand, it increases BLEU score by up to 5.3 BLEU points. We trained several other systems, gradually adding more parallel sentences, to measure the threshold where pseudo-parallel sentences stop helping. fig. 1 illustrates the relationship between translation quality and reveals that when we have more than 10k parallel-sentences, the unsupervised data augmentation techniques of adding pseudo-parallel sentence pairs is not beneficial anymore.

6 Conclusion

We trained several MT systems for translation between English and four Indic languages. The most promising outcomes were achieved by initially pre-training a multilingual NMT system, followed by fine-tuning using bilingual parallel data along with online back-translation. Our systems ranked between the 2th and 7th place among 10-14 participating teams, depending on the language pair and translation direction. Our systems performed relatively better at translation out of English.

Data augmentation with pseudo-parallel data does not bring any further benefits in the context of the shared task. Our experiments show that their positive effect disappears when we have access to more than 10k authentic parallel sentences.

We compared the results to completely unsupervised systems and we conclude that the domain mismatch between our English and Indic training data and the linguistic dissimilarity of the languages do not allow the unsupervised MT systems to learn to translate without seeing parallel sentences. Incorporating pseudo-parallel sentences into the training helps, but the translation quality remains low.

Abstract

The WMT 2023 Shared Task on Low-Resource Indic Language Translation featured to and from Assamese, Khasi, Manipuri, Mizo on one side and English on the other. We submitted systems supervised neural machine translation systems for each pair and direction and experimented with different configurations and settings for both preprocessing and training. Even if most of them did not reach competitive performance, our experiments uncovered some interesting points for further investigation, namely the relation between dataset and model size, and the impact of the training framework. Moreover, the results of some of our preliminary experiments on the use of word embeddings initialization, backtranslation, and model depth were in contrast with previous work. The final results also show some disagreement in the automated metrics employed in the evaluation.

1 Introduction

This paper describes our systems to the WMT 2023 Shared Task on Low-Resource Indic Language Translation. The task featured four low-resource languages indigenous to the northeastern regions of the Indian subcontinent. The translation was to be done to and from Assamese (Indo-Aryan), Khasi (Austroasiatic), Manipuri, Mizo (Sino-Tibetan) on one side and English on the other. We submitted supervised neural machine translation systems for each pair and direction and experimented with different configurations and settings for both preprocessing and training. We did not use large pretrained models, but trained transformers (Vaswani et al., 2017) of different size and with different parameters for each direction, both on bilingual and multilingual data. Even if most of our final systems did not reach a satisfactory or competitive performance, settling for the middle to low part of the scoreboard, we argue that our experiments brought up some interesting points that call for a deeper investigation. Chiefly, these are the relation between dataset and model size, and the impact of the training framework. Moreover, the final results seem to confirm recent research on the reliability of automatic evaluation metrics, with several cases of disagreements in the ranking of the systems, ranging from one to several places in the leaderboard.

2 Datasets

In the following Section, we first briefly present the languages involved, then we give a summary of the datasets, their contents, domains, and structure.

2.1 Languages

Assamese (*Asamiya*) is an Indo-Aryan language mainly spoken by more than 15 million people in the Indian state of Assam, where it is also the official language. Assamese is also one of the 22 official languages recognized by the Republic of India at the federal level. It is influenced by several other regional languages, mostly Tibeto-Burman varieties, and Bengali, another Indo-Aryan language, with which shares the Bengali-Assamese writing script, an abugida system. Assamese serves as a quasi *lingua franca* for the region and functions as one of the source languages for some pidgins and creoles of the area, such as Nefamese and Nagamese. Assamese is an inflected language with eight grammatical cases and a large collection of classifiers. It follows the subject-object-verb order.

Khasi (*Ka Ktien Khasi*) is an Austroasiatic language with 1 million speakers (the Khasi people) in the Indian state of Meghalaya. It is official in some districts of the state, but not in the state as a whole, and it is considered as "vulnerable". It is related with the other languages in the Khasian group native to the Shillong Plateau, and it is surrounded by unrelated languages such as Assamese, Bengali, Manipuri, and others. It is written both in the Latin, as is the case with this task's data, and the Bengali scripts. Khasi is a stress language

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 959–966

Language	ISO-639-3	Family	Script	Num. of Speakers	Official at:	Vitality
Assamese	asm	Indo-Aryan	Bengali	15M	Federal	-
Khasi	kha	Austronesian	Latin	1M	Local	VUL
Mizo	lus	Sino-Tibetan	Latin	1.8M	State	-
Manipuri	mni	Sino-Tibetan	Meitei, Bengali	0.85M	Federal	VUL

Table 1: Summary of the Indic languages involved in the task. For each language, the columns give its ISO code, its language family, the writing system(s) it employs, the number of its speakers and its status, both in terms of official recognition and conservation according to the UNESCO. Khasi and Manipuri are listed as "Vulnerable".

without tones. It has nine grammatical cases and follows the subject-verb-object word order.

Mizo (*Mizo ṭawng*) is a Tibeto-Burman language spoken by around 850 thousand Mizo people, primarily in the Indian state of Mizoram, where it is an official language. It is written in a modified version of the Latin script. Mizo is a tonal language with eight tones, it follows the object-subject-verb order, and it has six grammatical cases.

Manipuri (*Meiteilon*) is a Tibeto-Burman language official in the Manipuri state of India and also at federal level. It is spoken natively by 1.8 million people, the Meitei, both in Manipur and in small communities in the neighboring states. It is considered "vulnerable" by the UNESCO. Manipuri employs a wide array of writing systems, the official ones being the Meitei script and the Bengali script.[1] The Latin script is also used. Manipuri is a tonal language, It follows the subject-object-verb word order.

Table 1 summarizes the main facts about this task's Indic languages.

2.2 Composition

Table 2 gives, for each language pair, the size of the datasets. The parallel datasets made available for this task are small, with the biggest being *asm* and *lus*, at 50k sentence pairs. Of the Indic languages, two are written in Bengali script (*asm* and *mni*), and two in their own variations of the Latin script (*kha* and *lus*). Following the notation of the Flores-200 benchmark dataset (Goyal et al., 2022), we denote the collation of data in Bengali script with *Beng*, and in Latin script with *Latn*.

Monolingual data was released for all Indic languages: *asm*,*lus*, and *mni* have around 2/2.5M sentences each, while *kha* has only 180k. While we did not look at the domains for these data, we sampled the content of the parallel datasets.

[1]This is the writing system used in the task's Manipuri dataset.

Table 3 gives an outline of the contents of each split of each dataset. For *asm*, both the valid and test set differ from the training data. The former is composed mainly by dictionary definitions, while the latter mostly contains religious content. The *kha* dataset is consistent in terms of domains. The *lus* train split has almost exclusively religious content, the validation split contains both religion and instances of single words, and the test split is quite mixed in content. The *mni* data is almost entirely composed by news or otherwise informative text.

3 Methodology

This Section describes our methodology and the baselines we moved from.

3.1 Baselines

For our experiments, we set as our baseline a standard Transformer (Vaswani et al., 2017) with the hyperparameters in Table 4. We wanted to experiment with ways to make the most out of the training data given, and thus we did not use pre-trained models in our work. Almost all models were trained with Fairseq (Ott et al., 2019). The two final submissions to and from Assamese were trained with TorchScale (Ma et al., 2022).

3.2 Preprocessing

The preprocessing for our models was done with SentencePiece (Kudo, 2018), both BPE (Sennrich et al., 2016) and Unigram (Kudo, 2018), and HFT (Signoroni and Rychlý, 2022a). We chose these three segmentation algorithms either for their popularity, as it is the case with BPE and Unigram, or for their stated application, in the case of HFT. For all these algorithms, we set as our baseline parameters a vocabulary size of 2000, with separate dictionaries for source and target language, and a frequency threshold of 100. For other experimental and final runs, we explored different values and settings of segmentation algorithm, vocabulary size and learning, and frequency threshold.

Dataset	Train	Valid	Test	Monolingual	Script
eng-asm	50,000	2,000	2,000	2,624,715	Beng
eng-kha	24,000	1,000	1,000	182,737	Latn
eng-lus	50,000	1,500	2,000	1,909,823	Latn
eng-mni	21,687	1,000	1,000	2,144,897	Beng
eng-Beng	71,687	200	-	-	Beng
eng-Latn	74,000	200	-	-	Latn
eng-all	145,687	400	-	-	Both

Table 2: Size of the dataset for each language pair. Languages are given in ISO-639-3 codes. Train, valid, and test splits are in number of sentence pairs, whereas monolingual data are in number of sentences for the target language. To denote the collation of languages that in the task data are written in Bengali script (asm and mni) and Latin script (kha and lus), we use *Beng* and *Latn*, respectively. *all* denotes the collation of all train splits.

Dataset	Domain		
	Train	Valid	Test
eng-asm	rel,news	misc,news	misc
eng-kha	rel	rel	rel
eng-lus	rel	rel,misc	misc,rel
eng-mni	news	news	news,misc

Table 3: Domains contained in each split of each dataset. Our investigation was conducted on a random sample of each split. *rel(igion)* denotes Bible text and religious news; *news* stands for all non-religious news and information; and *misc* indicates all other miscellaneous domains, e.g. short conversational phrases, dictionary definitions, words.

Parameters	
encoder/decoder layers	6
enc/dec embedding dim	512
enc/dec feed forward dim	2048
enc/dec attention heads	8
optimizer	adam
learning rate	1e-3
warmup updates	4000
dropout	0.3
label smoothing	0.1
max tokens	16384

Table 4: Hyperparameters for our baseline models. Here encoder and decoder parameters are set at the same value.

3.3 Experiments

We explored several ideas and aspects of training during our experiments, which we summarize below.

3.3.1 System Architecture

We tried several configurations of encoder/decoder layers, inspired by previous work such as Araabi and Monz (2020) and van Biljon et al. (2020) which finds that shallower transformers work better in a low-resource scenario. This was the case also for most of our experiments, where smaller models always outperformed the baseline. This holds true even when training on multilingual data. Apart from the baseline, we tested bigger and deeper models, inspired by work such as (Narang et al., 2021; Wei et al., 2022; Wang et al., 2022), on *mni-eng*, which we considered as the "easiest" direction for the models. Preliminary results show degrading performance with the increase of number of encoder layers. We trained on data tokenized with Unigram and a jointly learned vocabulary of 2000, since this was the best performing setup on the validation split. The results of this experiment are given in Table 6, in terms of BLEU score.

One outlier is the translation to and from Assamese, where baseline models, albeit with a dropout of 0.1, outperformed the smaller ones. In these directions, our final systems turned out to be 18/6 models with an embedding dimension of 384 and a feedforward dimension of 1536. However, it should be noted that these final systems were trained in a parallel line of experiments and with a different framework, TorchScale (Ma et al., 2022), which provides further optimization options, such as DeepNorm. Whether the difference in model behavior is due to the difference in training framework is still not clear and could be explored in future work.

3.3.2 Multilingual Training

We trained parent systems on two different multilingual configurations: using all languages in the task, and using only the ones which shared the script. We called these collated dataset *eng-all*, *eng-Beng*, and *eng-Latn* respectively. The intuition here is

	BLEU	ChrF	RIBES	TER	COMET	Place
eng-asm	7.96	27.31	0.31	91.38	0.59	**10/13**
eng-kha	13.90	37.31	0.61	73.99	0.65	**7/11***
eng-lus	20.48	45.60	0.73	61.22	0.68	**9/10**
eng-mni	19.65	53.26	0.66	69.70	0.72	**12/14**
asm-eng	11.29	30.13	0.64	73.39	0.64	**9/13***
kha-eng	12.71	34.55	0.65	78.15	0.56	**6/11***
lus-eng	23.16	43.02	0.72	62.31	0.63	**6/10***
mni-eng	32.18	58.71	0.76	56.35	0.74	**8/14***

Table 5: Summary of the scores of our best submissions reported in the final evaluation. A star (*) denotes the subtasks in which we scored above the organizers' baseline.

enc/dec	BLEU	Increment
4/4	25.89	**+15.41**
6/6	10.48	baseline
8/4	9.52	*-0.96*
12/4	2.95	*-7.53*
16/4	3.08	*-7.4*

Table 6: An example of the effect of changing the depth of the Transformer on the quality of *mni-eng* translation. 4/4 and 6/6 share the same parameters as the final and baseline systems respectively, while other models have an embedding dimension of 384 and a feedforward dimension of 1536.

to leverage script and language relatedness, which we assumed to be present if not for typology, than for script or geographical closeness, in order to obtain better representations of shared subwords and tokens.

We then fine-tuned child systems for each direction, using *eng-Beng* for Assamese and Manipuri, and *eng-Latn* for Khasi and Mizo. *eng-all* was a parent for systems in all directions. We did not specify any language tag or direction for the parent training, since we did not intend to use them for multilingual translation directly. And since the child systems operate only in one direction, we did not need to specify any language tag for fine-tuning either.

Pretraining on all languages proved to be better than standard supervised training for translating into English from Khasi and Mizo, while translation from Manipuri had better performance with the same script parent.

3.3.3 Backtranslation

We experimented with backtranslation in the *eng-mni* direction, by normalizing and deduplicating the provided monolingual data down to around 300k sentence pairs. We then backtranslated the other side with our best available system for the *mni-eng* direction, which had a BLEU score of 32.18. Despite this decent performance, the systems we trained on the backtranslated data, both transformers with 4/4 encoder/decoder layers, embedding dimension of 256 and 384, and feedforward dimension of 1024 and 1536, did not outperform the previous best system. The bigger of the two models had a roughly 2.5 BLEU points on the smaller one, indicating that bigger architectures could have had even better performance. However, we did not test this at this point.

We also tried other back translation approaches, such as Data Diversification (Nguyen et al., 2020), which proved to be effective in the WMT22 Low-resource shared task for Lower/Upper Sorbian and German (Signoroni and Rychlý, 2022b). However, our results using the baseline systems were inconclusive and we decided to explore other approaches.

3.3.4 Word Embeddings Initialization

Previous work (Qi et al., 2018; Edman et al., 2021) showed that using word embeddings to initialize the model's weights improves, sometimes greatly, the performance for low-resource machine translation systems. We tested this in the *eng-mni* direction, training source side word embeddings on the train split with FastText (Bojanowski et al., 2017) in the skipgram setting. While training new baseline systems with the word embedding initialization we observed tiny gains of <0.5 BLEU, however the models converged faster, with 15 to 35 fewer epochs elapsed.

3.3.5 Tokenization Settings

We wanted to explore different settings for the vocabulary size and frequency threshold of the tok-

enizer, as well as for the segmentation algorithm itself, with the objective to find the best settings for each language pair and direction.

Jointly training the vocabulary never resulted in the best system when translating from English, however it gave the best performance for bilingual training of *lus-eng* and *kha-eng*. Nevertheless, these were not the best models overall. With respect to vocabulary size and frequency threshold, in all cases apart from *eng-mni* where we found size 500 and threshold of 200 as best settings, the baselines of 2000 and 100 for these parameters resulted in the best systems. Overall, the picture regarding tokenization and preprocessing settings is not clear and warrants for more investigation.

4 Final Systems

After the experimental phase, we submitted our best performing systems. Table 7 gives their settings and parameters, while Table 5 summarizes the final scores and our placements. Firstly, it should be highlighted that the systems were ranked according to BLEU (Papineni et al., 2002) score. Other metrics, such as ChrF (Popović, 2015), RIBES (Isozaki et al., 2010), TER (Snover et al., 2006), and COMET (Rei et al., 2020), were computed. Looking at the final scores, one can spot several instances in which the metrics do not agree with each other. As a matter of example, the best system for English-Manipuri has 51.96 BLEU, against our twelfth place with 19.65; however our "low-tier" system beats the first one in ChrF (53.26 > 52.61), RIBES (0.66 > 0.51), and COMET (0.72 > 0.57). Recent work has argued for the abandonment of BLEU as a metric of machine translation performance (Kocmi et al., 2021; Mathur et al., 2020; Tan et al., 2015; Sai et al., 2023) in favor of neural metrics which correlate better with human judgements, however this is not always possible when under-resourced languages are involved. While we did not conduct a full and systematic analysis and comparison of the final scores, cases such as the one cited above call for a deeper investigation on automatic evaluation in machine translation.

As our final systems, we obtained roughly two kinds of models: the ones trained on bilingual parallel data, and the ones fine-tuned from a multilingual pair. The former were our best for translating English to the all the Indic languages, and also to translate from Assamese into English. Multilingual pretraining and fine-tuning performed better for the remaining directions, Khasi, Mizo, and Manipuri into English. *kha-eng* and *lus-eng* were fine-tuned from a parent trained on all the parallel dataset, while *mni-eng* was fine-tuned from an Assamese and Manipuri parent. Parent models were trained according to the settings in Table 7, with a patience of 20. fine-tuning was done on only the data for the final translation direction, again with a patience of 20.

Regarding the preprocessing configuration, the settings varied across all the directions. In some cases, such as *eng-kha* and *eng-lus*, sticking to separate source and target vocabulary of size 2000 with a frequency filter of 100 resulted still in the best system. However, for *eng-mni* we found our best system with separate vocabularies of size 500 and a threshold of 200. For multilingual systems, we set the vocabulary size for the Indic side to 750 to try and force the learning of more shared subwords. For the English side, we left the value at 2000. There is no clear winner with respect to segmentation algorithm.

System architecture is the same for all systems, apart from English to and from Assamese. The best architecture was almost always a Transformer with 4 encoder/decoder layers, embedding dimension of 256, feedforward dimension of 1024, and 4 attention heads. For the models involving Assamese, we found that a deeper model of 18 encoder and 6 decoder layers, embedding dimension of 384, feedforward dimension of 1536, and 4 attention heads performed the best.

Other hyperparameters were not investigated extensively, so all of our models were trained with the *adam* optimizer, a learning rate of 1e-3, 4000 warmup updates, a dropout of 0.3, a label smoothing of 0.1, and max tokens for each batch at 16384.

5 Conclusions

This paper describes our experiments and the resulting supervised neural machine translation systems we submitted to WMT23 Low-resource Indic Machine Translation shared task. We trained systems for all directions in the task and experimented with hyperparameter tuning and multilingual training. We did not use transfer learning from pretrained systems, and thus our models were not competitive for some directions. Nonetheless, we argue that our investigation and preliminary analysis on the behavior of different architecture and preprocessing configuration can be useful to other researchers

	eng-asm	eng-kha	eng-lus	eng-mni	asm-eng	kha-eng	lus-eng	mni-eng
training data	bilingual				fine-tuned multilingual			
tokenization	hft			unigram	hft			bpe
src/tgt vocab. size	2000			500	2000	750/2000		
freq. threshold	100			200	100			
enc/dec layers	18/6	4/4			18/6	4/4

label smoothing	0.1							
max tokens	16384							

Table 7: Summary of the systems for our final submission. The columns give the values for various settings and parameters for preprocessing and training. *bilingual* training denotes a standard supervised training on parallel data, *fine-tuned multilingual* stand for a system fine-tuned on bilingual parallel data, from a parent system trained on more parallel corpora combined. *kha-eng* and *lus-eng* were fine-tuned from a parent trained on all languages, while *mni-eng* parent was trained only on *asm* and *mni* data, which shared the same writing system.

in the field and exposed some interesting points to be explored in future work. Some of our preliminary experiments, such as the use of word embeddings for initialization and backtranslation, did not give the expected results, thus prompting further inquiry.

Limitations and Future Work

As already mentioned above, some instances of disagreement between metrics in the final ranking signal the need for a deeper analysis of the automated evaluation of machine translation. Here, we did not conduct a methodical study on the matter in this instance, this should be the subject for future studies.

The disagreement between metrics notwithstanding, it could be said that overall the performance of our systems was limited. Supervised training showed all its limitations with the small amount of parallel data made available for training. A careful choice of hyperparameters and techniques may ameliorate the situation, but these factors are dependent on the specific dataset involved. Further research must be carried out to uncover clearer connections between the features of the dataset and the choice of parameters and methods to be used. This would cut experimental costs in terms of resources and time, and could lead to better and more efficient models.

However, even if the final systems did not reach competitive levels of performance in some of the cases, our experiments brought up some points that warrant for a deeper investigation. First, the performance of a certain configuration of settings may depend on the framework used for training. The experiments with transformer depth for *mni-eng* contradicts our best systems for Assamese. Whether this discrepancy depends on the languages or on the fact that we used different framework for different translation directions has to be clarified.

Moreover, the connection between dataset and model size has to be investigated further. Assamese worked better with bigger models, even if its dataset was smaller than the multilingual datasets. This goes against the common understanding that a model with fewer parameters is best to deal with fewer data, which will not be enough to train a bigger model. Why this happens only for the Assamese dataset, and not for others, should be better understood.

Ethics Statement

As with any other system trained on real-world data, our models may be biased. These must be taken into account, especially in light of the complex ethnic and religious situation of the region. [2]

Following Lacoste et al. (2019), we report that the experiments and the research that led to the results presented in this paper were conducted

Abstract

This paper describes the transformer-based Neural Machine translation (NMT) system for the Low-Resource Indic Language Translation task for the English-Manipuri language pair submitted by the Centre for Natural Language Processing in National Institute of Technology Silchar, India (NITS-CNLP) in the WMT 2023 shared task. The model attained an overall BLEU score of 22.75 and 26.92 for the English to Manipuri and Manipuri to English translations respectively. Experimental results for English to Manipuri and Manipuri to English models for character level n-gram F-score (chrF) of 48.35 and 48.64, RIBES of 0.61 and 0.65, TER of 70.02 and 67.62, as well as COMET of 0.70 and 0.66 respectively are reported.

1 Introduction

Our team from Centre for Natural Language Processing at National Institute of Technology Silchar, India (NITS-CNLP) participated in Low-Resource Indic Language Translation task for English-Manipuri language pair in the WMT 2023 shared task (Pal et al., 2023). The shared task involves developing Machine Translation (MT) systems with relatively small parallel datasets. Neural Machine translation (NMT) has been a trending topic for the last few years for translating human languages. Manipuri's MT task is still in its infancy because of the limited resources. Singh and Bandyopadhyay (2011a) conducted a study on supervised statistical methods in which the authors present a convincing study of the impact of morphosyntactic information and dependencies in the context of statistical machine translation. In another work, Singh and Bandyopadhyay (2011b) showed that the expression grounded Statistical Machine translation (SMT) system improves by incorporating verbal features including named entities and reduplicated multiword expressions. Despite the advancement in MT tasks, its investigation in low-resource languages is limited. MT researchers have introduced several approaches to overcome this bottleneck such as data augmentation using back-translation (Sennrich et al., 2016a), multilingual approach (Singh and Singh, 2022a), semi-supervised approach (Cheng et al., 2016; Singh and Singh, 2022b) and exploiting cues from multiple modalities (Gain et al., 2021; Meetei et al., 2023). There are also reports of a comparative study of MT systems on the low resource machine translation focusing on Indian languages such as Assamese (Baruah et al., 2021) and Mizo (Devi et al., 2022; Thangkhanhau and Hussain, 2023).

Driven by the benefits of NMT over traditional MT systems and the encouraging outcomes achieved by NMT in recent times, a study to assess its efficacy in the domain of Indian languages is conducted. Specifically, we have developed and assessed NMT models for translating English to Manipuri and Manipuri to English. The predicted translations are evaluated using automatic evaluation metric and qualitative analysis.

1.1 About the language

Manipuri is the lingua franca of Manipur and has been in existence since 2000 years back till present times with records preserved in the classical cultural heritage of literature. Manipuri is a language of Tibeto-Burman sub-family of the Sino-Tobentan languages family which is locally called as Meeiteilon/Meiteilon (hereon Meiteilon). It is one of the 22 official languages of the India included in the 8th schedule of the Indian constitution[1]. Meiteilon had its original script named Meitei/Meetei Mayek (hereon Meitei Mayek) which was in use up to the 18th century and was replaced later with the Bengali script. However, the wave of revivalist movement

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 967–971
December 6–7, 2023.

emerged later leading to the formation of Meitei Mayek Advisory committee in the year 1973. In 1982, the Government of Manipur announced its decision to include Manipuri in the school education and efforts to revive the Meitei Mayek are still on.

2 System Overview

2.1 Dataset

Language	Sentence	Word	Avg
Eng-Training	21687	390730	18
Man-Training	21687	330319	15
Eng-Validation	1000	16905	16
Man-Validation	1000	14469	14
Eng-Testing	1000	14886	14
Man-Testing	1000	12775	12

Table 1: Statistics of the experimental dataset. (Avg = Average Sentence length

The Manipuri text is written in Bengali script. Statistics of the training dataset are shown in Table 1.

2.2 Data preparation

Training the dataset is pre-processing with subword tokenization. For subword based tokenization we use a source and target BPE of 10000 subword tokens or vocabularies using sentences pieces over the parallel training dataset and applied to the remaining testing and validation dataset. The subword tokenization (Sennrich et al., 2016b) is carried out using the subword-nmt tool [2].

2.3 MT model

Our MT models are trained using OpenNMT toolkit (Klein et al., 2017) and is based on the transformer model (Vaswani et al., 2017).

2.4 Model parameter

Our models are trained for 300000 steps and validated after every 5000 steps. We set the parameter of batch type to tokens and batch size to 2048. The models are trained using Adam optimizer (Kingma and Ba, 2014) with a learning rate of 2 and the dropout set to 0.1. Early stopping mechanism is employed where the training is stopped when the accuracy does not improve for 30 consecutive validations.

In our transformer-based model, each source encoder has 4 layers and decoder also has 4 layers, with a word vector size of 512 and a shared encoder and decoder embedding. We measure the performance of our models by using BLUE (Papineni et al., 2002) and chrF (Popović, 2015).

3 Results and Discussion

In this section, we discuss the experimental results and the performance of models. The reported BLEU score is calculated upon the de-tokenized text using sacrebleu (Post, 2018) while remaining score such as chrF, RIBES, TER and COMET are calculated using tool provided by the organizer[3]. The scores of the system are given in Table 2. The Manipuri to English translation model obtained a BLUE score of 26.92 while English to Manipuri obtained 22.75.

3.1 Qualitative analysis

Automated evaluation metrics such as BLEU measures the precise lexical matches between the translated output and the reference sentences. However, it is inevitable for a natural language to exhibit linguistic variations in terms of synonyms and transformations between active and passive mode of communication. As a result, despite preserving the intended meaning of the source sentence in the translation output, the automated score based on the n-gram match suffers. Manipuri is a language of considerable linguistic diversity and the automated scores for English to Manipuri translations are typically lower than those for Manipuri to English despite the provision of a translation output of acceptable quality. Therefore, we enlist the services of a bilingual native speaker of Manipuri with fluency in English to evaluate the translation outputs for the English to Manipuri task. Table 3 and Table 4 present four randomly selected source sentences from the test set for each of the Manipuri to English and English to Manipuri translation models along with their corresponding output sentences with reference sentences to carry out subjective evaluation.

In Table 3, the difference between the reference and MT results are reported. For Source1, Source2 and Source4, the Manipuri to English MT system outputs (OutputE1, OutputE2 and OutputE4) are close to the reference sentence. In OutputE2, the sentence formation is incorrect where

Table 4: Sample input and output of the English to Manipuri MT system.

the words such as “maintain” and “operate” are incorrectly translated. In OutputE1, we observe a case where the word “call” is translated to its antonym “send” and “casualty” to “causality”. In OutputE4, “steady rise” is translated as “increasing” which could be considered as a synonym of the phase. Apart from the missing words “in india”, the output sentence preserve the meaning of the source sentence. In OutputE3, the MT output is not able to retain the intended meaning of the source sentence.

The Table 4 shows the results of the MT system for translating English to Manipuri. The OutputM1, OutputM3 and OutputM4 give a close meaning to the reference sentence. In OutputM1, the word “শেমবা” (meaning “build”) is translated to its infinitive form of the verb “শেমগৎপা” (meaning “to build”). The word “causes” has multiple translations in Manipuri such as “ফাউহল্লি”, “থোকহল্লিবা”and “মরমশীং” which are used in different context. In OutputM3, we observe that the translations of the word “causes” is repeated showing the challenges of the MT model in translating such words. In OutputM4, we observe a case where a word as multiple translation in Manipur but can be used in the same context. The word “for” can be translated as “গী” or “গীদমক” in Manipuri. Apart from the extra verb “পীবা” (meaning “give”), OutputM4 is grammatically correct despite not having a perfect n-gram match. In the case of OutputM2, the sentence is observe to have a poor adequacy with the incorrect translation for the word “chairperson” but the structure of sentences is well formed and grammatically correct.

4 Conclusion

Enabling MT for low-resource languages poses several challenges due to the lack of parallel resources available for training. In this work, we report the performance of the MT systems trained on low resource setting for English to Manipuri and Manipuri to English using a transformer-based encoder and decoder architecture. The automatic evaluation shows that English to Manipuri MT system achieved 22.75 BLEU and Manipuri to English MT system achieved 26.92 BLEU. The automated scoring mechanism is inadequate in capturing the linguistic nuances of the morphologically complex Manipuri language which requires the use of multiple references. Based on the subjective evaluation, we observed that the translation quality is deemed satisfactory and fluent in some cases, given the relatively small size of the dataset and the utilization of a single test reference.

Limitations

Translation model performs better for short sentences as compared to the longer sentences. There are several out of vocabulary words due to the fact that the model is built on a constraint environment.

Abstract

Even though, machine translation has seen huge improvements in the the last decade, translation quality for Indic languages is still underwhelming, which is attributed to the small amount of parallel data available. In this paper, we present our approach to mitigate the issue of the low amount of parallel training data availability for Indic languages, especially for the language pair English-Manipuri and Assamese-English. Our primary submission for the Manipuri-to-English translation task provided the best scoring system for this language direction. We describe about the systems we built in detail and our findings in the process.

1 Introduction

The ability to overcome linguistic barriers has emerged as the most critical issue in a society that is becoming increasingly interconnected. These linguistic barriers can be eliminated enabling effective communication among various linguistic communities, machine translation (MT) systems are not only capable of translating common languages but also less widely spoken or even endangered languages, ensuring that even marginalized communities can participate in the global conversation. The use of machine translation for regional Indian languages is both an intriguing and challenging application. India has an intricate mix of languages and dialects spoken all over its broad territory, making it a linguistically diverse nation (Mandal et al., 2021). Despite being culturally stimulating, this diversity poses substantial obstacles to effective communication. By automating the translation process and opening up content to speakers of different regional Indian languages, machine translation presents a viable remedy.

Due to deep learning, neural networks, and natural language processing developments, machine translation technology has made significant strides in recent years (Slocum, 1985). However, there are particular difficulties that must be overcome in order to adapt these technologies to the intricate linguistic features of Indian languages (Pal et al., 2013a). These difficulties include, among other things e.g., multi-word expressions (Pal et al., 2013b), the complexity of morphology, syntactic changes, and the scarcity of parallel training data (Pal, 2018). The challenge of producing accurate and relevant translations is further complicated by the requirement to preserve cultural nuances and context-specific meanings (Appicharla et al., 2023).

However, the translation problem for Indian regional languages is compounded by:

- **Morphological complexity:** Indian languages often exhibit rich morphology, leading to variations in word forms and sentence structures.
- **Low-resource languages:** Limited parallel training data is available for many Indian language pairs, leading to challenges in training accurate translation models.
- **Cultural and context preservation:** Accurate translation must account for context-specific meanings, idiomatic expressions, and cultural nuances.

So working on Indic languages has the challenge of designing translation models and techniques that address these complexities and constraints while achieving high-quality translations between Indian regional languages, contributing to effective cross-lingual communication and content accessibility in India's diverse linguistic landscape.

2 Related Work

Parul and Garg (2022) provides a survey of different approaches to Machine Translation (MT) for Indian languages, including Rule-based Machine Translation (RBMT), Corpus-based Machine

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 972–977

Translation (CBMT), and Neural Machine Translation (NMT). Researcher (Parul and Garg, 2022) highlights the initial slow progress in MT research and the subsequent popularity of NMT. The paper emphasizes that while there has been significant research on MT for top-level languages, there is a scarcity of research for low-level languages spoken by fewer people. It discusses the use of different MT models, such as Anusaarka for direct MT, AnglaHindi for Interlingual translation, and CBMT for translation using stored data corpus.

Jha et al. (2023) presents the development and evaluation of a multilingual neural machine translation system for Indian languages using the mT5 transformer. The system was trained on the modified Asian Language Treebank multilingual dataset to translate text between English, Hindi, and Bengali. The system achieved acceptable Bilingual Evaluation Understudy (BLEU) scores, with the English-to-Bengali system achieving a maximum BLEU score of 49.87 and the Bengali-to-English system achieving an average BLEU score of 42.43. Jha et al. (2023) claims that the field of Natural Language Processing (NLP) research in low-resource languages has been expanding rapidly, with transformers being the latest state-of-the-art systems.

Jayanthi et al. (2020) states that India is a multicultural and multilingual country, with a large number of regional languages. English is provided as the second extra official language in India, but its usage is limited, leading to a communication gap. Machine translation can help minimize this gap by translating languages. Jayanthi et al. (2020) focuses on translating Indic languages, specifically Telugu, using a sequence-to-sequence framework with an encoder-decoder attention mechanism of neural machine translation. The proposed framework aims to convert the Telugu language into English and vice versa. Their approach framework was trained using a Telugu parallel corpus and achieved good accuracy. It overcomes the limitation of reduced accuracy when faced with unknown words by using an attention mechanism. As per the author, the sequence-to-sequence model used in this paper allows for the conversion of the native language into the desired language, and the attention mechanism helps handle rare words.

S. and Bhattacharyya (2020) claims the use of Indowordnet helped handle ambiguity during translation and improved the performance of the machine translation systems. The author presents a comparative study of 440 phrase-based statistically trained models for 110 language pairs across 11 Indian languages and also discusses the principles followed in constructing the synsets, such as the minimality principle, coverage principle, and replaceability principle.

Research involving Indian languages is not very common due to the scarcity of parallel corpora. Baruah et al. (2014) using Statistical Machine Translation (SMT) with a small corpus (2,500 sentences), the Assamese-English bidirectional MT system for Assamese to English and English to Assamese obtained BLEU scores of 9.72 and 5.02, respectively. Das and Baruah (2014) investigated and reported a BLEU score of 11.32 for Assamese to English using SMT using 8,000 Tourism domain parallel sentences.

3 Method

3.1 Problem Definition

Given a source sentence in an Indian regional language, represented as $S = \{s_1, s_2, \ldots, s_n\}$, and a target sentence in a different Indian regional language or English, represented as $T = \{t_1, t_2, \ldots, t_m\}$, the objective of machine translation for Indian regional languages is to find the optimal translation function f that maximizes the translation quality while considering linguistic nuances, morphological complexities, and contextual information:

$$f^\star = \text{argmax}\, f(P(T \mid S)) \tag{1}$$

In equation 1, $f^\star$ represents the optimal translation function that produces the highest probability of the target sentence given the source sentence. $P(T \mid S)$ is the conditional probability of the target sentence T given the source sentence S, which is modelled using statistical or neural machine translation approaches. $S = \{s_1, s_2, \ldots, s_n\}$ denotes the sequence of words in the source sentence. $T = \{t_1, t_2, \ldots, t_m\}$ denotes the sequence of words in the target sentence. n is the length of the source sentence, and m is the length of the target sentence.

English-Manipuri	21,686	1,000	1,000

Table 1: Dataset statistics for Workshop on Machine Translation (WMT) 23

task. As per the organizers' guidelines, no additional parallel data was allowed for training with only constrained submissions.

3.3 Experimental Setup

IndicBART (Dabre et al., 2022) and mbart-large-50 (Tang et al., 2020) have been adjusted for the bidirectional Assamese-English and English-Manipuri language pairs in our suggested study. We fixed the source and target lengths in both scenarios to "128". With batch sizes of "16" and "8", respectively, and learning rates of "2×10^{-5}" for both scenarios, we improved our suggested IndicBART and mbart-large-50 models, We applied weight decay of "0.01" for both scenarios.

3.4 Corpus Pre-processing

We used IndicBART (Dabre et al., 2022) developed by AI4Bharat[2] for some of the models. Using IndicBART for Indic languages other than Hindi or Marathi requires the language to be transliterated into the Devanagari script. Hence, we had to transliterate the data given into the Devanagari script to use those models.

3.5 Experiments

3.5.1 Bidirectional Assamese-English Language Pair

We first experimented by using IndicTrans (Ramesh et al., 2022) from AI4Bharat to get the responses on the Validation Set provided, but the BLEU scores on the same were unsatisfactory. We experimented by finetuning IndicBART from AI4Bharat on the Training Set and evaluating the responses on the given Validation Set. This gave us better results so we decided that these responses would be our Primary Submissions. IndicBART is a multilingual, sequence-to-sequence pre-trained model focusing on Indic Languages and English. Currently, it supports 11 Indian languages, Assamese, Bengali, Gujarati, Hindi, Marathi, Odia, Punjabi, Kannada, Malayalam, Tamil, and Telugu based on mBART (Liu et al., 2020) architecture.

[2] https://ai4bharat.iitm.ac.in/

We used the transliteration module from the IndicNLP library (Kunchukuttan, 2020) for transliterations from Assamese to Devanagari, an example is shown in Figure 1.

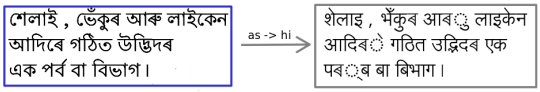

Figure 1: Transliteration from Assamese to Hindi

These experiments are discussed below:

- **Primary Submission**
  We took the training data and fine-tuned it on IndicBART for the translation settings from Assamese to English. This model gave good BLEU scores on the Validation set hence, this model was selected as the Primary System.

- **Contrastive - 1**
  Here, it was considered that since Assamese and Bengali share linguistic similarities, it may be that IndicBART fine-tuned on the training dats but this time for translations from English-Bengali, did give results, surprisingly similar to the Primary System

- **Contrastive - 2**
  Here we used IndicTrans from AI4Bharat, the translator was built and the responses on the Test Set were calculated. Note, that for this system no Transliteration was required.

For the models that used IndicBART, we had to transliterate the data from Assamese to Hindi using the IndicNLP transliterator. Moreover, the responses generated by these models, when the target language was Assamese also had to be back-transliterated from Hindi to Assamese for the evaluation of the Validation Set.

3.5.2 Bidirectional English-Manipuri Language Pair

Since resources available for the Manipuri language are very scarce, we decided to use existing models available for Bengali and Assamese. This was because Manipuri shares its script with Assamese and Bengali, so even with morphological differences the models gave good scores for Manipuri. We used mbart-large-50 (Tang et al., 2020) from Facebook and IndicBART by AI4Bharat.

For the language pair English-Manipuri there were no existing transliteration tools that we found,

Framework	BLEU	ChrF	RIBES	TER	COMET
English-to-Assamese					
Primary	34.82	56.58	0.87	55.10	0.77
Contrastive-1	34.71	56.59	0.87	54.75	0.78
Benchmark	8.57	25.24	0.44	86.14	0.59
Contrastive-2	6.57	39.71	0.45	86.26	0.79
Assamese-to-English					
Primary	66.36	75.88	0.93	37.44	0.84
Contrastive-1	66.33	75.88	0.93	37.38	0.84
Contrastive-2	23.19	48.42	0.61	71.79	0.75
Benchmark	11.28	28.70	0.53	83.10	0.56
English-to-Manipuri					
Primary	25.78	49.94	0.84	60.43	0.71
Contrastive-1	25.82	49.93	0.84	60.57	0.71
Benchmark	21.58	45.97	0.61	69.76	0.69
Contrastive-2	9.69	40.45	0.54	81.18	0.67
Manipuri-to-English					
Primary	69.75	78.16	0.94	32.08	0.84
Contrastive-1	69.75	78.16	0.94	32.10	0.84
Benchmark	24.86	46.37	0.64	70.26	0.63
Contrastive-2	22.10	48.03	0.63	72.19	0.70

Table 2: Results of Primary, Contrastive-1, and Contrastive-2 submissions evaluated on Benchmark results for the language pair Assamese-English and English-Manipuri.

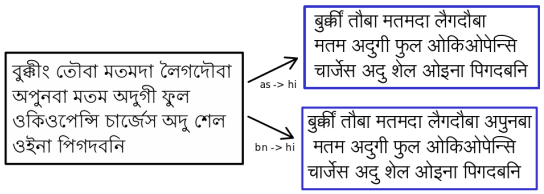

Figure 2: Transliteration from Manipuri to Hindi

but it was thought that, since Manipuri has script similarities with Bengali and Assamese we can experiment with transliteration tools from Bengali and Assamese to Hindi with the expectation for good results and it turns out it does give good results. For this task too we used the transliteration tools from the IndicNLP library, an example is shown in Figure 2.

We discussed in detail about these experiments as follows:

- **Primary Submission**
  The data was first transliterated into Hindi using the transliteration from Bengali to Hindi, then we finetuned IndicBART on the Training Data and evaluated the responses given for the Validation Set. This model gave the highest score on the Validation Set and hence, was picked as the Primary model.

- **Contrastive - 1 Submission**
  This model was similar to the Primary model, but instead of the transliteration and Translation settings, Bengali was the Indic language instead of Assamese.

- **Contrastive - 2 Submission**
  For this model, we fine-tuned mbart-large-50 with the Bengali-English configuration. This model gave a lesser score on the validation set than the models discussed before, even though this was a larger model.

Similar, to the Primary and Contrastive - 1 system for Task 1, responses from the models that used IndicBART had to be back-transliterated from Hindi to the Indic language, when the Indic language was the target language.

3.6 Post-processing

Along with the back-transliteration that was required for the models using IndicBART when the target language was the Indic language. We also

had to do some post-processing of the responses received, we saw that often the responses had random Chinese characters and emoticons in the responses. The emoticons were chalked up to encoding errors while saving the responses to a text file, on the other hand, the Chinese characters were something that we think were errors because of the model itself. These noisy characters were manually removed to ensure that they don't affect the accuracy.

4 Results and Analysis

Table 2 lists the findings of our experiments. We list our observations here:

- As we discussed in section 3.6 we believe that there might be noise in the responses saved that we missed or couldn't manually find, which can contribute to a lesser score even though the translations are accurate.
- We also believe that there might be some issues in translation because of transliteration problems while back-transliterating we often came across responses that still had some words in Hindi. Due to this we also believe that there might have been errors in transliteration from the Assamese/Manipuri to Hindi.
- For task 4, we also consider that the transliteration and translation models used were configured to Assamese and Bengali, so even though the models were fine-tuned on the data but still we assume that because of the morphological differences, there might be gaps in the understanding and generating of language by the model.
- An interesting observation that can be made is that there exists a large gap in the scores for when English is the target language and when the target language is the Indic language. This error can be attributed to the model understanding the target languages morphologically well, but not being able to generate the language that well.

5 Conclusion and Future Work

In this paper, We discussed the models and procedures our team used for the language pairs Assamese-English and English-Manipuri. According to our experiments, we claimed that Using language models like IndicBART and mbart-large-50 results in improvement for the low-resourced individual languages results. We hope that this will enable us to develop more precise and superior translation models for languages and domains with limited resources specially for Indian Languages where there is a presence of large language diversity. We also believe that, as seen with Manipuri, a language with very few resources for processing we can use languages close and similar to it to aid in its processing and create a better way of processing those low-resource languages. In future, we will include our models in online post-editing platforms (Pal et al., 2016; Nayak et al., 2015; Vela et al., 2019).

IOL Research Machine Translation Systems for WMT23 Low-Resource Indic Language Translation Shared Task

Wenbo Zhang, Zeyu Yan, Qiaobo Deng, Jie Cai, and **Hongbao Mao**
Transn IOL Research, Wuhan, China

Abstract

This paper describes the IOL Research team's submission systems for the WMT23 low-resource Indic language translation shared task. We participated in 4 language pairs, including en↔as, en↔mz, en↔kha, en↔mn. We use transformer based neural network architecture to train our machine translation models. Overall, the core of our system is to improve the quality of low resource translation by utilizing monolingual data through pre-training and data augmentation. We first trained two denoising language models similar to T5 and BART using monolingual data, and then used parallel data to fine-tune the pretrained language models to obtain two multilingual machine translation models. The multilingual machine translation models can be used to translate English monolingual data into other multilingual data, forming multilingual parallel data as augmented data. We trained multiple translation models from scratch using augmented data and real parallel data to build the final submission systems by model ensemble. Experimental results show that our method greatly improves the BLEU scores for translation of these four language pairs.

1 Introduction

This paper describes our submissions for the WMT23 low-resource Indic language translation shared task. We participated in 4 language pairs, including English↔Assamese (en↔as), English↔Mizo (en↔mz), English↔Khasi (en↔kha), and English↔Manipuri (en↔mn).

Our core approach is based on denoising language model pre-training(Devlin et al., 2019; Lample and Conneau, 2019; Song et al., 2019; Raffel et al., 2019; Lewis et al., 2020) and back-translation(Sennrich et al., 2016a) based data augmentation. Neural machine translation methods are almost the first choice for implementing translation systems at present, but they have certain requirements on the amount of parallel corpora. Low-resource or even zero-resource neural machine translation has been a daunting challenge due to the lack of adequate parallel corpora. Pre-training methods are popular solutions for low-resource cases. When the model parameter scale is large enough and there is enough training data, this method can even perform well in zero resource situations. For the machine translation task, as early as around 2019, XLM(Lample and Conneau, 2019) and MASS(Song et al., 2019) were able to build unsupervised machine translation systems with near-supervised effects using only monolingual data. Now, more advanced pre-training methods like BART(Lewis et al., 2020) and T5(Raffel et al., 2019) are popular choices for training machine translation models in low-resource situations. Therefore, in this paper, referring to the training methods of BART and T5, we trained a T5-style pre-training model and a BART-style pre-training model from scratch using monolingual data. Back-translation is a commonly used method in the field of machine translation. Whether it is low-resource, medium-resource or high-resource, this approach can almost help the model to obtain further improvements on the original basis. Therefore, we also use back-translation to help us further improve the translation quality.

The layout of the subsequent paper is as follows: In Section 2 We introduce the data source and processing strategy; In Section 3 we describes the implementation process of our translation systems; In Section 4 we describe the experimental settings and results; Finally, the conclusion is drawn in Section 5.

2 Data

2.1 Data Source

Bilingual corpus We just used the official en↔as, en↔mz, en↔kha, and en↔mn parallel data(Pal

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 978–982
December 6–7, 2023.

Data	en↔as	en↔mz	en↔kha	en↔mn
Bilingual Data	49808	49575	23996	20990

Table 1: Statistics of bilingual data

Data	en	as	mz	kha	mn
Monolingual Data	60598321	2206328	1864322	178036	298072

Table 2: Statistics of monolingual data

et al., 2023).

Monolingual corpus of Indic languages We also used only official monolingual data for Assamese, Mizo, Khasi and Manipuri.

English monolingual corpus Since the official did not provide English monolingual data, we obtained English monolingual data from the WMT23 general task. Specifically, we used the English side of bilingual data (English↔German and English↔Japanese) in the WMT23 general task as English monolingual data.

2.2 Data Preprocessing

For English monolingual data, we first filter out noisy sentences according to following rules:

- Remove invisible characters.
- Remove sentences containing too more than 300 words or more than 1000 characters or less than 3 characters.
- Remove English sentences containing words exceeding than 40 characters.
- Remove sentences that contain too many punctuation marks.
- Remove sentences that contain repeated substrings, which refers to a string composed of a single character that repeats more than 10 times, or two or more character that repeat more than 5 times.
- Remove sentences that contain HTML tags.
- Convert full-width characters to half-width characters.
- Remove duplicated sentence pairs.

Since all the officially provided data have been tokenized, we used the Moses scripts[1] to do tokenization for English monolingual data. Then we use an n-gram language model trained with KenLM(Heafield, 2011)[2] to calculate the perplexity of English monolingual data and remove sentences with high perplexity(more than 10 000). We just did deduplication for the official data, because the size of the official data is relatively small and the quality is high enough. The amount of data after processing is shown in Table 1 and 2.

We used the Sentencepiece(Kudo and Richardson, 2018) tool to train a multilingual BPE(Sennrich et al., 2016b) model for subword segmentation. Its training data includes all official training data and 2.5 million random samples from English monolingual data. The vocabulary size is set to 48 000.

3 System Overview

We chose Transformer(Vaswani et al., 2017) with pre-norm as our base translation model. In general, our procedure for improving the quality of low-resource translations is divided into two phases, an improvement phase based on pre-training methods and an improvement phase based on data augmentation. Instead of using the pre-trained model to initialize the parameters of the translation model, the pre-training phase merely provides synthetic data for the data augmentation phase, which means that the translation model in the data augmentation phase is trained from scratch. In addition to this, we also used model ensemble in the final submissions.

3.1 Pre-training

The pre-training phase is divided into two steps. In the first step, pre-training for the denoising autoencoder tasks are performed using monolingual data. In the second step, the pre-trained models are fine-tuned using bilingual data. We trained two denoising pre-training models, namely the T5-style(Raffel et al., 2019) model and the BART-style(Lewis et al., 2020) model. The training details

[1]https://github.com/moses-smt/mosesdecoder/

[2]https://github.com/kpu/kenlm

Original sentence	Since their articles appeared , the price of gold has moved up still further .
T5-style input sentence	Since their articles appeared , gold has moved up still further
T5-style target sentence	the price of .
BART-style input sentence	Since their of gold has up still **moved** further .
BART-style target sentence	Since their articles appeared , the price of gold has **moved** up still further .

Table 3: Examples of T5-style and BART-style training data

of the two models are as follows.

As shown in Table 3, Both T5-style and BART-style models are trained by recovering original sentences from corrupted sentences, which are produced by randomly replacing some fragments in the sentences with the mark. The most important difference is that the T5-style target sentence, that is, the label contains only the replaced part, while the BART-style label is the entire original sentence. Another difference is that in this paper we also randomly swap the two words that are not masked in BART-style input sentences. For both models, the proportion of replaced words is 0.15, and the length of replaced segments is 3. We randomly swap words in BART-style input sentences with a probability of 0.5.

We used monolingual data containing 5 languages to train the pre-training models, and then fine-tuned the pre-trained models using parallel corpora containing 4 language pairs in 8 translation directions. In order to keep the number of all languages balanced, we only used 3 million additional English monolingual data at this phase.

3.2 Data Augmentation

The pre-training phase is also divided into two steps, pre-training on synthetic data and fine-tuning on the real bilingual data. We employed the approach inspired by the back-translation(Sennrich et al., 2016a) and Zan et al. (2022) to generate synthetic data. Since we planed to train a multilingual translation model, in order to share knowledge across multiple languages, the synthetic data we generated contains 5 languages and 20 translation directions. In detail, by beam search, we translated an English monolingual sentence into 4 other languages, where any two sentences in different languages are also aligned as they are both translated from the same English sentence. To ensure the quality of the synthesized data, we also calculated the translation perplexity score from Indic languages to English direction via a multilingual translation model from pre-training phase and removed sentence pairs with high perplexity scores. For data diversity, we used both T5-style and BART-style pre-trained models to generate synthetic data, and leveraged the other model to compute the perplexity score, for example, the data generated by the T5-style pre-trained model is scored using the BART-style pre-trained model.

3.3 Model Ensemble

A well-known model ensemble trick is to increase the diversity between different models. However, we did not train multiple translation models from scratch due to time and computational resource constraints. Instead, we fine-tuned the three models, many-to-many, one-to-many, and many-to-one, based on model trained on synthetic data, and then selected the many-to-many and one-to-many or many-to-one models to complete the final submission by model ensemble.

4 Experiments

4.1 Experiment Settings

All of our translation models were implemented based on fairseq(Ott et al., 2019) and trained on 8 NVIDIA A100 GPUs. During training, we used the Adam(Kingma and Ba, 2014) optimizer with $\beta 1 = 0.9, \beta 2 = 0.98$, the learning rate scheduling strategy of inverse sqrt, the number of warmup step set to 4000, the maximum learning rate set to 0.0005 and FP16 to accelerate the training process.

We trained three models, Many2Many(M2M), One2Many(O2M), Many2One(M2O), with 12-encoder, 12-decoder transformer-big model as baselines. They were trained only on a real parallel corpus, with a batch size set at 13,000 tokens. For the models in the Pre-training phase, we used the same model structure as the baselines but with a batch size of 1 million. For the models in the data augmentation phase, we changed the number of layers of models to 10, and the embedding size to 1536.

System	en→as	en→kha	en→mni	en→mz	as→en	kha→en	mni→en	mz→en
O2M Baseline	5.1	11.8	9.1	15.0	-	-	-	-
M2O Baseline	-	-	-	-	14.3	10.6	19.8	18.8
M2M Baseline	7.0	14.8	13.4	19.2	15.9	11.7	23.3	20.6
BART-style Pre-training	11.4	19.3	20.1	25.2	22.4	15.1	35.4	26.5
T5-style Pre-training	12.0	19.6	21.5	26.3	23.6	16.4	35.6	26.9
O2M Data Augmentation	13.0	21.3	23.3	27.4	-	-	-	-
M2O Data Augmentation	-	-	-	-	28.2	20.1	42.1	31.8
M2M Data Augmentation	12.8	21.0	23.4	27.3	25.2	18.0	40.6	29.1
Model Ensemble	13.4	21.6	23.9	27.8	28.6	20.8	42.9	32.4

Table 4: BLEU scores of all translation direction on validation sets

4.2 Results

All experiments were evaluated using the sacrebleu(Post, 2018) tool to calculate BLEU(Papineni et al., 2002) scores on the official validation sets, and we did not detok before calculating the BLEU scores. We used beam search with beam size=5 to decode all models and the results are shown in Table 4.

According to Table 4, it can be seen that the many-to-many baseline preforms better than one-to-many and many-to-one. I believe this is because the parallel corpus size is too small where the many-to-many model can share knowledge across different languages. Both BART-style and T5-style pre-training significantly improved BLEU scores in all directions, with T5-style slightly better than BART-style. All translation directions are further improved after data augmentation. When English is the source language, the improvement is small, and when English is the target language, the improvement is larger. This is because this phase is mainly based on a large amount of real English monolingual data. The one-to-many and many-to-one models perform equally or better than the many-to-many model at this phrase, as there is no longer a severe lack of linguistic knowledge. Finally, the model ensemble helps the system to obtain further improvements.

5 Conclusion

In this paper, we describe IOL Research's submission to the WMT2023 low-resource Indic language translation shared task. We participated in four sub-tasks with a total of eight translation directions. Our system mainly improves the translation quality of these languages in the low-resource case through pre-training and data augmentation. Experimental results show that we achieved large improvements in all directions.

Abstract

Neural metrics trained on human evaluations of MT tend to correlate well with human judgments, but their behavior is not fully understood. In this paper, we perform a controlled experiment and compare a baseline metric that has not been trained on human evaluations (*Prism*) to a trained version of the same metric (*Prism+FT*). Surprisingly, we find that Prism+FT becomes more robust to machine-translated references, which are a notorious problem in MT evaluation. This suggests that the effects of metric training go beyond the intended effect of improving overall correlation with human judgments.

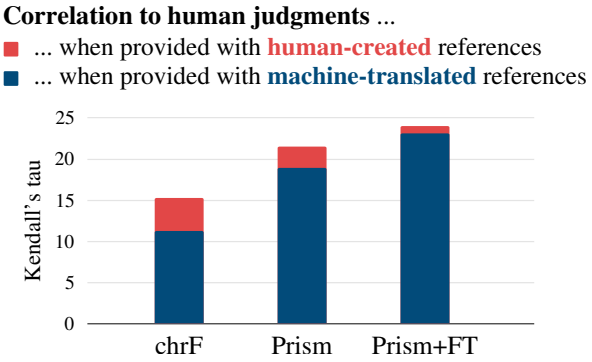

Figure 1: Metrics for MT quality have a lower segment-level correlation with human judgments when provided with machine-translated references. However, trained metrics, such as our Prism+FT, become more robust to the use of machine translations as references.

1 Introduction

While trained evaluation metrics for machine translation (MT) tend to have a high correlation with human judgments (Freitag et al., 2022b), they remain black boxes, sometimes behaving in unexpected ways (Amrhein and Sennrich, 2022; Rei et al., 2023). This calls into question whether a metric's utility can be measured solely by its correlation with human judgments.

In this paper, we intentionally provide MT metrics with *machine-translated reference translations*, as opposed to human-created references, and investigate how this factor influences the behavior of a metric. In MT evaluation research, the human translators who create reference translations are usually asked to produce them from scratch, in order to avoid references that are machine-translated or post-edited (Kocmi et al., 2022). Nevertheless, traces of MT have been detected in some reference sets (Kloudová et al., 2021; Akhbardeh et al., 2021; Kocmi et al., 2022). It is therefore important to understand how metrics behave under such references.

In our experiments, we use a surrogate for real post-edited references in the form of error-free output by various systems from the WMT 2021 news translation task (Akhbardeh et al., 2021). Our results show that there is a stark difference between trained and non-trained metrics: While trained metrics maintain most of their accuracy when provided with such MT-derived references, non-trained metrics exhibit a substantial drop in accuracy.

To corroborate this observation, we perform a controlled experiment involving Prism (Thompson and Post, 2020), a metric that is based on a multilingual MT system. The original version of Prism can be considered non-trained, since it learns from parallel sentences without human judgments. We then fine-tune Prism on a dataset of human judgments, using a bidirectional pairwise ranking approach.

As expected, the segment-level correlation of Prism increases during fine-tuning, indicating that the metric learns to better predict human judgments (Figure 1). Moreover, we find that fine-tuning narrows the gap in performance between human-created and machine-translated references. Our experiment thus indicates that training a metric on human evaluation data can influence its behavior in a way that is not captured by global correlation with human judgments. December 6–7, 2023.

findings will be made available.[1]

To summarize, the paper makes the following contributions:

- We propose a metric evaluation setup that intentionally uses machine-translated references, and demonstrate that non-trained metrics perform poorly in this setup.
- We present an approach for fine-tuning Prism on human judgments that significantly improves segment-level correlation on unseen test data.
- We show that fine-tuning Prism on human judgments makes it more robust to the use of machine-translated references.

2 Background

2.1 Reference-based Evaluation

Automatic evaluation of MT is often performed by comparing the system output with one or more reference translations, using an evaluation metric. Evaluation metrics can be roughly divided into *trained* and *non-trained* metrics. Trained metrics receive supervision from human judgments of past machine translations. For example, Sellam et al. (2020) and Rei et al. (2020; 'COMET') fine-tuned a pre-trained sentence encoder on such human judgments, using regression or ranking objectives.

Non-trained metrics, on the other hand, rely on a heuristic to make the comparison. Metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015) are based on the overlap of words or characters between the system output and the reference. Thompson and Post (2020) use the perplexity of a neural sequence-to-sequence model, called Prism, that has been trained on multilingual MT. Systematic comparisons of evaluation metrics (Freitag et al., 2022b) have shown that trained metrics tend to correlate better with human judgments than non-trained metrics do, especially if the latter are based on overlap heuristics.

2.2 Quality of Reference Translations

The reliability of reference-based evaluation metrics also depends on the quality of the references they are provided with (Freitag et al., 2021b). A notorious source of noise in references is *translationese*, which is characterized by monotonicity with respect to the source sequence and a high n-gram overlap with system translations (Freitag et al., 2020). Freitag et al. (2020) have shown that translationese references cause BLEU scores to be higher, and the scores are dominated by matches of common, unspecific n-grams. They find that BLEU scores under non-translationese references tend to be lower, but more precise.

Agarwal et al. (2023) observed that post-edited references for spoken language translation seem to inflate BLEU scores, but not the scores of COMET. However, the relationship between metric training and the quality of reference translations has not been studied in detail. In this paper, we hypothesize that robustness to machine-translated references may partially explain why trained metrics are more accurate in practice.

3 Experimental Setup

3.1 Measuring Global Correlation

For measuring the overall correlation of a metric to human judgments, we follow the WMT 2021 metrics task (Freitag et al., 2021b) and use MQM annotations of submissions to the 2021 WMT news translation task (Akhbardeh et al., 2021). The evaluation data cover two domains, news and TED talks. Table A5 reports statistics for these data.

We closely replicate the methodology of the WMT 2021 metrics task. On the segment level, we report Kendall's tau coefficient across all segments and systems; on the system level, we report *pairwise accuracy* (Kocmi et al., 2021), i.e., the ratio of system pairs that a metric ranks in the same order as human annotators have. Following the shared task, we only consider system translations and exclude human translations from the evaluation. We then perform *perm-both* hypothesis tests (Deutsch et al., 2021) to validate metrics comparisons at $\alpha = 0.05$.

3.2 Measuring the Effect of Machine-translated References

In the context of our analysis, we use error-free system translations from the WMT 2021 news translation task as a surrogate for real post-edited references. Specifically, we randomly select system translations that have been annotated according to the MQM standard and in which no annotator has marked an error. This approach allows us to simulate a post-editing process without the cost and noise incurred by actual post-editing.

Source sequence (English)
Face masks are mandatory across the state of California, even in fresh air.

Human-created reference (German)
Gesichtsmasken sind im ganzen Bundesstaat Kalifornien vorgeschrieben, auch im Freien.

Machine-translated reference (German)
Gesichtsmasken sind im gesamten Bundesstaat Kalifornien Pflicht, auch an der frischen Luft.

Figure 2: Example of a machine-translated reference compared to the standard reference created by a human translator. The machine-translated reference is more literal (*an der frischen Luft* 'in fresh air').

Figure 2 and Appendix F juxtapose some examples of error-free system translations and the standard, human-created reference translations. The former tend to be more literal and more aligned to the source, both in terms of syntax and content.

It should be noted that when we evaluate a metric in this analysis, we draw from the same set of systems and human annotations as we do for extracting the references. We take care to properly separate the system translations used as a reference from those that are evaluated based on that reference.

To calculate segment-level correlation, we sample a random error-free translation from an unrelated system, for each system output.[2] To calculate system-level pairwise accuracy, we use different sets of references depending on the pair of systems that is compared. Figure 3 shows that our approach is comparable to cross-validation. For every pair of systems that we consider when calculating the pairwise accuracy of a metric, we select one reference translation from an unrelated system, independently per segment. As a consequence, we use slightly different reference sets for ranking different pairs of systems.

We then compare the accuracy of a metric when provided with the machine-translated references to its accuracy when using the standard references. To ensure comparability, we skip all the segments where no machine-translated reference is available (which is either because the segment has not been part of the annotation study or because annotators have found an error in every system translation). The metric accuracies for both ref_{std} and ref_{mt} are

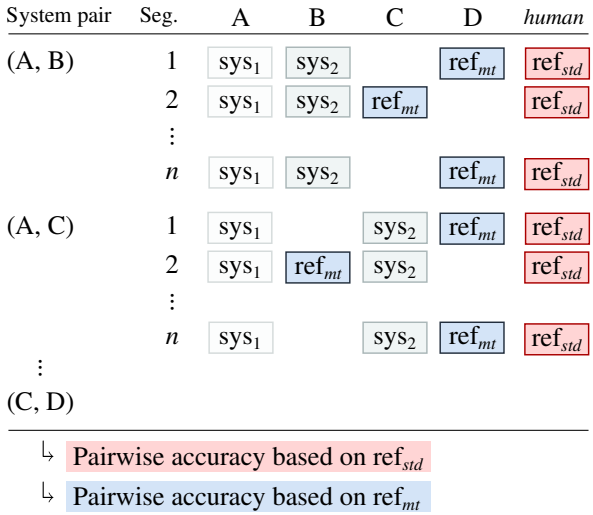

Figure 3: To measure the effect of machine-translated references, we use error-free output from other, unrelated MT systems as references. For example, when comparing system A to system B, we use a translation from either system C, D, etc. as a reference for each segment.

thus calculated based on a subset of the segments used to calculate global correlation. Table A5 shows that only for one language pair a substantial number of segments need to be skipped (Chinese–English news). For the other language pairs, between 0% and 4.5% of the segments are skipped.

4 Fine-tuning the Prism Metric

Prism (Thompson and Post, 2020) is a reference-based evaluation metric that relies on the paraphrasing probability between a system translation and a reference. The probability is estimated by a multilingual NMT model as a zero-shot translation direction. The model is expected to prefer mere copies of the source sequence to more creative paraphrases, which is especially useful for reference-based evaluation.

The NMT model uses the reference as a source

[2] Segment-level correlation is calculated jointly across all segments and systems, and as a consequence, using different references to evaluate the translations of different systems adds some noise to the correlation. However, we expect that the correlation is dominated by the segment axis and not by the system axis. Our findings on the segment level are consistent with our findings on the system level.

sequence x and the system translation as a hypothesis y, or vice versa. The segment-level score S is then calculated from token-level log-probabilities:[3]

$$S(y|x) = \frac{1}{|y|}\sum_{t=1}^{|y|}\log p(y_t|y_{i<t}, x).$$

By default, Prism uses the average of both paraphrasing directions:

$$\text{Prism}(\text{sys}, \text{ref}) = \frac{1}{2}S(\text{sys}|\text{ref}) + \frac{1}{2}S(\text{ref}|\text{sys}).$$

An overall score for a system can then be calculated as an average over a collection of segments.

4.1 Training Objective

In order to fine-tune Prism, we combine a standard cross-entropy objective and a bidirectional pairwise ranking objective.

For the *cross-entropy objective*, we use the source sequence (src) and the reference translation (ref) of the training examples to continue the cross-entropy training:

$$L_{\text{src}\to\text{ref}} = -S(\text{ref}|\text{src}).$$

Our goal in using this objective is to familiarize Prism with the segments to which the human judgments refer, and to prevent catastrophic forgetting during the fine-tuning stage.

In addition, we propose a *bidirectional pairwise ranking objective*. In the forward direction, we train Prism to correctly rank two system translations (sys^+ and sys^-), conditioned on the reference (*forward ranking*):

$$L_{\text{ref}\to\text{sys}} = \max\{0, \epsilon - S(\text{sys}^+|\text{ref}) + S(\text{sys}^-|\text{ref})\},$$

where ϵ is a margin value. We add a second ranking loss for the reverse paraphrasing direction, i.e., for reconstructing the reference from either of the system translations (*backward ranking*):

$$L_{\text{sys}\to\text{ref}} = \max\{0, \epsilon - S(\text{ref}|\text{sys}^+) + S(\text{ref}|\text{sys}^-)\}.$$

The complete fine-tuning objective is:

$$L = \alpha L_{\text{src}\to\text{ref}} + (\frac{1}{2}L_{\text{ref}\to\text{sys}} + \frac{1}{2}L_{\text{sys}\to\text{ref}}),$$

where α is a scalar to balance the two terms.

Figure 4 is a schematic illustration of the objectives for pre-training, fine-tuning, and inference.

[3]This score is called H in the original definition. We use S instead, to avoid confusion with cross-entropy (which is $-S$).

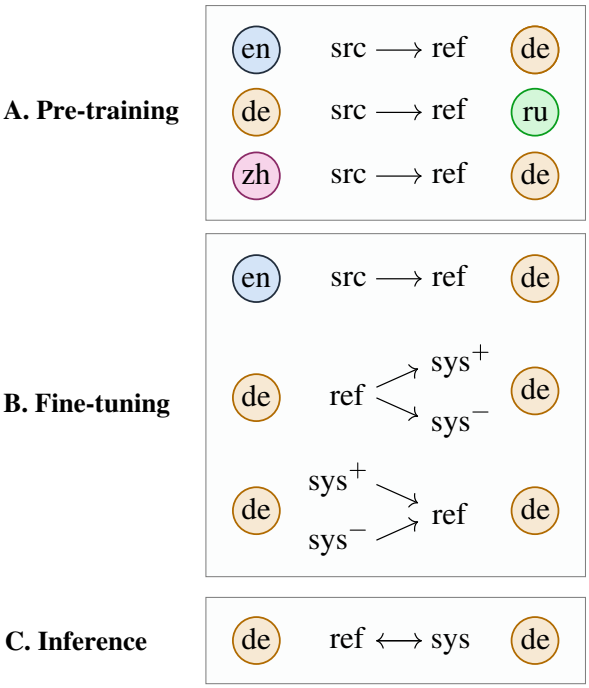

Figure 4: Schematic illustration of the sequences used for pre-training, fine-tuning, and applying the Prism model to MT evaluation. Prism has been **(A)** pre-trained on multilingual translation to and from 39 languages as described by Thompson and Post (2020); inference **(C)** makes use of the zero-shot paraphrasing capability acquired by the model during pre-training. We add a fine-tuning stage **(B)** with data derived from human evaluations of MT. In this illustration, Prism is fine-tuned on English–German examples.

4.2 Training Data

For fine-tuning Prism, we use human judgments of submissions to the 2020 WMT news translation tasks (Barrault et al., 2020), collected by Freitag et al. (2021a).[4] These annotations are based on the Multidimensional Quality Metrics (MQM) framework (Lommel et al., 2014) and have been shown to correlate better with automatic metrics than previous direct assessments, especially when the evaluation concerns high-quality translations (Freitag et al., 2021a,b). Specifically, we train Prism on human judgments for English–German and Chinese–English translations of news. We train a single model jointly on both language pairs.

To use the human judgments for training on pairwise ranking, the direct MQM assessments need to be converted into relative rankings of translation pairs. In previous work, direct (non-MQM) assess-

[4]Submission data are available at https://github.com/google-research/mt-metrics-eval and the MQM annotations are available at https://github.com/google/wmt-mqm-human-evaluation

ments have been normalized and aggregated across annotators before being compared (Ma et al., 2019). Since MQM ratings are known to have low inter-annotator agreement on the segment level (Freitag et al., 2021b), we opt for intra-annotator pairing instead. Specifically, we only pair translations that have been rated by the same annotator, and we do not compare MQM scores across annotators. Relative rankings are created independently for each annotator and then concatenated. Furthermore, we only pair translations that have a score difference greater than 0.1, which would correspond to a minor fluency or punctuation error. Taken together, these criteria should ensure there is a noticeable difference between the quality of two system translations sys^+ and sys^- in the eyes of at least one annotator. We hold out 5000 relative rankings from the resulting training data as a validation set and use it to select hyperparameters. Detailed statistics for the training data are provided in Table A4.

4.3 Implementation Details

The fine-tuning was implemented in Fairseq (Ott et al., 2019). We start with the original `Prism39` model released by Thompson and Post (2020).[5] We then fine-tune the model for a single pass over the training data, using Adam. The initial learning rate is set to 1e-4 without any warm-up steps. We use half-precision training and an effective batch size of 360k tokens. Other settings match the pre-training setup of Prism.

We set the margin hyperparameter ϵ to 0.1, and the cross-entropy weight α to 0.1 as well. The hyperparameters have been selected based on segment-level correlation on the validation set. Since we jointly train on two language pairs, we iterate over batches for each language pair in a round-robin fashion, upsampling the smaller language pair. Fine-tuning takes about one hour on a `p3.8xlarge` AWS instance, which has 4 Tesla V100 GPUs with 16 GB of memory.

5 Results

Effect of fine-tuning Prism Table 1 shows that fine-tuning Prism has the intended effect: *Fine-tuning Prism on human judgments of machine translations significantly improves correlation with human judgments on an unseen test set.* The effect of fine-tuning is especially pronounced for the English–German and Chinese–English language pairs, since the metric was fine-tuned on those pairs. Interestingly, we also observe positive cross-lingual transfer to the English–Russian language pair, which was not seen during fine-tuning. Table 2 shows that the positive effect of fine-tuning extends to the TED Talks domain, even though the metric was not fine-tuned on this domain.

	EN–DE	EN–RU	ZH–EN
Prism	19.3	22.4	28.8
Prism+FT	**25.3**	**23.7**	**31.5**

Bold font denotes that the improvement achieved through fine-tuning is significant with $\alpha = 0.05$. Note that Prism+FT has not been fine-tuned on the EN–RU language pair.

	EN–DE	EN–RU	ZH–EN
Prism	24.2	21.9	19.6
Prism+FT	**26.9**	22.3	**21.9**

Table 2: Out-of-domain accuracy of Prism on WMT 2021 system translations of TED talks in terms of segment-level Kendall's tau. Bold indicates that the improvement is significant with $\alpha = 0.05$.

Effect of using machine-translated references Table 3 reports the segment-level correlation of different metrics when using either standard references or machine-translated references. Note that the values for Prism slightly differ from Tables 1 and 2 because this analysis is based on a subset of the segments. *We find that the correlation of metrics to human judgments tends to decrease under machine-translated references.* For the Chinese–English dataset the relative decline is smaller than average, but is still noticeable for most metrics.

In Table 3, when comparing the non-trained metrics (above the horizontal line) to the trained metrics (below the line), we observe that the decline in correlation is smaller for the trained metrics. An especially interesting comparison is between Prism and Prism+FT, given that the two metrics differ only in the training data. *Prism+FT is consistently more robust to machine-translated references than Prism, indicating that the metric learns to cope with such references during the fine-tuning stage.*

With respect to system-level pairwise accuracy (Table 4), we observe a similar trend.

COMET	79.5	84.6 **(6.4%)**	68.1	65.9 **(-3.2%)**	60.3	55.1 **(-8.6%)**	69.3	68.5 **(-1.1%)**

Table 4: System-level pairwise accuracy of MT metrics when provided with the standard references of the WMT21 metrics news subtask (Freitag et al., 2021b), and with machine-translated references. Again, the trained metrics, Prism+FT and COMET (`wmt21-comet-mqm`), tend to be more robust to machine-translated references.

Prism+FT does not show significantly higher pairwise accuracy than Prism when using standard references, which is explained by the high statistical variance of the pairwise accuracy metric. But again, Prism+FT appears more robust to machine-translated references than Prism. Finally, Appendix B reports results for the TED talks domain, where the same patterns can be observed.

Ablation Study We perform an ablation study to measure the influence to the three terms in the Prism fine-tuning objective. Appendix A shows that removing either of the three terms decreases segment-level correlation. The ablation shows that the cross-entropy objective has the additional effect of stabilizing the model: Without cross-entropy, the average probability scores output by Prism shift from 0.47 to 0.35 after a single epoch of fine-tuning, and the BLEU achieved by the Prism translation model on an unseen test set clearly declines.

6 Related Work

Machine translations as references Popovic et al. (2016) first investigated the potential of using post-edited machine translations as references, finding that post-edited translations stemming from high-quality systems are better references than those from low-quality systems. Toral (2019) argued that post-edited machine translations can be seen as an exacerbated form of translationese (*post-editese*). Combined with the finding of Freitag et al. (2020) that translationese references are less favorable than intentionally paraphrased references, this suggests that machine translations, even if post-edited, are a challenge for MT evaluation.

Albrecht and Hwa (2007) propose to train an evaluation metric using non-annotated translations of other systems as *pseudo-references*. They hypothesize that a metric can learn to detect and to constructively utilize any errors in these references. Yoshimura et al. (2019) instead use a paraphrase identifier to filter pseudo-references based on their paraphrastic similarity to a human-created reference. Finally, minimum Bayes risk decoding (Kumar and Byrne, 2004) employs pseudo-references for generating translations, and has been shown to depend on robust metrics as well (Freitag et al., 2022a; Amrhein and Sennrich, 2022).

Training a sequence-to-sequence model on pairwise ranking Pairwise ranking has commonly been used to train SVM (Ye et al., 2007; Duh, 2008; Stanojević and Sima'an, 2014) and neural network encoders (Guzmán et al., 2015; Dušek et al., 2019). A more recent approach has been to fine-tune pre-trained sentence encoders so that the embedding similarities of two hypotheses and the reference and/or source are optimized for pairwise ranking (Rei et al., 2020; Zhang and van Genabith, 2020), in which case the max-margin loss reduces to a triplet margin loss (Schroff et al., 2015). In this paper, we do not rely on the similarity of sentence embeddings but use the perplexity of a sequence-to-sequence model as a metric.

Since we optimize perplexity given positive and negative examples, our fine-tuning approach becomes very similar to contrastive learning for NMT. Typical applications of contrastive learning try to eliminate specific translation error types by creating perturbed versions of the training references (Yang et al., 2019; Hwang et al., 2021). A similar objective has been used for discriminative re-ranking of translation candidates (Shen et al., 2004; Yu et al., 2020). In this paper, however, the goal is not to improve translation output but to train an evaluation metric on human judgments.

7 Conclusion

We have shown that metrics without supervision by human judgments, such as BLEU and chrF, tend to be inaccurate under machine-translated references, while trained metrics are more robust. In order to methodically examine this phenomenon, we have trained the Prism evaluation metric on a dataset of human judgments. Our experiments show that fine-tuning improves the segment-level accuracy of Prism on an unseen test set across multiple language pairs and domains, and clearly increases its robustness to machine-translated references.

One conclusion to draw from our findings is that post-edited references likely diminish the accuracy of reference-based metrics and should be avoided. A second conclusion is that if it cannot be ruled out that references originate from MT, as is often the case in practice, trained metrics are to be preferred. Fine-tuning a metric such as Prism on reference-based evaluation can thus be seen as a technique to let the metric make the best out of reference translations in the wild.

Limitations

Our study is mainly limited by the data we use for fine-tuning and evaluating Prism. The experiments are based on three language pairs only. Automatic MT evaluation is relevant for many more language pairs and language families, including and maybe especially so for low-resource settings.

Secondly, it should be mentioned that the machine translations we use in our analysis have been generated by systems based on a similar technology. Almost all of the systems seem to use the Transformer architecture, and they have all been trained on similar data (Akhbardeh et al., 2021). It is possible that our findings do not generalize to the evaluation of other varieties of MT, such as rule-based systems, or to reference-based evaluation metrics that use large language models (Kocmi and Federmann, 2023).

Gesichtsmasken sind im ganzen Bundesstaat Kalifornien vorgeschrieben, auch im Freien.

Randomly sampled error-free system translation (Nemo):
Gesichtsmasken sind im gesamten Bundesstaat Kalifornien Pflicht, auch an der frischen Luft.

Chinese–English News Example

Source sequence:
他已承认，是自己在教堂里点火。

Standard reference:
The parish volunteer has admitted that he had started the fire in the church.

Randomly sampled error-free system translation (metricsystem5):
He has admitted that it was himself who set the fire in the church.

English–German TED Talks Example

Source sequence:
Today I'd like to show you the future of the way we make things.

Standard reference:
Ich möchte Ihnen heute zeigen, wie wir in Zukunft Dinge herstellen werden.

Randomly sampled error-free system translation (Online-W):
Heute möchte ich Ihnen die Zukunft der Art und Weise zeigen, wie wir Dinge herstellen.

Chinese–English TED Talks Example

Source sequence:
今天我想向各位展示未来我们制作东西的方式。

Standard reference:
Today I'd like to show you the ways we make things in the future.

Randomly sampled error-free system translation (metricsystem1):
Today I want to show you how we will make things in the future.

Training and Meta-Evaluating Machine Translation Evaluation Metrics at the Paragraph Level

Daniel Deutsch, Juraj Juraska, Mara Finkelstein, and Markus Freitag
Google
{dandeutsch,jjuraska,marafin,freitag}@google.com

Abstract

As research on machine translation moves to translating text beyond the sentence level, it remains unclear how effective automatic evaluation metrics are at scoring longer translations. In this work, we first propose a method for creating paragraph-level data for training and meta-evaluating metrics from existing sentence-level data. Then, we use these new datasets to benchmark existing sentence-level metrics as well as train learned metrics at the paragraph level. Interestingly, our experimental results demonstrate that using sentence-level metrics to score entire paragraphs is equally as effective as using a metric designed to work at the paragraph level. We speculate this result can be attributed to properties of the task of reference-based evaluation as well as limitations of our datasets with respect to capturing all types of phenomena that occur in paragraph-level translations.

1 Introduction

Automatic evaluation metrics have always been a critical component to the progress of research on machine translation (MT). As the field of MT moves beyond translating individual sentences to translating full paragraphs, book chapters, or documents (Tu et al., 2018; Sun et al., 2022; Thai et al., 2022; Jiang et al., 2023; Post and Junczys-Dowmunt, 2023), automatic metrics need to be designed to work on these longer texts.

Currently, how well automatic metrics agree with human judgments of paragraph translation quality is an open question.[1] Few studies have meta-evaluated metrics on longer texts, and those that have are focused on the literary domain and are limited in the size of the evaluation dataset (Jiang et al., 2022; Thai et al., 2022; Karpinska and Iyyer, 2023). In this work, we investigate training and meta-evaluating metrics for scoring paragraph translations using the benchmark Workshop on Machine Translation (WMT) datasets that are widely used for metric development (Freitag et al., 2022).

Due to the scarcity of human ratings of paragraph translations, we propose a method to create paragraph-level training and meta-evaluation datasets from the existing WMT sentence-level datasets (§3). Although these ratings are typically only used at the sentence level, they were collected on contiguous paragraphs and performed with document context, so they can be used as paragraph-level datasets. We repurpose these datasets to benchmark existing sentence-level metrics as well as train new paragraph-level metrics for scoring paragraph translations (§4).

Our experimental results are somewhat surprising. We find that there appears to be little evidence that training on paragraph-level data is beneficial—at least given the limitations of our experimental setup. Using metrics trained on sentence-level data only to directly score full paragraphs achieves comparable agreement to human ratings as metrics trained on paragraph-level data (§6.1). Sentence-level metrics appear to generalize well to inputs much longer than they were trained on (§6.2).

We hypothesize these observations can be explained by the nature of evaluating translations and characteristics of our paragraph-level dataset (§7). We speculate that long range dependencies—which paragraph-level metrics can model but sentence-level likely do not—may not be too important for achieving high agreement with human ratings. Further, due to the fact that our training and evaluation datasets assume a sentence alignment between the reference and hypothesis paragraphs, certain translation phenomena that sentence-level metrics may struggle to handle, like sentence or information reordering, are not well represented in the dataset,

[1] Translation beyond the sentence level is often referred to as document-level MT. However, there is no clear definition for the term "document." We use "paragraph" in this work because we feel it most accurately describes the length of text in our datasets. See §2 for more details on this.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 996–1013
December 6–7, 2023.

limiting our ability to show the benefits of training on paragraph-level ratings.

The contributions of our work include (1) a method for constructing paragraph-level training and meta-evaluation datasets from sentence-level ratings, (2) an experimental study that demonstrates the comparable performance of sentence- and paragraph-level metrics, and (3) an analysis that aims to provide an explanation for our experimental observations.

2 Terminology

Throughout this paper, we use terms like segment, sentence, paragraph, and document to refer to different lengths of text. To the best of our knowledge, there are no agreed upon definitions for these terms in the MT literature, so here we define how they are used for the rest of the paper.

We refer to the input text to an MT system or evaluation metric as a *segment*, irrespective of its length. Traditionally, segments in MT have been roughly equivalent to one sentence, although sometimes they can be short phrases or even longer than a single sentence. Regardless, we use *sentence* to refer to this unit of text since it accurately describes the most common text length that is widely used in MT.

Our work investigates evaluating *paragraphs* of text, which we define to be multi-sentence segments. We do not require that the paragraphs used in this work obey the traditional definition of a paragraph (i.e., a unit of text separated by a newline character). We refrain from calling this unit of text a *document*—which we consider to be all of the possible input text—since each document can be broken down into multiple paragraphs and the term paragraph more accurately describes the length of text we use.

3 Paragraph-Level Datasets

The two main sources for training and meta-evaluating MT metrics are the direct assessment (DA) and Multi-dimensional Quality Metrics (MQM; Lommel et al., 2014; Freitag et al., 2021a) datasets that the Workshop on Machine Translation (WMT) has collected as part of the yearly metrics shared task (Freitag et al., 2022). The DA ratings were done by a mixture of expert and non-expert raters (depending on whether the translation direction is into or out of English) who assigned a quality score in the range 0-100 to translated sentences.

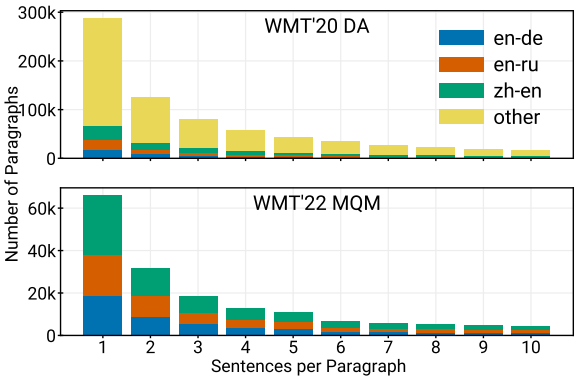

Figure 1: The number of contiguous paragraphs for the given number of sentences per paragraph where each sentence is rated by the same rater. Actual values are included in Appendix A.

Because of differences in rater behavior, the DA scores are z-normalized per rater.[2] In MQM, expert raters identify error spans in translated sentences and assign each error a category and severity level, which are used to calculate a score for that error. A sentence's MQM score is defined as the sum of the errors' scores.

Training and meta-evaluating metrics at the paragraph level requires a collection of translated paragraphs and paragraph-level quality scores. Luckily, the DA data since 2019 and the MQM data can be considered to be paragraph-level ratings. The ratings were performed on contiguous blocks of sentences that were translated by the same system (e.g., the first k sentences per document are rated for a system). Although the scores were collected at the sentence level, the ratings were done in context, meaning the raters had access to the document context for a sentence, so the scores should reflect paragraph- or document-level phenomena like discourse errors. Therefore, we use the sentence-level DA and MQM data to construct paragraph-level datasets as follows.

For each document translated by a system, we run sliding window of size k sentences from the start to the end. If all k sentences in the window have been rated, those k sentences are concatenated together to become a paragraph instance and the window shifts by k. Otherwise, the sliding window shifts by 1 and the process repeats. To maintain consistency between the sentence scores within a paragraph, we additionally require that every sen-

[2]The methodology for collecting DA ratings has changed throughout the years. See Barrault et al. (2020) for the description in 2020, the most recent year used in this work.

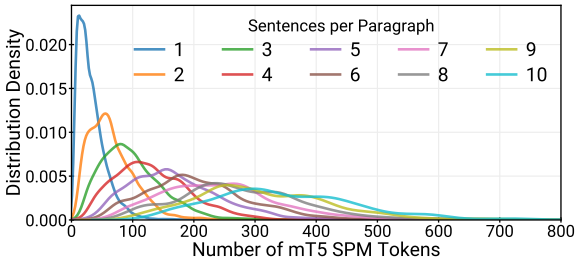

Figure 2: The distribution of paragraph lengths in SPM tokens (i.e., sub-word tokens; Kudo and Richardson, 2018) on the WMT'22 MQM dataset for different numbers of sentences per paragraph. Additional datasets' distributions are included in Appendix A.

tence is scored by the same rater. Then, we define the paragraph-level scores to be the average DA z-score or sum of MQM scores for each sentence in the paragraph.[3] The result is a dataset of rated paragraph translations of k sentences each.

We apply this dataset construction approach to the DA and MQM data for $k = 1, 2, \ldots, 10$ sentences per paragraph. The number of paragraphs is shown in Figure 1 and the distribution of the lengths of the new translated paragraphs is shown in Figure 2. As k increases, the number of paragraphs decreases because there are fewer candidate paragraphs, while the length of the paragraphs increases, roughly by an expected factor of k.

These paragraph-level DA and MQM datasets are used to train and meta-evaluate paragraph-level metrics for the rest of this paper.

4 Paragraph-Level Metrics

We explore two different methods for creating paragraph metrics: directly applying sentence-level metrics to paragraphs (§4.1) and training metrics on paragraph-level data (§4.2).

4.1 Applying Sentence-Level Metrics on Paragraphs

Although automatic metrics that have been used to evaluate sentence-level MT were not explicitly designed to evaluate paragraphs, they can be repurposed to score paragraphs in different ways.

First, the input paragraph can be treated as if it were one long segment and passed to the metric to calculate a score. For metrics that use bag-of-n-grams representations, like BLEU (Papineni et al., 2002), there is no input length limitation. However, some learned metrics, like BLEURT (Sellam et al., 2020), have a maximum possible sequence length due to restrictions related to neural network architectures. Therefore, the length of the input paragraph is restricted in some cases.

Then, if there is assumed to be an alignment between the source, reference, and hypothesis sentences within a paragraph (as is in the case with our datasets), a paragraph score can be calculated by averaging the sentence-level metric's score for each of the k individual sentences. While this sliding window approach more closely aligns how the metrics are being used to how they were designed, we argue this approach is less than ideal because the 1:1 sentence alignment between the source and hypothesis translations will not always exist. However, this approach is useful for understanding and analyzing the behavior of metrics when they are used to score full paragraphs directly.

4.2 Learning Paragraph-Level Metrics

While sentence-level metrics can be repurposed to score paragraphs, the lengths of the input paragraphs are significantly longer than the lengths of individual sentences (compare $k = 1$ to $k > 1$ in Figure 2) and there may be cross-sentence dependencies that are not learned by sentence-level metrics. Therefore, we explore creating a metric specifically for paragraph-level data.

To do so, we train a BLEURT-style regression model on the paragraph-level datasets: The reference and hypothesis paragraphs are tokenized and concatenated together (separated by a special token), then passed as input to a neural network. The network is then trained to predict the hypothesis paragraph's ground-truth quality score. Sections 5.2 and 5.4 contain more information about the model's architecture and implementation details.

It is desirable for the paragraph-level metric to be able to score paragraphs of any length, so we train the metric on paragraphs composed of $k = 1, 2, \ldots, 10$ sentences. Because the number of paragraph instances decreases significantly as k increases (see Figure 1), longer paragraphs will rarely be seen during training. Therefore, we explore two different techniques for weighting training data: one that selects paragraphs uniformly at random

[3] Summing MQM scores was done to generalize an MQM rating for paragraphs since a sentence's MQM score is the total error weight for that sentence. The choice of summing or averaging does not matter for metric meta-evaluation because the correlations are scale invariant.

and one that performs a stratified sample so the training data is composed of an equal number of paragraphs for each value of k.

Next, we describe the experimental setup to evaluate the paragraph-level metrics.

5 Experimental Setup

5.1 Datasets

The paragraph-level datasets used in our experiments are described in Section 3. The WMT'19 (Ma et al., 2019) and '20 (Mathur et al., 2020) paragraph-level DA data is used for training the metrics described in this work, and all metrics are evaluated on the WMT'21 (Freitag et al., 2021b) and WMT'22 (Freitag et al., 2022) paragraph-level MQM data. For both DA and MQM, we use $k = 1, 2, \ldots, 10$ sentences per paragraph. The different paragraph lengths are combined during training but separated for evaluation.

We additionally analyze the behavior of the metrics that we train on judgments collected by Karpinska and Iyyer (2023) on literary translations. Their dataset contains human preference judgments between paragraph translations. The translations come from translation models that translated the input one sentence a time in isolation, one sentence at a time in context, the full paragraph directly, and Google Translate. We evaluate how frequently the metrics agree with the human preference judgments.

5.2 Metrics

Paragraph-Level Metrics. We train two different paragraph-level metrics, one for each of the different weighting techniques, uniform and stratified sampling (see §4.2). We refer to these metrics as PARA-UNIF and PARA-STRAT.

Our metric uses the same architecture as the Metric-X WMT'22 metrics shared task submission (Freitag et al., 2022). The metric builds on the mT5 encoder-decoder language model (Xue et al., 2021), which was originally designed to be a sequence-to-sequence language model. We repurpose the model for our regression task as follows. The inputs to the encoder are the hypothesis and reference translations separated by a special token, and a single dummy token is passed as the first input to the decoder. We arbitrarily selected a reserved vocabulary token, then trained the model so that token's output logit in the first decoding step becomes the score for the input hypothesis translation. This modification of the sequence-to-sequence architecture for regression allows us to utilize all of the pre-trained weights from mT5.

The maximum input sequence length to our metric is 1024 SPM tokens (Kudo and Richardson, 2018). The inputs are truncated during training or inference if the input is larger than 1024.[4] In the worst case, this happens up to 27% of the time on the MQM data for 10 sentences per paragraph (see Appendix A for specific statistics.)

Sentence-Level Baseline. In addition to the paragraph-level metrics, we train a sentence-level version that is trained on the same DA data but only $k = 1$ sentences per paragraph. This baseline metric can be used to directly compare to the paragraph-level metrics that we train because the model architecture, training procedure, etc., are identical. The only difference is the training data. This metric is referred to as SENT-BASE.

Other Metrics. In addition to the metrics described in this paper, we evaluate BLEU (Papineni et al., 2002), COMET-22 (Rei et al., 2020, 2022), and PaLM-2 from Fernandes et al. (2023) as sentence-level metrics applied to paragraphs (i.e., §4.1) and document-level metric BlonDE (Jiang et al., 2022). BLEU scores translations using lexical n-gram overlap, and COMET-22 is a learned regression metric that first embeds the input hypothesis, reference, and source, combines them to a joint representation, then finally predicts a score.

The metric from Fernandes et al. (2023) is based on the PaLM-2 large language model (Anil et al., 2023). We evaluate both the zero shot version, in which PaLM-2 is prompted to score a translation on a scale from 0 to 100, and the regression version that finetunes PaLM-2 on MQM ratings to predict a floating point quality score, similar to COMET. Our analysis includes the Bison variant of PaLM-2.

BlonDE evaluates discourse phenomena in document translations via a set of automatically extracted features. It was designed to evaluate texts longer than paragraphs, like book chapters, but we compare against it in this work. BlonDE is available in English only.

We use the SacreBLEU (Post, 2018) implementation of BLEU and the `Unbabel/wmt22-comet-da` COMET-22 model that was trained on sentence-level WMT DA data from 2017-2020.[5]

[4] We experimentally saw no benefit from removing sequences longer than 1024 tokens during training.

[5] Note that the COMET-22 scores we report come from

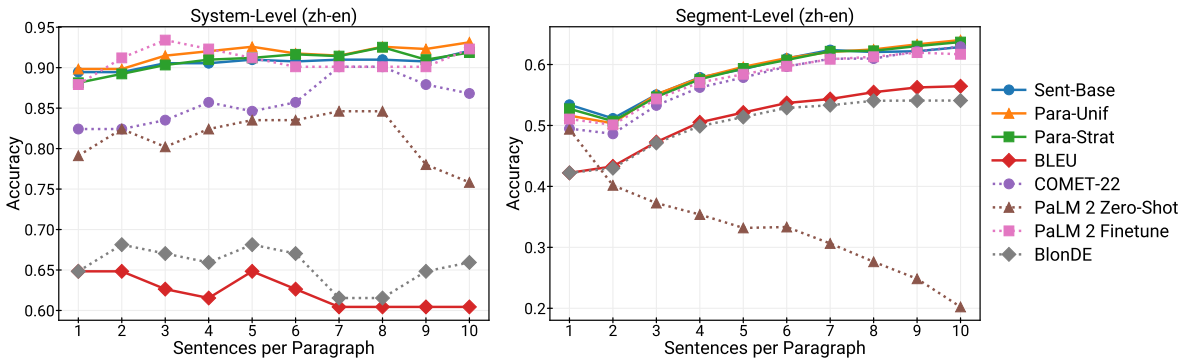

Figure 3: As the number of sentences per paragraph increases, the pairwise accuracy scores (y-axis) of the metrics appears to either not decrease (system-level, left) or increase (segment-level, right). This suggests that accurately scoring a paragraph is an easier task than an individual sentence, even for metrics that are not trained on paragraph-level examples. The results of metrics trained in this work presented here are an average of 5 different runs. Results for other language pairs follow the same trend and are included in Appendix B.

5.3 Meta-Evaluation Metrics

The quality of an evaluation metric is quantified by measuring the correlation of its scores to human ratings of translation quality, a process known as meta-evaluation. In this work, we meta-evaluate metrics using pairwise accuracy at both the system and segment levels.[6] A brief overview of how these accuracy statistics are calculated follows.

At the system-level, an automatic metric and human score is calculated per system by averaging scores over paragraphs. The system-level pairwise accuracy is then computed by enumerating all possible pairs of systems and then calculating the proportion of those pairs for which the automatic metric and human ground-truth ratings agree on their ranking (Kocmi et al., 2021). Thus, the accuracy score can be interpreted as the proportion of pairs of systems that the metric ranked correctly.

At the segment-level, we report segment-level pairwise accuracy using the group-by-item variant of the segment-level correlation in combination with tie calibration (Deutsch et al., 2023). In contrast to system-level accuracy, the group-by-item segment-level correlation calculates the proportion of pairs of *translations* of the same source segment that the metric ranks correctly, then averages that accuracy score over all source segments. The segments used in this evaluation are paragraphs, thus the interpretation of this accuracy score is the proportion of pairs of translations of the same source paragraph that are ranked correctly by the metric.

Because humans frequently assign the same score to translations and regression-based evaluation metrics almost never predict two translations are tied, we follow Deutsch et al. (2023) and run tie calibration before calculating the segment-level accuracy. This procedure automatically introduces ties in the metrics' scores by searching for an ϵ difference in metric score that, when two translations are considered to be a tie if they differ by less than ϵ, achieves the highest accuracy score. We report the accuracy score that corresponds to the best ϵ.

Results using Pearson's correlation follow similar trends to the accuracy results and are available in Appendix B.

5.4 Implementation Details

Our learned metrics are implemented with TensorFlow (Abadi et al., 2015) in the T5X library (Roberts et al., 2022). They are initialized with the XXL version of mT5, which contains 13B parameters. It is trained for a maximum of 20k steps and a batch size of 128 using Adafactor (Shazeer and Stern, 2018) on 64 v3 TPUs. Checkpoint selection was done by selecting the step that has the highest average segment-level pairwise accuracy across language pairs and all values of k sentences per paragraph after applying tie calibration. In general, we observed the specific checkpoint selection strategy was not too important.

only the reference-based regression model, not the ensemble that was submitted to the WMT'22 metrics shared task.

[6]The segment-level correlation could be referred to as a paragraph-level correlation in this work because the segments we evaluate on are paragraphs. However, to be consistent with the evaluation literature, we still use the term segment-level correlation.

6 Results

First, we directly evaluate how well metrics perform when used to directly score paragraphs (§6.1), then we further examine the behavior of different paragraph-level metrics by analyzing their performances with the context of their sentence-level counterparts (§6.2).

6.1 Paragraph-Level Evaluation

Figure 3 plots the system- and segment-level correlation results for different numbers of k sentences per paragraph. Each metric is used to directly score a full paragraph even if the metric was not designed to do so (e.g., SENT-BASE or COMET-22). There are several interesting observations.

Paragraph-Level Performance. First, as the length of the paragraphs increases, the system-level correlations remain relatively steady or increase and the segment-level correlations clearly improve for all metrics, except for PaLM-2 zero-shot. This is evidence that scoring paragraphs is an easier task than scoring individual sentences, a result that is counterintuitive; scoring more text should seemingly be a harder task. We hypothesize this result is explained by the fact that some noise in the human and metric scores is averaged away, leaving more reliable signals as the paragraphs get longer. If the metric scores are unbiased estimators, their agreement with human rating should then increase.

PaLM-2 zero-shot is an outlier in this case because it predicts a large number of ties between translations. Prompting large language models for MT evaluation is known to result in the model predicting a small number of unique scores, resulting in many ties (Kocmi and Federmann, 2023; Fernandes et al., 2023). As the length of the paragraph increases, the number of MQM ties decreases. Since pairwise accuracy penalizes incorrect tie predictions, the zero shot model has worse performance on longer texts. See Figure 4 for a visualization of the number of ties in the PaLM-2 output and MQM scores.

Sentence vs. Paragraph Level. Then, there appears to be little evidence that training on paragraph-level examples results in better correlations to human ratings on paragraph-level test data. For instance, increasing the weight of the paragraph-level data during training does not help compared to uniformly sampling data (compare PARA-STRAT to PARA-UNIF). Further, the baseline metric SENT-BASE that shares the same architecture as our paragraph-level metrics but is only trained on sentence-level data ($k = 1$) performs just as well as the paragraph-level metrics. This observation is additionally supported by COMET-22's results. The difference between the metrics we train versus COMET is relatively constant for all values of k, demonstrating that COMET is not systematically worse on longer inputs.

The generalization of sentence-level metrics on paragraph-level data is rather surprising. The length of the inputs for scoring paragraphs is up to 10x longer than those for scoring sentences (see Table 1). Even though the length of the test data is out-of-distribution with respect to the training data, the sentence-level metrics predict reliable scores on the paragraph-level data. Next, we further analyze the sentence-level metrics to better understand their scores.

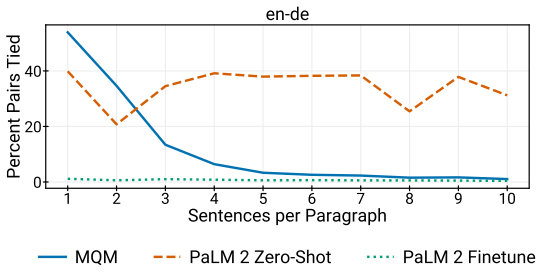

Figure 4: There are fewer MQM ties as the number of sentences per paragraph increases. The finetuned PaLM-2 model outputs a very small number of ties, whereas the zero-shot model consistently predicts a large number of ties. Since the pairwise accuracy meta-evaluation metric penalizes metrics for incorrect tie predictions, the zero-shot model will have worse performance as the inputs get longer.

Dataset	1 Sent. per Para.			10 Sent. per Para.		
	25th	50th	75th	25th	50th	75th
WMT'19 DA	20	31	47	300	362	431
WMT'20 DA	24	38	58	318	410	524
WMT'21 MQM	28	41	57	370	433	516
WMT'22 MQM	15	27	43	265	333	426

Table 1: The SPM token lengths for the given percentiles are in general around 10 times larger with 10 sentences per paragraph compared to a single sentence. Visualizations of the distributions for every paragraph length can be found in Appendix A.

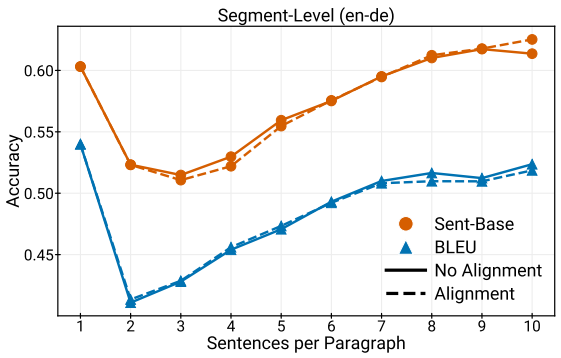

Figure 5: Metrics that score a paragraph directly (solid line) versus those that assume an alignment between the reference and hypothesis and calculate a score by averaging across the k sentence-level values (dashed line) perform very similarly. The drop from 1 sentence to 2 sentences per paragraph is likely due to the fact that a large number of ties in the ground-truth get broken, so introducing more ties via tie calibration is less helpful since doing so is right less often. This phenomenon does not happen with Pearson correlations (see Appendix B).

6.2 Understanding Sentence-Level Metrics

To further analyze the performance of the sentence-level metrics on paragraph-level data, we compare the two versions of applying a sentence-level metric to paragraphs discussed in §4.1. One version directly scores a full paragraph (thus, making no assumption about an alignment between the hypothesis and reference), whereas the other averages the scores of evaluating the individual k hypothesis sentences against the corresponding reference sentence (thus, assuming a sentence-level alignment exists).

Figure 5 shows that for two sentence-level metrics, the baseline trained in this work and BLEU, the performance of the two paragraph scoring variants is very similar. Then, Figure 6 shows that the Pearson correlation between the scores for those two variants is very high (≥ 0.85).

Together, these results point to the fact that there is little difference between these two methods. Directly scoring a paragraph or scoring individual sentences yield both similar scores and similar agreement to human ratings. The sentence-level metrics appear to be scoring full paragraphs in a desirable way—by calculating some average score across sentences.

This result is not obvious. As the length of the input increases, the bag-of-n-grams representation used by lexical matching metrics like BLEU

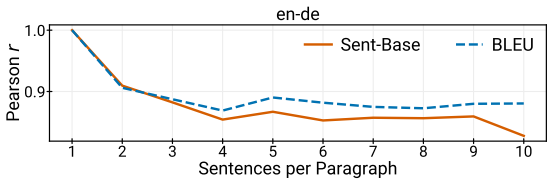

Figure 6: The plot shows the Pearson correlation on en-de between directly predicting a score for a paragraph of k sentences and calculating a paragraph score by averaging over k sentence-level scores. The correlations are quite high, demonstrating that the both methods result in very similar scores.

have an increased potential for erroneous matches between the hypothesis and reference sentences, which could result in misleading scores. Learned metrics, like the ones trained in this work, have not been trained on a significant amount of very long data, so it is not clear that the scoring functions they learn would generalize well to longer inputs. Despite this, the sentence-level metrics appear to predict high-quality scores for paragraphs.

In Section 7, we propose a hypothesis for why this is the case and why training on paragraph-level data does not appear to result in a better metric.

6.3 Literary Translation Evaluation

We compared how frequently SENT-BASE and PARA-STRAT agree with the 540 pairwise human preference judgments between paragraph literary translations from Karpinska and Iyyer (2023). We found that the two models agreed 285 and 305 times, respectively. While it is a positive signal that the paragraph-level model appears to be better aligned with human preferences of longer texts, the difference was not quite statistically significant under a pairwise permutation test with $\alpha = 0.05$ ($p = 0.09$). Future work should perform a more in-depth analysis of this data and collect a larger number of paragraph translations and judgments.

7 Discussion

In theory, training on paragraph-level data should have advantages compared to training on sentence-level data. The metric (1) should be able to handle longer input sequences, (2) it should be able to capture long range dependencies, and (3) it should be able to model different paragraph-level phenomena like information or sentence reordering. However, we were not able to demonstrate these advantages in practice, and we theorize why as follows.

Source Context: Maria said no.
Source: She did not slap the green witch.

Reference Context: Maria dijo no.
Reference: No le dió una bofetada a la bruja verde.

Hypothesis: Ella(✓)/Él(✗) no le dió una bofetada a la bruja verde.

Figure 7: An English-to-Spanish translation example where the reference translation does not have enough information to correctly evaluate the hypothesis. Gender in Spanish is marked on pronouns, and Spanish is a pro-drop language, which means the pronoun can be omitted if the context is clear. In this example, the pronoun is dropped from the reference, so determining whether the pronoun used in the hypothesis requires taking into account the previous reference sentence. We suspect such examples are not frequent, and if they do exist, the information required to resolve the ambiguity is relatively local to the reference sentence.

First, the analysis in §6.2 shows that sentence-level metrics generalize well to significantly longer input, so advantage (1) may not be so relevant. We hypothesize that the scoring function learned by sentence-level metrics like SENT-BASE or COMET could score a token in the hypothesis based on some alignment to the reference using its relative position in the translation. This function would be agnostic with respect to the global positioning, and thus the scoring function would generalize well to longer inputs. If this were true, training on paragraph-level data would not be necessary to obtain good performance on long sequences.

Second, evaluating translation quality seems to be a very "local" problem in the sense that modeling long range dependencies is not frequently necessary for evaluation. Often, the reference phrase that aligns to a hypothesis phrase has enough information to accurately evaluate the hypothesis. If it does not, the information is likely nearby, not several sentences away (see Figure 7). Although the sentence-level metrics were not trained on multiple sentences, we suspect they are able to capture nearby dependencies across sentences when evaluating paragraphs. In theory, a paragraph-level metric would have the ability to model long range dependencies since it could observe them during training. However, if they are infrequent, advantage (2) over sentence-level metrics may be small.

Finally, the ability for our learned paragraph metrics to capture phenomena like sentence reordering is limited by our dataset construction method. Since the paragraphs in our training and test sets come from MT systems that translated one sentence at a time, there are no phenomena like sentence reordering present in the datasets. Therefore, the paragraph-level metric cannot learn to model such cases, and the metrics are never evaluated on them either. Thus, the limitations of the dataset mean that we cannot demonstrate advantage (3).

We believe that paragraph-level metrics are necessary for evaluating true paragraph translations, where MT systems can be more creative with how a full paragraph is translated, rather than paragraph translations that are created by translating individual sentences. We hypothesize that sentence-level metrics will not generalize well when there is no sentence alignment or there is significant information reordering. To accurately evaluate actual paragraph translations, metrics need to be trained on similar data. Future work should invest in collecting human ratings for paragraph-level translations so that new metrics can be trained and evaluated.

8 Related Work

The vast majority of research on MT evaluation has worked at the sentence level (Papineni et al., 2002; Banerjee and Lavie, 2005; Snover et al., 2006; Popović, 2015, 2017; Lo, 2019; Sellam et al., 2020; Rei et al., 2020, 2022; Thompson and Post, 2020; Wan et al., 2022), although there has been recent interest in moving beyond sentence-level evaluation. Vernikos et al. (2022) propose a method to incorporate document-level context into a sentence-level metric by using the additional context when computing the representations for the hypothesis and reference sentences. Although they use document context in their metric, it is still scores single sentences at a time, in contrast to the paragraph-level metrics in our work that predict a score for entire paragraphs at once. Then Jiang et al. (2022) propose a document-level metric called BlonDE that targets evaluating discourse phenomena as opposed to overall translation quality (i.e., they do not model translation accuracy errors). To the best of our knowledge, ours is the first study aimed at training a learned metric that directly scores entire paragraphs.

Other studies that have evaluated sentence-level metrics beyond the sentence-level have done so in the literary domain. Thai et al. (2022) show that automatic metrics prefer MT output over human translations, and Karpinska and Iyyer (2023) show

that metrics prefer actual translations of paragraphs over sentence-by-sentence translations. Our work is complementary to theirs as we focus on the news domain, train metrics on paragraph-level data, and evaluate on a much larger set of human ratings. It is not clear whether conclusions reached about metrics in the news domain will apply to the literary domain or vice versa.

Some researchers have developed challenge sets that can be used to probe how well metrics capture discourse phenomena that appear when translating more than one sentence at a time (Bawden et al., 2018; Müller et al., 2018; Lopes et al., 2020). However, these challenge sets can be trivial for reference-based metrics because the reference often resolves the ambiguity in the translation. To the best of our knowledge, a challenge set that forces reference-based metrics to use context outside of a single reference sentence during evaluation (see Figure 7) does not exist.

Research on generating translations of text longer than single sentences directly use sentence-level metrics to score translations (Tiedemann and Scherrer, 2017; Miculicich et al., 2018; Ma et al., 2020; Wu et al., 2023; Post and Junczys-Dowmunt, 2023). Our work can be viewed as a justification for doing so.

9 Conclusion

In this work, we proposed a method for constructing paragraph-level datasets for training and meta-evaluating MT evaluation metrics from sentence-level data. Our experimental results showed that metrics trained on paragraph-level data do not necessarily out-perform those trained on sentence-level data, potentially due to the fact that sentence-level metrics seem to generalize well to longer inputs and limitations of our paragraph-level datasets. Future work should invest in collecting human judgments for paragraph translations generated by MT systems that directly translate full paragraphs instead of translating one sentence at a time. Such a dataset would be more likely to contain phenomena that do not exist at the sentence level, which we hypothesize would be more likely to require metrics designed to work at the paragraph level.

Limitations

There are a couple of limitations related to our dataset construction approach that are worth enumerating.

As discussed in Section 7, our ability to evaluate metrics' performances on all types of paragraph-level translations is limited by our dataset construction method. Our translated paragraphs are generated by MT systems that translate one sentence at time, which results in sentence aligned data. Therefore, we are unable to evaluate metrics on true paragraph-level translations that might have sentence or information reordering.

Then, the WMT data no longer contains information about the white space between the original source sentences. Therefore, the DA and MQM paragraph-level datasets do not contain the paragraph breaks that were in the original document. Each of the k sentences is concatenated together and separated by a space in our work, so it is very likely that the artificially constructed paragraphs do not perfectly resemble real paragraphs.

A Dataset Statistics

The exact number of paragraph-level instances by WMT year and language pair that we generaetd from our dataset construction procedure (see §3) can be found in Table 2 for DA and Table 3 for MQM. Figure 8 visualizes the distribution of the lengths of the hypotheses in the paragraph-level datasets based on mT5 SPM tokens. Then, Table 4 contains the number of paragraph examples that are too long to fit into the 1024 SPM maximum context length that is used by the metrics trained in this work.

B Additional Results

Figure 9 contains the system- and segment-level accuracy correlations on the en-de and en-ru language pairs from WMT'22 MQM that were not presented in the main body of the paper. Figure 10 contains the correlations for all 3 language pairs but uses Pearson correlation instead of pairwise accuracy.

Figure 11 shows the correlation between the two ways to apply a segment-level metric to paragraph-level data, directly scoring the paragraph or averaging the k segment scores, on the en-ru and zh-en WMT'22 MQM dataset.

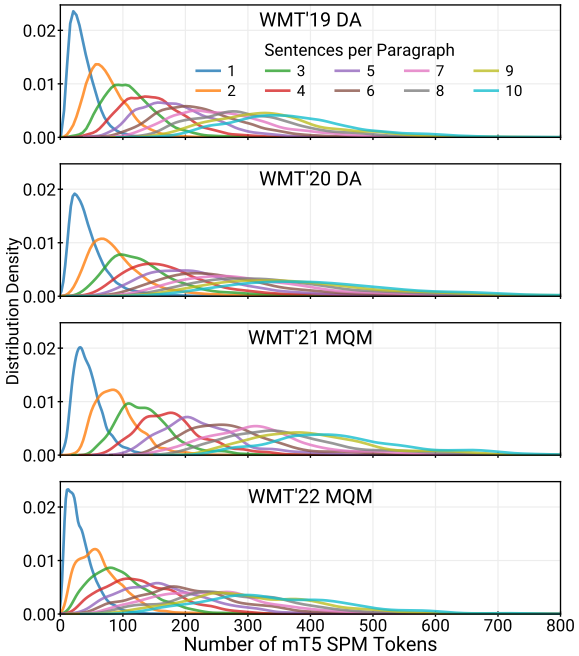

Figure 8: The distribution of the length of the hypothesis translations for the direct assessment (DA) and MQM datasets for a given number of sentences per paragraph.

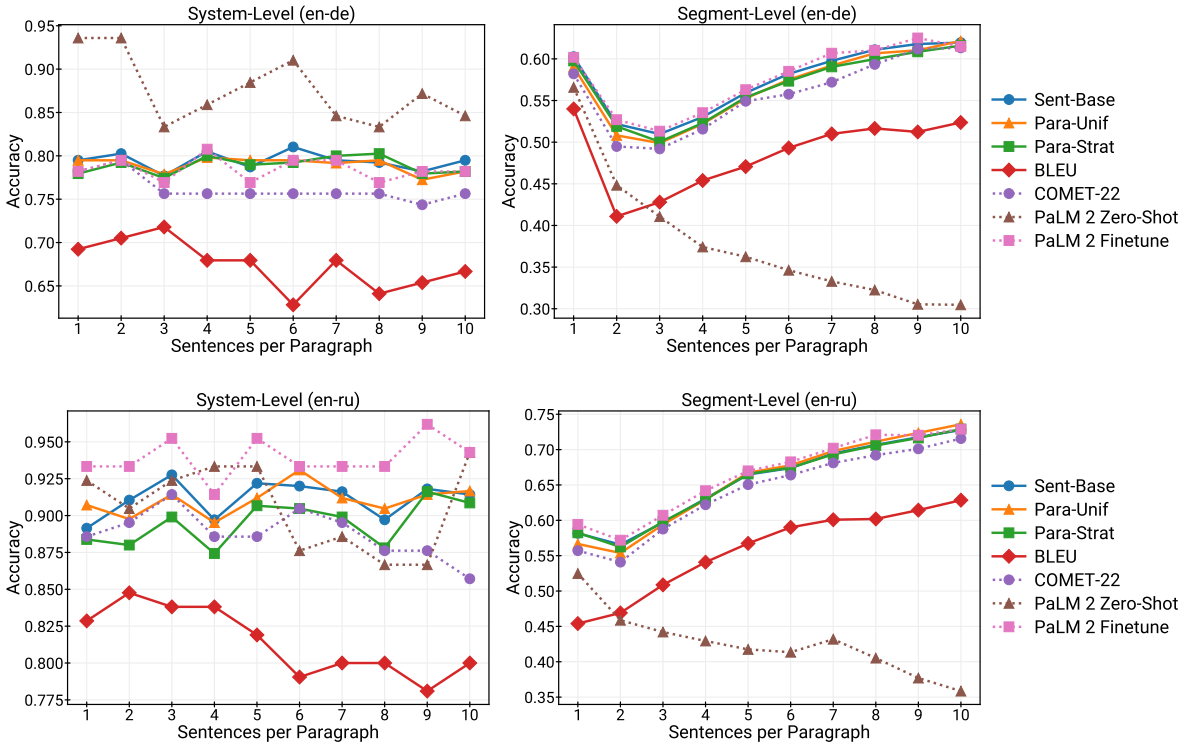

Figure 9: System- and segment-level accuracy results for the en-de and en-ru language pairs on the paragraph-level WMT'22 MQM data for different numbers of k sentences per paragraph. In general, the system-level correlations are relatively flat and the segment-level correlations increase as the number of sentences per paragraph increases. BlonDE is not included because it only supports English.

Abstract

Behavioral testing in NLP allows fine-grained evaluation of systems by examining their linguistic capabilities through the analysis of input-output behavior. Unfortunately, existing work on behavioral testing in Machine Translation (MT) is currently restricted to largely handcrafted tests covering a limited range of capabilities and languages. To address this limitation, we propose to use Large Language Models (LLMs) to generate a diverse set of source sentences tailored to test the behavior of MT models in a range of situations. We can then verify whether the MT model exhibits the expected behavior through matching candidate sets that are also generated using LLMs. Our approach aims to make behavioral testing of MT systems practical while requiring only minimal human effort. In our experiments, we apply our proposed evaluation framework to assess multiple available MT systems, revealing that while in general pass-rates follow the trends observable from traditional accuracy-based metrics, our method was able to uncover several important differences and potential bugs that go unnoticed when relying only on accuracy.[1]

1 Introduction

Automatic evaluation metrics such as BLEU (Papineni et al., 2002) and COMET (Rei et al., 2020) are the primary means of measuring the translation quality of MT systems. Researchers and practitioners rely on them for comparing systems, detecting regressions, and making deployment decisions. This poses an important concern: such metrics typically aggregate the performance of systems across a set of sentences into single scores. Unfortunately, these metrics by design tend to overlook specific infrequent but important error cases, making it difficult to reliably detect such issues in practice.

Property	Translation Errors
Integers	7000000 → 70.000.000
Decimals	500.75 → 500.75
Large Numbers	1.366 billion → 1.366 Milliarden
Idioms	ins and outs → Ins und Outs
Currencies	BRL → RL
Physical Units	miles → km
Web Terms	www.onlinegrocery.com → www.onlineegrocery.com
...	...

Table 1: Subset of linguistic properties tested with our proposed method, and examples (source → translation) of translation errors found in En→De MT models.

Behavioral testing, originally developed as a type of software testing (Beizer and Wiley, 1996), has been proposed as an approach that can alleviate such kinds of problems in natural language processing (Ribeiro et al., 2020). Behavioral tests focus on assessing a system's fine-grained linguistic capabilities by validating input-output behavior in a controlled fashion.

Table 1 shows examples of typical issues of MT systems that could be covered by behavioral tests. We argue that the availability of a comprehensive behavioral test suite for MT would be of high practical value: It would allow understanding how exactly two MT models differ, or to block an MT system from being deployed if a passing threshold for a certain linguistic capability is not met.

However, there are currently two major limitations that arise when attempting to apply behavioral testing to MT. First of all, behavioral testing was originally designed for evaluating systems characterized by a relatively small output space. For instance, Ribeiro et al. (2020) investigate sentiment classification, duplicate question detection, and machine comprehension. In contrast, the output space of MT systems grows exponentially as tokens are generated. Secondly, behavioral testing often requires rigid templates to create examples and their

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 1014–1030
December 6–7, 2023.

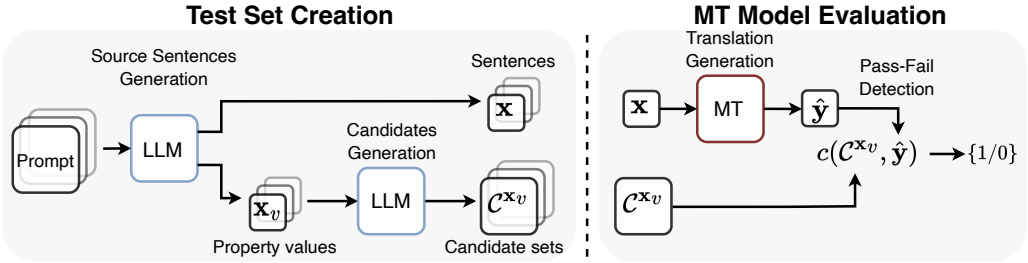

Figure 1: Pipeline of the proposed approach. Left: For each property type, a test set is created via a LLM, composed of source sentences $\mathbf{x}$ with property values $\mathbf{x}_v$ (§3). Subsequently, a candidate set of valid translations of each property value $\mathcal{C}^{\mathbf{x}_v}$ is generated (§4). Right: During evaluation, the translation $\hat{\mathbf{y}}$ generated by an MT model is compared against the candidate sets, and a pass-fail decision is made (§5).

corresponding labels, which involves a costly human effort to develop and expand to additional use cases. Otherwise, the diversity of sentences in the resulting test suite is too limited.

Several recent works have partially addressed these limitations. For example, Wang et al. (2021); Raunak et al. (2022) propose MT-specific test sets which include the ability to handle large output space. Yang et al. (2022) address the limitation of rigid templates. To the best of our knowledge, no prior work has addressed both limitations for MT.

In this study, we aim to bridge this gap by leveraging LLMs with in-context learning to automate the creation of behavioral tests in MT for the first time. Our main contributions are as follows:

- We use LLMs to automate the generation of a diverse set of source sentences for behavioral testing. Sentences are generated to exhibit the specific language property that is being tested.
- We verify whether an MT system's output contains an accurate translation of the language property that is being tested. To this end, we propose using LLMs to generate candidate sets of ground-truth translations of the property values in cases where exhaustive candidate sets are plausible. Otherwise, we generate contrastive candidates and evaluate via semantic similarity measures.
- We present an evaluation framework to robustly compute pass rates of MT models across various language properties, and show results for widely used open-source models on three language pairs.

2 Behavioral Testing for MT

Behavioral testing, as proposed by Ribeiro et al. (2020), uses input-output pairs tailored to evaluate a model capability to correctly handle certain language properties. The goal is to complement traditional aggregated accuracy scores, which, while useful by themselves, often fail to capture long-tail phenomena. In practice, manual inspection of system outputs is often crucial to make up for this shortcoming. Automated behavioral testing provides a more reliable and less cumbersome alternative that can reduce or eliminate the need for manual inspection, provided that a sufficient range of language properties is tested. Test results are presented in the form of a table of pass rates (one pass rate for each tested property) that is informative to decide on consequent steps, e.g. whether bugs must be addressed before deployment. Note that the creation of a *sufficiently comprehensive* behavioral test suite depends crucially on whether its creation can be automated to a high degree, which is also our main design goal in this work.

We are particularly interested in a specific type of behavioral tests, *minimal functionality tests* (MFTs) (Ribeiro et al., 2020).[2] In the context of MT, an MFT measures a model's ability to translate particular property values that appear naturally embedded in some given source sentences.

Figure 1 illustrates our proposed framework. First, a source sentence $\mathbf{x} = \{\boldsymbol{x}_1 \cdots, \boldsymbol{x}_{|\mathbf{x}|}\}$ that contains a tagged property value $\mathbf{x}_v \subseteq \mathbf{x}$ is generated (§3). For instance, if our test property is physical unit translation, we might have $\mathbf{x}$=*"I ran 3 miles."* and $\mathbf{x}_v$=*miles*. A main challenge comes from the fact that there is a potentially large space of correct translations. However, note that by design MFTs only need to check whether the property under test is translated correctly, while un-

[2] Ribeiro et al. (2020) also propose *directional* and *invariance* tests which check how model outputs change under certain input perturbance, but these appear less applicable to MT given the potentially large space of correct translations.

```
You are an assistant that generates sentences where only appears one B = {property}.
Don't be repetitive, change the topic and B between sentences. Write every B inside [].
B must happen only once in each sentence and can only contain {property}.

Write 3 examples.

- {Source sentence demonstration #1}
- {Source sentence demonstration #2}
- {Source sentence demonstration #3}

Now write 10 more diverse sentences itemizing them with '-':
```

Figure 2: General template of the prompt used for generating batches of source sentences.

related translation errors should be ignored. In many cases, this reduces the space of correct translations to a manageable size. We therefore propose to automatically generate a candidate set $\mathcal{C}^{\mathbf{x}_v}$ (either exhaustive or contrastive; see §4) and then apply a pass-fail detector that uses either string matching or semantic similarity measures (§5). In our example, we might generate an exhaustive candidate set $\mathcal{C}^{\mathbf{x}_v}$=$\{$*Meilen*, *mi*$\}$ for the case of translating into German. We now aim to evaluate an MT model $f : \mathbf{x} \mapsto \hat{\mathbf{y}}$. To do so, we compare $\hat{\mathbf{y}}$ against $\mathcal{C}^{\mathbf{x}_v}$. A correct translation $\hat{\mathbf{y}}$=*"Ich lief 3 Meilen."* would match the candidate set and therefore pass the test, while a typical incorrect translation $\hat{\mathbf{y}}$=*"Ich lief 3 km."* does not match the candidate set and therefore fails the test.

Given this general overview of our method, we now turn to a more precise description of each proposed step in the following sections.

3 Source Sentence Generation

To create source sentences for testing a certain language property, we pose several desiderata: Sentences should be *diverse* (e.g. not rely only on a handful of templates), *natural*, *numerous* enough to yield statistical significance, and *contain a property value* associated with our tested property.

Note that existing approaches often struggle to generate diverse test sets due to the reliance on hand-crafted templates (Wang et al., 2021). To overcome this shortcoming, we design a general template for prompting LLMs, in our case ChatGPT[3], OpenAI's model built on InstructGPT (Ouyang et al., 2022). This allows us to generate diverse source language sentences that contain property values suitable for testing different capabilities (see prompt[4] in Figure 2). We instantiate the prompt once for every language property that we wish to include in our test suite.

Candidates Examples
kilometers → kilómetros, km
watts → vatios, W
meters per second → metros por segundo, m/s

Table 2: Examples of En→Es set of candidates generated by ChatGPT.

To simplify the later verification step, we generate sentences that contain exactly one such property value $\mathbf{x}_v$.[5] We generate source sentences with brackets around the property value for easy parsing. A possible test sentence for the property of translating decimal numbers might look as follows:

$$\text{The company received [} \overset{\text{property value}}{\overbrace{\text{4200.4}}} \text{]€.} \qquad (1)$$

Note that brackets are removed before passing the sentence to the MT model.

We apply basic filters to remove duplicated sentences, examples with more than one property value, or those composed of more than one sentence. We repeatedly feed the same prompt to the LLM, and stop the generation process when reaching 1,000 sentences after filtering. Our experiments (§9) indicate that ChatGPT is able to generate sentences of adequate quality and diversity.

4 Candidates Generation

Next, in order to be able to verify whether an MT system correctly translated the property value in the source sentence, we automatically generate valid translation candidate sets for each property value. For some properties, such as number translation, we create exhaustive or near-exhaustive candidate sets. For other properties where the number of valid translations would be too big to do so, we instead

[3] `gpt-3.5-turbo` API accessed on May 2023.

[4] We set temperature=0.9, presence_penalty=2.

[5] For some types of properties, multiple property values may be more appropriate. This is left for future work.

create contrastive candidate pairs that demonstrate desired and undesired behavior. Note that candidate sets only need to be created once and can then be re-used for every tested system.

4.1 Near-Exhaustive Candidate Sets

In this approach, we follow Raunak et al. (2022) in creating a set of all valid translations of each property value in the test (see example in Table 2). However, instead of manually designing candidate sets, we propose using the in-context learning (Brown et al., 2020) and multilingual capabilities of instruction-tuned LLMs (Wei et al., 2022) to accomplish the task. For each property value $\mathbf{x}_v$, we generate a set of translation candidates $\mathcal{C}^{\mathbf{x}_v}$ with ChatGPT (`gpt-3.5-turbo`) (see prompt[6] in Figure 3). We tried to design demonstrations to encompass both correctness and completeness, including possible inflections. An example of demonstrations used for the currencies test can be seen in Appendix B. Note that while we aim for completeness, i.e. all valid translations should be included in the candidate set, in practice we found that some rare translation choices may not be included in the automatically generated candidate sets. However, this will not impact pass-rates much because by nature rare translation choices appear in the MT system's output only in rare situations. In §9 we perform a human assessment of the reliability of the generated candidate sets.

4.2 Contrastive Candidate Pairs

Some property values can span multiple words on the source side, potentially increasing the number of valid translations drastically. An example is idiomatic expressions, where there is an increased risk that the candidate set cannot exhaust all possibilities. To mitigate this issue, we propose using *contrastive* candidate sets an alternative approach.

Given a source property value, we generate a *contrastive* candidate set $\mathcal{C}^{\mathbf{x}_v}_{\text{contra}}$ formed by a correct translation $c^{\mathbf{x}_v}_{\text{corr}}$, and a foil (incorrect) translation $c^{\mathbf{x}_v}_{\text{foil}}$. Appendix C shows an example prompt. Intuitively, an MT model should pass the test sentence if its translation is closer to $c^{\mathbf{x}_v}_{\text{corr}}$ than it is to $c^{\mathbf{x}_v}_{\text{foil}}$.

5 Pass-Fail Detector

Equipped with these candidate sets, we now wish to mark every MT-translated sentence as either *pass* or *fail*. Depending on whether near-exhaustive or contrastive candidate pairs are used, we design pass-fail detectors based on string matching or semantic similarity, respectively.

As it is our goal to design tests that target specific language properties, our pass-fail detectors should only detect cases where the property value under the test is translated incorrectly. Unrelated translation errors should not cause a sentence to be marked as incorrect.[7]

Algorithm 1: Similarity score between translation and contrastive candidate.

Input: $\hat{\mathbf{y}}$: model translation; c: candidate translation; e: encoder
Output: max_sim$(\hat{\mathbf{y}}, c)$
max_sim $\leftarrow -\infty$
$n \leftarrow |c|$
$\mathcal{G}_{\hat{\mathbf{y}}} \leftarrow n$-gram$(\hat{\mathbf{y}}, n)$
$\boldsymbol{c}_{\text{emb}} \leftarrow e(c)$
for $\mathbf{g} \in \mathcal{G}_{\hat{\mathbf{y}}}$ **do**
  $\boldsymbol{g}_{\text{emb}} \leftarrow e(\mathbf{g})$
  if $sim(\boldsymbol{g}_{emb}, \boldsymbol{c}_{emb}) > max\_sim$ **then**
    max_sim $\leftarrow$ sim$(\boldsymbol{g}_{\text{emb}}, \boldsymbol{c}_{\text{emb}})$
return max_sim

5.1 String Matching for Near-Exhaustive Candidate Sets

For the near-exhaustive candidate sets, we define a pass-fail function $c(\hat{\mathbf{y}}, \mathcal{C}^{\mathbf{x}_v}) \in \{0, 1\}$ that takes the model's translation $\hat{\mathbf{y}}$, and the candidates set $\mathcal{C}^{\mathbf{x}_v}$, and returns 1 (pass) if $\hat{\mathbf{y}}$ has a valid translation of the property value, i.e. if it has an element in $\mathcal{C}^{\mathbf{x}_v}$, and 0 (fail) otherwise:

$$c(\hat{\mathbf{y}}, \mathcal{C}^{\mathbf{x}_v}) = \begin{cases} 1 & \text{if } \hat{\mathbf{y}} \cap \mathcal{C}^{\mathbf{x}_v} \neq \emptyset \\ 0 & \text{otherwise.} \end{cases} \quad (2)$$

Specifically, we consider as pass an exact case-insensitive substring matching. Following Example 1, where $\mathbf{x}_v = 4200.4$, if we are evaluating the En→De decimal numbers translation capabilities of the model, we would consider the model passes the test if it outputs '4200,4', or '4.200,4'.[8]

[6] We use the same set of parameters as for the source sentence generation.

[7] For our purposes, we do not consider whether the translated property is placed at the correct position in the target sentence, but only whether it is correct when considered in isolation. We argue that errors related to fluency and reordering are better evaluated through established accuracy-based metrics.

[8] Note that this involves a design decision: The test case writers must make a decision whether or not the added decimal point is acceptable for their particular use cases.

```
You are a {source_lang}-{target_lang} translator. Given a {property}, write as many valid {target_lang}
translations as you can. Use "|" to separate between valid translations.
Write "NA" if unable to accomplish the task.

{Source property #2}
{Candidates set source property demonstration #2}
{Source property #3}
{Candidates set source property demonstration #3}

{Source property}
```

Figure 3: General template of the prompt used for generating near-exhaustive sets of candidate translations.

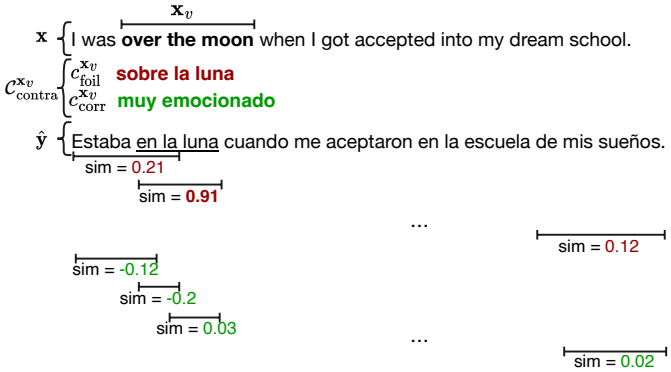

Figure 4: Example of the Contrastive Candidate Pairs approach, where `sim` indicates the semantic similarity between the correct candidate ('muy emocionado') and the 2-grams (in green), and the foil candidate ('sobre la luna') and the 3-grams of the MT translation (in red).

5.2 Semantic Similarity for Contrastive Candidate Pairs

For measuring the closeness of the property value translation to the contrastive candidates, we propose relying on the semantic similarity of word sequences representations extracted by a multilingual encoder (Reimers and Gurevych, 2019, 2020).[9] However, directly measuring the similarity between the translation of the property value and the candidate sets may be unreliable since they may differ in length and the location of the translation is unknown due to lack of word-level alignment. Instead, we propose that, for each candidate $c^{\mathbf{x}_v}_{\text{corr}}$ or $c^{\mathbf{x}_v}_{\text{foil}}$, we split the model's translation into n-grams, where n is the number of words of the current candidate. Then, we measure the similarity between each of the n-grams and the candidates.

Given a translation and the *contrastive* candidate set $\mathcal{C}^{\mathbf{x}_v}_{\text{contra}}$ formed by the correct and foil candidates, we define the pass-fail function as:

$$c(\hat{\mathbf{y}}, \mathcal{C}^{\mathbf{x}_v}_{\text{contra}}) = \begin{cases} 1 & \text{if } \max\_\text{sim}(\hat{\mathbf{y}}, c^{\mathbf{x}_v}_{\text{corr}}) \geq \max\_\text{sim}(\hat{\mathbf{y}}, c^{\mathbf{x}_v}_{\text{foil}}) \\ 0 & \text{otherwise.} \end{cases} \tag{3}$$

Algorithm 1 formalizes the computation of max_sim function, Figure 4 shows an example.

6 Evaluation Metrics

Having established pass-fail detection for individual sentences, the final step is to compute aggregated *pass rates* across test sets. Appealingly, pass rates are naturally expressed as percentages, making them intuitive to interpret.

6.1 Macro Pass Rate

Let us assume that we have computed pass-fail results across a behavioral test set consisting of N test cases (sentences). From a statistical viewpoint, we have access to a sample $\mathcal{X} = \{c(\hat{\mathbf{y}}^n, \mathcal{C}^{\mathbf{x}^n_v})\}_{n=1}^{N}$, drawn from some unknown distribution over test cases, F. The expectation of the true pass rate can be computed as follows:

$$\text{PR}^{(\mathcal{X})} = \frac{1}{N} \sum_{n}^{N} c(\hat{\mathbf{y}}^n, \mathcal{C}^{\mathbf{x}^n_v}) \tag{4}$$

[9] Employing LLMs is also possible but not explored here because it needs to be applied for every evaluated MT system, incurring higher computational costs.

Table 3: Translation scores of the different models used in FLORES-200 devtest set.

One issue that arises in practice is that property values themselves follow a long tail pattern: Certain values appear relatively frequently, while many other values appear only once across the generated test set. This can make pass rates overly sensitive to whether models happen to perform well for these particular values. To mitigate this issue, we assume a generative story in which property values are drawn from a uniform distribution, and consequently compute the expected pass rate as the macro average across property values:

$$\text{MPR}^{(\mathcal{X})} = \frac{1}{|\mathcal{V}|} \sum_{v \in \mathcal{V}} \frac{1}{N_v} \sum_{i}^{N_v} c(\hat{\mathbf{y}}^i, \mathcal{C}^{\mathbf{x}_v^i}) \quad (5)$$

where $\mathcal{V}$ refers to the set of distinct property values, and N_v to the number of examples associated with each specific property value.

6.2 Confidence Intervals

Although previous work performing behavioral testing for MT shows point estimate scores, confidence intervals provide a more reliable approach to statistical analysis, as they quantify the uncertainty associated with that estimate, and ensure the sample size is large enough. To compute confidence intervals for our estimator MPR we use the Bootstrap method (Efron, 1979), which performs sampling with replacement from $\mathcal{X}$, generating K resamples $\{\mathcal{Y}^1, \cdots, \mathcal{Y}^K\}$, from which we compute their corresponding macro pass rates $\{\text{MPR}^{(\mathcal{Y}^1)}, \cdots, \text{MPR}^{(\mathcal{Y}^K)}\}$ to construct the bootstrap distribution MPR_{boot}. Assuming the distribution of $\mathcal{X}$ is a reasonable approximation of the population distribution F, confidence intervals can be derived from MPR_{boot}. For that purpose, we compute the percentile bootstrap interval for $\alpha = 0.05$ provided by SCIPY library (Virtanen et al., 2020).

6.3 Paired Bootstrap

The paired bootstrap is a statistical resampling technique used to assess the uncertainty and make inferences about the difference between two samples. Paired bootstrap allows us to compare the property's sample of passes/fails for two different models (Koehn, 2004). By following the resampling process outlined in the previous section, if a model consistently outperforms the other in 95% of the iterations, we can assert with 95% statistical significance that it is superior.

7 Properties to Test

We design a number of tests and use our proposed framework to evaluate MT models in multiple properties. The chosen properties, also studied in the literature (Wang et al., 2021; Raunak et al., 2022), have two important qualities that make them useful for evaluating translation systems: vital for producing high-quality translations, yet posing a challenge when assessing through conventional evaluation metrics.

Numbers. We conduct independent assessments for integers (e.g. 1887), decimals (e.g. 154.32), and large numbers (e.g. 200 billion). Large numbers have the format "integer/decimal million/billion/trillion". We create near-exhaustive candidate sets of valid number translations and check if the translation matches any candidate.

Physical Units. We build near-exhaustive candidate sets for evaluating the translations of diverse units including those related to weight, length, time, or temperature *inter alia* (e.g. inches). Translations are evaluated by string matching.

Emojis, Names, and Web Terms. Via string matching we check whether the translated text retains the same property instantiation found in the

source text. Candidate sets for these tests are thus considered to be exhaustive.

Currencies. We consider currencies appearing in the ISO code format (e.g. EUR). Near exhaustive candidate sets are built allowing translations into the same ISO code, variations of the currency name or its symbol (e.g. for En→Es: EUR/euro/euros/€), then a string matching pass-fail detection is employed.

Idioms. Idiomatic expressions pose significant challenges for MT systems due to their non-literal nature and potential large sequence length. We use idioms as a test bench for the use of contrastive candidate pairs (incorrect literal translation candidate vs. correct meaning translation) and semantic similarity detection procedure.

8 Models Comparison

In this section, we introduce the tested models and present results obtained via standard metrics as well as our proposed framework.

8.1 Experimental Setup

We test widely-used open-source MT models, as well as a commercial system. We aim to select models that perform very strongly, while also differing in some important aspects (e.g. bilingual vs. multilingual).

In the multilingual domain, we experiment with the 600M and the 3.3B parameters models of No Language Left Behind project (NLLB) (Team et al., 2022), and the Many-to-Many (MLM-100) family of Multilingual models (Fan et al., 2021) (418M and 1.2B parameters models). Additionally, we evaluate the WMT21: multilingual (7 En→X directions) 4.7B dense model (Tran et al., 2021), part of Meta's WMT-21 News Translation task participation (Barrault et al., 2021). We also assess OPUS-MT (Tiedemann and Thottingal, 2020) En→Es and En→De bilingual models trained on OPUS dataset (Tiedemann, 2012). Lastly, we included results from an anonymous commercial system.

Besides our proposed metrics, we also evaluate the models on FLORES-200 (Team et al., 2022) in En→De, En→Es, and En→Ja via string-based metrics spBLEU[10] (Papineni et al., 2002) and ChrF[11] (Popović, 2015) as implemented in SACREBLEU (Post, 2018), as well as the neural-based metric COMET-22[12] (Rei et al., 2020).

Table 4: Examples flagged as failed translations.

8.2 General Translation Accuracy

We first measure general translation performance across language pairs for standard reference-based metrics (Table 3). The commercial system performs best across the board, followed by the WMT21 model. In the following sections, we dive deeper into the different capabilities.

8.3 Behavioral Tests Results

As an illustrative example, macro pass rate confidence intervals across property types and models for the En→De direction are presented in Figure 5. The complete results can be found in Appendix E.

Commercial system is most consistent across properties. This is especially true for emoji translations, where open-source models lack most emojis in their vocabulary. However, it is noteworthy that its performance is subpar in the context of En→Es integers and En→Ja large numbers. After manual inspection (see examples in Table 4), we attribute the lower integers translation performance to the fact that it uses the comma as the thousands separator. Note that this behavior can be acceptable depending on the country; behavioral tests must be designed to reflect the intended behavior.

Bilingual models struggle with web terms. Although the multilingual models mostly manage to preserve web terms without alteration, both tested bilingual models (for En→Es and En→De) underperform in that property (see Figure 5 and Figure 6 top). Most fail cases contain Spanish words inside the translated web terms (Table 4). We hypothesize that this occurs because they are trained to exclusively translate into Spanish, which consequently hinders their ability to generate content in other

[12] `Unbabel/wmt22-comet-da`

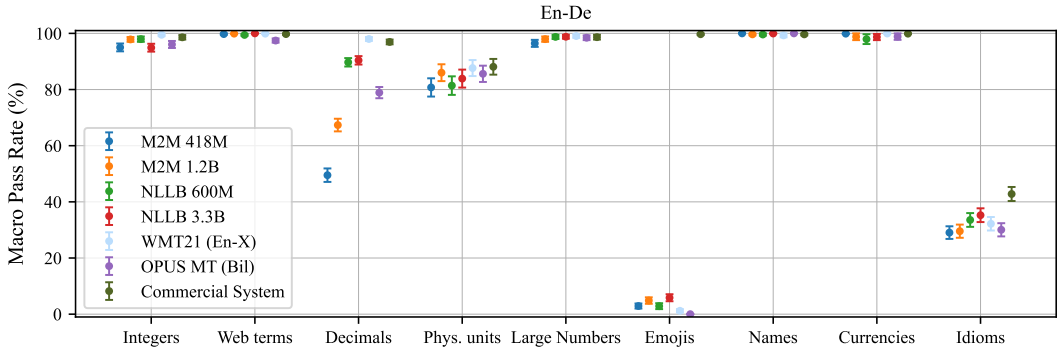

Figure 5: En→De macro pass rates and confidence intervals across tested systems.

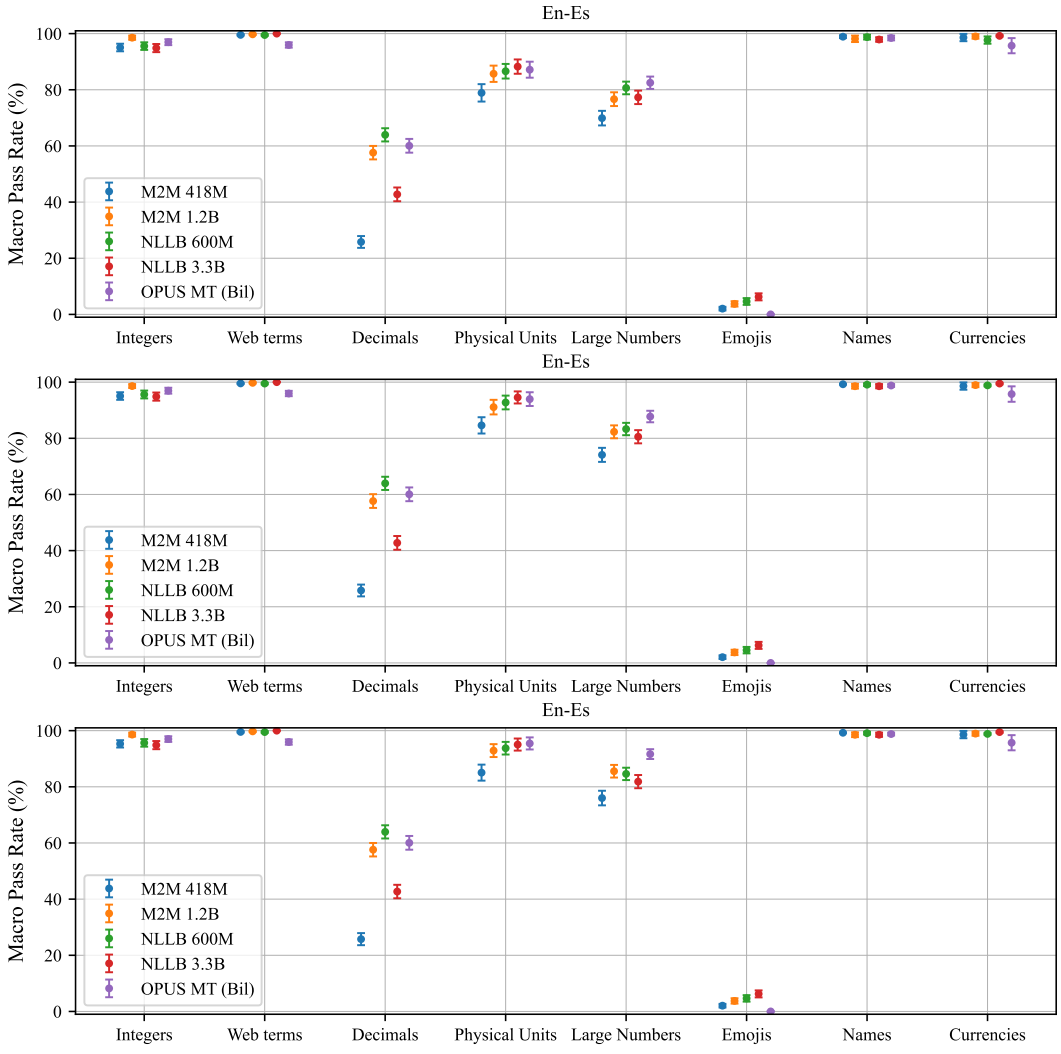

Figure 6: From top to bottom, En→Es Confidence Intervals after each annotation iteration (see §9).

languages, and is therefore an intrinsic limitation of bilingual models.

Scaling models help increase capabilities. In most of the settings, scaling the model of the same family shows increased performance, for instance, physical units and idioms in Figure 5. However, there are some counter-examples, like in the case of En→Ja decimals and integers tests.

WMT21 is the strongest open-source model. The WMT21 model consistently exhibits superior performance compared to other open-source models in both En→De and En→Ja tests. In Table 5 we show how paired bootstrap enables model comparison, revealing that WMT21 outperforms other

models in the integers En→De test.

Idioms. Results for the Idioms property test are presented in Appendix D. The ability to translate idioms is generally low (i.e. overly literal), in accordance with recent findings (Dankers et al., 2022). It is worth noting that results are similar in the three language directions, with the commercial system and NLLB 3.3B showing comparable performance.

9 Reliability of the Proposed Approach

To assess the reliability of the proposed approach, in this section we analyze the robustness of source sentence generation and pass-fail detection.

9.1 Analysis of Source Sentence Generation

One potential concern with the proposed method is whether the generated source sentences are diverse enough and do not become repetitive after a few rounds of generation.[13] A standard method for quantifying the diversity in a corpus is *distinct n-grams* (Li et al., 2016), which computes the ratio of unique n-grams to the total number of n-grams present. In our case, we are interested in assessing the diversity of each generated source sentence compared to the previous generations. To that end, we propose a metric to measure this aspect. Given the set of unique n-grams generated up to sentence $\mathbf{x}_t$ ($\mathcal{G}^n_{\mathbf{x}_{<t}}$), we measure the proportion of unique

[13]The *naturalness* of outputs, another potential concern, has been extensively dealt with elsewhere (Ouyang et al., 2022).

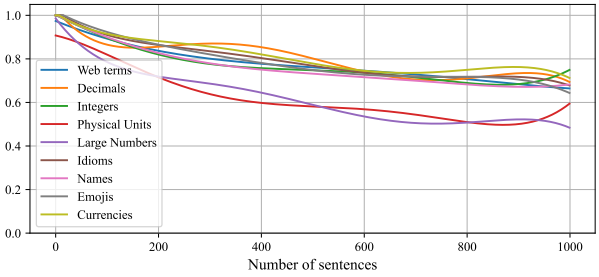

Figure 7: 3-gram diversity scores ($\text{div}_3(\mathbf{x}_t)$) along generation steps across different properties.

Property	Sentences kept	Unique values
Web Terms	79.3%	92.5%
Decimals	74.1%	76.9%
Integers	62.1%	39.3%
Physical Units	83.3%	15.9%
Large Numbers	66.1%	37.1%
Idioms	83.8%	69.0%
Names	86.1%	17.9%
Emojis	88.5%	29.7%
Currencies	66.8%	5.2%

Table 6: Percentage of source sentences that pass filtering, and percentage of filtered sentences that introduce a new property value.

n-grams in each newly generated sentence ($\mathcal{G}^n_{\mathbf{x}_t}$) that are not present in $\mathcal{G}^n_{\mathbf{x}_{<t}}$:

$$\text{div}_n(\mathbf{x}_t) = \frac{\mathcal{G}^n_{\mathbf{x}_t} \setminus \mathcal{G}^n_{\mathbf{x}_{<t}}}{\mathcal{G}^n_{\mathbf{x}_t}} \quad (6)$$

Figure 7 shows 3-gram diversity along 1000 generated sentences after fitting a polynomial regression. We observe that the diversity drop is mild even after 500 sentences, where for most of the tests, 60% of newly generated 3-grams are novel.

Furthermore, we observe that the sentence generator produces sentences that comply with instructions, indicated by the high proportion of the original sentences that pass filtering. In the majority of cases, over 70% of the LLM-generated sentences successfully pass the filtering steps outlined in §3, as seen in Table 6 (middle column). The right column shows the percentage of unique values, which naturally vary strongly depending on the property.

9.2 Analysis of Pass-Fail Detection

The reliability of the proposed pass-fail detection depends mainly on whether candidate sets are (1) complete and (2) do not contain wrong candidates.

We analyze this by sampling 100 random test cases that were marked as *pass* (positives), and an-

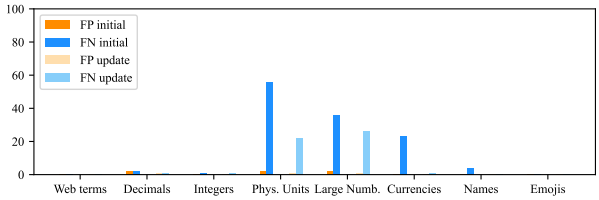

Figure 8: Error rates detected in two rounds of annotations on En→Es.

other 100 examples marked as *fail* (negatives). We manually annotate whether test results were correct or incorrect. Figure 8 shows false positives and false negatives (FP initial and FN initial). We observe that while for most properties these were low, for some test cases (namely physical units, large numbers, currencies) there were a significant number of FNs, which would lead to underestimated pass rates. We argue that erring on the side of FNs is generally preferable, because it prevents us from overestimating the strength of models, and because it would trigger a debugging effort which would quickly surface issues stemming from FNs.

To obtain more accurate pass-rates for all properties, we can manually remove candidates causing a FP and add missing candidates producing a FN. We do this for the test cases analyzed above, and then draw another random sample from both *pass* and *fail* categories. Figure 8 shows that the updated FPs and FNs are now negligible.

While in our experience, human intervention as outlined above is only a minor effort, the issue remains as to whether systems can be compared to one another without the need for human intervention, even in the presence of existing FNs. To understand this better, we plot macro pass rates with confidence intervals across annotation iterations in Figure 6. As expected, for physical units, large numbers, and currencies, pass rates move upwards. However, the effect is general across models, suggesting that relative ordering between models can be reasonably approximated in the initial attempt, i.e. without human intervention.

In addition, we assess the pass-fail detection of idioms. Given that the decision is made via semantic similarity for contrasting pairs, addressing issues in the candidate sets is more challenging. Consequently, we conducted a single evaluation iteration with 100 *pass*/*fail* examples, respectively, on two language pairs. For En→De, we observed 59 FPs / 16 FNs; En→Es had 50 FPs / 11 FNs. We hypothesize high FPs are caused by idiom and its figurative meaning being present within the source sentence, interfering with the n-grams comparison. We leave further investigation for future research.

10 Related Work

Recent works have applied behavioral testing for evaluating machine translation systems. Wang et al. (2021) designed tests for numerical translation capabilities by relying on fixed templates for source sentence generation. Raunak et al. (2022) proposed SALTED, a set of manually designed error detectors that are applied to millions of sentences from standard datasets. Beyond behavioral testing, a large number of *challenge sets* have been developed for machine translation (Popović and Castilho, 2019). Although useful, most of these evaluation tools require major human efforts for creation, evaluation, or expanding to other languages. Although there have been attempts to automatize the creation of behavioral tests (Yang et al., 2022), this has been limited to simple NLP tasks.

Our work also relates to the use of LLMs as evaluators for Machine Translation systems (Kocmi and Federmann, 2023), as well as for text generation in a broader sense (Liu et al., 2023; Xu et al., 2023), which extend the growing body of research on multi-dimensional text generation evaluation (Zhong et al., 2022; Yuan et al., 2021).

Behavioral testing aims to evaluate the behavior of systems under realistic conditions, contrasting it from the literature on adversarial data generation (Belinkov and Bisk, 2018; Zhang et al., 2021).

11 Conclusions

In this work, we have presented a method that automates the creation of behavioral tests to perform fine-grained evaluation of MT systems capabilities. We use Large Language Models to generate source sentences composed of fragments of specific language properties (integers, web terms, etc.), as well as translations of these properties. For property types formed by multiple words, we further extend the proposed method into a contrastive setting and show its usefulness in evaluating idiomatic expressions. To the best of our knowledge, our research represents the first attempt to develop MT behavioral tests by leveraging LLMs. Finally, we apply the proposed framework to evaluate open-source models on three language pairs.

A Limitations

While the proposed evaluation framework seeks to address a broad spectrum of languages, the experiments conducted in this study are limited to three language pairs. Due to its reliance on the capacity of LLMs to produce high-quality candidate translations, we cannot guarantee accurate results when applied to language pairs involving a low-resource language using current LLMs. Moreover, the method is designed to work only on properties that appear as a continuous chunk of text in both source and target languages and are not scattered across a sentence.

B Example of Demonstrations for Exhaustive Candidate Set Generation

```
You are a {src_lang}-{tgt_lang} translator. Given a {property}, write as many valid
{target_lang} translations as you can. Use "|" to separate between valid translations.
Write "NA" if unable to accomplish the task.

EUR
€|EUR|Euro

GBP
£|GBP|Pfund|Pfund Sterling|britisches Pfund|Pound Sterling

USD
$|USD|Dollar|US Dollar|amerikanischer Dollar|amerikanische Dollar|US-Dollar

{Source property}
```

Figure 9: General template of the prompt used for generating a set of candidate translations.

C Example of Demonstrations for Contrastive Candidate Pairs Generation

Foil:

```
You are an {src_lang}-{tgt_lang} literal translator. Given a sequence of words,
you have to write only a literal translation. Use "|" to separate alternatives.
Write "NA" if unable to accomplish the task.

break a leg
brich dir ein Bein|breche dir ein Bein|breche dein Bein|breche dir dein Bein

hit the ground running
im Laufen hinfallen|beim Laufen hinfallen|beim Laufen auf den Boden knallen|beim Laufen
auf den Boden fallen

put all your eggs in one basket
alle Eier in einen Korb tun|alle Eier in einen Korb setzen|alle Eier in einen Korb legen

{Source property}
```

Correct:

```
You are an {src_lang_name}-{tgt_lang_name} translator of idiomatic expressions. Given an
idiomatic expression, you have to write the translation of the figurative meaning of the
idiomatic expression. Use "|" to separate alternatives. Write "NA" if unable to accomplish the task.

She told him to “break a leg” just before he went up on stage.
figurative translation of: break a leg
viel Glück|alles Gute|viel Erfolg|du schaffst das|Sie schaffen das

He hit the ground running, so his employer was really happy.
figurative translation of: hit the ground running
voller Begeisterung angehen|enthusiastisch angehen|hart und erfolgreich arbeiten

{Source property}
```

Figure 10: Prompt used for generating contrastive candidate pairs for the case of idioms. For the literal translation (foil) we prompt ChatGPT with the idiom in isolation. Conversely, in order to facilitate the ‘understanding’ of the idiom’s figurative connotation, for generating correct candidates we present it within the full sentence.

Abstract

The Transformer architecture has two main non-embedding components: Attention and the Feed Forward Network (FFN). Attention captures interdependencies between words regardless of their position, while the FFN non-linearly transforms each input token independently. In this work we explore the role of the FFN, and find that despite taking up a significant fraction of the model's parameters, it is highly redundant. Concretely, we are able to substantially reduce the number of parameters with only a modest drop in accuracy by removing the FFN on the decoder layers and sharing a single FFN across the encoder. Finally we scale this architecture back to its original size by increasing the hidden dimension of the shared FFN, achieving substantial gains in both accuracy and latency with respect to the original Transformer Big.

1 Introduction

The Transformer architecture (Vaswani et al., 2017) has become the de facto paradigm in many Natural Language Processing (NLP) tasks, including Machine Translation (MT). Several studies have shown that Transformers exhibit impressive scaling-law properties (Gordon et al., 2021; Bansal et al., 2022; Ghorbani et al., 2022), wherein increasing the number of model parameters leads to further accuracy gains. In parallel with this architecture's impressive scaling of the numbers of parameters (Chowdhery et al., 2022), there is a growing trend towards reducing model footprints for real-world deployment, to satisfy practical constraints like latency requirements as well as memory and disk space limitations. In turn, researchers are actively exploring parameter sharing (Ge et al., 2022; Takase and Kiyono, 2023; Lou et al., 2022), reducing the dimensionality of Transformer components, and pruning components like attention heads (Voita et al., 2019; Michel et al., 2019).

Although the role of attention in learning pairwise dependencies between tokens is relatively well understood (Voita et al., 2019; Clark et al., 2019; Vig and Belinkov, 2019), the role of the Feed Forward Network (FFN) remains under-explored. Recently, Geva et al. (2021) established a connection between the FFN and attention by positing that the FFN corresponds to learnable *key-value* pairs where the weights of the first layer of the FFN corresponds to the *keys* and those of the second to the *values*. They find that the keys are able to capture salient textual patterns at each layer, and they notice that the classes of patterns tend to overlap between neighboring layers, indicating redundancy in the representation.

This observation motivates our work, where we revisit the conventional practice of allocating an individual FFN per layer. We investigate the effect of sharing and dropping the FFN across different layers on MT models. We conduct thorough experiments with different configurations of the Transformer, across different language pairs, including a low resource language pair and multilingual. In addition, we investigate the effect of the FFN in a decoder-only Transformer-based model. We find that a considerable level of redundancy exists between the encoder and decoder FFNs. As a result, we are able to eliminate the decoder FFN and share a single FFN across the encoder without significantly compromising the model's accuracy. This step leads not only to significant parameter savings but also opens up opportunities for further improvements. We also suggest using wider FFNs in the encoder while dropping the decoder's FFN, which results in a model with a similar size, but improved accuracy and reduced latency.

Finally we conduct a fine-grained analysis of the representational similarity between the original model, using one independent FFN per layer,

[*]Equal contribution.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 1031–1044
December 6–7, 2023.

and various models with shared FFNs. Our results reveal that both model accuracy and the internal representation of Transformer blocks remain stable when sharing the FFN.

2 Background and Methodology

2.1 Transformer

The Transformer architecture has two main components: attention and the FFN, which are connected via a residual connection (He et al., 2016) and layer normalization (Ba et al., 2016). In an encoder-decoder model, there are two types of attention: self-attention and cross-attention. Self-attention is used in both the encoder and the decoder, allowing the model to focus on relevant information within the same sequence. Cross-attention is exclusive to the decoder and allows it to attend to the encoder's output. Attention takes as input a set of *queries*, *keys* and *values*, projected using four $\mathbb{R}^{d_{\text{model}} \times d_{\text{model}}}$ matrices (one for the queries, keys, values, and final output) where d_{model} is the model's hidden dimension. It then applies the SOFTMAX function to allow it to focus on the most relevant values.

The FFN is applied after attention on both the encoder and the decoder and consists of the following 2-layer linear transformation:

$$\text{FFN}(\boldsymbol{x}) = \max(0, \boldsymbol{x}\mathbf{W}_1 + b_1)\mathbf{W}_2 + b_2, \quad (1)$$

where a RELU non-linearity is applied to the transformation of the input sequence ($\boldsymbol{x}$). At each layer, the FFN is parameterized with two matrices, $\mathbf{W}_1 \in \mathbb{R}^{d_{\text{model}} \times d_{\text{ff}}}$ and $\mathbf{W}_2 \in \mathbb{R}^{d_{\text{ff}} \times d_{\text{model}}}$ where d_{ff} is the *FFN dimension* and is usually set to $4 \times d_{\text{model}}$ (Vaswani et al., 2017).

Recent work has drawn a significant link between attention and the FFN (Geva et al., 2021), wherein $\mathbf{W}_1$ and $\mathbf{W}_2$ assume roles akin to the *keys* and *values* to an unnormalized attention where the input ($\boldsymbol{x}$) acts as the *query*. Unlike regular attention, the FFN employs a RELU, which allows *multiple* keys to significantly contribute to the final output (Geva et al., 2021). Additionally, these keys correspond to an inventory of salient patterns that are learned from the training data. Geva et al. (2021) suggest that at the lower layers the FFN learns shallow syntactic patterns and progressively learns deep semantic patterns on the deeper layers. Moreover, the authors find that there's a substantial overlap between patterns captured by adjacent layers, indicating that there are redundancies in the FFNs and suggesting a better allocation of these parameters might be beneficial for performance.

2.2 Sharing and Widening the FFN

The vanilla Transformer allocates one FFN for each layer of the encoder and decoder, i.e. FFN_i^{enc} or FFN_i^{dec}, respectively. Excluding embedding parameters, these FFNs occupy around two thirds of the parameter budget, while attention occupies the remaining third[1]. Earlier work found that constraining the parameterization of the decoder FFNs causes no degradation in accuracy (Ge et al., 2022). In this work, we share the parameters of the FFN across layers and/or across the encoder and decoder to minimize redundancy between FFNs.

Let N_{enc}, N_{dec} be the numbers of encoder and decoder layers, respectively. We consider multiple configurations for parameter sharing as follows:

- One $\textbf{FFN}_{all}^{enc}$ for the whole encoder:

  $$\text{FFN}_i^{enc}(\cdot) \overset{\text{tied}}{=} \text{FFN}_{all}^{enc}(\cdot), \forall i : 1 \leq i \leq N_{enc}$$

- One $\textbf{FFN}_{all}^{dec}$ for the whole decoder:

  $$\text{FFN}_j^{dec}(\cdot) \overset{\text{tied}}{=} \text{FFN}_{all}^{dec}(\cdot), \forall j : 1 \leq j \leq N_{dec}$$

- One $\textbf{FFN}_{all}^{encdec}$ for both the encoder and the decoder:

  $$\text{FFN}_i^{enc}(\cdot) \overset{\text{tied}}{=} \text{FFN}_j^{dec}(\cdot) \overset{\text{tied}}{=} \text{FFN}_{all}^{encdec}(\cdot),$$
  $$\forall i, j : 1 \leq i \leq N_{enc}, 1 \leq j \leq N_{dec}$$

Additionally, we explore modifying the dimension of the shared FFN, which we denote as $d_{\text{ff}'}$. Setting $d_{\text{ff}'} > d_{\text{ff}}$ widens the shared FFN while $d_{\text{ff}'} < d_{\text{ff}}$ narrows it. We also consider the extreme cases of setting $d_{\text{ff}'}$ to 0 or to $(N_{enc} + N_{dec}) \times d_{\text{ff}}$ (and beyond). Setting $d_{\text{ff}'} = 0$ is equivalent to dropping the FFN[2] while setting $d_{\text{ff}'} = (N_{enc} + N_{dec}) \times d_{\text{ff}}$ is akin to sharing the concatenation of all individual FFNs.

Sharing the FFNs directly affects the number of parameters and, to a certain extent, latency. For instance, sharing FFN_{all}^{enc} for the whole encoder reduces the number of parameters by $(N_{enc} - 1) \times 2 \times d_{\text{model}} \times d'_{\text{ff}}$[3]; whereas removing the FFN on the

[1] Ignoring layer normalization, there are $4 \times d_{\text{model}} \times d_{\text{model}}$ parameters for attention vs $2 \times d_{\text{model}} \times d_{\text{ff}} = 8 \times d_{\text{model}} \times d_{\text{model}}$ parameters for the FFN, assuming $d_{\text{ff}} = 4 \times d_{\text{model}}$.

[2] In our experiments without the FFN (i.e., $d_{\text{ff}'} = 0$) we remove the residual connection and layer normalization associated with it, as they become redundant.

[3] Plus the layer normalization parameters, which we are ignoring for simplicity.

decoder, i.e., setting $d_{\text{ff}'} = 0$ for FFN^{dec}_{all}, reduces the parameters by $(N_{dec}) \times 2 \times d_{\text{model}} \times d'_{\text{ff}}$ and reduces the amount of computation to be done. This is particularly important during inference since the forward pass of the decoder is autoregressive, and changing the decoder's FFN dimension has a higher latency impact than on the encoder.

Since different configurations have different impacts, we analyse the trade-off between model size, latency, and accuracy: (i) How many parameters can be shared/pruned with negligible (if any) accuracy degradation? (ii) Are the encoder and decoder FFNs affected similarly? (iii) Keeping the same model size, can the FFN parameters be allocated more efficiently?

We propose a novel configuration, which we call the *One Wide FFN* model, consisting of a single shared wide FFN on the encoder and no FFN on the decoder. To keep the number of parameters the same as in the baseline, we increase the shared FFN dimension accordingly: FFN^{enc}_{all} with $d_{\text{ff}'} = (N_{enc} + N_{dec}) \times d_{\text{ff}}$.

For completeness, we include similar experiments on the attention mechanism in Appendix B. These experiments show that, contrary to the FFN, individual layer-specific attention weights are more important and not as redundant, as sharing the attention leads to significant accuracy drops.

2.3 Representational Similarity

Besides investigating the impact on accuracy, we study the similarity between different models in terms of their *internal representations* and the *semantic space* they produce.

We use Linear Centered Kernel Alignment (CKA, Kornblith et al., 2019) to measure the similarity between the internal representations of different models. CKA uses inner products to estimate how similar the kernel matrices of two different representations are, and is based on the Hilbert-Schmidt Independence Criterion (HSIC, Gretton et al., 2005), a statistical measure of independence of two random variables. Linear CKA uses the dot product as a kernel and can be written as:

$$\text{CKA}(\mathbf{A}, \mathbf{B}) = \frac{||\mathbf{A}\mathbf{B}^{\text{T}}||^2_{\text{F}}}{||\mathbf{A}^{\text{T}}\mathbf{A}||_{\text{F}}||\mathbf{B}^{\text{T}}\mathbf{B}||_{\text{F}}},$$

where $||\cdot||_{\text{F}}$ is the Frobenius norm while $\mathbf{A}$ and $\mathbf{B}$ are mean-centered (i.e., we subtract the mean) feature matrices of the layers under comparison, computed on the same dataset. Both matrices are $n \times d$, where n is the number of sentences in the dataset and d is the output dimension of the component, and are obtained by averaging the activation of all tokens in each sentence[4]. The linear kernel is straightforward to compute and Kornblith et al., 2019 report strong empirical performance of linear CKA compared to other kernels and methods.

To measure the similarity between the semantic spaces of different models, we use Local Neighborhood Similarity (LNS, Boggust et al., 2022). Local neighborhood similarities have been previously been used in analyzing semantic shifts in word embeddings (Hamilton et al., 2016). The premise of LNS is that two semantic spaces are similar if a sentence has similar neighbors in the two spaces. The LNS of a sentence s between models 1 and 2 is defined as:

$$\text{LNS}(s) = Sim(k\text{-NN}_1(s),\ k\text{-NN}_2(s)),$$

where k-NN(s) is the set of k nearest neighbors of sentence s for a model and Sim is the intersection-over-union (Jaccard similarity) of the two sets of neighbors. For each pair of components (attention and FFN) in models 1 and 2 we compute the LNS of all sentences in the evaluation dataset and take the mean LNS as our layer similarity measure. The smaller the value of k the more local the neighborhoods we are comparing, and the more specific the retrieval task. We pick k to be small enough to visually inspect sentence neighborhoods if necessary. In our analysis, we use cosine distance as the distance metric between activations and set k to 5% of the dataset size ($\sim$ 100 sentences).

3 Experimental Setup

Data In our experiments, we show results on WMT22 English (EN) $\rightarrow$ German (DE) (296M pairs), which we obtained using the provided `mt-data` scripts[5], WMT16 EN $\rightarrow$ Romanian (RO) (610K pairs), and for the multilingual setup of Pires et al. (2023), consisting of 10 languages: German, English, Spanish, French, Italian, Japanese, Korean, Portuguese, Swahili, and Chinese. In our analysis, we mostly focus on WMT22 EN $\rightarrow$DE.

Following Schmidt et al. (2022), we use WMT'16 provided scripts to normalize the RO side. EN $\rightarrow$RO keeps diacritics for producing accurate translations. For more details refer to Schmidt et al.

[4]We use the source sentence and force decode the first reference to compute the encoder and decoder representations, respectively.

[5]https://www.statmt.org/wmt22/mtdata/

(2022). For the multilingual experiments, we replicated the setup of Pires et al. (2023), which includes all details, including data preprocessing and dataset sizes.

Metrics We compute BLEU[6] using `sacreBLEU`[7] version 2.3.1, with evaluation signatures `nrefs:1 | case:mixed | eff:no | tok:13a | smooth:exp` for BLEU, and `nrefs:1 | case:mixed | eff:no | tok:flores101 | smooth:exp` for SPBLEU. For our main results, we also report COMET using the `wmt20-comet-da` model and CHRF using the signature `nrefs:1 | case:mixed | eff:yes | nc:6 | nw:0 | space:no`.

Latency We report inference time in tokens/second (the higher, the better), averaged over 5 runs. For the multilingual models, we use the DE →EN test set. Our measurements were collected using a single NVIDIA V100 GPU on a single-threaded Intel(R) Xeon(R) Gold 6148 CPU @ 2.40GHz with batch size of 1 and beam size of 5, in order to realistically mimic the inference of a deployed model. For experiments with larger batch sizes, see Appendix D.

Tokenization For WMT22 EN →DE, we use SENTENCEPIECE (Kudo and Richardson, 2018), with a vocabulary size of 32K and a character coverage of 1.0, while for the multilingual experiments we use a vocabulary size of 250k and a character coverage of 0.9995. For WMT16 EN →RO we use byte-pair encoding (BPE, Sennrich et al., 2016) with $40,000$ merge operations.

Model Architectures We focus our analysis on the Transformer `Big` where $N_{enc} = N_{dec} = 6$, $d_{model} = 1024$, $d_{\text{ff}} = 4096$, and it has 16 attention heads. We also report results on Transformer `Base` ($N_{enc} = N_{dec} = 6$, $d_{model} = 512$, $d_{\text{ff}} = 2048$, and 8 attention heads), and a deep encoder shallow decoder (Kasai et al., 2021) Transformer Big with 12 encoder layers, and 2 decoder layers. For our decoder-only experiments, the model is identical to the Transformer Big, except that all 12 layers are on the decoder. Our decoder-only model is similar to a Transformer-based language model, particularly Prefix-LM (Raffel et al., 2020), where we apply a non-autoregressive mask on the source side and an autoregressive mask on the target. The source and target embeddings and the output projection matrix are shared in all models (Press and Wolf, 2017).

Hyperparameters All experiments are implemented using FAIRSEQ (Ott et al., 2019). Our optimizer is ADAM (Kingma and Ba, 2015) with a learning rate of 0.0007. We train for 80k, 80k, 150k steps on WMT22, WMT16, and multilingual, respectively, at which point the models had converged. We use 4000 warm-up steps, and an inverse square root learning rate scheduler (Vaswani et al., 2017). We use a dropout rate of 0.1 for WMT22, 0.3 for WMT16, and 0 for the multilingual experiments due to the abundance of data, following Pires et al. (2023). All models are trained using `fp16` (Ott et al., 2018).

Nomenclature In our experiments, we run a number of different configurations per model architecture that differ in the way the FFN is used, shared, or dropped, as well the size of the shared FFN ($d_{\text{ff}'}$). To facilitate our discussion, we introduce in Table 1 the nomenclature that will serve as reference for the rest of the text. Unless otherwise stated, the dimension of the shared FNN^{*}_{all}, i.e. $d_{\text{ff}'}$ is equal to the d_{ff} of the original model.

For decoder-only models, only `SharedDec` and `NoDec` configurations are defined. For conciseness, we drop the mention of FFN from the text when possible, i.e. `SharedEnc` instead of `SharedEncFFN`.

FFN Description	Encoder	Decoder
`SharedEnc`	FNN^{enc}_{all}	FNN^{dec}_{i}
`SharedDec`	FNN^{enc}_{i}	FNN^{dec}_{all}
`SharedEncSharedDec`	FNN^{enc}_{all}	FNN^{dec}_{all}
`SharedEncDec`	$\text{FNN}^{encdec}_{all}$	
`NoDec`	FNN^{enc}_{i}	`No-op`
`SharedEncNoDec`	FNN^{enc}_{all}	`No-op`

Table 1: Nomenclature used in our experiments. `No-op` indicates an identity function, which is equivalent to dropping the FFN.

Representational Similarity We use the WMT22 EN →DE evaluation set for both CKA and LNS analysis. We analyze encoder and decoder representations independently and present these metrics in a matrix heatmap plot showing pairwise similarity between layers. The diagonal of this matrix is the similarity of corresponding layers, i.e., layer i on both architectures. In order to

[6]For the multilingual experiments, we select the Flores101 tokenizer in `sacreBLEU`, so technically we report SPBLEU.

[7]https://github.com/mjpost/sacrebleu

facilitate an "apples-to-apples" comparison across models, we extract decoder representations by force decoding the (first) reference. We establish 2 crucial similarity scores: a *benchmark* on similarity for each of these metrics, where we train two additional models using the same architecture but with different random seeds; a similarity lower bound, where we compare the baseline Transformer Big with a randomly initialized (i.e., untrained) model with the same architecture. We present these bounds in Appendix C.

4 Experimental Results

4.1 Sharing FFNs

The results of various FFN sharing configurations are summarized in Table 2, including their impact on accuracy and model size (in millions of parameters and percentage). Sharing either the encoder (SharedEnc) or the decoder FFN (SharedDec) results in just a 0.2 to 0.3 BLEU point decrease, while reducing the parameter count by nearly 20%. Sharing the FFN on each side (ShareEncShareDec) leads to a more substantial degradation of 0.9 BLEU points, albeit reducing the parameter count by 37%, while sharing a single FFN on the encoder and decoder (ShareEncDec) results in a slightly higher degradation of 1.1 BLEU points. Nonetheless, these findings support the hypothesis that the FFN contains some degree of redundancy, as we expected a greater accuracy degradation given the substantial $(20-40\%)$ reduction in model size.

Architecture	BLEU	$\lvert\theta\rvert$	(%)
Transformer Big	35.6	228M	(100)
+ SharedEnc	35.4	186M	(82)
+ SharedDec	35.3	186M	(82)
+ SharedEncSharedDec	34.7	144M	(63)
+ SharedEncDec	34.5	136M	(59)

Table 2: sacreBLEU results on WMT 22 EN →DE for different FFN sharing configurations. $\lvert\theta\rvert$ is the number of parameters.

While we focus on sharing *one* FFN for all layers within a module, we compare with sharing multiple FFNs following Takase and Kiyono (2023) in Appendix A. We find that sharing one FFN is as accurate as sharing multiple FFNs within a module, while being more parameter-efficient.

4.2 Dropping FFNs

Table 3 summarizes the performance of models with no FFNs. Besides BLEU and number of parameters, we report the inference speed for each architecture. Dropping the FFN on the encoder (NoEnc) leads to a 0.9 BLEU point drop while reducing the parameter count by 22% and with minimal effect on inference speed. Dropping the FFN on the decoder (NoDec), on the other hand, causes a degradation of only 0.4 BLEU points while increasing the inference speed by 20%[8]. The highest latency reduction is obtained by removing the FFNs on both the encoder and the decoder (NoEncNoDec), but it comes with a significantly larger degradation of over 2 BLEU points.

Architecture	BLEU	Speed	$\lvert\theta\rvert$	(%)
Transformer Big	35.6	$111^{\pm 1.2}$	228M	(100)
+ NoEnc	34.7	$112^{\pm 1.0}$	178M	(78)
+ NoDec	35.2	$133^{\pm 0.9}$	178M	(78)
+ NoEncNoDec	33.5	$138^{\pm 1.9}$	127M	(56)
+ SharedEncNoDec	35.3	$136^{\pm 1.1}$	136M	(60)
+ NoEncSharedDec	33.9	$127^{\pm 1.0}$	136M	(60)

Table 3: sacreBLEU results on WMT 22 EN →DE for different FFN dropping configurations.

Combining sharing and dropping These results, together with those from Table 2, suggest that the encoder and decoder FFNs have different contributions: the decoder's are more redundant, corroborating previous work on FFNs parametrization (Ge et al., 2022). With this in mind, we experiment with one shared FFN on the encoder and dropping it on the decoder, reported as SharedEncNoDec in Table 3. As shown, with just approximately 60% of Transformer Big parameters we observe a 22% improvement in inference speed, at the cost of 0.3 BLEU point.

4.3 One Wide FFN Model

Previous sections describe models that share and/or drop FFNs, effectively reducing model size at some modest accuracy cost. In this section, we investigate whether we can regain the accuracy lost while preserving the parameter efficiency and the latency reduction. We focus on ShareEncNoDec model as

[8]The reason for this difference between NoEnc and NoDec is that the encoder output is computed in parallel, while the decoder operates in a step-by-step fashion.

	BLEU	CHRF	COMET	Speed	$\mid \theta \mid$ (%)
Transformer Big EN →DE	35.6	62.6	57.2	$110.8^{\pm 1.2}$	228M (100)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 4,096$	35.3	62.1	56.1	$135.7^{\pm 1.1}$	135M (60)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 24,576$	35.7	62.7	57.9	$138.2^{\pm 0.9}$	177M (80)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 49,152$	**36.5**†	**63.2**†	**59.6**	$137.5^{\pm 1.6}$	228M (100)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 98,304$	36.4†	**63.2**†	59.0	$134.5^{\pm 1.6}$	328M (145)

Table 4: Accuracy of One Wide FFN for Transformer Big EN →DE on WMT22. † implies the system is statistical significantly different at $p < 0.05$.

it provides a strong baseline with significant parameter savings and inference speedups.

We propose increasing the dimension of the shared FFN to match the number of parameters of the original (fully-parameterized) model, so as to avoid increasing the overhead of model storage. In particular, ShareEncNoDec saves around $(N_{enc} + N_{dec} - 1) \times 2 \times d_{model} \times d_{\text{ff}}$ parameters as there's one single shared FFN in the encoder. On the other hand, the Transformer Big has $(N_{enc} + N_{dec})$ FFNs. Thus, we match the size of the original model by setting the dimension of the shared FFN, $d_{\text{ff}'}$, to $(N_{enc} + N_{dec}) \times d_{\text{ff}}$.

Table 4 summarizes our results. It includes our proposed model, the *One Wide FFN* model ($d_{\text{ff}'} = 49,152$), as well as the baseline Transformer Big, and the corresponding ShareEncNoDec ($d_{\text{ff}'} = 4,096$). It also includes a wide model with $d_{\text{ff}'} = 24,576$, which uses the same number of parameters as NoDec, with $d_{\text{ff}'} = N_{enc} \times d_{\text{ff}}$. This model achieves an accuracy on par (or slightly above) the baseline Transformer Big with 20% fewer parameters and a significant inference speed-up.

Our proposed model with $d_{\text{ff}'} = 49,152$ goes beyond that, achieving a gain of 1.2 BLEU points over the vanilla ShareEncNoDec and 0.9 BLEU points over the Transformer Big. These gains remain consistent across CHRF and COMET. Furthermore, it has a similar inference speed as the ShareEncNoDec model. For completeness, we include a wider model with $d_{\text{ff}'} = 98,304$. Despite the extra capacity, this model does not provide any additional accuracy gains, which we suspect is due to the lack of data to train such a large model.

4.4 Analyzing Internal Representations

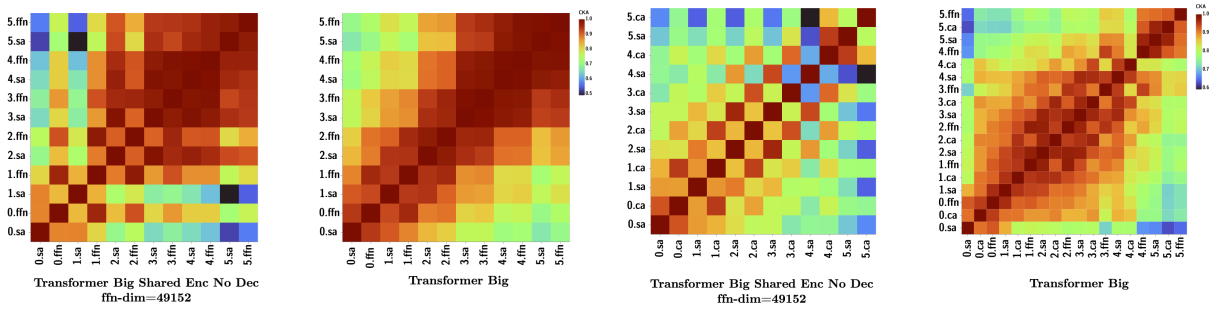
We now report a *post-hoc* analysis of the internal representations of the models introduced in preceding sections. Our objectives are twofold: 1) to ascertain whether the proposed models' internal representations exhibit a significant degree of similarity to those of the original base model; 2) to delve into the impact of the proposed methods on redundancy. We adopt the definition of redundancy of Dalvi et al. (2020), who *visually* inspect the similarity between adjacent modules within a model (high similarity entails high redundancy).

Architecture	Encoder		Decoder	
	CKA	LNS	CKA	LNS
Benchmark	100.0	100.0	100.0	100.0
SharedEnc	98.0	96.2	100.8	100.6
SharedDec	100.2	101.4	98.3	94.6
SharedEncSharedDec	98.9	97.2	99.5	95.4
SharedEncDec	97.6	94.4	98.4	93.5
NoEnc	90.0	70.5	101.0	96.8
NoDec	100.0	98.6	96.0	87.4
SharedEncNoDec	97.6	98.9	97.5	89.0
SharedEncNoDec$^{d'_{\text{ff}}=49152}$	97.0	83.2	94.0	82.9

Table 5: Similarity of the representations (%) of corresponding modules of different architectures vs. the Transformer Big for WMT22 EN →DE. These scores are normalized by comparing them to the CKA and LNS benchmark scores. For NoDec configurations we compare the final output of the Transformer layer as a whole as they have different modules than the baseline. The columns for shared and for dropped FFNs are highlighted in gray and blue respectively.

4.4.1 Similarity to Baseline

We ground the pairwise similarity metrics, by normalizing them against a benchmark. As mentioned in Section 3, we establish the *benchmark scores* by training two additional Transformer Big models, but using different random seeds. These models achieve similar accuracy as the baseline model (see Appendix C.1 for more details). The benchmark score is the similarity between the baseline and these models Because the benchmark is calculated by averaging similarity scores from different train-



(a) Encoder self similarity.

(b) Decoder self similarity.

Figure 1: CKA self similarity of encoder and decoder layers of the *One Wide Encoder* model vs. the Transformer Big baseline. We identify each component with a label: `index.name`. For example, `0.sa` refers to the self-attention on layer 0, while `4.ca` refers to the cross-attention on layer 4.

ing runs of our baseline, individual runs can have a normalized score above 100%.

Table 5 shows normalized similarity scores for several models. Under the Encoder columns we compare the encoder representations, and under the Decoder columns we compare decoder representations. Sharing FFNs leads to consistenly lower (normalized) similarity scores than models that do not share, both in terms of internal representation (CKA) and semantic spaces (LNS). As shown, although models that share FFNs have lower similarity scores compared to those that do not, the scores are still very close to 100%. Moreover, these decreases align with the drops in BLEU seen in Table 2, where the model with the lowest similarity score (`ShareEncDec`) is also the least accurate model. We observe a similar trend for models that drop the FFNs in the encoder or decoder, these models exhibit lower similarity scores with the respective component than models sharing them, as shown by `NoEnc` and `NoDec`. In addition, the former result again suggests the FFNs in the encoder are more important than in the decoder as the similarity shifts drastically compared to all other settings.

For completeness, we report on the last row the similarity scores for the One Wide FFN model, which is more accurate than the base model. The internal representations generated by that model diverge from those of the base model. Interestingly, we observe a larger drop in LNS scores than in CKA scores, indicating that the shift occurs mostly in semantic space, rather than the Euclidean space captured by CKA. For a detailed layer-wise similarity analysis that breaks out the aggregate analysis in Table 5 see Appendix C.2.

4.4.2 A Qualitative View of Redundancy

We now study into the impact of our One Wide FFN model on the redundancy of the internal representations. In addition to adopting their definition of redundancy, we also adopt Dalvi et al. (2020)'s method of computing self-similarity, namely looking at how the representations change as they go through each module (self-attention, FFN, or cross-attention) of the model. In particular, we use CKA to compute similarity between the output of different modules within the same model.

In Figure 1a, we show the CKA self-similarity matrices for the encoders of the One Wide FFN model and the `Transformer Big`. We do the same for the decoders in Figure 1b. These matrices show how similar each module of the network is to all other modules *within that network*. The diagonal of the matrix is the similarity between a module and itself and is always 1.

As shown, there is high similarity between adjacent modules of the `Transformer Big`, both on the encoder and decoder, indicated by areas with darker red around the diagonal. The prevalence of high similarity patterns among adjacent modules suggests a substantial degree of redundancy, and eliminating a module has a negligible impact on the final representations. On the other hand, we observe a distinct checkerboard pattern on the self-similarity matrices of the One Wide FFN model, where individual modules tend to exhibit lower similarity with their immediate neighbors than with their second neighbors (i.e., the neighbors of the neighbors). On the encoder, the checkerboard pattern emerges especially in the earlier modules while on the decoder, that pattern appears more consistently throughout the layers. This pattern gives an indication that our model is learning non-trivial

transformations of the input, leading to decreased redundancy within the network.

4.5 Other architectures and Languages

So far, all our experiments focused on the Transformer Big and on WMT22 EN →DE. In this section, we apply what we learned to other architectures and language pairs. We run experiments on the low resource language direction EN →RO and a large scale multilingual model.

For EN →DE, we apply our proposal to a Transformer Base model, a Deep Encoder Shallow Decoder model (Kasai et al., 2021), and a Decoder-Only model. For the Transformer Base, we observe an accuracy gain of 0.5 BLEU (2.2 BLEU over the vanilla `SharedEncNoDec` model) and an inference speedup of around 25%. In the Deep Encoder Shallow Decoder model, we observe a more modest accuracy gain of 0.2 BLEU points (0.9 BLEU over the vanilla `SharedEncNoDec` model). However, the inference speedup from dropping the decoder FFNs is minimal ($< 1\%$), which is expected because of the small depth of the decoder in this architecture.

Decoder-only models With the advent of Large Language Models (LLMs) like GPT (Brown et al., 2020), and PaLM (Chowdhery et al., 2022), a lot of effort has been put on decoder-only Transformer models. We train a decoder-only model on WMT22 EN →DE, as shown on Table 6. Due to the absence of an encoder, we are limited to applying a wide FFN on the decoder side. As in the other setups, we get an accuracy gain of +0.3 BLEU over the baseline decoder-only model (+1.7 BLEU over `ShareDec`), but the latency degrades by 12%. This is not surprising: due to the autoregressive nature of the decoder, increasing the size of its FFN has a bigger impact on speed.

Low-resource languages In EN →RO the accuracy of the One Wide FFN Model is only on par compared to the base model, even though it is a higher than the vanilla `SharedEncNoDec` model. We hypothesize that due to the low resource condition, our proposed model already reaches saturation as there are not that many salient textual patterns to be learned by the FFN.

Multilingual Finally, we observe the similar trend on the multilingual setup, where the One Wide FFN Model is +1.2 SPBLEU points more accurate than the baseline Transformer Big and +2.5 SPBLEU points more accurate than the vanilla `SharedEncNoDec`, this gain is significant in 79 out of 90 directions and when all tests sets are concatenated. Additionally, this large accuracy gain also comes with around 18% inference speed-up, consistent with our previous results.

5 Related Work

Weight pruning and parameter sharing are well-known techniques to reduce a model's footprint. Given the scale of the latest models (Chowdhery et al., 2022), there have been multiple efforts to prune neurons based on different automatic methods (Dalvi et al., 2020; Michel et al., 2019; Voita et al., 2019), sharing parameters efficiently (Ge et al., 2022; Reid et al., 2021), and factorizing certain components (Lan et al., 2020; Hu et al., 2022).

Neuron pruning methods often focus on finding and pruning redundant neurons through correlation methods (Dalvi et al., 2020), but also on how Transformer components like the multi-head attention can be pruned significantly due to model redundancy in the encoder or decoder either by checking the gradients salience (Michel et al., 2019) or a differentiable relaxation of the l_0 regularization at training time (Voita et al., 2019).

For parameter sharing, the Universal Transformer (Dehghani et al., 2019) proposed a model where all layers are shared (i.e., in effect it reduced the model to a single shared layer). Takase and Kiyono (2023) proposes finding an optimal configuration of shared layers in the encoder or decoder through different methods of sharing (in sequence, in cycle, or in reversed cycle) always keeping a specified number of final layers[9]. Similarly, Reid et al. (2021) proposes an approach where just the middle layers are shared, while the bottom and top layers are independent, and using a lower dimensionality for the embedding layer. Analogously, Ge et al. (2022) focus on minimizing the number of parameters and the number of calls to each parameters' group in order to optimise on-device models. They achieve this by sharing the encoder and decoder in a similar way to both previous methods, particularly by sharing all layer parameters in cycle like Takase and Kiyono (2023).

Previous works also focus on reducing the dimensionality of certain parameters, mostly through low rank factorization. Lan et al. (2020) decomposes the embedding layer into a lower rank em-

+ SharedEncNoDec FFN $d_{\text{ff}'} = 2,048$	$22.2^{\dagger}$	$52.5^{\dagger}$	45.8	$152.8^{\pm 1.4}$	41M (64)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 24,576$	**22.9**	52.8	46.7	$150.6^{\pm 0.5}$	64M (100)
Transformer Big Multilingual	26.8	46.3	47.7	$94.6^{\pm 1.6}$	422M (100)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 4,096$	$25.5^{\dagger}$	$45.1^{\dagger}$	40.8	$107.1^{\pm 1.4}$	330M (78)
+ SharedEncNoDec FFN $d_{\text{ff}'} = 49,152$	$\mathbf{28.0}^{\dagger}$	$\mathbf{47.3}^{\dagger}$	**50.7**	$111.5^{\pm 1.1}$	422M (100)

Table 6: Accuracy of One Wide FFN for EN →DE with Transformer Base, Decoder Only, and Deep Encoder Shallow Decoder on WMT22; for low resource EN →RO with Base version on WMT16, and multilingual with Transformer big on Flores. † implies the system is statistical significantly different at $p < 0.05$.

bedding matrix and a projection to the actual hidden size while also sharing all parameters across all layers. In addition to sharing parameters efficiently, Ge et al. (2022) proposes a lightweight decomposition of the FFN where instead of a single component there are 2 projections with a smaller dimensionality than vanilla Transformers. Our work is close to Ge et al. (2022) but instead of factorizing we explore sharing and full pruning of the FFN. In contrast with previous works, we also explore increasing the encoder FFN size while dropping the decoder's completely.

6 Conclusion

In this work, we studied the importance of the FFN in Transformer models. We analyzed the impact of removing and/or sharing the FFN across layers and found that, due to this component's redundancy, the model sizes can be substantially reduced with little impact on accuracy for Machine Translation. In particular, we found that sharing the FFN across all encoder layers while making it larger and removing it from the decoder layers leads to models that are more accurate and faster at inference.

Our findings are applicable across multiple settings, including decoder-only and multilingual models. In a low-resource setting the results are modest but our approach can still recover the baseline's performance with a faster inference.

Finally, we conducted a thorough similarity analysis between the vanilla Transformer and our proposed architectures, and found that the latter's internal representations do not differ significantly from the former's, except in that they are less redundant.

Limitations

In this work, our focus was Machine Translation. Although we expect the results to generalize to other sequence-to-sequence tasks, further experiments are needed, which we leave for future work.

Ethics Statement

One important consideration is the energy consumption for model training, which results in greenhouse emissions (Strubell et al., 2019). Our work uses existing datasets, and inherits some of the risks associated with them, such as privacy leakage (Carlini et al., 2021) and gender bias (Cho et al., 2019). Mitigation strategies such as those from Vanmassenhove et al. (2018) may be necessary.

A Custom Sharing of Multiple FFNs

There is a combinatorial number of ways of sharing $M < N$ FFNs within a module of N layers. Since this is prohibitive, we investigate the following strategies from Takase and Kiyono (2023):

- `Sequence`: assign one FFN for every M/N consecutive layers, forming a block pattern.

  $\text{FFN}_i(\cdot) \overset{\text{tied}}{=} \text{FFN}_{seq_m}(\cdot), \forall i : 1 \leq i \leq N, m = \lfloor (i-1)/(N/M) \rfloor$

- `Cycle`: stack M FFNs in an identical order, forming a repetitive checkerboard pattern.

  $\text{FFN}_i(\cdot) \overset{\text{tied}}{=} \text{FFN}_{cyc_m}(\cdot), \forall i : 1 \leq i \leq N, m = (i-1) \textbf{ modulo } M$

- `Cycle (Rev)`: stack M FFNs in a reverse order, forming a repetitive palindrome series.

  $\text{FFN}_i(\cdot) \overset{\text{tied}}{=} \text{FFN}_{cycrev_m}(\cdot), \forall i : 1 \leq i \leq N, m = N/M - i$

Note that we assume that N is an even number and divisible by N. `Cycle (Rev)` is only valid for $M = N/2$. The `EdgeFormer` (Ge et al., 2022) adopts `Cycle` with $M = 2$ for the encoder FFNs.

Table 7 shows the results of these strategies applied on the encoder. As references, we copy the results of the `Transformer Big` and `ShareEnc` from Table 2. Not only is the accuracy of `ShareEnc` similar to Takase and Kiyono (2023)'s strategies, but it also uses fewer parameters and is easier to extend.

Architecture	BLEU	$\lvert\theta\rvert$	(%)
`Transformer Big`	35.6	228M	(100)
+ `SharedEnc (M=1)`	35.4	186M	(82)
+ `Sequence M=2`	35.2	194M	(85)
+ `Sequence M=3`	35.3	202M	(88)
+ `Cycle M=2`	35.2	194M	(85)
+ `Cycle M=3`	35.5	202M	(88)
+ `Cycle Rev M=2`	35.2	194M	(85)
+ `Cycle Rev M=3`	35.5	202M	(88)

Table 7: Accuracy of different FFN sharing strategies on WMT22 EN → DE.

B Sharing or Dropping Attention

We report the results of sharing attention modules (either self, cross or both) across layers in Table 8. In contrast with the FFN, attention seems to play a more crucial role in the model's performance, as sharing the different attention mechanisms in both encoder and decoder causes a large accuracy drop across all settings, with the exception of sharing the decoder's cross attention and the encoder's self attention.

Encoder Self-Att	Decoder Self-Att	Decoder Cross-Att	BLEU	$\lvert\theta\rvert$	(%)
`Transformer Big`			35.6	228M	(100)
Shared	Shared	Shared	27.5	165M	(72)
Shared	Shared	Indiv.	27.6	186M	(82)
Shared	Indiv.	Indiv.	35.5	207M	(91)
Indiv.	Shared	Indiv.	26.5	207M	(91)
Indiv.	Shared	Shared	25.7	186M	(82)
Indiv.	Indiv.	Shared	35.5	207M	(91)

Table 8: BLEU scores on WMT 22 EN →DE when sharing the attention of both encoder and decoder (self and cross). Nomenclature follows Section 3 but with Self Attn an Cross Attn as the encoder/decoder's self attention and cross-attention (decoder), respectively.

C Details on Internal Representations Analysis

C.1 Raw Similarity Scores for Benchmarking

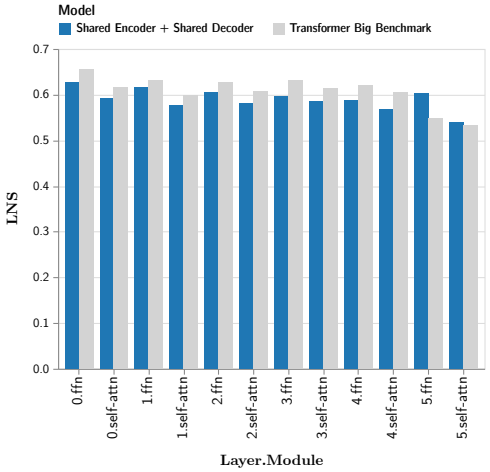
We establish a *benchmark* score for the expected similarity of our two metrics by comparing the baseline Transformer Big with identical models trained from different random seeds. Table 9 presents the raw similarity scores from which we compute the normalized scores presented in Table 5. As shown, the similarity between

Architecture	Encoder		Decoder	
	CKA	LNS	CKA	LNS
TransformerBig Seed 2	.96	.61	.94	.62
TransformerBig Seed 3	.96	.62	.95	.62
SharedEnc	.94	.58	.95	.62
SharedDec	.97	.62	.93	.59
SharedEncSharedDec	.95	.59	.94	.59
SharedEncDec	.94	.57	.93	.58
NoEnc	.87	.43	.95	.60
NoDec	.96	.60	.90	.54
ShareEncNoDec	.94	.59	.92	.55
ShareEncNoDec$^{d'_{ff}=41952}$	.94	.51	.89	.51

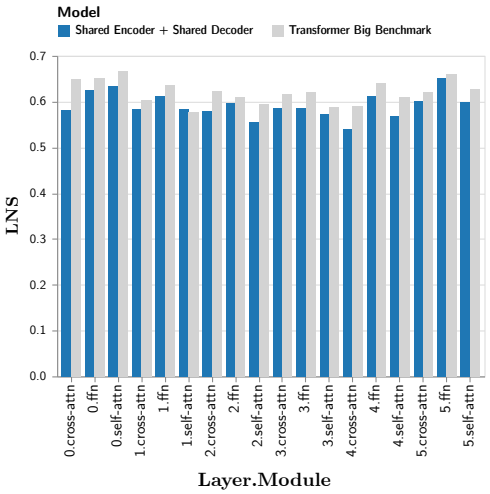
Table 9: Raw similarity of the representations of corresponding layer-modules of different architectures vs. the Transformer Big for WMT22 EN →DE. For *NoDec* configurations we compare the final output of the transformer layer as a whole as they have different submodules. The columns for shared and for dropped FFNs are highlighted in gray and blue respectively.

C.2 Layer-wise Analysis

In Table 5, we report the aggregated similarity scores across all layers of Transformer encoder and decoder. Here, we report a more fine-grained layer-wise similarity score mostly to showcase the reliability of the aggregated scores. In Figure 2, we plot layerwise LNS to study how similar the semantic information captured at each layer is to that of the baseline model at *every layer*. When LNS scores are high, the network is producing similar local neighborhoods for each sentence in our evaluation set. In particular, we are interested in comparing the benchmark LNS scores and those of SharedEncSharedDec at each layer. As shown, the layer-wise LNS scores of SharedEncSharedDec track the baseline scores at almost every layer, confirming the reliability of the aggregated score. We observe similar pattern for all the models that we evaluate in this paper.



(a) Encoder



(b) decoder

Figure 2: Layerwise LNS between SharedEncSharedDec and Transformer Big (blue bars). LNS between two versions of Transformer Big trained from different random initializations are shown by the grey bars to ground the comparison. FFN sharing does not dramatically change activations produced at each layer.

D Effect of batch size on decoding speed

In Section 4.3, we compared the decoding speeds of the One Wide FFN model and the Transformer Big, with a batch size of 1. In Table 10, we delve into how the decoding speed evolves as the batch size increases. As shown, the One Wide FFN model is faster for smaller batch sizes, but its advantage diminishes as the batch size increases, being slower than the Transformer Big for large batch sizes. We suspect this slowdown is due to the fact that the

Batch	Transformer Big	*One Wide FFN*	Speed-up (%)	*# batches*
1	$110.8^{\pm 1.2}$	$137.5^{\pm 1.1}$	24	2,047
2	$221.7^{\pm 14.3}$	$260.9^{\pm 6.5}$	18	1,024
4	$397.4^{\pm 8.0}$	$448.9^{\pm 2.0}$	13	512
8	$718.3^{\pm 8.0}$	$748.7^{\pm 10.6}$	4	256
16	$1,220.7^{\pm 56.2}$	$1,226.9^{\pm 17.2}$	1	128
32	$1,958.5^{\pm 112.4}$	$1,837.6^{\pm 15.3}$	−6	64
64	$1,319.1^{\pm 36.7}$	$1,259.0^{\pm 70.0}$	−5	32
128	$1,925.1^{\pm 64.8}$	$1,705.0^{\pm 62.3}$	−11	16
256	$2,312.1^{\pm 67.4}$	$1,976.5^{\pm 123.2}$	−15	8
512	$2,512.0^{\pm 50.1}$	$1,957.9^{\pm 32.6}$	−22	4

Table 10: Effect of batch size on decoding speed (in tokens/s) for the Transformer Big and *One Wide FFN* ($d_{\text{ff}'} = 49,152$). Δ is the percentage change in inference speed, and # batches is the number of batches used to evaluate. For large batch sizes, there are fewer batches (since the dataset size is fixed), which leads to higher variance in the measurements.

large FFN size requires higher peak memory, making the larger sizes non-optimal for this model.

A Benchmark for Evaluating Machine Translation Metrics on Dialects Without Standard Orthography

Noëmi Aepli[1] **Chantal Amrhein**[1,2] **Florian Schottmann**[2,3] **Rico Sennrich**[1,4]

[1]University of Zurich, [2]Textshuttle, [3]ETH Zurich, [4]University of Edinburgh

{naepli,sennrich}@cl.uzh.ch, {amrhein,schottmann}@textshuttle.com

Abstract

For sensible progress in natural language processing, it is important that we are aware of the limitations of the evaluation metrics we use. In this work, we evaluate how robust metrics are to non-standardized dialects, i.e. spelling differences in language varieties that do not have a standard orthography. To investigate this, we collect a dataset of human translations and human judgments for automatic machine translations from English to two Swiss German dialects. We further create a challenge set for dialect variation and benchmark existing metrics' performances. Our results show that existing metrics cannot reliably evaluate Swiss German text generation outputs, especially on segment level. We propose initial design adaptations that increase robustness in the face of non-standardized dialects, although there remains much room for further improvement. The dataset, code, and models are available here: https://github.com/textshuttle/dialect_eval

1 Introduction

As multilingual NLP models include more and more languages, the community's focus on low-resource languages has also grown. This not only includes languages for which we have "little data" but also language varieties and dialects which often pose additional challenges, especially if they do not have a standardized orthography. Recent work has shown some progress in classification tasks (e.g. Wang et al., 2021; Touileb and Barnes, 2021; Aepli and Sennrich, 2022) as well as generation tasks where such language varieties appear on the input side only (e.g. Zbib et al., 2012; Honnet et al., 2018; Alam et al., 2023). For these scenarios, we can use established evaluation schemes. However, for research towards NLP models *generating* language varieties, Sun et al. (2023) have shown that current evaluation metrics are not robust to translations into different dialects.

en		... *viewed on a website.*		

Figure 1: Example sentence that shows the extent of spelling variability in language varieties, here Swiss German dialect (GSW), with German (de) and English (en) translations.

What their evaluation does not consider is that language varieties often lack a standardized orthography and do not adhere to consistent spelling rules. This implies that even *within* a single dialect, notable orthographic variations can be observed, as illustrated in the Swiss German example in Figure 1. The same utterance with a similar but different spelling would result in a high word error rate of $\frac{3}{4}$.

Many languages have multiple regional variants, such as Spanish (Mexican, Argentinean, etc.), French (Canadian, Belgian, etc.), or English (British, American, Australian, Indian, etc.), among others. Such language varieties exhibit various lexical, grammatical, and orthographical distinctions. Importantly, these differences are *standardized*, meaning that they adhere to specific spelling rules and conventions, albeit with variations specific to each variant. This suggests that if a neural metric is exposed to a sufficient amount of data encompassing various language varieties, it should be able to develop similar representations and provide comparable scores for a given sentence in different varieties. Sun et al. (2023) show that pre-training a metric on data from multiple dialects indeed makes metrics more inter-dialect robust.

However, for a substantial number of languages and language varieties, there exists no established standard orthography. Many regions exhibit a dialect continuum where language varieties lack precise boundaries, and each dialect displays a significant range of diversity within itself. Furthermore, when speakers write in their dialect, they follow

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 1045–1065
December 6–7, 2023.

their individual writing styles. Such kinds of variabilities, as can be observed in the example in Figure 1, are much less consistent and localized and will differ significantly between different writers. A metric designed to handle these kinds of varieties must be capable of addressing frequent spelling differences, which is considerably more challenging to learn solely from data compared to the standardized language variation differences mentioned in the previous paragraph.

In recent years, embedding-based metrics have gained increasing popularity (Sellam et al., 2020; Rei et al., 2020a) which – in theory – could be more appropriate for assessing non-standardized language varieties than string-based MT metrics like BLEU (Papineni et al., 2002) or chrF (Popović, 2015). However, these neural metrics are often not trained on the language varieties in question. Additionally, recent work showed that reference-based learned metrics still rely too much on subword overlap with the reference (Hanna and Bojar, 2021; Amrhein et al., 2022).

In this work, we follow Sun et al. (2023) and analyze the dialect robustness of machine translation metrics but specifically focus on non-standardized language varieties that were not seen during pretraining. Our contributions are:

- We collect a new dataset and design a challenge set for evaluating MT metrics on two Swiss German dialects.
- We benchmark existing string-based and neural metrics on our dataset and find that they are not reliable, especially on segment level.
- We propose initial adaptations to make metrics more robust for Swiss German but find that there is still a lot of room for improvement.

2 Related Work

There is a substantial amount of research on MT *into* language varieties (Scherrer, 2011b; Haddow et al., 2013; Fancellu et al., 2014; Hassani, 2017; Costa-jussà et al., 2018; Lakew et al., 2018; Myint Oo et al., 2019; Wan et al., 2020; Garcia and Firat, 2022). Most of these works exclusively evaluate with surface-level metrics like BLEU (Papineni et al., 2002) but some voice their concerns over a lack of reliable evaluation metrics (Kumar et al., 2021; Bapna et al., 2022).

Sun et al. (2023) confirm that existing machine translation evaluation metrics are not dialect-robust. They show that it is possible to train more robust metrics by including a language and dialect identification task in a second language model pre-training phase. While they focus on inter-dialect robustness between well-defined dialects, i.e. Brazilian and Iberian Portuguese, our study focuses on a setting where dialects lack standardized orthography. This absence of standardization introduces additional variability, resulting in distinct challenges and necessitating different solutions for MT systems, which need to generalize to often limited data; MT metrics, which need to be robust to spelling differences; and also meta-evaluation, which has its own challenges when collecting human assessments for dialects without standardized orthography as we outline in Section 3.1. To investigate how reliable MT metrics are for non-standardized varieties, we collect a new dataset with human translations and human judgments for MT outputs from English to two Swiss German dialects.

While other works also evaluate MT metrics on language varieties and dialects, Sun et al. (2023) is closest to our work: Alam et al. (2023) only look at language varieties on the source side and Riley et al. (2023) only evaluate language varieties for which a standard was included in the language model pretraining. Both studies also conclude that existing metrics are not robust to dialects. Riley et al. (2023) further propose a new automated lexical accuracy metric based on term dictionaries, similar to metrics used for automatic speech recognition (ASR) (Ali et al., 2017; Nigmatulina et al., 2020) which allow for more flexible string matching by using a look-up table of acceptable spellings. Riley et al.'s approach may work well if there is a limited set of term differences between dialects. However, such a metric is difficult to employ for language varieties without standardized spelling rules. Instead, we experiment with increasing dialect robustness by introducing character-level noise during metric training which has been shown to be useful for cross-lingual transfer to language varieties without standardized orthography (Aepli and Sennrich, 2022; Srivastava and Chiang, 2023; Blaschke et al., 2023).

3 Evaluation Data for Swiss German Dialects

While we focus on Swiss German because there are enough different MT systems that can be eval-

uated, Swiss German is by no means the only language where its varieties do not have standardized spelling. Many medium to high-resource languages like Arabic (Darwish et al., 2021) or Italian (Ramponi, 2022) include dialectal varieties that lack a standardized orthography. Additionally, this phenomenon extends to numerous low-resource settings (Bird, 2022), encompassing a wide array of language varieties across Africa (Adebara and Abdul-Mageed, 2022), Asia (Roark et al., 2020; Aji et al., 2022), Oceania (Solano et al., 2018) and the Americas (Littell et al., 2018; Mager et al., 2018). Historically, even many language varieties that now have a standardized orthography did not always have one, including English (Scragg, 1974). This makes our work on robust metrics for non-standardized dialects also relevant for NLP for historical texts.

To measure robustness against non-standardized dialects, we design two new datasets. With the first, we investigate how metrics behave in a realistic setup where we compare them against human judgments. The second is a challenge set that allows us to investigate score changes between different spellings and compare them to score changes when meaning is changed. This is inspired by similar experiments in Sun et al. (2023).

3.1 Human Judgement Data

In order to realistically evaluate machine translation metrics on Swiss German dialects, it is essential to obtain human-translated reference segments and human judgments for machine-translated translation hypotheses. Since no such data exists for Swiss German, we compile our dataset based on the English NTREX-128 data[1] (Federmann et al., 2022). We selected this dataset because it originates from a standard test set[2], already contains human translations into 128 languages including some regional variants, has a permissive license[3] and offers document context which is important for collecting reliable human judgments (Läubli et al., 2018; Toral et al., 2018).

Human reference translations: For the reference translations, we provided two Swiss German translators with the English NTREX-128 source data (i.e. 1997 sentences from 123 documents). Translators saw sentences in document context and were asked to translate them into their respective native dialects (i.e. Bern and Zurich region). We provided translators with simple instructions where we stated that they must not post-edit machine translation outputs to translate the texts.

Human judgment scores: The hypotheses come from ten machine translation systems translating from English to Bern dialect and ten systems translating from English to Zurich dialect. For each dialect, we include nine neural MT systems in our rating setup and one rule-based system.

The neural models are provided by Textshuttle. They are based on a standard Transformer architecture (Vaswani et al., 2017) trained using different amounts of data, making use of data augmentation techniques like backtranslation (Sennrich et al., 2016). Some of the systems use German as a pivot language. In collaboration with Textshuttle, we decided to evaluate models for which they expect noticeable translation differences and not to compare the nine models that they think would perform the best. The rule-based system works by morphosyntactically analyzing the standard German NTREX-128 translation of the English source and then sequentially applying a set of dialect-specific rewriting rules to generate Swiss German output. The system is described in detail in Scherrer (2011a). The system version used for this task operates word by word without taking syntax into account. Notably, this means that past tense and genitive forms produce unpredictable output because they would require larger changes in the sentence structure.

We translated the English NTREX-128 source data with each neural system and the German NTREX-128 translation with the rule-based systems and let native dialect speakers rate the outputs via Appraise[4] (Federmann, 2018), a framework for the evaluation of machine translation outputs. Raters only had access to the source for context because providing the reference could incentivize raters to "quickly compare the surface forms of translation against reference without understanding" (Freitag et al., 2022). Note that in order to mitigate dialect preference biases as documented by Riley et al. (2023) and Abu Farha and Magdy (2022), the translators and raters were all native speakers of the dialect they were asked to rate or translate into. We collected continuous Direct Assessment (DA) scores (Graham et al., 2013) where the slider

presented to the raters was annotated with Scalar Quality Metric (SQM) labels which increases the rating stability across annotators (Kocmi et al., 2022). Raters viewed segments in a document context and rated translations on the segment level as well as the document level. The document-level ratings are collected to enable future research on document-level metrics; in this study, we only focus on segment-level ratings.

Ideally, we would recruit professional translators for both the translation and the rating tasks. However, there exist no professional translators for Swiss German. Instead, we recruited translators and annotators from a pool of reliable candidates who already worked on similar Swiss German projects. To ensure the quality of the ratings we collect, we included control segments as implemented in Appraise. Based on this control, no raters needed to be excluded.

As Swiss German constitutes a dialect continuum, its various variations lack precise boundaries, and each dialect displays a significant range of diversity within itself. Consequently, during the recruitment process, we placed our trust in the annotators' self-identification of their native dialects. Furthermore, it is worth noting that all our contributors, comprising six women and five men, belong to younger generations, with raters ranging in age from 23 to 30, and translators aged 35 to 40, respectively. This age factor has an impact on their dialect. All translators and annotators were paid 30 CHF per hour for their work.

3.2 Challenge Set

As an additional evaluation, we compile a challenge set to directly pinpoint how robust metrics are to dialect variability. In the creation of this challenge set, we draw inspiration from the work of Sun et al. (2023), who propose measuring inter-dialect robustness by comparing metric scores between two language varieties and between one variety and a version with significant meaning changes. If segment pairs of the latter type are judged more or equally similar by a metric than those of the two varieties, Sun et al. (2023) argue the metric is not dialect-robust.

We build our challenge set from the collected data presented in the previous section. We filter for all MT hypotheses that humans rated as perfect (i.e. received a score of 100). If more than one unique hypothesis exists for a segment, we create all combinations of these hypotheses. For example, if four different machine translation outputs for the same source all receive a perfect human rating, this results in six pairs of semantically equivalent translation hypotheses that feature orthographic differences. For each pair, we then manually create a modified version of one of the hypotheses to change its meaning. Following Sun et al. (2023), we consider deletion, insertion, and substitution operations for introducing meaning changes which we randomly assign to each hypothesis pair. All changes are made either to a single word or if necessary a whole phrase. This process results in hypothesis triples as seen in this example:

A: S e chs Mitarbeiter s i wäg e Verletzige behandlet worde.
B: S ä chs Mitarbeiter s y wäg Verletzige behandlet worde.
Six members of staff have been treated for injuries.

C: Sechs Mitarbeiter si wäge Verletzige **beschtraft** worde.
*Six members of staff **were punished because of** injuries.*

Hypotheses A and B are semantically equivalent but exhibit spelling differences. Hypothesis C is very similar to hypothesis A on the surface level but differs significantly in meaning. During evaluation, metrics will have access to one of these hypotheses, as well as the reference and/or the source (depending on whether it is a reference-free or reference-based metric). We describe how we compare the different scores for these hypotheses in Section 4.3.

4 Experiment Setup

4.1 Benchmarking Existing Metrics

To document the performance of current MT metrics on dialects without a standard orthography, we evaluate the following metrics:

- **BLEU**[5] (Papineni et al., 2002), a string-based metric with a brevity penalty that calculates the word-level n-gram precision between a translation and one or multiple references.
- **chrF++**[6] (Popović, 2017), another string-based metric that provides a character n-gram, word unigram, and bigram F-score by computing overlaps between the hypothesis and reference translation.

[5]computed with SacreBLEU (Post, 2018), signature: nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.3.0.
[6]computed with SacreBLEU (Post, 2018), signature: nrefs:1|case:mixed|eff:yes|nc:6|nw:0|space:no|version:2.3.0.

We expect surface-level, string-based metrics to perform badly on dialects without standard spelling rules as they are entirely based on overlap with a reference translation. These are also the metrics used by most works that explored text generation for language varieties without standardized orthography (e.g. Jeblee et al., 2014; Meftouh et al., 2015; Kumar et al., 2021). We further benchmark the following neural metrics:

- **COMET-20**[7] (Rei et al., 2020b) and **COMET-22**[8] (Rei et al., 2022), two reference-based neural metrics built on the COMET framework (Rei et al., 2020a). These are trained neural metrics that are built on top of a large, pre-trained language model and are fine-tuned on human judgment data from previous metric evaluation campaigns. COMET-20 is fine-tuned to predict DA scores. COMET-22 is an ensemble between a COMET-20-like model and a multi-task model that predicts segment-level Multidimensional Quality Metric (MQM) scores (Uszkoreit and Lommel, 2013) as well as word-level error tags.
- **COMET-20-QE**[9] (Rei et al., 2020b) and **COMET-Kiwi**[10] (Rei et al., 2022), two reference-free neural metrics for quality estimation. COMET-20-QE is trained similarly to COMET-20 and COMET-KIWI to COMET-22, but both versions do not have access to the reference during training on human judgments.

While these metrics go beyond surface-level comparisons to the reference due to their hidden representations and embedding-based nature, we expect that they still struggle to reliably evaluate translations into Swiss German for several reasons: First, no Swiss German data was included for pre-training the language model (XLM-R; Conneau et al., 2019) that is used as the basis for training COMET. Second, neural metrics are often fine-tuned on Standard German data which shares many similar words with Swiss German and could falsely bias metrics towards Standard German spelling. Third, reference-based metrics have been shown to still be influenced by surface overlap with the reference (Hanna and Bojar, 2021; Amrhein et al., 2022) which is a disadvantage in situations where numerous spelling variations exist.

4.2 Developing Dialect-Robust Metrics

Similar to Sun et al. (2023), we also experiment with training more robust metrics but we focus on robustness against non-standardized dialects rather than inter-dialect robustness. The following list summarizes our metrics:

- **COMET-REF** and **COMET-QE**, a baseline trained as a reference to compare our modifications to because our COMET models differ slightly from COMET-20 and COMET-22 (see details below).
- **+gsw**, same as the baseline but the pre-trained model is fine-tuned on Swiss German data before the COMET models are fine-tuned on human judgment data. This is similar to the second pre-training phase for the inter-dialect-robust metric proposed in Sun et al. (2023). However, we do not include the additional language and dialect identification task during continued pre-training as we do not have dialect labels for the Swiss German pre-training data.
- **+noise**, same as the baseline but during the fine-tuning process on human judgment data we introduce character-level noise. This is inspired by previous work that showed that this method allows for better cross-lingual transfer to closely related languages (Aepli and Sennrich, 2022; Srivastava and Chiang, 2023). Blaschke et al. (2023) hypothesize that injecting noise into standard language data results in a similar tokenization rate as for unseen dialects. We apply noise injection to all languages within the COMET fine-tuning dataset that have an alphabetic writing system, therefore excluding languages like Chinese which were not considered in the original work introducing character-level noise. Following Aepli and Sennrich (2022), we inject character-level noise (essentially typos) into a random selection of 15% of the tokens within each sentence. Specifically, we alter, delete, or add one character per chosen token. We execute this process using the characters specific to the relevant language, taking into account all characters that occur more than 1,000 times in the respective dataset. We apply this noise

injection to all segments, including the source, translation, and reference segments.

We provide details of how we trained those models here:

Continued pre-training of XLM-R To expose our models to Swiss German data, we modify the encoder model upon which COMET models are usually based: XLM-RoBERTa[11] (Conneau et al., 2019). We continue the training of the XLM-R model on SwissCrawl[12] (Linder et al., 2020), a corpus containing 500K dialect sentences crawled from the web in late 2019. For the continued pre-training, we work with the Huggingface Transformers library[13] (Wolf et al., 2020), following the default configurations for language model fine-tuning which involves a training duration of three epochs.

Training COMET models We train COMET models using the official code base[14] with the default settings from version 2.0.2. We use the "regression model" configuration for the reference-based models and the "referenceless model" configuration for the reference-free models. Our models are trained on the direct assessment data collected by the organizers of the WMT news translation task spanning the years 2017 to 2021 (2021 as dev set)[15] (Bojar et al., 2017, 2018; Barrault et al., 2019, 2020; Akhbardeh et al., 2021). It is important to highlight that our models are not directly comparable to the original WMT shared task COMET models, for which the 2020 models were exclusively trained on data from 2017-2019 and the 2022 models used a different configuration.

4.3 Evaluation

We evaluate our metrics in five different ways. For the human judgment data, we compute two scores on system (sys) and two on segment (seg) level using the reference implementation from the WMT metrics shared task[16] (Freitag et al., 2022), except for *success rate* where we use our own implementation.

[16] https://github.com/google-research/mt-metrics-eval

System level The *pairwise accuracy* as defined by Kocmi et al. (2021), measures the accuracy with which a metric agrees with human preference between pairs of systems where the human ratings are significantly different according to a two-sided Wilcoxon test. Note that the score difference between the two systems is not important in this analysis. Furthermore, we provide results for the *sys-level Pearson correlation*, quantifying the strength of the linear relationship between metrics and human judgment scores for systems.

Segment level At the segment level, our evaluation includes the *seg-level accuracy* with an optimized tie threshold, which resembles a global accuracy but also acknowledges metrics for correctly predicting tied human judgment scores (Deutsch et al., 2023). Further, we present the *seg-level Kendall correlation*, akin to pairwise accuracy but employing a distinct normalization technique.

Challenge set For the challenge set, we compute the *success rate* (seg level) following Sun et al. (2023). This measures the accuracy with which a metric assigns more similar scores (s) to two equivalent translations A and B compared to a version with a semantic change C. Consequently, a metric is considered robust to non-standardized dialects for a segment if the score difference between s_A and s_B is smaller than the score difference between s_C and either s_A or s_B (depending on which score is smaller):

$$|s_A - s_B| < min(s_A, s_B) - s_C \quad (1)$$

5 Results

Table 1 provides a comprehensive summary of our results with scores for existing metrics (top), COMET models trained for this work (bottom), system-level evaluations (left), and segment-level evaluations (right). Additional results can be found in the appendices. Appendix A.1 contains results related to the incorporation of additional languages in the pre-training process, Appendix B presents an evaluation of performance on an official WMT benchmark, and Appendix C presents pairwise accuracy plots for our metrics.

Existing vs. GSW metrics As expected, the surface-level metrics perform worse than trained metrics in almost all evaluations. Our baseline metrics often perform a bit worse than the existing COMET metrics, this is particularly true for

	system-level			segment-level					
	pairwise accuracy	**Pearson correlation**		**tie-optim. accuracy**		**Kendall correlation**		**success rate**	
		BE	ZH	BE	ZH	BE	ZH	BE	ZH

Table 1: Results for the baselines metrics (above) and our trained metrics (below) on system level (left) and segment level (right). Darker shades indicate lower scores. Bold denotes statistically significant improvement compared to their respective baselines COMET-REF or COMET-QE-KIWI. There is no information about significance for tie-optim. accuracy (columns 4-5) and success rate (columns 8-9). Note that BE and ZH represent the abbreviations for the two Swiss German (GSW) dialect regions under consideration.

our reference-free model. However, continued pre-training on Swiss German data improves their performance considerably and they strongly outperform existing metrics. This highlights the importance of the model to have seen the target language (variety) during the language model pre-training. It also shows that metrics can be extended to include new languages and language varieties with limited effort although this impacts their performance on other language pairs as we show in Appendix B. Continued pre-training on multiple languages and language varieties can mitigate this effect (see Appendix A.1).

Noise injection While continued LM pre-training on Swiss German data generally outperforms noise injection during task fine-tuning, we still see gains over the baselines. This suggests that metrics that were trained on noised data are more robust to unseen language (varieties) and may be a good strategy for language (varieties) without sufficient data for continued pre-training. Combining both continued pre-training and noise injection generally does not lead to further improvements.

Reference-based vs reference-free While both types of metrics perform similarly with continued pre-training on Swiss German, both existing reference-free metrics perform worse than the existing reference-based metrics in the segment-level evaluations. Since these metrics did not see any Swiss German during the pre-training phase, having access to the reference as an anchor might help the reference-based metrics for unseen languages. Amrhein et al. (2022) reported a similar finding where the reference acted as an anchor when metrics were used to identify copied source sentences.

Challenge set The success rate for all metrics is extremely low. Metrics assign more similar scores to a hypothesis with a semantic change than to a different translation hypothesis in the majority of cases. Again, continued pre-training on Swiss German results in the best metric performance. However, even these scores are lower than a random success rate of 50% by far. Our findings highlight that even though system-level correlations may seem convincing, none of the metrics studied in this work are robust to non-standardized dialect variations.

Since our results show that there is still significant room for improvement toward metric robustness to non-standardized language varieties, we provide suggestions for future work.

6 Open Questions

We hope that our benchmark inspires more work on robust evaluation metrics for language varieties in the future. In this section, we list several directions we think are worthwhile exploring:

Expanding the benchmark: We were not able to include additional language varieties in our benchmark at the time because we could not find enough *different* machine translation systems that translate into these varieties. While we recognize that without reliable metrics this is a "chicken-and-egg" problem, we still advocate for more MT research that focuses on translating *into* language varieties. Expanding our benchmark would not only allow us to draw more general conclusions but would also help with sample size for the *pairwise accuracy* analysis (Kocmi et al., 2021) since we find that a large number of systems are required for confident results.

More focus on segment level: Segment-level metric scores tend to be much less correlated with human judgments when contrasted with system-level correlations (Freitag et al., 2022) and have also been shown to be unreliable in downstream tasks (Moghe et al., 2023). We hope that future work aimed at enhancing metric performance on our challenge set will also contribute to greater metric reliability on segment level in general, as over-reliance on reference overlap is also a problem for languages with standardized spelling (Hanna and Bojar, 2021; Amrhein et al., 2022).

Training neural metrics that model character-level similarities: A segment in a dialect often resembles a reference in certain characters only rather than in full words (see Figure 1 as an example). As the underlying language models of neural evaluation metrics use a fixed tokenization scheme that was learned on text that likely does not include many examples of language varieties, these similarities might be hard to account for by the neural metric. Thus, we believe that character-based language models, such as Canine (Clark et al., 2022), could provide a better basis for neural evaluation metrics to model character-level similarities.

7 Conclusion

We evaluated the reliability of machine translation metrics when evaluating dialects without standard orthographies. As part of this work, we collected a new dataset consisting of human translations, human judgments, and a challenge set from English to two Swiss German dialects. We benchmark several existing metrics and find that they are not robust to variation featured by non-standardized dialects. Based on this finding, we explore several modifications that allow us to train metrics that are more robust towards spelling variation. Our results show that there is still a lot of room for improvement and we offer a set of recommendations for future work on dialect robust metrics.

Limitations

The goal of this work is to evaluate and develop machine translation metrics that take into account the spelling variability of dialects and languages without established writing norms. We recognize that evaluating metrics on varieties from different languages would help generalize our results. However, we were not able to find enough differing machine translation systems that translate *into* the same language variety for other languages. Therefore, we had to limit this study to two Swiss German dialects. We hope to include further language varieties in our benchmark in the future (when such machine translation systems become available) to encourage research toward metrics that are reliable for many non-standardized language varieties.

We did our best to avoid dialectal preference bias within our annotators by selecting only annotators who consider themselves native speakers of the respective dialect. However, as Swiss German is a dialect continuum, this can only be controlled to a certain degree.

Ethics Statement

This work includes the compilation of a new dataset as a test set for evaluating various machine translation metrics. All translators and annotators were compensated at a rate of 30 CHF per hour. Our dataset is based on a publicly available dataset and will be released under the same license for future use. **Intended use:** The dataset and the models resulting from this work are intended to be used by the research community to evaluate machine translation metrics.

Acknowledgements

We thank Yves Scherrer for providing the rule based systems and helpful comments. Furthermore, we thank Annette Rios, Tom Kocmi, Mathias Müller, and the anonymous reviewers for their valuable inputs. We are also grateful to the Swiss German raters and translators for their important contribution. This work was supported by the Swiss National Science Foundation (project nos. 191934 & 176727), Textshuttle, and the Department of Computational Linguistics at the University of Zurich.

A Appendix

A.1 Mixed Continued Pre-training

In our main experiments in Section 5, we evaluate continued language model pre-training only on Swiss German data. While this increases the performance on our benchmark, it remains unclear whether this leads to a "specialized" metric that does not perform well on other language pairs. We will evaluate this in the next section, but first, we introduce a set of contrastive models that are less specialized to Swiss German. Continued pre-training for contrastive models involves incorporating mixed data from five languages apart from Swiss German, namely: German (de), English (en), French (fr), Hindi (hi), and Chinese (zh). We train one metric based on XLM-R with continued pre-training only on these five languages ("5 langs"), and another one where we also add GSW to the training data ("6 langs"). For both settings, we also test character-level noise in the COMET fine-tuning step, as described in Section 4.2. The data for the five additional languages is sourced from the CC-100 corpus[17] (Wenzek et al., 2020), which is a reconstructed version of XLM-R's training dataset. Specifically, we utilize the first 100,000 sentences from the training data of each language.

Table 2 shows the results we obtained from incorporating mixed data into the continued LM pre-training. We see a similar effect as when continuing the pre-training only on GSW in the main results in Section 5. The performance of the metrics increases in all evaluations. Comparing these results to the metric where we only continued pre-training on Swiss German (+6 langs vs. +gsw), the results are comparable and often not significantly different. In the next section, we investigate how these metrics behave on other language pairs.

B Correlations on WMT Benchmarks

As discussed in the previous section, we evaluate the performance of our metrics on an official WMT benchmark to monitor their performance on language pairs that do not involve Swiss German. To do this, we reproduce the evaluations from the WMT 2022 metrics task (Freitag et al., 2022) for a subset of language pairs. We evaluate on the following five language pairs:

[17] https://data.statmt.org/cc-100/

	system-level			segment-level					
	pairwise accuracy	**Pearson correlation**		**tie-optim. accuracy**		**Kendall correlation**		**success rate**

Table 2: Results for systems with continued pre-training only on Swiss German (+ gsw), on 5 other languages (+ 5 langs) and the same languages including Swiss German (+ 6 langs). Darker shades indicate lower scores. Bold denotes statistically significant improvement compared to their respective baselines COMET-REF or COMET-QE-KIWI. There is no information about significance for tie-optim. accuracy (columns 4-5) and success rate (columns 8-9). Note that BE and ZH represent the abbreviations for the two Swiss German (GSW) dialect regions under consideration.

- **en-de:** evaluation against MQM ratings collected specifically for the metrics shared task.
- **en-zh:** evaluation against MQM ratings collected specifically for the metrics shared task.
- **de-en:** evaluation against reference-based DA scores collected for the translation shared task.
- **cs-uk:** evaluation against DA + SQM scores collected for the translation shared task.
- **en-liv:** evaluation against DA + SQM scores collected for the translation shared task.

Note that all these languages except for Livonian (liv) are part of the CC-100 corpus[18] (Wenzek et al., 2020). Consequently, they form a part of the training dataset for XLM-R and are thus included in the COMET models. Moreover, English (en), German (de), and Chinese (zh) were incorporated into the mixed continued pre-training, as explained in Section A.1. Lastly, all the languages mentioned above, with the exception of Ukrainian (uk) and Livonian (liv; a language of Latvia), are included in the COMET training data.

This evaluation allows us to assess the effects of our modifications both on language pairs that were included during COMET training, during continued LM pre-training, and those that were not.

The results are shown in the following Tables: 3 (system-level Pearson correlation), 4 (segment-level accuracy), and 5 (segment-level Kendall). We do not report pairwise accuracy here because they cannot be directly compared with the WMT22 results, given that we have only included a subset of the language pairs. Versions of COMET-ref that were continued pretrained on Swiss German data demonstrate comparable or improved performance compared to the baseline metrics. In contrast, continued pretrained COMET-qe performs worse. When examining individual languages, we observe that fine-tuning is advantageous for translations into Livonian (liv), which is the only language in our selection not included in XLMR. Conversely, for translations into English, continued pretrained systems, particularly COMET-qe, tend to perform slightly worse.

C Pairwise Comparison Plots

In the subsequent plots displayed in Figures 2 (existing metrics), 3 (our trained COMET-ref metrics), and 4 (our trained COMET-qe metrics), every point represents a difference in average human judgment (y-axis) and a difference in automatic metric (x-axis) over a pair of systems. Metrics disagree with human ranking for system pairs in pink quadrants. These plots follow the example of Figure 1 in (Kocmi et al., 2021).

Abstract

Automatic evaluation of machine translation (MT) is a critical tool driving the rapid iterative development of MT systems. While considerable progress has been made on estimating a single scalar quality score, current metrics lack the informativeness of more detailed schemes that annotate individual errors, such as Multidimensional Quality Metrics (MQM). In this paper, we help fill this gap by proposing **AUTOMQM**, a prompting technique which leverages the *reasoning* and *in-context learning* capabilities of large language models (LLMs) and asks them to identify and categorize errors in translations. We start by evaluating recent LLMs, such as PaLM and PaLM-2, through simple *score prediction* prompting, and we study the impact of labeled data through in-context learning and finetuning. We then evaluate AUTOMQM with PaLM-2 models, and we find that it improves performance compared to just prompting for scores (with particularly large gains for larger models) while providing interpretability through error spans that align with human annotations.

1 Introduction

Evaluating natural language generation systems has always been challenging, and as the output quality of these systems has improved, evaluation has become even more challenging and critical. For example, in Machine Translation (MT), a field where evaluation has garnered considerable attention, previous standard automatic surface-level metrics such as BLEU (Papineni et al., 2002) are becoming less reliable as the quality of generation systems improves, with little remaining correlation with human judgments (Freitag et al., 2022).

To keep pace with the constantly improving quality of MT output, the next generation of automatic metrics is rapidly evolving. *Learned* automatic metrics that leverage human-judgments to finetune

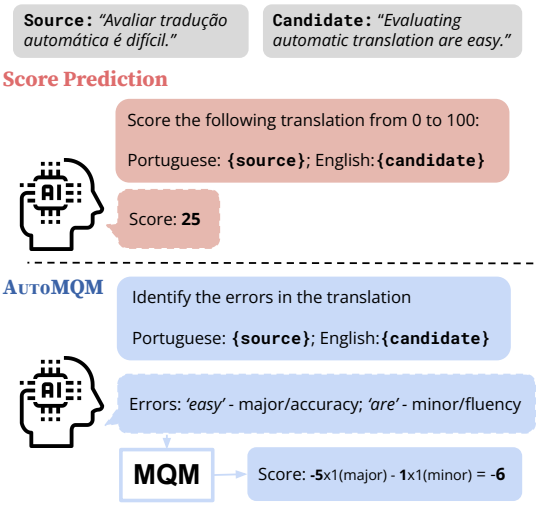

Figure 1: Illustration of how AUTOMQM uses LLMs to assess the quality of a translation. Rather than asking for a single quality score, AUTOMQM prompts models to identify and classify errors, and uses the MQM framework to produce a score.

language models (Sellam et al., 2020; Rei et al., 2022a) currently represent the state-of-the-art in automatic evaluation benchmarks like the WMT Metrics task (Freitag et al., 2022), and show high correlation with human judgments. However, these metrics typically output a single, *uninterpretable* quality score, making it difficult to understand the type and extent of errors identified by them. The lack of insights makes it difficult for model developers to leverage these metrics to improve their systems.

Unlike automatic metrics that only provide a single scalar value as quality score, state-of-the-art human evaluation methodologies like Multidimensional Quality Metrics (MQM; Lommel et al., 2014; Freitag et al., 2021a) ask professional annotators to identify and label error spans with a category and severity. This much richer feedback can be used to gain a better understanding of the current limitations of the model under evaluation and improve it.

In this paper, we ask whether large language

[*] Work done while working part-time at Google.

Proceedings of the Eighth Conference on Machine Translation (WMT), pages 1066–1083
December 6–7, 2023.

models (LLMs) in combination with a few human annotations can be used to design an automatic metric that generates rich feedback similar to that generated by human experts in MQM. This work is motivated by recent papers that demonstrated that LLMs can be used as automatic metrics (Liu et al., 2023b) to generate a single quality score. In particular, Kocmi and Federmann (2023) showed that LLMs can be prompted to assess the quality of machine-generated translations, even achieving state-of-the-art performance on assessing system-level quality. However, previous work only provides a limited view of the capabilities of LLMs for machine translation evaluation: the focus has predominantly been on *score prediction* (i.e. predicting a numerical value for quality), without considering the use of *any* annotated data (either through in-context learning or finetuning), and only in *high-resource* language pairs.

We provide a large-scale study of the capabilities of LLMs (from the PaLM and PaLM-2 families; Chowdhery et al., 2022; Anil et al., 2023) for machine translation evaluation (both with and without a reference translation), provide a novel comparison between prompting and finetuning, and investigate the performance in the low-resource scenario. Inspired by findings that the performance of LLMs can be improved by prompting them for *rationales* of their predictions (Wei et al., 2022; Lu et al., 2023), we also propose **AUTOMQM**, a prompting technique for MT evaluation that asks LLMs to identify error spans in a translation and to classify these errors according to the MQM framework, with a quality score derived automatically from the identified errors. A key advantage of AUTOMQM is its *interpretability*, as users can inspect the errors responsible for a score (Figure 1).

Our contributions can be summarized as follows:

- We confirm the finding of Kocmi and Federmann (2023) that LLMs are *zero-shot* state-of-the-art system-level evaluators, but show low correlation with human judgment compared to *learned* metrics at the segment-level.
- We show that *finetuning* an LLM with human judgment mitigates its low segment-level performance (particularly for smaller LLMs), showing similar correlations with human judgment at both the system-level and segment-level to state-of-the-art learned metrics.
- We are the first to evaluate LLM-based evaluation methods on low-resource language pairs. We find that their performance is promising, but lags behind state-of-the-art learned metrics.
- We find that, with AUTOMQM, PaLM-2 models can be prompted to generate rich MQM-like annotations, outperforming their score prediction counterparts at the segment-level.
- Furthermore, annotations predicted by PaLM-2 models correctly identify over 50% of words that are part of *major* errors, and are comparable to the ones produced by state-of-the-art *supervised* word-level evaluators.

Our findings might have significant implications for not only MT evaluation, but evaluation of machine-generated text in general, and further highlight the potential of using LLMs to provide *AI Feedback* (Fernandes et al., 2023).

The outputs of our models prompted with AUTOMQM are available at github.com/google-research/google-research

2 Background: MT Evaluation

Machine translation evaluation is one of the most well-studied evaluation problems in NLP (Callison-Burch et al., 2008; Freitag et al., 2022). In this task, given

1. a *source* sentence in a (source) language
2. a *candidate* translation in a (target) language

an evaluation metric assesses the quality of the candidate translation by how well it conveys the meaning of the source sentence while considering other factors like *fluency*. Like many other natural language generation evaluation problems, this task is difficult because the set of correct translations for a given source sentence is often very large and not entirely known in advance. To simplify the problem of machine translation evaluation, often (3) a *reference* translation (typically created by a professional human translator) is included as additional information when assessing the candidate translation. This sub-problem is known as *reference-based* evaluation (as opposed *reference-less* evaluation or *quality estimation*).

Up until recently, human evaluation of machine translation was carried out predominantly with the aim of assigning a single quality score to a candidate translation. Consequently, *learned* metrics, which leverage collected human judgment data, are trained for and evaluated on the same task of *score*

prediction (i.e., assigning a single quality score to a candidate translation), and can achieve high correlation with human-provided scores (Freitag et al., 2022).

However, framing machine translation evaluation as a score prediction task is problematic: any scoring or ranking of translations is implicitly based on an identification of errors in the candidate translations, and asking raters to solely provide a single score can lead to rushed and noisy judgments (Freitag et al., 2021a).

This insight has led to the adoption of the Multidimensional Quality Metrics (MQM) framework (Lommel et al., 2014; Freitag et al., 2021a) as the gold standard for evaluating machine translation. The MQM framework asks human evaluators to identify error spans in candidate translations and classify those errors according to various dimensions, e.g., *fluency*, *accuracy*, ... (see Appendix A for a more detailed description of MQM). Importantly, the MQM framework *does not* ask annotators to provide a quality score for each translation, and instead derives one automatically from the identified error spans and their classifications. However, despite its richness, *most* automatic metrics that leverage MQM data only use the final quality score produced by the framework and discard the error span information and classification.

3 Related Work

The success of *learned* machine translation metrics (Sellam et al., 2020; Rei et al., 2022a; Freitag et al., 2022; Qin et al., 2022), which finetune neural network models pretrained on large amounts of (unsupervised) data, highlighted the importance of leveraging *transfer learning* to achieve metrics with better correlation with human judgments. More recently, *generative* LLMs (OpenAI, 2023; Anil et al., 2023) have consistently demonstrated impressive results in natural language understanding and *zero-* and *few-shot* transfer and, naturally, interest in employing these models for (translation) evaluation has increased. Kocmi and Federmann (2023) first explored the use of GPT models for evaluating machine translation tasks, showing their potential as *zero-shot* evaluators, and others have since extended GPT-based evaluation to other generation problems (Jain et al., 2023; Liu et al., 2023b).

Perrella et al. (2022) first highlighted that MQM annotations could be leveraged to allow pretrained models to predict major and minor errors and, similarly to AUTOMQM, used the identified errors to automatically score translations. However, their approach relied on weaker encoder-only or encoder-decoder language models, required *supervised* data to work, and overall underperformed other top metrics. We compare against their *MaTASe* metric in our experiments. Lu et al. (2023) showed that doing *error analysis*, a prompting technique similar to AUTOMQM, could lead to better ChatGPT-based evaluators. However, they still relied on the LLM to provide a score once it identified errors (rather than do it automatically using something like the MQM framework). Furthermore, they provided a very limited meta-evaluation using only 40 examples per language pair. Concurrently with our work, Xu et al. (2023) proposed INSTRUCTSCORE, a LLaMA-based evaluator that asks models to identify and categorize errors in translation (as well as providing a natural language explanation for each error). However, the authors only explore a 7B parameter model and don't leverage zero- and few-shot capabilities of models as in this work. Instead, they rely on a more complex approach of distilling the knowledge of a more capable GPT-4 LLM.

Additionally, WMT Word-Level Quality Estimation shared tasks (Fonseca et al., 2019; Zerva et al., 2022) leverage MQM data by converting span-level annotations of errors (normally of *major* severity) to word-level tags and Task 2 in the WMT19 Quality Estimation shared task evaluation explicitly evaluated submissions of span-level annotations (although most submissions still consisted of models that predicted word-level tags which were converted to spans). We also compare against state-of-the-art word-level quality estimation models.

4 Using LLMs to Predict Quality Scores

Recent works have shown that large language models are versatile, general-purpose models that can be used to tackle many problems in NLP, including evaluation (Kocmi and Federmann, 2023; Jain et al., 2023; Liu et al., 2023b). We begin by exploring how LLMs can be used for machine translation evaluation through *score prediction*.

4.1 Prompting

We start by measuring how far we can push the performance of LLMs with just *prompting* (Liu et al., 2023a): by defining the task of MT evaluation and quality estimation as *textual templates* (with

a general description of the problem and "slots" for the inputs and outputs), we can use general-purpose LLMs to perform these tasks at inference-time, without any parameter updates.

Throughout the paper, we choose to use Kocmi and Federmann (2023)'s `GEMBA-SQM` prompt (Figure 9, Appendix C), which asks models to generate (a string representation of) a score from 0-100. We choose this prompt for two reasons: firstly, early explorations with various prompts showed that this generally performed well. Secondly, using a single prompt ensures a fairer comparison between the capabilities of different models.[1]

In-Context Learning A surprising emergent capability of LLMs is their ability to improve on prompting-based tasks by including a very small amount of labeled data as part of the prompt/context (Brown et al., 2020) and *without* parameter updates, a technique called *in-context learning* (ICL) or *few-shot prompting*. We thus investigate the impact that ICL has on LLMs' ability to assess translation quality. Recent works have shown that the impact of ICL is tightly tied with the exact examples included in the prompt, with a poor selection procedure leading to no improvements or even worse performance than the zero-shot case (Jain et al., 2023). We therefore explore two sampling approaches to select in-context examples from a pre-defined "pool" of translation quality assessments: **uniform** and **stratified sampling**, where the example pool is bucketed by score ranges and examples are sampled from each bucket.

4.2 Finetuning

It has previously been shown that LLMs are capable of zero-shot evaluation (Kocmi and Federmann, 2023), but the extent to which *finetuning* on human judgment data can further boost the performance of LLMs has not been studied. In the WMT'22 Metrics Shared Task (Freitag et al., 2022), all top submissions were learned metrics; that is, pretrained models finetuned on human judgment data[2].

Thus, we investigate whether LLMs are amenable to finetuning on human judgment data. LLMs used in top-performing metrics are generally much larger than the pretrained language models leveraged by previous learned metrics (which generally have fewer than 1 billion parameters). Moreover, most learned metrics leverage pretrained encoder-only rather than (decoder-only) prefix language models. We experiment with finetuning LLMs using two objectives:

- *Regression* (**R**): Commonly used for training learned metrics (Rei et al., 2022a), the objective here is a regression loss (e.g., mean squared error) between continuous scores obtained from the model (for example, with a *regression head*) and the human scores.
- *Generative Classification* (**GC**): We bucket scores into discrete classes (e.g. *"bad"*, *"ok"* and *"good"*) and treat the MT evaluation task as a text-to-text classification problem (Raffel et al., 2020) by having the model generate a template sentence with the class. See §6.1 for more details.

5 Using LLMs to Predict Error Spans

While producing quality scores that correlate with human judgments is an important part of translation quality assessment, metrics that solely do score prediction suffer from problems of **interpretability**: if a metric assigns a low score, the downstream users are left in the dark about which parts of the translation were responsible for the score and thus need to be corrected. This is especially problematic in cases where the metric assigns a *wrong* score to a translation, as it is much harder to diagnose why the evaluation model made a mistake, and identify and prevent similar mistakes in the future. In fact, reducing translation quality to a single score has proven problematic even for human annotators: asking raters to solely provide a single score can lead to rushed and noisy judgments (Freitag et al., 2021a) and the current gold standard for translation quality evaluation involving human annotators is instead based on methodologies like the MQM framework (see §2) , which provide richer feedback by identifying error spans, categorizing them, and evaluating their severity.

Interestingly, another emergent phenomenon in LLMs is the success of *chain-of-thought* prompting (Wei et al., 2022): when defining a prompt for a particular task, if we instruct the model to produce a series of intermediate reasoning steps (*"let's think step-by-step"*), it tends to generate a free-text *rationale* before generating an output, and this often improves the performance on the

[1] While this prompt wasn't the best for *system-level*, it led to the best *segment-level* performance in GEMBA.

[2] While these metrics all leverage powerful pretrained (language) models, these generally aren't considered LLMs

```
Based on the given source and reference, identify the major and minor errors in this
translation. Note that Major errors refer to actual translation or grammatical errors,
and Minor errors refer to smaller imperfections, and purely subjective opinions about
the translation.

{src_lang} source: "{source}"
{tgt_lang} human reference: "{reference}"
{tgt_lang} translation: "{candidate}"
Errors: {error1:span} - {error1:severity}/{error1:category}; {error2:span} - ...
```

Figure 2: The AUTOMQM prompt used in this paper. Parts in purple are only included for *reference-based* evaluation, while parts in orange represent slots for outputs, and are only included for in-context examples.

task at hand (Liu et al., 2023b). Furthermore, this *chain-of-thought* prompting can be used to obtain *structured* rationales from LLMs, and this can lead to better performance than with free-text rationales (Lu et al., 2023).

Motivated by these findings, we propose **AUTOMQM**, a prompting technique for translation quality assessment that instructs LLMs to *identify* errors in a translation, and *categorize* the type of error according to the MQM framework (Lommel et al., 2014). Furthermore, we *don't* ask the model to produce a score, as the MQM framework provides an algorithmic procedure to obtain one from identified errors: the total score is the sum of penalties for all errors identified, where (roughly) *major* errors get penalized with -5 and *minors* with -1 (see Appendix A for a more detailed description of the scoring algorithm).[3] Figure 2 shows the main AUTOMQM prompt used in this paper.

Importantly, obtaining meaningful AUTOMQM results in a zero-shot setting is a substantially more challenging task compared to score prediction: we found that, without any in-context examples, LLMs tend to produce outputs that are either uninformative or difficult to parse. Thus we only consider the AUTOMQM task in the *few-shot* scenario. Based on the findings from §6.2, we explore the impact of in-context learning by sampling from the example pool using stratified sampling extended with a set of *rejection criteria* (Appendix D), which ensures that the example set has a balance between major and minor errors as well as diversity in the categories of errors.

6 Experiments

6.1 Experimental Setup

Data The metrics in this work are evaluated on both *high-resource* and *low-resource* language pairs. The three high-resource language pairs come from the WMT'22 Metrics Shared Task (Freitag et al., 2022): en→de, zh→en, and en→ru. The ground-truth translation quality scores are derived from MQM ratings in which expert annotators marked error spans in the translations with different severity levels which are automatically converted to a numeric score (see §2). The four low-resource language pairs come from the WMT'19 Metrics Shared Task (Ma et al., 2019): en↔gu and en↔kk. Since MQM ratings are not available for the low-resource pairs, the ground truth quality scores are direct assessment (DA) scores. DA scores are quality assessments assigned by non-expert raters on a scale from 0-100, normalized per rater. See Table 9 (Appendix B) for statistics about the number of MT systems and segments for every language pair.

Additionally, in our experiments, AUTOMQM required in-context examples with MQM annotations to work, so we restrict our evaluation of AUTOMQM to en→de and zh→en because there are available MQM ratings from the WMT'21 Metrics Shared Task (Freitag et al., 2021b) that we can use as in-context learning example pools.

Models We base most of our experiments on the following LLMs:

- **PaLM**: A 540 billion parameter autoregressive Transformer model trained on 780 billion tokens of high-quality text (Chowdhery et al., 2022). It showed remarkable performance on a wide-range of NLP tasks, including Machine Translation (Vilar et al., 2022).
- **PaLM-2**: The successor to PaLM, the PaLM-2 family of LLMs (Anil et al., 2023) builds upon recent research insights, such as compute-optimal scaling, a more multilingual and diverse pre-training mixture, and architectural/optimization improvements. We mainly use two model sizes in the family: PaLM-2 BI-

[3] This is similar to methods that leverage external *executors* to improve the performance of LLMs (Gao et al., 2022)

SON and (the larger) PaLM-2-UNICORN.[4] In addition we explore the impact of instruction-tuning by using a UNICORN model finetuned on the FLAN dataset (Wei et al., 2021).

For *score prediction*, we compare PaLM and PaLM-2 against the GPT family of LLMs (Brown et al., 2020; OpenAI, 2023) by leveraging the results and outputs from the GEMBA evaluator (Kocmi and Federmann, 2023). We then evaluate the performance of AUTOMQM with only PaLM-2 models (which performed best in score prediction).

Additionally, for the high-resource languages, we compare to a set of strong baseline evaluation metrics, MetricX-XXL and COMET-22, which were the two top-performing metrics in the WMT'22 Metrics Shared Task. MetricX-XXL and COMET-22 are both finetuned regression models trained on DA data from WMT that are initialized with mT5 (Xue et al., 2021) and XLM-R (Conneau et al., 2020), respectively.

For the AUTOMQM experiments, we also compare against MATESE, a comparable submission to the WMT'22 Metrics Shared task that finetuned a XLM-R model to identify major and minor errors, and computed a score automatically. Since we were unable to obtain the span-level predictions for the MATESE submission, we also compare against the top submission to the WMT'22 Word-Level Quality Estimation Shared Task (Zerva et al., 2021): word-level COMETKIWI (COMET-WL) (Rei et al., 2022b), also based on an XLM-R model trained on a combination of sentence- and word-level data. To do so, we re-run this model on the WMT'22 Metrics Shared Task data, and convert the predicted *word-level* `OK/BAD` tags into spans.[5]

Finetuning For *regression* finetuning, we use a real-valued logit, extracted from a fixed index in the first target token's logit vector, as the quality signal. (In particular, we leverage a special, *unused*, vocabulary token.) This was the technique used to train MetricX-XXL in the WMT 2022 Shared Task submission (Freitag et al., 2022). The regression-based model was trained on WMT direct assessment (DA) data from the years 2015 through 2020.

For *generative* classification, we bucket the scores in the training data into five classes, where class boundaries are assigned so that each class contains an equal number of training examples. We then map labels to verbal ratings from the following set, based on their bucket: [*"very bad"*, *"bad"*, *"ok"*, *"good"*, *"very good"*]. To evaluate the model, predictions are mapped back to integer labels from 1 to 5. Any predictions not containing a substring in the label set are considered invalid and are mapped to 0. We experimented with finetuning on both DA and MQM 2020 (Freitag et al., 2021a) data, and found that the latter performed slightly better.

To assess the impact of *model size*, we also finetune two additional (smaller) PaLM-2 models, which we call S and M, comparing their finetuned and zero-shot performance.[6]

Metric Meta-Evaluation The quality of an automatic evaluation metric is estimated by comparing the agreement between the metric scores and ground-truth quality scores on a large number of translations from different MT systems, a process known as metric meta-evaluation. This work reports three different agreement scores, as follows.

The first is system-level accuracy, which calculates the percent of system pairs that are ranked the same by the metric and ground-truth scores, micro-averaged over a set of language pairs (Kocmi et al., 2021). System-level scores are defined as the average score across all segments.

At the segment-level, the standard correlation that is reported by WMT is Kendall's τ. However, recent work pointed out problems with Kendall's τ with respect to ties (Deutsch et al., 2023). In short, different variants of τ are inconsistent with respect to ties and even biased against metrics that predict ties, as our metrics do in this work. Deutsch et al. (2023) recommend reporting a pairwise accuracy score, which rewards metrics for correctly ranking translations as well as correctly predicting ties, in combination with a tie calibration procedure that automatically introduces ties into metric scores so that the meta-evaluation is fairer. This accuracy score, denoted acc*, ranges between 0 and 1, and a random metric would achieve 33% accuracy. We report the "group-by-item" variant of the pairwise accuracy score from Deutsch et al. (2023) in addition to Pearson's ρ, a complementary signal to rank-based correlations that measure the strength of the linear relationship between two variables (and one of the standard correlations reported in WMT).

[4] Information about exact number of parameters of PaLM-2 models is not publicly available.

[5] We consider a span as any maximal consecutive sequence of words marked as `BAD`, assigning every span the *major* severity.

[6] We use a small variation of the *zero-shot* prompt, asking models for scores from the same 5 buckets used in finetuning.

Span Meta-Evaluation Since AUTOMQM provides not only scores but also the identified error spans, we can compare the predicted spans with the errors marked by annotators in the MQM annotations. We evaluate quality of predicted spans using: (1) *Span Precision* (SP), which measures the overlap of predicted spans and gold (annotated) spans; and (2) *Major recall* (MR), which captures the percentage of gold major errors that were predicted as errors (either minor or major).

More formally, consider the set of ground truth spans $S^\star$, where each span consists of a sequence of words, i.e., $s_i = (w_{(a)}, w_{(a+1)}, \cdots)$. Let $S^\star_{\text{maj}} \subseteq S^\star$ be the subset containing only the major errors. Given a span set S, we define its positional set $P(S)$ as the set containing the positions of all the words in every span in S. For example, assuming a span $s_i = (w_{(n)}, w_{(n+1)}, \cdots)$ in S starts at the nth position in the text, its corresponding positional set will include the positions $\{n, n+1, ..., n+\text{len}(s_i)-1\}$. Then for a set of *predicted* spans $\hat{S}$, SP and MR are defined as:

$$\text{SP}(\hat{S}) = \frac{|P(\hat{S}) \cap P(S^\star)|}{|P(\hat{S})|} \quad (1)$$

$$\text{MR}(\hat{S}) = \frac{|P(\hat{S}) \cap P(S^\star_{\text{maj}})|}{|P(S^\star_{\text{maj}})|} \quad (2)$$

Intuitively, we care for overall precision (regardless of severity) since we want to make sure predicted errors tend to be marked by annotators as well, but for recall we care mostly for *major* errors, as these have a larger impact on translation quality and are more critical to identify. Additionally, we also report the (3) *Matthews Correlation Coefficient* (MCC), one of the official metrics in the word-level quality estimation tasks (Zerva et al., 2022).

6.2 Results

6.2.1 Score Prediction

Table 1 summarizes the meta-evaluation results, at the *system* and *segment* level, for both the *zero-shot prompting* and *finetuning* settings.

Prompting A first observation is almost all zero-shot LLM evaluators have higher *system-level* performance than learned metrics (with and without references), with PaLM 540B and PaLM-2 UNICORN achieving the best performance. At the segment level, the story is more complicated: similarly to Kocmi et al. (2022), we find that none of the LLMs we explored was able to consistently outperform the baseline learned metrics. We see that PaLM-540B is a particularly poor reference-based evaluator, which is surprising given its system-level performance. Unexpectedly, instruction-tuning with FLAN seems to *degrade* performance, with FLAN-PaLM-2 UNICORN achieving poor performance at both the system and segment levels.[7]

Nevertheless, PaLM-2 models achieve high correlations with human judgments, and the *reference-*

[7]Note that this might be a problem with the FLAN dataset and not instruction-tuning in general, as the GPT models are also instruction-tuned and perform well.

Table 2: Comparison between PaLM-2 and GPT-based GEMBA (Kocmi et al., 2022) at the system and segment levels for the *high-resource* language pairs.

less PaLM-2 BISON is competitive with the *learned* baselines, particularly at assessing alternative translations of the same sentence (acc*). When comparing PaLM-2 models with Kocmi et al. (2022)'s GPT-based GEMBA evaluator (Table 2), we see that both families of LLMs perform similarly, with PaLM-2 models exhibiting higher system-level performance than GPT-based GEMBA, while GEMBA achieves better segment-level accuracy, particularly in the reference-less setting.

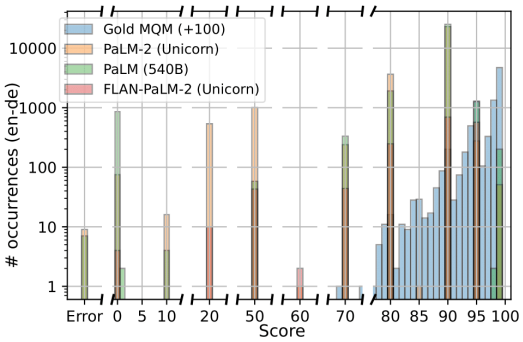

Figure 3: Distribution of scores for various LLM *reference-based* evaluators, on the EN-DE test set. Note that the y axis is in *log-scale*.

Figure 3 shows the distribution of scores produced by PaLM- and PaLM-2-based evaluators. We find that, despite being prompted to give a score in the 0-100 range, these models almost always output one of a very limited set of scores (e.g. 0, 50, 90, 95). Given Kocmi and Federmann (2023)'s similar findings with GPT models, it seems that this is a consequence of the pretraining objective.

Finetuning Despite their already-great performance in the zero-shot setting, we find that finetuning LLMs can further improve LLM evaluators' segment-level scores. This is particularly obvious for the *reference-less* evaluators, where a finetuned PaLM-2 BISON achieves state-of-the-art performance in segment-level correlations and comparable system-level accuracy across all language pairs. Moreover, when we look at how performance *scales* with parameter count (Figure 4), we observe an interesting trend: while smaller models are not capable of being effective zero-shot evaluators, finetuning them leads to competitive performance, and only a slight decrease when compared to their larger finetuned counterparts.

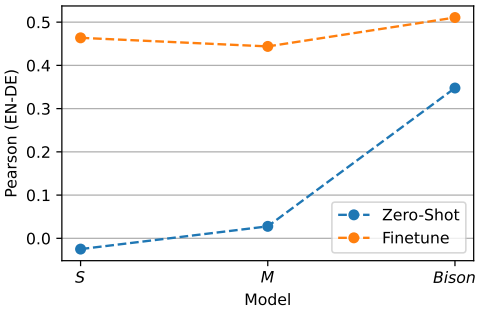

Figure 4: Behavior of *Pearson* as we scale the LLM's parameter count. Note that the x axis is not to-scale with regard to parameter count.

In-context Learning Figure 5 shows the mean and interquartile range (IQR) of the performance as we increase the number of in-context examples k (with 100 example sets per k) sampled with *stratified* sampling (see Appendix E for *uniform*). Surprisingly, despite evidence of the benefits of in-context learning for many tasks, we found that including in-context examples during evaluation (almost) never led to better performance, either with *uniform* or *stratified* sampling.

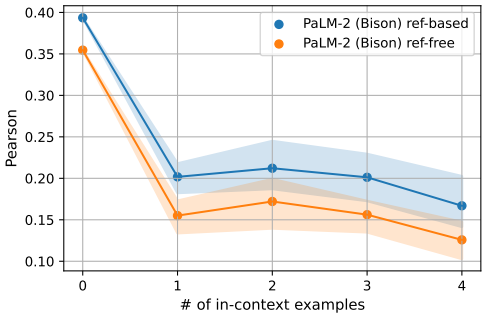

Figure 5: Mean *Pearson* and its interquartile range (IQR) in the WMT22 EN-DE test set, as we increase the number of in-context examples with *stratified* sampling

To investigate the cause of this disappointing performance, we looked at how *particular* in-context example sets affect the distribution of scores produced by LLM-based evaluators. Figure 6 shows the distribution of scores *over the whole test set* for the 1-shot and 2-shot settings, with different in-context examples sets. We can see that output distribution is heavily biased by the scores in the in-context examples: despite *never* predicting 79

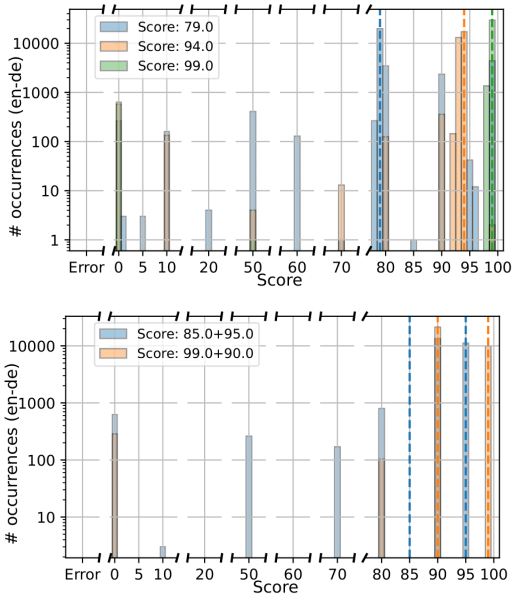

Figure 6: Distribution of scores for PaLM-2 (BISON) models for 1-shot (top) and 2-shot (bottom) setups, with various in-context learning sets for each (and their scores in the legend)

in the zero-shot setting, when a single example with that score is included, it starts to dominate the model predictions. This seems to hint that LLMs "overfit" to the specific scores provided as examples, rather than generalizing to the broader evaluation task, which could explain the lackluster performance of in-context learning.

6.3 Low Resource Languages

Table 3 shows the performance of PaLM-2 models at *score prediction* for *low-resource* translation. Overall, we find that similar to high-resource LPs, these models are good zero-shot evaluators, with system-level accuracies around 90%. However, *zero-shot* LLMs underperform *learned* metrics, even when these metrics also weren't exposed to data in these low-resource languages.

		System	Segment ρ

BISON	✗	89.8%	0.567	0.478	0.381	0.313
UNICORN	✗	84.4%	0.536	0.523	0.433	0.334

Table 3: Meta-evaluation results for system-level *accuracy* and segment-level *Pearson* on the low-resource languages, using PaLM-2 for *score prediction*. *Note that the baseline is slightly different from the high-resource case, being trained on the same data but *without* these *low-resource* language pairs.

6.3.1 AUTOMQM

Figure 14 shows the mean and interquartile range (IQR) of the performance of PaLM-2 BISON with AUTOMQM, as we increase the number of in-context examples (again, with 100 example sets per k). Contrary to the performance with score prediction, we find that performance with AUTOMQM seems to (mostly) scale with the number of in-context examples: performance increases monotonically with up to 4 in-context examples and plateaus thereafter. Additionally, the variance across the in-context learning sets seems to be lower, with most example sets exhibiting less than 0.05 *Pearson* difference from the best-performing sets. All this suggests that LLM evaluators are much more robust to the choice of in-context examples when prompted for AUTOMQM rather than for score prediction. We also find that the behavior of in-context learning is quite similar for both reference-based and reference-less evaluation tasks. Finally, we observe that the example sets that perform well for one task generally work well for the other, with performance on both settings given a fixed in-context set being highly correlated, as shown in Figure 7.

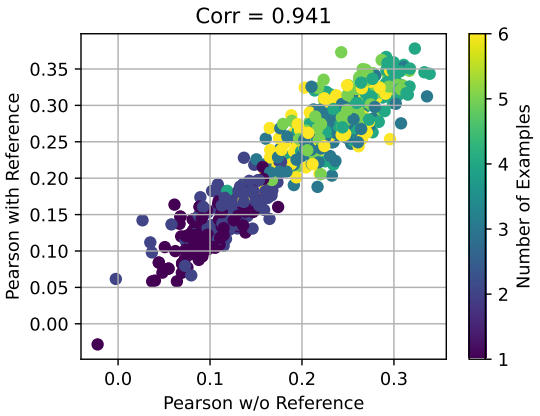

Figure 7: Scatter plot of the *Pearson* of PaLM-2 (BISON) models, with/without including the *reference* in the prompt, for each in-context learning setting tried.

Table 4 shows the meta-evaluation results for PaLM-2 BISON and UNICORN prompted with AUTOMQM (using the best-performing in-context learning sets in Figure 14). For ease of comparison, we also report their performance when prompted for *score prediction*, as well as the performance of the baselines. Overall, prompting LLMs with AUTOMQM seems to lead to significant improvements in evaluating machine translation quality, particularly for larger models: UNICORN achieves better performance (across all meta evaluations) with it than when prompted for *score prediction*,

Table 4: Meta-evaluation results for PaLM-2 models using *AutoMQM* and score prediction, at the system and segment levels for multiple language pairs.

and its reference-less version is competitive with the best learned metric even at the segment level. However, for the smaller BISON, the benefits of AUTOMQM are less clear, with both techniques performing comparably. This hints that *scale* is necessary for *zero-* and *few-* shot fine-grained evaluation (like with AUTOMQM). We also find that the *distribution* of scores produced by LLMs prompted with AUTOMQM is much closer to the gold MQM distribution, with models outputting a much larger set of scores, and in the same ranges as annotators do (see Figure 8).

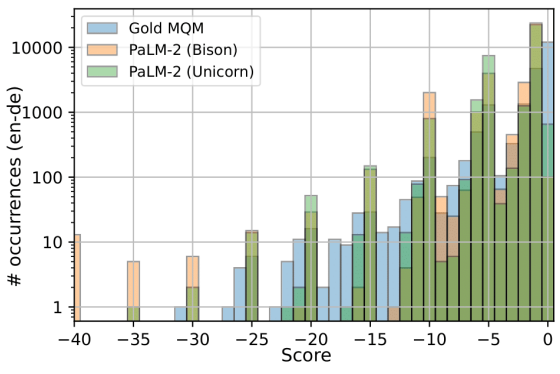

Figure 8: Distribution of scores for PaLM-2 models using AUTOMQM, on WMT22 EN-DE

Finally, when evaluating the error spans produced by LLMs prompted with AUTOMQM (Table 5), we find that PaLM-2 models are able to identify most of the *major* errors. However, it does seem to *over-predict* errors (with errors predicted by UNICORN having on average ∼5 words per span vs ∼2 words in the ground truth) and have overall low span precision. Similarly to overall *score* correlations, *scale* also seems to be important for the quality of spans produced by AUTOMQM, with UNICORN outperforming BISON at most metrics. Additionally, UNICORN prompted with AutoMQM predicts spans of comparable quality to the ones produced by current state-of-the-art *learned* word-level evaluators (trained on a considerable number of fine-grained annotations derived from MQM): while word-level models are more precise, their overall span correlation (MCC) is comparable, and they miss considerably more *major* errors than LLMs (despite only leveraging a handful of annotations).

7 Conclusion

In this study, we have systematically investigated the capabilities of large language models for machine translation evaluation through *score prediction*, and proposed AUTOMQM, a novel

prompting technique that leverages the Multidimensional Quality Metrics (MQM) framework for interpretable MT evaluation using LLMs.

We demonstrated that just prompting LLMs for score prediction leads to state-of-the-art system-level evaluators, but still falls short of the best *learned* metrics at the segment-level (with finetuning being necessary to close this gap). Then we showed that AUTOMQM can further improve the performance of LLMs without finetuning while providing interpretability through error spans that align with human annotations.

Our findings surrounding finetuning LLMs for *score prediction* hint that LLMs' performance in machine translation evaluation could be further improved by finetuning these models on fine-grained human judgment data (like MQM) and is a direction we are actively pursuing. Additionally, the general-purpose nature of LLMs may enable the application of similar prompting techniques (leveraging some fine-grained evaluation schemes) to other evaluation problems (Wu et al., 2023).

A Multidimensional Quality Metric (MQM)

The Multidimensional Quality Metrics (MQM) framework is a flexible human-evaluation framework developed to evaluate and categorize errors in translations. Annotators are instructed to identify all errors within each segment in a document, paying particular attention to document context. See Table 6 for the annotator guidelines provided.

Annotators are asked to assign both an error *severity* and *category*. Error *severity* (either *major* or *minor*) is assigned independently of category. Spans with no marked errors have *neutral* severity and no category. Possible error categories are displayed in Table 7.

You will be assessing translations at the segment level, where a segment may contain one or more sentences. Each segment is aligned with a corresponding source segment, and both segments are displayed within their respective documents. Annotate segments in natural order, as if you were reading the document. You may return to revise previous segments.

Please identify all errors within each translated segment, up to a maximum of five. If there are more than five errors, identify only the five most severe. If it is not possible to reliably identify distinct errors because the translation is too badly garbled or is unrelated to the source, then mark a single *Non-translation* error that spans the entire segment.

To identify an error, highlight the relevant span of text, and select a category/sub-category and severity level from the available options. (The span of text may be in the source segment if the error is a source error or an omission.) When identifying errors, please be as fine-grained as possible. For example, if a sentence contains two words that are each mistranslated, two separate mistranslation errors should be recorded. If a single stretch of text contains multiple errors, you only need to indicate the one that is most severe. If all have the same severity, choose the first matching category listed in the error typology (eg, *Accuracy*, then *Fluency*, then *Terminology*, etc).

Please pay particular attention to document context when annotating. If a translation might be questionable on its own but is fine in the context of the document, it should not be considered erroneous; conversely, if a translation might be acceptable in some context, but not within the current document, it should be marked as wrong.

There are two special error categories: *Source error* and *Non-translation*. Source errors should be annotated separately, highlighting the relevant span in the source segment. They do not count against the five-error limit for target errors, which should be handled in the usual way, whether or not they resulted from a source error. There can be at most one *Non-translation* error per segment, and it should span the entire segment. No other errors should be identified if *Non-Translation* is selected.

Table 6: MQM annotator guidelines

Since MQM doesn't ask annotators for quality scores, those scores are derived automatically from the identified error spans and their classifications, based on a *weighting* of each error severity and category. Table 8 summarizes this weighting scheme, in which segment-level scores can range from 0 (perfect) to 25 (worst). The final segment-level score is an average over scores from all annotators. In some settings (e.g. calculating correlation for learned metrics), the scores are negated.

We use the same weighting to obtain scores from errors identified by AUTOMQM.

B Datasets' Statistics

See Table 9 for a summary of the number of systems and annotated segments per system in the evaluation datasets used in this work.

C Score Prediction Prompt

Figure 9 contains the GEMBA-SQM prompt that we used for our 0-shot experiments.

D Sampling in-context learning examples for AutoMQM

Figure 10 shows the rejection criteria used when sampling example sets as discussed in §4.

E Additional Results

Figures 11, 12, 13 and 8 present additional experimental results.

Error Category		Description
Accuracy	Addition	Translation includes information not present in the source.
	Omission	Translation is missing content from the source.
	Mistranslation	Translation does not accurately represent the source.
	Untranslated text	Source text has been left untranslated.
Fluency	Punctuation	Incorrect punctuation (for locale or style).
	Spelling	Incorrect spelling or capitalization.
	Grammar	Problems with grammar, other than orthography.
	Register	Wrong grammatical register (eg, inappropriately informal pronouns).
	Inconsistency	Internal inconsistency (not related to terminology).
	Character encoding	Characters are garbled due to incorrect encoding.
Terminology	Inappropriate for context	Terminology is non-standard or does not fit context.
	Inconsistent use	Terminology is used inconsistently.
Style	Awkward	Translation has stylistic problems.
Locale convention	Address format	Wrong format for addresses.
	Currency format	Wrong format for currency.
	Date format	Wrong format for dates.
	Name format	Wrong format for names.
	Telephone format	Wrong format for telephone numbers.
	Time format	Wrong format for time expressions.
Other		Any other issues.
Source error		An error in the source.
Non-translation		Impossible to reliably characterize distinct errors.

Table 7: MQM hierarchy.

```
Score the following translation from {src_lang} to {tgt_lang} with respect to the
human reference on a continuous scale from 0 to 100 that starts with "No meaning
preserved", goes through "Some meaning preserved", then "Most meaning preserved
and few grammar mistakes", up to "Perfect meaning and grammar".

{src_lang} source: "{source}"
{tgt_lang} human reference: "{reference}"
{tgt_lang} translation: "{candidate}"
Score (0-100): {score}
```

Figure 9: The *score prediction* prompt used in this paper. Equivalent to the `GEMBA-SQM` prompt in Kocmi and Federmann (2023). Parts in purple are only included for *reference-based* evaluation, while parts in orange represent slots for outputs and are only included for in-context examples.

Severity	Category	Weight
Major	Non-translation	25
	all others	5
Minor	Fluency/Punctuation	0.1
	all others	1
Neutral	all	0

Table 8: MQM error weighting.

LP	#Sys	#Seg
en→de	13	1315
zh→en	14	1875
en→ru	15	1315

LP	#Sys	#Seg
en→kk	11	998
kk→en	11	1000
en→gu	11	998
gu→en	11	1016
